A VACUUM TUBE POTENTIOMETER FOR RAPID E.M.F. MEASUREMENTS[1]

BY H. M. PARTRIDGE

RECEIVED MARCH 24, 1928 PUBLISHED JANUARY 8, 1929

Applications of one or more triode valves to various forms of apparatus suitable for the determination of PH values, electrode potentials, electro-titrations and the like have been described by several writers.[2] Nearly all of these require a calibration of the valves, are dependent upon the constancy of the characteristics of the valves and require sources of filament and plate potentials which will not vary over a considerable period of time. These limitations have been the motive for the development of the apparatus herein described and which has the following attributes: (a) it is a direct reading, no current device; (b) it is independent of the characteristics of the valves and of their power supply; (c) the "balance" condition is definite and very stable; (d) since the e.m.f. is read directly from a voltmeter in the grid circuit of the first (four element) tube, the values obtained will be dependent on the precision of this meter; (e) the maximum current taken from the cell is of the order of 10^{-9} ampere—at "balance" it is 0. The unknown cell may, therefore, be left continually in circuit during the balancing, which requires only a single operation; (f) the resistance of the cell under measurement is unimportant. No difficulty has been experienced in measuring the e.m.f. of a cell containing two glass electrodes; (g) when used with a cell containing properly prepared electrodes, PH values may be rapidly determined and are reproducible to 0.02 of the Sorensen unit.

Principle of Operation

In place of the conventional "bridge" a vacuum tube amplifier consisting of a tetrode and a triode is substituted. For a more complete descrip-

[2] Van der Bijl, "The Thermionic Vacuum Tube," McGraw-Hill Book Co., Inc., New York, 1920; Goode, THIS JOURNAL, 44, 26 (1922); 47, 2483 (1925); Fitch, J. Opt. *Soc. Am.*, 14, 348 (1927).

tion of the operation of the valves than will be attempted here, the reader is referred to a text on wireless communication or to the articles by Goode. Several of the more common types of broadcast receiver tubes can be adapted to this work, but after a study of the characteristics of different audions, the types "—22" and "—20" were, respectively, selected. A of Fig. 1 shows the mutual conductance curve for the "—22" type of valve.

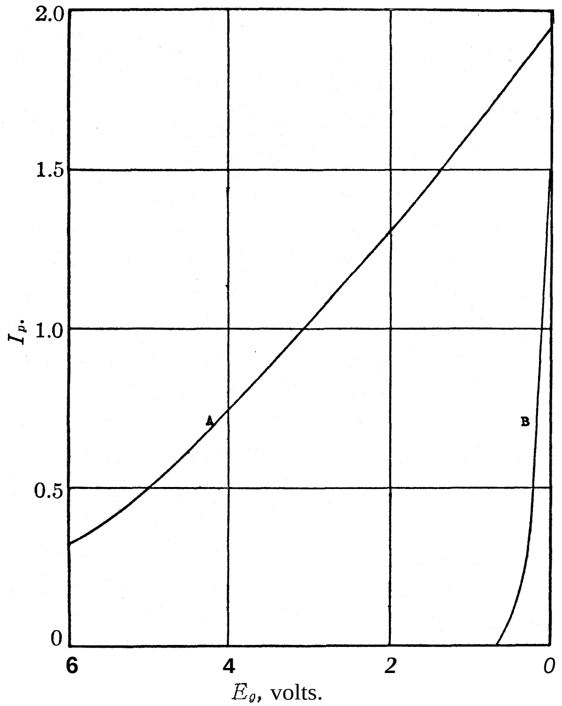

Fig. 1.

A—Grid voltage–plate current characteristic for shielded plate valve, plate voltage = **135** volts; outer grid voltage = 45 volts; inner grid voltage = E_g. B—Grid voltage–plate characteristic of vacuum tube potentiometer. E_g = potential applied between inner grid and filament of tetrode. I_p = plate current of triode in milliamperes.

The inner grid of the four element tube is used as the control grid. The outer grid is made positive with respect to the filament by 45 volts. The plate is operated at a potential of 135 volts. If the inner grid of this tube is connected directly to the negative lead of the filament, the resulting grid voltage is zero and a glance at the curve shows that the plate current under these conditions is 1.95 milliamperes. If now a cell with an unknown e.m.f. is connected between inner grid and filament with the negative side toward the grid, an unknown negative grid voltage results and the plate current drops to some lower value. An extremely feeble current will, under these conditions, be drawn from the cell being measured. A source of variable potential supplied by a dry cell or a storage cell and spanned by a voltmeter is inserted in the grid-filament circuit in such a manner that the variable potential opposes the unknown e.m.f. The variable potential is altered until the plate current again becomes 1.95 milliamperes. The unknown cell is now giving no current and the true e.m.f. of the cell may be read directly from the voltmeter. The measurement is also independent of the characteristics of the valve since the initial and final plate current values are identical, and are represented by a single point on the mutual conductance curve. The assumption is made, of course, that the tube characteristics and batteries have remained constant during the minute or so which has been spent in taking the readings. As a precautionary measure, a simple switch is provided by which the operator may, in a few seconds, check the plate current value before and after each reading. A more complete description of this procedure will be found elsewhere in the paper.

Actually, two valves are employed in such a manner that the variation in plate current of the tetrode is amplified by the triode. Curve B of Fig. 1 shows this change in plate current in the triode with accompanying variation of grid potential at the tetrode. The increased sensitivity of this arrangement over that of a single tube is apparent by contrasting the slopes of the two curves of Pig. 1. Obviously the actual principle of operation is the same as if a single tube were used.

Apparatus and Circuit Constants

The circuit employed is shown in Fig. 2. The filaments of both tubes are heated by battery A, which consists of three ordinary lead storage cells. **A** 20-ohm rheostat F regulates the potential applied to the filaments, which should be operated at *3.3* volts for maximum useful life and efficiency. The plates of the valves are supplied from batteries B_1, B_2 and B_3, which may be "B" batteries of the type used for broadcast reception and having values of 45, 22.5 and 67.5 volts, respectively. Storage cells may be used if preferable but they must be kept free from dust and charging spray or troublesome leakage will result. The plate current of the triode is registered on the milliammeter MA, which should have a full-scale deflection for 1.5 milliamperes. The absolute precision of this instrument is of secondary importance since no direct readings of the plate current need be taken. Coupling resistance R is a 100,000-ohm wire-wound resistance of the cartridge type having a small temperature coefficient and capable of dissipating 0.75 watt. The apparently large power rating of this resistance is specified to make certain that there is no rise in temperature due to the plate current of the tetrode, which it is continually required to pass.

If the grid and filament of the tetrode are connected together, the magnitude and direction of the current through resistance R is such that too great a negative potential is applied to the grid of the triode to allow any plate current to flow through MA. In order that MA may show full-scale deflection, the grid of the tetrode will have to be negative with respect to its filament by a value between two and three volts. This is accomplished by the 400-ohm "potentiometer" C with its winding spanning resistance F. The values selected for the source of the opposing potential O, for the voltage divider D and for the voltmeter V will depend upon the e.m.f. of the cell E which is to be measured. For values up to six volts, D also may be a good grade "potentiometer" of the broadcast receiver type. For all PH work and for most work in determining electrode potentials, the opposing battery O may be a single dry cell or a storage cell. The choice of the voltmeter V will depend upon the range of voltage to be covered and the accuracy desired. The writer has found the Weston Model I "Electrolysis Voltameter" with its five voltage ranges a very useful instrument, although some other types of meter are capable of a little better precision. The switch S is of the single pole double-throw type with its blade connected to the grid as shown in Fig. 2.

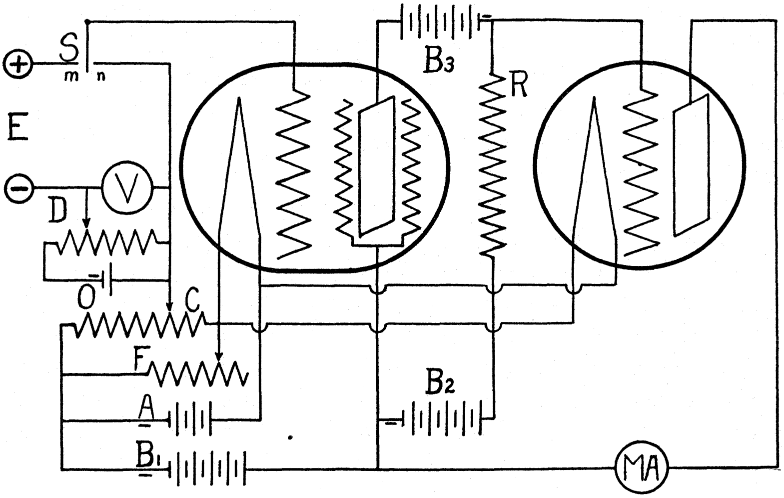

Fig. 2.—Diagram of connections.

Operation

If the circuit has been properly connected, the milliammeter MA should read zero when the switch S is thrown to position n and the slider arm of C is in such a position that it is directly connected with the filaments of both valves. If the slider arm of C is cautiously advanced toward the battery end of the winding, a point will be found at which MA will register nearly 1.5 milliamperes. If the cell E whose e.m.f. is to be measured has been attached in the proper manner and with the switch S connecting it to the circuit at m, the reading of MA is reduced in magnitude. The switch S is now thrown to n so that it connects grid and filament directly through C and the reading on MA noted. For convenience C may be adjusted until the needle of the milliammeter is exactly coincident with a marked value on the scale, for example, 1.4. The switch S is returned to its former position, m, and voltage divider D is advanced until the triode plate current has reached its former value, 1.4. Care should be taken not to force the plate current meter off the scale lest it be damaged. The reading on the voltmeter V at this point registers the e.m.f. of cell E.

Advantages

The device described herewith is somewhat more convenient than most vacuum tube potentiometers for chemical measurements in that the valves do not have to be calibrated and it is not essential that their characteristics remain constant over long periods. It is considerably more rapid than the average potentiometer in that only one adjustment is necessary for one measurement. Owing to the conditions under which the device is operated, the maximum current taken from the cell is exceedingly small. It may be used for the measurement of a cell whose internal resistance is too great to allow it to be measured by a potentiometer employing the conventional Poggendorf system. Glass electrodes furnish such an example. W. S. Hughes[3] has found that the average glass electrode made from soft glass has a resistance of between 23 and 100 megohms. In this connection curves are given in Figs. 3 and 4 plotted from data obtained in neutralization titrations employing glass electrodes. Fig. 3 is an HCl–NaOH ti-

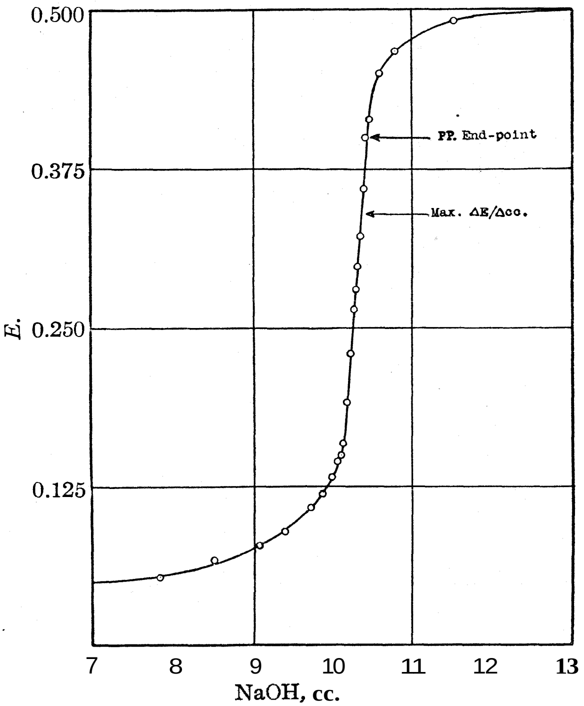

Fig. 3.—Neutralization of hydrochloric acid.

tration employing one calomel and one glass electrode. Fig. 4 represents an NaOH–acetic acid neutralization in a cell containing two glass electrodes. While the points in the latter case do not represent a curve remarkable for its smoothness, they were obtained under conditions of extreme atmospheric humidity and electrical disturbances which would make the electrometer, ordinarily used for glass electrode measurements, quite useless.[4] For a more complete discussion of the glass electrode the reader is referred to papers by Watson and others.[3,5]

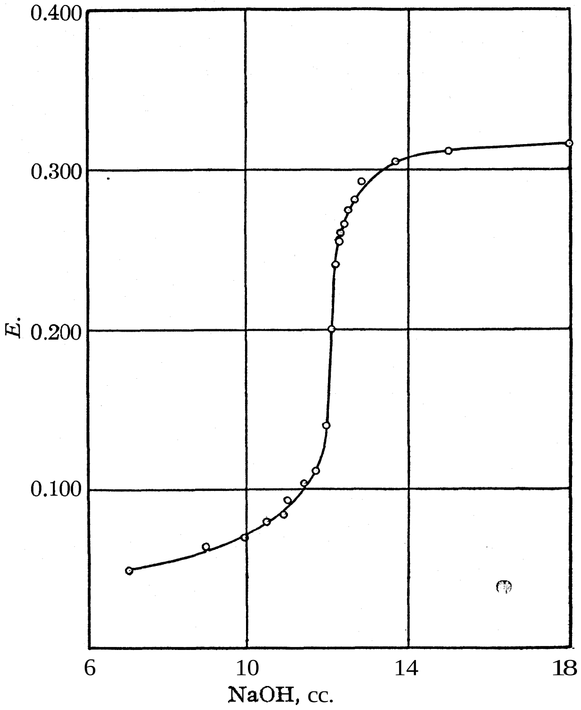

Fig. 4.—Neutralization of acetic acid—cell containing two glass electrodes.

Precautions

No trouble should be experienced from leakage if the apparatus is used on a dry wooden table. If, however, it is desirable to employ the potentio-

---

[4] If greater accuracy is desired than can be obtained with a voltmeter, V, D and O of Fig. 2 may be substituted by a potentiometer connected in such a manner that a known potential opposes E. If MA has 150 scale divisions for 1.5 milliamperes, an accuracy of 0.00015 volt will be obtained.

meter on a stone-topped table or upon one which has at some time been bespattered with reagents, careful insulation of all batteries from each other and from the table will be necessary. All wiring should be done so that conductors do not touch one another even though they carry "insulation." The cell E to be measured should be placed upon a dry hardwood board, hard rubber or other insulating material. Due to the high amplification obtained, the valves should he kept as free as possible from mechanical vibration. The inner grid of the tetrode should be connected with flexible wire. In some instances connecting the negative side of the filaments to earth may be helpful although in all work done by the writer this has been found unnecessary.

Summary

A device has been described which employs a tetrode and a triode in a simple potentiometer circuit and arranged in such a manner that calibration of the valves and the constancy of their characteristics are unnecessary. Since the apparatus is essentially electrostatic in operation, it is particularly adapted to the measurement of cells having high internal resistance. As only one adjustment is necessary, measurements may he made with comparative rapidity.

THE SYNTHESIS OF WATER WITH A SILVER CATALYST. II. ENERGY OF ACTIVATION AND MECHANISM

BY ARTHUR F. BENTON AND JOSEPH C. ELGIN

RECEIVED MAY 10, 1928 PUBLISHED JANUARY 8, 1929

Introduction

In a number of examples of homogeneous, bimolecular gas reactions it has been shown[1] that the absolute rate of reaction may be expressed by the equation

$$-\frac{dC}{dt} = Ze^{-\frac{E}{RT}}$$

where C is the concentration of the reacting species at time t, Z is the number of collisions in unit time per unit of volume, and E is the energy of activation per two moles of reactant. $e^{-E/RT}$ is, therefore, the fraction of the total number of collisions which is effective. Since the fraction of the molecules which have energy of any particular kind, kinetic, rotational, vibrational or electronic, in excess of E calories per mole is also approxi-

[1] Lewis, J. Chem. *Soc.*, 113, 471 (1918); Hinshelwood, "Kinetics of Chemical Change in Gaseous Systems," Oxford University Press, 1926, pp. 50 *et seq.*

mately equal to $e^{-E/RT}$, it has been concluded that all collisions are effective in which at least $E/6.06 \times 10^{23}$ cal. of energy of an appropriate kind are available in the two colliding molecules.

The corresponding hypothesis suggests itself for the rate of reaction between two gases in contact with a solid catalyst, particularly for those cases in which only one of the reactants is adsorbed. It has not been possible to test such an assumption hitherto because catalytic studies have seldom been accompanied by the necessary adsorption measurements, and in the few cases in which these have been carried out it has usually been found that both reactants are adsorbed.[2] While it is conceivable that the hypothesis might be applicable to cases of the latter kind, adequate data are not available on the general problem of adsorption in mixtures.

In a previous paper[3] it was shown that the combination of hydrogen and oxygen in contact with metallic silver is a convenient example for experimental test, since under the conditions employed silver strongly adsorbs oxygen but does not take up hydrogen in measurable quantity. The rate of reaction was found to be proportional to the pressure of hydrogen, independent of the oxygen pressure and markedly retarded by water vapor. Since the oxygen adsorption is nearly independent of the pressure, these results are evidently in qualitative agreement with the hypothesis that the reaction mechanism depends on collisions of gaseous hydrogen molecules with those parts of the surface which are covered by adsorbed oxygen but free from adsorbed water. Since the previous work did not include measurements of the adsorption of water vapor, it was not possible to test the hypothesis quantitatively.

The necessary adsorption measurements have now been carried out on a new silver catalyst and the reaction kinetics have been redetermined for this new sample at two temperatures. The results are found to be in agreement with the hypothesis that reaction occurs at every collision of hydrogen with "dry" adsorbed oxygen in which the total energy available on collision exceeds the true energy of activation.

Apparatus and Procedure in Kinetic Experiments

The apparatus and procedure were the same as those employed previously,[3] with one exception. It was feared that when the hydrogen–oxygen mixtures entered the catalyst dry, as in the earlier work, the greater freedom from adsorbed water at the entering end of the catalyst would lead to so great an evolution of heat due to reaction at this point

---

[2] See, for example, the extensive studies by Pease and collaborators on the combination of ethylene and hydrogen in contact with various metals, THIS JOURNAL, 45, 1196, 2235, 2296 (1923); 47, 1235 (1925); 49, 2503, 2783 (1927).

[3] Benton and Elgin, THIS JOURNAL, 48, 3027 (1926).

that even the high thermal conductivity of silver might be insufficient to prevent a considerable temperature gradient in the catalyst. For this reason the present experiments were carried out with a constant concentration of water vapor in the enteriog gases, amounting to approximately 10% by volume.

The introduction of this water vapor was accomplished by adding the desired quantity of hydrogen to the oxygen stream, or *vice* versa, and passing the mixture over heated platinized asbestos or copper oxide.[4] The mixture of oxygen and water vapor thus produced, after uniting with a current of hydrogen in the desired proportion, was passed downward over the silver catalyst. All tubing through which water vapor passed was heated externally by passing an electric current through coils of chromel wire in order to avoid condensation. The total rate of flow of the gas mixture entering the catalyst was in all cases 50 cc. per min. (0°, 760 mm.).

The silver catalyst was obtained from another sample of the silver oxide previously employed and the reduction with hydrogen at low temperature was carried out in the manner already described, the final temperature being 100°. Preliminary experiments with the catalyst thus prepared showed that the activitv was inconveniently high, since hydrogen–oxygen mixtures were exploded when passed over it at room temperature. It was therefore heated in hydrogen at 310° for four hours to reduce its activity to a suitable value. The mass was cylindrical in shape, 3 cm. in diameter and approximately 5 cm. high, giving an apparent volume of 35 cc. The weight was 47.70 g.

The method of procedure was the same as previously reported. To avoid possible uncertainties due to previous history, the catalyst was given a uniform treatment before every experiment, consisting in heating in hydrogen at 96° for one hour. Check runs were made alternately throughout the investigation. Correction for the small changes in activity which were thus observed was made by adding to, or subtracting from, the yield in each run the percentage amount per run necessary to bring the checks into agreement.

Results of Kinetic Experiments

The results of the experiments on reaction kinetics are given in Table I in the order in which they were made. The values for the observed yields, in the next to the last column, represent the net water formation after subtracting the 20.2 mg. per five minutes present in the entering gas.

The values in Cols. 5 and 6 were calculated as follows. The pressure of hydrogen in the entering gas is V_HP/V, where V_H and V are the volumes (at 0°, 760 mm.) of hydrogen and total gas, respectively, entering the catalyst per five minutes and P is the corrected barometric pressure.[5] The hydrogen pressure in the exit gas is

$$\frac{V_{\mathrm{H}} - \frac{22.4}{18}\,Y}{V - \frac{11.2}{18}\,Y}\,P$$

---

[4] Copper oxide was found preferable to platinized asbestos, as the use of the latter occasionally led to mild explosions.

[5] The pressure drop in the catalyst bed was negligible at a rate of flow of 50 cc. per min.

where Y is the observed yield in mg. of water per five minutes. Hence the average hydrogen pressure is

$$P_H = \frac{P}{2}\left(\frac{V_H}{V} + \frac{V_H - \frac{22.4}{18}Y}{V - \frac{11.2}{18}Y}\right)$$

Similarly, the average pressure of water vapor (P_W) has been calculated from the expression

$$P_W = \frac{22.4}{18}\cdot\frac{P}{2}\left(\frac{20.2}{V} + \frac{20.2 + Y}{V - \frac{11.2\,Y}{18}}\right)$$

An attempt was made (Runs 5 and 9) to use mixtures containing an excess of hydrogen, but such experiments were always followed by a permanent decrease in catalytic activity. This effect is probably attributable to the fact that at the higher rates of reaction obtained with excess hydrogen, the catalyst surface is kept comparatively free from adsorbed oxygen with the result that local overheating causes a sintering of the active surface.

An earlier series of kinetic experiments was carried out with another catalyst, using 10 mg. of water per five minutes in the entering gas. The results are omitted because an explosion destroyed the catalyst before its adsorptive power had been determined. The general character of the results is similar to those in Table I, and the data are fitted by the same type of kinetic equation.

Apparatus and Procedure in Adsorption Experiments

The amount of oxygen adsorbed by the catalyst was determined by the static method described in the previous paper.

The adsorption of water was determined by a flow method. Mixtures of water vapor with oxygen or hydrogen in proper proportions to give the desired partial pressure were passed over the catalyst, heated in a suitable vapor bath, until equilibrium was reached. The water in the entering gas was then shut off and the water adsorbed plus that in the free space was swept out and collected in a calcium chloride weighing tube. At the conclusion of these measurements the catalyst bulb was removed from the kinetic apparatus and sealed to the apparatus used for the determination of the oxygen adsorption. After removal of the adsorbed oxygen by treatment with hydrogen the free space in the bulb and connecting capillary was determined with hydrogen, which had previously been shown not to be measurably adsorbed by a silver catalyst. Prom this measured volume the weight of water in the free space at any partial pressure could be calculated, and hence the amount adsorbed.

Results of Adsorption Experiments

When mixtures of water vapor with hydrogen are used the adsorption of water occurs on a bare silver surface, since hydrogen is not adsorbed at the temperatures in question. Under the conditions of the catalysis, however, it has been shown that the surface is largely covered with adsorbed oxygen, and it is the adsorption of water by such a surface that is

TABLE II

of importance in the reaction kinetics. For this reason the majority of the measurements were made with mixtures of oxygen and water vapor (Series 1 and 2, Table II). Three partial pressures of the latter gas were used, covering the range obtaining in the kinetic experiments, at each of two temperatures, 100° (boiling water) and 110° (boiling toluene). The results are shown in Table II. The volumes given are those at 0° and 760 mm. After the first three measurements in Series 1, the catalyst was transferred to a new bulb of somewhat smaller volume than the original.

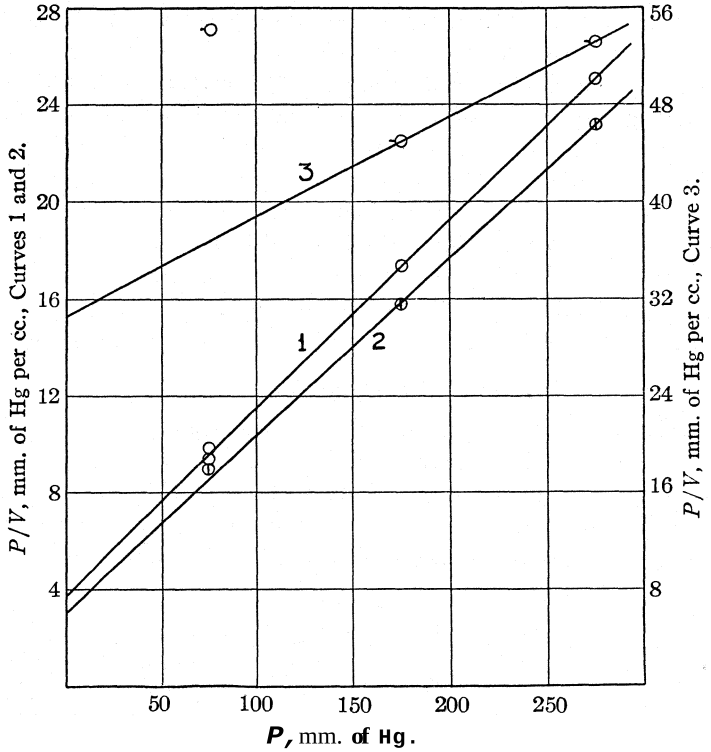

Fig. 1.—Adsorption of water vapor by the catalyst. Curves 1 and 2: oxygen-covered surface at 110 and 100°, respectively. Curve 3: bare surface at 100°.

These results are not even approximately fitted by an isotherm of the Freundlich type but agree well with the simplest form of adsorption equation derived by Langmuir[6] on the hypothesis of a unimolecular layer, namely $V = V_0aP/(1 + aP)$, where V and V_0 are the volumes adsorbed at pressure P and at infinite pressure, respectively, and a is a constant at a given temperature. This may be put in the form $P/V = 1/aV_0 + P/V_0$. A plot of P/V against P should, therefore, yield a straight line

---

[6] Langmuir, THIS JOURNAL, 40, 1370 (1918).

whose slope and intercept permit a calculation of a and V_0. The results of the three series of measurements have been plotted thus in Fig. 1. With the exception of the lowest point in Series 3, where the experimental error may be relatively great, the straight lines drawn in the figure fit the data closely. For Series 1, 2 and 3, respectively, the values of the constants are: $V_0 = 12.8, 13.7, 12.1$; $a = 0.0209, 0.0236, 0.0027$.

It may be noted that although the bare surface adsorbs much less water at a given pressure than the oxygen-covered surface, the maximum adsorptions at saturation (V_0) are nearly the same. However, the adsorption of oxygen by this catalyst at 110° was found to be 6.2 cc. (0°, 760 mm.), a value which is approximately half that obtained for water vapor.

The simplest interpretation of these facts seems to be as follows. Since the results of the previous work show that the adsorption of oxygen by silver catalyst is nearly independent of pressure and temperature over the range in question, it appears probable that this gas is taken up in a monatomic layer such that each silver atom in the surface is covered by one adsorbed oxygen *atom*. In the absence of oxygen, each exposed silver atom may take up one molecule of water, so that the volume of the latter gas adsorbed at saturation is twice as great as for oxygen molecules. When the surface is covered with oxygen, each atom of the latter can hold one molecule of water. Since the oxygen adsorption is irreversible, there can be no question of a displacement of the adsorbed oxygen by water vapor, and we conclude, therefore, that the water is held in a second layer on top of the oxygen layer.

Although in the light of previous work on adsorption by metallic catalysts the above assumption that the oxygen is taken up in a monatomic layer appears most probable, nevertheless it is obvious that other assumptions are possible, for example, that each silver atom is covered by one oxygen molecule, or perhaps that two silver atoms are required to saturate each oxygen atom. In either case the conclusions to be drawn in regard to the mechanism of the reaction between hydrogen and oxygen will not be seriously affected. This will be clear from the facts, first, that these alternative assumptions do not affect the calculations of the next paragraph on the retarding action of water vapor, because these calculations do not require a knowledge of the absolute surface of the catalyst, but only of the fraction covered by water; and, second, that the doubling or halving of the calculated absolute surface which these assumptions would require would alter the value of the energy of activation as found below by about 500 cal., which is less than the possible experimental error.

Calculation of Fraction of Surface Free from Adsorbed Water

Taking the above interpretation as substantially correct, and assuming that at the temperatures employed hydrogen is incapable of reacting with those adsorbed oxygen atoms which are covered with adsorbed water, we can calculate the retarding influence of water vapor on the reaction. If we denote by Θ the fraction of the adsorbed oxygen atoms which are covered by water under any given conditions, then $\Theta = V/V_0 = aP/(1 + aP)$. The fraction not so covered is $1 - \Theta = 1/(1 + aP)$.

If the values of a obtained in the previous section are inserted in this equation, approximate values of $1 - \Theta$ may be obtained, but it has seemed best to proceed in a somewhat different manner. From the values of V_0 already given, it is evident that the limiting adsorptive capacity for water is appreciably greater at 100° than at 110°. This probably means that as we approach a point at which the vapor is saturated, some of the adsorbed oxygen atoms become capable of taking up a second molecule of water. To overcome this difficulty, we may calculate the values of a as follows. Noting that when $\Theta = 1/2$, $a = 1/P$, and assuming as before that the total surface is measured by the 6.2 cc. of oxygen adsorbed, we may take the value of a at each temperature as the reciprocal of the pressure at which 6.2 cc. of water vapor are adsorbed. From Series 1 and 2 of Fig. 1, these values are found to be 0.0224 mm.^{-1} at 110° and 0.0284 mm.^{-1} at 100°.

From the derivation of the adsorption isotherm as given by Langmuir,[6] it may be shown that the variation of a with temperature should follow an equation of the form

$$\frac{d \log a/T^{1/2}}{d(1/T)} = \frac{Q}{4.58} = \text{constant} \qquad (1)$$

Accordingly, $\log a/T^{1/2}$ was plotted against $1/T$, and a straight line drawn through the two observed points. In this way values of a were obtained for the temperatures used in the catalysis: 0.0233 at 108° and 0.0327 at 94°.

Calculation of Specific Reaction Rate Constant

In the earlier paper it was shown that the kinetics of this reaction in flow system follow the equation

$$Y = \frac{k \cdot P_H}{1 + aP_W} \qquad (2)$$

where Y is the rate of reaction in mg. of water per five minutes, P_H and P_W are the averages of the entering and exit pressures (in mm. of mercury) of hydrogen, and water vapor, respectively, and k is the specific reaction rate constant. Considerations outlined in another place[7] show that when, as in these experiments, the conversion does not exceed 50% no serious error is introduced by the use of these arithmetical average pressures instead of the true averages obtained by integration.

From the values of a obtained in the previous section and from the data

---

[7] Benton, *Ind. Eng. Chem.*, 19, 494 (1927).

of Table I, the values of k in Equation 2 may now be calculated. The results are given in Table III.

TABLE III

SPECIFIC REACTION RATE CONSTANTS

Temperature, 108°			Temperature, 94°		
Run	$1 + aP_W$	*k*	Run	$1 + aP_W$	*k*
13	*2.96*	*0.521*	*21*	*3.56*	0.293
15	*3.14*	.477	*23*	*3.73*	.274
11	*3.46*	.513	*24*	*3 90*	.220
17	*4.06*	.498	*25*	*4.13*	.214
19	*4.46*	.485	*27*	*4.44*	.220
	Av.,	.499		**Av.,**	.244
				Av. of last *3,*	.218

Some inconsistency is evident in the results at 94°, particularly in Runs 21 and 23, where the smallness of the observed yields involves a relatively large experimental error. For this reason the average of the last three runs at 94° is considered more reliable than the average of all five runs. With the exceptions noted, Equation 2 is satisfactorily confirmed.

Calculation of True Energy of Activation

According to Arrhenius' original formulation[8] of the effect of temperature on reaction rate, the energy of activation, E, may be calculated from the equation $k \propto e^{-E/RT}$, where R is the gas constant per mole and T is the absolute temperature. For reactions in which the rate is proportional to the collision frequency, however, a slight modification is necessary,[9] since the rate of collision is itself a function of temperature. At constant pressure the rate at which gas molecules collide with a solid surface is inversely proportional to the square root of the absolute temperature; accordingly, the variation of k with temperature should follow the equation $k \propto T^{-1/2} e^{-E/RT}$. Taking logarithms on both sides, and solving for E. we obtain

$$E = \frac{4.58 T_1 T_2}{T_1 - T_2} \log \frac{k_1 T_2^{1/2}}{k_2 T_1^{1/2}}$$

From the averages given in Table II ($T_1 = 381$, $k_1 = 0.4'3'3$, $T_2 = 367$, $k_2 = 0.218$), E is found to be 16,800 cal. per mole of water formed. If k_2 is taken as 0.244, E = 14,600. The unmodified Arrhenius equation leads to values about 250 cal. smaller.

Since measurements of water adsorption were not made on the catalyst employed in the earlier work, the true energy of activation can be calculated from the data there obtained only on the assumption that the same values of the adsorption constant, *a*, are applicable to both catalysts.

---

[8] Arrhenius, *Z. physik.* ***Chem., 4, 226 (1889).***

[9] Compare Hinshelwood, "Kinetics of Chemical Change in Gaseous Systems," Oxford University Press, 1926, p. 100.

This assumption is not altogether unreasonable, since it does not require that equal quantities of water be adsorbed by the two catalysts, but only that the shape of the adsorption isotherms be similar at equal temperatures. On this assumption we have calculated from Equation 1 values of a for the original catalyst at the temperatures used, and have employed these to determine the reaction rate constants, k, and the energy of activation. From the data of Tables I and VI of the earlier paper, E is found in this way to be 15,900 (Table I), 16,100 (Table VI, First Series) and 15,600 (Table VI, Second Series).[10]

From a consideration of these several calculations, we may take the value of the energy of activation obtained from the temperature coefficient as 16,000 cal., with an uncertainty of perhaps 1000 cal.

Test of Collision Mechanism of Reaction

On the basis of the proposed mechanism, every collision of gaseous hydrogen with adsorbed oxygen, which is free from adsorbed water, should be effective, in which the total energy available in the collision exceeds the energy of activation, E. In the previous paper it was shown that the rate of collision (R) of hydrogen with the surface, expressed in terms of the equivalent milligrams of water per five minutes, is

$$R = \frac{2.22 \times 10^5}{\sqrt{T}} \cdot S \cdot P_H$$

where S is the area, in sq. cm., of the surface occupied by adsorbed oxygen. If we denote by f the fraction of these collisions which are effective, it is evident that the specific reaction rate constant, k, is given by the equation

$$k = \frac{2.22 \times 10^5}{\sqrt{T}} \cdot S \cdot f \qquad (3)$$

If the energy of activation is furnished entirely by the impinging hydrogen or entirely by the adsorbed oxygen, or however it may be distributed between the two, the fraction of the collisions in which the total energy available is in excess of E is given approximately by the expression $e^{-E/RT}$

The surface area S which is occupied by oxygen may readily be calculated on the assumption that the adsorption of this gas represents a monatomic layer in which a single oxygen atom is attached to each adsorbing silver atom. The argument in favor of this assumption has been given in a previous section. On this basis, the 6.2 cc. (0°, 760 mm.) of oxygen adsorbed by the catalyst represents a surface containing 3.4×10^{20} silver

---

[10] In the earlier paper it was stated incorrectly that the observed energy of activation would necessarily be reduced when corrected for the change of water adsorption with the temperature. This statement overlooked the fact that the higher partial pressure of water vapor corresponding to the increased yields at the higher temperature may more than counterbalance the decrease in the constant a.

atoms. Since the molecular volume of silver is 10.3 cc., each silver atom occupies 1.70×10^{-23} cc., and the area assignable to each atom in the surface is $(1.70 \times 10^{-23})^{2/3}$, or 6.6×10^{-16} sq. cm. Hence the adsorbing surface of the catalyst is 2.2×10^5 sq. cm.

Inserting this value of S in Equation **3,** we obtain

$$k = \frac{4.9 \times 10^{10}}{\sqrt{T}} e^{-\frac{E}{RT}}$$

From this equation, with E taken as 16,000 cal., the calculated values of k are 1.9 at 108° and 0.88 at 94°, which may be compared with the experimental values of 0.50 and 0.22, respectively. Owing to the exponential form of the equation, however, a better comparison may be obtained by inserting the observed values of k, and calculating E. In this way E is found to be 16,900 cal. The discrepancy between the two values of E is probably within the possible limit of experimental error.

It may be mentioned that the value of the surface area employed in this calculation is certainly too large. Measurements reported in the previous paper showed that while at least half of the oxygen adsorption occurs practically instantaneously, the remainder of the gas is taken up with great slowness, so that the quantity of oxygen actually on the surface during a catalytic experiment must be less than the amount present when adsorption equilibrium has been established. From a consideration of the relative rates at which oxygen is adsorbed and removed by reaction with hydrogen it appears that the quantity actually present on the surface during the catalysis was only about half as great as the value found in the adsorption measurements. When the new value of S thus obtained is employed in Equation 3, the value of E calculated from either of the observed values of k is 16,400 cal.

Conclusion

Although the results confirm the hypothesis that reaction occurs at every collision of hydrogen with "dry" adsorbed oxygen, in which the energy available on collision exceeds the energy of activation, no information is furnished as to the proportion in which this energy is contributed by each of the reacting species, or the kinds of energy involved. If the hydrogen must be in an exceptional energy state, this energy is presumably either kinetic or rotational or both, since the specific heat at the temperatures in question shows the absence of vibrational energy, and electronic excitation is precluded by the small magnitude of the energy of activation observed.

The theory of the catalytic surface proposed by Taylor[11] postulates that the surface of a typical catalyst is composed of atoms of widely

---

[11] **Taylor,** *Proc. Roy. Soc., London,* **108A, 105 (1925).**

varying catalytic activity. If this view is correct in the case of silver, it would follow that collisions of hydrogen with oxygen adsorbed on the most active parts of the surface would be much more effective than elsewhere. Thus the energy of activation calculated from the observed reaction rates would represent a statistical average taken over the whole surface, varying from very small energies of activation for the most active spots to very high energies for the least active spots. The energy of activation calculated from the temperature coefficient of the reaction rate would represent a similar average, since the activity of the relatively inactive spots must increase more rapidly with temperature than the activity of those which are already more active. Hence it would appear that, while the results of this investigation do not lend any additional support to the theory of active spots, they can probably be satisfactorily reconciled with it.

Summary

An earlier study of the rate of combination of hydrogen and oxygen in contact with a silver catalyst has been in part repeated and extended to include measurements of the adsorption of all the gases concerned. The principal results are as follows.

1. Hydrogen is not measurably adsorbed by the catalyst under the conditions employed but oxygen is strongly adsorbed and to an extent nearly independent of temperature and pressure. The effective surface area of the catalyst has been calculated from the oxygen adsorption, on the assumption that the latter represents a monatomic layer.

2. Water vapor is somewhat adsorbed by a bare silver surface but much more strongly when the surface is already occupied by adsorbed oxygen. The results follow adsorption isotherms of the Langmuir type and permit a calculation of the fraction of the surface free from adsorbed water under the conditions of the catalysis.

3. The rate of the reaction is found to be independent of the pressure of the oxygen but proportional to the hydrogen pressure and to the fraction of the surface free from adsorbed water. The true energy of activation, obtained from the temperature coefficient, is 16,000 cal., with an uncertainty of about 1000 cal.

4. It has been found that the absolute rate of reaction agrees with that calculated on the hypothesis that reaction results from every collision of gaseous hydrogen with "dry" adsorbed oxygen in which the total energy available on collision exceeds 16,400 cal. Since these two values of the energy of activation differ by less than the experimental error, the hypothesis is considered to be confirmed for this particular reaction.

AN EQUATION OF STATE FOR GASEOUS MIXTURES. I APPLICATION TO MIXTURES OF METHANE AND NITROGEN

BY JAMES A. BEATTIE

RECEIVED MAY 16, 1928 PUBLISHED JANUARY 8, 1929

1. Introduction

Recently a new equation of state has been proposed by O. C. Bridgeman and the author[1] and applied to the compressibility data on the ten gases helium, neon, argon, hydrogen, nitrogen, oxygen, air, carbon dioxide, methane and ethyl ether. The measured pressures were reproduced over the experimentally measured temperature range and for a wide range of densities with an average deviation of 0.18% for all ten gases. This equation of state is

$$p = \frac{RT(1-\epsilon)}{V^2}[V+B] - \frac{A}{V^2} \qquad (1)$$

where A $= A_0\,(1 - a/v)$; $B = B_0\,(1 - b/v)$; $\epsilon = c/VT^3$; R is the gas constant and A_0, a, B_0, b and c are constants whose values depend upon the kind of gas under consideration.

In the present paper this equation is applied to the comprehensive set of data taken by Keyes and Burks on mixtures of methane and nitrogen, by the use of a simple rule for the calculation of the values of the constants of the mixture from those of the pure component gases. The agreement between the observed and calculated pressures is good and leads to the expectation that the method used for the calculation of the values of the constants in the case of the methane and nitrogen mixtures will also apply to other gaseous mixtures.

In his treatment[2] of binary systems, van der Waals assumed that the equation of state of a gaseous mixture was of the same general form as that for a pure gas, *i. e.*

$$p = \frac{RT}{V-b} - \frac{a}{V^2}$$

He suggested that the value of the b constant for a mixture of two gases could be calculated by "linear combination" of the b values for the pure gases

$$b_x = b_1\,(1-x) + b_2x$$

where x is the mole fraction of the second component. However, through-

[1] Beattie and Bridgeman, THIS JOURNAL, 49, 1665 (1927); *ibid.*, **50**, 3133, 3151 (1928). A comprehensive treatment of the equation of state and a detailed comparison with the compressibility data are given in Proc. *Am. Acad. Arts Sci.*, **63**, 229 (1928).

[2] Van der Waals, "Die Continuitat des Gasformigen und Flussigen Zustandes," Part II, Barth, Leipzig, 1900.

out his book van der Waals employed the relation deduced from kinetic theory by Lorentz[3]

$$b_x = b_1(1-x)^2 + 2\,b_{12}x(1-x) + b_2x^2$$

in which

$$b_{12} = \left(\frac{1}{2}\sqrt[3]{b_1} + \frac{1}{2}\sqrt[3]{b_2}\right)^3$$

If, however, b_{12} can be represented as the average of b_1 and b_2

$$b_{12} = (b_1 + b_2)/2$$

the Lorentz equation for b_x reduces to the linear combination rule of van der Waals.

For the cohesive constant van der Waals used the relation

$$a_x = a_1(1-x)^2 + 2a_{12}x(1-x) + a_2x^2$$

a_{12} being an interaction constant which cannot in general be calculated from a_1 and a_2.

Galitzine[4] applied an equation of the Clausius type to Andrews'[5] data on mixtures of nitrogen and carbon dioxide and calculated the interaction constant by the relation $a_{12} = \sqrt{a_1a_2}$; the complete expression for a_x becoming

$$a_x = a_1(1-x)^2 + 2\sqrt{a_1a_2}\,x(1-x) + a_2x^2$$

or

$$\sqrt{a_x} = \sqrt{a_1}(1-x) + \sqrt{a_2}\,x$$

i. e., the square root of the a constant is linearly combined. He also used the same method of combination for the b constant,

Somewhat later D. Berthelot[6] proposed that in the application of van der Waals' equation to binary mixtures, the parameters b_x and $\sqrt{a_x}$ for the mixture be obtained by linear combination of the b and $\sqrt{a}$ constants of the component gases. This method was criticized by van der Waals,[7] who believed than in general the properties of a mixture cannot be calculated from those of the component gases, because a_{12} cannot be obtained from the constants of the pure gases. This view is also held by Happel,[8] who shows that a_{12} cannot be calculated from a_1 and a_2 unless some assumption is made regarding the law of the attractive force between the unlike molecules of the gas mixture.

Trautz and Emert[9] have measured the increase in pressure resulting from mixing two gases for many binary systems at about one atmosphere

and at several temperatures. They computed the values of a and b of the van der Waals' equation for the pure gases at each temperature by means of van Laar's[10] temperature functions. The constants for the mixtures were obtained from these values, using the Lorentz method of combination for b, and the Galatzine–Berthelot method for a. The experimental results were explained reasonably well, although not within the experimental error.

Keyes and Burks[11] have presented a series of measurements on mixtures of methane and nitrogen and have treated these data by means of the Keyes equation for a non-associating gas

$$p = \frac{RT}{V - \beta e^{-\alpha/V}} - \frac{A}{(V + l)^2}$$

They found that the values of the constants obtained by passing an equation of state through the compressibility data on the mixtures could be calculated from the constants for the pure gases and the compositions of the mixtures when each of the constants R, β, α, $\sqrt{A}$, 1, was combined linearly.

Dalton's law of the additivity of pressures at constant volume and temperature has been the basis of much of the treatment of gas mixtures, although this principle has long been known to hold only approximately for real gases. Amagat,[12] from a study of his measurements of the compressibility of oxygen, nitrogen and air to 3000 atmospheres, found that at constant temperature and pressure the pV product for air could be obtained by linear interpolation between the pV products of the pure gases. Since the pressure is the same throughout, this rule states that the volume of a gas mixture is given by the sum of the volumes of the component gases, each measured under the total pressure of the mixture. In this form, the Amagat law of the additivity of volumes at constant pressure and temperature was studied by Leduc,[13] who claimed that it was quite exact for mixtures of the permanent gases. Penning[14] has used the exactness of this relation for air as a test of the accuracy of his measurements, and Holborn and Otto[15] have employed the rule to calculate the compressibility of pure neon from measurements on a neon–helium mixture containing 28% of helium. Keyes and Burks[11] have shown that the Amagat law is a better approximation than Dalton's

law for methane–nitrogen mixtures and the same has been found true for oxygen–argon mixtures by Masson and Dolley[16] although the reverse was the case for argon-ethylene and oxygen-ethylene mixtures. Gillespie[17] has demonstrated that the Lewis and Randall[18] rule, which can be taken as the additivity of fugacity for gaseous mixtures at constant pressure and temperature, is correct only if the Amagat law holds.

Verschoyle[19] has shown that in the isothermal expansion

$$pV = A + Bp + Cp^2$$

the constants B and C for mixtures of hydrogen and nitrogen are not linear functions of the compositions but lie on smooth curves. Lennard-Jones and Cook,[20] from a consideration of the interaction between molecules, obtain for the B coefficient of a mixture the relation

$$B'_x = B'_{11}(1 - x)^2 + 2B'_{12}x(1 - x) + B'_{22}x^2$$

in which B'_{12} arises from the interaction of molecules of unlike species. A relation for the temperature dependence of B'_{12} is deduced and compared with the experimental results, with substantial agreement.

2. Calculation of the Values of the Constants for Gaseous Mixtures

It seems reasonable to suppose that the equation of state of a given gaseous mixture would be of the same general form as that for a pure gas and that the values of the constants could be obtained from the compressibility data in the same manner as from similar data on a pure gas. Whether the constants so obtained can be computed with sufficient accuracy for purposes of thermodynamic calculation from the values of the constants of the pure gases and the composition of the mixture is a question which must be settled experimentally. In the present paper a simple method for calculating the values of the constants of a mixture is studied from the standpoint of the experimental measurements on methane–nitrogen mixtures.

Kinetic theory considerations lead in general to quadratic equations such as those deduced by Lorentz for the calculation of the equation of state constants of a binary mixture from those of the component gases. If the interaction constant (*i. e.*, b_{12} or a_{12}) can be taken as the average of the constants of the pure gases, the equation for combining the constants reduces to a linear one; while if the interaction constant can be taken as the square root of the product of the constants of the pure gases, the rule

[20] Lennard-Jones and Cook, *ibid.,* **115A, 334** *(1927).*

reduces to linear combination of the square roots of the constants. The former assumption is more logical when the constant contains the dimension of density to the first power and the latter when the constant contains the dimension of density squared.

It is proposed that the values of the constants of Equation 1 for mixtures can be obtained from the constants of the pure gases by linear combination for those constants in which the dimension of density is contained to the first power, namely, a, B_0, b, c and R, and by linear combination of the square root of the constant A_0, in which the dimension of density is contained to the second power.

The volume V of Equation 1 may be (a) the total volume of n moles of the mixture, (b) the volume of an average mole or (c) the volume of one gram of the mixture.

(a) When V is the volume of n moles consisting of n_1 moles of Gas 1, n_2 moles of Gas 2, etc., the rule of combination becomes

$$\begin{aligned} A_m &= (n_1\sqrt{A_{01}} + n_2\sqrt{A_{02}} + n_3\sqrt{A_{03}} + \ldots)^2 &&= (\Sigma n_1\sqrt{A_{01}})^2 \\ a_m &= n_1a_1 + n_2a_2 + n_3a_3 + \ldots &&= \Sigma(n_1a_1) \\ B_{om} &= n_1B_{01} + n_2B_{02} + n_3B_{03} + \ldots &&= \Sigma(n_1B_{01}) \\ b_m &= n_1b_1 + n_2b_2 + n_3b_3 + \ldots &&= \Sigma(n_1b_1) \\ c_m &= n_1c_1 + n_2c_2 + n_3c_3 + \ldots &&= \Sigma(n_1c_1) \\ R_m &= n_1R + n_2R + n_3R + \ldots &&= \Sigma(n_1R) \end{aligned} \tag{2}$$

where the subscript m refers to the value of the constant for the mixture, the subscript 1 refers to Gas 1, and the summation extends over all of the gases in the mixture.

(b) When V is the volume of an average mole of the mixture, the number of moles n_1, n_2, etc., of the relations given under (a) are replaced by the mole fractions x_1, x_2, . . . of the gases composing the mixture.

(c) When V is the volume of one gram, the constants are combined according to the methods given in Equation 2, the mole numbers n_1, n_2, . . . being replaced by w_1, w_2, . . . where w is the weight fraction and the values of the constants R_1, A_{01}, a_1, B_{01}, etc., are the appropriate values for one gram of the pure Gas 1.

It is now possible to write the complete equation of state for a mixture. Using for instance the relations (2) we obtain

$$p = \frac{\Sigma(n_1)RT\,(1 - \epsilon)}{V^2}\,[V + B] - \frac{A}{V^2} \tag{3}$$

where $A = (\Sigma n_1\sqrt{A_{01}})^2[1 - \Sigma(n_1a_1)/V]$, $B = \Sigma(n_1B_{01})[1 - \Sigma(n_1b_1)/V]$, and $\epsilon = \Sigma(n_1c_1)/VT^3$. When a mixture of a given composition is studied it is more convenient to calculate from Equation 2 the values of the constants for the mixture, and use these values in Equation 1, the mixture then being treated as a pure substance. When, however, the effect of a variation in composition is considered, the general equation of state of mixtures (3) or its counterpart using the mole fraction or weight fraction must be used.

3. The Virial Equation of State for Mixtures

Since the equation of state **(3)** is completely algebraic, it can be rearranged into the virial form

$$pV = \Sigma(n_1)RT + \frac{\beta_m}{V} + \frac{\gamma_m}{V^2} + \frac{\delta_m}{V^3} \tag{4}$$

where

$$\beta_m = \Sigma(n_1)RT\Sigma(n_1B_{01}) - (\Sigma n_1\sqrt{A_{01}})^2 - \left(\frac{\Sigma(n_1)R\Sigma(n_1c_1)}{T^2}\right)$$

$$\gamma_m = -\Sigma(n_1)RT\Sigma(n_1B_{01})\Sigma(n_1b_1) + (\Sigma n_1\sqrt{A_{01}})^2\Sigma(n_1a_1) - \left(\frac{\Sigma(n_1)R\Sigma(n_1B_{01})\Sigma(n_1c_1)}{T^2}\right)$$

$$\delta_m = \frac{\Sigma(n_1)R\Sigma(n_1B_{01})\Sigma(n_1b_1)\Sigma(n_1c_1)}{T^2}$$

The parameters β_m, γ_m and δ_m are algebraic functions of temperature, the mole numbers and the values of the constants of the gases composing the mixture. For a mixture of constant composition these parameters depend only on the temperature. By use of Equation 4 most of the usual thermodynamic equations can be integrated and hence many of the more important properties of gas mixtures calculated.[21]

The second virial coefficient β_m for a binary mixture can be written in the form obtained by Lennard-Jones and Cook[20]

$$B'_x = B'_{11}(1-x)^2 + 2\,B'_{12}x(1-x) + B'_{22}x^2$$

where $B'_x = \dfrac{\beta_m}{\Sigma(n_1)^2RT}$ and x is the mole fraction of the second constituent. By comparison with Equation 4, it can be seen that

$$B'_{11} = B_{01} - A_{01}/RT - c_1/T^3$$

$$B'_{22} = B_{02} - A_{02}/RT - c_2/T^3$$

$$2B'_{12} = B_{01} + B_{02} - 2\sqrt{A_{01}A_{02}}/RT - (c_1 + c_2)/T^3$$

Thus by use of the method of combining the constants given in Section 2, it is possible to calculate the value of B'_{12} from the equation of state constants of the pure gases composing the mixture and also determine its temperature variation.

4. Comparison of the Equation of State for Mixtures with the Experimental Data

It is generally true that two sets of pressure–volume–temperature data taken by different observers on the same gas do not agree with each other to the same order of accuracy as the consistency of each group of measurements within itself. Hence for a study of gas mixtures, the observations on the pure gases as well as on the mixtures should be made in the same apparatus. There exist several sets of data which fulfil this condition but in almost every case the investigator studied so few isotherms that it is not possible by a treatment of these data alone to obtain reliable constants for the pure gases.

---

[21] *Cf.* Beattie, *Phys. Rev.*, *31*, *680 (1928)*; *ibid.*, *32*, *691*, *699 (1928)*.

In the bibliography on the compressibility of gas mixtures given by Pickering,[22] the only measurements which are complete enough to test an equation of state for mixtures are those of Bartlett, which will be treated later.

Recently Keyes and Burks have measured the compressibility of methane[23] and three mixtures of methane and nitrogen[23,24] for five isotherms from 0 to 200° and for pressures extending to about 250 atmospheres. Using the same apparatus, Smith and Taylor[25] had previously measured the compressibility of pure nitrogen over the same temperature and pressure range. There is thus presented a complete series of pressure–volume–temperature data extending from pure nitrogen to pure methane covering the same temperature and pressure range. They were taken in the same apparatus using the same methods for calculating the results and hence the relative values should be very good, probably better than the absolute values.

In a previous publication,[1] the data of Smith and Taylor on pure nitrogen and of Keyes and Burks on pure methane have been considered, and the constants of the equations of state, based on these two sets of measurements alone, determined in units of international atmospheres, liter per mole and degrees Kelvin. Since all of the original **data** of these two groups of observers are in the volume unit of cubic centimeters per gram, the constants have been calculated to this basis. In Table I are given these values of the constants for the pure gases, together with those for the

TABLE I

VALUES OF THE EQUATION OF STATE CONSTANTS FOR NITROGEN, METHANE AND THEIR MIXTURES

Units: international atmospheres; cc. per gram; degrees Kelvin (**T°K.** = t°C + 273.13). Compositions are in weight fractions. The values of the constants for the mixtures are calculated from the constants of the pure gases and the compositions by means of the relations (2).

Gas	$\Sigma(w_1R_1)$	$(\Sigma w_1\sqrt{A_{01}})^2$	$\Sigma(w_1a_1)$	$\Sigma(w_1B_{01})$	$\Sigma(w_1b_1)$	$\Sigma(w_1c_1)$
Nitrogen	2.92904	1457.5	0.6382	1.5398	−0.5740	2.00 × 10^6

5. Discussion of the Results

It may be well to emphasize that the values of the constants for the mixtures were calculated by means of the relations (2) from the constants of the pure gases and the composition of the mixtures, *and were not derived by passing an equation through the mixture data.*

The volume of the piezometer used in all the measurements of Smith and Taylor and of Keyes and Burks was about **13** cc., and hence for specific volumes below 7 cc. per gram the total volume of the gas was small—from 2 to 3 cc. At these large densities, a small error in the specific volume makes a large error in the pressure. Therefore, in taking the "Total Average Deviations" the two isometrics below **7** cc. per gram were not included. With this exception and two points in Table V all the measured pressures were used in taking the averages.

The equation reproduces the measured pressures for the pure gases nitrogen and methane very satisfactorily, as can be seen by an examination of Table VII. Two independent sets of measurements were made by Keyes and Burks with mixtures containing about 70% methane. The equation of state for mixtures reproduced these data with average deviations of 0.11 and 0.23%, which is again a very satisfactory result. It will be noticed that for the 70.31% methane mixture, all the deviations are positive and increase in a regular manner with the density, which could be explained by a slight error in the measured composition and hence account for the somewhat larger average deviation. The average deviation for the 30% methane mixture, which was not checked, is larger than for either of the others, being 0.55%. This could be explained on the basis of an error in the composition of the mixture, especially as the deviations are all positive and progress in a regular manner with the density. A small variation in the values of the constants A_{0m} and B_{0m} for a mixture, due to a variation in the assumed composition, will cause a large variation in the calculated pressure at the larger densities.

The question of whether or not the method of combining the constant used in the case of methane and nitrogen will prove satisfactory for other gas mixtures must be settled by further experimental work. If the equation of state constants for the two gases composing a mixture have about the same values, it may be impossible to conclude that one method of combining the constants is better than any one of several other possible methods. In the case of methane and nitrogen the B_0 constants (on a molal basis) are not so very different from each other; but for all of the ten pure gases so far treated[1] the B_0 constant does not show a wide variation (with the exception of ethyl ether). The A_0 constant for methane is about twice that for nitrogen (on a molal basis), which represents a rather wide variation. Thus it is believed that the method of combining constants used in the present paper for methane and nitrogen will hold for many other gas mixtures.

6. Summary

The equation of state proposed by Beattie and Bridgeman has been applied to mixtures of methane and nitrogen by use of a simple method for calculating the values of the constants of the mixture from those for the pure gases. The constants R, a, B_0, b and c which contain the dimension of density to the first power are combined linearly, thus $B_{0x} = B_{01}(1 - x) + B_{02}x$; the A_0 constant contains the dimension of density to the second power and hence the square root of A_0 is combined linearly, $A_{0x} = [\sqrt{A_{01}}(1 - x) + \sqrt{A_{02}}x]^2$.

It is concluded that it is possible to write a single equation by means of which pressures for the entire series of mixtures of methane and nitrogen, including the pure gases, can be calculated from the temperature, density and composition.

The satisfactory nature of the agreement between observed and calculated pressures for the mixtures of methane and nitrogen leads to the expectation that this method of combining the constants will prove applicable to mixtures of other gases. The general equation of state for mixtures is presented in Equation 3 and the virial form in Equation 4. This equation of state is completely algebraic and can be used for the integration in terms of elementary functions of many thermodynamic relations.

THE FORMATION OF OZONE IN THE ELECTRICAL DISCHARGE AT PRESSURES BELOW THREE MILLIMETERS[1]

BY JAMES K. HUNT

RECEIVED MAY 17, 1928 PUBLISHED JANUARY 8, 1929

Ozone formation in the electrical discharge has been studied chiefly at atmospheric pressures under conditions which give a non-uniform distribution of ionization. The purpose of this investigation was the study of the factors involved in the formation of ozone in an electrical discharge at low pressures, under conditions of somewhat greater uniformity. Pressures below three millimeters of mercury were employed and a high precision in the chemical analysis was demanded for these minute quantities of ozone.

In a previous communication from this Laboratory[2] the influence of the electrodes was studied down to 14 mm. and the ratio of electrode area to

---

[1] This *communication is based on a thesis submitted for the degree of Doctor of Philosophy at the University of Wisconsin in 1926, under the direction of Farrington Daniels.*

[2] Newsome, THIS JOURNAL, **48**, **2035** (1926).

the volume of the discharge was made large. In the present research this ratio was made as small as possible in order to minimize the influence of the electrodes.

In one other research using a Siemens ozonizer and alternating current,[3] the pressure range has been carried down to 27 mm.

Apparatus and Procedure

The apparatus is shown in Fig. 1. The electrodes E, E' of the discharge tube T were connected to a source of high potential, S. An adjustable alcohol-xylene rheostat, R, of high resistance, was used for stabilizing and regulating the current. The induction coil, C, served to initiate the discharge, and the air gaps B, B' in the circuit prevented the short circuiting of the battery through the secondary of the coil. The potential drop across the tube was indicated by a Braun electrostatic voltmeter, V.

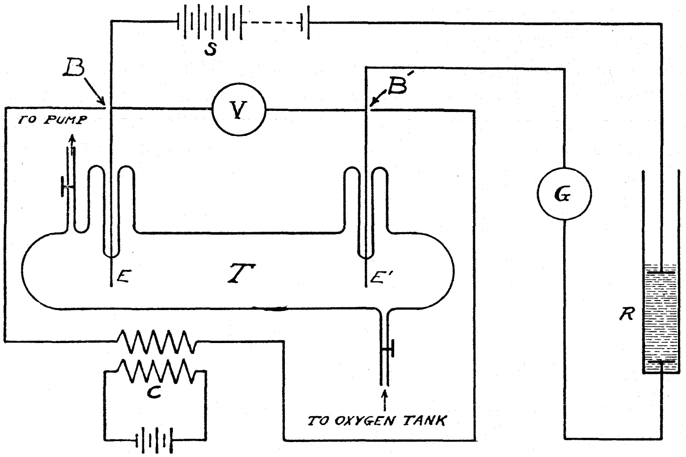

Fig. 1.—Discharge chamber and electrical connections.

The discharge tube was of soft glass about **60** cm. long and **7.2** cm. in diameter, with electrodes **45** cm. apart. These tubes had all-glass seals, but later another tube was used in which the electrode holders were sealed in with wax at a ground-glass joint to facilitate the interchange of different kinds of electrodes and to permit variation of the electrode distance.

Pressures within the discharge tube were read with a modified McLeod gage capable of measuring quickly and accurately from **3** mm. to **0.01** mm. of mercury. A Hyvac oil pump was used for evacuating the discharge tube down to **0.001** mm. The voltage for maintaining the discharge was obtained from 36 B batteries,[4] in series, giving a total potential of over 1600 volts. The current through the tube was measured with a shunted galvanometer which was calibrated to **0.05** milliampere. The electrodes of platinum, gold, aluminum and carbon were **0.4, 0.4, 1** and **2** mm. in diameter, respectively, and each was **3** cm. long. The electrodes of platinum foil were **1** cm. wide and **3.5** cm. long.

The whole tube was filled with a uniform blue glow during the discharge but the

---

[3] Warburg and Rump, *Z. Physik*, **32,245 (1925).**

[4] These batteries were kindly donated by the French Battery Co., Madison, Wis.

light was much more intense and somewhat lavender in shade around the electrodes, particularly around the negative electrode. The region of intense glow appeared to extend out about a millimeter from the electrodes under most of the conditions.

Carefully purified oxygen was used in the earlier experiments but subsequent experiments showed that the traces of hydrogen present in the electrolytic oxygen from a tank had no appreciable effect on the yield of ozone under the conditions of these experiments.

Preparatory to making a determination the tube was alternately exhausted and filled with oxygen several times to remove the nitrogen remaining in the tube. At a pressure of oxygen of about **2** mm. a current of **4** milliamperes was passed through the tube for five minutes to "age" the electrodes.

"Aging" was necessary since preliminary experiments had shown that with fresh electrodes the results were discordant and somewhat lower. This aging phenomenon was also observed by Anderegg[6] and Newsome.[2] After the preliminary discharge, the tube was twice evacuated and filled with oxygen to remove the ozone produced in the aging process. No ozone remained absorbed on the walls or electrodes after this treatment, as shown by the potassium iodide test.

After filling again with oxygen and evacuating to the desired pressure, the discharge was passed through the tube for a definite period of time while the current was carefully controlled and the voltage recorded. The tube was then disconnected and into it was carefully admitted about **80** cc. of **2%** potassium iodide solution. After shaking intermittently for half an hour the solution was run out, acidified with dilute sulfuric acid and titrated with $M/1000$ sodium thiosulfate solution, **1** cc. of which is equivalent to **0.000024** g., or **3.03** $\times$ 10^{17} molecules of ozone. Freshly prepared starch was used as an indicator and the titrations were carried out in **100-cc.** Nessler tubes. The end-point was accurate to about **0.1** cc. of thiosulfate solution.

Experimental Results

The variables of time, pressure, current, electrode area, electrode distance and electrode material were studied and the results are summarized[6] in Figs. 2, 3 and 4 and in Tables I, II and III.

The points in Figs. 2, 3 and 4 indicate the agreement to be expected. In general the yields of ozone increase slightly with successive check experiments.

Interpretation of Experimental Results

Time.—In a closed tube the yield of ozone does not increase directly with the duration of the discharge, since an equilibrium is soon reached

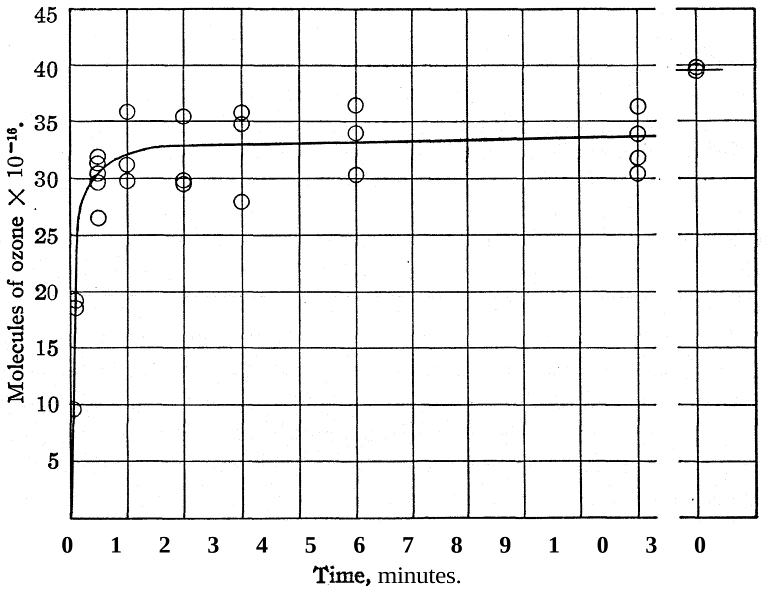

Fig. 2.—Variation in ozone yield with time. Pressure, **1.9** mm.; current, **2** milliamperes; potential drop, **850** volts; electrodes of platinum wire.

and the ozone is decomposed as fast as it is formed. The yields approach a limiting value, as shown in Fig. 2, and the yields per faraday and per kilowatt hour decrease with longer periods of time. During the first thirty seconds, however, the quantity of ozone is approximately proportional to the input of electricity, that is to the time, because the equilibrium mixture has not been reached and the concentration of ozone is so low that its decomposition is less important.

Pressure.—In Fig. **3** it is seen that the yield of ozone is greater at the higher pressures, perhaps on account of the greater number of collisions. Since the yield is limited by equilibrium conditions, it is not to be expected that the yield of ozone will vary directly with the pressure.

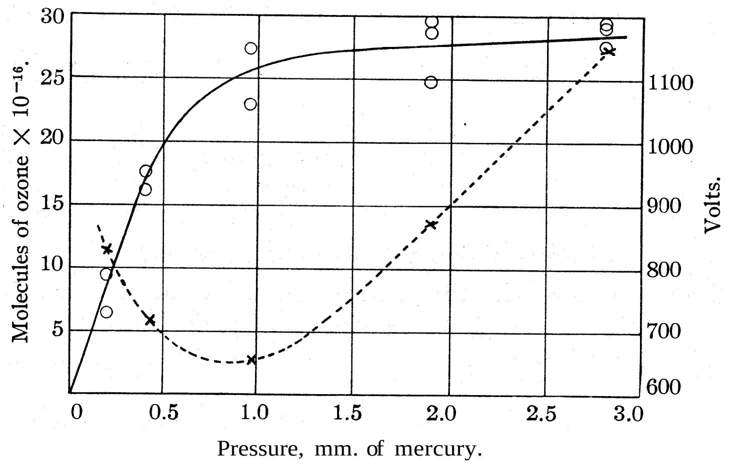

Fig. 3.—Full line: variation in ozone yield with pressure; broken line: variation in voltage with pressure at constant current; time, 30 seconds; current, 1 milliampere; electrodes of platinum wire.

Current.—Since the formation of ozone depends on the formation of ions, the yield must depend on the electrical energy input rather than on the current, for the current and the time constitute only the capacity factor of the electrical energy. Fig. 4 shows that as much ozone is formed with 1 milliampere as with 6 milliamperes. These facts indicate that the energy of which 1 milliampere is the capacity factor is sufficient to bring about in thirty seconds a state of approximate equilibrium and therefore it is not to be expected that more current (or energy) will result in a greater ozone yield.

Electrode Distance.—The full effect of increasing the distance between the electrodes is quite complicated but the chief factor is probably the greater energy input caused by the greater potential drop across the tube required to maintain a constant current. In Table I it is interesting to note that as the electrode distance increases the ozone yield increases, but the yield per kilowatt hour remains practically constant.

Electrode Area.—Table II shows that in most cases the yield of ozone is independent of anode area but somewhat dependent on cathode area. It is known that the potential drop is greatest at the cathode and that the ionization in the region around the cathode is much more intense than the ionization at the anode. Rideal and Kunz[7] found more ozone around the cathode than around the anode. An increase in the area of the cathode gives an increase in the volume of the cathode glow and increases the yield of ozone. The two experiments in which foil was used as the cathode are similar to those of Newsome[2] and suggest that in these two cases ozone may be decomposed at the anode.

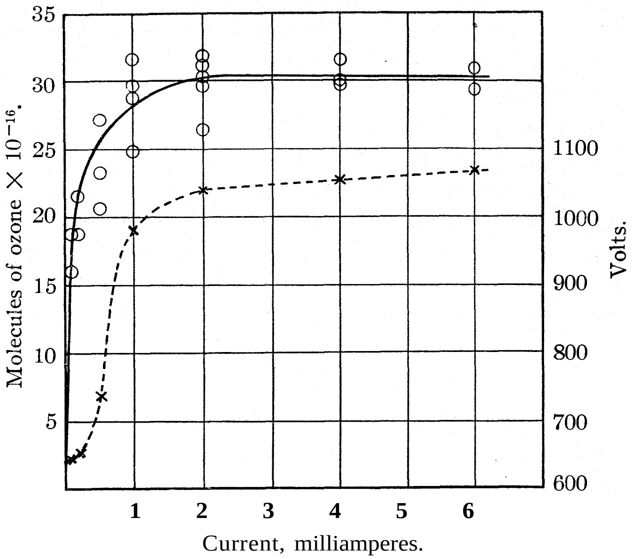

Fig. 4.—Full line: variation in ozone yield with current; broken line: variation in voltage with current at constant pressure; pressure, 1.9 mm.; time, **30** seconds; electrodes of platinum wire.

In the case of the etched electrodes, the volume of the cathode glow was the same as with the smooth electrodes and the yield of ozone was the same. The surface of the etched electrodes must have been greater than the surface of the smooth electrodes, but since the yield of ozone was no greater it may be concluded that the formation of ozone in these experiments was not strictly a surface phenomenon.

Electrode Material.—The data of Table III indicate that, with the exception of aluminum, the yield of ozone is independent of the electrode

---

[7] Rideal and Kunz, J. Phys. *Chem.*, **24**, **379** (1920).

material. This fact supports the view that under the conditions of the experiment, with small electrodes and low pressures, the formation of ozone occurs chiefly through the formation of gaseous ions in the discharge, probably in the vicinity of the cathode. In the work of Newsome[2] the conditions were different and the large electrodes led to the decomposition of the ozone at the surface after its formation.

An examination of the experimental data suggests that the influence of the electrodes was not completely eliminated in the present investigation, for a preliminary aging was found necessary, and even after the aging process there was an unmistakable tendency for each successive experiment of a series to give a slightly greater yield. The effect was so small, however, as to be nearly negligible in all cases except in that of the aluminum electrodes.

The results with aluminum electrodes are interesting. In the present investigation with small aluminum electrodes the ozone yield was high, while in the work of Newsome[2] with large aluminum electrodes and small current density the yields were very low. These two researches taken together appear to furnish a good example of the catalytic behavior of an electrode, giving an abnormally high yield when the ionization around the electrode is great and abnormally low yield when the ionization is small.

Theoretical Discussion

Before consideration of a possible mechanism of ozone formation it is necessary to make a calculation concerning the number of ions which is theoretically possible.

Taking the maximum potential necessary for the complete dissociation and ionization of oxygen as 23 volts,[8] it is easily calculated that 3.7×10^{-11} erg is required to form a pair of atomic ions in oxygen. The largest yield of ozone obtained in this investigation is the one corresponding to a current of 0.1 milliampere in Fig. 4, in which the time was thirty seconds, the potential drop 640 volts and the number of molecules of ozone produced 16.1 and 18.8×10^{16}. The energy input was 1.9 joules, giving an average yield of 26 g. of ozone per kilowatt hour. If all the energy of the discharge was used in making monatomic oxygen ions, it would be possible to produce during this thirty-second period 5.2×10^{17} pairs of ions ($1.9 \times 10^{7} \div 3.7 \times 10^{-11} = 5.2 \times 10^{17}$). Since 1.8×10^{17} molecules of ozone was obtained, the ratio of molecules of ozone to calculated ion pairs is 1/23.

It must be emphasized that this ratio gives only the order of magnitude, for it is assumed that all the ions require the maximum energy of 23 volts for their formation and that there is no decomposition of ozone. These

---

[8] **(a)** Smyth, *Proc. Roy. Soc.*, **105,** 116 (1924); (b) Franck and Jordan in "Anregung von Quantenspriingen durch Stösse," J. Springer, Berlin, 1926, p. 275, give 20 ± 1 volt.

assumptions are valid only as first approximations. The ionization potential for molecular oxygen is 15 volts instead of 23 volts, and the resonance potential is about 8 volts. As a matter of fact oxygen can be converted into ozone by ultra-violet light, which corresponds to this resonance potential (158 mμ) but other evidence indicates that the ionic reactions are more important in the electrical discharge. If 8 volts is taken as the energy necessary for ozone formation instead of 23 volts, the number of ozone molecules formed for a given energy input is three times as great and if 15 volts is taken, the ratio of molecules of ozone to calculated number of ion pairs becomes 1/3.6 instead of 1/2.8.

There is considerable decomposition of ozone even at the low concentrations, and a rough extrapolation of the yield per kilowatt hour to zero current indicates a yield about three times as large as the largest yield obtained in these experiments, namely, 3 × 26 g. per kilowatt hour. This extrapolation suggests an M/N ratio of approximately 1, if an ionization potential is used for the calculation, but the extrapolation is too inaccurate and the uncertainties of analysis for the short experiments are too great to draw any conclusions.

The discharge tube contained 2.3 liters of oxygen at 1.9 millimeters' pressure, or about 1.5×10^{20} molecules of oxygen. The number of pairs of ions produced in thirty seconds was about 5.2×10^{17}, or a ratio of about 150 molecules to 1 ion if the ions retained their charges as long as 30 seconds. Actually the ratio of the concentration of molecules to the concentration of ions was much greater than this, because the ions were discharged very rapidly.

The large excess of molecules over ions demands a predominating mechanism which involves reactions between ions and molecules, rather than between ions and ions. It must be borne in mind, however, that although the collisions between ions and molecules predominate greatly the collisions between positive and negative ions are not entirely fortuitous, since a force of attraction tends to draw them together.

The following reactions are offered as giving a possible mechanism for ozone formation in the electrical discharge. Several other intermediate steps also may be involved.

$$O_2 = O^+ + O^-$$

$$O^+ + O_2 = O_3^+ \text{ and } O^- + O_2 = O_3^-$$

$$O_3^+ + O_3^- = 2O_3 \text{ or } O_3^+ + O^- = 2O_2 \text{ and } O_3^- + O^+ = 2O_2$$

According to these reactions, one molecule of ozone should be produced by each pair of ions and this M/N ratio of 1 is not incompatible with the experimental results of this investigation.

Other mechanisms are possible such, for example, as the formation of an ion cluster surrounding an ionized molecule (instead of an ionized atom), but at least three oxygen molecules are required for each cluster in order that it may break up into O_3 molecules, and the mass spectrograph data so far available show a high concentration of charged atoms of oxygen and very low concentration of O_6 ions.

The author desires to express his appreciation to Professor Farrington Daniels for his guidance throughout this investigation and to E. I. du Pont de Nemours and Company for the fellowship held during a portion of the time this work was in progress.

Summary

1. The formation of ozone in the glow discharge has been investigated in a closed tube at pressures from 0.2 to 2.8 mm. The ozone was determined by chemical analysis.

2. The electrodes were small, minimizing any catalytic effect.

3. The effect of the following variables on the ozone yield has been studied: *(a)* duration of discharge, (b) pressure, (c) current, (d) distance between electrodes, *(e)* area of electrodes, *(f)* material of electrodes.

4. An equilibrium concentration of ozone was reached in less than a minute.

5. The yield of ozone increased with increasing pressure, but at a decreasing rate.

6. The yield of ozone increased with increasing cathode area.

7. The yield of ozone was independent of electrode material, except that aluminum gave abnormally high results.

8. The highest yield obtained was 26 g. per kilowatt hour, but all yields were low on account of the decomposition of ozone.

9. A calculation on the basis of ionization potentials indicates that the number of pairs of ions and the number of molecules of ozone produced are both of the same order of magnitude.

10. The predominating mechanism of ozone formation is possibly one involving collision between monatomic oxygen ions and neutral molecules.

THE ELECTROMETRIC TITRATION OF MANGANESE BY THE VOLHARD METHOD[1]

BY B. F. BRANN AND M. H. CLAPP

RECEIVED JUNE 25, 1928 PUBLISHED JANUARY 8, 1929

The Volhard method is generally recognized as one of the best of the volumetric methods for the determination of considerable amounts of manganese, the chief objection to its use being the difficulty in recognizing the end-point in the presence of the heavy brown precipitate which forms during the titration. An electrometric method of determining the end-point would seem, therefore, to be particularly desirable in this case.

Several attempts have been made in this Laboratory[2] to apply the electrometric method to this titration, using the ordinary potentiometer system with calomel–platinum electrodes and also using the polarized electrode system described by Willard and Fenwick.[3] Neither of these methods gave satisfactory results. A break was obtained near the end-point but it was uncertain and irregular. Miiller and Wähle,[4] using the ordinary potentiometer system, state that about seven minutes is required to attain constant potential when near the end-point. The method of differential titration described by Cox[5] and modified by MacInnes and Jones——as also tried but without satisfactory results, due probably to the slowness with which constant potential is attained. Finally, the method described by Foulk and Bawden,[7] and called by them the "dead stop end-point" was tried and, after some modification, was found to give satisfactory results.

Discussion

In the dead stop end-point as described by Foulk and Bawden, two platinum electrodes were used in the solution to be titrated and a very small potential was applied to the electrodes, a potential so small that the back electromotive force of polarization balanced it and no current flowed, as shown by the zero deflection of a galvanometer in the circuit. At the end-point of the titration both electrodes were depolarized and a permanent galvanometer deflection was obtained. Assuming the polarization to be due to oxygen at the anode and hydrogen at the cathode, it is evident that in order to obtain a permanent galvanometer deflection the

anode must be depolarized by some suitable reducing agent and the cathode by some suitable oxidizing agent.

Now in the Volhard titration of manganese, a practically neutral solution of a manganous salt is being titrated with permanganate and accordingly the cathode will become depolarized as soon as a slight excess of permanganate has been added to the solution. No satisfactory means of depolarizing a platinum anode in this solution could be devised, but if the platinum is replaced by silver and a trace of chloride ion is added to the solution, a permanently depolarized anode is obtained and the flow of current through the solution and consequent galvanometer deflection is controlled wholly by the polarization or depolarization of the cathode. Furthermore, when a silver anode is substituted for platinum, a potential is developed between the two electrodes and no outside source of current is required.

Experimental Method

The apparatus required is very simple; the titrations may be made in a 400-cc. beaker, a short piece of platinum wire being used as the cathode and a piece of silver wire as the anode. The electrodes are connected directly to a galvanometer. A good mechanical stirring device is also essential and it is desirable to have the apparatus so arranged that the beaker may be heated during titration either by a small hot-plate or directly by a burner.

The solutions are prepared for titration in the usual way with the addition of 2 or 3 drops of 6 *N* hydrochloric acid to furnish the necessary chloride ion. As the permanganate is added the galvanometer needle fluctuates violently but no permanent deflection is obtained and if the addition of permanganate is stopped for a short time the needle returns slowly to zero. As the end-point is approached, the needle returns more and more slowly toward zero, and at the end-point a full scale deflection is obtained which remains unchanged for a considerable time.

The temporary depolarization of the cathode before the end-point is reached may be due in part to deposition on the cathode of finely divided zinc manganite, which acts as a depolarizer and produces a galvanometer deflection which may be mistaken for the true end-point unless the titration is conducted with due care. The last few drops of permanganate should be added one at a time, waiting after each drop until the galvanometer needle begins to return toward the zero point. The final drop produces a full scale deflection which persists for a considerable time, the exact time depending on the sensitiveness of the galvanometer and the surface area of the cathode. In case of doubt, the end-point may be checked by filtering a little of the solution and noting the color. With the proper combination of galvanometer and electrodes, a definite electrometric end-point may be obtained with a very slight excess of permanganate, giving an almost imperceptible pink color to the solution.

The following table shows the results actually obtained in two series of nine consecutive titrations. The test solutions were made by reducing approximately 0.1 N permanganate with hydrogen peroxide in sulfuric acid solution. Three drops of 6 *N* hydrochloric acid were then added and the solution was made just neutral to methyl orange with ammonia. Five grams of zinc sulfate was added, the solution was diluted to about 300 cc., heated to 90° and titrated as previously described with the approximately 0.1 N permanganate. The first column of the table shows the volume of permanganate reduced; the second column gives the theoretical volume of permanganate required for titration, which is two-thirds of the volume reduced plus a 0.05 cc. blank for the zinc sulfate used; the third and fourth columns give the volume of permanganate actually used and the titration error.

TABLE I

RESULTS OF TITRATIONS

$KMnO_4$ reduced, cc.	$KMnO_4$ required, cc. Theoretical	Actual	Error	$KMnO_4$ reduced, cc.	$KMnO_4$ required, cc. Theoretical	Actual	Error
16.37	10.97	11.03	+0.06	18.10	12.11	12.11	0.00

25.48	17.03	17.03	.00	28.42	18.99	18.98	− .01
26.29	17.57	17.57	.00	28.02	18.73	18.68	− .05
28.03	18.68	18.71	+ .03	28.52	19.07	19.03	− .04
32.07	21.43	21.40	− .03	47.77	31.89	31.86	− .03
32.48	21.71	21.71	.00	42.59	28.45	28.40	− .03
34.78	23.18	23.22	+ .04	36.08	24.11	24.08	− .03

The galvanometer used in most of this work was a pointer type instrument with a rated sensitivity of one scale division per microampere and a resistance of 250 ohms. With this galvanometer connected directly to the electrodes, and using 3 cm. of platinum wire (about 0.05 cm. in diameter) as a cathode, the end-point was shown by a full scale deflection which remained unchanged for a full minute. With a galvanometer of twice this sensitivity and 1000 ohms' resistance, about a minute and a half had to be allowed at the end-point when the same electrodes were used. With a given galvanometer, the time required for the end-point probably can be regulated to a considerable extent by varying the area of the cathode.

The size and nature of the silver anode seem to be immaterial. Ordinary silver wire was used most of the time, but both platinum wire and platinum foil plated with silver were used also with no apparent difference in result. The silver plate, however, is gradually converted into silver chloride and requires occasional renewal.

It seems to be necessary to clean the electrodes frequently, possibly after each titration. The adhering zinc manganite may be removed easily by dipping the electrodes in acidified hydrogen peroxide solution and the film of silver chloride can be dissolved from the anode with ammonia.

Summary

A modification of the "dead stop end-point" method of electrometric titration has been described, and it has been shown that this method may be applied satisfactorily in the Volhard titration of manganese.

STUDIES ON THE HIGHER OXIDES OF SOME RARE-EARTH ELEMENTS[1]

BY H. ARMIN PAGEL AND PAUL H. M.-P. BRINTON

RECEIVED JUNE 27, 1928 PUBLISHED JANUARY 8, 1929

Introduction

The sesquioxide, R_2O_3, may be assumed as the type of the normal oxides of the rare-earth elements; on that all are agreed, but the literature dealing with oxides of types higher than R_2O_3 is full of uncertainty and contradictions. Yet in the placing of these elements in the periodic table we find many assumptions of higher oxides, the existence of which has never been proved, and without this proof there seems little justification for placing several of the rare-earth elements in the columns with quadri- and quinquivalent elements. Of the oxides of the true rare earths those of praseodymium have been investigated most frequently, but with very uncertain results. The oxide resulting from the ignition of praseodymium compounds in air, formerly considered as Pr_4O_7, has been shown[2] to conform more nearly to the formula Pr_6O_{11}. Another oxide, PrO_2, has been prepared, although never quite pure, and divergent opinions have been expressed as to the methods of its formation and the conditions for its stability. Brauner[3] claimed to have prepared the dioxide by heating a mixture of praseodymium and potassium nitrates at 400°. He also reported[4] the preparation of Pr_5O_9, Pr_2O_5, Nd_2O_4 and Nd_2O_5, but failed to give details for their preparation. Marc[5] concluded that the presence of a little cerium is necessary for the higher oxidation of praseodymium, and that under these conditions neodymium is also oxidized. These results, as well as those of Meyer and Koss,[6] were obtained with mixtures, the relative proportions of which were arrived at indirectly, and the results cannot be regarded as entirely conclusive, as Meyer[7] admits in a later paper. Von Scheele[8] reported the preparation of the dioxide by heating praseodymium oxalate in air to incipient redness. His analyses showed from 4.09 to 4.97% "excess oxygen" "(that is, over that demanded by the

formula Pr_2O_3)." The calculated "excess oxygen" for PrO_2 is 4.64%, so his "yields" were approximately from 88 to 107%. Meyer[7] obtained a dioxide of about 97.5% purity by heating praseodymium nitrate with potassium nitrate at 440–450°, as recommended by Brauner. Prandtl and Huttner,[2d] attempting to duplicate the experiments of Meyer and Brauner, found a product corresponding to the formula $Pr_6O_{11}\cdot 7H_2O$ instead of PrO_2. Their purest dioxide was obtained by heating the sesquioxide for five days in an atmosphere of oxygen at about 300". Neodymium was found to form no higher oxides when fused with sodium chlorate. Other investigations will be reviewed later in connection with our own conclusions.

In this paper we present the results of studies on the preparation and stability ranges of the oxides of lanthanum, praseodymium, neodymium, samarium, gadolinium, erbium and ytterbium. It is hoped that oxides of other rare-earth elements, especially terbium, will be treated in a later paper.

Materials and Apparatus

The lanthanum, praseodymium, neodymium, samarium and gadolinium compounds were those described in a previous communication,[9] and further discussion of their high purity is not necessary. Before final precipitation as oxalates finely divided ashless filter pulp was added to the solutions in order to impart the desired fineness and porosity to the ignited oxides. Otherwise the oxides are so coarse and dense that reduction by hydrogen is very slow, and possibly not entirely complete.

The erbium and ytterbium compounds were purchased in the market. Special investigation of their purity was deferred, pending evidence of positive results in the formation of higher oxides.

For pressure oxidations tank oxygen of 99.5% purity was employed, after passage through a drying train. The use of hydrogen generated in the Laboratory was soon abandoned in favor of commercial electrolytic hydrogen, since after passage through the purification train the gas from the two sources gave identical results. The train consisted of (1) acid permanganate solution, (2) alkaline permanganate solution, *(3)* heated copper spirals in a copper tube, (4) moistened silver nitrate crystals, (5) potassium hydroxide solution, (6) concentrated sulfuric acid and (7) a tower of phosphorus pentoxide.

Balance.—It soon became evident that errors due to absorption of moisture and carbon dioxide by some of the very hygroscopic rare-earth oxides were quite appreciable, when dealing with small changes in weight, so a special balance was arranged to eliminate this source of error. A Christian Becker No. 8A chainomatic balance, having a graduated notched beam which allowed weights up to 1.1 g. to be adjusted without opening the door, was found entirely reliable as to constancy. The beam and chain

---

[9] Sarver and Brinton, THIS JOURNAL, 49,943 (1927).

readings were accurately calibrated. The balance case was dismantled, all woodwork was varnished, and all cracks were filled with melted paraffin. The hole through the base accommodating the pan-arrest bar was covered with a thin rubber membrane (a dental rubber dam), which was sealed to the bar and base with adhesive tape. The front door was permanently sealed with tape and paraffin. Under the back door, which was raised about 10 cm., was sealed a board containing a brass tube, C, Fig. 1, of very slightly larger bore than the Pyrex tube, **A.** This tube was located directly behind the left pan of the balance. **A** nail driven into a wooden block, F, serves as a bumper to prevent disalignment of the pan when the boat is pushed onto it from the tube. B represents a wooden frame in which operates a snugly fitting metal slide-gate, D, which serves to seal the entrance when the Pyrex tube is not in place. **A** velvet lining, E, gives an almost air-tight joint between the wood and the glass tube. Behind the right pan a hole, ordinarily closed with a 1-hole stopper, allows the integral weights to be handled with a wire fork. **A** gentle stream of purified air passed through this stopper into the balance case at all times except when weighing. Thus it was never necessary to open the balance door except to change the desiccating and decarbonating reagents kept in the case. The technique of weighing will be described later.

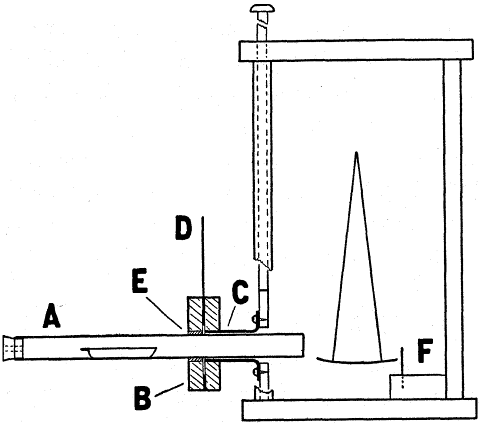

Fig. 1.—Side view of balance.

Pressure Furnace.—While a rebuilt Hoskins furnace with projecting core served for air ignitions and hydrogen reductions, a special furnace had to be built for the oxidations by oxygen under high pressures.[10] The furnace is diagrammatically shown in Fig. 2. **A** is the outer shell, 46 cm. long, of triple strength wrought iron, 8 mm. thick. The dotted lines just inside this shell, and at the ends, represent heavy wire screening, to facilitate the rapid distribution of oxygen when building up the pressure.

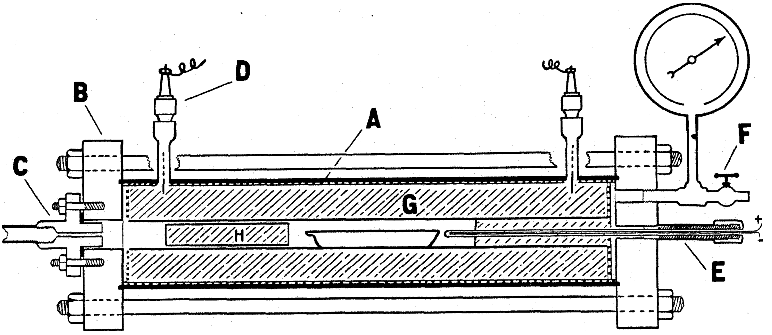

Fig. 2.—Pressure oxidation furnace.

---

[10] After the completion of this work a somewhat similar type of furnace was found described by Fischer and Ploetze, *Z. anorg. Chem.*, **75**, 1 (1912).

The ends, B, are solid cast iron caps, 17.8 by 3.8 cm., grooved to take copper gaskets, and they were drawn against the accurately machined ends of the shell, A, by eight iron bolts, only two of which are shown in the cut. This gave a perfectly tight joint. C is a flanged bronze coupling, secured by four bolts, with copper–asbestos gaskets to prevent leakage. This coupling leads to the oxygen supply and provides an entrance to the silica tube, which is wound with 22-gage Chromel wire. To prevent too high a temperature at the junction points, 15 cm. of heavy Chromel wire was welded to each end of the heating wire. Eight-cm. lengths of regular $^3/_8$ inch iron pipe coupling were fitted into the jacket about 8 cm. from each end, and to these couplings Champion spark-plugs, D, were fitted by means of reducers, the joints being made air-tight with "Caulk" dental cement. Litharge-glycerin cement proved less satisfactory for joints which could not be water cooled, as there was a slight decomposition of organic matter at high temperatures. The terminals of the heating elements, insulated with Pyrex tubing, were attached to the spark-plugs with small hollow brass cylinders, slotted on each end, driven on the protruding end of the electrodes. After screwing the body of the plug into the reducer, the core of the plug was introduced, slipping the slot onto the terminal wire. This gave a very satisfactory contact. E shows a quartz thermocouple tube sealed into an iron nipple, fitted with a brass cap. This was made tight with lithare-glycerin cement and was water-cooled. The brass needle valve, F, was used for evacuating the furnace The pressure gage was calibrated at the Air Reduction Plant, in Minneapolis, by comparison with their standard test gages. The annular space between the furnace wall and the combustion tube was packed with ignited asbestos wool, *G*, as was also the end of the combustion tube into which the thermocouple extended. To prevent radiation toward the other end of the heating chamber an Alundum tube. H, loosely packed with asbestos fiber, was inserted. Acknowledgment is gratefully made to Mr. F. W. Fullerton, Mechanician of the School of Chemistry of the University of Minnesota, and to Mr. Frank L. Heyer, Jr., of Dakota, Minnesota, for valued assistance in the construction of this furnace.

The temperature gradient was determined by means of two thermocouples. One was in its permanent position, as shown in the cut, while the other was moved, in 1 cm. stages, over the space occupied by the longest boat. These thermocouples were calibrated against one certified by the U. S. Bureau of Standards. Over the range tested a maximum variation of 7° was found, and except at the very ends of the longest boat the temperature range was not over 2° greater or less than the temperature found by adding 4° to the reading of the regular thermocouple. Therefore all temperatures recorded in this paper were obtained by adding 4° to the observed temperature. All temperatures were read with a potentiometer indicator.

Experimental Part

Composition of the Oxide of Praseodymium after Ignition in Air.— In a previous communication[2] it has been shown that the formula for praseodymium oxide obtained by ignition in air at ordinary pressures agrees very closely with Pr_6O_{11}. This oxide had been slowly cooled in the furnace before being transferred to a desiccator. Later experiments confirmed the correctness of this formula for the slowly cooled oxide, but a question arose as to the effect of varying the conditions of cooling. The following set of experiments was planned to throw light on this point.

3.4636 *g.* of purest praseodymium sesquioxide was employed. This had been prepared by igniting the oxalate in a large porcelain boat and then reducing with hydrogen at about 900" to constant weight. To guard against the possible presence of weighable amounts of sulfur, as basic sulfate, the sample was treated with steam and hydrogen, and again reduced in dry hydrogen. No change in weight was observed. In these hydrogen reductions the gas was allowed to pass during the cooling until a temperature of about 50" was reached, after which purified air was substituted for the hydrogen. While the purified air continued to flow, the Pyrex tube, A in Fig. 1, was attached to the combustion tube, and the boat was pulled into it. The tube was stoppered and carried to the balance. Purified air was again passed through the tube, the gate, D in Fig. 1, was raised and the tube was slipped into place. The air current was then disconnected from the tube A, and passed into the balance case through the hole back of the right pan. With the stopper in the back end of the tube now removed, the purified air passed in the reverse direction through this tube, and this enabled the boat to be pushed onto the balance pan without the introduction of any unpurified air. After shutting off the air and stoppering the Pyrex tube, a brief pause was allowed for subsiding of air currents, and the boat was then weighed. The same technique was used in all weighings of such oxides as showed a tendency to absorb moisture. Controls with samples of ignited calcium oxide, mixed with a little calcium chloride, proved this method ideally suited to the handling of hygroscopic and carbon dioxide susceptible substances.

In Table I are shown the results of several variables. It will be readily understood that with the furnace slightly tilted, both ends of the tube being open, a current of air would be induced during the cooling, so that conditions would be more favorable for re-oxidation. When the cooling conditions are spoken of as "rapid" in the table it means that the boat at its maximum temperature was pushed to the cool end of the tube outside the furnace. A great many experiments, carried out with smaller quantities of the oxides, gave results agreeing closely with those shown in the table. Tabulation of these runs is omitted for economy of space. In the interest of later discussion the results in this table are placed in the order of decreasing yields.

It will be seen that the slowly cooled runs give the highest values. Under conditions of rapid cooling in a level furnace we find the minimum values. In the last run of this series a hinged furnace was used, so the tube could be lifted from the heat, stoppered and cooled very rapidly in diminished oxygen pressure. It seems justifiable to conclude that the rate of cooling and the supply of oxygen during the cooling period are the main factors in determining the composition of the oxide.

That the oxide heated over long periods of time at relatively low temperatures gives oxygen ratios higher than Pr_6O_{11} was found in an attempt to determine roughly the rate of decomposition of the dioxide. **A** sample

[a] CALCULATIONS.—In most papers dealing with the higher oxides of praseodymium the compositions have been indicated in terms of "excess oxygen." Thus PrO_2 contains 4.647, oxygen in excess over Pr_2O_3. This method is somewhat unsatisfactory because the percentages of "excess oxygen" in the higher oxides are so small that even a slight difference in this percentage actually represents a considerable difference in the composition, and concordance of analytical figures with "theory" gives one the impression of much greater purity than is actually the case. Much of the past work on these oxides, when viewed in the light of a 100% basis, is not convincing. It is for this reason that we have used the largest possible samples, and adopted the manipulative refinements described in this paper. In our tabulations and discussions results are expressed in terms of molecular percentages of praseodymium dioxide formed. For example 98 mole % of PrO_2 means that oxidation of the sesquioxide has occurred to such a degree that the empirical composition of the resulting oxide could be expressed by saying that for every 98 molecules of PrO_2 formed, 1 molecule of Pr_2O_3 remains unoxidized. Pr_6O_{11} would correspond to 66.67 mole 7, of PrO_2, and if the actual percentage purity of a sample in terms of molecules of Pr_6O_{11}, considered as a definite compound, is desired, it can be obtained by simply multiplying the mole % of PrO_2 by 1.5.

of about 93 mole % of PrO_2 heated for five hours in a current of pure air at 375° yielded a composition of 83.6%. Further heating for thirteen hours at 385–395° changed the composition to 70.7%. The heating was continued for periods of thirteen, twenty-one and twenty-two hours at the same temperature and in each of these determinations a constant value of 68.1% was found. Attempting to approach this constant value from the lower side, a sample of 64.5 mole % of PrO_2 was heated in a gentle air current at 385–395° for periods of seven, twenty-four and six hours, and compositions of 68.0, 68.4 and 68.4% were found. This sample was then heated in the open furnace, tilted at an angle of 7°, without forced air current, for twenty hours at 460–495°, and again for twenty hours at 480–510°, and identical values of 67.7% were obtained.

In the work on pressure oxidation to be described later it was frequently necessary to prepare samples of known weight of Pr_2O_3 by hydrogen reduction. The reduced oxide was then re-oxidized in air at 900–950°

for twenty minutes, in the tilted tube furnace and rapidly cooled. Consistent values of **64.1–64.3** mole % of PrO_2 were always obtained, and this regardless of whether we started with pure Pr_2O_3 or almost pure PrO_2.

Thus it is seen that the composition of the air-ignited oxide of praseodymium can be made to vary with the conditions of ignition and cooling—especially are the conditions of cooling important—but with any specified set of conditions reasonably concordant results are found.

Preparation of Praseodymium Dioxide by Pressure Oxidation.—From the evidence of work thus far done it was thought likely that a quantitative yield of praseodymium dioxide could be obtained by heating and cooling in an atmosphere of pure oxygen at very high pressure. Preliminary tests in the first pressure furnace constructed gave apparent yields of **100.6** to **100.7** mole % of PrO_2 by heating for twenty hours at 350° in pure oxygen at a pressure of **195** lb./sq. in. Fearing that the high values might be due to adsorption of oxygen during the cooling under high pressure, the furnace was thoroughly evacuated at high temperature, then filled with oxygen and cooled to room temperature. An oxide sample of constant weight was introduced, allowed to stand for five hours at a pressure of **215** lb. of oxygen and weighed. An increase of only **0.2** mg. was found. The excess in yield over **100%** was not large, but with the highly refined manipulations employed it could not be considered as allowable experimental error. Moreover, a slight odor had been noticed in the exhaust oxygen, and it was thought that the error might be due to absorption of volatile organic matter from the decomposition of the cement used. This led to the construction of the new furnace, substituting dental cement for the litharge-glycerin mixture. The work was started anew, and the pressure oxidation results obtained up to that time were discarded.

To determine the effects of the variables, time, temperature and pressure, series of runs were made in which two of the factors were held constant while the third was varied. Each pressure oxidation was followed by a quickly-cooled air ignition in the tilted furnace, which gave uniform

compositions corresponding to 64.1–64.3 mole % of PrO_2. In all reports true pressures are given, that is, gage pressures plus 15 lb./sq. in. At the end of each series the sample was reduced in hydrogen and weighed as sesquioxide, to make certain that no manipulative loss had occurred.

The results in Table II are graphically shown in Fig. **3.** The sharp drop in yield beyond 405° suggests that at temperatures above that point the dissociation pressure of the dioxide exceeds 215 lb. The curve would undoubtedly drop to a minimum much lower than that shown at temperatures 440–585° if the true conditions existing during the entire run could be shown. It is impossible to cool the furnace instantaneously, and thus preserve the stage of oxidation which exists at any instant. It was found that from temperatures around 500° a nearly uniform rate of cooling of about 10° per minute held for the first twenty minutes. It seems reasonable to expect that a certain amount of re-oxidation occurs in passing through the temperature range most favorable to a high rate of oxidation, 400–325°. This point was, in fact, proved by introducing the air-ignited oxide (64.2 mole % of PrO_2) into the furnace at temperatures of 506, 504, 454 and 448°, letting in oxygen as rapidly as possible up to 215 lb. pressure, and then immediately shutting off the heating current. These four runs showed, respectively, 75.0, 75.5, 75.4 and 75.6%, values which lie only about 1% lower than those obtained in five and one-fourth hours at the same temperatures.

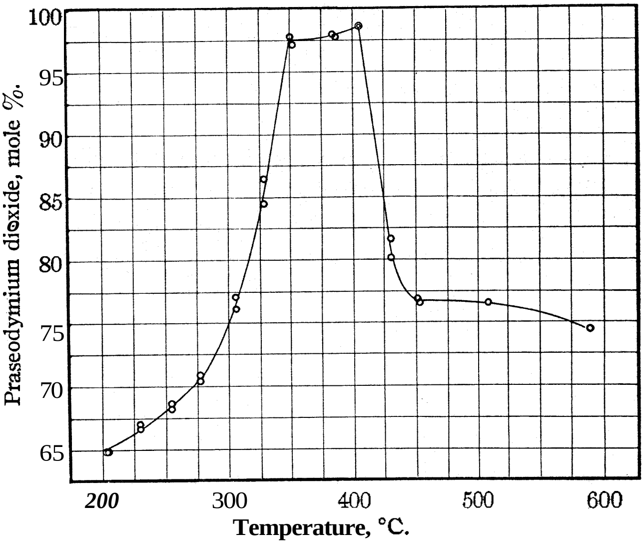

Fig. 3.—Effect of temperature on the formation of praseodymium dioxide; time of each heat, $5^1/_4$ hrs.; oxygen pressure, 215 lb./sq. in.

The effect of varying the time of heating, at the optimum temperature, and at three different pressures, is shown in Table III.

3	97.4						

The values in this table are shown graphically in Fig. 4, Curves A, B and C showing values for pressures of 65, 115 and 215 lb., respectively.

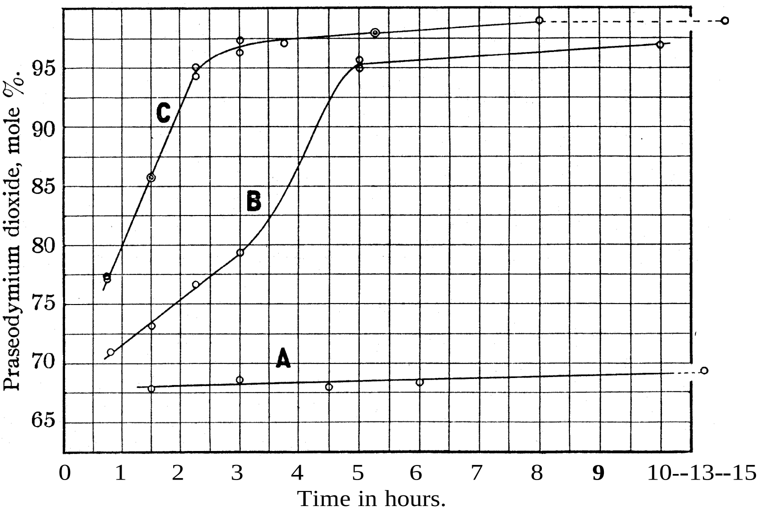

Fig. 4.—Effect of heating time on formation of praseodymium dioxide at pressures of A, 65 lb.; B, 115 lb.; and C, 215 lb. of O_2/sq. in.

It seemed impossible to increase the yield beyond 99.2% of PrO_2. (At figures near 100% the molecular percentage and the weight percentage are almost synonymous.) To be certain of the completeness of the hydrogen reductions upon which the calculations are based, four successive hydrogen reductions were made, and they showed splendid concordance. Then, after ignition in air, another hydrogen reduction of two hours' duration showed perfect agreement with the former values. It seems unreasonable, then, to question the completeness of the reduction. Nevertheless, if one wished to dispute this point, an argument could be made of the fact that the maximum oxidation shows as good concordance as the maximum reduction, and perhaps we have obtained pure dioxide, but never pure sesquioxide. This, however, is less likely.

In a final attempt to get a perfect yield, a larger sample of the sesquioxide (over 3.5 g.) was taken to minimize experimental errors and subjected to pressures up to 400 Ib., with temperatures varying from 345 to 405°, approaching this range from the higher as well as from the lower side. Increased pressure showed more rapid oxidation, 99.2% being obtained in three and five-tenths hours at 365 lb. and 353°, and 98% in thirty-five minutes at 390 Ib. and 400°, but the final result of continued heating could not be made to exceed 99.2% of praseodymium dioxide.

Effect of **Ceria** on the Formation of Higher Oxides of Praseodymium.—The catalytic effect of small amounts of ceria has been held responsible by some investigators for the contradictory results obtained in the study of the higher oxides of praseodymium.

A mixture of 98% praseodymium sesquioxide and 2% ceric oxide was prepared by precipitating as oxalate a nitrate solution containing 1.0637 g. of Pr_2O_3 and 0.0213 g. of CeO_2. Hydrogen reduction of the mixed oxides gave 1.0852 g. (calculated value, on the assumption that ceria is not reduced, 1.0850 g.). Ignition in air followed by rapid cooling in the tilted furnace yielded 64.0 mole % of PrO_2. This was the result of four runs, all of which agreed within 0.1 mg. The composition of the oxide obtained by ignition in air seems unaffected by the presence of small amounts of ceria.

This sample was next subjected to pressure oxidation. The results of these runs are shown in Table IV.

TABLE IV

RESULTS OF PRESSURE OXIDATION

Hours of heating	1.5	1.5	0.75	2.25
Lb. O_2/sq. in.	65	115	115	115
Temp., °C.	376–380	376–380	381–386	381–386
Mol. % of PrO_2	83.7	96.1	92.2	95.3

Experiments under practically similar conditions with ceria-free praseodymia showed, in the order of the runs above given, 67.9, 73.2, 71.0 and 76.6%. Thus it is seen that ceria causes an abnormally high degree of oxidation when the oxidation is accomplished under pressure.

The Attempt to Prepare Higher Oxides of Other Rare-Earth Elements.—Pressure oxidation of the sesquioxides of lanthanum, neodymium, samarium, gadolinium, erbium and ytterbium was investigated. Since it is universally recognized that the oxides of these elements are of the type R_2O_3, and cannot be reduced by hydrogen at temperatures ordinarily employed, it was considered unnecessary to include hydrogen reductions in these runs.

The ignition, cooling and weighing of the sesquioxides were carried out in purified air, with all the precautions previously described, since some of these oxides gain weight very rapidly on exposure to ordinary air. The attempts to produce oxides of type higher than R_2O_3 failed with all these elements, so tabulation of the runs may be omitted. Suffice it to say that in no case, with samples varying from 0.5 to 1.4 g., were increases greater than 0.3–0.4 mg. found, that is, increases of 0.03–0.06%, with the exception of erbium, in which an increase of 0.1% was registered. Since, however, we could not be certain of the complete absence of terbium, which admittedly forms a higher oxide, from this sample, we could not accept this slight gain in weight as evidence of any tendency toward higher oxide formation. The effective temperature ranges were covered, and pressures up to 405 lb. of oxygen were employed.

The interest attaching to the element terbium in its higher oxides, and the difficulty in getting enough of this element in a high state of purity, cause us to withhold our data obtained on a small sample of not established purity. It is hoped that this investigation will be finished later.

Discussion

Equilibrium which gives an oxide corresponding approximately to the formula Pr_6O_{11} seems to be rather rapidly attained, so that cooling from higher temperatures to ranges below 400" in an ordinary electric furnace produces this oxide from one of lower oxygen content, provided a sufficient supply of oxygen be present. The results in Table I, calculated to the basis of "mole % of Pr_6O_{11}" give, in the order there used, 100.3, 100.0, 100.0, 99.4, 96.7, 96.1, 95.8, 95.1, 95.1, 91.4 and 83.5%. These figures, considered with the experimental conditions described in the table, show clearly that there is a dissociation of this oxide above 700° (and probably somewhat below this temperature), but that re-oxidation occurs in cooling to below 400". Meyer, and Prandtl and Huttner, both state that Pr_6O_{11} is formed by heating at any temperatures between 500 and 900°, and assuming that the oxides were slowly cooled in the presence of plenty of air, this is just what our results would lead one to expect. But that a composition of higher oxygen constant than Pr_6O_{11} can be obtained, evidently in equilibrium, at temperatures around 390" we have shown by getting a constant composition of 68.1–68.3 mole % of PrO_2 when approaching from both sides, that is, from initial compositions of about 64 and 93%. A composition corresponding to 67.7 mole % of PrO_2 (which is 1% higher than theoretical for Pr_6O_{11}) seems to be in equilibrium at about 500°, since on successive heatings of twenty hours each at this temperature no change in composition was shown. It is probable, however, that in ordinary slow cooling insufficient time is allowed for the establishment of this equilibrium and therefore the composition corresponding to Pr_6O_{11} is found.

In the preparation of praseodymium dioxide by heating in oxygen we can offer no definite explanation of our failure to reach a purity higher than 99.2%. Curve C, of Fig. 4, shows that the complete oxidation of the last few per cent. of the oxide requires considerable time, and yet the results in Table III indicate that equilibrium had been reached at about 99.2%. It is unlikely that the dissociation pressure of this oxide exceeds 400 lb./sq. in. at the temperatures investigated. This would seem incompatible with our curve in Fig. 3, which shows that the pressure exceeds 215 lb. only when the temperature is raised above 405°. At 378° the longer the heating the higher the yield of PrO_2 at a pressure of 115 lb., while at 65 lb. pressure we get almost the same figure (around 68%) at 378° whether we heat for one hour or thirteen hours. This suggests almost complete dissociation of the dioxide at this temperature in pure oxygen at 65 lb. pressure, and Prandtl and Huttner found complete dissociation of the dioxide in inert gases, in oxygen and in air at atmospheric pressure at temperatures above 350°. Thus our results show clearly, as do also those of Prandtl and Huttner, that praseodymium oxide could not have been formed, as was claimed by Brauner and by Meyer, at 400° at atmospheric pressure.

The experiments with lanthanum, neodymium, gadolinium, erbium and ytterbium would surely have shown a tendency toward higher oxide formation if such tendency exists; failure to obtain positive results with these elements leads us to challenge the placing of any of these elements in a periodic group other than the third.

Summary

1. It has been shown that the composition of the oxide of praseodymium obtained by ignition in air varies with the conditions of ignition and cooling, but with a given set of conditions reasonably constant results are obtained.
2. Praseodymium dioxide of 99.2% purity has been prepared by heating lower oxides in pure oxygen at high pressures.
3. Data on the stability of praseodymium dioxide at different temperatures and pressures have been presented.
4. The effect of ceria in promoting higher oxide formation by praseodymium has been shown negligible at ordinary pressures, but quite marked in high concentrations of oxygen.
5. No higher oxides of lanthanum, neodymium, samarium, gadolinium, erbium and ytterbium could be formed.
6. A furnace generally applicable for the study of oxidation under

pressure and a balance and technique for the weighing of very hygroscopic substances have been described.

A FURTHER TEST OF THE RADIATION HYPOTHESIS

BY LOUIS S. KASSEL[1]

RECEIVED JULY 16, 1928 PUBLISHED JANUARY 8, 1929

Introduction

Since its statement by Perrin[2] the Radiation Hypothesis has been subjected to many experimental tests, with results that have been uniformly opposed to it. Its present position has been summarized by Daniels.[3] This recent rapid decline of the Radiation Hypothesis has been accompanied by the production of an improved theory of activation by collision. Christiansen suggested that the number of internal degrees of freedom of the molecule must be taken into account, and this suggestion was adopted by Hinshelwood[4] and by Fowler and Rideal,[5] who worked out a simple theory of what the former has called "quasi-unimolecular" reactions, that is, reactions which are unimolecular at high enough pressures, but whose rate begins to fall off at lower pressures. Several such reactions are known, as well as some whose rates have not been shown to decrease.

The theory of Hinshelwood was extended by Rice and Ramsperger,[6] and a second theory developed which was in better agreement with the facts; this differed from the former one only in assigning different specific reaction rates to activated molecules of different energy content. A somewhat similar theory, in equally good agreement with experiment, was worked out by the author.[7] Both Rice[8] and the author[9] have since given quantum theories of the effect, also, but without changing much the numerical results obtained. The position of these theories with respect to the experimental facts is that they can account quantitatively for the way in which the rate falls off with decreasing pressure in the decompositions of propionaldehyde, ethyl ether, methyl ether and azo-

methane; they can also account for the fact that it has not fallen off noticeably at the lowest pressures studied with acetone, pinene and azo-*iso*propane; they can account for the decomposition of nitrogen pentoxide around atmospheric pressure without difficulty, a thing which the older theories were unable to do, and indeed down to about three mm. pressure; but Hibben[10] finds that the rate is maintained down to much lower pressures, 0.03 mm. at least. It is hard for the theories mentioned to account for more than 50% maintenance of the rate at this pressure, using kinetic theory diameters, such as are found satisfactory for the other substances. It would be possible to account for the results down to 0.03 mm. by using a "diameter for collisional deactivation" of 10^{-6} cm. The case for such large diameters has been stated by Bernard Lewis,[11] but the author, at least, is as yet reluctant to use them.

Thus, of all the unimolecular reactions known, nitrogen pentoxide is the only one whose rate causes any difficulty. It is possible to account for the variation of rate with pressure in all the other reactions quantitatively; more important for this comparison, there is a considerable margin of safety, so that if the rates were greater than they are, or were maintained to lower pressures, they could still be accounted for. In nitrogen pentoxide, on the other hand, if the method of activation is collisional, there seem to be a hundred times as many activations and deactivations as the theory allows. In searching for a way out of this difficulty, it occurred to the author that radiation, which has been shown to be without effect at higher pressures,[12] might still be the mechanism responsible for maintaining the rate at low pressures. The general reason why this would be so is that collisional activations and deactivations are of course bimolecular, while radiational ones are unimolecular; the latter would thus gain in importance as the pressure decreased. The results with azomethane and the other quasi-unimolecular reactions show that in these cases at least radiation has not become of importance in time to prevent the falling off in rate, and it is a little hard to see how enough radiation can be absorbed to be of much use, but it nevertheless seemed worth while to investigate the action of infra-red radiation on nitrogen peritoxide at low pressures.

Experimental Part

The most difficult problem in work of this character is to obtain a good source of light. Nernst glowers have been used, but, although they may be operated at a very high temperature, the actual area of the emitting surface is small; for this reason it seemed best to use some other source. The one adopted was a rod of a substance whose trade name is "Glowbar" and which is used as the heating element in some of the small

domestic electric heaters now in common use. This is a black substance of unknown composition, with a rather fine granular structure; it has a moderately high electric resistance, and may be conveniently heated by the passage of a current through it. A piece 20 cm. long and 9 mm. in diameter was ground down to about 6 mm. diameter in the central 4 cm. It was shielded along most of its length by a hollow fire-clay cylinder, to reduce heat losses; this had a rectangular opening, 1.5 X 3.6 cm., cut in it to serve as a source of light. The ends were mounted in heavy brass electrodes cooled by a blast of air and a potential of 220 volts was applied. The entire central portion, both the rod and the surrounding cylinder, attained an intense white heat, while the constricted portion of the rod reached a temperature evidently considerably greater.

It seemed almost impossible to place a reaction vessel within a few cm. of a source such as this and prevent it from heating up, and accordingly the light was focused some distance away by a simple optical system. A concave mirror of 30.5 cm. radius of curvature and 20.3 cm. diameter was placed at a distance of 60 cm. from the source; the reflected light was intercepted by a small plane mirror placed about 17 cm. from the large mirror and making an angle of 45° with the path of the light; this second mirror reflected the light down, and it came to a focus upon the window of the reaction vessel. Both mirrors, of course, were silvered on their outer surfaces. The energy flux through the window was determined by absorbing the radiation in a 2% solution of cupric chloride, which absorbs everything beyond 0.6μ. As the mean of a number of determinations made in this way, there was obtained the value 6.2×10^7 ergs/sec. It was estimated that the temperature of the rod was 2200°K. and that of the protecting cylinder 1800°. Using those figures, and those given for the dimensions of the apparatus, it is possible to calculate the energy flux which would be expected; it is found to be 6.6×10^7 ergs/sec.; if the lower temperature is taken as 1700°, the expected flux comes out 6.0×10^7 ergs/sec. This shows that the temperatures assumed are approximately correct. If the enclosure was all at a uniform temperature of 1900°, it would produce a flux of 5.5×10^7 ergs/sec., and at 2000° one of 6.7×10^7 ergs/sec. In all of these calculations the losses on reflection at the mirrors and transmission by the window have been neglected. The necessary corrections could be made, but they would not change the conclusions in any way.

The reaction vessel used was a 250-cc. bulb; the neck was cut off near the bulb and ground very carefully; a window of rock salt, which has very good transmission in the infra-red region, was attached by sealing wax, care being taken to get the wax only on the outer edge, so that the contact with the reacting gas would be very poor; no visible change took place in the sealing wax, nor was there any other reason to suspect that an appreciable amount of reaction was occurring at the window. The bulb was placed in a jar, which was filled with water or ice and water to a point just below the window, during all of the runs. The pressure readings were obtained by a bifilar quartz fiber gage and were at all times accurately reproducible.

The nitrogen pentoxide was prepared by letting nitrogen dioxide vapor diffuse into a stream of ozonized oxygen and passing the resulting gases through a trap cooled to about −50°. It usually required about ten minutes to collect sufficient nitrogen pentoxide for a run. The supply of nitrogen dioxide would then be sealed off and the ozone continued for a few minutes longer; then it, too, would be sealed off. The nitrogen pentoxide was next cooled with liquid air and connected through a stopcock to a two-stage mercury vapor pump, a second liquid-air trap preventing diffusion of any mercury vapors into the apparatus. After the pumping had been continued for some time, and a vacuum of 10^{-5} mm. or better obtained, the jar around the reaction vessel was filled with ice and water, the liquid air surrounding the nitrogen pentoxide replaced by a mush of frozen ethyl acetate (−83.6') and the pumping continued; after some time, usually about one-half hour, the liquid air was replaced, and the apparatus sealed off from the pumps; at this stage it consisted merely of the reaction bulb, the fiber gage, and the trap containing solid nitrogen pentoxide. The residual pressure was then read on the fiber gage, after which the liquid air was replaced by the ethyl acetate mush, and the decomposition allowed to proceed thermally for a definite period; the liquid air was then replaced and after equilibrium had been reached the pressure was again read; the increase represented oxygen liberated by the decomposition; the source of infra-red light was then turned on, the ethyl acetate replaced and the reaction allowed to proceed for the same period as before, after which liquid air was replaced and the pressure read. Runs were made alternately with and without the light in this fashion.

There was no heating of the bulb when the light was on and except for the presence of the radiation all conditions were unaltered. Hence it is only necessary to compare the pressure increases during the period with illumination with those without to see whether radiation has had an effect. In some of the later runs solid chloroform (–63.5°) was used as a refrigerant and the reaction vessel was kept at 25° instead of at 0°. This gave pressure increases which were considerably larger and easily measurable, so that the same relative increase in rate could have been more easily detected than before. On the other hand, it made conditions less favorable, so that a smaller relative increase was to be expected.

The usual period of each run was thirty minutes, though some were shorter. With ethyl acetate as a refrigerant and the reaction vessel at 0° no pressure increase was ever noted except on one occasion, which was afterward found to be due to a leak which developed at the window. With chloroform and the reaction vessel at 25°, the pressure increases found with illumination were no greater than those without. A typical set of results under the latter conditions is: initial pressure, 0.00035 mm.; increase, dark, 0.00141; increase, light, 0.00147; increase, dark, 0.00153; increase, light, 0.00140. The third figure is not accurate, the probable error being of the order of the fluctuations in the values given. Similar results were found on several occasions. There was no evidence that infra-red radiation influences the rate of reaction of nitrogen pentoxide under the experimental conditions used, although a 10% increase in rate could have been definitely detected.

The vapor pressure equation of Daniels and Johnston[13] gives a pressure of 0.00068 mm. at –83.6° and one of 0.0245 mm. at –63.5°.

A simple calculation shows that the reaction rate constant found in the experiment quoted is about the same as that at higher pressures. This is not to be regarded as a measurement of the thermal rate at low pressures, however, since the experimental conditions did not permit absolute rate measurements. Thus it was impossible to bake out the reaction vessel; the possibility of slight reaction with the sealing wax is not excluded; adsorption on the walls may have affected the pressure measurements. Due to the comparative method used, it is not believed that any of these objections affect the conclusions as to the inactivity of radiation.

Discussion

It having been found that under the experimental conditions used no additional reaction was produced, it becomes important to decide for what spectral region the test is significant. This may be done by comparing the amount of radiation present in the reaction bulb normally with the amount introduced at various wave lengths. The calculation has been made for the rod at 2200°K. and the protecting cylinder at 1700°K., and also for the entire area at 1900°K. This may be very

---

[13] Daniels and Johnston, THIS JOURNAL, 42, 1131 (1920).

easily done from a knowledge of the geometry of the apparatus, assuming that the source of light behaves as a black body, The volume of the reaction system was taken as 300 cc. and the average length of path of the light through the nitrogen pentoxide as 12 cm. Absorption by the nitrogen pentoxide was neglected. It was found that at 5μ the average intensity in the reaction system was increased about 7 times when the vessel was at 0° and 3 times when it was at 25°. Nearly the same result was obtained whether the calculation was made for the rod at 2200°K. and the cylinder at 1700° or for both at 1900°. It is possible that the use of the black body law is not justified, but in that case the actual temperature of the source must have been greater, and the amount of radiation in the far infra-red would scarcely be much less than that calculated. For wave lengths shorter than 5μ the relative increase is much greater, while for only slightly longer wave lengths the increase is too small to be significant. Therefore this test applied only to wave lengths of 5μ and less. Since in the experiments at 25° a 10% increase in rate would have been observed, and was not, and since the intensity of all wave lengths less than 5μ was increased at least 3 times, one is tempted to say that not more than 3% of the thermal reaction at this temperature can depend upon radiation of this spectral region. Closer analysis, however, shows that this statement is unjustified, and it is necessary to be content with the milder conclusion that not more than 3% of the total thermal reaction can be caused exclusively by radiation of wave lengths less than 5μ.

Now there is no difficulty about the production of any except the more highly activated molecules. Collisions are quite capable of accounting for the maintenance of the Maxwell-Boltzmann quota of all the unactivated molecules and even of the activated molecules of low energy content; these, however, do not contribute very much to the total reaction. Thus if radiation is to be of any help, it must produce the final activation, that is, it must keep up the quota of highly activated molecules. If radiation of the wave lengths tested was able to do this effectively, a considerable increase in the reaction rate would have been obtained. The experiments do not show that this radiation is unable to produce highly activated molecules, but they do seem to show that in the actual thermal reaction it is not the important agency in their production. There remains the possibility that radiation of longer wave lengths is of importance. A quantum even at 10μ corresponds to about 3000 calories per mole, which is far from negligible; the addition of that much energy to a molecule just barely activated, which has very little chance to react, will convert it into one which will probably decompose before its next collision. Still longer waves may be of some use, but it is hard to believe that they can be the really important factor in the reaction. It would seem that the final hope of the Radiation Hypothesis rests in the region from 5 to 10μ. Even here it is difficult to understand how sufficient radiation can be absorbed to maintain the rate. Some calculations which have been made by Dr. Ure, in this Laboratory, seem to show that radiation is doomed to fall short by a factor of about 100; these calculations have taken into account the internal degrees of freedom of the molecule and are about as favorable to radiation as seems at all reasonable.

Thus the decomposition of nitrogen pentoxide at low pressures remains mysterious. There are a hundred times too few collisions to account for the rate; there does not seem to be any help from radiation of wave lengths less than 5μ, and it is hard to see how radiation of any wave length can account for more than a very few per cent. of the reaction. There are apparently three possible explanations of the difficulty. One is that the low pressure experiments have been incorrectly interpreted, due perhaps to adsorption; there is evidently some feeling in various quarters that this is the proper solution, but the burden of proof surely rests upon those who wish to adopt this view. Another is to assert that the long wave length radiation is responsible, even though it is impossible to give a theoretical explanation of how it can be. It seems very hard to test this view, a suitable source being non-existent. A third escape is in the acceptance of diameters for collisional deactivation of about 10^{-6} cm. It has been said that the use of a large diameter for deactivations does not mean that an equally large one is required for other collisions, in particular for activations. Let us examine this statement closely. A large diameter for deactivations means that the high-energy molecule has a very great desire to get rid of its extra energy. The result of this large diameter is that the number of deactivations is increased; to maintain the Maxwell-Boltzmann quota of high energy molecules an increased number of activations is required, and these may be obtained either by a large diameter for activations also, or by an abnormal tendency to produce activation whenever it is energetically possible, that is, by having nearly all of the energy of both molecules flow into one of them oftener than the distribution laws for harmonic oscillators would require. The existence of equilibria maintained in this last way is denied by the Principle of Microscopic Reversibility. According to this principle, if the mechanism of deactivation is the transfer of energy across distances large compared to molecular dimensions, the mechanism of activation must be of the same nature.[14] The author has been among those guilty of talking about diameters for collisional deactivation, with the implication that they might be much larger than other diameters. But if we are going to use large diameters for internal energy transfers, it would be better to use them consistently. It would of course be possible that the diameter for

---

[14] See also Tolman, Yost and Dickinson, *Proc. Nat. Acad. Sci.*, 13, 188 (1927).

such transfers might be a function of the amount of energy involved; but in the application of the author's theory to azomethane the chief difficulty was to get sufficient spread between the theoretical curves at different temperatures; the same trouble was experienced by Rice and Ramsperger; if the diameter for internal energy transfers increased very much with the amount of energy involved in this case, it would become impossible to fit the experimental data. If, as therefore seems not unlikely, the diameter for internal energy transfer is approximately independent of the energy, and if it is really much larger than kinetic theory diameters, the heat conductivity of nitrogen pentoxide should be abnormally large. There do not seem to be any data on this.

As a matter of fact, it seems rather strange to speak either of collisions or of diameters in connection with energy transfer at such a distance, for the phenomenon, if it occurs, is more nearly "coupling" of the type suggested by Polanyi,[15] with the difference that the result of the energy transfer is only activation, not immediate dissociation.

In this connection it may be pointed out that the chief objection to these "large diameters" is not an a *priori* one, since they are not inherently unreasonable (at least, not until they are somewhat greater than 10^{-6} cm.) but is based on a reluctance to use diameters for nitrogen pentoxide at least 15–20 times greater than for any of the other substances which decompose unimolecularly, but there is apparently some feature about nitrogen pentoxide which is unique, so that some abnormality in the explanation of its rate can scarcely be avoided.

Since the submission of this paper, Rice, Urey and Washburne[16] have found that a molecular ray of nitrogen pentoxide is not decomposed by black body radiation. Loomis and Smith[17] have reported experiments which seem to show that under some circumstances adsorption may vitiate low pressure reaction rate measurements on nitrogen pentoxide. Sprenger[18] has found the very curious result that at low pressures the decomposition of nitrogen pentoxide does not go to completion, even at 100°; and Rice, Urey and Washburne[16] mention that preliminary experiments in their Laboratory show a falling off in rate even at several millimeters' pressure. Thus five separate researches on the thermal reaction at low pressures have led to five widely different conclusions.

This investigation was aided financially from a grant made to Professor **A. A.** Noyes by the Carnegie Institution of Washington. The author wishes also to express his appreciation of the advice and assistance which he received from many members of the staff of the Chemistry Depart-

ment, in particular Professor R. C. Tolman and Dr. M. E. Nordberg. The very excellent rock salt windows used were kindly furnished by Mr. Rene Engel of the Geology Department of this Institute.

Summary

1. It has been suggested that the maintenance of rate in the decomposition of nitrogen pentoxide may be due to assistance from radiation, which becomes important only at low pressures.

2. It has been found experimentally, however, that radiation of wave length less than 5μ is not able to increase the reaction rate even at low pressures.

3. It is concluded that the important region, if there is any, will probably lie between 5 and 10μ, but that it is hard to see how enough radiation can be absorbed to maintain the rate. An experiment which might detect this activity, if it exists, has been suggested.

4. The other possible escapes from the nitrogen pentoxide dilemma have been considered. No definite conclusion has been reached.

STUDIES OF COPPER CATALYSTS PREPARED FROM PRECIPITATED HYDROXIDE. I.
ACTIVITY AS A FUNCTION OF THE TEMPERATURE OF PRECIPITATION

BY PER K. FROLICH, M. R. FENSKE AND D. QUIGGLE

RECEIVED JULY 19, 1928 PUBLISHED JANUARY 8, 1929

In the course of a study of the high pressure synthesis of methanol undertaken by this Laboratory some three years ago, it was observed that certain catalysts prepared from precipitated hydrates showed variations in activity which might be attributed to differences in the temperatures at which the hydrates had been precipitated from the corresponding nitrate solutions. To obtain more quantitative information concerning this temperature effect, a series of experiments was made with copper catalysts under carefully controlled conditions in order to eliminate in so far as possible the effect of variables other than the temperature of precipitation. The copper hydroxide was precipitated with ammonium hydroxide from aqueous solution of one of the standard makes of high purity (C. P.) copper nitrate. Since any occluded ammonium hydroxide or nitrate was easily volatilized in subsequent operations, the resulting catalysts might be expected to be of identical chemical composition.

Six different temperatures of precipitation were used, *viz.*, 0, 10, 22, 55, 85 and 100°.

Preparation of Catalyst and Experimental Procedure.—One hundred grams of copper nitrate crystals ($Cu(NO)_3\cdot 3H_2O$) was dissolved in **1500** cc. of water and heated or cooled to the temperature chosen for precipitation. An ammonia solution containing one part by volume of concentrated ammonia (sp. gr. **0.89)** to two parts of water, was brought to the same temperature and added to the nitrate solution at a constant rate of **20** cc. per minute until a faintly alkaline reaction was obtained. During the precipitation the solution was continuously agitated by a motor-driven stirrer. The hydroxide was allowed to settle and then washed three times by decantation, each time using one liter of distilled water at the same temperature as that used in the precipitation. In some cases the third settling was very slow and the gel was therefore placed on the suction filter. After washing on the filter with a fourth liter of water at the same temperature, the gel was transferred to an electric oven and dried at 110°. In order to remove any occluded ammonia salts, the hydroxide was then heated at **220**° for four hours in a stream of nitrogen. By this procedure the hydroxide was converted into copper oxide.

The apparatus was exactly the same as that employed in previous studies on methanol catalysts and described in detail elsewhere.[1] It consisted essentially of an electrically heated pyrex tube in which the catalysts were exposed to methanol vapor supplied at a constant rate of flow. At the exit end of the apparatus means were provided for collecting the products of reaction, that is, formaldehyde, methyl formate and gaseous products.

A fixed amount of copper oxide, **0.43** g., prepared as above by heating at 220°, was reduced by passing over it **0.0462** mole of methanol at the lowest temperature at which reduction could be made to take place, varying between **190** and **210**°. The resulting catalyst was then raised to operating temperature, 360°, and **0.1156** mole of methanol vapor passed over it at a constant rate of flow for a period of ninety-three minutes. Formaldehyde and methyl formate were absorbed in low-head scrubbers containing water and methanol, while the gaseous products, consisting of hydrogen, carbon monoxide, carbon dioxide and methane, were collected in a graduated gasometer. All analyses were made according to standard methods.[1]

Discussion of Results.—The percentage of methanol decomposed as a function of temperature of precipitation is shown in Fig. 1, plotted from the data in Table I. It is seen that the maximum decomposition occurs with the catalyst prepared by precipitating the hydroxide at 22° and that this point stands out markedly from the others, corresponding to a five-

fold increase in activity over the catalyst resulting from precipitation at 0°. Another catalyst prepared by the same procedure gives a perfect check of the 22° point, and the entire general shape of the curve is checked in another series of experiments using smaller amounts of catalyst.[2]

As already mentioned above, these results were obtained with constant weights of catalyst. However, the specific volumes of the copper oxide samples and of the resulting catalysts were rather constant throughout, and hence the shape of the decomposition curve in Fig. 1 cannot be explained on the basis of variations in the time of contact of methanol vapor with the catalysts. Furthermore, it was observed that the more active the catalyst the lower the temperature required to start reduction. This initial reduction temperature is an inherent property of the copper oxide; it seems to be the result of the catalytic activity of the substance in question, rather than the cause, although it is of course impossible to distinguish completely between the two effects. The variation in the temperature of reduction is undoubtedly closely associated with the chemical composition and physical structure of the gels from which the catalysts are prepared. That the gels precipitated at various temperatures vary profoundly in these respects, is apparent from the following observations. The low temperature hydroxides are blue, while those precipitated at higher temperature are black, with a gradual transition in color between the two extremes. The gels resulting from low temperature precipitation

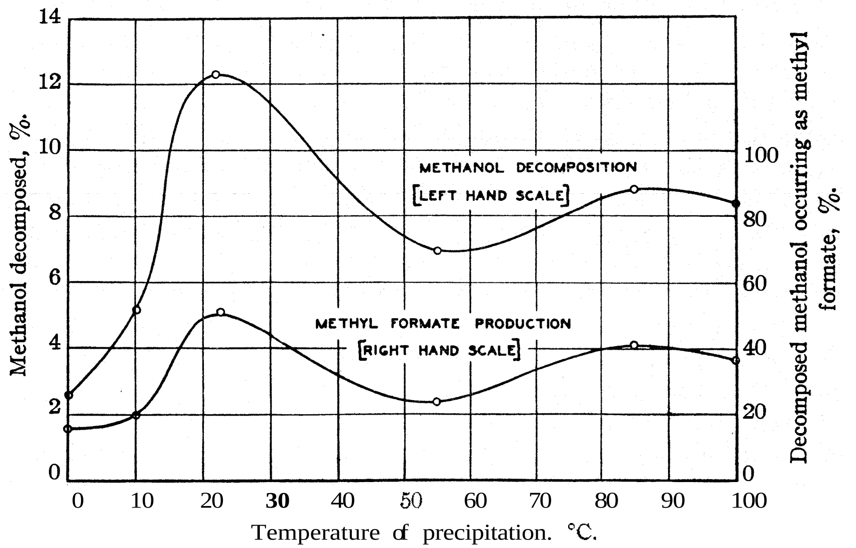

Fig. 1.—Data on copper catalysts prepared from the ammonia precipitated hydroxides, showing activity as a function of temperature of precipitation.

---

[2] G. L. MacLaughlin, M. I. T. "Thesis," 1927.

are also much more hydrated and bulky than those obtained at high temperature.[3]

Interesting light is also thrown upon the character of the gels by means of x-ray analysis. The gels precipitated at 85° and higher temperatures consist essentially of copper oxide with only small amounts of hydroxide. As the temperature of precipitation decreases, the amount of copper hydroxide present in the dried gels increases, until finally the material obtained by precipitation at 30°, or lower, shows only faint indications of copper oxide. The particle size of the dried gels is quite small and, in a qualitative way, the x-ray pictures indicate smaller gel particle size to be associated with the more active catalysts.

Based on these admittedly qualitative data on particle size, an explanation of the decomposition curve in Pig. 1 may be offered. Thus it seems that the particle size of the hydroxides decreases with decreasing temperature of precipitation, but at the same time the degree of hydration increases markedly. When the resulting gels are subsequently dried at 110° there is a tendency for the particle size to increase, as is commonly observed in analytical chemistry when highly insoluble precipitates as, for instance, barium sulfate and calcium oxalate, etc., are left wet for a few hours at 80 to 100°. However, since it takes a longer time for the water to be removed from the highly hydrated low temperature gels, these particles will have more chance to grow than will the particles precipitated at the higher temperature and containing practically no water of hydration. The result is that the final particle size of the dried gel is determined by two opposing factors: (1) the tendency for the initial particle size to decrease with decreasing temperature of precipitation, and (2) the tendency for the initially formed particles to grow while the drying proceeds at 110°. This might well explain the occurrence of a minimum particle size corresponding to a temperature of precipitation of about 22°. It may then be assumed that the particle size of the dried gel determines the activity of the catalysts resulting from subsequent reduction, either by determining the size of the catalyst particles or their form. This line of reasoning is further substantiated by the work of MacLaughlin,[2] showing that the most active catalyst results by precipitation at 0° when the gels are dried at room temperature (25°), rather than at 110°, as was done in this series of experiments.

The particle size of the metallic copper catalysts, in contrast to the gel from which they are prepared, is relatively large, a result which might be expected because there is no foreign material present to interfere with growth of crystals during the reduction process. However, x-rays fail to

---

[3] An interesting discussion of the various hydrated copper oxides or hydroxides is given by H. B. Weiser, "The Hydrous Oxides," McGraw-Hill Book Co., New York, 1926, p. 134.

disclose any perceptible difference in particle size of the individual catalysts.

From the data in Table I it will be seen that these catalysts decompose methanol largely into formaldehyde, but that considerable methyl formate is produced simultaneously. The more active the catalyst the larger is the percentage of decomposed methanol occurring as methyl formate, as shown in Fig. 1.[4] Apparently this effect of the active catalysts producing mainly methyl formate is characteristic of promoted copper, as has already been demonstrated to be the case for mixtures of copper and zinc oxide.' A similar effect is observed when alkali is used as a promoter, as will be shown in the second paper of this series.

Acknowledgment.—The data presented here are abstracted from a considerable amount of experimental work conducted in the Research Laboratory of Applied Chemistry during the past years. The writers are indebted to Messrs. G. L. MacLaughlin and R. O. Spurdle for preparation of some of the catalysts discussed, and to Mr. W. C. Asbury who obtained the x-ray data in cooperation with Dr. G. L. Clark.

Summary

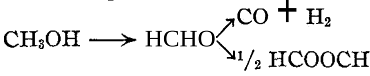
The activity of copper catalysts prepared from the ammonia precipitated hydrate varies markedly with the temperature of precipitation. There appears to be a maximum in activity corresponding to a temperature of precipitation in the neighborhood of 22".

On the basis of x-ray examination of the dried gels prior to reduction, it is suggested that the activity is determined by the particle size at this stage in the catalyst preparation. An explanation is also attempted to account for the apparent minimum in particle size of the gels precipitated at about 22°.

CAMBRIDGE, MASSACHUSETTS

---

[4] Roughly, the methyl formate curve runs parallel to the activity curve, the curve for formaldehyde (not plotted) being the reverse of the methyl formate curve. No doubt the methyl formate is a polymer of formaldehyde formed in accordance with the following scheme for the decomposition of methanol



$$CH_3OH \longrightarrow HCHO \begin{cases} \nearrow CO + H_2 \\ \searrow {}^1/_2\ HCOOCH_3 \end{cases}$$

That aldehydes can polymerize to form esters is well known [Mannich and Geilmann, *Ber.*, **49**,585 (1916)] and this same type of reaction is apparently employed for the production of butyl butyrate by dehydrogenation of butyl alcohol by means of copper catalysts [U. S. Patent 1,580,143, April 13, 1926].

SOLUBILITY. XII. REGULAR SOLUTIONS[1]

BY JOEL H. HILDEBRAND

RECEIVED JULY 23, 1928 PUBLISHED JANUARY 8, 1929

In a systematic study of deviations from Raoult's law, or other relations which may be derived from it, the author[2] has made much use of solubility data for solids and has shown that, particularly among substances of low polarity, there exist families of solubility curves which bespeak a marked regularity even where the deviations are very large. Evidently, the equations for the curves belonging to these families for systems which we will call ***regular***, are to be sought before those of divergent and often highly individualistic curves, shown by ***irregular*** systems. In the case of iodine, for example, the solvents which give a violet color, similar to that of iodine vapor, give regular solubility curves, while the solvents which give brown solutions give irregular curves. Fig. 1, giving solubility curves for stannic iodide in various solvents found by plotting log N_2, where N_2 is the mole fraction of the solute, against $1/T$, illustrates such a family of regular curves. It has been easy to show that the positions of the curves accord fairly well with the differences in internal pressure between the solvents and the solute, but it has not heretofore been possible to get from the solubility data as a whole any simple measure of the deviations from Raoult's law, for the spacing of the curves depends upon the distance from the melting point of the solute.

Mortimer,[3] it is true, has given an approximate treatment by assuming that the solubility curves are straight lines converging to the melting point, the slopes representing the heats of solution calculable upon an additive basis from a table of relative internal pressures. While this treatment is practically useful for systems deviating but moderately from Raoult's law, it is unsatisfactory, first, because the solubility curves are not linear, as Mortimer himself recognized; second, because where the solute melts to give a second liquid phase, its solubility curve does not converge to the melting point, but behaves as does heptane in Fig. 1; and, third, because the slope of the solubility curve does not, in general, give directly the partial molal heat of solution but requires a correcting term to be discussed later.

The course of the solubility curve for a solid depends upon the variation

[1] A brief preliminary paper has been published in the *Proc. Nat. Acad. Sci.*, 13, 267 (1927).

[2] (a) Hildebrand, THIS JOURNAL, a series of ten papers beginning in 1916, *cf.* "Bibliography," ref. 2b, p. 200; (b) Hildebrand, "Solubility," American Chemical Society Monograph, Chemical Catalog Company, New York, 1924; (c) ref. 2(b), Chap. XIV, see also Dorfman and Hildebrand, THIS JOURNAL, 49, 729 (1927).

[3] Mortimer, THIS JOURNAL, 44, 1416 (1922); 45, 633 (1923).

in its activity with both composition and temperature. Margules[4] long ago suggested for the variation in activity, a_2, with mole fraction, N_2, of Component 2 of a binary liquid mixture, the expression

$$\ln a_2 = \ln N_2 + {}^1/_2\beta_2 N_1^2 + {}^1/_3\gamma_2 N_1^3 + \ldots..$$

and, similarly, with subscripts interchanged, for the other component. Porter[6] called attention to a fact that had also been noted by the writer, *i. e.*, that terms higher than N^2 may be omitted for many systems. In 1906, van Laar[6] gave an equation based upon the van der Waals equation of state for mixtures, which in our notation reads

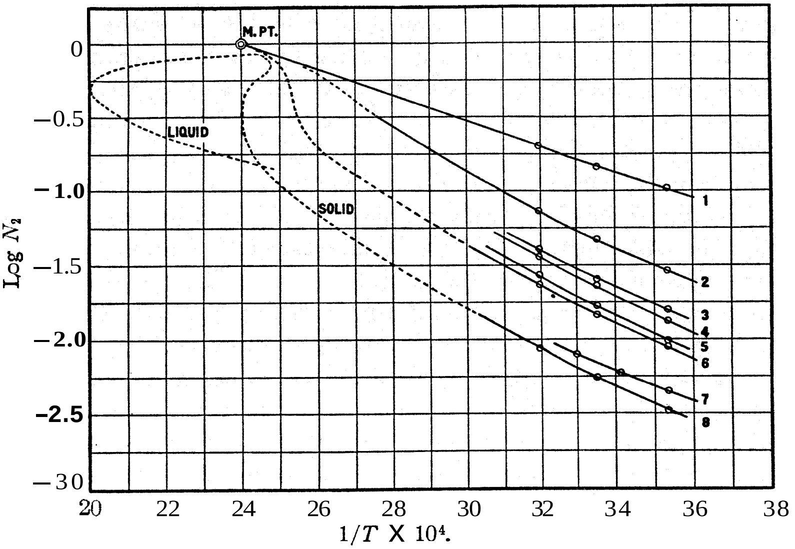

Fig. 1.—Solubilities of stannic iodide in: 1, carbon disulfide; 2, ethylene bromide; 3, m-xylene, 4, benzene; 5, chloroform; 6, carbon tetrachloride; 7, ether; 8, heptane.

$$RT \ln a_2 = RT \ln N_2 + \alpha N_1^2/(1 + rN_1)^2$$

where α and r are functions of the van der Waals "constants." When the van der Waals "b" is the same for the two components this reduces to

$$RT \ln a_2 = RT \ln N_2 + \alpha N_1^2$$

The term αN_1^2 is intended to represent the partial molal heat of mixing, and would be independent of temperature if the van der Waals equation were strictly applicable.

More recently van Laar and Lorenz[7] have published a derivation of

the above equation. Experimental tests of their equations have rarely been made by the van der Waals "school" beyond the mere citing of systems which conform as to type, and the present case is no exception. It is also unfortunate that the generally accurate thermodynamic methods employed in Holland have been so inextricably bound up with an inadequate equation of state.

Shortly before the publication of the previous paper by the writer on this subject, there appeared an important paper by Heitler[8] in which the simplified equation given by van Laar was derived without reference to the van der Waals constants, by considering the solution as a lattice, examining the probability of the various arrangements of the two molecular species therein, and by the aid of certain other assumptions that cannot be repeated here. He tested the formula by showing that the isotherms for the vapor pressure of five mixtures can be calculated with fairly good agreement by getting the heat of mixing from the curve itself, although the agreement with the experimental heat of mixing was not at all good. He further applied the formula to the calculation of the liquid–liquid solubility curve, and tested it with existing data for eight systems, finding that the experimental curves are in all cases somewhat flatter.

Most of the systems cited by Heitler involve one more or less polar constituent and one involves solvation. The writer believes it to be important in this connection to distinguish the systems here designated as regular from those involving solvation or association, in order to gain a correct prediction of the temperature effect, and also that the change in volume on mixing should be taken into consideration. The following simple considerations are advanced regarding the entropy of regular solutions.

If a solution is ideal, in the sense of obeying Raoult's law, the change in free energy corresponding to the transfer of a mole of component X_2 from the pure liquid state to a large amount of solution, in which its mole fraction is N_2, is[9]

$$\bar{F}_2^i - F_2^\circ = RT \ln N_2 \tag{1}$$

The corresponding entropy change is

$$\bar{S}_2^i - S_2^\circ = \frac{d(\bar{F}_2^i - F_2^\circ)}{dT} = R \ln N_2 \tag{2}$$

which thus depends upon composition only. From the standpoint of the interpretation of entropy in terms of probability, we can say that a mixture represents a more probable state for such a system than do the separate liquids. Now suppose that the component X_2 is transferred from an ideal solution to any regular solution in which it has the same

---

[8] Heitler, *Ann. Physik,* [4] 80, 630 (1926).

[9] Ref. 2b, p. 29.

mole fraction. From our picture of a regular solution as one in which orienting and chemical effects are absent, and in which the distribution and orientations are random, just as in the ideal solution, we may conclude that the probability of X_2 is the same in the two solutions and, therefore, that the difference in entropy is zero. We cannot expect this conclusion to hold unless the random distribution of the molecules persists. We may expect, further, that a small correction should be applied to take care of the change in entropy accompanying changes in volume, given by

$$\left(\frac{\partial S}{\partial V}\right)_T = \left(\frac{\partial P}{\partial T}\right)_V \qquad (3)$$

or we may state our principle in the following form. *A regular solution is one involving no entropy change when a small amount of one of its components is transferred to it from an ideal solution of the same composition, the total volume remaining unchanged.* Let us examine the consequences of this simple postulate.

When one mole of X_2 is transferred from the pure liquid to a regular solution, the change in free energy is

$$\bar{F}_2 - F_2^{\circ} = RT\ ln\ a_2 \qquad (4)$$

where a_2 is the activity of X_2 in the solution referred to the pure liquid as the standard state, The change in free energy in transferring one mole of X_2 from the ideal solution to a regular solution is found by subtracting Equation 1 from Equation 4, giving

$$\bar{F}_2 - \bar{F}_2^{1} = RT\ ln\ \frac{a_2}{N_2} \qquad (5)$$

The corresponding entropy change is zero, according to our postulate, except for the volume correction, hence the right-hand member of Equation 5, as a first approximation, is not a function of temperature, and is equal to the partial molal heat of mixing

$$\bar{F}_2 - \bar{F}_2^{1} = \bar{H}_2 \qquad (6)$$

This is, however, a function of composition, the approximate form of which has been derived by Heitler as parabolic. This follows, also, in a less rigid way, from the following simple considerations. The excess of heat content of a mole of regular solution over an ideal solution, AH, may be expected to be greatest in an equimolal mixture, falling off continuously to zero at the ends, as shown in Fig. 2. A simple equation for the course of such a curve is $AF = bN_1N_2$, where b is a constant. Since $N_1 + N_2 = 1$, either mole fraction could be eliminated, but we prefer to keep the symmetrical form. From the definition of partial molal quantities, it follows that

$$\bar{H}_2 = bN_1^2, \text{ and } \bar{H}_1 = bN_2^2 \qquad (7)$$

Substituting in Equation 5 by the aid of 6, we get

$$RT\ ln\ \frac{a_2}{N_2} = bN_1^2 \qquad (8)$$

and the same, with subscripts interchanged, for the other component. One may prefer to express a_2/N_2 as γ, the activity coefficient.

The parabolic shape of the exponential term is illustrated by figures in Ref. 2b, pp. **43,** 49 and **63.**

In cases where the system proves unsymmetrical, we may add higher powers of N_1 and write Equation 8 as

$$\ln \frac{a_2}{N_2} = \frac{1}{RT}\,(bN_1^2 + cN_1^3 + \ldots\ldots) \tag{9}$$

where b, c, etc., are not functions of temperature, except for the correction due to volume changes, which we shall, in general, neglect. The corresponding equation for the other component then becomes, by the aid of the Duhem equation

$$\ln \frac{a_1}{N_1} = \frac{1}{RT}\left(b + \frac{3}{2}\,c\right)N_2^2 + cN_2^3 + \ldots\ldots \tag{10}$$

We will examine extensive experimental evidence in support of this formulation, using the simpler Equation 8, so far as possible.

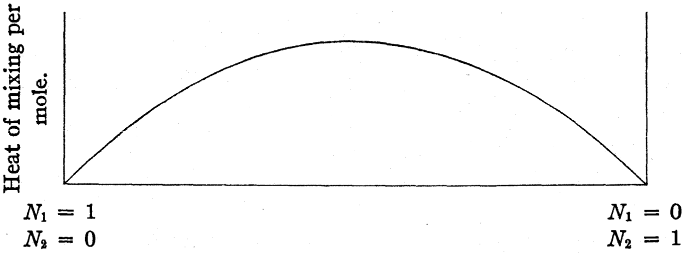

Fig. 2.—Relation between mole fraction and heat of mixing per mole.

Solubilities in Regular Solutions.—We can test Equation 8, first, by the use of solubility data, provided that they cover a considerable range in temperature. Since the activity of the solute, a_2, is the same in its saturated solutions in all solvents, including those in which it obeys Raoult's law, we may write $a_2 = N_2^i$, where N_2^i is the solubility in the ideal solution, which can be calculated by the aid of a knowledge of the melting point and heat of fusion of the solute. Equation 8 thus becomes

$$\ln \frac{N_2^i}{N_2} = \frac{bN_1^2}{RT} \tag{11}$$

which may be written

$$\log \frac{N_2^i}{N_2} = \frac{kN_1^2}{T} \tag{12}$$

where $k = 0.4343b/R$.

We will first apply this equation to data upon the solubility of sulfur in various solvents published by Hildebrand and Jenks,[10] together with

---

[10] Hildebrand and Jenks, THIS JOURNAL, 43, 2172 (1921); *cf.* also ref. 2b, p. 151.

some data by Étard reproduced in the same paper. Table I contains values for 100 N_2, the mole per cent. of sulfur in the solutions, and the corresponding value of k calculated from the solubilities. It will be seen

TABLE I

that, in spite of the large variations in N_2 and *t*, the value of k is remarkably constant. It is true that N_1^2 does not vary greatly from 1, hence the constancy of k does not indicate at all certainly that the system is to be described by Equation 8 rather than Equation 9. It is even conceivable that the constancy of k is only apparent, due to a canceling of a variation with temperature and a more complex variation with N_1. That this should be the case in so many systems is, however, very improbable, or is, at any rate, an effect of a higher order, not seriously interfering with the practical value of the simpler Equation 8. Moreover, we shall see evidence later in which N_1 undergoes large variations with but little effect on k.

There appears to be a slight increase in k with increasing temperature for xylene, and a slight decrease for benzene. This is borne out by the fact that the critical mixing temperature with benzene is lower than that with xylene, indicating a crossing of the solubility curves at higher temperatures. It is noteworthy that this is in harmony with the correction for volume change given in Equation 3. The volume of liquid sulfur at 20" is 135 cc. (extrapolated), while the partial molal volumes of sulfur in the solvents benzene, toluene and xylene at 25° are, respectively, 138.7 cc., 133.4 cc. and 123.6 cc., indicating an expansion in forming the benzene solution and a contraction for the xylene solution.

Further evidence is furnished by the solubility data for violet solutions of iodine, which are taken from a paper by Hildebrand and Jenks.[11] Table II gives, as in Table I, the values of k for a series of temperatures. As in the previous table, k shows a very satisfactory constancy. In the case of carbon disulfide, the variation in N_1 is sufficient to make a considerable difference between N_1^2 and N_1^3, which are 0.83 and 0.75, respectively, at the highest concentration, showing that the equation with N_1^2 only suffices. It is interesting to state two further facts. The first is that the value of k for carbon disulfide falls to 181 at −20° and to 106 at −63°, but in this region the solution becomes brown and is no longer regular. Arsenic trichloride, which likewise gives brown solutions, behaves similarly, giving for k, 337 at 96°, 112 at 15° and 93 at 0°. The second fact is that while k remains constant for carbon disulfide solutions between 0 and 40°, there is a slight falling off for both heptane and carbon tetrachloride. It is possible, however, to correlate this behavior with the effect of volume changes mentioned earlier. From measurements of the density of these solutions made by Dawson,[12] we have calculated the partial molal volumes of liquid iodine in heptane, carbon tetrachloride and carbon disulfide to be, respectively, 63.9, 65.8 and 61.1 cc., which may be compared with the volume of 58.5 cc. for the extrapolated molal volume of liquid iodine.

the concentrations of naphthalene become very high, so that the use of a cN_1^3 term would lead to very different results.

The data for stannic iodide obtained by Dorfman and Hildebrand[14] offer further opportunity for testing the equation. Unfortunately, we have no direct value for the heat of fusion of stannic iodide wherewith to calculate the ideal solubility; however, we have two ways of making reasonably good estimates. The first is to assume that all tetrahalides of this type will have about the same entropy of fusion. Table IV gives values of the melting points, T_m and heats of fusion, ΔH_m for several such halides, together with their quotient, the entropy of fusion. The values for ΔH_m are from Latimer,[15] except the last, which is from Tolloczko.[16]

TABLE IV

CONSTANTS OF HALIDES

	T_m	ΔH_m	$\Delta H_m/T_m$
Silicon tetrachloride	203.3	1845	9.08
Titanium tetrachloride	248	2233	9.00
Stannic chloride	240	2188	9.11
Stannic bromide	303	2750	9.08
		Mean	9.07

If we assume that $\Delta H_m/T_m$ for stannic iodide is also about 9.07, then, since T_m is 416.5, ΔH_m = 3775. Another estimate may be made by assuming that stannic iodide forms a nearly ideal solution with carbon disulfide, the evidence for which is given in the paper by Dorfman and Hildebrand. The slope of this solubility curve gives ΔH_m = 3940. We shall select in round numbers 3850. Calculating the ideal solubilities from this value, Equation 12 gives the values of k shown in Table V, omitting the figures for mole per cent.

TABLE V

VALUES OF k FOR SOLUTIONS OF STANNIC IODIDE

t, °C.	C_7H_{16}	CCl_4	$CHCl_3$	C_6H_6	$C_6H_4(CH_3)_2$	$C_2H_4Br_2$
10	434	315	305	268	249	177
25	436	317	298	267	249	174
40	440	313	296	261	246	171

It is interesting to note the form of the curve given by Equation 12 in Fig. 1, for several systems, using the mean values of k given in Table V. It can be seen that while the curves are nearly linear for small values of k, illustrated by ethylene bromide, as k becomes larger the curves take on the reversed S-shape noted particularly by Mortimer.[3] Furthermore, as the value of k becomes still larger, as in the case of heptane, there appear three values of log N_2 for a single temperature, two of which are stable

corresponding to the appearance of a second liquid phase, all three phases, containing stannic iodide at the same activity. Above this triple point the solid disappears and we are in the region of two liquid phases. The equation thus accounts for the type of system previously encountered with sulfur.[10] This portion of the system will be discussed in the following section. Illustrations similar to the above might be multiplied almost indefinitely, but that is hardly necessary.

Two-Phase Liquid Systems.—Equations 8, 9 and 10 invite application to systems of incompletely miscible liquids, as has been done by Heitler. Part of this section parallels his work, but this is done for the sake of completeness. We have as the condition of equilibrium that the activity of each component is the same in both phases, that is, $a_1' = a_1''$ and $a_2' = a_2''$, where the primes distinguish the two phases. Equation 9 then gives

$$\ln a_2' = \ln N_2' + \frac{b}{RT} N_1'^2 = \ln a_2'' + \ln N_2'' + \frac{b}{RT} N_1''^2$$

from which, since $N_{1'} + N_{2'} = 1$, and $N_{1''} + N_{2''} = 1$, we get

$$\ln \frac{1 - N_1'}{1 - N_1''} = \frac{b}{RT} (N_1''^2 - N_1'^2)$$

Equation 9 for component 2 is identical except for the exchange of subscripts. The two equations are simultaneous when $\frac{1 - N_1'}{1 - N_1''} = \frac{1 - N_2'}{1 - N_2''} = \frac{N_1'}{N_1''}$, when $N_1'' = N_2' = 1 - N_1'$. Substituting this in the above gives

$$\ln \frac{1 - N_1'}{N_1'} = \frac{b}{RT} (1 - 2N_1') \tag{13}$$

which can be used for calculating the composition of the liquid phases when b is known, or ***vice versa.*** The former calculation, unfortunately, requires the method of successive approximations, so it is best to calculate T from given values of b and N. This equation becomes indeterminate at the critical mixing temperature, T_c, so that it is best to relate T_c to N in the following way.

At the critical mixing point, we have the conditions that[17] $\left(\frac{\partial a}{\partial N}\right)_T = 0$ and $\left(\frac{\partial^2 a}{\partial N^2}\right)_T = 0$. Applying these to Equation 8 gives $RT_c = 2bN_1N_2$, and $N_1 = N_2 = 0.5$, whence

$$2RT_c = b \text{ or } T_c = 1.15\text{ k} \tag{14}$$

The same methods can be applied to the unsymmetrical Equation 9, giving, in place of Equation 13, two simultaneous equations requiring a graphic solution, and in place of Equation 14 two equations giving b and c in terms of T_c and the critical composition, from which calculation can be made in either direction. The discussion will be confined, however, to the simpler symmetrical case given by Equations 13 and 14.

---

[17] **Ref. 2b, p. 55.**

The solubility of stannic iodide in heptane between 10 and 40° gives $k = 437$. If we assume that there is no entropy of expansion and that k remains constant to the region of two liquid phases, above about 125°, we would have from Equation 13 the liquid solubility curve shown in Fig. 1, with a critical mixing temperature of 230°, instead of the experimentally determined value of 137°.[18] This discrepancy would be reduced somewhat, 10°, by the use of the unsymmetrical equation, and the uncertainty regarding the heat of fusion of stannic iodide permits of some variation between the two figures. We have noted, however, some tendency of k to diminish with rising temperature, and have seen in Equation 3 a reason why it should. It is evident, therefore, that an extrapolation of over 100° from solid solubility to critical mixing temperature would be extraordinarily sensitive to slight changes in k. If we calculate k from the critical mixing temperature by Equation 14, we get 356, while around 25° we found 437. The drift may be expressed by using $k = 643 - 0.7T$. If we use 356 as constant to calculate the liquid solubility curve, it is especially significant that, although this gives the correct critical temperature, the descending branches are too near together, while if we use the slightly variable k, the spread of the curve is nearly satisfactory, bringing the liquid and solid curves into approximate agreement. The values of k in Table V indicate that instead of the variation being linear with T, a more rapid variation exists; this would satisfy also the experimental points for the liquid–liquid system.

Mr. A. Wachter, at the author's request, has made a determination of the solubility of stannic iodide in iso-octane (2,2,4-trimethylpentane) at 25°, getting for the mole per cent. of stannic iodide 0.3399 and 0.3441, mean 0.342. This gives a value of k of 503. The critical solution temperature for the two liquid phase system is 195°, from which we can calculate k from Equation 14 to be 407. If the change of k with T is assumed to be linear, we can write $k = 671 - 0.565T$, which very nearly accounts for the experimental points, although here again a slightly more rapid variation with T would be required to give perfect agreement.

Sulfur solubility curves suggest an application of these same equations and a number of calculations have been made with results agreeing about as well as with stannic iodide. They are not here reproduced, however, since the presence of S_μ in the liquid adds a considerable complication.

The E.m.f. of Concentration Cells.—The measurements made in this Laboratory by Taylor[19] on the e.m.f. of molten alloy concentration cells and their temperature coefficients offer a peculiarly direct check on the existence of regular solutions of the sort conforming to our definition. A cell consisting of a pure metal and its alloy with a nobler metal, as

---

[18] Dice and Hildebrand, THIS JOURNAL, 50, *3023 (1928).*

[19] *N. W.* Taylor, THIS JOURNAL, *45,2865 (1923); cf.* also ref. 2b, Chap. XVI.

electrodes, separated by an electrolyte containing the ion of the baser metal, has an e.m.f. given by the equation

$$\mathrm{E} = \frac{RT}{\mathrm{NF}} \ln a_2 \tag{15}$$

Combining this with Equation 9 gives

$$\mathrm{E} = \frac{RT}{\mathrm{NF}} \ln \mathrm{N}_2 + b\mathrm{N}_1^2 + c\mathrm{N}_1^3 + \ldots\ldots \tag{16}$$

The temperature coefficient of the cell is then

$$\frac{\mathrm{dE}}{\mathrm{d}T} = \frac{R}{\mathrm{NF}} \ln \mathrm{N}_2 \tag{17}$$

that is, the temperature coefficient is the same as for an ideal solution of the same composition. That various alloys obey this relation remarkably well is shown in Table VI. This is all the more striking because only the first alloy conforms to Equation 8, the other two requiring the more complicated Equation 9. What difference there is is in the direction expected, that is, the observed values are greater.

TABLE VI

TEMPERATURE COEFFICIENTS OR E.M.P. OR ALLOY CONCENTRATION CELLS, IN MILLIVOLTS PER DEGREE

$\frac{\mathrm{dE}}{\mathrm{d}T}$ (calcd.)	.090	.057	.026	
	Alloy, Zn-Cd			
Mole *per cent.* of Zn	15.0	25.1	34.4	69.1
$\frac{\mathrm{dE}}{\mathrm{d}T}$ (obs.)	0.079	0.061	0.047	0.016
$\frac{\mathrm{dE}}{\mathrm{d}T}$ (calcd.)	.082	.060	.046	.016

Not all such solutions are regular. The alloys of zinc and tin, and also of cadmium and bismuth, investigated by the same author, are irregular. This is not surprising in view of the departure of each, especially the latter, from the usual type of relation between log (a/N) and N.

Other Relations. 1. The Heat of Solution.—When the temperature of a saturated solution of X_2 is changed, saturation is maintained by having the change in fugacity of the solid phase, with the temperature only, equal to the change in fugacity of the same substance in solution, due to changes in both temperature and composition. Formally expressed this gives

$$\mathrm{d} \ln f_2^s = \mathrm{d} \ln f_2 = \left(\frac{\partial \ln f_2}{\partial T}\right)_{\mathrm{N}} \mathrm{d}T + \left(\frac{\partial \ln f_2}{\partial \ln \mathrm{N}_2}\right)_T \mathrm{d} \ln \mathrm{N}_2$$

But

$$\frac{d \ln f_2^s}{dT} = \frac{H_2^* - H_2^s}{RT^2} \text{ and } \frac{\ln f_2}{T} = \frac{H_2^* - \bar{H}_2}{RT^2}$$

where H_2^* and H_2^s are the heat contents of the vapor and solid, respectively, and $\bar{H}_2$ is the partial molal heat of solution; we can write, therefore

$$\frac{\bar{H}_2 - H_2^s}{RT^2} = \left(\frac{\partial \ln f_2}{\partial \ln N_2}\right)_T \frac{d \ln N_2}{dT} \tag{18}$$

For regular solutions, the partial differential can be obtained from Equations 8 or 9. Using the latter, and remembering that $f_2/f_2^\circ = a_2$, where f_2° is the fugacity of the pure liquid, we get

$$\left(\frac{\partial \ln f_2}{\partial \ln N_2}\right)_T = 1 - \frac{2b\, N_1N_2}{RT} \tag{19}$$

where $N_1 + N_2 = 1$. This equation expresses the deviation of a system from either Henry's law, $f_2 = lN_2$, where l is a constant, or from Raoult's law, where the constant becomes f_2°. It occurs frequently in the derivations of thermodynamic equations. It should be noted that $(\partial \ln f_2/\partial \ln N_2)_T$ approaches unity, first, when b approaches zero, that is, when Raoult's law is obeyed throughout the entire range of composition; second, when either N_1 or N_2 approaches zero, that is, when the solution is very dilute in either component. Only under these conditions, therefore, does the slope of the solubility curve, log N_2 *vs.* $1/T$, give directly the heat of solution. The equation for the heat of solution results from the substitution of Equation 19 in 18, giving

$$\frac{\bar{H}_2 - H_2^s}{RT} = \left(1 - \frac{2bN_1N_2}{RT}\right) \frac{d \ln N_2}{dT} \tag{20}$$

In view of the form of the curve for large deviations from ideal shown in Fig. 1, it is evident, as stated earlier, that a straight line drawn through the melting point gives a very erroneous value for the heat of solution. On the other hand, the tangent to the curve when log N is small gives the heat of solution rather accurately.

2. The Heat of Mixing.—In deriving Equation 8, the assumption was made that the heat of mixing is given by an equation such as 7. It may, of course, prove necessary in dealing accurately with some regular systems to add higher powers of N. Data upon heats of mixing are very meager, but the evidence is favorable for the approximate equality of free energy and heat of mixing. Taylor[19] pointed this out in connection with his measurements, and more recently Butler[20] has given a more quantitative calculation based upon these same measurements.

It is noteworthy that Equation 16 becomes equivalent to the well known Cady[21] equation, in view of the identification of the terms $bN_1^2 + cN_1^3 + \ldots$

---

[20] Butler, THIS JOURNAL, **47,** 117 (1925).

[21] Cady, *J. phys. Chem.,* 2,551 (1898).

with the heat effect. The failure of this equation to give a more complete agreement with the experimental data we attribute to its application to irregular systems, and to the use of concentration instead of mole fraction to express composition.

3. Volume Change on Mixing.—Differentiating Equation 8 with respect to the pressure, P, upon the liquid phase at constant N and T gives

$$\left(\frac{\partial \ln a_2}{\partial P}\right)_{\text{N,T}} = \frac{\text{N}_1^2}{RT}\frac{db}{dP}$$

(the second differential is not written as a partial since b is practically independent of N and T) but this is equal[22] also to $(\bar{\text{v}}_2 - \text{v}_2)/RT$, where v_2 is the molal volume and $\bar{\text{v}}_2$ the partial molal volume. We therefore write

$$\bar{\text{v}}_2 - \text{v}_2 = \text{N}_1^2\frac{db}{dP} \tag{21}$$

This harmonizes with a relation discovered by Biron[23] that the expansion of two liquids upon mixing to form a mole of mixture is

$$\Delta V = (\bar{\text{v}}_1 - \text{v}_1)\text{N}_1 + (\bar{\text{v}}_2 - \text{v}_2)\text{N}_2 = K\text{N}_1\text{N}_2$$

where K is db/dP. It also gives justification for the relation discovered some years ago by the writer[24]

$$\ln\frac{a_2}{\text{N}_2} = K'(\bar{\text{v}}_2 - \text{v}_2)$$

where K' is an empirical constant. Comparing this with Equation 8 gives $K'(\bar{\text{v}}_2 - \text{v}_2) = b\text{N}_1^2$. Combining with Equation 21 gives $K'\text{N}_1^2(db/dP) = b\text{N}_1^2$ or $(d \ln b/dP) = (1/K)$, that is, K' is a constant for a given system calculable from b and its change with pressure.

4. The Gibbs adsorption equation is

$$\left(\frac{\partial\gamma}{\partial \ln f_2}\right) = -u_2RT \tag{22}$$

where γ is the surface tension of a solution, and u_2 the amount of adsorbed solute per cm.^{2} of surface. The partial differential signifies constant surface. We may write the mathematical identity

$$\left(\frac{\partial\gamma}{\partial \ln \text{N}_2}\right) = \left(\frac{\partial\gamma}{\partial \ln f_2}\right)\left(\frac{\partial \ln f_2}{\partial \ln \text{N}_2}\right)$$

The first differential on the right is given by Equation 22, and the second by Equation 19, giving

$$\frac{\partial\gamma}{\partial \ln \text{N}_2} = -u_2RT\left(1 - \frac{b\text{N}_1\text{N}_2}{RT}\right) \tag{23}$$

This equation is usually written with the concentration in place of the mole fraction and without the term in parenthesis. The omission of this correcting term may be serious, for it is those solutions which deviate

---

[23] Biron, *J. Russ. Phys.-Chem. Soc.*, **44**, 1264 (1912).

[24] *Cf.* ref. 2b, pp. 61–65.

most strongly from Raoult's law (that is, which show a large value for *b)* that show large adsorption. Of course this is compensated by the fact that when the solution is very dilute, $N_2 = 0$, and the correcting factor approaches unity. The usual neglect of the deviation from the ideal solution is undoubtedly partly responsible for the lack of agreement often found when testing the Gibbs equation in the simplified form. Equation 23 offers a simple means for making the correction for regular solutions.

Evaluation of the Constant.—The application of the various equations given in this paper requires, of course, the evaluation of the constant b, or, when necessary, additional constants in Equation 9. The numerous solubility data already discussed by the author show clearly that the deviations from ideality, now expressed by the magnitude of b or k, are rather closely determined by the difference in internal pressure of the two components. There is evidence, however, that this is not the only factor and efforts are being made to formulate the exact relation between b and internal pressure. This study demands certain experimental data that we are now endeavoring to secure, after which it is hoped that a report upon the subject may be made.

Meanwhile, it would be possible to give an improved substitute for Mortimer's table of solubility "factors" by constructing a table of internal pressure functions that would give values of k by difference. This is too long a task for inclusion with this paper, but anyone confronted with problems involving regular solutions may make rather good estimates of the constant upon an additive basis by the aid of existing data involving other systems. Again, where a single experimental point involving the activity of a system is at hand, its general behavior can be calculated.

In plotting activity data, it has been pointed out[25] that log (a_2/N_2) (or log γ_2, where γ_2 is the activity coefficient), when plotted against mole fraction, gives a simple expression for deviations from ideality. It is becoming rather general practice, even with aqueous solutions, which are far from regular, to plot log γ. The present treatment suggests that where temperature changes are involved the most advantageous function to plot would be T log γ_2 against N_1^2.

Summary

1. Certain solutions of a common solute in various solvents which give families of solubility curves, and from which chemical effects and association changes are absent, are designated as regular solutions. They are defined as solutions in which no change in entropy, except for the small entropy of expansion, is involved in the transfer of a constituent from it to an ideal solution of the same concentration.

2. An equation given by van Laar upon the basis of the van der Waals

---

[25] Ref. 2b, Chap. V.

equation of state, and recently derived by Heitler upon different assumptions, is applied to a large number of solutions with very satisfactory results.

3. The equation is applied to the calculation of other properties dependent upon activity, including the e.m.f. of concentration cells, the heat of solution of solids, the expansion on mixing and the Gibbs adsorption equation.

PHOTOCHEMICAL STUDIES. VIII. THE PHOTOCHEMICAL DECOMPOSITION OF MALONIC ACID BOTH IN THE PRESENCE AND ABSENCE OF URANYL SULFATE

BY WILLIS CONWAY PIERCE, A. LEVITON AND W. ALBERT NOYES, JR.

RECEIVED JULY 24, 1928 PUBLISHED JANUARY 8, 1929

The photochemical decompositions of many organic acids have been studied in some detail. Of these none has received more attention than the decomposition of oxalic acid. It is not necessary, at the present time, to summarize all of the work that has been done.[1] Earlier work on the nature of the products formed has been shown by Allmand and Reeve[2] not to agree with the composition of the products formed during the early stages of the reaction. These authors show that the principal reaction consists in the formation of formic acid and carbon dioxide. Since the former may be decomposed photochemically, other products would result with long exposures. They found, further, that the quantum efficiency varied with wave length, the highest value obtained being 1/100 at 265 $m\mu$. Anderson and Robinson[3] report an average yield of 1/1392 molecule per quantum for radiation from a quartz mercury arc lamp.

The photochemical decomposition of oxalic acid sensitized by uranyl salts has also received considerable attention. Measurements of quantum efficiency of the sensitized reaction are somewhat at variance, but the best evidence indicates that the value is approximately one.[4,5] Büchi,[4] from a consideration of his determinations of the rate of photochemical decomposition of oxalic acid in solutions of varying concentration and with various amounts of uranyl sulfate, has come to the conclusion that a complex molecule, or a molecule of uranyl oxalate, is the photosensitive mole-

Kistiakowsky, "Photochemical Processes," The Chemical Catalog Co., Inc., New York, 1928, pp. 146,229, has given a partial summary of recent work on this reaction.

cule in the reacting system. He further supports this conclusion by the data of Henri and Landau,[6] which show that the absorption coefficients of oxalic acid and uranyl salts are not additive in solutions containing both substances, but that a marked increase in the absorption of uranyl sulfate solutions is brought about by the addition of small amounts of oxalic acid. As pointed out by Kistiakowsky,[1] there is further evidence in favor of the sensitivity of the complex in the comparison of the quantum efficiencies with and without catalyst.

Corresponding work on other acids has been attempted, Thus Müller[7] has found that approximately one molecule of lactic acid was decomposed per quantum absorbed in the presence of uranyl sulfate. Bolin[8] found, however, that uranyl salts in the presence of lactic acid are quantitatively reduced. The rate of reaction reached a steady value with increase in concentration of uranyl sulfate. No evidence for or against complex formation is contained in either of these papers.

Some work has been done on the photochemical decomposition of malonic acid. Fay[9] in the presence of catalyst, found that the rate of decomposition in sunlight was exceedingly slow. Kailan[10] found that more carboxyl groups were decomposed in the case of malonic acid than in the case of oxalic acid when the two were exposed to full radiation from a quartz mercury arc lamp. Berthelot and Gaudechon[11] found that uranyl salts acted as catalysts in the photochemical decomposition of malonic acid. Volmar[12] states that the main products of the photochemical decomposition of malonic acid are acetic acid and carbon dioxide.

The present work was undertaken with the object of determining the possible mechanisms of the action of uranyl sulfate in catalyzing the photochemical decomposition of malonic acid.

I. Experimental Procedure and Results

In all of the work which follows the amount of decomposition of malonic acid was determined by titration with sodium hydroxide solutions (free from carbonate) with the use of phenolphthalein as the indicator. The solutions were boiled to remove carbon dioxide. In solutions containing uranyl sulfate (below 0.01 M), the uranyl sulfate titrated toward phenolphthalein as though it were an equivalent amount of sulfuric acid. This point was repeatedly checked by making up solutions containing a known weight per unit volume of $UO_2SO_4 \cdot 3H_2O$. The amount of decomposition

agreed roughly with that determined by gas evolution, but the latter method of measurement was not considered to be as accurate as the titration method.

(a) Analysis of the Gas Evolved during Decomposition.—A solution of malonic acid was placed in a quartz reaction vessel sealed to a Toepler pump by means of a graded seal. The solution was outgassed as thoroughly as possible and then exposed to the full radiation from a quartz mercury arc lamp. The evolved gases were pumped off and collected in a small test-tube over mercury. The gases were then analyzed by the micro method of Reeve.[13] The total volume was measured in a capillary tube. The gas was swept into the test-tube again and a small piece of fused potassium hydroxide introduced to absorb the carbon dioxide. The residual gas was measured in the capillary tube. An attempt was made to analyze the residual gas by sparking with air, but no contraction (beyond experimental error) was noticed. After sparking the gas was again tested for carbon dioxide but no further absorption was found. Sparking alone, without admixture of air, did not produce any consistent change in volume. This probably indicates that no appreciable quantity of methane or carbon monoxide is formed. Table I presents the results obtained. The residue seems to be largely air.

TABLE I

ANALYSIS OF THE GAS FORMED DURING PHOTOCHEMICAL DECOMPOSITION OR MALONIC ACID

Concn. of malonic acid, 0.05 M. 1 cm. = 0.0227 cc.

Conditions	Total gas, cm.	Residue, cm.	CO_2 by vol., %
No catalyst	12.6	0.7	94.5
No catalyst	10.0	.4	96.0
No catalyst	16.2	.7	95.7
No catalyst	18.6	.75	96.0
Catalyst 0.005 M	54.5	2.3	96.0
Same (Pyrex vessel)	80.0	0.4	99.5

It is probable that the difference between the last analysis and the others is due to more thorough outgassing in the Pyrex vessel.

We feel safe in stating that the early stages of malonic acid decomposition lead almost exclusively to the formation of carbon dioxide and acetic acid. This seems to be true both in the presence and absence of catalyst and in the presence of catalyst whether the full mercury arc spectrum is used or just those wave lengths longer than 300 mμ.

(b) Effect of Uranyl Sulfate on the Rate of Photochemical Decomposition with Radiation from the Full Mercury Arc.—A series of decompositions was carried out in which solutions 0.05 M with respect to malonic acid and containing various concentrations of uranyl sulfate were exposed to radiation from the full mercury arc in a vessel open to the air. It was shown that the rate was practically the same in the absence of air by carrying out a few experiments in a closed vessel evacuated to the vapor pressure of water over the solution. The determinations were made by titration (see above). Table II (see also Fig. 1) shows the relative rate of decomposition with varying concentration of catalyst. The values are averages of three determinations.

(c) The Determination of the Quantum Efficiency.—The light intensities were all measured by means of a thermopile calibrated by a standard source of radiation

furnished by the Bureau of Standards; 1 cm. deflection corresponded to 2.0 ergs per mm.^{2} per second.

The percentage absorption was determined by a modification of the procedure used by Herr and Noyes.[14] A perforated plate was placed in front of a quartz mercury arc lamp. The radiation was made into a slightly diverging beam by means of a quartz lens and then passed through a water cell about 3.2 cm. in thickness. The absorption cell containing water was then fixed in such a way that it could be interposed between the water cell and the thermopile. After the decrease in deflection due to interposition of the cell filled with water had been determined, the cell was filled with the solution to be studied and the decrease in deflection again determined. The difference between the two percentage decreases was taken as the percentage of the radiation absorbed by the solution.

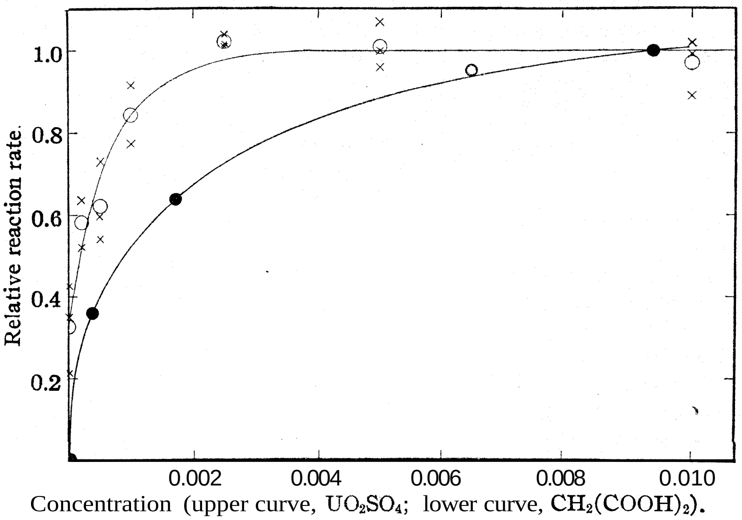

Fig. 1.—Upper curve is that of Equation 1. Crosses are observed values, circles are average values. The concentration of $CH_2(COOH)_2$, is 0.05 M. Through quartz. The lower curve shows the variation in rate with concentration of malonic acid (see Table VII). Concentration of UO_2SO_4 is 0.01 M. Through Pyrex glass.

The actual determination of the amount of decomposition required a more intense radiation than could be obtained by the system described in the preceding paragraph. The radiation was passed (without a lens) through an opening about two centimeters in diameter, through the water cell and then through the solution to be studied. The

[14] Herr and Noyes, THIS JOURNAL, 50, 2345 (1928).

intensity of the incident radiation was obtained by placing the thermopile in the position to be occupied by the reaction vessel. The value of the incident intensity and the percentage absorption together with the amount of decomposition permitted a calculation of the quantum efficiency, providing the average wave length of the radiation were determined. From a consideration of the absorption coefficients of malonic acid as determined by Bielecki and Henri[15] and the distribution of the intensity of the radiation from the mercury arc given by Reeve,[16] the average wave length was calculated to be 250 mμ in the absence of catalyst. In the presence of catalyst, absorption was assumed to be complete for lines below 320 mμ and the average wave length was calculated to be 290 mp. Both of these values should be good to about 10 mp, although it is recognized that the intensity distribution given by Reeve would probably not imply high accuracy to the lamp used in these experiments. That they were in approximate agreement was ascertained by the use of a monochromatic illuminator with the thermopile. For radiation transmitted by Pyrex, the average wave length absorbed in the presence of catalyst was taken as 320 mp. The absorption of the Pyrex plate used was determined with a spectrograph and rotating sector. Log $I/I_0 = -0.5$ at 313 mμ and -1.2 at 301 mp. Thus very little radiation below 300 mμ was transmitted. The following tables show the data obtained.

TABLE III

THE QUANTUM EFFICIENCY OF THE PHOTOCHEMICAL DECOMPOSITION OF MALONIC ACID WITHOUT CATALYST

Normality of NaOH	0.0327	0.0327	0.0327	
Molecules decomp. × 10^{-19}	8.02	3.80	5.82	
Molecules per erg × 10^{-11}	0.390	0.411	0.442	
Average wave length, $m\mu$	320	320	320	
Quantum efficiency	0.24	0.25	0.27	av. 0.25

The fractions absorbed should be accurate to ±0.02. The average quantum efficiency is 0.25 ± 0.04.

Since the thermopile was calibrated for relatively feeble light intensities and used for high light intensities in the above experiments, the question might arise as to the validity of the light intensity measurements. To test this point a 1000-watt lamp was used and the inverse square law assumed. It was found that within the accuracy of the application of the inverse square law, the measurements of the high light intensities by the thermopile were justified.

(d) Determination of Absorption Coefficients.—It has already been pointed out that Henri and Landau[6] have shown that the addition of small amounts of oxalic acid to uranyl sulfate causes a marked increase in the absorption coefficients. This is, in general, good evidence for the formation of a complex. Similar experiments were carried out with malonic acid using a rotating sector in conjunction with a spectrograph. Absorption coefficients for the uranyl sulfate alone were in approximate agreement (although slightly higher) with those of Henri and Landau. Addition of malonic acid did not produce a change greater than the experimental error. A solution containing both malonic acid and uranyl sulfate showed nearly the same absorption as a solution of malonic acid placed in series with a solution of uranyl sulfate in such a manner that the total number of molecules traversed by the radiation was the same. We find, therefore, no evidence for or against complex formation from this source.

(e) Effect of the Addition of Sulfuric Acid.—Two solutions, each 0.05 M with respect to malonic acid, to one of which was added 0.005 M sulfuric acid, were exposed under identical conditions to radiation from a quartz mercury arc lamp. The amounts of decomposition were identical within about 2%.

(f) Effect of Variation of the Malonic Acid Concentration with Constant Concentration of Uranyl Sulfate.--Six test-tubes (Pyrex) were filled with ten cc. each of solutions made up to 0.01 M with respect to uranyl sulfate and with varying amounts of malonic acid. Three concentrations were used so that duplicates were made of each determination. In addition one tube was filled with a solution 0.01 M with respect to uranyl sulfate and 0.05 M with respect to oxalic acid. The tubes were rotated in regular order before a quartz mercury arc lamp (without water filter) so that each received the same extent of illumination. The oxalic acid (since it decomposed more rapidly than the malonic acid) and one solution of malonic acid were exposed for a shorter time than the others. Table VI shows the data for these two tubes which were titrated early.

As will be seen in Table VII, a similar solution with 0.1 *M* malonic acid decomposes 1.58 times as rapidly as 0.02 M malonic acid. If it is assumed that the light absorbed by the malonic acid-uranyl sulfate solution is the same as for the oxalic acid-uranyl

sulfate solution and that the quantum efficiency for the decomposition of the latter is one,[4] the quantum efficiency for the decomposition of malonic acid (0.1 *M*) in the presence of uranyl sulfate 0.01 M is found to be 0.23, which is in good agreement with the values given in Table V.

Since the oxalic acid solution probably absorbs more than the malonic acid solution, this figure is too low rather than too high. Table VII shows the variation of rate of decomposition with concentration of malonic acid with constant concentration of uranyl sulfate.

(g) Effect of Pyrex on the Rate of Decomposition of **Malonic** Acid without Catalyst.—One experiment was carried out with a Pyrex filter in the absence of catalyst. Decomposition was observed at about one-sixth the rate without Pyrex. Attempts to measure the light absorption failed, however, as the amount of light absorbed by the solution was so slightly different from that absorbed by water. This may be taken to indicate that the quantum efficiency for the pure acid is not greatly variable with frequency.

II. Discussion of Results and Conclusions

We may summarize the results reported above as follows. 1. The decomposition of malonic acid, both with and without addition of uranyl sulfate, gives carbon dioxide and acetic acid.

2. The rate of decomposition in the presence of radiation from a mercury arc lamp increases with addition of uranyl sulfate and approaches a constant value. The average rates indicate a slight falling off when the concentration of uranyl sulfate exceeds about 0.005 M, but this falling off is smaller than the experimental error.

3. The quantum efficiency of the catalyzed reaction is smaller than for the uncatalyzed reaction,

4. With constant uranyl sulfate concentration, the rate of photochemical decomposition of malonic acid decreases with the decrease in malonic acid concentration. However, the rate is not proportional to the malonic acid concentration but varies approximately as the cube root of the latter.

5. There is no evidence which indicates a complex molecule, with the possible exception of the observation by Fay[9] that uranyl malonate is soluble in an excess of malonic acid.

6. In view of the fact that addition of sulfuric acid produces no marked change in rate of decomposition, the extent of ionization of the malonic acid does not make an appreciable difference.

7. The effect of wave length on the quantum efficiency is not marked.

It is of interest to ascertain what type of equation will satisfactorily reproduce the effect of uranyl sulfate on the reaction rate. Since the malonic acid concentration was kept constant during these runs, there is only one variable concentration to consider. In Table II are given values calculated by means of the following equation

$$-\mathrm{d}[\mathrm{H_2Ma}]/\mathrm{d}t = K_1I_0(1 - 10^{-kCl}) + K_210^{-kCl} \qquad (1)$$

where $[\mathrm{H_2Ma}]$ represents the concentration of malonic acid, C is the concentration of uranyl sulfate in millimoles per liter, l is the thickness of the solution (here kept constant), I_0 is the incident intensity, k is the absorption coefficient of the uranyl sulfate and K_1 and K_2 are constants. The values in Table II (see also Fig. 1) were obtained by using $K_1I_0 = 1.00$, $K_2 = 0.327$, $kl = 0.64$; l was about 2 cm. in these experiments, so that the absorption coefficient is rather high. However, monochromatic light was not used and the absorption coefficient of uranyl sulfate increases very rapidly below 330 mμ.[6]

Equation 1 may be derived by assuming that there are two independent reactions, one due to the light absorbed by the catalyst and the other due to the light absorbed by the malonic acid. The first term on the right-hand side of the equation would represent the rate of the former reaction and the second term the rate of the latter. $1-10^{-kCl}$ would represent the fraction of the light absorbed by the catalyst and 10^{-kCl} would represent the fraction unabsorbed. Of the latter a definite fraction would be absorbed by malonic acid since its concentration is maintained constant in all runs.

With the values chosen, Equation 1 shows that the relative reaction rate should approach unity asymptotically. The fact that such small concentrations of uranyl sulfate cause the relative rate to approach unity so rapidly means that the absorption coefficient is very high.

In Table II are also given values calculated by means of the following equation.

$$-\mathrm{d}[\mathrm{H_2Ma}]/\mathrm{d}t = \frac{K_1'I_0(1-10^{-kCl})}{1+K_3C}[\mathrm{H_2Ma}] + K_2I_0\,10^{-kCl} \qquad (2)$$

All terms have the same meaning as in Equation 1. For the values listed in the row marked I, the following constants were used: $K_1'I_0 = 12.9$, $kl = 0.0411$, $K_3 = 1.0$, $K_2 = 0.327$. For the row marked II, $K_1'I_0 = 3.97$, $kl = 0.1$, $K_3 = 0.402$, $K_2I_0 = 0.327$. This equation may be derived by assuming that a complex molecule is formed when an excited uranyl sulfate molecule (or uranyl ion) collides with a malonic acid molecule and that this complex may either decompose into the final products of the reaction (a first order reaction) or may be deactivated by collision with a uranyl sulfate molecule (or uranyl ion). The second term on the right-hand side of the equation has the same significance as the similar term in Equation 1.

Equation 1 agrees with the experimental values satisfactorily. Equation 2 is of such a nature that the rate passes through a maximum as C increases. It may be made to fit the data at lower concentrations as well as Equation 1, but the rate calculated by its use always falls off more rapidly than the experimental value beyond 0.005 M uranyl sulfate if a reasonably good fit is made for the lower part of the curve. We may conclude, therefore, that the assumption that with constant concentration of malonic acid the rate of the catalyzed reaction is proportional to the intensity of the light absorbed by the catalyst does not disagree with the experimental facts.

When attention is turned to the variation of rate with concentration of malonic acid, the question becomes somewhat more complicated. If the rate were independent of concentration of malonic acid, every activated uranyl sulfate molecule (or uranyl ion) would have a chance to react and the low quantum efficiency would be due to the low probability of reaction of the malonic acid after activation by a collision of the second kind. The variation of reaction rate with concentration indicates, however, that part of the absorbed radiation is ineffective in producing activation of malonic acid. This is also borne out by the low value of the quantum efficiency. Likewise complex formation does not offer a simple explanation of the results obtained. The most logical explanation is based on the assumption that uranyl sulfate is activated by absorption of the radiation and that it may lose its energy before encountering a malonic acid molecule. If the deactivation process is a first order reaction and the activation of the malonic acid proportional to the concentration of activated uranyl sulfate molecules and to the concentration of malonic acid, an equation of the following type is obtained

$$\textit{Rate} = KC'/(1 + kC) \qquad (3)$$

if the light absorbed remains constant. C' is the concentration of malonic acid. This equation does not satisfy the data completely.

One other possibility may be considered. If an activated uranyl sulfate molecule could be deactivated by a collision with another uranyl sulfate molecule or could activate a malonic acid molecule upon collision, the reaction rate should be proportional to the ratio $C'/(C' + C)$, where C' is the concentration of malonic acid and C the concentration of uranyl sulfate. Using average concentrations during each run, relative rates in Table VII may be calculated to be 1.00, 0.70 and 0.30 instead of 1.00, 0.64 and 0.36, respectively. This is a reasonably good check in view of the fact that the water may easily play a part in the deactivation process. It is to be noted that this simple explanation would also account for the slight decrease in rate with high concentrations of uranyl sulfate.

The decomposition of malonic acid in the presence of uranyl sulfate seems, therefore, to be of a type differing from that of oxalic acid. Complex formation seems to offer a reasonable explanation of the results obtained with the latter, although there may still be some doubt as to the quantum efficiencies (the quantum efficiencies in the absence of catalyst would seem to be too low). Most authors are in agreement that addition of uranyl sulfate to oxalic acid increases the quantum efficiency, while addition of uranyl sulfate to malonic acid causes a lowering. While no definite evidence has been obtained for the existence of a light-sensitive complex in solutions containing both uranyl sulfate and malonic acid, such an explanation has not been definitely eliminated. A complex, if present, must either be small in concentration compared to the amount of uranyl sulfate added or be relatively insensitive to the action of radiation.

Summary

1. Malonic acid, both in the presence and absence of uranyl sulfate, decomposes initially to give carbon dioxide and acetic acid.
2. The rate of decomposition in the presence of radiation from the mercury arc increases with addition of uranyl sulfate and approaches a constant value (although there may be a slight decrease at high concentrations).
3. The quantum efficiency of the catalyzed reaction is lower than for the uncatalyzed reaction at the concentrations studied.
4. With constant concentration of uranyl sulfate (0.01 M), the rate of decomposition decreases with decrease in concentration of malonic acid. Empirically, the rate is approximately proportional to the cube root of the malonic acid concentration.
5. No good evidence is obtained for the presence of a complex molecule which is light sensitive.
6. Various mechanisms of the reaction have been discussed.

THE INHIBITIVE ACTION OF ALCOHOLS ON THE OXIDATION OF SODIUM SULFITE

BY HUBERT N. ALYEA[1] AND HANS L. J. BÄCKSTRÖM[2]

RECEIVED JULY 25, 1928 PUBLISHED JANUARY 8, 1929

In a previous paper by Backstrom[3] it was shown that the photochemical oxidation of a sodium sulfite solution is a chain reaction, and that those substances which are known to inhibit the thermal reaction[4] have a similar effect on the photochemical reaction. The results obtained with alcohols as inhibitors were particularly striking, showing a quantitative agreement between light and dark reaction. It must be assumed, therefore, that the thermal reaction also is a chain reaction, and that the role of the inhibitor, in the thermal as well as in the photochemical oxidation, consists in the breaking of reaction chains.

In a later paper,[5] Backstrom discussed the different ways in which the inhibitor might act in this process and concluded that the mechanism by which the chains are broken is probably an induced reaction between the inhibitor and one of the reactants. In the particular case of the alcohols this is indicated by Bigelow's[4a] results on the inhibitory power of the four butyl alcohols in the oxidation of sulfite solutions. He found that the primary, the secondary and the isobutyl alcohols all acted as inhibitors, but that the tertiary had no effect. Since the first three alcohols can be oxidized easily to aldehydes and ketones, whereas the tertiary can only be oxidized with the simultaneous destruction of the molecule, there seems to be a direct relation between inhibitory power and oxidizability in this case;[6] and the logical conclusion seems to be that the alcohols are actually oxidized in the process of breaking the reaction chains. Without postulating any special mechanism of chain propagation, we may describe the reaction chain as a series of processes whereby the oxidation of one sulfite ion induces the oxidation of another, and so on. The assumption would be, then, that in the presence of the alcohol this sometimes leads, instead, to

an induced oxidation of an alcohol molecule, and that this reaction is incapable of inducing further oxidations.?

In view of these considerations, it was decided to make a study of the oxidation of sulfite solutions in the presence of alcohols, in order to see whether the oxidation of the sulfite is accompanied by an induced oxidation of the alcohol, and, if so, whether the extent of this reaction is in accordance with the theory.

Theoretical

Bäckström found that his results on the rate of oxidation of sulfite solutions in the presence of alcohols could be expressed by the formulas

$$v_d = \frac{k_1}{kC + k_2} \tag{1}$$

$$v_l = k_3 v_d = \frac{k_3 k_1}{kC + k_2} \tag{2}$$

where v_l = light rate; v_d = dark rate; C = concn. of alcohol and k_1, k_2, k_3 and k are constants. The value of k depends on the nature of the alcohol and is a measure of its relative inhibitory power. The formulas express the facts that under a given set of experimental conditions the ratio between the rates of light and dark reaction remains constant, independent of the nature and concentration of the alcohol present, and that both rates are inversely proportional to a sum of two quantities, one being a constant, k_2, and the other proportional to the concentration of the inhibitor. The form of the equations and the complete analogy between light and dark reactions which they reveal indicate that the presence of the alcohols does not affect the number of chains *started* per unit time, but that they act solely by breaking the reaction chains.[8]

The fact that the chain length is inversely proportional to the factor $(kC + k_2)$ shows that the chains may be broken in two ways: (1) by the alcohol, its activity in breaking the chains being proportional to its concentration, C, and its relative inhibitory power, k, or (2) due to some other cause represented by the constant k_2. In the present paper we are concerned only with the former of these two processes.

In view of what was said in the preceding section, we shall now make the assumptions (1) that the alcohol is oxidized in breaking the reaction chains, and (2) that this induced oxidation is completely incapable of carrying on (that is, always breaks) the reaction chains. Let us then consider what results we should expect under different experimental con-

---

[7] Or, at least, less efficient than the corresponding reaction involving a sulfite ion.

[8] This is in agreement with the fact that they were present only in small concentrations and that, with one exception, they do not absorb the activating light. Consequently, in neither thermal nor photochemical reaction would they be expected to affect the **primary** process by which the reaction chains are started.

ditions. For convenience we shall assume that we are dealing with *iso*-propyl alcohol.

Every time a chain is broken by the alcohol, an acetone molecule will be formed. If we call the total number of chains started and broken per minute n, then the number of chains broken in that time by the alcohol will be $n[kC/(kC + k_2)]$, and this number of acetone molecules will be formed per minute. Since the velocity of sulfite oxidation V is expressed by the formula $V = k_1/(kC + k_2)$, it follows that the amount of acetone formed in a given time will always be proportional to CV, the product of velocity and inhibitor concentration.

At small inhibitor concentrations this product increases with increasing values of C, and the rate of acetone formation will increase in proportion.

At large inhibitor concentrations, on the other hand, where k_2 is negligibly small compared to kC, this product becomes virtually constant, independent of the alcohol concentration. In this region practically all the chains are broken by the alcohol. Increasing the alcohol concentration causes the chains to be broken sooner and, therefore, lowers the rate of sulfite oxidation, but the *number* of chains broken remains the same, and the amount of alcohol oxidized in a given time will therefore remain constant, independent of its concentration.

For the same reasons the number of alcohol molecules oxidized in a given time will be the same for different alcohols. The only difference will be that the amounts of these alcohols which have to be added in order to reach the region where k_2 can be neglected will vary inversely as their specific inhibitory powers, k.

This reasoning applies equally well to mixtures of alcohols in a given solution. They will be oxidized in proportion to their concentrations and relative inhibitory powers, but the total number of molecules oxidized in a given time will still be the same. All of this will, of course, be true only if the formula continues to be valid at high inhibitor concentrations; that it does is shown by our results.

The predictions above apply equally to the thermal and the photochemical reactions. In the case of the latter still another prediction may be made, namely, as to the number of alcohol molecules oxidized; in the region of constant *CV* it should be equal to the number of light quanta absorbed by the solution. This is assuming, however, that every absorbed light quantum starts a reaction chain, an assumption which is not necessarily correct, but which can be tested by experiments of this kind. If it is correct, that is, if the quantum efficiency actually evaluates the chain length of the photochemical reaction, then we should also expect it to measure the chain length of the thermal reaction. On this basis we may predict approximately the quantity of alcohol which should be oxidized, in the region of constant *CV*, by dividing the rate of oxidation of the pure sulfite solution by the value found by Backstrom for the quantum efficiency in the absence of inhibitors, namely, about 50,000 molecules of oxygen reacting per $h\nu$. The thermal oxidation rate of a pure sulfite solution under the conditions of our experiments was about 5 cc. of oxygen absorbed per minute per 10 cc. of solution, which leads to a value of about 0.000025 mole of alcohol oxidized per liter per hour.

These and other consequences of the theory were subjected to experimental test and were found to be completely verified except that the results indicate that two alcohol molecules, rather than one, are oxidized in the process of breaking a chain. This would, of course, not materially change the argument presented above. The inhibitors used were *iso*propyl, *sec.*-butyl and benzyl alcohols.

Materials

Water.—Tap water was distilled a few minutes before use into Pyrex flasks from a tin-lied still and block-tin condenser. Precautions were taken to use this water throughout all operations.

Sodium Sulfite.—Merck's C. P. crystals of $Na_2SO_3 \cdot 7H_2O$ were recrystallized from pure water four times. The third and fifth crystallizations gave identical oxidation rates, so there was no advantage in crystallizing any further.

Isopropyl Alcohol.—Standard Oil Company product. All the ordinary methods for removing acetone from isopropyl alcohol failed for this research. For example. with the usual bisulfite method,[9] it was extremely difficult to lower the acetone content of isopropyl alcohol below 0.001%, whereas it was necessary in this work to use alcohol containing less than 0.0001% of acetone. The following method therefore was developed and found to be a simple and direct method for removing very minute traces of ketones from the lower boiling alcohols. Several liters of the alcohol was refluxed with 2 g. of *p*-nitrophenylhydrazine per liter for several hours on a water-bath. Nitrogen bubbled through the solution during refluxing served both to stir the solution and to exclude oxygen. At the end of this time the alcohol was distilled over in a stream of nitrogen, using a 2-foot fractionating head. It contained less than 0.0001% of acetone; b. p. 81.9–82.9'.

Secondary Butyl Alcohol.—Standard Oil Company product. It received the same treatment as the isopropyl alcohol; b. p. 99.7–99.8°.

Benzyl Alcohol.—Merck's C. P. alcohol was used without further purification. It contained less than 0.0001 M benzaldehyde per liter as shown by Schiff's test.

Acetone.—Redistilled Merck's C. P. grade.

Methylethyl Ketone.—Eastman Kodak Company product. It was redistilled twice: shaken three times with equal volumes of a saturated solution of pure sodium chloride, in which it is insoluble, to remove acetone.[10] Subsequent distillation of the ketone layer yielded a pure methylethyl ketone, free from acetone.

Benzaldehyde.—Kahlbaum's DAB5 benzaldehyde was redistilled in an atmosphere of nitrogen. It contained less than 0.01% of benzoic acid, as determined by titration with sodium hydroxide in the presence of phenolphthalein.

Ethyl Alcohol.—It gave a coloration with Schiff's reagent corresponding to less than 0.001% of benzaldehyde.

Experimental

The apparatus consisted of a shaker which turned a set of glass-stoppered, narrow-mouthed 125-cc. bottles end-over-end at about 180 revolutions per minute. Each of these was charged with 20 cc. of 0.6 M sodium sulfite solution, buffered by the addition of 0.01 equivalent per liter of sulfuric acid, and containing varying quantities of alcohol. These solutions had the same composition as in Backstrom's work. The bottles were then filled with oxygen and the glass stoppers sealed in with paraffin. Preliminary experiments showed that during the above operations, consuming about fifteen minutes for a set of six bottles, the oxidation was negligible.

The strength of the sulfite was determined by titration with $N/2$ sulfuric acid, using brom-cresol green as indicator, as in Backstrom's work. Extreme precautions were taken in order to obtain reproducible results by preparing the distilled water and all solutions immediately before use and by washing all glassware repeatedly with distilled water to remove all traces of impurities.

The length of the shaking period, generally from two to thirty-five hours, was regulated to be such that less than 1.5 millimoles per 10 cc. of sulfite was oxidized. At the end of this period, 5 cc. of the sulfite was titrated with $N/2$ sulfuric acid, as above, and the quantity of sulfite oxidized obtained from this value. Other samples were immediately removed from the bottles and tested colorimetrically for the aldehyde or ketone formed, using the methods given below.

Throughout the run the average temperature of the room was 21 ± 0.5°, orientation experiments on the temperature coefficients of the sulfite and alcohol oxidations showing that the maximum error from temperature fluctuation was about 2%.

Dependence of Oxidation Rate on Experimental Conditions.—Preliminary measurements were made in a specially constructed shaking apparatus which permitted a study of the dependence of the oxidation rate on shaking conditions, volume of solution, and oxygen pressure. It was found that as the "reactivity" of the solution is decreased, by removing positive catalysts or adding increasing quantities of inhibitor, the oxidation rate (in moles per unit volume per unit time) becomes virtually independent of all these factors, including oxygen pressure.[11] The oxidation rate of a strongly inhibited solution, as directly observed in cc. of oxygen absorbed per minute at the working pressure, is thus four times higher at $^1/_4$ atm. than it is at 1 atm.

As a result of these experiments it may be stated that (with very few exceptions) the values given in this paper represent true oxidation rates, in the sense that neither an increase in oxygen pressure nor an increased shaking efficiency would have raised the results.

These preliminary experiments also included a study of the oxidation rate as a function of the concentration of the solution. It was found that the oxidation of a pure sulfite solution proceeds more slowly the more concentrated the solution, a fact which has previously been observed by Milbauer and Pazourek.[12] In accordance with this the rate increases

---

[11] This confirms an observation by Reinders and Vles, *Rec. trav. chim.*, *44*, **249** **(1925).**

[12] Milbauer and Pazourek, Bull. *soc. chim.*, *31*, **676** **(1922).**

steadily during a single run, as the sulfite concentration decreases, until a sudden drop occurs when the reaction is almost complete.

These facts are of great theoretical interest and will be investigated further in a more systematic study of sulfite oxidation.

Colorimetric Determinations

Since the quantity of alcohol oxidized in a run is of the order of 0.0005 millimole/10 cc./hour, the problem of measuring this change is of course the difficult feature of this research. The literature supplies tests only one-tenth as sensitive as are needed here. The following colorimetric methods were therefore developed, and if carried out as described will give accuracies of determinations as listed in Table II.

Acetone

Colorimetric Determinations in Concentrations of 0.00005 M to 0.002 M.—A development of the Kolthoff modification[13] of the Fabinyi-Frommer method[14] was found applicable. The test is specific for acetone, no color being given by methylethyl ketone or aromatic ketones.

Reagents.—The following solutions are employed: 10% vanillin in methyl alcohol, Merck's C. P. (not ethyl alcohol at these dilute acetone concentrations); should be made up fresh every few days; a potassium hydroxide solution, 100 g. of potassium hydroxide in 60 cc. of water; a series of standard acetone solutions made by dissolving 1 cc. of freshly distilled acetone in water and diluting to approximate concentrations of 0.004 M, 0.002 M, 0.0018 *M*, 0.0012 M, 0.0006 *M*, 0.0003 M and 0.00015 *M*, each solution containing 0.02 equivalent of sulfuric acid per liter.[15] The standards are then accurately determined by titration with *N*/100 thiosulfite and iodine, by the well-known Messinger method.[16] The strength of the standard acetone solutions fell less than 1% during two weeks, as shown by titrations.

Preparation of Standard and Unknown Test Solutions.—In a test the standard solution consists of 1 cc. of standard acetone solution, 1 cc. of 1.2 M sodium sulfite solution arid the same quantity of alcohol as in the unknown. The latter is made up by diluting 2 cc. of solution to be tested to a volume equal to that of the standard solution. The media of unknown and standard will then be exactly alike, differing only in acetone content. The color test is not affected by the extent to which the sodium sulfite in the unknown has been oxidized.

The Test.—Three unknown samples falling between the limits of two standard solutions may be tested conveniently at a time. Run 2 cc. of potassium hydroxide from a 10-cc. graduated pipet into each of the five tubes to be tested and swirl momentarily. Then into each run 1 cc. of the vanillin solution from a 5-cc. graduated pipet, shake thoroughly and place the five test-tubes simultaneously in a water-bath at the

[15] According to Folin and Denis, *J. Biol. Chem.,* 18, 263 (1914), the sulfuric acid also helps to prevent polymerization of the acetone in the standards.

[16] J. Messinger, *Ber.,* 21, 3366 (1888); *J. Biol. Chem., 43,* 43 (1920), and *J. Soc. Chem. Ind.,* 10, 166 (1891).

proper temperature. Allow to stand for exactly twenty minutes. In the meantime prepare five test-tubes each containing 10 cc. of water. Upon removing the acetone tubes from the water-bath immediately mix the water in the test tubes with the contents of the acetone tubes. The sulfates and sulfites which were precipitated by the concentrated potassium hydroxide will then redissolve, permitting a comparison of the reddish brown colors in a colorimeter. The above experimental procedure minimizes the time consumed between addition of reagents to the test solution and colorimeter readings, so that the colors in all five tubes will be strictly comparable. The readings are completed within fifteen minutes after removing the tubes from the bath.

The temperature of the water-bath is most important in obtaining reproducible results. A bath with thermoregulator attachment was used, giving the desired temperatures to within ±0.1°. For acetone concentrations within the range 0.00005 M to 0.0005 M, 65° was found to be the temperature at which the bath should be kept. For higher concentrations of acetone, between 0.0005 and 0.002 *M*, 50° should be used.

The colorimeter was of the standard DuBoscq type, Bausch and Lomb 1924 model. The colorimeter settings are plotted and the value of the unknown is determined graphically. Thus when the standards 0.0001 and 0.0002 *M* acetone give colorimeter readings of 50 and 30, respectively, a colorimeter setting of 40 would correspond to 0.00015 M acetone. While this method is not absolutely exact when the color does not vary directly with the acetone concentrations, the values it yields, nevertheless, fall well within the limits of error given in Tables I and II, where a typical set of colorimeter readings is presented.

TABLE I

TYPICAL COLORIMETER READING DATA

Acetone concn., *M*/l.	Colorimeter readings, a	Aa	b	Av. error in acetone detns. throughout the range, % (*c*)
0.002	26	24	−0.50	11.3
.001	50			
.00030	31	19	±0.75	±2.6
.00015	50			
.000150	38	12	±1.00	±5.5
.000075	50			

Aa = difference between colorimeter readings; that is, the number of colorimeter units representing a change from $^2/_3$ to $^4/_3$ the average acetone concentration in each range.

b = error of reproducibility of lower colorimeter settings, expressed in colorimeter units. (Higher setting always at 50.0.)

c = $(2/3)(b/\Delta a) \times 100$.

TABLE II

TYPICAL COLORIMETER READING DATA

Molarity of aldehyde or ketone	Average exptl. error, *c* %		
	Acetone	Methylethyl ketone	Benzaldehyde

.002 to .001	±1.3	...	±1.7
.001 to .0005	...	±1.4	±3.8
.0005 to .0002	±2.6	...	±7.0
.0002 to .0001	...	±4.6	...
.0001 to .00005	±5.5	−6.0	...

Tests conducted in the presence of 0.6 *M* Na_2SO_3.

Methylethyl Ketone

The same procedure was employed as for the acetone, with the following changes: the vanillin in methyl alcohol was replaced by a 10% solution of salicylaldehyde in ethyl alcohol. The temperature of the bath was kept at 40 ±1°, since at above 60° the accuracy of the determination fell off rapidly at these low concentrations. Upon removal from the bath, instead of diluting with 10 cc. of water as was done in the acetone test, 15 cc. of a 20% by volume ethyl alcohol solution in water was added, This concentration was sufficient to dissolve the sulfite and salicylaldehyde; other proportions of alcohol and water will precipitate one or the other of the ingredients.

The comparison of the greenish-yellow tints obtained with the standards is done exactly as in the case of acetone, standard solutions being 0.002, 0.001, 0.0005 and 0.0002 *M*/liter, respectively, each containing 0.02 equiv. of sulfuric acid per liter. They, too, were accurately standardized by titrating with *N*/100 thiosulfate and iodine by the Messinger method.[16]

See Table II for the accuracy of the determinations.

Benzaldehyde

The sensitivity of Schiff's reagent[17] has long been known, and was employed by Woodman and Lyford[18] in determining benzaldehyde in minute quantities. However the much smaller concentrations of benzaldehyde obtained in this work required a refinement of their method.

Reagents

Schiff's Reagent.—The less sulfur dioxide present in the Schiff's reagent, the more sensitive is the test, although some sulfur dioxide is necessary for the color reaction.[19] The following procedure was found to work satisfactorily down to 0.0002 M benzaldehyde solutions. Bubble sulfur dioxide into 100 cc. of water for about five minutes and determine the amount absorbed by measuring the increased weight of the solution. Add a volume of this solution corresponding to 0.60 g. of sulfur dioxide to 0.17 g. of rosaniline hydrochloride in 50 cc. of water in a 250-cc. glass-stoppered volumetric flask. Allow to stand for one hour, shaking at frequent intervals, by which time most of the color will have disappeared. Fill up to the mark and use immediately. Fresh solutions should be made up every six hours when testing benzaldehyde in the ranges 0.0001 to 0.0005 mole/liter, but the reagent is good for several days when testing higher concentrations.

Aldehyde-Free Ethyl Alcohol.[18,20]—By distilling alcohol from solid potassium hydroxide (80 g./liter) an alcohol was obtained which gave a negligible coloration with Schiff's reagent under the conditions employed below.

Standard benzaldehyde solutions were made by successively diluting 10.00 cc. of benzaldehyde with aldehyde-free alcohol to give 0.005 0.002, 0.001, 0.0005 and 0.0002 *M* benzaldehyde solutions. These solutions will keep several months when stored in amber bottles.

Separation from Sulfite.—Before applying the Schiff's test, the aldehyde was separated from the sulfite by distillation. It was found that if 10 cc. of the solution containing partially oxidized sulfite and traces of benzaldehyde was distilled, the first

[19] Wieland and Schiering, *Ber.*, 54, 2527 (1921).

[20] See purification processes for ethyl alcohol in Tolman, THIS JOURNAL, 28, 1625 (1906).

5 cc. of distillate contained all of the benzaldehyde. When the PH of the solution was changed slightly from its original value[3] of PH = 8.4, the benzaldehyde still came over quantitatively, but at PH = 4.3, where all of the sulfite is present as the bisulfite, or at very high *PH's* (13) only about 70% of the benzaldehyde was recovered, possibly due to the stability of the bisulfite–benzaldehyde compound in the one case or the Cannizzaro reaction in the other.

A number of test-tubes 18 × 150 mm. were constricted in the middle to about 7.0 mm. inside diameter and graduated to hold exactly 10 cc. up to a mark on the constriction. Into one of them 5 cc. of aldehyde-free alcohol was run, and a 10-cc. sample solution distilled over in an atmosphere of nitrogen into the alcohol until the mark on the constriction was reached; 5 cc. of distillate was thereby collected. The volume caught could be reproduced to within 1% by this method. The benzyl alcohol present in the sample also distilled over, but it neither oxidized nor introduced any error in the benzaldehyde determination, as shown by blank tests. The mixture was then shaken, and the tube placed in an ice-bath at 0° for one minute along with two tubes containing standard solutions. These latter were made by adding 5 cc. of standard benzaldehyde solutions to 5 cc. of water; 2.5 cc. of the special Schiff's reagent, similarly cooled, was added to each of the three tubes, and the contents thoroughly shaken and allowed to stand at 0° for thirty minutes. At the end of this time their reddish pink colors were compared in the colorimeter. The strengths of the unknowns were determined graphically as with acetone; the accuracy is given in Table II.

Results

At High Inhibitor Concentrations.—The results, summarized in Table III, verify the predictions made in the introduction. The detailed experimental data are given in Tables IV, V and VI.

V = decrease in sulfite concentration per hour. All concentrations expressed as moles per liter.

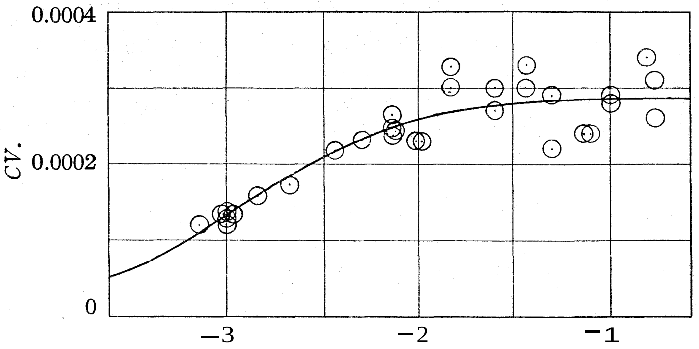
In order to prove that the oxidation of the alcohol was definitely induced by the oxidation of the sulfite, 5-cc. samples of alcohol solutions were shaken with 15 cc. of (1) water, (2) N/2 KOH and (3) phosphate buffer of PH = 8.4, the initial PH of the sulfite solutions in Table IV. The alcohol solutions added were: benzyl, 0.04 M; *sec.*-butyl, 1.0 M; isopropyl, 1.0 M. In addition to these, 15-cc. samples of a previously oxidized 0.8 M sulfite solution were shaken with 5 cc. of 0.04 M benzyl, of 0.5 M *sec.*-butyl and of 0.25 M isopropyl alcohol. With a shaking time of seventy-two hours, less than the following quantities of alcohol were oxidized: benzyl alcohol, 0.0002 mole/liter; *sec.*-butyl alcohol, 0.00005 mole/liter;

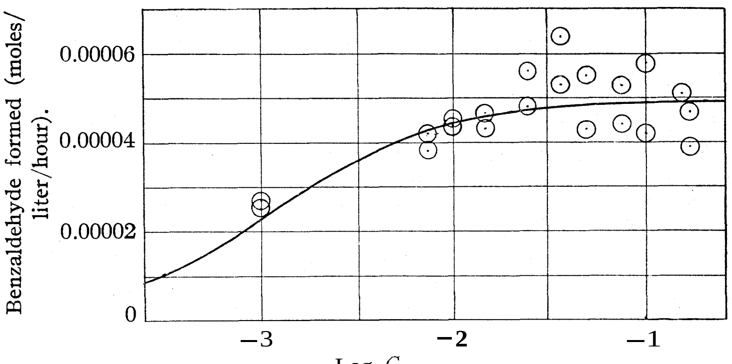
isopropyl alcohol, 0.00005 mole/liter, compared with the amount normally oxidized in seventy-two hours: (Table III) 0.00356 mole/liter.

At Low Inhibitor Concentrations.—In these experiments, which were made with benzyl alcohol, the shaking period was necessarily so short as to produce only a very minute quantity of benzaldehyde in the sulfite sample. By successive distillations of a 90-cc. sample (six 15-cc. samples from a set of bottles in a normal run), however, the benzaldehyde was obtained in concentrations sufficiently large to permit of accurate colorimetric analysis.



○, values observed; ——, values calculated from $V = 0.00029/(C + 0.0012)$.

Fig. 1A.



○, values observed; ——, values calculated from: Benzaldehyde formed = CV × 0.48/2.8 (see Table VI).

Fig. 1B.

The results given in Table VII, and represented in the upper graph of Fig. 1, show that the rate of sulfite oxidation obeys a formula of the type discussed in the introduction, namely, $V = 0.00029/(C + 0.0012)$, throughout the entire range studied.

Table VIII establishes that the dropping off in CV at lower alcohol concentrations is accompanied by a corresponding decrease in benzaldehyde formed. This is demonstrated in Fig. 1, where the lower graph summarizes the results on the amount of benzaldehyde formed and shows that it is given within experimental error by the expression (0.48/2.8) X CV throughout the range of benzyl alcohol concentrations studied.

Mixtures of Inhibitors

Benzyl Alcohol–Isopropyl Alcohol.—Experiments were made with sulfite solutions containing equal molal quantities of benzyl and *iso*propyl alcohols. Five cc. of the solutions shaken was titrated to determine sulfite oxidized, 2 cc. was removed and tested for acetone and, finally, a 10-cc. sample was tested for benzaldehyde. Preliminary measurements showed that the presence of as much as 0.01 *M* benzaldehyde or 0.02 M acetone had no effect on the accuracy of a colorimetric determination of acetone or of benzaldehyde, respectively, carried out as described above.

Tables IX and X show that the inhibitory power of a mixture is an additive property and confirm the prediction in the introduction as to the relative amounts oxidized of the two alcohols.

[a] k, the inhibitory power for isopropyl alcohol is here taken as unity, giving a value of **12.5** (Table III) for benzyl alcohol. Compare with the value of **13,** obtained above, Table IX, from the relative amounts oxidized.

Benzyl Alcohol–Hydroquinone Mixtures.—In this case most of the chains are broken by the hydroquinone, as is shown by the fact that the CV value for hydroquinone is practically independent of the presence of benzyl alcohol (see Table XII). The quantity of benzaldehyde formed was less than one-twelfth of that which would have formed in the absence of hydroquinone. It is a duplication of the phenomena observed in the benzyl alcohol–*iso*propyl alcohol mixtures.

Attention should be directed toward the increasing *CV* values for hydroquinone with increasing concentration of the latter in Tables XI and XII. Bäckström[3] had previously observed that hydroquinone and some other substances behave differently from the alcohols, apparently inhibiting the light reaction much more strongly than the dark reaction. The fact that these substances are themselves capable of reacting with oxygen, especially in alkaline solution, suggests that in these cases the phenomena are complicated by a direct oxidation of the inhibitor. The rate of this reaction would naturally increase with the concentration[21] which would account for the increasing values of CV; and the increase in the observed "dark rate" caused by this direct oxidation of the inhibitor, which would probably not be accompanied by a corresponding increase in the light rate, would give the impression that the light reaction has been suppressed to an abnormal degree. Since, in the present case, the oxidation rate was determined by measuring the decrease in sulfite concentration, and not the oxygen consumption—as in Bäckström's experiments—the observed facts can only be accounted for on this basis if the oxidation of hydroquinone involves a reaction with sulfite. It might, for instance, lead to the for-

---

[21] The true inhibitory power would therefore be more nearly given by the experiments at the low concentrations of inhibitor in Table XII. They indicate that the inhibitory power of hydroquinone is more than ten times that of benzyl alcohol.

mation of the hydroquinone sulfonates observed by Pinnow[22] in oxidized developer solutions.

Photochemical Measurements.—The applicability of the theory to the photochemical reaction was tested in a series of experiments with *iso*propyl alcohol. The apparatus consisted of a quartz shaker similar to that used in Bäckström's work, except that the tube was shaken horizontally. Conditions of shaking were such that, as shown by preliminary experiments, the oxidation rate of the sulfite was independent of volume of solution shaken, number of strokes per minute, length of stroke and oxygen pressure. The light from a Hanovia Quartz lamp, burning at 69 ± 0.5 volts and 3.5 ± 0.05 amperes was filtered through a chlorine–bromine filter, so that only wave lengths 2300 to 2800 Å. were transmitted, as shown by visual observation of the filtered light through a monochromator in the exit slit of which was placed a piece of uranium glass. This light illuminated about a 5-cm. length of the quartz shaker. Under these conditions the photochemical reaction was about fourteen times greater than the thermal reaction so that, within limits of error, the reaction measured could be considered entirely photochemical.

The results, given in Table XIII, are completely analogous to the ones previously obtained for the thermal reaction. Over a considerable range of high inhibitor concentrations, *CV* and alcohol oxidized remain constant. The ratio between *CV* and acetone formed (510/6.6 = 77) is the same as was found for the thermal reaction, Table IV (34/0.46 = 74); that is, in a solution of a given composition the chain length is the same whether the chains are started thermally or photochemically.

---

[22] Pinnow, *Z. Elektrochem.*, 19, 262 (1913).

Blank experiments in which there was no sulfite present in the solution showed that the direct photochemical oxidation of the alcohol was negligible (0.00001 in a blank against 0.00066 mole per liter per hour in a normal sulfite run).

Chain Length and Quantum Efficiency.—As was shown in Tables III to VI, the amount of alcohol oxidized, in the region of constant CV, is of the order of magnitude expected, being just about twice the predicted value of 0.000025 mole per liter per hour. This indicates the correctness of the assumption underlying the prediction, namely, that the chain length of the thermal reaction is equal to the photochemical quantum efficiency, but it does not constitute an accurate test since it is based on measurements on uninhibited sulfite solutions; these give high oxidation rates that are difficult to measure accurately and that vary considerably with shaking conditions. However, a more satisfactory comparison, utilizing the data for strongly inhibited solutions, gives the same result.[23] Bäckström's formula for the light rate,[3] when applied to a solution which is 0.1 *M* with respect to benzyl alcohol, gives a quantum yield of 64 molecules of oxygen or 128 of sulfite reacting per $h\nu$. On the other hand, the data in Table VI show that in a solution of this composition the number of sulfite molecules oxidized for every alcohol molecule oxidized is $28/0.48 = 58$, a figure which is of the same order of magnitude but which again indicates that in the process of breaking a reaction chain, two molecules of the alcohol are oxidized rather than one: this would make the chain length equal to $2 \times 58 = 116$. The question whether 1 or 2 molecules are oxidized in this process is of no importance to the arguments presented in this paper, but it is obviously of great importance to a complete elucidation of the reaction mechanism. By a repetition of the quantum efficiency measurements it is hoped to decide this question more definitely.

Utilizing the result of the preceding section, namely, that the chain lengths of thermal and photochemical reaction are identical,[24] we may state the above result in a different way by saying that, in the photochemical reaction $128/58 = 2.2$ molecules of benzaldehyde are formed for every quantum absorbed by the solution; that is, the induced oxidation of the benzyl alcohol obeys the Einstein photochemical equivalence law.

This is a result which is completely analogous to the one obtained by Cremer,[25] in a study of the photochemical hydrogen–chlorine combination in the presence of oxygen. Here oxygen acts as an inhibitor and

---

[23] This throws an interesting light on Bäckström's results on the quantum efficiency of the photosensitized reaction (ref. 5, pp. 26–29).

[24] No measurements were made on the induced oxidation of benzyl alcohol, in the photochemical reaction, since it was feared that the light absorption of the alcohol might introduce complications. Unlike the aliphatic alcohols, benzyl alcohol has an absorption spectrum extending farther toward the visible than that of the sulfite.

[25] Cremer, *Z. physik. Chem.*, 128, 285 (1927).

the reaction is accompanied by an induced, or "photosensitized," formation of water. This induced reaction was found by Cremer to be independent of the oxygen pressure and to obey the equivalence law, two molecules of water being formed for every light quantum absorbed by the chlorine.

Copper Accelerated Solutions.—It is well known that copper ions tremendously accelerate the oxidation of pure sulfite solution.[26] If the effect of copper ions is merely one of starting more than the usual number of sulfite chains per unit time, both CV and the quantity of benzaldehyde formed would be proportionately higher, but otherwise the phenomena observed for pure sulfite solutions would be unchanged.

Table XIV gives some results in the presence of 2.5 X 10^{-6} mole/liter of copper sulfate.[27] It shows that CV and the rate of benzaldehyde formation, are constant, independent of alcohol concentration, and that both have been proportionately increased over the normal values.

Table XIV

					Averages		2.6	2.8

At higher copper concentrations, however, the results are more complex, due probably to the deficiency of the shaker in supplying oxygen at these high reaction rates, and possibly also to the limited solubility of the copper (as $Cu(OH)_2$?).[28]

It should be emphasized at this point that it is quite possible, as first suggested by Titoff,[4b] that a sulfite solution which is perfectly free from positive catalysts such as copper salts would not react with oxygen in the dark; but no satisfactory evidence has been presented to substantiate the idea of Luther and Titoff that the inhibitors act by combining with, or in some way destroying, this positive catalyst. Moreover, it seems

---

[26] Titoff, *Z. physik. Chem.*, 45, 641 (1903).

[27] Blank tests on solutions of 5 cc. of 0.04 M benzyl alcohol with 15 cc. of water; of potassium hydroxide; of phosphate buffer, $P_H = 8.4$; or of oxidized 0.8 N sulfite, all in the presence of 2.5×10^{-6} mole per liter copper sulfate, gave no benzaldehyde after fifty hours of shaking.

[28] Reinders and Vles, *Rec. trav. chim.*, 44, 249 (1925).

impossible to explain our results, as well as those of Backstrom, on this theory.[29]

Summary

It has previously been shown that the action of alcohols in inhibiting the oxidation of sulfite solutions must consist in the breaking of reaction chains, in the thermal as well as in the photochemical reaction. The present investigation leads to the conclusion that the mechanism of this process involves an induced oxidation of the alcohol, two molecules of the oxidation product (an aldehyde or ketone) being formed whenever a chain is broken.

The following experimental results, chiefly obtained for the thermal reaction, may be accounted for on this basis.

1. The oxidation of the sulfite induces an oxidation of the alcohols.
2. At low inhibitor concentrations the amount of alcohol oxidized increases with increasing alcohol concentration.
3. At high inhibitor concentration the amount of alcohol oxidized per unit time is constant, independent of its concentration. This was shown to apply to the photochemical as well as to the thermal reaction.
4. In this concentration region the number of inhibitor molecules oxidized per unit time is quantitatively the same for different alcohols of widely different inhibitory powers.
5. Two alcohols present in the solution at the same time have an additive inhibitory effect. They are oxidized in proportion to their inhibitory powers, the total number of alcohol molecules oxidized being the same as when only one alcohol is present.
6. Copper sulfate accelerates the thermal reaction without altering the ratio of sulfite oxidized to alcohol oxidized.
7. The chain length is the same for the thermal and photochemical reaction and is equal to the photochemical quantum efficiency. This may also be expressed by saying that in the light reaction the induced oxidation obeys the Einstein equivalence law.

The alcohols used as inhibitors were isopropyl, *sec.*-butyl and benzyl alcohols. In order to determine quantitatively the minute traces of acetone, methylethyl ketone and benzaldehyde that were formed in the reaction, colorimetric tests were developed for concentrations to as low as 0.00005 mole per liter, about ten times as sensitive as those previously described in the literature.

Some experiments with hydroquinone gave results that suggest an ex-

---

[29] A recent investigation by Mason and Mathews, J. *Phys.* Chem., 30, 414 (1926), gave a result which is not consistent with our views on the role of copper in this reaction; they stated that copper sulfate acted as an inhibitor to the photochemical reaction. We have found, however, by a series of experiments with copper sulfate, that this does not hold true under our experimental conditions.

planation for the anomalous behavior of this substance as an inhibitor to the oxidation of sulfite solutions.

MECHANISM OF THE PHOTOCHEMICAL DECOMPOSITION OF NITROGEN PENTOXIDE

BY WARREN P. BAXTER AND ROSCOE G. DICKINSON

RECEIVED JULY 30, 1928 PUBLISHED JANUARY 8, 1929

Introduction

The photochemical decomposition of nitrogen pentoxide into nitrogen dioxide and oxygen was first studied by Daniels and Johnston.[1] Their method of experimentation was to illuminate, with sunlight or light from a tungsten lamp, a glass bulb containing nitrogen pentoxide crystals immersed in ice water and measure the pressure increase attending the illumination. By the use of light filters these authors were able to demonstrate that only light of wave length shorter than 4600 Å. was effective in producing decomposition. They also established the important result that, at least with radiations in the neighborhood of the violet part of the spectrum, the presence of nitrogen dioxide is necessary for the reaction, that is, this decomposition of colorless nitrogen pentoxide is photosensitized by the brown dioxide.

Two important suggestions have been made as to the mechanism of this reaction. Fazel and Karrer[2] have advanced the hypothesis that a light quantum is absorbed by a nitrogen dioxide molecule, which is thereby raised to a higher quantum state, and that this excited molecule, NO_2', then makes a collision of the second kind with a pentoxide molecule, transferring energy of activation to the pentoxide molecule. The activated nitrogen pentoxide molecules subsequently decompose. Norrish,[3] on the other hand, has shown that nitrogen dioxide is decomposed by light from a mercury arc into nitric oxide and oxygen. He has accordingly suggested that in the sensitized decomposition of the pentoxide, the first reaction is the decomposition of the dioxide, and that this is then followed by a dark reaction between nitric oxide and nitrogen pentoxide, $NO + N_2O_5 = 3NO_2$. For this mechanism to play an important part in the pentoxide decomposition, it is necessary that the thermal reaction between nitric oxide and nitrogen pentoxide have a rate at least comparable with the rate of recombination of nitric oxide and oxygen. Busse

[3] Norrish, J. *Chem. Soc.*, 761 (1927).

and **Daniels**,[4] by mixing nitric oxide and nitrogen pentoxide and observing the immediate appearance of the brown dioxide, have shown that this reaction is indeed very rapid.

It is to be noticed that if photochemical equivalence obtained, the decomposition of two molecules of nitrogen pentoxide per quantum absorbed could result no matter whether the initially activated NO_2 molecule transferred its activation to an N_2O_5 molecule, or whether it reacted with another NO_2 molecule. For in the first case we might have $NO_2' + N_2O_5 = N_2O_5' + NO_2$, followed by $N_2O_5' + N_2O_5 = 4NO_2 + O_2$ or by $N_2O_5' = NO + NO_2 + O_2$ and $NO + N_2O_5 = 3NO_2$; while in the second case we might have $NO_2' + NO_2 = 2NO + O_2$ followed by $2(NO + N_2O_5 = 3NO_2)$. However, the authors have shown[6] that in the decomposition of the dioxide, various wave lengths are quite unequally effective; thus the yields expressed in molecules of oxygen produced per quantum absorbed were 0.0046, 0.36, and 0.77 for the wave lengths 4350, 4050 and 3660 Å., respectively. Since the decomposition of the dioxide depends so markedly on the wave length of the light used, measurement of the pentoxide decomposition with monochromatic light might distinguish between these two mechanisms. Should, for example, the radiation 4350 Å. prove to be effective in the pentoxide decomposition, this could hardly be explained by the Norrish mechanism because of the ineffectiveness of this radiation in decomposing the dioxide.

In the present paper are described measurements of the relative rates of nitrogen pentoxide decomposition produced by these three radiations and measurements of the relative rates of pentoxide and dioxide decomposition.

This investigation was aided financially from a grant made to Professor **A. A. Noyes** by the Carnegie Institution of Washington.

Experimental Arrangement

The present work was carried out at 0° with the reactants and products present only in the gas phase. The apparatus is shown in Fig. 1. The reaction vessel, A, made of Pyrex glass, was oblong shaped with flat sides 2.2 cm. wide and 6.5 cm. high. Three of these sides were silvered, while the front surface was unsilvered and served as a window for the entrance of light. The dicker-type glass-diaphragm gage, B, described by Smith and Taylor[6] was used to measure the pressure after the reaction chamber was sealed off at C and C'. Pressure readings were reproducible to 0.2 mm. or better. A Moll thermopile, mounted in a water-tight brass container with a glass window and a shutter, was rigidly fastened immediately beside the reaction vessel, as indicated at D. This was used to make relative measurements of light intensity during the illumination.

The thermostat, K, was a flat-sided glass jar. On the front of the thermostat was

[5] Dickinson and Baxter, *ibid.*, 50, 774 (1928).

[6] Smith and Taylor, *ibid.*, 46, 1393 (1924).

fastened a flat copper sulfate absorption cell 1.2 cm. in thickness in such a way as to have a pocket 2.2 cm. in thickness between the cell and the front of the thermostat. A light filter mounted on a brass sheet with an opening 4.5 cm. square was placed in this pocket; the space was then filled with water to minimize light reflection losses. These filters were for the isolation of the mercury radiations at 4350, 4050 and 3660 Å. and were the same as used previously.[7] A mercury arc lamp together with a reflector was placed immediately outside the copper sulfate cell and directly in front of the reaction vessel; the distance from the lamp to the reaction chamber was 6 cm. A shutter was provided between the lamp and the copper sulfate cell.

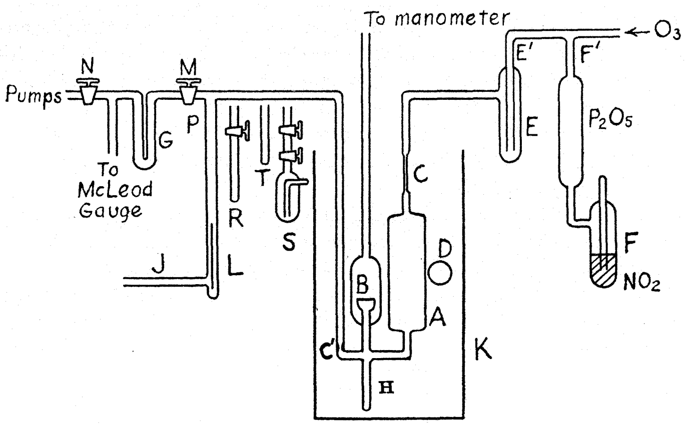

Fig. 1.

Temperature control was maintained by keeping the thermostat well packed with ice. A fine jet of air blown into a glass tube 1 cm. in diameter pumped water continuously from the bottom of the thermostat to near the top. A thermocouple with one junction near the bottom of the reaction chamber and the other in a Dewar tube filled with ice and water showed that the temperature was maintained constant to 0.1° or better.

The Experimental Procedure

Nitrogen pentoxide was prepared by oxidizing nitrogen dioxide in a stream of ozone and collecting the pentoxide in the trap, E, surrounded by ice and hydrochloric acid. The nitrogen dioxide had been previously prepared by heating c. p. lead nitrate in an all-glass apparatus, passing the gas evolved over phosphorus pentoxide and condensing it in the trap. F, using ice and salt. The ozone was prepared by passing tank oxygen over phosphorus pentoxide and then through a Siemen's ozonizer. During the pentoxide preparation the cock, M, was closed and the excess gases passed out through J.

When sufficient nitrogen pentoxide had been collected in E, the supply of nitrogen dioxide was sealed off at F' and the stream of ozone continued for a short time. The ozonizer was now turned off and, after sweeping out the ozone with oxygen, the apparatus was sealed at E'. A bulb of nitrogen dioxide was now placed in the tube, J, which was then sealed off. Liquid air was applied at E and G, the stopcock M opened and the whole system evacuated. The click gage was protected from breakage by evacuating both sides simultaneously. When the system was well evacuated, the bulb of nitrogen dioxide was broken by the magnetically operated plunger, L, the nitrogen dioxide im-

---

[7] Dickinson and Baxter, ref, 5, p. 778.

mediately freezing out in the trap, E'. After a final evacuation, the apparatus was sealed off at C'. Then ice-baths were placed around the reaction vessel and around E'. After the pressure had-risen sufficiently, the tube, C, was sealed off. In order to determine the original pressure of oxygen produced by decomposition on sealing off, liquid air was applied at the side-tube, H, and the pressure read. In no case was this pressure as large as 0.5 mm. The liquid air was now removed, the thermostat put in place, packed with ice and the initial pressure read.

The mercury arc was started and run for a time to become steady, pressure readings being taken at intervals. The shutter was now opened with pressure readings still being made during illumination. During this time measurements were made on the light intensity by reading the galvanometer connected with the thermopile when the shutter on the thermopile was opened and closed at intervals of one minute. The illumination was now discontinued but pressure readings were still made. The times of opening and closing the shutter were accurately noted. Another illumination was now carried out with a different filter interposed. In this way several illuminations could be made during a run with each of the wave lengths used before the supply of nitrogen pentoxide was exhausted.

The illuminations were continued until the nitrogen pentoxide was exhausted. The final total pressure was obtained from readings made several hours after the last illumination. The final pressure of oxygen was obtained by freezing out the nitrogen dioxide in the tube, H, with liquid air, measuring the pressure of uncondensed oxygen at room temperature; this measured pressure was first increased by 2% because of the fact that a definite volume of oxygen was at liquid-air temperature, and was then reduced to 0°.

Experimental Results

Fig. 2 shows the results of a typical series of successive illuminations (Nos. 3a, 3b and 3c) made with light of the wave lengths 3660, 4350 and 4050 Å., respectively. The ordinates are total pressure in mm. and the abscissas time in minutes; the periods during which illumination occurred are indicated on the plots. In these particular experiments the partial pressure of NO_2 was about 12 mm. and that of N_2O_5 about four times as great. The absorption, estimated from previous measurement, was probably greater than 60% in each case. The radiations 3660 and 4050 produced continuous pressure increases which ceased when the radiations were shut off. The radiation 4350 produced no detectable pressure increase although its intensity was more than three times that of the other radiations.

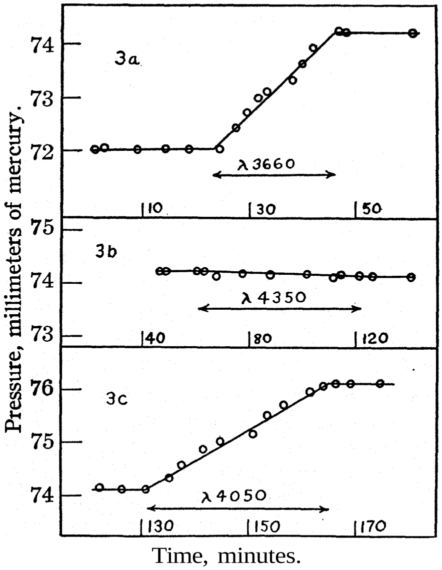

Fig. 2.

---

[8] Dickinson and Baxter, ref. 5, p. 780.

The results of these and other similar experiments are given in the first nine columns of Table I. In Cols. 3–6 are given the mean partial pressures of the gases present during each illumination; their calculation involved, in addition to the pressure measurements described above, the constant[9] for the equilibrium between NO_2 and N_2O_4 at 0°. The amount of nitrogen pentoxide decomposed is not proportional to the observed pressure increase, Δp_{total}, in different parts of a run. Instead, it may be shown that when the total pressure changes as a result of pentoxide decomposition

[a] These illuminations were continued until the decomposition of nitrogen pentoxide was complete. The rates given in the tenth column were obtained from the slopes of the curves plotted as in **Fig.** 2 for the interval in which nitrogen pentoxide was known to be present.

$$\frac{dp_{N_2O_5}}{dp_{\text{total}}} = -\frac{2K + 8p_{NO_2}}{3K + 4p_{NO_2}}$$

where $K = p^2_{NO_2}/p_{N_2O_4}$ and has the value 11.7 at 0° when pressures are expressed in mm. of mercury. The change in the partial pressure of N_2O_5 during an illumination was then calculated from the expression

---

[9] Schreber, *Z. physik.* Chem., **24, 651 (1897).**

$$\Delta p_{N_2O_5} = -\Delta p_{\text{total}} \frac{2K + 8p_{NO_2}}{3K + 4p_{NO_2}}$$

using the mean partial pressure of NO_2; p_{NO_2} ordinarily underwent only a small change during an illumination. In the tenth column are given the changes in $p_{N_2O_5}$ per ten minutes per cm. of galvanometer scale deflection. It will be noted that at all values of p_{NO_2}, including the larger ones at which absorption was presumably fairly complete, the radiation 3660 Å. is considerably more effective than the radiation 4050 Å. This fact, as well as the ineffectiveness of the radiation 4350 Å., is entirely accountable if the mechanism is the decomposition of NO_2 into NO and O_2 followed by a dark reaction between NO and N_2O_5; for these N_2O_5 rates closely parallel the quantum yields in the NO_2 decomposition. In order to determine whether the N_2O_5 rates have the proper absolute magnitude to be accounted for in this manner, as well as to eliminate, so far as possible, uncertainties arising from incomplete absorption and from the fact that the previous NO_2 work had been done at room temperature rather than at 0°, we have undertaken measurements of the rate of NO_2 decomposition in the same reaction vessel.

For this purpose the apparatus was sealed at C and P (Fig. 1) and a reservoir, S, containing nitrogen dioxide, was sealed on at the point indicated, as were also a trap, T, and a receptacle, R, which served as a sink for nitrogen dioxide after it had been illuminated once. Liquid air was maintained at a constant level around the trap, G, and the thermostat kept packed with ice. The nitrogen dioxide in S was kept frozen out with liquid air, out of contact with stopcock grease, except at the time of its introduction into the reaction vessel.

The method followed was to evacuate the whole system, close stopcock M, remove the liquid air from the reservoir, S, thus introducing some nitrogen dioxide into the apparatus, freeze this out in T, evacuate well, then remove the liquid air from around T with the stopcock M closed. The pressure of nitrogen dioxide and tetroxide was now measured and a measured illumination of from two to four minutes made with λ4050 or 3660. Immediately after illumination, liquid air was applied at T, the stopcock, M, opened and the pressure of oxygen read on the McLeod gage. It has been shown in the previous research that nitric oxide is frozen out along with nitrogen dioxide. The amount of decomposition was kept low enough so that the recombination of NO and O_2 could be neglected. A blank run, in which the illumination was omitted, showed the development of non-condensable gas while the NO_2 was in contact with the stopcocks to be entirely negligible.

The volume of the apparatus between the points C and C′ was found by filling with water to be 37.8 cc. In order to be able to calculate the pressure the oxygen formed would exert if it were all in this volume at

0°, air was trapped in the McLeod gage of known volume and its pressure read. In the meantime the rest of the apparatus, with liquid air and ice in place as in the oxygen measurements, was well evacuated. Then with the cock, N, closed the air was released from the McLeod gage and the pressure again read.

The rates of production of oxygen in the NO_2 experiments, expressed as millimeters per ten minutes per centimeter of scale deflection and reduced to the volume and temperature of the reaction vessel, were plotted against p_{NO_2} and a representative curve was drawn. From this curve were read the rates of oxygen production corresponding to the particular values of p_{NO_2} occurring in the N_2O_5 experiments. Twice these rates are given in the last column of Table I. The multiplication by two is made in order to permit direct comparison of the last two columns.

Discussion of Results

The last two columns of the table, which summarize the results for the wave length 3660 and 4050 Å., may be considered to agree within the experimental error. It may be noted that in Expts. 4a and 4b the ratios of $p_{N_2O_5}$ to p_{NO_2} were about 10 and 6.5, respectively. The agreement of the rate of N_2O_5 decomposition with twice the rate of O_2 production in the absence of N_2O_5 but at the same NO_2 pressure is to be expected if the N_2O_5 does not interfere with the photochemical decomposition of NO_2 ($2NO_2 = 2NO + O_2$), and if the N_2O_5 decomposition is simply a dark reaction with NO ($N_2O_5 + NO = 3NO_2$). In other words, the comparative rates in the two sets of experiments are in agreement with the N_2O_5 mechanism proposed by Norrish. The fact that the effect of $\lambda 4350$ is too small to detect with the arrangement we have used is likewise in agreement with this mechanism if consideration be taken of the low quantum yield of this radiation in decomposing NO_2.

The possibility that the N_2O_5 decomposition results from collisions of the second kind between activated NO_2 molecules and N_2O_5 molecules is not completely ruled out. But this mechanism would, in view of the present results, require very special assumptions concerning the efficiencies of these collisions as compared with the efficiencies of the collisions involved in NO_2 decomposition. However, since the efficiencies of collisions of the second kind are ordinarily highly specific with respect to the colliding molecules,[10] such assumptions could only fortuitously be in agreement with present views. The possibility that such collisions might account for a small part of the decomposition would appear to be difficult to eliminate. However, certainly the major part of the N_2O_5 decomposition which we have observed is predicted satisfactorily by the Norrish mechanism.

Summary

The photochemical decomposition of gaseous nitrogen pentoxide in the presence of nitrogen dioxide has been investigated with approximately monochromatic radiations of the wave lengths **4350, 4050** and **3660 Å.** From a comparison of the rates of photochemical decomposition of nitrogen pentoxide and nitrogen dioxide, it is concluded that the mechanism of this sensitized photochemical decomposition is essentially that suggested by Norrish, namely, the formation of nitric oxide and oxygen from the photodecomposition of nitrogen dioxide, followed by dark reaction between nitric oxide and nitrogen pentoxide.

VAPOR PRESSURES OF RELATED COMPOUNDS. THE APPLICATION OF DÜHRING'S RULE

BY A. R. CARR AND D. W. MURPHY

RECEIVED AUGUST 8, 1928 PUBLISHED JANUARY 8, 1929

Several methods have been proposed to show the relation between the vapor-pressure data for various substances. The approximate Clausius-Clapeyron equation states that the slope of the vapor-pressure curve of any substance is proportional to its molal entropy of vaporization. In other words, the slopes of the vapor-pressure curves of non-associated substances at the same pressure should be the same. However, due to deviation from the gas laws and for other reasons, over wide pressure ranges this is not the case. Hildebrand[1] has suggested that this equation would be more nearly correct if the comparisons between various liquids were made at equal vapor concentrations rather than at equal pressures. Wilson and Bahlke[2] found that this method is applicable to the paraffin hydrocarbons.

Another common method, also based on the Clapeyron equation, is to plot the logarithm of the vapor pressure against the reciprocal of the absolute temperature. Over short ranges of temperature the data for related substances give straight lines which are nearly parallel. However, as the temperature range increases, the straight lines are replaced by curves. Still other methods are empirical, such as those proposed by Ashworth[3] and Cox.[4] Calingaert and Davis[5] applied the Cox method to several groups of related substances and found that the lines representing

---

[5] Calingaert and Davis, *ibid.*, 17, 1287 (1925).

the vapor-pressure data for each substance in the groups so plotted tend to intersect in a common point.

It is the purpose of this paper to show that the Diihring lines, representing the vapor-pressure data for each one of a family of substances, intersect in a common point. As will be shown, this simplifies the construction of the vapor-pressure curve for each substance in the group. Relatively few experimental determinations are required to obtain these vapor-pressure data, which are sufficiently accurate for many purposes.

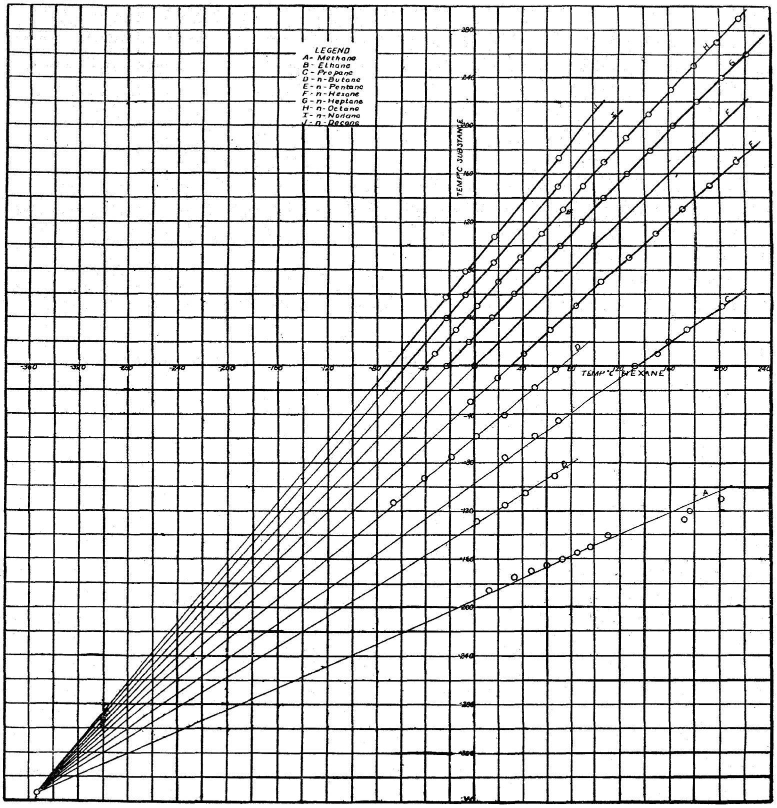

Fig. 1.

In 1878, Dühring[6] discovered a simple relation between the boiling points of pure substances. He plotted the boiling point of one substance at a given pressure as the ordinate against the boiling point of water at the same pressure as the abscissa. Repeating this process for several widely different pressures, he showed that a straight line could be drawn through all the points thus determined. This rule greatly simplifies the

---

[6] **Diihring, "Neue Grundgesetze zur Rationelle Physik und Chemie," Leipzig, 1878.**

construction of vapor-pressure curves. Once the Diihring line for the substance or compound is constructed, the pressure corresponding to any boiling point may be found in the following manner. Through any temperature representing the boiling point of the substance, draw a line parallel to the horizontal axis and intersecting the Diihring line. Through this point of intersection, draw a line parallel to the vertical axis and read the boiling point of the reference substance under the same pressure as that of the substance in question. From the vapor-pressure curve of the reference substance read the pressure corresponding to this temperature. By repeating this process for various temperatures, the vapor-pressure curve for the substance may be determined.

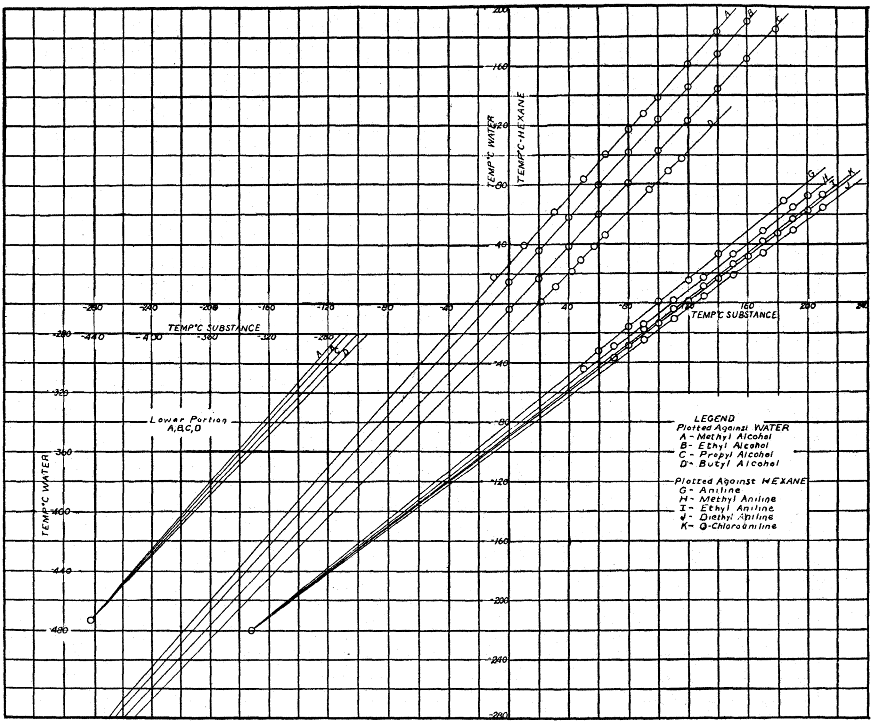

Fig. 2.

Diihring expressed his rule algebraically as follows

$$\frac{T_1 - T_2}{\Theta_1 - \Theta_2} = K$$

in which T_1 and $1'_2$ are the boiling points of one substance at two different pressures, while Θ_1 and Θ_2 are the boiling points of the other substance at the same two pressures and K is a constant which is the slope of the line. Diihring's rule has been shown to hold remarkably well for substances and compounds over pressure ranges of several thousand millimeters when the boiling points of the substance or compound in question are plotted against the known boiling points of a chemically similar substance. In general the broader the pressure range and the less similar the substances, the greater will be the deviation from a straight line.

Furthermore, it may be seen from the charts that the Diihring lines for **a** family of substances either intersect in a common point or are parallel.

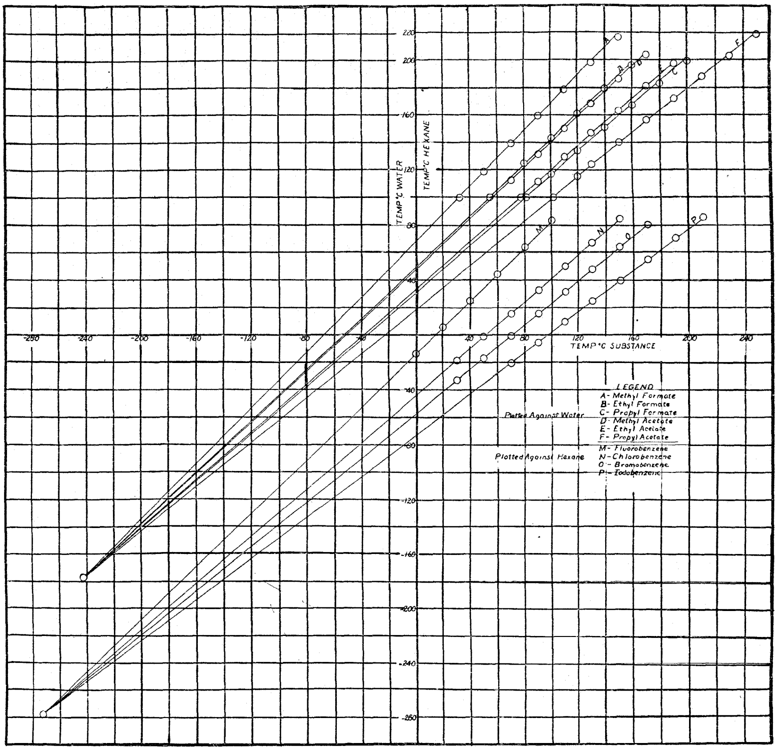

Fig. **3.**

The requirements for the construction of a Diihring chart for a family of substances are as follows: (1) the vapor pressure of some reference substance, such as water or hexane, must be accurately known and (2) at least two boiling points at different pressures of two substances in the family should be determined in order to establish the common point of intersection of the Diihring lines for the family. After this point of intersection is established, it is possible to construct the vapor-pressure curve of any member of the family of substances from a single boiling point.

Fig. 1 shows the normal paraffin hydrocarbons from methane through decane. These are plotted against normal hexane as the reference substance. The lines for most of these hydrocarbons fit the data very accurately through wide pressure ranges, but from butane down the data become somewhat discordant, with that of methane deviating most widely from a straight line. The vapor-pressure data of the reference substance, hexane, which we have used were taken from Von Rechenberg.[7] The Dühring lines for the isomers of the normal hydrocarbons, not shown in the figure, intersect in a different point from that of the normal hydrocarbons.

In Fig. 2, A, B, C and D are, respectively, methyl, ethyl, propyl and butyl alcohols plotted against water as the reference substance, while

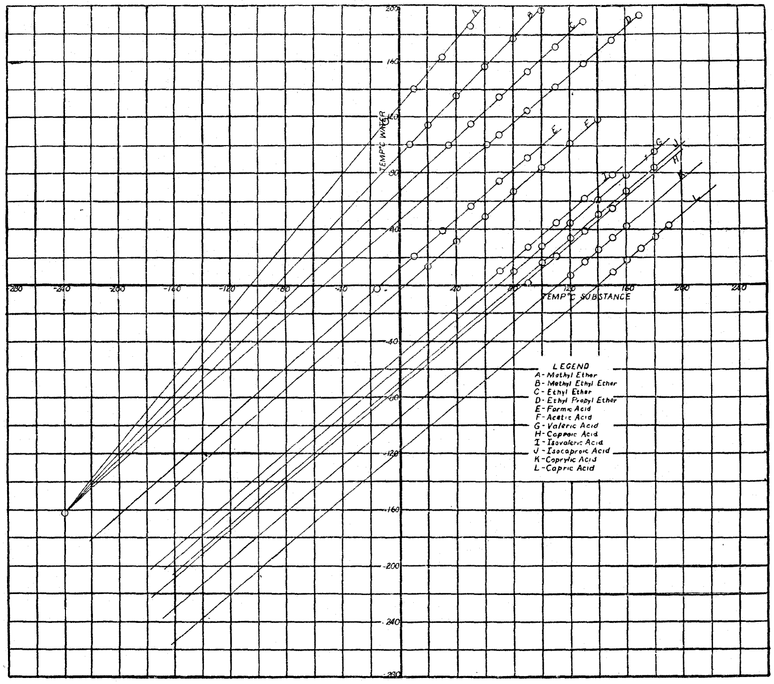

Fig. 4.

G, H, I, J and K are aniline, methylaniline, ethylaniline, diethylaniline and o-chloro-aniline, respectively, plotted against hexane. The anilines when plotted against water showed curves of similar shape, but with hexane as the reference substance they formed straight lines which intersected in a common point.

In Fig. 3, A to F inclusive are the lines for several organic esters plotted against water, while M to P inclusive are halogen derivatives of benzene plotted against hexane. Fig. 4 gives several ethers and several acids with

---

[7] Von Rechenberg, "Einfache und Fraktionierte Destillation in Theorie und Praxis," Von Schimmel and Company, Leipzig, 1923.

water in both cases as the reference substance. It is a curious fact that the Dühring lines for the various organic acids studied are parallel.

The literature does not yield complete vapor-pressure data over wide temperature ranges for many whole families of compounds. Where such data were available and were plotted against a similar substance for reference, the Dühring lines so formed were straight and intersected in a common point.

Acknowledgment

The authors wish to acknowledge the aid of Miss Elinor Batie in collecting data from the literature and in checking calculations.

CRITICAL STUDIES ON THE FUSION OF RARE METAL ORES. III. DETERMINATION OF TANTALUM AND COLUMBIUM[1]

BY GEORGE W. SEARS[2]

RECEIVED AUGUST 21, 1928 PUBLISHED JANUARY 8, 1929

In a previous investigation[3] it was shown that tantalum and columbium can be completely separated from each other by the action of concentrated sulfuric acid on the compounds obtained by fusion with sodium pyrosulfate at 835 to 875°C. Fusion under these conditions renders the tantalum insoluble in concentrated sulfuric acid while the columbium remains soluble. This action was explained on the basis that the sodium salts of tantalic and columbic acids are formed during the fusion and that the sodium tantalate is decomposed at 835° while the corresponding columbium compound remains unaffected at temperatures as high as 875°. The present investigation was undertaken in order to find the conditions, if possible, whereby these reactions can be applied to a quantitative determination of the two elements.

Among the available methods for the determination of tantalum and columbium, those involving the difference in solubility of the potassium double fluorides appear to be the most satisfactory. All of these[4] necessitate the fractional precipitation of tantalum as K_2TaF_7. The double fluoride is weighed as such or is converted to the oxide and weighed as Ta_2O_5. The columbium remaining in the solution is usually converted to the oxide and weighed as Cb_2O_5, although it may be determined volumetrically by reduction and subsequent oxidation with standard potassium permanganate. Titanium, which usually occurs with tantalum and columbium, is not removed by the double fluoride method and is weighed with the columbium. Its estimation colorimetrically with hydrogen peroxide has been found by Chesneau[4] to involve an error of at least 0.5%. Treadwell,[5] and also Schoeller and Waterhouse,[6] investigated the methods of reducing columbium and found that in no case could it be reduced to the tervalent state and that the degree of reduction varied so much with conditions that

a definite factor was not possible. The method was therefore declared unsatisfactory. Schoeller and Powell[7] attempted a separation and determination by fusing with potassium carbonate. The greater solubility of the columbium compound afforded a fairly complete separation after two or three fusions. Interfering elements, however, make the method unreliable for the determination of tantalum.

It may be concluded, therefore, that the present methods for the determination of tantalum and columbium involve fractionation processes which are at best only approximate. Interfering elements are very difficult to remove and hence often contaminate the precipitated tantalum and columbium. Iron and titanium, almost universally found associated with tantalum and columbium, are among the most troublesome and most difficult elements to remove.

Experimental Part

Since titanium sulfate, formed by fusion with sodium pyrosulfate below 700°C., is soluble in hot 3 N hydrochloric acid[8] and both tantalic and columbic acids are known to be relatively insoluble in water and dilute mineral acids, fusion of the ore or mixed oxides with sodium pyrosulfate should offer a possible means of separating any titanium that might be present. Iron and other more basic elements should also be soluble under these conditions.

Solubility of Tantalic and Columbic Acids in Dilute Hydrochloric Acid.—Tantalic and columbic acids were obtained by fusing the mixed oxides with sodium pyrosulfate and leaching the cold melt with water This procedure dissolved a large proportion of the excess sodium sulfate and left all the tantalum and columbium as a fine granular or flocculent residue, the density of which depended somewhat on the temperature at which the fusion was made. The residue was allowed to settle and the liquid decanted through a filter. Three normal hydrochloric acid was then added to the residue remaining in the beaker and the mixture was digested near the boiling temperature for some time. It was then filtered and the filtrate evaporated to a few cubic centimeters and tested for columbium according to the method outlined in the previous paper.[3] Several experiments were carried out in this way on mixtures that had been fused at different temperatures. In no case was even a trace of columbium detected. Although the tests for tantalum are somewhat less satisfactory than for columbium, tests were made by adding hydrofluoric acid and potassium chloride to the concentrated filtrate, allowing excess water to evaporate, and examining the residue under the microscope for the needle-like crystals of K_2TaF_7. No evidence of tantalum was obtained in any case. It was therefore assumed that no loss of either tantalum or columbium would result from washing with hot 3 N hydrochloric acid.

Removal of Contaminating Substances.—From the difficulties encountered a number of years ago in washing large quantities of tantalic and columbic acids free from potassium sulfate it seemed probable that similar difficulties might arise in the removal of the sodium sulfate obtained during the fusion. Accordingly a number of samples of the mixed oxides were

---

fused with sodium pyrosulfate, the cold melt was leached with water and the residue washed with hot 3 N hydrochloric acid. By repeated digestion in the hot wash liquid it was found that no further test for sulfate could be obtained after six or seven washings if the sample taken for analysis was less than half a gram. Larger samples were much more difficult to wash free from sulfate. In order to determine whether sodium sulfate might be occluded in such a way as to prevent its being washed out, two samples of pure potassium fluotantalate were fumed with sulfuric acid to remove the fluorine and then analyzed for tantalum oxide as described above. The results are given in Table I.

TABLE I

DETERMINATION OF Ta_2O_5 IN K_2TaF_7

K_2TaF_7 taken, g.	Ta_2O_5 found, g.	Ta_2O_5 present, g.	Error, g.
0.6227	0.3520	0.3512	+0.0008
.5180	.3914	.3917	− .0003

The removal of iron presented a somewhat greater difficulty. The iron compound obtained during the fusion appeared to be almost completely insoluble in water, regardless of whether the fusion was made at a low or high temperature. Repeated digestion with hot 3 N hydrochloric acid proved efficient for removing the iron when the fusion was carried out at a low temperature. High-temperature fusions, however, appeared to decompose the iron compound or otherwise render it very difficultly soluble in the dilute acid. By fusing at a low temperature (about 650°) and leaching the cold melt with water to remove it from the crucible, much of the excess sodium sulfate was dissolved and the tantalum and columbium were left as a fine, white, granular residue that settled readily. All iron and sodium sulfate could be removed from the residue by repeated digestion with hot 3 N hydrochloric acid and final washing with water. When the insoluble residue of tantalic and columbic acids which had been washed until the washings gave no further test for iron or sulfate was filtered, dried and ignited, a pure white powder was obtained.

The results so far obtained, together with the fact that the fusion of titanium ores below 700° renders the titanium completely soluble[8] in hot 3 N hydrochloric acid, made it seem quite probable that titanium could be quantitatively removed along with the iron. In order to test this point a sample of pure tantalum oxide, to which was added a small amount of titanium oxide, was fused with the pyrosulfate at about 650° and analyzed as described above. The final washing with hot 3 N hydrochloric acid was continued until no further test for titanium was obtained in the washing liquid when tested with hydrogen peroxide. A portion of the residue was then fused and tested for titanium and gave a negative result. It was evident, therefore, that the chief interfering substances could be removed by fusing at about 650°, washing first with hot 3 N hydrochloric acid and then with water.

Separation of Tantalum and Columbium

In order to effect a separation between the tantalum and columbium by means of the pyrosulfate fusion the temperature of the fusion mixture must reach 835 to 875°. In the earlier investigation[3] fusions were made in platinum over a Bunsen flame and the temperatures were obtained by means of a thermocouple placed in the fused mass. Since this procedure was not feasible for a quantitative determination, it was decided to use an electric resistance cup furnace as the source of heat. The thermocouple was suspended just above the crucible containing the melt. A number of experiments were carried out in order to determine the furnace temperature and the rate of heating necessary to decompose completely the tantalate without affecting the columbate. It was soon found that time is a factor in the decomposition of the tantalate. This fact did not appear in the earlier investigation, probably because the temperature had to be raised much more slowly in order to prevent boiling when the flame was used as the source of heat. A satisfactory separation was found possible if the temperature was held at 835 to 850° for ten to fifteen minutes.

Determination of Total Tantalum and Columbium

For the purpose of a quantitative determination of the two elements by this method, a filter medium unaffected by the hot concentrated sulfuric acid would be necessary. A Gooch crucible provided with an asbestos pad seemed to be the most logical substance available; hence a quantity of the washed asbestos fiber commonly used in quantitative analysis was heated with concentrated sulfuric acid for two to three hours and then carefully washed with water to remove the sulfuric acid and any other soluble material that might have been present. A suspension of this was made in the usual way and used in a series of determinations made with pure potassium fluotantalate. The procedure consisted in converting a weighed quantity of the fluotantalate to the oxide by fuming with sulfuric acid in a platinum crucible, evaporating the excess sulfuric acid and fusing the residue with twelve parts of sodium pyrosulfate at about 850". The cold melt was then leached with water to remove it from the crucible and dissolve as much of the sodium sulfate as possible. It was then filtered through a Gooch crucible provided with an asbestos pad, the dry weight of which had previously been determined.

The residue of tantalic acid was washed with hot 3 N hydrochloric acid and finally with water until no further test for sulfate could be obtained in the washings. The residue of tantalic acid together with the asbestos pad was transferred to the original beaker with as little water as possible and 10 to 15 cc. of concentrated sulfuric acid was added. The resulting mixture was carefully evaporated until dense white fumes of sulfur trioxide appeared, and was then held at that temperature for about ten minutes. When cold the mixture was filtered through a weighed Gooch crucible, washed, dried, ignited and weighed.

The results were irregular, showing some unexpected interfering factor. It seemed, therefore, that the asbestos was being attacked by the sulfuric acid. In order to determine to what extent this was being done, a weighed quantity of the asbestos was subjected to the action of hot concentrated sulfuric acid in a manner similar to that required by the analysis. Several determinations of this kind showed a small but distinct loss of weight during the treatment. A number of alundum filtering crucibles were tested in a similar manner, but they were found to be much less resistant than the asbestos. The solvent action of hot concentrated sulfuric acid on platinum indicated that a Monroe crucible would be little better for this purpose than the ordinary Gooch. From these results it seemed doubtful whether a material entirely resistant to the action of the hot acid could be found.

Two possible methods of procedure presented themselves. A correction might be made for the asbestos dissolved during the treatment with sulfuric acid or the weight of tantalum oxide could be obtained by difference. Investigation of these two methods was carried out in the following manner, using a mixture of the oxides of tantalum and columbium containing a small amount of iron oxide. From 0.2 to 0.3 g. of the mixed oxides was weighed in a platinum crucible, 4.5 to 5.0 g. of sodium pyrosulfate added and the mixture fused over a Bunsen flame at as low a temperature as possible to obtain a clear fusion. By keeping the crucible covered and the flame just high enough to keep the mass liquid but not boiling, a satisfactory fusion could be obtained in about forty-five minutes to an hour. The crucible containing the cold melt was placed in a beaker containing enough water to cover it and was allowed to stand for one to two hours, when the undissolved residue was disintegrated and easily removed from the crucible. After thorough mixing the residue was allowed to settle and the liquid was decanted through a filter. A small quantity of 3 N hydrochloric acid was then added and the mixture digested near the boiling temperature for 10 to 15 minutes. This served to dissolve most of the iron, which was decanted through the same filter. By repeating this process three to four times no further test for iron could be obtained in the washings. Several washings with hot water were required to remove all the sulfate. The residue was then transferred quantitatively to the filter, dried, ignited and weighed. In all cases the ignited residue was pure white, indicating the absence of iron. A small portion held in the flame by means of a platinum wire gave no yellow color, showing the absence of sodium. A small amount of silica, however, was found to be present. This was removed by treatment with hydrofluoric and sulfuric acids. The final residue was assumed to be the pure oxides of tantalum and columbium. Consecutive analyses gave results calculated in per cent. as follows: 98.00, 98.20, 98.11, 97.97, 98.04; average, 98.06.

Separation and Determination of Columbium

For the separation and determination of columbium the pure oxides obtained by the above method were fused as before over a Bunsen flame. When the fusion was complete and a clear liquid resulted, the crucible and contents were placed in the furnace, the temperature was brought to 850° and maintained at approximately that temperature for ten to fifteen minutes. At the end of this time they were removed from the furnace and allowed to cool. Fumes of sulfur trioxide ceased to be evolved sometime before the temperature of the furnace reached 850°, and the mass solidified. When taken from the furnace it was quite porous and had a flaky appearance. This was most easily removed from the crucible by digesting for one to two hours with water kept near the boiling temperature. A small portion, however, clung very tenaciously to the crucible. It was found impossible to remove this except by fusing again with the pyrosulfate at a low temperature. Since this would necessarily introduce an error into the determination, some container other than a platinum crucible would be necessary for the high-temperature fusion. A silica crucible not being available at the time, a Coors glazed porcelain crucible was tried. The results were very satisfactory. Not only was the fused mass very easily and completely removed from the crucibles but the loss in weight caused by the fusion was very much less than that sustained by the platinum. In five fusions two porcelain crucibles lost a total of 3.0 and 2.3 mg., respectively, while a platinum crucible similarly treated lost 7.7 mg. Porcelain was therefore used for all high-temperature fusions thereafter. The cold melt was leached with water and washed with two or three portions of hot 3 N hydrochloric acid to remove any iron that might have been introduced with the pyrosulfate, decanting each time through a Gooch crucible provided with an asbestos pad.

The residue of tantalic and columbic acids, together with the asbestos pad, was then transferred to the original beaker with the aid of as little water as possible, and 15 cc. of concentrated sulfuric acid was added. The mixture was evaporated until the white fumes of sulfur trioxide appeared. The beaker was then covered with a watch glass and the heating continued for twelve to fifteen minutes; this served to dissolve all of the columbium without affecting the tantalum. On cooling, it was filtered through a weighed Gooch crucible, washed with two or three portions of cold 6 *N* sulfuric acid,[3] and then with water until the washings gave no further precipitate with ammonia.

A good deal of difficulty was encountered in this filtration owing to the fact that the finely divided tantalum residue tended to pass through the filter. After the sulfuric acid treatment the tantalum is left as a dense, granular mass, some of which is very finely divided. A small amount may pass into the filtrate and entirely escape notice since it appears to give little or no cloudiness to the concentrated acid solution. Until its presence was suspected and the solution carefully examined for it, a good many unaccountably high columbium values were obtained.

On diluting the filtrate containing the columbium it was noticed that in most cases a distinct cloudiness developed, indicating hydrolysis, although in some cases the solution remained perfectly clear. It seemed probable, therefore, that the concentrated acid solution might be diluted without fear of hydrolysis if the correct conditions could be found. After some investigation it was found that no hydrolysis occurred and that a complete separation could be obtained if the cold acid solution were slowly poured, with constant stirring, into about 100 cc. of water kept cold with ice or running water.[9] This simplified very much the process of filtering and washing the residue free from columbium.

---

[9] After this work was completed and the paper had been sent to Washington, an article by S. J. Kiehl and David Hart, appeared (THIS JOURNAL, 50, 1608 (1928)) describing a similar method for diluting a sulfuric acid solution of columbic oxide without causing precipitation.

The most favorable conditions found for the precipitation and separation of columbium were to neutralize the solution, which had been diluted to about 300 cc., with ammonia and then heat to boiling. This caused the precipitate to settle well and make it more easily washed. A number of attempts were made to precipitate the columbium by means of hydrolysis in acid solution but conditions could not be obtained under which complete precipitation could be assured. The precipitate of columbium usually contained a small amount of silica, which was removed by treatment with hydrofluoric and sulfuric acids. Consecutive analyses gave results calculated in per cent. as follows: 21.90, 21.86, 22.42; average, 22.06.

Attempts to obtain the weight of the tantalum oxide by igniting and weighing the residue did not meet with success. The correction for the asbestos which had to be placed in the hot concentrated sulfuric acid apparently was not constant in value and could not be obtained for each determination.

Method of Analysis

The procedure finally adopted as giving the most satisfactory results consisted in fusing the weighed sample at about 650° with 12 to 13 parts of sodium pyrosulfate and leaching the cold melt with water to remove it from the crucible and dissolve most of the excess sodium sulfate. The clear supernatant liquid is then decanted through a filter, the residue digested with hot 3 N hydrochloric acid to remove iron and titanium, transferred to the filter, washed free from sulfate with hot water, dried and ignited. This product contains all of the tantalum and columbium along with a small amount of silica, which is removed by treatment with hydrofluoric and sulfuric acids. After weighing the pure mixed oxides, a definite portion is transferred to a porcelain crucible and fused in the furnace with 5 g. of sodium pyrosulfate. The temperature is slowly raised to 850° and held at 835 to 850° for ten to fifteen minutes. It is then removed from the furnace, leached with water, filtered through a Gooch crucible, provided with an asbestos pad and washed two or three times with hot 3 N hydrochloric acid. The residue, together with the asbestos pad, is then transferred to the original beaker, with the aid of as little water as possible, and 15 cc. of concentrated sulfuric acid is added. The mixture is then evaporated to the appearance of white fumes and kept at that temperature for ten to fifteen minutes with occasional stirring. When cold the concentrated acid solution is slowly poured with constant stirring into 100 cc. of water kept cold with ice or running water. The mixture is then filtered, washed with cold water, and the columbic acid precipitated from the filtrate with ammonia. The precipitate is filtered, dried, ignited, and the silica removed by treatment with hydrofluoric and sulfuric acids. The final residue is weighed as Cb_2O_5.

Summary and Conclusion

The pyrosulfate fusion as a means for the quantitative determination of tantalum and columbium has been studied with results and conclusions as follows.

1. When fused at a low temperature (about 650°) iron and titanium are completely separated from the tantalum by digestion near the boiling temperature with 3 N hydrochloric acid. The tantalic and columbic acids are left in the insoluble portion.

2. When the fusion mixture is held at 835 to 850° for ten to fifteen minutes, the columbium only is dissolved by fuming with concentrated sulfuric acid. The solution may be diluted without precipitation if the cold acid mixture is slowly poured into water kept cold with ice or running water.

3, A method of procedure for the determination of tantalum and columbium is given.

4. The possibility of more economic extraction and separation of tantalum and columbium is indicated in the method used for the removal of iron and titanium and in the fact that the sulfuric acid solution may be diluted without precipitation of columbium.

THE EQUILIBRIUM BETWEEN METHANOL, CARBON MONOXIDE AND HYDROGEN. PRELIMINARY PAPER[1]

BY DAVID F. SMITH[2] AND BRIANT F. BRANTING[3]

RECEIVED AUGUST 27, 1928 PUBLISHED JANUARY 8.1929

Introduction

Although our work on the equilibrium between methanol, carbon monoxide and hydrogen is still in progress, it has been decided to present the results so far obtained. The results heretofore available are very conflicting and no direct experimental measurements of equilibrium appear to have been made. The many inquiries which have been received concerning the data indicate the general interest and practical importance attached to the thermodynamic properties of methanol.

Published values of the free energy of methanol have been obtained in several ways. Kelley[4] has calculated his value from the specific heat of

[4] Kelley, *Ind. Eng. Chem.*, 18, 78(1926).

liquid methanol down to liquid-air temperatures, extrapolating to 0°K. and using the Third Law of Thermodynamics. Christiansen[5] has used a Nernst approximation formula, and also his preliminary measurements of equilibria in the two sections $HCOOCH_3 + 2H_2 = 2CH_3OH$ and $CH_3OH + CO = HCOOCH_3$. The calculation of Smith[6] involved substantially the same data that were used by Kelley, except for the substitution of a better value for the high temperature specific heat of methanol vapor. The data of Kelley were at that time considered more reliable than those of Christiansen, partly because of the latter's own statements regarding the preliminary nature of his equilibrium measurements. While the calculations of Kelley and of Smith were in substantial agreement, they were widely different from Christiansen's results. Although not much confidence can usually be placed in the results from the Nernst approximation formula, the formula as presented by Christiansen gave results in fair agreement with his equilibrium measurements.

The equilibrium constant $(CH_3OH)/(CO)(H_2)^2$, where concentrations are expressed in terms of the partial pressures in atmospheres, is 10.6 at 200° according to Smith's calculation from Kelley's data. Christiansen's equilibrium data[7] give 0.055 at this temperature. The Nernst approximation formula, as proposed by Christiansen, gives 0.042. Recently Morgan, Taylor and Hedley[8] have discussed the results of the Nernst formula which Audibert and Raineau[9] state to be in substantial agreement with the results they obtained in practical operation at high pressures. They note that the discrepancy between the results obtained from this formula and from the equation derived by Kelley increases with increasing temperature. At 600°K. the formula gives a constant about one-hundredth of that calculated from Kelley's results.

Apparently, apart from the preliminary equilibrium measurements of Christiansen, the only direct experimental estimates of the methanol equilibrium have been obtained from results of actual operation of the methanol process at high pressures—operations which were of course neither designed for nor well adapted to furnishing accurate equilibrium data. In addition to the inherent difficulties in precise measurement at high pressures, the theoretical accuracy obtainable on measurements of this equilibrium at high pressure is unsatisfactory; for example, a relatively small error in determination of the conversion of carbon monoxide to methanol would, at very high pressures, introduce a disproportionately large error into the value of the equilibrium constant so derived. Of

course, standard free energy data cannot be obtained from equilibrium measurements at high pressures without a much more complete knowledge of the equations of state of the separate gases, both in the pure state and in the mixtures, than is at present available. Also, when a considerable amount of reaction is taking place on the catalyst, the temperature control is likely to be poor. In view of the importance of this reaction, the conflicting nature of the existing equilibrium data makes a direct determination of the standard free energy of methanol highly desirable

Experimental Procedure

At 300° and a total pressure of 1 atmosphere, Kelley's data would give the limiting (equilibrium) decomposition of methanol to CO and $2H_2$ as about 96.4%. With an active catalyst, therefore, it should be possible under these conditions to determine the limiting decomposition of methanol vapor and, under the same conditions, to determine readily the maximum yield of methanol from mixtures of carbon monoxide and hydrogen.

Our method was first to pass pure methanol vapor over an active catalyst at a rate slow enough to give substantially equilibrium conditions. This set a maximum value on the constant of the reaction. Second, a mixture of carbon monoxide and hydrogen was passed over the catalysts at a rate slow enough to give the maximum yield of methanol. The latter experiment set a minimum limit on the value of the constant.

The methanol used was made from the commercial "absolute" product which we freed from aldehydes, ketones and water according to the method described by Danner and Hildebrand[10] for ethyl alcohol. One catalyst used was zinc oxide made from pure, freshly precipitated carbonate. Another catalyst was made by adding chromic acid to purified zinc oxide, in the atomic proportions 4Zn:1Cr.[11] About 600 cc. of 8-mesh per inch catalyst was used in each experiment. The $CO-H_2$ mixture was made by adding electrolytic hydrogen from a cylinder to water gas generated by a small generator available at this Laboratory. The gas mixture was pumped from a 7-cu.m. gas holder through a liquid-air cooled trap to remove sulfur compounds and all heavy gases, over heated copper to remove oxygen and into a high-pressure cylinder.

In our early decomposition experiments, when we were guided by the data of Kelley, methanol vapor at 1 atm. pressure was passed over the catalyst. It was soon found, however, that the final concentration of methanol resulting after passage over the catalyst, even at very slow rates, not only was much smaller than was expected, but was always much larger than the maximum yield of methanol from the $CO-H_2$ mixture. It was decided that this was due either to some adsorption effect on the catalyst or to the fact that the mechanism of the reaction changes to a higher order at very low pressures of methanol. The reaction should obviously be started at somewhere near equal distance from equilibrium in the decom-

position and in the synthesis experiments. We therefore introduced methanol vapor into the CO–H_2 mixture by passing the latter through a saturator containing purified methanol at the temperature of a liquid ammonia bath (–38°). The vapor pressure of methanol at this temperature was still over 40 times the equilibrium pressure, so that the experiments were thus started definitely on the methanol side of equilibrium.

Fig. 1 shows the apparatus used. The gas from the cylinder, previously purified, passes into the apparatus at *a*. The flow of gas is adjusted by the head in a tube of water, *b*. The gas then passes through heated platinized asbestos in *c* to remove oxygen, then through a liquid-air trap, *d*, to remove all heavy gases, through the methanol saturator, *e*, surrounded by a bath of liquid ammonia, through the first catalyst tube, *f*, and through a liquid-air trap, *g*, to condense the remaining methanol. The gas then passes through a second catalyst tube, h, and the yield of methanol is caught in a second liquid-air trap, *i*. The gas emerging from the apparatus is passed through a flow meter, j, and a carefully calibrated meter,[12] k, in order to determine its volume. Samples of the gas after passage over each catalyst were collected and carefully analyzed to determine the partial pressures of carbon monoxide and of hydrogen with which the methanol came to equilibrium.

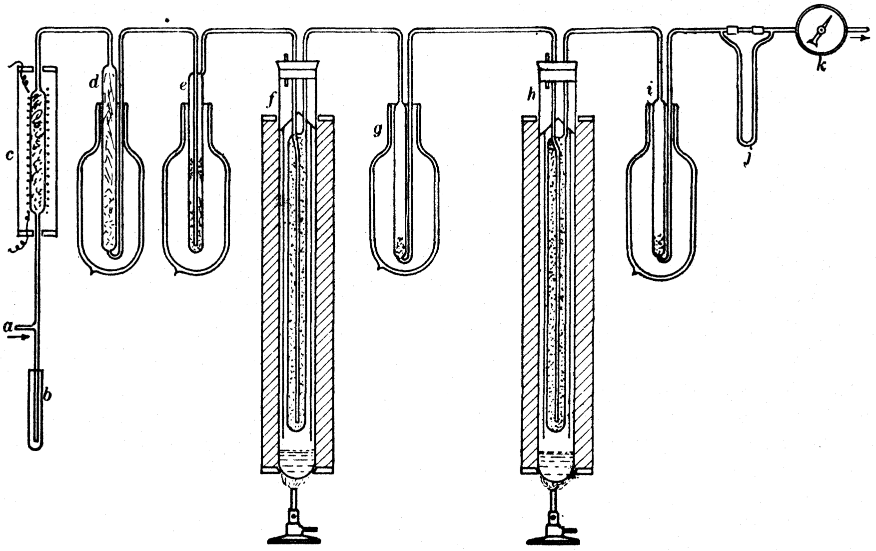

Fig. 1.—Apparatus for measuring equilibrium in the methanol reaction.

The catalyst was maintained at a constant temperature by surrounding it with the vapor of boiling benzophenone. The catalyst tubes were shielded with thin sheet-iron tubes and umbrellas, as recommended by the Bureau of Standards.[13] The benzophenone was purified by distillation before use and the boiling temperature was checked with a carefully calibrated resistance thermometer.

---

[12] In regard to calibration and use of wet-test meters, see Bureau of Standards Circular No. 309 (1926), and Technologic Paper No. 36 (1926).

[13] Bureau of Standards Scientific Paper, No. 339 (1919).

At the beginning of an experiment, in order to bring the catalyst to equilibrium with the gas mixture used, the apparatus was always completely purged with the gas to be used, before the yields of methanol were collected.

The methanol yields were determined colorimetrically, according to a method which suggested itself to us from the work of Wright.[14] The method depends upon oxidation of the methanol to formaldehyde with permanganate. The excess of permanganate is destroyed by oxalic acid, and the color is developed upon the addition of a modified Schiff's reagent, prepared as described by Wright, which forms a blue compound with the formaldehyde. It was determined that no detectable amounts of formaldehyde were formed directly by the catalyst, and that other alcohols and dimethyl ether[15] do not interfere with the test in this case. Since no other known by-products of the methanol reaction which could have been present in the solution used for the methanol determination would have interfered, the method may be regarded as an absolute determination of the methanol. Careful checks were made upon several series of known solutions and it was shown that by the colorimetric method the concentration of methanol in aqueous solutions as dilute as 1 part in 10,000 could be determined with an accuracy of 1% or better. In each determination a series of standard solutions was made up and treated in exactly the same way as the unknown solution. A calibration curve of intensity of transmitted light against the concentration of solution was plotted for interpolation purposes and the unknown solutions were always compared with a standard solution whose concentration was very close to that of the unknown solution. Since the colors were compared in a colorimeter by transmitted light, the curve of concentration against intensity was approximately logarithmic, as given by Beer's Law. Although it took a short time for the color to develop (and the color, of course, faded upon long standing), a comparison of the color in a standard solution with that in the unknown solution after each had stood for forty-five to sixty minutes gave the same result as did a comparison made an hour or more later.

The condensers containing the yields of methanol, after removal from the apparatus, were maintained at about 1° above the temperature of carbon dioxide snow until the small amount of carbon dioxide which is formed in the reaction and subsequently condensed, had evaporated from the condenser. At this temperature the vapor pressure of methanol is so low that no appreciable quantity of it could be lost. Also, there was always water present from the reaction in amount comparable to that of

---

[14] Wright, *Ind. Eng. Chem.*, *19,* 750 (1927).

[15] McKee and Burke [*Ind. Eng. Chem.*, *15,*788 (1923)] were able to determine the equilibrium between methanol and dimethyl ether using an Al_2O_3 catalyst at 350°; and Smith and Hawk [*J. Phys. Chem.*, 32,415 (1928)] showed that dimethyl ether is probably formed from methanol vapor at 1 atm. on chromium oxide catalysts. However, it is known that zinc oxide probably would give no appreciable quantities of ether at 300° [Adkins and Perkins, *J. Phys. Chem.*, 32, *221* (1928)]. Probably zinc oxide–chromium oxide catalysts which contain excess of zinc oxide would be relatively inactive also. If, as would be supposed in the absence of complete experimental information, the formation of the ether from methanol is a higher order reaction than is the formation of CO and H_2 from methanol, the rate of formation of ether from methanol at very low pressures would be negligible compared to the rate of formation of CO and H_2. Furthermore, dimethyl ether if it had been present would doubtless have disappeared during the removal of CO_2 from our condensed product as described below. At any rate, we showed by actual tests that dimethyl ether does not enter into the reaction we used to determine methanol. (Since this test for methanol is so sensitive, it is of course necessary to assure that the dimethyl ether used in the test does not contain traces of methanol.)

the methanol. Exactly 5 cc. of water was introduced into the condenser, which was then sealed, allowed to come to room temperature and shaken to dissolve the methanol into a uniform solution. The methanol in aliquot portions of these solutions was then determined, as described above.

Experiments showed that, with the type of liquid-air cooled receiver used, no methanol escaped even at much higher rates of gas flow than we had ever used in equilibrium measurements.

Since it soon became evident that the equilibrium decomposition of methanol at 304.4" was relatively far more than the expected 96.4%, it was necessary when working at atmospheric pressure to deal with rather small quantities of methanol. In spite of this, however, it was thought better to work at atmospheric pressure for the reasons mentioned and since the small quantities of methanol could nevertheless be determined accurately.

Experimental Results

The experimental results are presented in Tables I and II. In a single experiment a total gas volume of from 17 to 30 liters was passed over the catalyst. The methanol yields in Table I have been corrected, on the basis of the gas composition as given in Table II, for the volume of carbon dioxide caught in the liquid-air condensers. These yields are thus those which would be obtained from 1 cubic meter of a gas having the composition given in Table II. The analyses of the gas from different experiments were, within the limits of the error in gas analysis, not significantly different. We have thus preferred to use an average gas composition throughout. An uncertainty in the values of the equilibrium constants results from the gas analysis. The best results obtainable with this gas, using any standard method of gas analysis, may be uncertain to about 1% of the amount of carbon monoxide and about 0.5% of the amount of hydrogen. In the product $(CO)(H_2)^2$, and thus in the equilib-

rium constant, there may be introduced in this way an error of about 2%. Further, since the ordinary wet-test meter was used to measure the total gas volumes, an error of 2% or so may also be introduced on account of change in the vapor pressure of the water and change in level of the water in the meter with variations in the room temperature during the course of an experiment—about one week. The calibration of the meter was made at the rates of gas flow used in the equilibrium measurements and in a room where the temperature was usually nearly constant. Of course, there is also an error involved in assuming that all three gases obey the perfect gas law from room temperature to 300°. However, this error is doubtless inconsiderable. In further work it is planned to eliminate these uncertainties by constructing a special gas-analysis apparatus and using a better means of measuring the gas volumes.

It was found that evacuation of the catalysts, between experiments, considerably improved their activity, probably on account of the removal of the small amounts of carbon dioxide and water adsorbed during the reaction. The promoted catalyst did not seem to be as much affected by adsorbed carbon dioxide and water as did the pure zinc oxide catalyst. It is thought that since the catalyst used in experiment 5a was pure zinc oxide that had not recently been evacuated, the constant from this experiment is somewhat high. The last two pairs of experiments (Nos. 5 and 5a, 6 and 6a) were performed most carefully and obviously came closest to equilibrium. As the best value of K we take that from Expts. Nos. 6 and 6a—namely, 5.57×10^{-4} at 303.8°.

Although the rates of gas flow were very low, and perhaps in many cases unnecessarily so, the linear rate of gas flow through the small diameter tubing connecting the various units in the apparatus was great enough to avoid possible complications due to self-diffusion of the gases.

The values, in the last column of Table I, of the integration constant, I, of the free energy equation were obtained through use of the best available heat data as given by Smith.[16] The equation expressing the free energy change in the reaction $CO + 2H_2 = CH_3OH$ is, then, $\Delta F = -20{,}857 + 41.17T \log T - 0.01423T^2 - 54.42T$. The heat data would seem to be reliable, although they have been questioned.[8] This equation gives the standard free-energy change for this reaction as 16,070 cal. at 700° K., which may be compared with the value 8930 cal. used by Lewis and Frolich[17] in their paper giving the practical yields obtained in the methanol process. Our data give $K = 6.51 \times 10^{-4}$ at 300°; the equation given by Audibert and Raineau gives $K = 11.3 \times 10^{-4}$; Christiansen's data give 4.27×10^{-4}; and Kelley's data give 8.2×10^{-2}. If Audibert and Raineau's equation was derived from their work at high pressures and the

[16] Smith, *Ind. Eng. Chem.*, 19,801 (1927).

[17] Lewis and Frolich, *Ind. Eng. Chem.*, 20,285 (1928).

equilibrium constants calculated without the use of fugacities, their constants would come out too high. Christiansen's data are fairly close to ours. However, the difference between our data and the values calculated from Kelley's data is unaccountably large. Various possible explanations for this discrepancy have been considered, but so far no satisfactory explanation can be given. In further work we hope to obtain the equilibrium constant more accurately and at several temperatures and thus throw some light on the question.

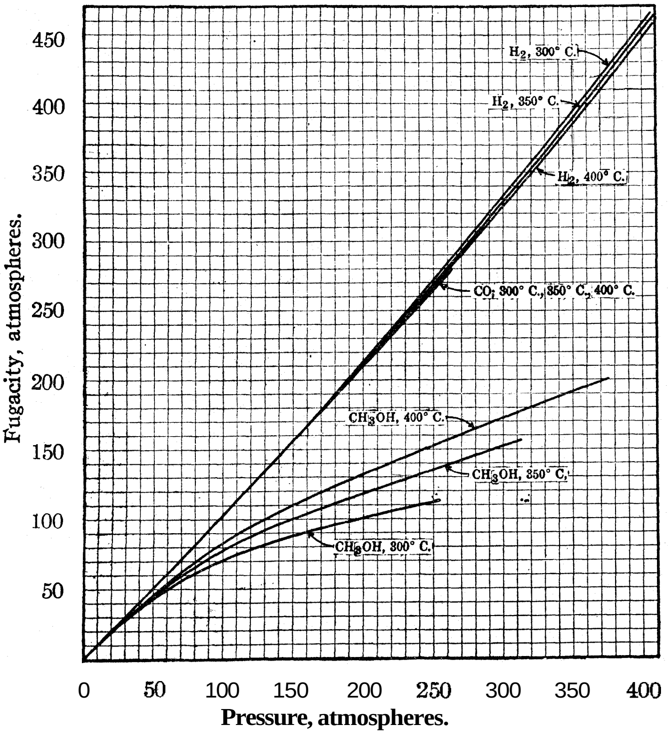

Fig. 2.—Fugacities of H_2, CO and CH_3OH.

It may be of interest to compare briefly our theoretical yields with the yields of methanol which have been obtained in the practical operation of the methanol process. In order to do this it is necessary first to estimate the fugacities of the three gases involved. The results of these calculations are presented in Fig. 2. The data for carbon monoxide were calculated from van der Waals' equation, with $a = 1.487 \times 10^6$ and $b = 39.87$, derived from compressibility data of Amagat[18] which are given up to 400 atm. at 20°. The data for hydrogen were derived, using the rule

---

[18] Amagat, *Ann. chim. phys.*, [6] **29**, 68 (1893).

of Lewis and Randall,[19] from compressibility data of Bartlett, which are given at intervals up to 1000 atm. at 300 and 400°.[20] The data for methanol were calculated from van der Waals' equation, with $a = 9.534 \times 10^6$ and $b = 76.06$, derived from compressibility data of Ramsay and Young[21] which are given up to 78 atm. at 240°. Although the fugacity data are admittedly rough, their use will give better results at high pressures than would the use of the pressures. The fugacities of hydrogen and of carbon monoxide are in general somewhat higher than the pressures

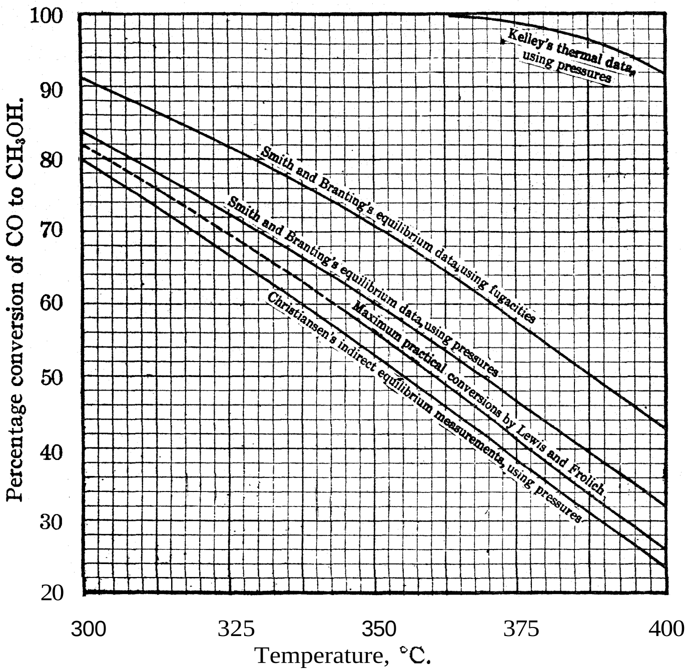

Fig. 3.—Comparison of conversions of CO to CH_3OH as calculated from thermodynamic data and as obtained practically, at several temperatures and at a total pressure of 204 atm. with a gas containing 26% of CO and 70% of H_2.

whereas the fugacities of the methanol are considerably lower than the pressures, as would be expected. This, in each case, results in larger practical yields of methanol than would be predicted from the pressures.

In Fig. 3 are presented comparisons of practical conversions of carbon monoxide to methanol, with the maximum possible conversions predicted

[21] *Ibid.*, p. 436.

from various thermodynamic data.[22] The practical yields are taken from Lewis and Frolich. It is seen from the figure that the practical conversions are definitely lower than those predicted from our data, irrespective of any reasonable assumptions as to the fugacities of the gases under these conditions. Lewis and Frolich state that their data at 300° are uncertain. Although it is not possible to draw from these comparisons any definite conclusions regarding the reliability of the thermodynamic data, the comparisons between the predictions from our data and the yields obtained at high pressures are as one would expect. A further comparison may be made between our $K = 2.07 \times 10^{-5}$ and the estimation of $K = 1.1 \times 10^{-5}$ at 400° made by Brown and Galloway[23] from their work on the production of methanol at 180 atm. pressure. It is to be noted in connection with the yields obtained by Lewis and Frolich that, if the gas composition of 26% of carbon monoxide and 70% of hydrogen refers to the original gas, the concentrations of reactants during reaction, especially at the higher temperatures, would be somewhat less because of side reactions. If this were taken into account, the practical yields would be somewhat closer to the theoretical. If the results of the high-pressure work can be relied upon, it would seem that the heat data we have used in the equation giving the temperature function of the free energy are not seriously in error, since the theoretical and experimental curves parallel each other between 300 and 400°.

The value of K we obtained at 304° would seem to have a maximum uncertainty of about 10%; the probable error is not more than about 5%.

Of course, before thermodynamic data can be accurately applied to high pressure work, it would be necessary to know the equations of state for the three gases involved, in mixtures of different compositions. However, the thermodynamic data here presented, together with estimated fugacities, will probably give results which, at present, are sufficient for all practical purposes. A more immediate interest in obtaining accurate thermodynamic data on this reaction at several temperatures would be to show wherein the error lies in the calculations from Kelley's data.

Summary

1. The equilibrium between methanol, carbon monoxide and hydrogen has been experimentally determined at 304° and a total pressure of 1 atmosphere, by a direct method.

2. The equilibrium constant, $K = CH_3OH/(CO)(H_2)^2$, is 5.57×10^{-4} at 303.8°, with a probable error of ± 5%. Calculations from Kelley's

---

[22] The practical conversions used are to be regarded as the maxima obtained in the particular tests referred to. There is no evidence from the curves of conversion against space–velocity, that these conversions are the maximum possible.

[23] Brown and Galloway. Ind. *Eng. Chem.*, **20**, 960 (1928).

low temperature specific heat measurements, extrapolated from room temperature with aid of the best available heat data, give a constant more than 100 times this value. Christiansen's indirect equilibrium measurements give a constant about 34% smaller than our value.

3. The equation for the standard free-energy change in the methanol reaction, derived from our equilibrium measurements and the best available heat data, is $\Delta F = -20{,}857 + 41.17T \log T - 0.01423T^2 - 54.42T$.

4. The yields of methanol at high pressures, as obtained practically and as predicted by our thermodynamic data, compare favorably.

CERIC SULFATE AS A VOLUMETRIC OXIDIZING AGENT. VIII. THE DETERMINATION OF CHROMIUM IN THE PRESENCE OF MANGANESE, IRON AND VANADIUM

BY H. H. WILLARD AND PHILENA YOUNG

RECEIVED AUGUST 27, 1928 PUBLISHED JANUARY 8, 1929

Introduction

The present volumetric methods for chromium depend upon its oxidation to the hexavalent form by an excess of some suitable reagent and its subsequent reduction, after removal of the excess oxidizing agent, by standard ferrous sulfate added either (1) directly to an end-point which may be determined either electrometrically, with diphenylamine or diphenylbenzidine[1] as internal indicator, or with ferricyanide as external indicator, or (2) in excess, the excess being determined by back titration with standard dichromate or permanganate. In the absence of oxidizing agents such as ferric iron, excess iodide may be used as the reducing agent, the iodine liberated being titrated with thiosulfate. A method using arsenite[2] and another with excess arsenite, followed by back titration with bromate have been described.[3] If persulfate in the presence of silver ions[4] is employed to oxidize the chromium, the excess is destroyed by boiling, and moderate amounts of manganese, converted into permanganate, are reduced to manganous salt by the addition of chloride ions and further boiling. If permanganate is the oxidizing agent, a filtration is always required. In certain cases oxidation is effected by per-

---

[1] The authors have described the use of diphenylbenzidine as an indicator in the titration of chromic plus vanadic acids with ferrous sulfate, Willard and Young, *Ind. Eng. Chem.*, 20,769 (1928). The results using this indicator are the same when chromic acid alone is titrated with ferrous sulfate.

oxide in alkaline solution.[5] Thus it is seen that all of the methods in use require considerable time to remove the excess of oxidizing agent, and the presence of manganese always lengthens the time for an analysis.

A more rapid volumetric method for chromium, and one in which large amounts of manganese cause no interference or delay, is, therefore, highly desirable. The present paper describes such a method in three different modifications: in one case the chromium is oxidized by a measured excess of standard ceric sulfate, the excess being titrated differentially in the presence of chromic acid with standard sodium nitrite or oxalate; in the second method the chromium is oxidized by excess ceric sulfate, nitrite added in slight excess to destroy the ceric salt, then urea to remove all nitrite, after which the chromic acid is titrated with standard ferrous sulfate; in the third method the chromium is oxidized by excess ceric sulfate, sodium azide added in excess to destroy the ceric salt and the chromic acid titrated with standard ferrous sulfate. In all three procedures iron may be present and also vanadium. With the latter element the sum of chromium and vanadium is determined, but it is possible to obtain the percentage of vanadium later with the same solution.

Experimental

In the experimental work chromium was used in the form of a potassium chrome alum solution standardized by the persulfate method, vanadium as vanadyl sulfate and manganese as manganese sulfate. The ceric sulfate solution was that prepared for earlier work[6] and was 0.5 M in sulfuric acid. It was standardized against sodium oxalate.[6] The sodium nitrite,' ferrous sulfate[6] and vanadyl sulfate[8] solutions were standardized against ceric sulfate of known strength.

Preliminary experiments showed that the direct titration of chromic salt in hot solution with ceric sulfate was not possible although the oxidation is more rapid than with any other oxidizing agent. With an excess of ceric salt the oxidation of chromium was very rapid in hot solution. Before this reaction could be studied, a method for removing the excess of ceric salt had to be devised.

A number of reducing agents were tested for their differential possibilities by titrating with them 200 cc. of solution containing 20 cc. of 0.1 *N* ceric sulfate, 100 mg. of chromium as potassium dichromate, 0–40 mg. of

vanadium as ammonium vanadate and varying amounts of acid. Using sodium nitrite[7] the reduction of ceric sulfate was selective in the presence of 5–10 cc, of concd. nitric, sulfuric or perchloric acid. The temperature of the solution during titration was held between 50 and 60°. The reaction at the end-point was a little slow but satisfactory and the break in potential averaged 150–200 mv. per 0.05 cc. of 0.1 *N* sodium nitrite. Using sodium oxalate the reduction was selective with 2–5 cc. of concd. sulfuric acid or 5–20 cc. of concd. nitric or perchloric acid per 200 cc. The temperature during titration was 70–80°, the reaction at the end-point about as rapid as with nitrite and the break in potential from 100–150 mv. per 0.05 cc. of 0.1 *N* oxalate. Experiments using either hydrogen peroxide or ferrous sulfate as the reducing agent were not successful.

Oxidation of Chromium with Ceric Salt

A. Use of Standard Ceric Sulfate and Titration of the Excess with Standard Sodium Nitrite.—To measured portions of a standard solution of potassium chrome alum were added the indicated volumes of acid and standard ceric sulfate. The volume of the solution at the time of oxidation and the temperature maintained during the oxidation process are shown in Table **I.** After the oxidation the solution was diluted to 200 cc. and the excess ceric sulfate titrated electrometrically at 50–GO° with standard sodium nitrite added from a buret with the tip beneath the surface of the liquid.

[b] Solution heated to 100° and titrated at once.

Forty cc. of ceric sulfate for 45–46 mg. of chromium represents 12 cc. excess of oxidizing agent. The first four experiments show that the rate of oxidation of the chromium increases with the volume of ceric salt used. It is also seen that the oxidation proceeds more quickly in nitric or perchloric acid than in sulfuric acid solution. Variations in acid, volume of solution at time of oxidation and amount of chromium did not alter the accuracy of the method. Other experiments in which as much as 2 g. of iron or 24 mg. of vanadium or both were added were entirely satisfactory. In the presence of iron the reaction with nitrite was somewhat slower, although not more than ten to fifteen minutes was required for a titration and the break in potential was smaller, while in the presence of vanadium the ceric salt used for the oxidation gave accurately the vanadium plus chromium content of the solution. In all later experiments the procedure of oxidizing the chromium with the ceric salt in a volume of 150 cc. by heating to 100° was adopted. If there was no nitric acid present, the solution was allowed to stand for three to five minutes before diluting it to 300 cc. and titrating with nitrite (this dilution gave the correct temperature for the nitrite titration). Such a procedure for chromium is obviously much more rapid than any in use at the present time.

Stability of Nitrite Solution

The supply of 0.1 N sodium nitrite which was used over a period of five weeks remained constant in normality within less than one part in a thousand, even though the stock bottle was opened a number of times during this interval and no precautions were taken to exclude air. Thus nitrite has a decided advantage in this respect over a number of reducing agents.

B. Use of Standard Ceric Sulfate and Titration of the Excess with Standard Sodium Oxalate.—Solutions in which the oxidation of the chromium was carried out exactly as indicated in Table I were titrated electrometrically at 70–80° with standard sodium oxalate. These titrations were slightly more rapid than the nitrite reaction provided that iron was absent. Satisfactory results were obtained in the presence of as much as 1 g. of iron but with larger amounts the nitrite titration is to be preferred. Since sodium nitrite solution, however, is more stable than oxalate, it was used in the greater part of the later work.

C. Use of Ceric Sulfate, Removal of the Excess with Nitrite Followed by Urea and Titration of Chromic Acid with Standard Ferrous Sulfate.—Acid solutions of chromic salt similar to those described in Table I were prepared and the chromium oxidized in hot solution with an excess of ceric salt. After cooling to room temperature nitrite was added, from 5 to 15 cc. more than that required to destroy all ceric sulfate, followed at once by urea to remove excess nitrite. After the addition of 25 cc. of sulfuric acid, sp. gr. 1.5, the chromic acid was titrated electrometrically with standard ferrous sulfate. The results for chromium were always low, the error varying from 0.1–1.5 mg. according as 5 to 15 cc. excess of nitrite had been used. It seemed probable, therefore, that quantitative results could be obtained if the volume of nitrite was controlled more accurately. It was found that an excess of 0.25–0.50 cc. gave no trouble and the error with 1.0 cc. was very slight, provided always that any excess of nitrite was removed at once with urea. Results were identical whether the nitrite was added to the solution at room temperature or at 50–60°. In the method finally adopted the chromium was oxidized in hot solution in a volume of 150 cc., the solution diluted to 300 cc., 0.1 *N* sodium nitrite added in rapid drops until the potential indicated that an excess was present, followed at once by 0.2–0.3 g. of urea. After adding sulfuric acid the solution was titrated with standard ferrous sulfate. Results obtained from a number of experiments are given later in Table II.

Effect of the Presence of Manganese. Nitrite Method

Preliminary experiments showed that a manganous salt is oxidized to a considerable extent in acid solution by ceric sulfate with the formation of permanganate, which changes to manganese dioxide if much manganese or nitric acid is present or if the solution is heated. It was also noticed that nitrite is very effective in dissolving manganese dioxide in acid solution. Solutions similar to those used in Table I, containing also varying amounts of manganese, were oxidized in a volume of 150 cc. with ceric salt. During the heating the permanganate color disappeared but a precipitate was not formed unless nitric acid was present, the manganese content high or the chromium content low. It appeared as if some of the manganese was oxidized first by the ceric salt to permanganate, which was effective in oxidizing chromium. The hot solution was diluted to 300 cc. and treated at once with excess nitrite followed by urea, as described in the preceding paragraph. After the addition of sulfuric acid, the chromic acid was titrated electrometrically with 0.1 N ferrous sulfate. Forty cc. of 0.1 N ceric sulfate, an approximately 10 cc. excess, was used for the oxidation. Results are given in Table II.

In experiments in which a precipitate of manganese dioxide was formed, the nitrite had to be added slowly, drop by drop, especially if a nitric acid solution was used or much iron was present, to avoid an excess of nitrite at any time. The end-point was reached directly after the solution had cleared. If no MnO_2 was present the nitrite could be added in much more rapid drops. The total time required for the determination of chromium by either method was seldom more than twenty minutes. Results were most satisfactory in perchloric and in sulfuric acid solutions, and only slightly less satisfactory in the sulfuric acid solutions containing nitric acid. With nitric acid alone quantitative results were obtained but the reduction of the MnO_2 was quite slow. The experiments also show that

the reducing action of the nitrite on the chromic acid becomes evident with a large excess of nitrite or with high acid concentration. It is seen that ferric salts are effective in preventing the formation of MnO_2. One extremely important point is that this procedure for chromium is accurate and simple, even in the presence of as much as 100 mg. of manganese.

Since the action between nitrite and MnO_2 is quite rapid in many instances, the possibility of a direct titration with standard nitrite was investigated. Solutions prepared and oxidized as in Table II were **used.** Representative results are shown in Table III.

Sulfuric or sulfuric and nitric acid solutions were most satisfactory, nitric acid solutions least so. Perchloric acid solutions were satisfactory in the absence of iron. With no MnO_2 precipitate the reaction between ceric salt and nitrite was rapid; otherwise, the precaution of adding the nitrite quite slowly to avoid any excess during the titration had to be taken. Even then a titration always required less than ten minutes if a sulfuric or sulfuric and nitric acid solution was used.

Effect of the Presence of Manganese. Oxalate Method

It was found that the direct titration of excess ceric sulfate with oxalate in the presence of MnO_2 precipitate after a chromium oxidation was slightly more rapid than the nitrite titration, In the oxalate method results accurate to a few hundredths of a milligram of chromium were always obtained in solutions containing 5–20 cc. of concd. nitric acid, 5–15 cc. of perchloric acid or 2 cc. of concd. sulfuric plus 5 cc. of concd. nitric acid per 200 cc., the titrations being made at 70–80°. In a sulfuric acid solution the reaction was quantitative but much slower, as was to be expected from earlier work.[6] The results were quantitative with as much as 40 mg. of manganese in the nitric acid solutions, or with 50 mg. of manganese in the perchloric or nitric plus sulfuric acid solutions. When the manganese precipitated out during the oxidation process, the oxalate was added in rather slow drops. The results were satisfactory in the presence of 1 g. of iron, but with more iron the titration became very slow.

Sodium Azide Method

Since hydrazoic acid may be determined by oxidation to nitrogen with excess ceric salt: it seemed important to test the differential possibilities of this reagent for reducing ceric sulfate in the presence of chromic acid. In preliminary experiments 25 cc. of 0.1 N potassium dichromate was diluted with 10 cc. of sulfuric acid (sp. gr., 1.5) and water to a volume of 300 cc. Five to twenty cc. of 0.1 M sodium azide was added and the solution allowed to stand for thirty minutes before titration of the chromic acid with ferrous sulfate. A blank varying from —0.44 to —0.55 cc. was obtained, indicating slight reduction of the chromic acid by the hydrazoic acid. It was thought that some stronger reducing agent in the commercial sodium azide might be causing the trouble, though the blank varied only slightly when the azide content was changed from 5 to 20 cc. One portion of azide solution was purified by acidifying and distilling the hydrazoic acid into sodium hydroxide solution; another portion by acidifying, adding enough dichromate to destroy any stronger reducing agent present and to react with about 10% of the hydrazoic acid and distilling into sodium hydroxide. After adjustment to 0.1 M, 20 cc. portions of these two solutions were tested for their action on dichromate, using the procedure described above. The blank in each case was —0.56 cc. Therefore nothing was accomplished by purifying the azide.

Experiments were then made involving the oxidation of a standard chromic salt solution with excess ceric sulfate, addition of excess azide and titration of the chromic acid electrometrically with standard ferrous sulfate. The oxidation procedure already described was used. After oxidation the solution was diluted to 300 cc., cooled to 35–40°, the amount of azide indicated in Table IV added (a solution of the commercial salt was used) and the solution allowed to stand for the given time. Twenty to 25 cc. of sulfuric acid (sp. gr., 1.5) was added and the chromic acid titrated. In the results given under the column "Cr found" in Table IV,

a correction of +0.2 mg. of chromium has been added in every experiment, as an absolute error of this magnitude was always evident.

The hydrazoic acid acts more slowly on the manganese dioxide than either nitrite or oxalate. Six to eight minutes was always sufficient, however, to dissolve a heavy precipitate. Expts. 10 and 11 indicate that the azide may be added at a higher temperature without causing reduction of the chromic acid. In this warmer solution the effect of the hydrazoic acid may be unpleasant to some persons. If such experiments are conducted in a hood or the solution cooled to 35–40° before the azide is added, the odor of the acid is hardly noticeable. The tendency for the results to be uniformly low by 0.2 mg. of chromium might indicate slight reduction of chromic acid, but the constancy of this error with variation in the amounts of chromium and azide used and in the time the azide acts is difficult to explain. The fact that an error of less than 1 mg. of chromium is caused by leaving the hydrazoic acid in contact with the chromic acid for twelve hours shows that commercial sodium azide is an ideal substance for removing excess of ceric salt after a chromium oxidation. The method is rapid in the presence of large amounts of manganese.

A thermionic voltmeter, Type DP-2, purchased from the General Electric Company was used for the titrations described in this paper The instrument has infinite resistance and can therefore be connected directly to the platinum and silver chloride electrodes throughout a titration without danger of polarization. This makes unnecessary the use of a galvanometer or potentiometer and a continuous reading of the potential is obtained.

Use of Indicator

After the excess of ceric sulfate has been reduced by a very slight excess of nitrite, and the latter destroyed by urea, the chromic acid may be titrated with ferrous sulfate, using about 0.3 cc. of 0.1% diphenylbenzidine or diphenylamine as indicator. Five to 10 cc. of phosphoric acid (85%) must be added and if the solution contains 2 cc. of concd. sulfuric acid in 200 cc. the end-point is sharp and cerous phosphate precipitates so slowly that the solution is hardly opalescent when the titration is finished. If 4 cc. of sulfuric acid is present, the end-point is less distinct but still fairly good. Cerous phosphate does not precipitate at all under these conditions. With more acid the end-point becomes very poor. If too much sulfuric acid is present, a suitable amount of sodium phosphate may be added.

The indicator method has no advantage over the electrometric, because in any case the latter is required to determine the amount of nitrite to be added.

When sodium azide is used to reduce the excess of ceric salt, the color of the indicator is so weakened that a satisfactory titration is impossible.

The application of the methods described above to the rapid determination of chromium in steel will be made the subject of a subsequent paper.

Summary

1. A volumetric method for chromium, more rapid than any in use, has been developed. The chromium is oxidized with excess ceric salt, three possibilities in procedure being described: (u) oxidation with a measured excess of standard ceric sulfate, the excess being titrated differentially in the presence of chromic acid with standard sodium nitrite or oxalate; (b) oxidation with excess ceric sulfate, addition of nitrite in slight excess to destroy the ceric sulfate, followed by urea to remove all nitrate, after which the chromic acid is titrated with standard ferrous sulfate; (*c*) oxidation with excess ceric sulfate, the excess being removed with sodium azide, and the chromic acid titrated with standard ferrous sulfate. The excess of nitrite must be small and the time of action short, while with azide a large excess acting for a considerable time has no reducing action on the chromium.

2. Iron does not interfere. If vanadium is present, the sum of the chromium and vanadium is determined.

3. The method is equally applicable and rapid in the presence of large amounts of manganese. Even though some of the latter may precipitate as manganese dioxide during the oxidation, it is readily dissolved by the reducing agent.

4. Diphenylbenzidine or diphenylamine may be used as indicator in method (b) but not in (c).

CERIC SULFATE AS A VOLUMETRIC OXIDIZING AGENT. IX. PREPARATION AND STABILITY OF SOLUTIONS

BY H. H. WILLARD AND PHILENA YOUNG

RECEIVED AUGUST 27, 1928 PUBLISHED JANUARY 8, 1929

Introduction

The method used by the authors to purify U. S. P. cerous oxalate and to prepare a large supply of ceric sulfate has been described in the first paper in this series.[1] Prom subsequent work,[2] especially from that dealing with the determination of vanadium and of chromium, it seemed important to investigate more thoroughly the grades of ceric oxide available in order to find the most convenient and inexpensive materials for use. Information concerning the stability of ceric sulfate solutions has also been obtained.

---

[1] Willard and Young, THIS JOURNAL, 50, 1322 (1928).

[2] Willard and Young, *ibid.*, 50, 1334, 1368, 1372, 1379 (1928); 51, 139 (1929); *Ind. Eng. Chem.*, 20, 972 (1928).

Experimental

Solutions were prepared from four samples of ceric oxide kindly furnished by Dr. H. S. Miner of the Welsbach Company of Gloucester, New Jersey. The approximate amount of the oxide required for a liter of 0.1 N solution was taken, treated with sufficient sulfuric acid of the density indicated in Table I to make the final solution 0.5 or 1 *M* in sulfuric acid and the paste heated at the proper temperature until the conversion into ceric sulfate appeared complete. This material, when cool, was added to about 500 cc. of water, the liquid heated to 70–80° and filtered. The normality of the solution was determined with standard ferrous sulfate, and from this factor the weight of material required for a liter of 0.1 N solution was calculated as well as the cost of the ceric oxide for a liter of such a solution, based on the price per 500 g. In large quantities the cost would be 20–30% less.

TABLE I

PREPARATION AND COST OF CERIC SULPATE SOLUTIONS

	Material	Sp. gr. of H_2SO_4 used	H_2SO_4 in the $Ce(SO_4)_2$ soln., molar	G. of oxide per liter of 0.1 *N* soln.	Cost of oxide per liter of 0.1 *N* soln. based on price per 500 g.
1	High grade, anhydrous	1.83	0.5	19.2	$0.17
		1.83	1.0	18.9	.17
2	High grade, hydrated	1.5	0.5	22.5	.15
		1.5	1.0	22.3	.15
		1.3	0.5	24.0	.16
3	Commercial, hydrated	1.5	.5	46.9	.05
		1.3	.5	47.3	.05
4	Commercial, anhydrous	1.5	.5	57.9	.10

With Material 1, a temperature of 150–160° was maintained for a half hour to convert the oxide into sulfate. A small amount of the oxide was not attacked. Sample 2 was converted very rapidly by dilute sulfuric acid into ceric sulfate, a temperature of 130–135° being required with acid of sp. gr. 1.5 and 105–110° with acid of sp. gr. 1.3. The ceric sulfate in the former case dissolved in water to give an almost clear solution; in the latter case there was a small amount of unattacked oxide. Sample 3, when treated with acid of sp. gr. 1.5, was heated to 120–125°, and to 110° if treated with acid of sp. gr. 1.3. Sample 4, the commercial anhydrous material, was not satisfactory. The commercial hydrated oxide contained iron and phosphate and a considerable amount of precipitate settled out in solutions prepared from it. The solution decanted from this precipitate was found entirely satisfactory for chromium determinations[2] in which an excess of ceric sulfate was used as the oxidizing agent, the excess being destroyed by sodium azide or by sodium nitrite followed by urea[2] before the titration of the chromic acid with ferrous sulfate. Since the oxide for a liter of such a solution costs only four or five cents, depending upon whether the price per one-half kilo or per fifty kilos of oxide is used, the cost of the reagent for a single chromium determination is very small. There seems to be no reason why this commercial hydrated material cannot be used in all the methods described by the authors[1,2] except in the case of the titration of iodide where the ferric salt might cause trouble. Even when the high grade, hydrated oxide is used, the cost of the reagent is not excessive, being only ten to fifteen cents per liter, depending on the quantity of material purchased.

Stability of Ceric Sulfate Solutions

Furman has given data over a period of twelve weeks on the stability of ceric sulfate solutions containing free sulfuric acid.[3] Table II contains data over a longer period obtained by the authors on four different solutions.

TABLE II

STABILITY OF CERIC SULFATE SOLUTIONS OVER AN EXTENDED PERIOD

Time, weeks	Normality I	II	III	IV
0	0.09493	0.1043	0.05012	0.09410
10	.09488	.1042	.05009	....
16	....	...	,04996	....
20	.09497	...	....	....
27	.09480	...	....	....
33	....	.1044	....	,09400
40	....	.1042	....	....

Solutions I and III were 0.5 M in sulfuric acid, II and IV, 1.0 *M*. Twenty liters each of I and II and 2 liters of III were prepared, and the stock bottles were opened a number of times during the periods indicated. Only with Solution IV is the normality expressed in terms of weight normality. The values for this solution are the most accurate indication of the stability of ceric sulfate, for the portion tested after a 33-week interval had been standing during that time in a sealed flask in a well lighted room. These data indicate that ceric sulfate solutions are far more stable than perrnanganate solutions, the latter oxidizing agent being the only one which is of the same relative oxidizing power as ceric sulfate.

A number of experiments were made to test the stability of ceric sulfate solutions on boiling. In each case 25 cc. of 0.1 N solution was diluted with acid and water to a volume of 100 cc. This solution was boiled gently under a reflux condenser for the stated time, cooled to room temperature and titrated electrometrically with standard ferrous sulfate. The values for the normality after such treatment are given in Table III.

These results show that ceric sulfate solutions containing free sulfuric

	20	5	.09322
HNO_3, sp. gr., 1.42	10	1	.09111
	5 + 10 cc. H_2SO_4 (sp. gr., 1.5)	1	.09328
	10 + 10 cc. H_2SO_4 (sp. gr., 1.5)	1	.09288
$HClO_4$, 70%	5 + 10 cc. H_2SO_4 (sp. gr., 1.5)	1	.09322
	10 + 10 cc. H_2SO_4 (sp. gr., 1.5)	1	.09310

acid, or sulfuric acid with moderate amounts of nitric or perchloric acid, are extremely stable toward heat. Such solutions, because of their strong oxidizing power, great stability, utility in a hydrochloric acid solution,[1] ease of preparation and small cost, should find extensive use in analytical work.

Summary

1. The types of ceric oxide available for the preparation of ceric sulfate have been investigated. A high grade, hydrated material supplied by the Welsbach Company meets the most exacting requirements, but the commercial, hydrated product is satisfactory in nearly all cases.

2. The cost of such solutions has been shown to be very small, that of the oxide for a liter of 0.1 N solution from the high grade, hydrated material being ten to fifteen cents, and from the commercial, hydrated material four to five cents.

3. The normality of a ceric sulfate solution containing free sulfuric acid has been found to be practically constant over a period of forty weeks. Such a solution is not sensitive to light or air.

4. The normality of a ceric sulfate solution containing free sulfuric acid, or sulfuric acid with a little nitric or perchloric acid, is not changed by boiling the solution for an hour or longer, but the solution loses oxygen if a high concentration of either of the two latter acids is present.

INVESTIGATION OF SURFACE TENSION CONSTANTS IN AN HOMOLOGOUS SERIES FROM THE POINT OF VIEW OF SURFACE ORIENTATION

BY K. W. HUNTEN AND O. MAASS

RECEIVED SEPTEMBER 10, 1928 PUBLISHED JANUARY 8, 1929

Investigations of surface energy temperature coefficients have shown that for some substances high abnormal values of the Ramsay-Shields constant are obtained. These abnormalities cannot be explained by dissociation. Ramsay and Miss Aston[1] noticed that the constant increases with the number of CH_2 groups in the molecule. Miss Homfray and Guye[2] found for amyl stearate the high value of **3.34,** and similar cases multiplied in number rapidly. Walden and Swinne[3] gave an empirical relation by which they claimed that the Ramsay-Shields constant, K, could be calculated approximately, $K_e = 1.90 + 0.011\ (nA)$, where nA is the sum of the square roots of the atomic weights of the elements in the compound. Each atomic weight is multiplied by the corresponding subscript as given by the formula for the compound.

Just as Ramsay and Shields chose a molecular weight larger than the theoretical in order to account for a low value of their constant, so a high value might be explained by assuming dissociation, for in that case the proper value could be obtained by choosing a molecular weight smaller than the normal. This explanation, which was suggested by Miss Homfray and Guye, is possibly the true one for some cases, but it does not appear reasonable to apply it to a great many others in which dissociation is most unlikely. In this paper, work is described, the incentive of which was to show that high values might possibly be explained in another way. In this proposed explanation it is assumed that there are too many molecules in the molecular surface when the latter is calculated by using the normal molecular volume, but the presence of these extra molecules is ascribed to a cause other than dissociation, namely, orientation. If the axes of the surface molecules are, on the average, perpendicular to the surface, each one effectively occupies a smaller area than it would if it were not so orientated, with the result that a greater number can crowd into a given area.

An homologous series is best suited for an examination of orientation, and for this purpose the fatty acids were chosen, since their orientation in surface films has been so definitely established by the work of Langmuir[4]

and Adam.[5] Altogether, ten acids were examined and, for comparison, a saturated hydrocarbon, dicetyl. The purification of the compounds used is described, then the method of measuring the surface tensions. The data obtained are tabulated and then discussed from the point of view of the orientation theory.

Purification of Compounds

Propionic Acid.—A specimen of Kahlbaum's acid was purified by crystallization. The procedure consisted in cooling the acid in a flask until crystallization started and then maintaining the temperature of the bath just below the freezing point.[6] The crystals grew slowly and when three-quarters of the liquid had solidified the remainder was rejected. The solid was allowed to warm up until a little melted and this liquid was shaken to wash the crystals and also rejected. The remainder was allowed to melt and was put through the same cycle. This was repeated until a constant melting point was obtained for three successive crystallizations. In all twelve crystallizations were carried out.

The criterion for the melting point was chosen as the condition where a sample two centimeters long in a sealed melting-point tube froze completely within one-tenth of a degree. Great care and patience were exercised in the melting-point determination, as the time required for equilibrium to be established between solid and liquid is long; −22.4" was found to be the melting point after each of the last three crystallizations.

The butyric acid was found to contain acetic acid as an impurity. It was therefore fractionated five times at atmospheric pressure. The fraction boiling between 160 and 163" was converted into the calcium salt by the addition of milk of lime. The solution was evaporated down and the calcium butyrate was filtered out while hot, since, unlike calcium acetate, it is less soluble in hot than in cold water. The salt was crystallized again and butyric acid was liberated by the addition of hydrochloric acid, slightly less than the theoretical quantity calculated on the basis of the calcium butyrate. The mixture was allowed to separate into two layers and the butyric acid removed with a pipet. It was then distilled in a Pyrex apparatus with joints all glass-sealed as far as the receiver. A small amount of aqueous solution came over at a little above 100°. The temperature then rose rapidly to 161.4" and nearly the whole of the acid distilled within 0.9°.

The portion of acid boiling over the 0.9° range was next distilled under reduced pressure in an apparatus which consisted of three bulbs sealed to a mercury pump. One of the bulbs was the tube in which the surface tension was to be measured. The acid, about 25 cc., was frozen in one bulb while the apparatus was evacuated as thoroughly as possible. A small amount (10 to 15 cc.) was then distilled into the third bulb, which was immediately sealed off. The second portion was distilled into the surface tension tube, which in turn was sealed off. The third fraction was used for the determination of the density.

Caproic, caprylic and capric acids were obtained from the Eastman Kodak Company. They were purified in much the same manner as was propionic acid. The whole of the purified substance chosen froze over a range of not more than 0.2 or 0.3°.

Lauric, myristic, palmitic, margaric and stearic acids were Kahlbaum's acids purified by crystallization from 95% alcohol until the melting point was constant. For instance, the stearic acid used was a specimen which was crystallized fifteen times.

[6] Maass and Wright. THIS JOURNAL, 43,1098 (1921).

The hydrocarbon dicetyl, or ditriacontane, was obtained through the kindness of Dr. R. F. Ruttan. It was crystallized from alcohol in order to get a solution which could easily be filtered from suspended impurities and then recrystallized several times from ether.

Measurement of Surface Tension.—The surface tensions were measured by the capillary rise method. The temperature bath was a 2-liter beaker of glycerin. Vigorous circulation of the glycerin was maintained by motor-driven stirrers of the propeller type. The temperature was regulated by hand, by means of a gas burner, and it was possible, by means of an auxiliary jet, to keep the temperature constant to within 0.2° over any desired length of time. All of the thermometry involved, except at temperatures below zero, was carried out by means of thermometers for which certificates of calibration of the Reichsanstalt were available. The accuracy is of the order of 0.2° absolute.

Measurements were made on each substance from the melting point up to about 150°. In the case of propionic acid the observations were continued down to the limit of supercooling, and the properties calculated were found to be continuous down to this temperature.

The tube in which the surface tensions were measured was of the type used by Richards,[7] with this modification, that millimeter scales were etched on the two arms of the tube so that the height of a column of liquid could be read directly to 0.1 mm. The capillary was kept vertical by the use of two plumb-lines. The tube was calibrated by making use of Richards' very accurate determination of the surface tension of benzene.

The readings were always taken with a falling meniscus. If necessary the tube was tilted for a moment in order that the liquid might rise, and then fall to its equilibrium position. A reading was not recorded until the top of the column had been stationary for some minutes.

In the case of margaric acid a series of readings was taken both with rising and with falling meniscus, in order to see how much difference there would be. It was found that the two readings differed by as much as 1.7 mm. near the melting point, and did not coincide until the temperature reached 170°; also that those taken with an ascending column did not lie on as smooth a curve as did the others. The descending values give correct results, as a rising column is apt to create an angle of contact due to the viscosity of the liquid. Since margaric acid gave a greater difference between the two values than did any of the others, and since it was the only one of the higher acids examined that contained an odd number of carbon atoms, it was thought of interest to measure its viscosity. The viscosity results are discussed later.

The butyric acid was distilled into the tube as described above. Of the other acids those which are liquid at ordinary temperatures were

---

poured in through a funnel. In the case of the solid compounds, the tube was put into a steam-jacket and the substance was melted in a specially constructed funnel. In every case the tube was supported at such an angle that the desired amount of melted acid could be introduced without any entering the capillary. The whole apparatus was allowed to cool without being disturbed until the substance had become solid, when the tube could be handled freely. The tube was sealed to a mercury pump and exhausted. It was attached to the pump in the same inclined position as before, in order that, after a preliminary exhaustion, the substance might be melted again by means of a hot water-bath, while under vacuum. After the tube was cool, it was again exhausted and then sealed off. When everything was ready for a series of readings, the substance was entirely melted and then allowed to run into the capillary. These precautions were taken in order to have a fresh surface, as any traces of impurity are likely to collect in the surface after a time and change the surface tension.

Measurement of Density.—The densities, which are required in the calculations, were all measured over the necessary temperature ranges. A dilatometer with a bulb of about 2.5 cc. capacity was used. A millimeter scale was etched on the stem. Known weights of water were weighed with the bulb, and the volume was plotted against scale reading. The volume occupied by any substance under examination could then be read from the curve. Weighings were corrected for air displaced and allowance was made for the expansion (or contraction) of the bulb at temperatures differing from that at which the calibration was carried out. In the case of propionic acid special precautions, as described by Maass and Wright, were taken on account of the volatility of the substance.

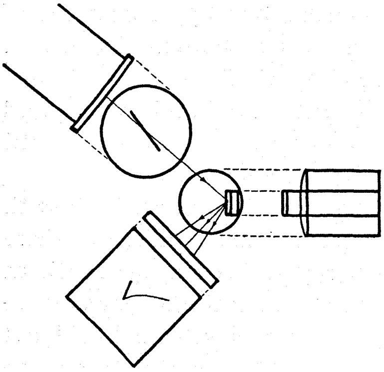

Fig. 1.

Angle of Contact.—It is commonly held that many substances make zero angle of contact with glass, but this cannot be assumed without some verification as the capillary rise method can only be used if such is the case. Specimens of the substances dealt with were examined by the optical method originated by Richards and Carver.[8]

The apparatus is illustrated diagrammatically in Pig. 1. The method consists in directing a slit-shaped beam of light rays upon the junction of solid and liquid surfaces in such a way that the reflected rays may be caught upon a screen. The diagram shows the collimator, the screen

---

[8] Richards and Carver, This Journal, 43,827 (1921).

and the cell containing the liquid. For visual observation a ground-glass plate is used; for more minute examination and for xecording, a photographic plate is substituted for the ground glass. The experiments were carried out in a dark room which itself served as a camera, and the back of an ordinary camera was held in clamps as near as possible to the cell containing the liquid. After the desired image was obtained on the ground glass, the latter was swung aside and the plate-holder was slipped in, exactly as in the regular method of manipulation of a camera. The room was then darkened, the plate was uncovered and the beam of light was turned on for the length of time required for the exposure.

The cell in which the liquid was contained was merely one-half to three-quarter of an inch of test-tube with the bottom flattened. A slip of plate glass about one and one-half inches long stood in the liquid in the cell. The latter was filled over-full, so that the junction between the liquid and the plate glass was not obscured by the wall of the cell. For the same reason it was found best to have both the collimator and the screen tilted toward the cell, so that the actual path of the rays was downward and then up again. This could not be easily shown in the diagram.

It was necessary to have the glass slip absolutely clean. Before it was used, it was cleaned with hot sulfuric acid and bichromate, if necessary, until when it was washed with distilled water and allowed to drain, interference colors would appear in the film of water upon the surface.

In the examination of the higher melting substances (60–70°) it was necessary to use a diminutive electrical heater made by rolling up asbestos paper and nichrome wire with a hollow in the middle in which the cell could be placed. The whole was not more than two inches in diameter, and could be held by a clamp in any position desired. The current was regulated by lamps. One 16-c. p. carbon lamp in series with the heater was suitable in nearly all cases. If the cell was allowed to become too hot the substance would vaporize a little and condense on the upper part of the glass slip which was, of course, comparatively cold, and spoil the photograph.

Richards and Carver placed their cell in a box, the atmosphere in which was kept saturated with the vapor of the substance in question by a dish of the warm liquid. It was not deemed necessary to take this precaution in the present work because the liquids were examined at temperatures but little above the melting point. Even in case of liquids like octane and propionic acid, which were the most volatile ones of which photographs were taken, there was no evidence of evaporation from the edge of the film at ordinary temperatures.

Not only fatty acids but also a few related compounds and a few quite unrelated ones were examined. The degree of difficulty experienced in obtaining the continuous surface may be roughly given as follows: lower fatty acids, water, lower saturated hydrocarbons, higher fatty acids, higher saturated hydrocarbons except paraffin wax, hexadecylene (the only unsaturated hydrocarbon examined), concentrated sulfuric acid, glycerol, paraffin wax.

The end desired was achieved, namely, to show that the surface tension measurements made on the fatty acids were not vitiated by the existence of a finite angle of contact.

Viscosity.—As was mentioned above, it was deemed advisable to measure the viscosity of margaric acid in relation to that of its neighbors in the series. Accordingly the viscosities of palmitic, margaric and stearic acids were measured over a range of temperature.

The viscosities were measured in the same tube as was used for surface tension, which had a 2-cc. bulb just above the capillary. To provide a means of drawing the liquid into the upper bulb, a small tube bearing a cork was plugged into the main tube of the viscosimeter just below the side arm. The narrow tube passed up through a T-tube and was continued to a safe distance away from the vapors of the bath. The T-tube was connected to the top of the viscosimeter by a short length of wide rubber tubing and the top of the T was made air tight by a rubber sleeve through which the small tube could be moved up or down. By applying suction to the side arm of the T, the liquid could be pulled up. Before it passed the upper mark on the way down, the small tube bearing the plug was pulled above the side arm of the viscosimeter in order to allow the air pressure to be the same on both sides. The tube was calibrated at 30.3° with water according to the method described by Maass and Boomer.[9]

The values obtained for the absolute viscosities are given in the following table.

TABLE I

RESULTS OF VISCOSITY DETERMINATIONS

Palmitic acid		Margaric acid		Stearic acid	
Temp., °C.	Viscosity, millipoises	Temp., °C.	Viscosity, millipoises	Temp., °C.	Viscosity, millipoises
74.0	71.7	67.6	92.6	100.7	45.6
91.3	48.0	76.0	74.7	115.9	34.3
111.4	32.8			130.3	26.7
127.5	24.9	107.1	40.3		
144.0	19.4				

When plotted on graph paper it was seen that the viscosity of margaric acid was almost identical with that of stearic acid, both of them being about 10% higher than the viscosity of palmitic acid at 90°.

The results of the determinations of surface tensions and densities are given in Table II, which also contains the surface energies calculated from them.

The precision which may be claimed in the measurements tabulated above is one part in two hundred for the surface tensions and one part in two thousand for the densities. All values were plotted on large scale graph paper and the temperature coefficients of the surface tensions and the Ramsay-Shields constants were determined from these graphs.

The data of interest are condensed in Table III. The last columns refer to "parachors," the apt name invented by Sugden[10] for the volume temperature relationship suggested by McLeod.[11] The experimental values of the parachor are the average obtained over eighty-degree tem-

perature ranges. For all substances tabulated the parachor varied less than 1% over the eighty-degree range. Sugden discovered the additive character for the parachor and his values for carbon, hydrogen, oxygen and the double bond were used in the calculated values. Data required for the discussion based on experimental determinations not described in this paper are also included in Table III, together with the source from which they were obtained.

The first column in Table III is of particular interest from the point of view of the theory of orientation of Harkins[12] and Langmuir.[4b] Briefly this may be stated as signifying that the surface molecules are orientated with the most strongly attracting groups toward the bulk of the liquid and that the total surface energy is determined by the outer groups. According to this, then, the total surface energy in an homologous series should reach a constant value, and in the case of straight chain compounds the same value for all homologous series should be reached, namely, that of the saturated hydrocarbons. The first of these predictions seems to be proved by the values of the total surface energy of the fatty acids. There is a marked decrease in total surface energy from formic to acetic to propionic acid, but by the time the 4-carbon acid is reached a value *is* obtained which differs only slightly from the values of the subsequent acids up to the 18-carbon acid.

The variation in total surface energy between butyric and stearic acids is given by 54 ± 1 ergs. The question arises whether even this variation really exists. Undoubtedly the experimental determinations of the surface tensions were made with greater accuracy than necessary to detect this variation. However, in spite of the precautions taken in the purification of the compounds some of the rarer acids may have contained sufficient impurity to account for the variations found, and taking into account those acids for which large quantities were available and which could therefore be purified to a greater extent, the variation is given by 54.6 ± 0.3. On the whole, therefore, it may be concluded that the total surface energy reaches a constant value in this homologous series after the first few members of the series. However, as far as can be judged from the total surface energies of the saturated hydrocarbons, the series value for the acids is definitely higher. It is true that dicetyl and hexacosane have values approaching that of the fatty acids and that the low value for hexacontane may easily be due to an impurity in the latter. Nevertheless, taking all the evidence so far established, the value is decidedly less.

It does not seem probable that there is complete orientation in the surfaces of pure liquids such as exists in a monomolecular film spread over the surface of water. That there is a certain amount of orientation

---

[12] Harkins, THIS JOURNAL, 39, 541 (1917).

may explain the rapidity with which the total surface energy reaches a constant value in the fatty acid series. These compounds have a polar group and a tendency for orientation in the surface exists. But this tendency is counteracted by thermal agitation with the result that the surface orientation is partial. By partial orientation is meant that, taken over a time interval, the average position of the axes of the surface molecules is perpendicular to the surface with the polar group nearest the main body of the liquid. The surface orientation differs from regional orientation (which may exist in the bulk of the liquid) both in its greater magnitude and in the fact that it is always in the same direction in the surface, whereas the direction of momentary orientation inside a liquid region changes from instant to instant.

The extent of the orientation in a surface will be increased by a strong polar group and by increased molecular size. In the paraffins, where there is no polar group, it seems probable that there is less chance for orientation and consequently the series constant will be reached far more slowly, which is in agreement with the facts.

The series constants of the fatty acids and the paraffins approach one another. This is, however, no proof of complete orientation since it seems likely that in any case the effect of X on the total surface energy in differentiating $C_nH_{2n+1}X$ from $C_nH_{2n+1}H$ must become nil when n is large enough.

It is desirable to bring more conclusive evidence in support of these views by further experimental determinations of the constants for the saturated hydrocarbon series and work along this line is under way.

The Ramsay–Shields constant K_e increases in a continuous way with length of carbon chain and this might be accounted for by orientation if $K_e = 2.12$ for all equimolecular surfaces. If all the fatty acids are completely orientated, the area occupied by any acid molecule is the same as the area occupied by a formic acid molecule. Hence, the volume which should be considered in the case of the higher fatty acids to obtain equimolecular surfaces is not that given by their molecular volume but by the portion which is proportional to the volume of formic acid. This reasoning gives $K_e = 0.94(M/46)^{2/3}$, where 0.94 is arbitrarily taken as the constant for formic acid (molecular weight 46) and K, the constant for a higher acid of molecular weight M. The values for K, calculated in this way are given in Table IV and are seen to be in reasonable agreement with the experimental values.

The above calculation is anything but rigorous and besides assumes that all the acids are associated to the same extent and have the same density. The agreement between calculated and experimental values may be purely accidental. Another relationship, based on still more dubious reasoning, gave $K_e = N^{4/9}(2.12/3.95)$, where N stands for the

TABLE IV

8	2.12	2.01	2.14	18	3.04	3.16	3.04

number of carbon atoms in the acid. In Table IV the values of K_e calculated in this way are shown to be in close agreement with all the experimental values and in absolute agreement as far as the last seven acids are concerned. This relationship may, therefore, be used as an empirical one but possessing sufficient accuracy for extrapolating the values of K_e for higher fatty acids.

If the high values of the Ramsay and Shields constant are to be explained by the complete orientation in the surfaces of the fatty acids, then the high values of this constant in the case of the higher paraffins show that these are orientated to the same extent. The fatty acid with **32** carbon atoms would have a value 4.0, which is approximately that found for dicetyl. This might not be so bad were it not for the values of the Ramsay and Shields constant which have been obtained for tristearin and tripalmitin.[13] These are 5.4 and 5.5, respectively, whereas the extrapolated values for straight chain fatty acids of 57 and 51 carbon atoms are 4.9 and 5.1, respectively. In other words, the tristearin molecule has the same effect on the Ramsay-Shields constant as a fatty acid of the same number of carbon atoms, although the latter is three times as long. It seems unlikely, therefore, that the high values for the Ramsay-Shields constant can be accurately interpreted in terms of complete orientation. It is far more striking that hexacontane, tristearin and a fatty acid of similar carbon atom content have practically the same abnormally high value for the Ramsay-Shields constant.

It is of considerable interest to compare simultaneously the Ramsay-Shields constant and the percentage difference of calculated and observed values of Sugden's parachor. The parallelism is perhaps to be expected due to the manner in which the two are related. The figures in Table III show that in both series the Ramsay-Shields constant is first too low and then too high and that the observed parachor is at first too low and then too high. That the latter are too high in the case of the compounds of high molecular weight is established beyond the limit of experimental error.

---

[13] Walden, *Z. physik. Chem.*, **75**, **55** (**1910**).

It has been suggested that where the observed value of the parachor is too low this is due to association, just as the low value of the Ramsay-Shields constant is ascribed to the same cause. If this is so it appears reasonable to suppose that the cause for the abnormally large values of parachor and Ramsay-Shields constant are due to the same cause, whatever it may be. From the nature of the constants the Ramsay-Shields constant is more sensitive to the surface tension factor, while the parachor is more sensitive to the density factor. The former shows a more marked change from the normal than the latter with increase in molecular weight, so that something must be taking place which affects the surface in an abnormal way. That this something is a partial orientation of the surface molecules is a plausible hypothesis. The suggestion that the variation from the normal in the case of the Ramsay-Shields constant is due to the form of the molecule or spiral formation is not sufficient unless orientation in the surface is supposed to take place also.

Summary

The surface tensions and densities of ten fatty acids and one long chain paraffin have been measured over a hundred degree range of temperature and their angles of contact with glass were shown to be zero.

The viscosities of palmitic, margaric and stearic acids were measured.

It was shown that the total surface energies of the fatty acids quickly reach a series constant, whereas the series constant for the paraffins is reached more slowly. As far as can be judged from the known experimental data the two series constants approach each other but do not reach the same value rapidly.

The Ramsay-Shields constant was shown to increase rapidly in the case of the fatty acids and could be represented by the relationship $K_e = N^{4/9}(2.12/3.95)$. The constant was found to have abnormally high values in the case of the higher paraffins.

The parallel variation from the normal of the Ramsay-Shields constant and Sugden's parachor was pointed out and ascribed to the same cause, whatever it might be.

It was shown in the discussion on the total surface energy and the abnormally high values of the Ramsay-Shields constant that the former do not indicate complete orientation at the surface and the latter cannot be calculated quantitatively in terms of complete orientation. Nevertheless, it is suggested that *a* partial orientation takes place in the surface of a pure liquid and that the regularities in the former and the abnormal values of the latter are due to this partial orientation.

A BACTERIOLOGICAL CONDUCTIVITY CULTURE CELL AND SOME OF ITS APPLICATIONS

BY L. B. PARSONS, E. T. DRAKE AND W. S. STURGES

RECEIVED SEPTEMBER 10, 1928 PUBLISHED JANUARY 8, 1929

Introduction

It has been shown in previous investigations[1] that putrefactive anaerobes grown in gelatin or other suitable liquid media cause changes in specific conductance which are proportional to the ammonia production. The latter is an end product resulting from the proteolytic action of these bacteria and hence furnishes a convenient index of biochemical activity and growth.

It appeared that the new method of conductance measurement could be made doubly valuable in studies of the growth of certain anaerobes under various environmental conditions if a conductance cell could be made to function also as a growth vessel. After several trials a type of cell was devised which has been in constant use for a period of two years with satisfactory results.

The method developed has distinct advantages over the usual procedures since a number of consecutive observations may be readily made upon *a* single culture, sealed in glass, thus eliminating all possibility of evaporation, change in anaerobic conditions or chance contamination. The purpose of this paper is to present a description of the cell and to illustrate several applications to definite biochemical problems.

culture cell.

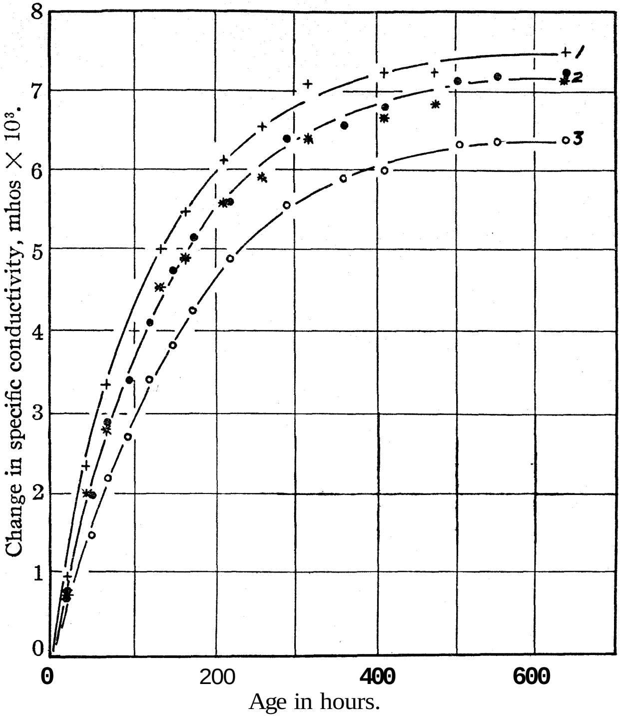
The Conductivity Culture Cell

The cell, Fig. 1, is made of 25-mm. tubing constricted at the lower end to a portion 12 mm. X 40 mm. Electrodes of No. 18 B. and S. gage platinum wire are sealed into the latter so that about 6 mm. of wire projects into the tube. Electrodes are placed 8 to 10 mm. apart. A piece of 8-mm. tubing sealed to the upper portion serves to introduce medium and for inoculation. After inoculation this tube is constricted, evacuated and sealed off. By sealing on 8-mm. tubing, when necessary, the cell can be used indefinitely. The volume of the completed cell is approximately 75 cc. The cell is designed for 5 cc. of culture medium. The large free space is required because most proteolytic organisms evolve considerable quantities of gas. Electrodes must be kept well platinized. Cell constants vary from 1.5 to 2.5. Constants are determined at the end of each run and seldom vary more than 2% from former determinations, showing that repeated sterilization does not affect the cell. It has been found convenient to immerse the cells in 30-mm. tubes containing paraffin oil which are in turn immersed in a water thermostat. The copper lead wires are thus satisfactorily insulated. The latter are arranged to dip into mercury cups making contact with the leads from the bridge.

Parsons and Sturges, *J. Bact.*, 11, 177 (1926); 12, 267 (1926).

Reproducibility of Results

In Fig. 2 curves are plotted showing the change in conductivity with time for C. *putrefaciens* in gelatin at 25°. The data were obtained from two separate runs of five cells each. Run 1 is shown by crosses and Run 2 by circles. Curve 1 represents the maximum rate and Curve 3 the minimum rate observed in the 10 individual cells used. The averages of Runs 1 and 2 show practically perfect agreement and are represented by Curve 2.



O, Minimum, series I and II; ●, average, series I; +, maximum, series I and II; a, average, series II.

Fig. 2.—Reproducibility of results. *C. putrefaciens* in 10% gelatin at 25°.

It has been found that in general the average results obtained with any putrefactive organism using 5 cells per run can be satisfactorily checked in subsequent runs under similar conditions.

Effect of Ph on the Biochemical Activity of C. Sporogenes

The conductivity culture cell is well adapted to the study of the effect of *Ph* on the growth and biochemical activity of anaerobes. In Fig. 3 are presented data on the effect of initial Ph upon the activity of C. *sporogenes*, which is the most common putrefactive organism. The medium was 10% nutrient gelatin adjusted to the required PH by the addition of acid or alkali. PH was measured electrometrically on portions of the sterilized inoculated medium. The cells were incubated at 37.5' and conductances measured at the intervals noted. The sharp maxima at the younger ages are especially noticeable. The tendency of the curves to become more symmetrical at older ages is noteworthy. The zones of optimum reaction at 115 and 211 hours are rather wide. This is due to the high ammonium salt accumulation tending to raise the PH toward the optimum of 8.0 with consequent rapid growth of the organisms. It is evident that the most significant curves are those at 19 and 27 hours.

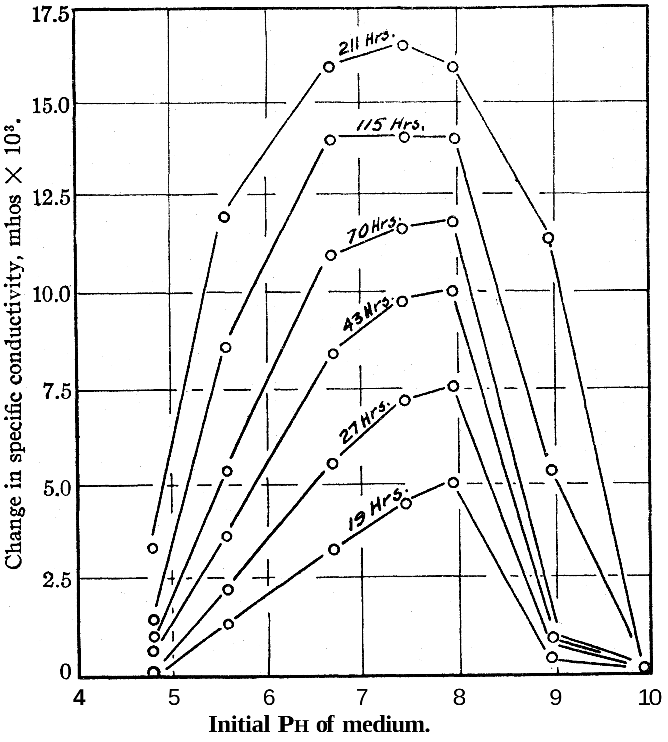


Fig. 3.—Effect of *PH* on biochemical activity of *C. sporogenes* at 37.5° in 10% gelatin.

The Effect of Temperature on the Growth and Activity of C. *Putrefaciens*

The exact effect of temperature on the growth and biochemical activity of proteolytic anaerobes is easily investigated by means of the conductivity culture cell. In Fig. 4 curves are presented showing the averages of runs of 5 cells each at 25, 30, 35 and 40° for *C. putrefaciens* in gelatin medium at PH 7.8.

Since the cells were incubated in separate thermostats and the conductances were measured at the temperatures indicated, it was necessary to refer the data to some standard temperature for comparison. Twenty-five degrees has been selected as the comparison temperature and **all** observations have been calculated to this temperature, using experimentally determined temperature coefficients.

A distinct lag period always occurs in bacterial cultures before growth starts. If allowance is made for this period, the curves in Fig. 4 follow the monomolecular law very closely, that is, the rate of change of conductance is logarithmic. From large scale logarithmic plots the velocity

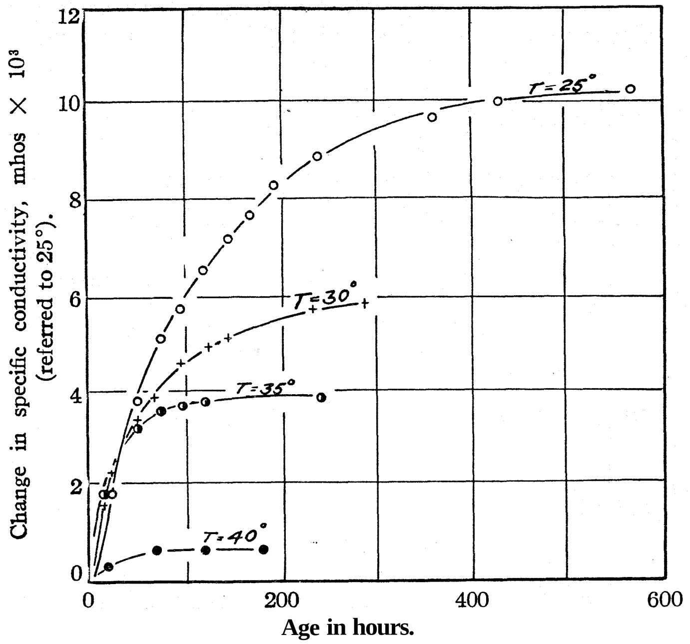

Fig. 4.—Effect of temperature on biochemical activity of C. *putrefaciens* in gelatin.

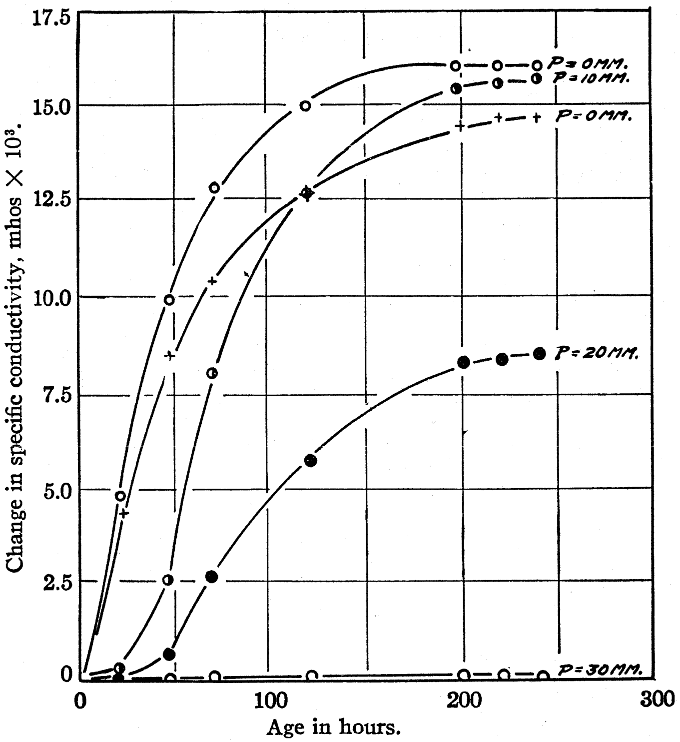
constants in terms of mhos × 10^3/hours have been calculated to be at 25, 30 and 35°, respectively, 0.0034, 0.0066 and 0.0151. Thus the reaction is more rapid at the higher temperatures, although the quantities of ammonia finally accumulating are much smaller. The velocity is approximately doubled for each 5° increase in temperature, that is, 1.95 for 25–30° and 2.28 from 30–35°.

The Effect **of Oxygen Tension** on the Growth **of** C. *Sporogenes* at **37.5°**

The conductivity culture cell is especially useful in the study of the effect of oxygen tension on the growth of anaerobes. The data presented in Fig. 5 were obtained on C. *sporogenes* by sealing the culture cells at suitable air pressures to give the desired oxygen tensions. It was found that shaking was necessary to secure uniform results at the various oxygen concentrations. Presumably shaking insures saturation of the medium at the tension of oxygen present. A modification of the cell was made by sealing the neck at right angles to the cell. A shaker was arranged in the incubator at 37.5° so that about 15 excursions per minute were made. Since the long axis of the cell was in the horizontal direction a thorough exposure of the medium to the oxygen was obtained. Readings of conductance were made at 30°. This involved exposure of the cells to a lower temperature for about half an hour per day. As a check on the effect of shaking, a cell which was not shaken has always been included in the series. In all cases it has been found that greater increases in conductance occur in the shaken cell.



+, Not shaken; all others shaken 15 r.p.m.

Fig. 5.—The effect of oxygen on *C. sporogenes* in 10% gelatin at 37.5°.

The results are uniform. The lag period becomes more noticeable the higher the oxygen tension, while between 20 and 30 mm. oxygen tension, *C. sporogenes* can no longer grow.

Possible Applications of the Cell

The preliminary results which have been presented show that the cell is peculiarly adapted to the study of such environmental factors as temperature, PH and oxygen tension on the growth and activity of the proteolytic, ammonia-producing anaerobes. There is no reason why the cell might not be successfully applied to the effects of antiseptics, carbon dioxide tension, antagonistic action of salts or the stimulating effect of extractives on this type of organism.

The cell may possibly be applied to the study of any metabolic process involving the production of conducting substances from slightly or non-conducting substrates, for example, the rate of acid production from carbohydrates. It should also lend itself to investigations of the rate of disappearance of conducting substances as, for example, the conversion of nitrate into nitrogen by denitrifying bacteria.

Summary

A new method of studying biochemical activities of certain organisms involving a combined culture conductivity cell has been developed.

This has been successfully applied to the study of biochemical activities of anaerobes at different *P*H's, temperatures and oxygen tensions.

Further possible applications of the new cell have been enumerated.

THE PREPARATION AND STUDY OF TWO AMMONIUM MOLYBDOTELLURATES

BY V. W. MELOCHE AND WILLARD WOODSTOCK

RECEIVED SEPTEMBER 10, 1928 PUBLISHED JANUARY 8, 1929

Considerable work has been done by Denigès[1] on the adaptation of the complex phosphomolybdate to the colorimetric determination of small amounts of phosphorus. His method depended upon the formation of a blue color upon the addition of stannous chloride to an acid solution of the phosphomolybdate. Since Gibbs[2] and Klein[3] have already mentioned the formation of complex molybdotellurites and tungstotellurites and Pechard[4] has isolated complex molybdoselenites, it was thought that a study of the possible combinations between telluric acid and molybdic acid might furnish the basis for a delicate determination of tellurium similar to the one used for small amounts of phosphorus. The following

---

[1] M. G. Denigb, *Compt. rend.*, 171, 802 (1920).

[2] Gibbs, *Am. Chem. J.*, 17, *177* (1895); *Ber.*, 18, 1089 (1895).

[3] Klein, Bull. *soc. chim.*, *42*, 169 (1884).

[4] *Pechard, Compt. rend.*, 117, 104 (1893).

contribution includes the isolation and analysis of two new molybdotellurates, together with a discussion of some of their properties.

Materials Used

Telluric Acid.—Telluric acid was prepared by the Staudenmeier[5] method. This procedure depends on the chromic acid oxidation of pure tellurium dioxide in dilute nitric acid solution. The product was recrystallized from water solution until it was free from nitric acid, chromic acid and chromic nitrate.

Molybdic Oxide.—Two types of C. P. molybdic oxide were used, the one being 99.9% MoO_3 and the other 85% MoO_3. The latter variety is sometimes referred to as H_2MoO_4 but in this instance it contained variable amounts of ammonia and nitrate. None of the samples contained sodium, potassium or sulfate.

Ammonium Nitrate.—Ordinary C. P. ammonium nitrate was recrystallized from aqueous solution and used without further treatment.

Preparation

The isolation of two different ammonium molybdotellurates was accomplished by the preparation of aqueous solutions containing varying amounts of telluric acid, molybdic acid and ammonium molybdate and subsequent separation of the resulting products by evaporation and crystallization. When an aqueous solution was prepared which contained equimolar portions of telluric acid and molybdic acid and sufficient ammonia to satisfy three of the hydrogens of the H_6TeO_6, clear white crystals separated upon evaporation and cooling which had the formula $3(NH_4)_2O \cdot 2TeO_3 \cdot 6MoO_3 \cdot 10H_2O$. If the above proportion was so changed that the solution contained a considerable excess of molybdic acid in the ratio of one mole of telluric acid to four moles of molybdic acid, and ammonia was present in sufficient quantity to satisfy the telluric acid completely, the solution upon evaporation and cooling would yield clear white crystals having the formula $3(NH_4)_2O \cdot TeO_3 \cdot 6MoO_3 \cdot 7H_2O$. Each of the two different compounds was recrystallized six times and the complete analysis of samples taken from the last crystallization was compared with that of samples taken from the first and second crystallizations. In the instances where the pure molybdic anhydride was used for the preparation, it was found necessary to use aqua ammonia to facilitate the solution of the molybdic oxide. Variations of the general procedure showed that the ammonium ion could also be provided by the addition of ammonium molybdate or ammonium tellurate.

In order to prepare samples for analysis, the crystals were dried by successive washing with alcohol and ether.

Methods of Analysis

Tellurium.—The tellurium content of the compounds was determined by the Lenher-Homberger[6] method in which elementary tellurium was precipitated by the

---

[5] Staudenmeier, *Z. anorg. Chem.*, **10**, 189 (1895).

[6] Lenher and Homberger, THIS JOURNAL, 30, 387 (1908).

combined action of saturated sulfur dioxide water and hydrazine hydrochloride solution upon a dilute hydrochloric acid solution of the sample. It was found desirable to digest the sample in concentrated hydrochloric acid solution before attempting to precipitate the tellurium in the dilute acid solution.

Molybdic Oxide.—The filtrate from the determination of tellurium was evaporated to small bulk on a water-bath and was then fumed with about twenty cubic centimeters of concentrated sulfuric acid. The resulting sample was diluted until the acid concentration was about 6% and the molybdenum was determined by reduction in a Jones reductor and titration with potassium permanganate. The titration was corrected by a blank which was run on the reagents used. Standardization of the permanganate was made upon both sodium oxalate and pure molybdic oxide.

Ammonia.—The original sample was treated with an excess of sodium hydroxide and the liberated ammonium hydroxide distilled into a standard solution of hydrochloric acid. The excess acid was titrated with standard sodium hydroxide and the results were calculated in terms of $(NH_4)_2O$.

Water.—On account of the presence of the ammonium group in the compounds, it was found necessary to modify the ordinary method which is used for the determination of water. Instead of heating the sample and collecting the liberated water in a weighed U-tube which contained concentrated sulfuric acid, the sample was heated in a stream of oxygen in an organic combustion furnace. The porcelain tube contained the usual reduced copper spiral and the finely divided copper oxide. The water evolved was collected in a weighed tube which contained phosphorus pentoxide. Since the oxygen available contained appreciable amounts of hydrogen, it was necessary to pass the oxygen over hot copper oxide and remove the water formed by passing the gas through phosphorus pentoxide before using it in the combustion furnace. The total water obtained in the determination was corrected for that amount due to the oxidation of the hydrogen from the ammonia. This amount of hydrogen was calculated from the results of the ammonia determination already described.

TABLE I

RESULTS OF ANALYSES

For $3(NH_4)_2O{\cdot}2TeO_3{\cdot}6MoO_3{\cdot}10H_2O$	Calcd.	Found	For $3(NH_4)_2O{\cdot}TeO_3{\cdot}6MoO_3{\cdot}7H_2O$	Calcd.	Found
TeO_3	22.62	22.61	TeO_3	13.28	13.20
MoO_3	55.70	55.38	MoO_3	65.36	65.20
$(NH_4)_2O$	10.07	10.18	$(NH_4)_2O$	11.82	12.02
H_2O	11.61	11.75	H_2O	9.54	9.49
	100.00	99.92		100.00	99.91

Properties

Both compounds decompose upon heating at 550° to give a residue containing tellurium dioxide and a small amount of molybdic oxide. This does not constitute a method for the separation of the two oxides since the removal of the molybdic oxide is generally incomplete. If alcohol is added to aqueous solutions of the compounds, finely divided crystals are thrown out of solution. Analysis shows these crystals to have exactly the same composition as those obtained from water solutions by evaporating and cooling. If the dry crystals are allowed to stand over fused calcium chloride in a desiccator, they disintegrate rapidly. The loss of water in the desiccator is not accompanied by the loss of ammonia. The original compounds are readily soluble in water and insoluble in alcohol or ether.

When the ditellurate was recrystallized from a solution containing a large excess of ammonium nitrate, the composition of the compound was unchanged. However, when an excess of ammonium hydroxide was added to the solution and the excess ammonia was driven off by evaporation until a clear solution was obtained, crystals were deposited which upon analysis were shown to have the composition of the monotellurate.

Although it was possible quantitatively to determine the molybdenum in the ammonium molybdotellurates by reduction with stannous chloride,[1] and comparison of the blue color with that obtained from a standard ammonium molybdate solution, it was not found possible to adapt this procedure to the determination of small amounts of tellurium. In the determination of phosphorus the stannous chloride reduces the molybdenum of the ammonium phosphomolybdate, producing the molybdenum blue, while the molybdenum of the excess ammonium molybdate reagent is unaffected. Under similar conditions for tellurium not only is the molybdenum of the molybdotellurate reduced but also the molybdenum of the ammonium molybdate reagent and the tellurium originally present as tellurate.

Summary

Two new ammonium molybdotellurates have been isolated. The analyses of the compounds have been described and formulas assiqned on interpretation of these analyses. The formula for the monotellurate was given as $3(NH_4)_2O \cdot TeO_3 \cdot 6MoO_3 \cdot 7H_2O$, while that of the ditellurate was $3(NH_4)_2O \cdot 2TeO_3 \cdot 6MoO_3 \cdot 10H_2O$.

Some of the general properties of the compounds have been described. It was mentioned that although molybdotellurates were shown to exist, it was not possible to adapt them to the determination of small amounts of tellurium in a procedure similar to that used for the determination of small amounts of phosphorus.

THE POTENTIOMETRIC DETERMINATION OF OCTAVALENT OSMIUM

BY WILLIAM R. CROWELL AND H. DARWIN KIRSCHMAN

RECEIVED SEPTEMBER 14, 1928 PUBLISHED JANUARY 8, 1929

Introduction

In order to facilitate the study of a number of problems concerning the chemistry of osmium, it became desirable to develop a method for the determination of octavalent osmium which would be more rapid and not less reliable than those usually employed. The generally accepted gravimetric methods are those involving the reduction of osmium compounds to the metal; and the most commonly mentioned volumetric method is the iodide method of Klobbie with its modifications. The former methods, while reliable if conducted under proper conditions, are tedious, and require rather elaborate precautions; the latter has a very difficult end-point and, even under the best conditions, it is hard to obtain reproducible results. In the light of the past experience of one of us with ruthenium[1] it was thought that a potentiometric method would prove most satisfactory. It has already been shown[2] that hydrazine compounds reduce octavalent osmium in an alkaline or alcoholic solution to the tetravalent state. It is shown in this paper that this reduction can be carried out in acid solution, and that the progress of the reaction can be followed potentiometrically. Conditions for obtaining reproducible results have been worked out and comparisons made with results obtained by the iodide and gravimetric methods. A study is being made of other reducing agents, such as titanous, chromous and ferrous salts, the results of which will be presented in a later paper.

Apparatus and Materials

The apparatus used consisted of (1) a motor-driven stirrer; (2) a 1 N potassium chloride-calomel reference half-cell; (3) an oxidation-reduction electrode, made by fusing a platinum wire 2 cm. long and 0.05 cm. in diameter into the end of a small glass tube; (4) a certified buret; (5) a Leeds and Northrup student potentiometer, using a Leeds and Northrup portable galvanometer of 2.84 megohms sensitivity; (6) a 125-cc. beaker as a titration vessel. Calibrated precision pipets were used throughout.

A stock solution of osmium tetroxide in potassium hydroxide was prepared as follows. Metallic osmium, either as purchased or as recovered from residues by reduction with zinc and subsequent ignition in a current of hydrogen, was fused with potassium hydroxide and potassium nitrate. The melt was treated with water and distilled with nitric acid into a solution of potassium hydroxide, whereby a solution of osmium tetroxide was obtained free from ruthenium tetroxide. After acidification the metal

[1] Crowell and Yost, THIS JOURNAL, 50, 374 (1928).

[2] (a) Ruff and Borneman, *Z. anorg. Chem.*, 65,436 (1910); (b) *Ber.*, 50,484 (1917); (c) Paal and Amberger, *ibid.*, 40, 1378 (1907).

was again precipitated with zinc from this solution and fused with potassium hydroxide and potassium permanganate. The fused material was again treated with water and distilled from sulfuric acid with a current of oxygen into a definite volume of potassium hydroxide solution of known strength (about 0.4 N), free from traces of organic matter. The solution of osmium tetroxide thus obtained was free from nitric acid, nitric oxide and other volatile impurities. The alkaline solutions of the tetroxide are much more stable than neutral solutions and behave identically on titration.

Hydrazine sulfate solutions were standardized with potassium iodate by the method of Bray and Cuy.[3] The thiosulfate solutions used were frequently compared with a potassium permanganate solution which had been standardized by means of sodium oxalate from the Bureau of Standards.

Pure hydrobromic acid was obtained by distillation of the 48% acid. The middle fraction was used. All reagents were of standard C. P. quality.

The Potentiometric Method

In order to determine the best conditions for the potentiometric titration of octavalent osmium with hydrazine sulfate, preliminary experiments were conducted at different temperatures using various concentrations of osmium tetroxide and of acid. The acids used were sulfuric, hydrochloric and hydrobromic. Since the last was found to give the most satisfactory end-point, the results with this acid will be described in detail.

In hydrobromic acid solutions below 2 N at room temperatures (20–25°) there is apparently no reaction between hydrazine sulfate and octavalent osmium. As the temperature is raised to 50–60° the occurrence of a reaction is shown by the formation of gas bubbles and by a color change of the solution, which depends upon the acid concentration. At acidities below 1 N an amber color of varying intensity or a black precipitate appears, probably due to hydrolyzed compounds of tetravalent osmium. At acidities above 1 *N* the color change is from light yellow to a deep red.

Under the conditions finally adopted a large drop in potential occurs when four equivalents of hydrazine sulfate have been added for every gram atom of octavalent osmium present. Further additions of the reducing agent produce no additional break, even when five or six equivalents are used. It is evident that the osmium is reduced from the octavalent to the tetravalent state, as is the case in an alkaline or alcoholic solution.[2a] The reaction is probably the following

$$N_2H_6SO_4 + H_2OsO_5 + 6HBr = N_2 + H_2SO_4 + H_2OsBr_6 + 5H_2O$$

Analyses conducted at various temperatures between 60 and 80" gave practically the same results. It is desirable, however, to keep the temperature constant to within 2° because of the rather large temperature coefficient of the cell.

Preliminary experiments showed that quantitative results could not be obtained by a titration of octavalent osmium solutions in open vessels, probably because of a loss of the tetroxide from the acidified solution at the temperature used for the titrations. The procedure finally adopted was as follows. By preliminary direct titration the

---

[3] Bray and Cuy, THIS JOURNAL, 46,858 (1924).

amount of hydrazine sulfate necessary was roughly determined, several per cent. less than the theoretical amount being required because of loss by vaporization. Sealed glass tubes were then prepared containing this amount of hydrazine sulfate, sufficient concentrated hydrobromic acid to make the final acidity 1.5 *N*, and the sample of the stock octavalent osmium solution, these being added in the order mentioned. The tubes were then heated in a boiling water-bath from half an hour to several hours. A tube was then cooled, broken and its contents washed into the titration vessel with from 10–20 cc. of a 1.5 *N* hydrobromic acid solution, the potentiometric titration being completed at 70°. A time of heating longer than half an hour was found to be unnecessary. The same results were obtained even if the quantity of hydrazine sulfate added to the tube before heating was as high as 99% of the total required for titration.

During the electrometric titration the equilibrium voltage is attained within two millivolts in less than three minutes, except in the immediate vicinity of the end-point. The volume of hydrazine sulfate used was determined from the point of inflection in the curve obtained by plotting voltage against volume of reagent added. The voltage drop at the end-point is from 30–60 millivolts for a 0.1-cc. change in volume of reagent added, depending upon the acid concentration and the condition of the platinum electrode. It was found necessary to replace the platinum electrode after 10–12 titrations, since the usual methods of reconditioning electrodes did not prove satisfactory. The inflection is sufficiently abrupt, as is shown by the curve in Fig. 1.

Determinations were made with solutions of osmium tetroxide of various concentrations. Corresponding concentrations of the reducing agent were used. The end-points in the most dilute solutions were not so sharp as in those of higher concentrations but the reproducibility was fairly satisfactory. Amounts of tetroxide as small as 10^{-5} mole may be determined by this method.

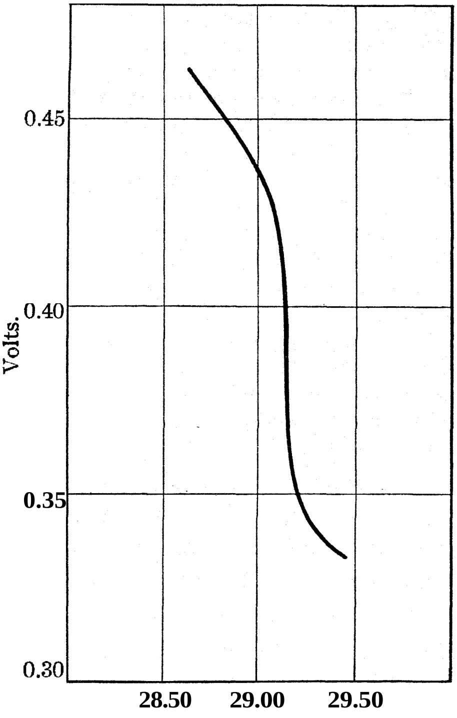

Fig. 1.

The Gravimetric and Iodometric Determinations

Comparative analyses by the gravimetric and iodometric methods were carried out at the same time as those by the potentiometric method, since it was found that the alkaline tetroxide solutions slowly decreased in concentration on standing, owing probably to loss of the osmium tetroxide formed by hydrolysis.

The procedure used in the gravimetric determinations was as follows. A measured portion of the stock osmium solution was pipetted into a glass-stoppered flask, several pieces of zinc sticks (Kahlbaum's) added and the solution made slightly acid with hydrochloric acid. The reaction was allowed to continue for several hours, acid being added from time to time. Too great an acid concentration, especially at the start, causes a too violent evolution of hydrogen and a consequent loss of the osmium tetroxide before reduction to a non-volatile compound has taken place. If the acid concentration is too low, there is a precipitation of basic salts of osmium, from which it is very difficult to reduce the osmium completely. To complete the reduction the solution was digested in the presence of an excess of zinc slightly below the boiling-point until no trace of color was observable. The acidity was then increased to dissolve the zinc completely and rapidly. The osmium metal was then filtered into a weighed Gooch crucible, ignited in a current of pure hydrogen and cooled in a stream of pure carbon dioxide. Duplicate results agreed within 0.2%.

The iodide method as described by Klobbie[4] and Krauss and Wilken[5] was modified as follows: 20 cc. of 2 N hydrochloric acid was heated to boiling, cooled in a current of carbon dioxide and to this was added one gram of potassium iodide dissolved in a few cc. of air-free water. To this solution was added a measured volume (2–10 cc.) of the stock tetroxide solution and the whole allowed to stand for three minutes. The solution was diluted to 200 cc. with air-free water and the liberated iodine titrated with standard thiosulfate solution. Unless these precautions are taken, the results are both high and variable due to the iodine liberated by the action of the oxygen of the air on the iodide. The addition of a few drops of a standard iodine solution enables the disappearance of the blue color of the starch to be determined several times with a given sample. Starch solution was added just before the end-point was reached. Usually from 4 to 6 end-points were determined on each of three samples. A strong light placed beneath the titration vessel aided materially in the determination of the end-point in the deeply colored solution.

The concentration of thiosulfate that seemed most satisfactory was approximately 0.025 *N* and the amounts of osmium solution taken were the equivalent of 8 to 15 cc. of the thiosulfate. The larger sample of tetroxide did not increase the precision of the titration because of the deeper color of the solution. The use of thiosulfate solutions as low in concentration as 0.01 N did not make it possible to obtain results of greater precision since the change in color with addition of thiosulfate was slow. The end-point correction for such solutions is comparatively large.

Under the conditions described the average deviation of each end-point determination from the mean was about 0.25%.

Results of the Potentiometric, Gravimetric and Iodometric Determinations

Table I contains the results of the various determinations by the three methods. For the potentiometric process there was always used 2.005 cc.

---

[4] Klobbie, *Chem. Centr.*, 11, 65 (1898).

[5] Krauss and Wilken, *Z. anorg. Chem.*, 145,151 (1925).

of stock osmium solution, which varied from 0.005 to 0.05 mole per liter. The titration was made at 70° in a total volume of 35-46 cc.

TABLE I

DETERMINATIONS OF OCTAVALENT OSMIUM BY POTENTIOMETRIC, GRAVIMETRIC AND IODOMETRIC METHODS

Normality of acid	Hydrazine solution Millimoles per liter	Hydrazine solution Volume used, cc.	Calcd. concn of osmium soln., millimoles/liter Potentiometric	Calcd. concn of osmium soln., millimoles/liter Gravimetric	Calcd. concn of osmium soln., millimoles/liter Iodometric
1.5	2.880	16.86, 16.88, 16.88, 16.93	24.32	...	24.26
1.5	2.880	16.76, 16.65, 16.73, 16.70	24.00	...	24.02
1.5	4.800	19.98, 20.15, 20.05	...	...	...
2.5	4.800	19.97, 19.98	47.94	....	47.82
1.5	2.880	16.48, 16.50	23.69	23.77	...
1.5	3.840	25.49, 25.43	...	...	...
2.5	3.840	25.41, 25.42	48.73	48.83	48.79
1.5	3.840[a]	12.41, 12.55, 12.57	23.96	...	23.80
1.5	0.960[b]	9.74, 9.76, 9.83	4.683	...	4.728
..	...	... ...	...	22.08	22.12

[a] The concentration of the hydrazine sulfate used to complete the titration was 0.960 millimole per liter.

[b] The concentration of the hydrazine sulfate used to complete the titration was 0.3840 millimole per liter.

From the above table it can be seen that the average difference between the results obtained by the potentiometric titration and those obtained by the gravimetric and iodometric methods is about 0.3%. The agreement of the hydrazine sulfate results among themselves is excellent, the average deviation of each volume required in titration from the mean volume being 0.04 cc.

Summary

A potentiometric method for the determination of octavalent osmium by reduction with hydrazine sulfate solution has been developed and a comparison of the results has been made with those obtained by modifications of the iodometric and gravimetric methods previously described. The accuracy of the method is estimated at 0.2–0.3%.

THE HEAT CAPACITY OF METHYL ALCOHOL FROM 16°K. TO 298°K. AND THE CORRESPONDING ENTROPY AND FREE ENERGY

BY KENNETH K. KELLEY[1]

RECEIVED SEPTEMBER 21, 1928 PUBLISHED JANUARY 8, 1929

The measurements of the heat capacities of aliphatic compounds made by Parks and his co-workers[2] have brought forth interesting regularities in the entropies and free energies of members of homologous series. They find that when the members are considered in the liquid state at 298.1°K. there is a definite entropy increase per CH_2 group of about 9 units, while the free energies have the same value within their limits of accuracy. The measurements upon which these conclusions are based do not go below liquid-air temperatures and consequently a very large and uncertain extrapolation is involved in the entropy calculations. It seemed desirable therefore to carry the measurements to liquid hydrogen temperatures in order to throw further light on these regularities. Also, in view of the important theoretical calculations[3] which are being made concerning the formation of aliphatic compounds from carbon monoxide and hydrogen under pressure, accurate values of the entropies of these compounds are now essential.

This paper contains results of measurements on methyl alcohol and will be followed later by data for other substances. Since little extra labor was involved in making the measurements from 90 to 298°K., this region, which Parks covered, was re-investigated and data were obtained for the intervals between his bath temperatures.

Method and Apparatus

The method used has been described by others and the apparatus is of the general type used by them,[4] so that only a brief description seems necessary.

The calorimeter, which is of the design used by Parks, was made from copper tubing and is 6.5 cm. long and 3 cm. in diameter. It is equipped with 38 thin perforated copper disks which are in good thermal contact with the calorimeter walls. These disks are essential for the assurance of rapid heat distribution. A layer of rice paper

saturated with Bakelite lacquer was baked on the outside and a bare gold resistance thermometer-heating coil of B. and S. gage No. 40 wire was wound on, the turns being separated by silk thread. The resistance of the coil at 22° is 140 ohms. The gold wire had been annealed previously at temperatures from 350 to 600° for four days. This coil serves both as a heater for the energy input and as a thermometer, as will be described later. Another layer of rice paper and Bakelite lacquer was applied over the coil and the outside covered with gold leaf to decrease radiation. A piece of small-diameter copper tubing one cm. long filled with Wood's metal was soldered to the bottom and serves as a holder for the thermocouple junction. The calorimeter is filled through a small copper tube silver soldered through the bottom. This tube is plugged with solder after filling the calorimeter.

The calorimeter hangs by linen threads inside a heavy metal block, the lower part of which is a copper cylinder of 1.1 kg. mass and the upper part solid lead of about 1.75 kg. mass. This block is equipped with a 260-ohm constantan heater and a thermocouple. All lead wires to external circuits and the calorimeter thermocouple are in good thermal contact with this block, thus minimizing the flow of heat along the wires into the calorimeter.

The block is suspended by heavy twine inside a brass container 21.5 cm. long and 7.5 cm. in diameter. A German silver tube hard soldered in the top of this container serves as support for the container, outlet for the heater lead wires and thermocouples and connection to the evacuating system. On top of this can about 3 kg. of lead is stacked, which together with the heavy block furnishes sufficient heat capacity to make it possible to obtain the entire specific heat curve from 16 to 298°K. without the use of temperature baths other than liquid hydrogen and liquid air. This implies, of course, that measurements be made continuously from about 200" to room temperature; with such a procedure the container warms at just about the right rate.

A pyrex Dewar 76 cm. long and with an inside diameter of 11 cm. was used to contain the temperature baths. This Dewar rests inside a Monel metal can 81 cm. by 16 cm. The top of this can, which is soldered on, is attached to the German silver tube before mentioned and is equipped with an inlet for liquid air or hydrogen, an outlet for the outgoing gas and a safety valve.

The liquid hydrogen is made with a liquefier similar to that described by Giauque and Wiebe and is transferred into the apparatus through a German silver Dewar tube.

Further heat insulation is given by a sheet iron case 100 cm. long and 40 cm. in diameter which is filled with silk floss.

The apparatus is attached by means of a de Khotinsky seal to a glass vacuum line and a pressure of 10^{-5} mm. or better is maintained by a mercury diffusion pump backed by a Nelson oil pump.

The Measurements

The instruments and the method of measuring the energy current and voltage are those described by Gibson and Giauque. The time of energy input was measured with a stop watch which was frequently calibrated against an accurate chronometer of the Department of Astronomy. The temperature rise was measured with the resistance thermometer. The latter was calibrated against the calorimeter thermocouple at intervals of 5 to 15° depending upon the temperature. Care was always taken to have the block and calorimeter within 0.5° of each other when these comparisons were made. Since the resistance was found to increase slightly with the time, it is necessary to make these calibrations for each filling of the calorimeter. The graphical method of Giauque and Wiebe was used in handling these data.

The temperature scale used has been described.[5] The calorimeter thermocouple was compared at 28 points between 14 and 298°K. with one of the laboratory standard couples with conditions as nearly identical as possible with those under which the couple is used. The temperature measurements are considered accurate to 0.05°.

Purification of Methyl Alcohol

The methyl alcohol was Mallinckrodt's "reagent quality." It was allowed to stand over lime for two weeks and carefully fractionated several times. The final product, 300 cc. in volume, had a boiling-point range of 0.01° and density $d_4^{25} = 0.78675$. The value interpolated from the data in "International Critical Tables"[6] is 0.78677, a fortuitous agreement. Also the melting point was very sharp, there being but little pre-melting, which indicates high purity.

Heat Capacities

The heat capacities of methyl alcohol and the mean temperature of each determination are given in Table I and are shown graphically in Fig. 1.

TABLE I

SPECIFIC HEATS OF METHYL ALCOHOL

[6] Vol. III, p. 116.

Methyl alcohol has two crystalline forms with the transition at 157.4°K. The transition is not sharp but is of the type first found by Simon[7] for ammonium chloride and later for the other ammonium halides by Simon, Simson and Ruhemann.[8] Such maxima have also been investigated by Giauque and Wiebe[9] in the case of hydrogen bromide and by Millar[10] for manganous oxide. The methyl alcohol transition becomes perceptible at about 145°K. and is over at 160°K.

All attempts to supercool appreciably the high temperature form failed. The experiment which was tried several times consisted in having the block at about 85°K. while the calorimeter was heated *in vacuo* to temperatures well above the transition range and allowed to stand for some time. The vacuum was then broken with hydrogen and the calorimeter and contents cooled rapidly. Even with such temperature differences this form failed to supercool by more than 25° at most.

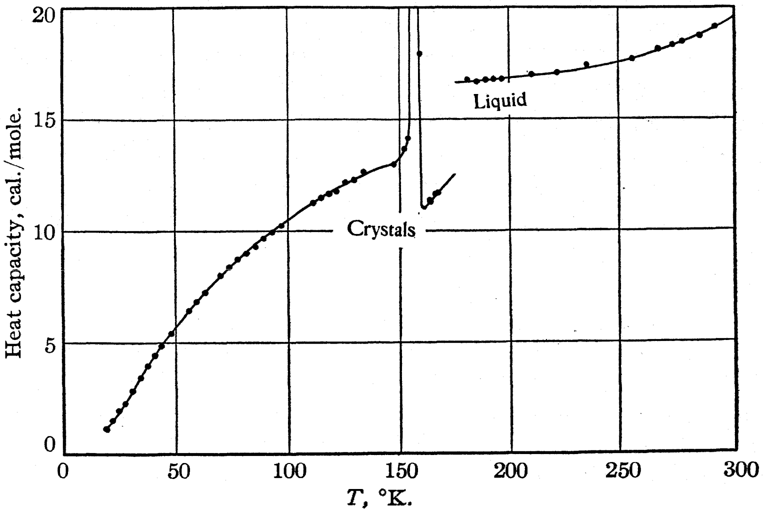

Fig. 1.—Heat capacity in calories per mole of methyl alcohol.

In making the calculations corrections were made for the heat interchange with the block (taking into account the source of error discussed by Giauque and Wiebe),[11] for the heat loss in the calorimeter heater lead wires, for the heat capacity of the small amount of solder used in plugging the calorimeter and for the heat capacity of the empty calorimeter itself. The latter was determined separately in the same manner as when full

[11] Ref. 4 b, p. 109.

of methyl alcohol, being filled with hydrogen to increase the speed of heat distribution.

In converting joules to 15° calories the factor 4.185 adopted by "International Critical Tables"[12] was used. All weighings were reduced to a vacuum basis.

The accuracy of the results depends upon the temperature. Below 20° the error may be of the order of 1% due to the rapid decrease of the dR/dT for the resistance thermometer. Between 20 and 40° the error decreases to about 0.2% and remains such to about 130°. Between 130 and 200° the error increases to about 0.5%. Above 200° certain points may be in error by 1% due primarily to large corrections caused by increased radiation. These estimates do not apply to the determinations made in the transition range where the heat capacity is changing very rapidly and where thermal equilibrium is slow. Here the error may be as much as 3%. It is important to note, however, that these determinations are not used in the entropy calculation.

The specific heats are somewhat lower than those obtained by Parks. Above 200° part of this difference (0.5 to 1%) is due to the additional heat interchange correction discussed by Giauque and Wiebe which was made in the present work but not in that of Parks.

The Transition Heat

For the purpose of obtaining the entropy, since specific heat measurements in the transition range could not be made accurately, it was necessary to determine the total heat required to bring one mole of methyl alcohol from a temperature below the transition range to a temperature above it and also to determine what might be called the "mean temperature" of the transition. The latter was determined by the method used by Gibson and Giauque for the melting point of glycerol and also the mean temperature of the hump was read from the C_p vs. T plot. The average of these two values is 157.4°K. Parks reported 161.1°K. for the temperature of transition. The difference between these values is easily explained. Parks measured the temperature during the course of the heat of transition measurements by means of a thermocouple immersed in a central, longitudinal well. This well was soldered to the top of his calorimeter so that it was joined by metal to the calorimeter walls. In the present work with the thermocouple attached to the outside of the calorimeter it was impossible to decide upon any temperature from data taken during a heat of transition measurement since in an ordinary specific heat determination where energy was being supplied slowly a temperature head of from 3 to 5° was built up on the calorimeter walls due to the poor thermal conductivity of the substance in this region. The head was appreciably

---

[12] Vol. I, p. 24.

larger when heat was supplied rapidly, as is done in determining the heat of transition.

The quantity designated "heat of transition" in Table II is the total heat before mentioned from which has been subtracted the area under the "normal" heat capacity curves which were extrapolated to 157.4°K.

TABLE II

HEAT OF TRANSITION, CAL./MOLE

Temp.	1st result	2nd result	Mean
157.4°K.	153.8	154.9	154.3

Melting Point and Heat of Fusion

The melting point and heat of fusion were determined by the methods of Gibson and Giauque. Both values check those of Parks very closely. Table III contains these data.

TABLE III

HEAT OF FUSION, CAL./MOLE

Temp.	1st result	2nd result	3rd result	Mean
157.22°K.	757.2	757.2	756.5	757.0

The Entropy

The entropy, $\int_{16.5}^{298.1} dQ/T$, was calculated in the usual manner. The entropy below 16.5°K. was obtained by extrapolation, using the Debye function with $\Theta = 138$. This procedure in obtaining a value of 0.26 E. U. per mole can certainly cause no appreciable error. The calculations are tabulated below.

TABLE IV

ENTROPY OF METHYL ALCOHOL

0–16.5°K.	extrapolation	0.26
16.5–157.4	crystals	14.18
154.3/157.4	transition	0.98
157.4–175.22	crystals	1.24
757.0/175.22	fusion	4.32
175.22–298.1	liquid	9.28
$S_{298.1}$ for 1 mole of CH_3OH		30.3 ± 0.2 E. U.

This value is 2.3 E. U. lower than that obtained by Parks; however, 1.9 units of this difference is the error in Parks' extrapolation below 90°K. (that is, about 20% of his extrapolated value). This error is due *to* the use of the well-known "*n*" formula of Lewis and Gibson.

The Free Energy

The free energy of formation of methyl alcohol at 298.1°K. may now be calculated from the thermodynamic equation, $AF = \Delta H - TAS$.

The heat of combustion of methyl alcohol was determined by Richards and Davis.[13] Their value when recalculated in terms of the 15° calorie, taking into account the slight error pointed out by Verkade and Coops,[14] corresponds to 170,760 cal. per mole at constant pressure (weighing in vacuum). This result is for the heat of combustion measured at about 291°K. and must be corrected to 298.1°K. by means of the necessary specific heats. This correction is 110 cal. per mole, making the heat of combustion at 298.1° become 170,650 cal. per mole. Combining this latter result with the best values for the heats of formation at 298.1°K. of carbon dioxide and water,[15] one obtains −60,260 cal. for the $\Delta H_{298\cdot1}$ in the above equation.

In calculating $\Delta S_{298\cdot1}$, the entropy of graphitic carbon was taken as 1.3 E. U. per g. atom,[16] that of hydrogen as 29.6 units per mole,[17] and for oxygen 48.9 units per mole.[18] The result is $\Delta S_{298\cdot1} = -54.6$ E. U.

Substituting these values in the equation, the free energy of formation of liquid methyl alcohol is found to be, $\Delta F_{298\cdot1} = -44{,}000$ cal. per mole.

The relation of these results to the thermodynamics of the synthetic methyl alcohol process will be considered elsewhere.

In conclusion the author wishes to thank Mr. G. F. Nelson for the excellent mechanical construction of the apparatus, Professor W. F. Giauque for many helpful suggestions and Professor G. S. Parks of Stanford University for his interest and encouragement.

Summary

1. The specific heat of methyl alcohol has been determined from 16 to 298°K.

2. The transition between the two crystalline forms was found to be of the ammonium chloride type and the heat of transition and temperature were determined.

3. The temperature and heat of fusion were determined.

4. The entropy of methyl alcohol was found to be 30.3 ± 0.2 units per mole.

STUDIES OF COPPER CATALYSTS PREPARED FROM PRECIPITATED HYDROXIDE.

II. COMPARISON OF SODIUM HYDROXIDE AND AMMONIA AS A PRECIPITATING AGENT

BY PER K. FROLICH, M. R. FENSKE, L. R. PERRY AND N. L. HURD

RECEIVED SEPTEMBER 24, 1928 PUBLISHED JANUARY 8, 1929

In order to obtain copper of the highest purity, the catalysts discussed in the preceding paper were prepared from the hydroxide precipitated from copper nitrate with ammonia. While this method of preparation was useful for a study of the temperature effect, it was apparent that the resulting copper catalysts, on the whole, possessed very low activity.[1] In this respect, as well as in appearance, they resembled the clear, red, very compact metal with low catalytic power which Sabatier[2] prepared by calcination of copper nitrate and subsequent reduction with hydrogen. No doubt both these types of catalysts owe their large particle size and low activity to their high purity, which does not leave any foreign matter to interfere with the crystallization of the metal during reduction.

Reduction of the ammonia precipitated product with hydrogen gave the same low activity that was obtained when using methanol vapor. On the other hand, highly active catalysts were prepared by reduction of the tetra cupric hydroxide precipitated from a boiling copper nitrate solution with sodium hydroxide.[2] This copper, in contrast to that resulting from precipitation with ammonia, was a light violet-colored metal with all the appearance of possessing a smaller particle size.

Experimental Work

These observations pointed to a promoter effect of the small amount of sodium salts which undoubtedly were occluded in the copper hydroxide precipitated with sodium hydroxide. To test this supposition the experiments reported in Table I were made.

Two hundred grams of copper nitrate ($Cu(NO_3)_2 \cdot 3H_2O$) was dissolved in 1500 cc. of water and from this solution the hydroxide was precipitated either with ammonium hydroxide or with sodium hydroxide, as indicated in the table. In each case the hydroxides were heated at 220° in a stream of nitrogen for four hours prior to reduction

with methanol vapor at the same temperature.' In Expt. 1 copper hydroxide was precipitated with ammonia at 100° and the gel was not further washed, only the supernatant liquor being drawn off. A sample of this same gel was dialyzed for two weeks at about 60° and used in Expt. 2. Expts. 3 and 4 are duplicates of the first two except that sodium hydroxide was used for precipitation instead of ammonia.

CH_3OH dec. occur. as CH_2O, %	27.2	19.2	11.3	...

[a] Dialyzed.

From these data it follows that the catalyst prepared by precipitation with sodium hydroxide without washing possesses a much higher activity than the corresponding catalyst resulting from precipitation with ammonia. This is brought out by the figures for percentage of methanol decomposed, 44.0 and 8.0%, respectively, in spite of the fact that the sodium hydroxide precipitated catalyst is operated about 30° lower than the other. While the ammonia precipitated catalyst is practically unchanged after two weeks' dialysis, the one prepared with sodium hydroxide loses its activity completely at the somewhat lower temperature of 356°. These results point very strongly to promoter action of the sodium salts occluded in the hydroxide.[3]

From Table I it will be seen that the sodium hydroxide precipitated catalyst remained active for only about twenty minutes, at which time the activity proceeded to fall off rapidly until the catalyst became completely dead. The ammonia precipitated catalyst, however, showed constant activity throughout the entire one and one-half-hour period of the run. This temperature effect on the sodium hydroxide precipitated catalyst was studied in a subsequent series of experiments illustrated in Fig. 1. As before, the catalysts were prepared by precipitation with sodium hydroxide with no further washing than drawing off the supernatant liquor on the suction filter. It is seen that by operating at 313°, or below, the activity does not change appreciably with time, but that

---

[3] It will be noticed that the temperature differed for the two types of catalysts. The reason for this was that the activity of the ammonia precipitated catalyst would be too low for reliable measurements at the lower temperature, whereas the sodium hydroxide precipitated copper would lose its activity too rapidly at the higher temperature, as will be apparent from the discussions to follow.

the higher the temperature of operation above this temperature, the shorter is the time the catalyst remains active. At about 380° the catalyst is "dead" before the run can be started. It will also be noted that these curves break very definitely, and for the higher temperatures sharply, indicating the occurrence of some sudden change in the state of the catalyst.

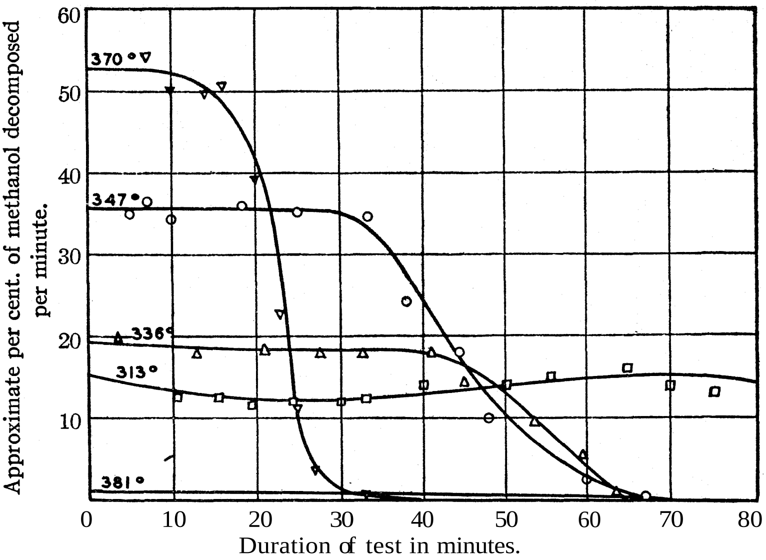

Fig. 1.—Effect of temperature on life of unwashed sodium hydroxide precipitated copper catalysts.

In order to investigate more thoroughly the effect of sodium salts on the catalytic activity of pure copper, a copper hydroxide gel was prepared by precipitation with ammonia and, after careful washing, divided into several portions, to which were added various amounts of sodium nitrate. The following percentages of sodium nitrate, calculated on the basis of copper oxide present, were incorporated in the gel: 0.01, 0.1, 1.0 and 5.0%. From these mixtures catalysts were prepared by the regular procedure of drying and reduction and then run at 300° with the results shown in Table II. The data prove beyond doubt that the sodium nitrate, presumably changed into sodium hydroxide during the preparation of the catalyst, is responsible for the higher activity of the sodium hydroxide precipitated catalyst.

TABLE II

RESULTS OF RUNS

Sodium nitrate added, %	0.0	0.01	0.1	1.0	5.0
Methanol decomposed, %	0.0	0.5	3.6	36.6	**37.0**

Apparently, the dying-out effect observed with the sodium hydroxide precipitated catalysts, as illustrated by Fig. 1, is due to the fusion of the occluded salts, the melting points of sodium nitrate and sodium hydroxide being 316 and 318°, respectively. Since the sodium salt has a marked promoter effect on the copper, it must be in very close proximity to the activated copper atoms or nuclei, and when it melts it apparently covers or blots out these active patches of the catalyst. This explanation is substantiated by the fact that the activity curve breaks only when the temperature is above 313°, as shown by Fig. 1. A pure copper catalyst, such as is prepared by precipitation with ammonia, does not lose its activity within the temperature range studied.

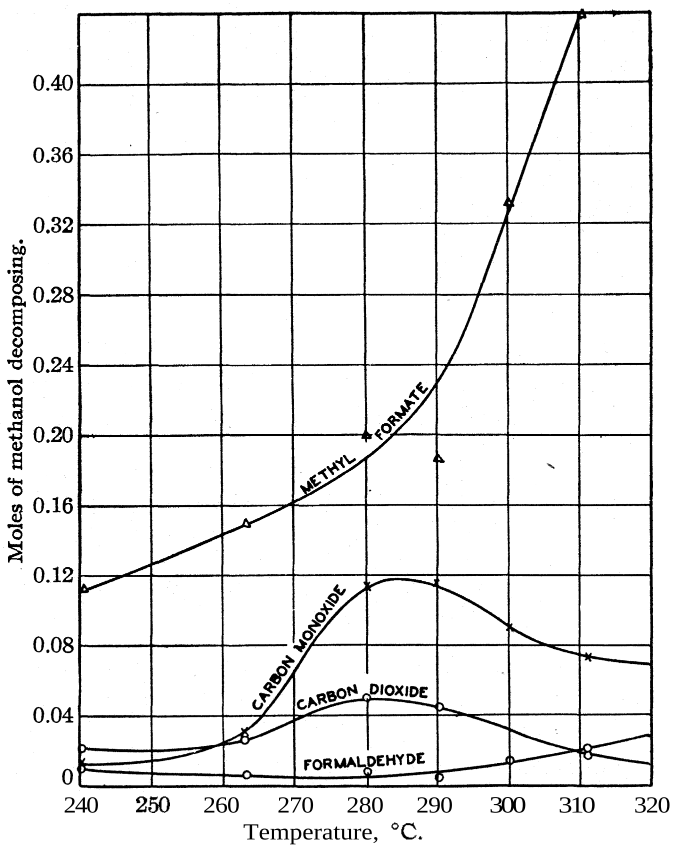

Fig. 2.—Moles of methanol decomposed into the various products as a function of temperature with unwashed sodium hydroxide precipitated copper catalysts. Basis: one mole of entering methanol.

It is to be noted that the decomposition of methanol is an endothermic reaction. Thus when methyl formate is the product, 9000 cal. are absorbed per mole of methanol decomposed, while with carbon monoxide as the product, the corresponding amount of heat is 24,000 cal. Since the reaction is assumed to occur on the surface, it is apparent that the catalyst must be at a somewhat lower temperature than the surrounding space. This may explain why the catalyst is active for a short time even though the temperature is well above the critical value of 315–320°. It also follows that the higher the temperature, the shorter will be the time required for the catalyst to retain this critical temperature, as is brought out by the data in Fig. 1.

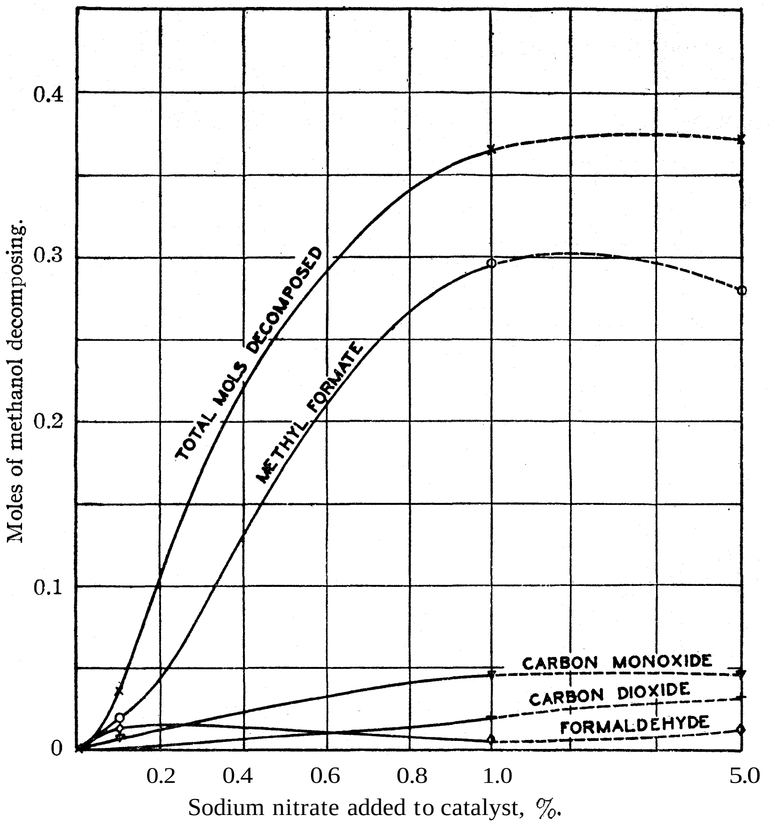

Fig. 3.—Effect of sodium nitrate on the activity of copper and on the mechanism of the decomposition.

In order to incorporate into and promote the copper with other sodium salts of higher melting points, the hydroxide was prepared from copper chloride and copper sulfate by precipitation with sodium hydroxide. The results are shown in Table III, from which it will be seen that the

TABLE III

RESULTS OF EXPERIMENTS

Catalyst	Temp., °C.	Methanol decomposed, %
$CuCl_2$ precip. with NaOH at b. p., unwashed	336–392	0.0
Same but washed with large amt. of water	387400	2.2

Same but washed with large amt. of water	385	0.0
Calcination of copper nitrate	336400	4.0
Calcination of copper acetate	336400	0.0

traces of sulfate and chloride which are retained even on washing are sufficient to poison the catalysts practically completely.

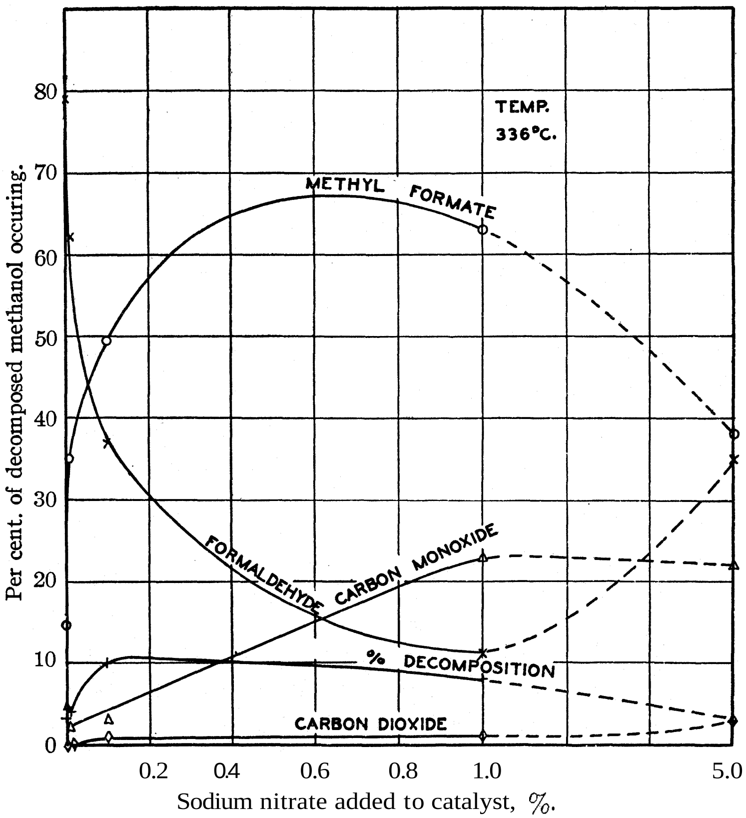

Fig. 4.—Effect of sodium nitrate on the activity of copper and on the mechanism of the decomposition.

Referring again to the sodium hydroxide precipitated catalysts, Fig. 2 shows the effect of temperature on the amounts of the various products of decomposition. The plot shows that the yield of methyl formate increases more rapidly than that of any other constituent, as the temperature increases.

Figs. 3 and 4 give the products of decomposition as a function of the amount of sodium nitrate added to the ammonia precipitated gel. Here it is seen again that the more active catalyst favors the production of methyl formate, as was pointed out in the first paper of this series and in a previous publication on copper catalysts promoted with zinc oxide.[4] Thus, in going from a pure to a promoted copper catalyst, the predominating constituent in the decomposition products changes from formaldehyde to methyl formate.

Conclusions

From the results presented above, it is apparent that copper catalysts prepared by precipitation with sodium hydroxide owe their high activity to the sodium salts thereby incorporated. It is not possible, however, to foretell what effect sodium hydroxide precipitation has on other types of catalysts as, for instance, on those composed of metallic oxides and used in the high pressure synthesis from water gas. In the absence of similar data for such catalysts, it is nevertheless advisable to precipitate with ammonia in order to avoid any disturbing influence of sodium salts, particularly when quantitative information is sought on the effect of promoters purposely added to a catalyst. In the past precipitation with ammonia and with sodium hydroxide has been used interchangeably, and this undoubtedly accounts for the divergent results reported by different experimenters. Thus Patart[5] states that copper gave very poor results when used as a catalyst for the high pressure synthesis of methanol, while Audibert[6] obtained good yields with alkali precipitated copper. Experiments made in the past in this Laboratory with ammonium hydroxide as the precipitating agent check Patart's observations in so far as lack of activity of the pure copper is concerned.[7]

Summary

Copper catalysts prepared by precipitation with sodium hydroxide are more active than those resulting from precipitation with ammonia, the difference being due to promoter action of occluded sodium salts.

These sodium hydroxide precipitated catalysts resemble other promoted copper catalysts in that they favor methyl formate rather than formaldehyde production by decomposition of methanol vapor.

It is suggested that failure to realize the significance of the promoter action of occluded alkali salts may account for the divergent results reported by workers in the field of high pressure synthesis from water gas.

OXIDE CELLS OF CADMIUM, COPPER, TIN AND LEAD[1]

BY CHARLES G. MAIER[2]

RECEIVED OCTOBER 4, 1928 PUBLISHED JANUARY 8, 1929

In the course of a program of investigation of the thermodynamic properties of oxides, the Bureau of Mines at its Berkeley Station carried out a series of measurements upon certain galvanic cells involving oxide electrodes. Work upon zinc oxide previously reported[3] had furnished very satisfactory values of the free energy of formation of the oxide as compared to results by other methods. The results of further measurements were in no case as satisfactory as those upon zinc, for reasons which will appear, and publication was withheld until substantiation by entropy determinations was accomplished. These entropies have now been determined.[4] Enough work was done to indicate the limitations of the cell measurement method for free-energy determination upon oxide materials. Only the briefest outline of methods, and data from the most satisfactory of nearly a hundred cells which were set up in the course of the work, will be recorded here.

Apparatus and Methods

The types of cells used were of three sorts: the ordinary H-type cell with and without a stopcock in the cross arm, unstirred cells with hydrogen electrode and circulating cells with automatic magnetic pump, such as were used by Smith and Woods.[5] The H-cells were used exclusively for measurements in which the oxide electrode was compared to the mercury oxide half-cell in dilute barium hydroxide solution. These cells were completely sealed from the atmosphere, and the contents were stirred to a slight degree by slow rocking upon an oscillating support under the cross arm. Early measurements showed that the transfer of solid oxides between the legs of the H seriously affected the electromotive force when only a glass wool plug was used, so that all measurements recorded here were made in cells with a stopcock, which was opened only during the time of making a voltage measurement. The unstirred cells with hydrogen electrode were similar to the cells with magnetic pump, with the omission of the latter. The cells will not be further described here. When the latter type was used, it is designated below by the symbol $H_2(p)$. All hydrogen cell values recorded have been corrected for barometric pressure and for the effect of water vapor in the saturator, which decreases the partial pressure of hydrogen.

The electrical measuring device was a modern type of potentiometer, with galvanometer sensitive to better than 0.01 millivolt, properly shielded, and whose standard cell was frequently checked against another of a different manufacture. In all cases the

[4] Millar, *ibid.*, 51, 207, 215 (1929).

[5] Smith and Woods, *ibid.*, 45, 2632 (1923).

accuracy of the measurement was considerably beyond the limiting deviations of electromotive force involved in the inherent fluctuations of the cell value.

Thermostats were of an automatic oil type, controlled to about 0.03°. The true temperature of the first thermostat nominally at 25° was 24.83°, as determined by a sensitive thermometer with Bureau of Standards calibration, and the second thermostat nominally at 45° had a true temperature of 44.92°

Barium hydroxide solution was used throughout as electrolyte. The material was purified by recrystallization before the solution was made up, was stored in large bottles with atmospheric vent through a long column of soda lime, and was repurified just before use by boiling with shavings of pure zinc in a flask with a trap to prevent re-access of air. Various concentrations were made by aliquot dilution with air-free and carbon dioxide-free distilled water. The solutions were standardized against benzoic acid (Bureau of Standards calorimetric standard).

The sign of the electromotive force given in the tables is such that a spontaneous reaction has a positive e.m.f. and negative free-energy change. In the case of the HgO cells, we have assumed the reaction to be $M + HgO = MO + Hg$, and for the hydrogen cells $M + H_2O = MO + H_2$.

I. Cadmium Oxide

The first cadmium oxide cells were made of a C. P. grade of reddish brown, "amorphous" oxide, which had been further purified of traces of electronegative metals by boiling with C. P. cadmium metal shavings in dilute barium hydroxide solution. The cadmium electrodes were of 8.00 and 12.46% cadmium amalgam, made electrolytically from carefully purified materials. The usual purifications for the preparation of the mercury and mercury oxide for the mercury oxide half-cell were carefully made. The results of the first cells are shown in Table I.

TABLE I

EARLY CADMIUM OXIDE CELLS AT 24.83°

8.00% Cadmium Amalgam

C	HgO(red)	.0809	15	8	+ ,8569	± .0017
D	HgO(yellow)	.2426	22	10	+ .8616	± .0019
				Average	+ .8596	* .0037
1	H_2(p)	.1213	11	7	− .0667	* .0017
2	H_2(p)	.2308	10	8	− .0925	± .0024
3	H_2(p)	.1154	7	4	− .0911	± .0063
4	H_2(p)	.0231	7	6	− .07260	* .0014

The considerable fluctuation of the values for the cells in Table I seemed ascribable to changes in the cadmium oxide. It was noted that the color of the oxide became slightly lighter when the purification was carried out by boiling with cadmium shavings. This phenomenon could be explained by the slow hydration of the oxide. A sample of the oxide was then boiled for about one week in a flask with reflux condenser, using a small amount of barium hydroxide (about **0.0002** M), and protecting from the atmosphere with a barometric mercury trap. At the expiration of this time the color of the oxide had nearly disappeared, indicating that a considerable amount of hydration had occurred. The gradual change with time of electromotive force observed in the first cells may have been due to this action.

Further samples of cadmium oxide were prepared by calcining the purified c. p. "amorphous" oxide and by the ignition of precipitated cadmium oxalate. Material prepared by ignition becomes markedly crystalline, ranging in color from dark brown to blue black, depending on the time and temperature of calcination. A temperature of 750° was found to slow up the hydration without producing too large crystals, which were to be avoided because of the length of time required for the electrolyte to become saturated with oxide. Results for cells with the new materials are given in Table II. Since the presence of the barium hydroxide seemed to increase the rate of hydration, lower concentrations were used.

A preliminary calculation of the free energy of formation of the oxide from the data of Table II showed practically identical results to be obtained with the mercury or hydrogen reference electrode. When Cells I, J and L, which had been at 24.83° for several weeks, were brought to 44.92°, the results shown in the first part of Table III were obtained, but similar calculations did not give results consistent with *new* Cells 7 and **8** compared to the hydrogen electrode.

In order to determine whether this discrepancy was caused by peculiarities of the cadmium amalgam, new Cells Nos. **25** to **28,** inclusive,

were set up, using electrodeposited cadmium in place of amalgam. Getman[6] has shown that the electromotive force of electrodeposited metallic cadmium compared to amalgam in cells of the type

$$\text{Cd} \left| \tfrac{1}{2}\text{ Sat. Sol. CdSO}_4 \right| 8\% \text{ Cd Amal.}$$

depends on the history of the cells, and that cells "stabilized" above 40° have an electromotive force of $E = 0.04280 + 0.000170\,(t - 25)$, or 0.04619 volt at 44.92". If this figure be subtracted from —0.01232 volt found for new oxide cells using electrodeposited cadmium, the result, —0.05851 volt, is obtained, a fair check with —0.05813 found from Cells 7 and 8.

In view of the above, old cells which had been at 24.83° for several weeks, and subsequently at 44.92° for several weeks longer, were brought back to 24.83°, with the results shown in the last part of Table III. The satisfactory constancy thus achieved failed to substantiate the original values of these cells.

Some explanation of the behavior of these cells may be found in an accessory experiment. Cadmium amalgam was anodically polarized by a continuous current of 0.5 micro-ampere per square centimeter in barium hydroxide solution for a period of several months. There was produced not cadmium oxide but a hydrated mixture of cadmium and mercury oxides. Although amalgam gives reversible electrodes in neutral or acid solutions, it is certain that such electrodes are not immediately and completely reversible in these basic solutions, where the solubility

---

[6] F. H. Getman, THIS JOURNAL, 39,1806 (1917).

of the mercury oxide is apparently so low that cadmium cannot precipitate mercury ions at these concentrations, or at best can do so only with extreme slowness.

The amalgam cell equivalent to the measurements on Cells 25 to 28, inclusive, may be calculated from Getman's results, as above, and from the free energies of water and mercuric oxide given by Lewis and Randall,[7] to be +0.86235 volt. The data may be summarized as follows

$$\text{New Amalgam Cells} \begin{cases} E_{24.83} = +0.85858 \text{ volt} \\ E_{44.92} = +0.86235 \text{ (equivalent)} \end{cases}$$

$$\text{Old Amalgam Cells} \begin{cases} E_{24.83} = +0.84659 \\ E_{44.92} = +0.85143 \end{cases}$$

A plausible assumption concerning these discrepancies may be that one set represents a cell reaction forming hydroxide and the other oxide. Getman's results for a-cadmium, the supposed stable form, are represented by the equation E = 0.04742 – 0.000200 $(t - 25)$, from which, for the reaction Cd, + Hg = Cd amalgam, $\Delta F_{298} = -2188$ cal., and $\Delta H_{298} = -4940$ cal. (from the differential Gibbs-Helmholtz equation). From the summarized measurements above, we have for the reaction Cd amalgam + HgO = CdO + Hg, or, alternatively, Cd amalgam + HgO + H_2O = $Cd(OH)_2$ + Hg

$$\text{New Cells} \Big\{ \qquad\qquad \text{Old Cells} \begin{cases} \Delta F_{298} = -39{,}068 \\ \Delta H_{298} = -35{,}756 \end{cases}$$

Combining the results of Getman's work with these values, and taking the free energies of mercury oxide and liquid water as –13,808 and –56,560, respectively, from Lewis and Randall, if the new cells represent oxide formation, $\Delta F^{\circ}_{298}(\text{CdO}) = -55{,}618$; $\Delta H_{298} = -63{,}584$. From these figures, A S for the formation of CdO from its elements is –26.73. Lewis and Randall give for the entropy of solid cadmium, $S_{298} = 11.80$; but instead of their value for oxygen, $S_{298}(^1/_2O_2) = 24.0$, we shall use 24.47, based on recent unpublished determinations of the entropy of oxygen at the boiling point and 1 atmosphere (40.57), and the data of Scheel and Heuse[8] (8.37) from thence to room temperature. From these quantities, $S_{298}(\text{CdO}) = 9.54$.

From the data of the old cells, similar calculations lead to the result for the formation of cadmium oxide: $\Delta F^{\circ}_{298} = -55{,}064$; $\Delta H_{298} = -62{,}305$; $S_{298} = 11.98$. The data of Millar[9] lead to a value for cadmium oxide, $S_{298} = 13.17$, indicating that the old cells more nearly represent the cell reaction involving CdO. Recalculating the results for the new cells on the basis of cell reaction to form $Cd(OH)_2$, for the formation of this substance from its elements, $\Delta F^{\circ}_{298} = -112{,}178$; $\Delta H_{298} = -131{,}850$; and

---

[7] G. N. Lewis and Merle Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, **1923**, pp. 484–485.

[8] Scheel and Heuse, ***Ann. Physik*, 4,** 40, 484 (1913).

[9] Millar, THIS JOURNAL, 50, 2653 (1928).

for the reaction $CdO + H_2O = Cd(OH)_2$, $\Delta F^\circ_{298} = -554$; $\Delta H_{298} = -1288$ (based on cell coefficients).

Thermal values for the heat of formation of cadmium oxide are Berthelot,[10] 66,400; J. Thomsen,[11] 65,780; Ditte,[12] 60,800; Mixter,[13] 5'1,000 for "amorphous" and 63,000 for crystalline, and Moose and Parr,[14] 65,200; whereas the free energy from the old cells, combined with Millar's direct entropy determination, leads to 61,950. For the hydroxide, Thomsen's value of the heat of formation from metal, oxygen and water was 65,680, which combined with Lewis and Randall's average for water, 68,270, gives 133,950 for the formation from the elements. However, Berthelot's figure for the heat of neutralization for cadmium hydroxide is 20,200 which, combined with Richards and Burgess'[15] heat of solution, 17,200, gives for the hydroxide −133,450.

The assumption of an oxide cell reaction for old cells implies that the oxide is the stable form at 25°, whereas according to the free-energy calculations, the hydroxide should be stable at this temperature. In view of this anomalous condition, no accuracy greater than perhaps 500 calories may be claimed for the free energy of the oxide.

II. Cuprous Oxide

The cuprous oxide electrode has been investigated by Allmand,[16] first against a hydrogen reference electrode in sodium or potassium hydroxide, later against the calomel electrode. Allmand found the hydrogen electrode in his solutions, to be unsatisfactory but this may have been due, in part at least, to his use of caustic alkali. Experience in this Laboratory has shown that with care the hydrogen electrode in barium hydroxide solution is fairly satisfactory. The calculated values of e.m.f. corresponding to the reaction $Cu_2O + H_2 = 2Cu + H_2O$ at 17° are given by him as 0.473 volt in 0.1 N alkali and 0.466 volt in normal alkali; part of this divergence may have been due to the uncertain liquid potentials involved in the use of the calomel reference electrode.

In the first cells of the present investigation, cuprous oxide made by dissociating a supposedly C. P. grade of cupric oxide (from nitrate) was used, with the results against the mercury oxide reference electrode of 0.4395 and 0.4479 volt, but these cells were quite unstable and maintained a steady progressive decrease of voltage. It seemed possible that this was caused by the presence of impurities in the oxide; therefore, a further

preparation was made by first oxidizing electrolytic copper wire in a muffle at 700° to a depth of about 0.1 mm., heating in an evacuated silica container at 1000°, and at a pressure of 0.002 mm., until no further oxygen was evolved, sealing off and permitting the contents to cool slowly. In setting up the cells, connection to the copper electrode was made through a platinum spiral upon which a dense, coherent and non-crystalline copper deposit had been electroplated.

The most satisfactory of the cells measured are shown in Table IV. Because of lack of thermostat capacity, no cells against the hydrogen reference electrode were measured at 25°. Although the cells are regarded as somewhat more satisfactory than Allmand's, previous experience had shown that the *accurate* calculation of heats of formation from cell coefficients is somewhat unsatisfactory with most oxide cells, and is barely worth while for these cells, unless gross errors exist in the thermal data, as in the previously reported case of zinc, or where it is a question of deciding between several possible cell reactions.

TABLE IV

CUPROUS OXIDE CELLS

Cell no.	Temp., °C.	Ref. electrode	Molality of $Ba(OH)_2$	No. of readings	Time, days	E.m.f.	Av. dev. of mean
M	24.83	HgO	0.2130	13	15	+0.45201	±0.00038
N	24.83	HgO	.1065	21	24	+ .45335	± .00085
O	24.83	HgO	.0532	6	7	+ .45184	± .00057
P	24.83	HgO	.0426	9	11	+ .45146	± .00046
Q	24.83	HgO	.0426	5	6	+ .45182	± .0011
				Average		+ .45210	± .00050
9	44.92	$H_2(p)$	.1065	6	7	− .46270	± .00030
10	44.92	$H_2(p)$	.0426	4	5	− .46298	± .00090
				Average		− .46284	

From the values of e.m.f. given in Table V, we calculate for Cu_2O, $\Delta F_{318} = -34{,}426$, $\Delta F_{298} = -34{,}672$, while Allmand's results give $\Delta F_{290} = -34{,}920$. From calculated free energies of mercuric oxide and water at 44.92, as derived from Lewis and Randall's free energy equation for these materials, the equivalent mercury oxide reference cell value of

				Average	− .6396	

hydrogen cells at 44.92° is calculated to be +0.45806 volt. The value of ΔH for the formation of Cu_2O is then calculated to be —38,400 cal. Thomsen[17] gave 40,800, and Berthelot[18] 43,800. It is perhaps not to be expected that values for the heat of reaction calculated in this way from two different types of cells could give much better agreement.

Millar[19] has given a preliminary value for the entropy of cuprous oxide as 21.7 ± 1.0. Taking the entropy of copper as 8.18, in accordance with Lewis and Randall, and 24.47 for $^1/_2O_2$ as previously, ΔS for the formation of Cu_2O from its elements becomes —19.13 and ΔH is calculated from this and the free energy to be —40,375 cal., a fair substantiation of Thomsen's figure.

III. Cupric Oxide

Cupric oxide reacts with metallic copper in neutral or basic aqueous solutions, resulting in the formation of cuprous oxide. Two cells were set up, one consisting of copper in contact with CuO, with 0.0414 molal $Ba(OH)_2$, using the mercury oxide reference electrode, and the second cell Pt | CuO | 0.0414 M $Ba(OH)_2$ | Cu_2O | Pt. The first cell had an initial voltage of 0.1820 and the second of 0.1889, but the electromotive force of the first showed a rapid and continuous increase until at the end of two weeks 0.394 volt had been reached. It seemed apparent that it would ultimately increase to an amount corresponding to Cu_2O vs. HgO. The second cell was highly polarizable and showed plus and minus variations between the initial value and a maximum of about 0.244 volt.

Despite these preliminary experiments, it was decided to try the Cu | CuO electrode against a hydrogen reference electrode. It was realized that such a cell could not become completely stabilized, but might show a "steady state" value over a period of time corresponding to the reduction of CuO to Cu_2O.

Reference to Table V will show that this expectation was realized, at least in part, at 25°. At 45° the local action in the cell is so rapid that difficulty is experienced in maintaining an electroplated deposit of copper on platinum, even though copper itself (in the form of wire) was mixed with the cupric oxide. The copper oxide was of the same sample that was used in the preparation of cuprous oxide but consisted of completely oxidized wire prepared at 700°.

Assuming the cell reaction in this case to be $Cu_2O + H_2O = 2CuO + H_2$, and using the previously determined results for Cu_2O, the free energy of formation of CuO is calculated as ΔF°_{298} = —30,800, and from the integrated Gibbs-Helmholtz equation, ΔH = —38,652. Thomsen's[17] thermal value was 37,160. Millar[19] gives for the entropy of CuO, 9.75 ±

---

[19] Millar, THIS JOURNAL, 51, 215 (1929).

0.05, from which ΔS of formation is −22.90. Calculating ΔH from the cell value of free energy and the entropy as before, the result is ΔH = −37,626, a result intermediate between Thomsen's thermal value and that from cell coefficients.

IV. Stannous Oxide

Stannous oxide was prepared by boiling a solution of freshly prepared stannous chloride with sodium carbonate in the absence of air. The stannous chloride, after recrystallization, had been boiled for some time with metallic tin (shavings of special electrolytic metal) to reduce traces of stannic chloride. The original tin from which the chloride was made was of especial purity from an electrolytic refining process and contained less than 0.1% of impurity.

The stannous oxide electrode was made through a platinum spiral with an electroplated deposit of tin. The plating solution was of stannous sulfate with aloin as addition agent. In all cases except the last three cells against the mercury oxide electrode, the deposit was dense, coherent and non-crystalline. In the last three cells of this set the deposit was spongy and the cells were arranged for comparison against the same HgO electrode as the previous set.

The cells against mercury oxide showed a slow rise in voltage for about a week's time, after which they were nearly constant for the same period, but later showed a progressive decrease. It is assumed that the initial increase was caused by the slow disappearance of traces of oxygen from

TABLE VI

MEASUREMENTS OF STANNOUS OXIDE CELLS

Cell no.	Temp., °C.	Ref. electrode	Molality of $Ba(OH)_2$	E.m.f.
R1	24.83	HgO	0.2120	+1.0221
R2	24.83	HgO	.0707	+1.0205

			Average	+ .0925

the cells and the slow attainment of saturation with oxide, and that the final decrease resulted from the gradual spoiling of the tin surface by traces of electronegative impurities. The values given in Table VI correspond to the average for a week's period in each case at the maximum voltage attained. Despite the apparent reproducibility of the hydrogen cells, they were still showing a rise of 0.3 millivolt per day after three weeks of life, and the results are considered to be too low. This is further indicated by the calculation of free energies and heats of formation for SnO, which are

$$\left.\begin{array}{ll}\Delta F^\circ_{298} = & -61{,}332 \\ \Delta F^\circ_{318} & -60{,}054\end{array}\right\} \Delta H = -80{,}000$$

Millar[20] has found the entropy of SnO to be $S_{298} = 13.56$. Using Lewis and Randall's figure for the entropy of white tin, $S_{298} = 11.17$, and 24.47 for $^1/_2O_2$, ΔS of formation is —22.08, and ΔH from this and the measured free energy is —67,914, a good check with Andrews'[21] thermal value, 67,600.

V. Stannic Oxide

Stannic oxide was made by the oxidation of electrolytically purified tin by nitric acid, with subsequent washing, and with final calcination at 400° of the metastannic acid so formed.

Cells of this material behaved in a manner similar to the cupric oxide cells, but changed even more rapidly. In one case a cell with an initial voltage of 0.11 had changed to 0.79 volt in ten days' time. The few results recorded below represent no very definite value but rather the order of magnitude of a constantly increasing voltage, beginning at the second day of the cell's life and extending for the time recorded. After this period a more rapid rate of increase occurred. Table VII shows the results.

TABLE VII

THE STANNIC OXIDE ELECTRODE AT 44.92°

HYDROGEN REFERENCE ELECTRODE

Cell no.	Molality of $Ba(OH)_2$	No of readings	Time, days	E.m.f.	Av. dev of mean
18 Mossy Sn	0.2170	5	5	+0.1161	±0.0008
19 Coherent Sn	.2170	5	5	+ .1155	± .0010
20 Coherent Sn	.1085	2	2	+ .1148	
			Average	+ .1155	

According to the value of e.m.f., the cell reaction should have a free-energy change of $\Delta F_{318} = -10{,}660$, or —5330 cal., depending upon whether the tin is reduced to metal or the lower oxide. If the reaction was $Sn + 2H_2O = SnO_2 + 2H_2$, the free energy of formation of SnO_2

---

[20] Millar, THIS JOURNAL, 51, 207 (1929).

[21] Andrews, Phil. *Mag.*, *[3]* **32,** 321 (1848).

becomes —122,230 at 318° K., but if the cell reaction was $SnO + H_2O = SnO_2 + H_2$, $\Delta F_{318}(SnO_2) = -122,115$. It is apparent that in this case it is impossible to distinguish between the cell reactions on the basis of the evidence available. For calculation the first case is assumed. Because of lack of definiteness of electromotive force and cell reaction, further experimental work was not attempted but tentative calculations will be made.

From the specific heats of white tin and oxygen, and Lewis and Randall's entropy at 298°, the entropies at 318° are estimated as follows: $S_{318}(Sn) = 12.2$, $S_{318}(O_2) = 49.4$. Similarly, from Millar's[20] specific heat data, $S_{318}(SnO_2) = 13.3$. Then ΔS_{318} for the reaction of formation of stannic oxide is —48.3, and since $(\partial \Delta F/\partial T)_P = -\Delta S$ which varies but little with the temperature, the value of $\Delta F^\circ_{318} = -122,230$ may be corrected to 298°K. by the subtraction of 20 X 48.3 = 966 cal. Then $\Delta F_{298}(SnO_2) = -123,200$ in round numbers.

Again, calculating the entropy change of formation at 298°K. from the data, $S_{298}(Sn) = 11.18$ (Lewis and Randall), $S_{298}(O_2) = 48.94$ (as previously), $S_{298}(SnO_2) = 12.51$, $\Delta S = -47.61$. From this latter, and the estimated free energy of $-123,200$ cal., $\Delta H = -137,392$—a satisfactory check with the figures of both Mixter[22] and Andrews,[21] who gave 137,800.

The work of Fraenkel and Snipischski[23] on the reduction equilibria of stannic oxide by carbon monoxide does not permit calculation of a definitive value of free energy of stannic oxide.

VI. Lead Dioxide

The monoxide of lead electrode has been investigated by Smith and Woods,[5] who found for the free energy of formation of PbO, $\Delta F^\circ_{298} = -45,050$ cal. Lead dioxide, lead sesquioxide and red lead have been studied by Glasstone,[24] who gave for the Pt | PbO, PbO_2 N–NaOH electrode potential 0.27 volt, and concluded that PbO and PbO_2 combine in the presence of N alkali to give Pb_3O_4.

In the present work we wished to ascertain whether these results were duplicable in barium hydroxide electrolyte. Lead dioxide was made electrolytically in a lead perchlorate solution which was hot and strongly acid. The lead electrode was made by deposition from a lead perchlorate solution with peptone as addition agent. Comparisons of the Pb | PbO_2 | $Ba(OH)_2$ electrode with the mercury oxide and hydrogen electrode are given in Table VIII.

If the cell reaction be assumed to be the reduction of lead dioxide to

				Average		– .69144	
21	H_2(p)	44.92	.2030	7	8	– .1983	± .0009
22	H_2(p)	44.92	.1085	6	7	– .1924	± .0003
23	H_2(p)	44.92	.0543	6	7	– .1967	± .0009
24	H_2(p)	44.92	.2170	4	5	– .1977	± .0011
				Average		– .1962	

monoxide, these voltages lead to a free energy of the dioxide of approximately —90,000 cal., but if the cell reaction is assumed to be the complete reduction of the dioxide, the order of magnitude of the calculated free energy of the dioxide is not changed. Calculations from either type of cell are moderately concordant and it is obvious that the cell reaction could not involve a reduction of PbO_2. If, however, it is assumed that the cell reaction may be only the formation or reduction of monoxide, the free energy of formation of the monoxide calculated from the observed voltage is $\Delta F^\circ_{298} = -45{,}717$. This figure is sufficiently close to Smith and Woods' result of —45,050 to justify belief that the actual cell reaction was principally lead monoxide formation.

It is of interest to calculate for copper, tin and lead the free-energy change resulting from the reduction of the higher to lower oxide by the metal at 25°. The free energies used for copper and tin are taken from this work, but for lead dioxide the figure calculated by Millar[20] and for lead monoxide the result of Smith and Woods are used.

$$Cu + CuO = Cu_2O$$
$$-30{,}800 \qquad -34{,}672 \qquad \Delta F = -3872$$
$$Sn + SnO_2 = 2SnO$$
$$-123{,}200 \qquad 2 \times (-61{,}332) \qquad \Delta F = +536$$
$$Pb + PbO_2 = 2PbO$$
$$-52{,}010 \qquad 2 \times (-45{,}050) \qquad \Delta F = -38{,}090$$

The large negative free-energy change for the lead reaction is adequate explanation for the disappearance of the dioxide in contact with the lead electrode, and the rapid degeneration of the cell as made with dioxide to give only monoxide reactions. The degeneration of the cupric oxide cells noted in an earlier part of this paper is consistent with the calculation showing that cupric oxide is not stable in contact with copper, and in this case the reaction occurring was actually the transformation from one to the other oxide. Stannous oxide has been described by T. Maeda[25] as unstable with respect to tin and stannic oxide at 700–950°. The small calculated positive value of the reaction for tin as written above accounts

[25] T. Maeda, *Bull. Japan Inst. Phys. Chem. Research,* 2,350 (1923).

for the lack of definiteness in the tin cells, since the formation or reduction of either oxide could not be expected to take place exclusively.

It is not probable that a lead monoxide electrode made up originally with lead dioxide could give results of sufficient accuracy to serve as criticism of Smith and Woods' figures, and their result is undoubtedly the accurate one.

VII. Comment Concerning Oxide Electrodes

In this work it was found that cells involving oxide electrodes were highly polarizable and very sensitive to the presence of traces of electronegative impurities in the oxide material and electrolyte. Much of the difficulty with oxide or electrolyte containing more electronegative elements as impurity and resulting in rapid deterioration of the cells because of strong local action is readily eliminated by treating the oxide in suspension in the electrolyte with turnings of the pure metal in question for some time before use (preferably at a boiling temperature). Such turnings added to the cell contents are not entirely satisfactory, since the electrodeposited metal of the electrode proper usually acts preferentially in replacing the electronegative elements. In spite of such precautions, it was found impossible to produce cells which were *permanently* stable, although it was often possible to produce cells having constant e.m.f.'s for several weeks. Because of the inherent variations and polarizability of the cells, the temperature coefficient of oxide cells is usually difficult to determine with sufficient accuracy to give satisfactory thermal data.

Entropy calculations have been of great use in determining the cell reaction and furnishing assurance of the validity of the measurements. It is thought that free-energy determinations combined with entropy values will make possible the calculation of heats of formation, in many cases much more accurately than any possible direct determination. Because of the difficulty of obtaining thermal data from these cells, the selection of the cell reaction is uncertain in some cases; for this reason the results have been found acceptable only when substantiated by check with other independent methods, especially entropy determinations.

TABLE IX

SUMMARY OF MEASUREMENTS AND CALCULATIONS

Subs.	ΔF°_{298} of formation	S_{298} (Millar)	ΔH_{298} (formation) from cell coef.	ΔH_{298} (formation) from ΔF and S
CdO	$-55{,}064 \pm 500$	13.17 ± 0.1	$-62{,}305 \pm 500$	$-61{,}950 \pm 500$
$Cd(OH)_2$	$-112{,}178 \pm 500$	....	$-131{,}850 \pm 500$	....
Cu_2O	$-34{,}672 \pm 200$	21.7 ± 1.0	$-38{,}400 \pm 2000$	$-40{,}375 \pm 400$
CuO	$-30{,}800 \pm 200$	9.75 ± 0.05	$-38{,}652 \pm 1000$	$-37{,}626 \pm 200$
SnO	$-61{,}332 \pm 300$	13.56	$-80{,}000 \pm 15000$	$-67{,}914 \pm 300$
SnO_2	$-123{,}200 \pm 400$	13.51	....	$-137{,}400 \pm 400$

Summary

1. Oxide electrodes of cadmium oxide, cuprous and cupric oxide, stannous and stannic oxide and lead dioxide have been compared to the hydrogen or mercuric oxide electrode in barium hydroxide solutions.

2. Free energies of formation from these results and calculated heats of formation are summarized in Table IX.

THE HEAT CAPACITIES AT LOW TEMPEMTURES OF THE OXIDES OF TIN AND LEAD[1]

BY RUSSELL W. MILLAR[2]

RECEIVED OCTOBER 8, 1928 PUBLISHED JANUARY 8, 1929

In continuation of the general program of determination and compilation of thermal and equilibrium data concerning the oxides and sulfides of metals, the heat capacities of SnO, SnO_2, Pb_3O_4 and PbO_2 have been measured from about 70°K. to room temperature. The method and apparatus employed were those previously used by the author.[3]

Materials.—The stannous oxide was made by the precipitation of stannous hydroxide with ammonia from a boiling solution of pure stannous chloride. Dehydration was accomplished by boiling the solution. The addition of a few crystals of stannous chloride, as recommended by Ditte,[4] hastened the reaction. The oxide was at first dark red but soon changed to the stable bluish black modification. It was cooled, filtered, washed with cold water and dried *in vacuo* over fused potassium hydroxide to constant analysis. Air was excluded as well as possible during filtration and washing. Titration with standard iodine solution of two samples dissolved in hydrochloric acid showed 98.0% of SnO. The impurity was probably SnO_2. Metallic-tin, determined by reduction with hydrogen, was 87.36 to 87.21%, whereas the theoretical percentage is 88.12.

Stannic oxide was made by the action of dilute nitric acid on pure electrolytic tin. The material, when washed and ignited at 400°, was analyzed by reduction with hydrogen. Two determinations gave 99.84 and 99.73% of the theoretical amount of tin.

Lead dioxide was prepared by the electrolysis of an acid solution of lead nitrate, according to the method of Palmaer.6 Lead carbonate was added to maintain the lead-ion concentration and to prevent the hydrogen-ion concentration from rising. Crystalline lead was formed at the cathode and dense plates of lead dioxide, which attained a thickness of 2–3 mm., at the anode. The product was ground to pass a 14-mesh screen, washed with boiling water until the washings showed no trace of nitrate and dried at 120°. Analysis by oxidation of hydrochloric acid, absorption of the chlorine evolved

[5] Palmaer, *Medd.* Kgl. *Vetenskapsakad, Nobelinst.*, *5*, 1 (1919).

in potassium iodide solution, and titration of the iodine with standard thiosulfate showed 99.8, 99.2 and 99.6% of the theoretical amount of active oxygen.

Lead orthoplumbate, or minium, was prepared by decomposition of electrolytic lead dioxide in a stirred bath of molten potassium nitrate at 460°, according to Milbauer.[6] The salt was washed out and the product was dried at 120°. Analysis by the method used for lead dioxide indicated only 98.7, 96.1, 96.5, 96.5 and 97.2% of the theoretical quantity of active oxygen. Reduction by hydrogen showed 90.62% lead, whereas the theoretical percentage is 90.66. Probably decomposition of the dioxide was carried too far by excessive heating of the sides of the nitrate bath, but an impurity of considerable lead monoxide cannot be serious, since the heat capacity of lead orthoplumbate is only slightly more than three times that of the monoxide throughout the range of temperature of the measurements.

In the following tables heat capacities are expressed in gram calories (15°) per mole. One calorie is equal to 4.185 absolute joules. The calculations were made on the basis of O = 16, Sn = 118.7 and Pb = 207.20.

TABLE I

THE MOLAL HEAT CAPACITY OF SnO

T, °K.	69.6	73.0	81.7	93.3	108.1	125.0	140.8	156.9
C_p	4.067	4.300	4.910	5.432	6.251	6.975	7.594	8.145
T, °K.	181.7	193.5	209.7	230.2	251.3	268.3	284.3	292.5
C_p	8.856	9.172	9.536	9.917	10.17	10.24	10.51	10.52

TABLE II

THE MOLAL HEAT CAPACITY OF SnO_2

T, °K.	71.8	75.2	79.3	84.8	93.8	103.6	118.2	126.0	
C_p	3.087	3.323	3.619	3.995	4.532	5.242	6.165	6.621	
T, °K.	142.2	154.6	181.8	202.7	215.5	271.6	273.4	287.2	289.4

TABLE III

THE MOLAL HEAT CAPACITY OF Pb_3O_4

T, °K.	71.5	78.5	85.6	100.1	111.7	127.1	138.6	151.3	172.1
C_p	16.65	17.82	18.81	20.55	22.33	24.29	25.82	27.08	28.77
T, °K.	187.4	208.8	227.1	247.1	259.8	266.2	278.2	292.6	
C_p	30.34	31.66	32.73	34.24	33.00	34.44	34.37	34.46	

Owing to its low apparent density, only about 0.3 mole of lead orthoplumbate could be loaded into the calorimeter, so that the empty calorimeter had more heat capacity than the sample. The result was a loss in accuracy. Usually the heat capacity of the sample was 1.5 to 4 times that of the empty calorimeter. The large errors in Points 13, 14 and 15 can be explained only by poor contacts in the potentiometer switches, which were causing trouble at the time.

An uncertainty at the lower end of the temperature scale caused inaccuracy in the calculations for Points 1, 2 and 3 in Table IV.

TABLE IV

THE MOLAL HEAT CAPACITY OF PbO_2

T, °K.	69.9	73.1	84.5	89.8	98.9	111.6	126.0	140.7	151.8	166.9
C_p	5.430	5.688	6.345	6.866	7.484	8.337	9.160	9.971	10.46	11.23
T, °K.	183.4	198.4	212.9	227.9	242.0	261.6	270.5	298.1	297.2	
C_p	11.94	12.72	13.11	13.50	13.95	14.60	14.83	15.42	15.43	

As before, the entropy of the oxide at 25° was calculated by graphical integration in the range covered by the data, using the relation

$$S_{298} - S_T = \int_T^{298} C_p \mathrm{d} \ln T$$

and by extrapolation to the absolute zero by means of combinations of Debye and Einstein functions. The following equations indicate the values of $\beta\nu$ used in these functions, denoted by $D(\beta\nu/T)$ and $E(\beta\nu/T)$, for the substances named, and the maximum temperatures for which the combinations of theoretical curves reproduce the experimental values of C_p.

SnO,	$D\left(\frac{215}{T}\right) + E\left(\frac{494}{T}\right)$	0.5% to 178°K.
SnO_2,	$D\left(\frac{305}{T}\right) + E\left(\frac{487}{T}\right) + E\left(\frac{968}{T}\right)$	0.5% to 200°K.
Pb_3O_4,	$3D\left(\frac{119}{T}\right) + E(f)$	......
PbO_2,	$D\left(\frac{183}{T}\right) + E\left(\frac{342}{T}\right)$	0.5% to 94°K.

The curve for Pb_3O_4 follows closely that of 3PbO drawn from the data of Nernst and Schwers[7] and of Russell.[8] The difference decreases rapidly with decreasing temperature, and probably does not reverse sign, so that, at low temperatures, the two curves follow the same Debye curve. Although better agreement with C_v, if sufficient data for the calculation of this quantity existed, could doubtless be obtained if more complicated combinations of these two functions were devised, nothing would be gained, since the extrapolation gives the entropy with only a slight error in any case.

The entropies of these oxides at 25° are: SnO, 13.56; SnO_2, 12.51; Pb_3O_4, **60.53;** PbO_2, 18.27.

In order to calculate the free energy according to the equation

$$AF = \Delta H - T\Delta S \tag{1}$$

for the reaction metal + oxygen = oxide, we must know the entropies of metallic tin, lead and of oxygen. From Bronsted's[9] data, Lewis, Gibson and Latimer[10] have calculated for Sn (white), $S^\circ_{298} = 11.17$, and

---

[7] Nernst and Schwers, *Sitzb. preuss. Akad. Wiss.*, 355 (1914).

[8] Russell, *Physik. Z.*, 13, 59 (1912).

[9] Bronsted, *Z. physik. Chem.*, 88, 479 (1914).

[10] Lewis, Gibson and Latimer, THIS JOURNAL, 44, 1008 (1922).

from those of Griffiths and Griffiths[11] for Pb, $S^{\circ}_{298} = 15.53$. As before, for O_2, $S^{\circ}_{298} = 49.2$.

Stannous Oxide.—No reliable values of the heats of formation of the oxides of tin exist. For the reaction $Sn(s) + 1/2O_2(g) \doteq SnO(s)$, Mixter[12] gives $AH = -66{,}800$, Andrews[13] $-67{,}600$, Delephine and Hallopean[14] $-70{,}700$, and G. Chaudron[15] $-69{,}000$. The results of measurements made in this Laboratory of the e.m.f. of cells, which will soon be published, give an accurate value of the free energy of stannous oxide, from which will be calculated a value of its heat of formation more accurate than any of the above.

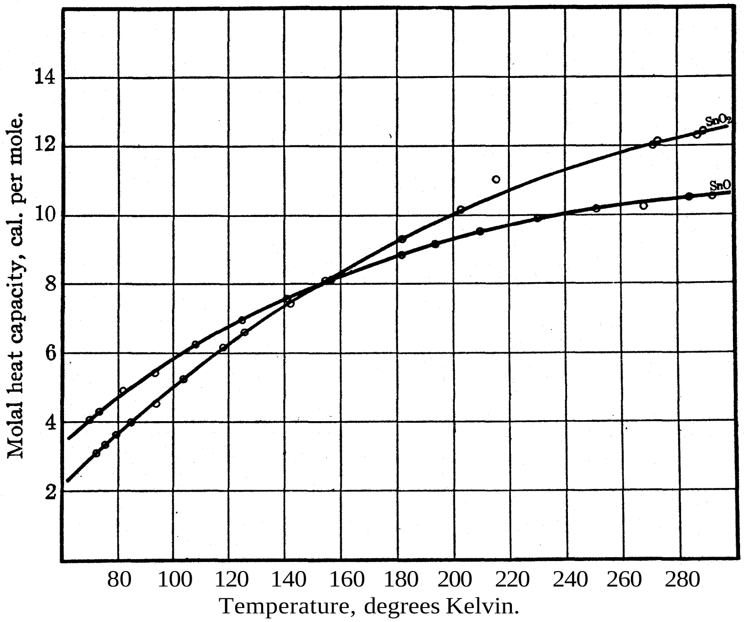

Fig. 1.—The molal heat capacities of SnO and SnO_2.

Stannic Oxide.—For the reaction Sn (white) + $O_2(g) = SnO_2(s)$, Mixter gives $\Delta H = -137{,}800$; Andrews $-137{,}800$; Moose and Parr[16] $-138{,}200$; and Maeda[17] $-130{,}260$. Mixter's value, $-137{,}800$, is probably but little in error. From the entropies of white tin, oxygen and stannic oxide, $\Delta S^{\circ}_{298} = -47.86$ and, finally, for $SnO_2(s)$, $\Delta F^{\circ}_{298} = -123{,}540$.

Lead Monoxide.—For the reaction $Pb(s) + 1/2O_2(g) = PbO(s)$,

[17] Maeda, *Bull. Japan Inst. Phys. Chem. Research,* 2, 350 (1923).

G. Chaudron[15] gives $\Delta H = -50{,}200$, Treadwell[18] $-50{,}400$, Berthelot[19] $-50{,}800$, Thomsen[20] $-50{,}300$, Gunther[Zl] $-52{,}900$ and Smith and Woods[22] $-52{,}360$. With the exception of the last two, these values are exceptionally concordant and would ordinarily be accepted, but the cells of Smith and Woods,[22] which were of the form Pb(s) + PbO(red) | $Ba(OH)_2$ soln. | H_2(g) were exceptionally reproducible at both 25 and 45°. Günther, who determined accurately the heat of formation of lead chloride by means of cell measurements, concluded that Thomsen's value for that quantity

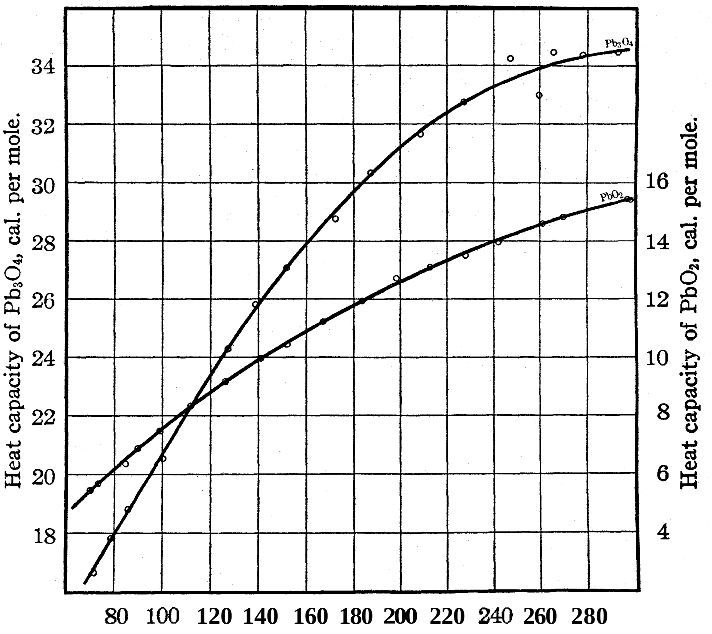

Fig. 2.—The molal heat capacities of Pb_3O_4 and PbO_2.

was too large by 2600 calories, and recalculated the latter's data for lead monoxide on that basis. Since Smith and Woods are the only investigators who definitely state that they used the red, tetragonal form, which is the stable one at room temperature, instead of the yellow, orthorhombic form, and since their measurements are undoubtedly accurate, their values of the free energy and the heat of formation are accepted and are quoted here for later reference.

$$\text{Pb(s)} + 1/2\text{O}_2\text{(g)} = \text{PbO(red)};\quad \Delta F^\circ_{298} = -45{,}050;\quad \Delta H_{298} = -52{,}360 \qquad (2)$$

---

[21] Giinther, Z. *Elekfrochem.*,23, 197 (1927).

[22] Smith and Woods, THIS JOURNAL, 45,2632 (1923).

Randall and Spencer,[23] from measurements of the solubility of red and yellow lead monoxide in solution of sodium hydroxide, have calculated the difference in free energy of the two forms

$$\text{PbO(yellow)} = \text{PbO(red)};\quad \Delta F_{298} = -163 \qquad (3)$$

Lead Dioxide.—For the reaction $PbO(s) + 1/2O_2(g) = PbO_2(s)$, Tscheltzow[24] gives $\Delta H = -12{,}140$, which added to Equation 2 gives for the reaction $Pb(s) + O_2(g) = PbO_2(s)$, $\Delta H = -64{,}500$. Mixter[25] gives $-65{,}600$.

Glasstone,[26] from cell measurements, has calculated the free energy changes at 17° of several reactions involving the oxides of lead. Apparently his lead monoxide was the red form. A recalculation of his two most reliable sets of measurements gives

$$PbO_2(s) + H_2(g) = \text{PbO(red)} + H_2O(l);\quad \Delta F^\circ_{298} = -49{,}600 \qquad (4)$$

$$3PbO_2(s) + 2H_2(g) = Pb_3O_4(s) + 2H_2O(l);\quad \Delta F^\circ_{298} = -104{,}360 \qquad (5)$$

From Equations 2 and 4 and the free energy of water

$$H_2(g) + 1/2O_2(g) = H_2O(l);\quad \Delta F^\circ_{298} = -56{,}560 \qquad (6)$$

given by Lewis and Randall[27]

$$Pb(s) + O_2(g) = PbO_2(s);\quad \Delta F^\circ_{298} = -52{,}010 \qquad (7)$$

Wescott,[28] from determinations of the equilibrium constant of the reaction $PbCl_2(s) + Cl_2(g) + 2H_2O = PbO_2(s) + 4HCl(soln.)$ and the free energy of lead chloride, calculated for $Pb(s) + O_2(g) = PbO_2(s)$, $\Delta F^\circ_{298} = -52{,}330$, but he used an old value, $-56{,}620$, as the free energy of liquid water. When the more recent value given in Equation 6 is used, his results give $-52{,}210$ for the free energy of lead dioxide. The good agreement with Glasstone's value given in Equation 7 must, however, be considered as fortuitous, since the activity of the hydrochloric acid in Wescott's solution was somewhat uncertain. By combining Equations 1 and 7 with the entropies of lead, oxygen and lead dioxide, the heat of formation of lead dioxide can be calculated:

$$Pb(s) + O_2 = PbO_2(s);\quad \Delta H_{298} = -65{,}960 \qquad (8)$$

in fair agreement with Mixter's value.

Lead Orthoplumbate.—By combining Equations 2, 4, 5 and 6

$$3Pb(s) + 2O_2(g) = Pb_3O_4(s);\quad \Delta F^\circ_{298} = -147{,}270 \qquad (9)$$

a value which can be compared with one calculated from careful measurements of the decomposition pressure of lead orthoplumbate by Reinders

and Hamburger.[29] They showed that, at the temperatures of their measurements, yellow lead monoxide was formed, and that it did not form solid solutions with the lead orthoplumbate. Their data have been treated by the method described by Lewis and Randall,[30] whose equations and symbols will be used in what follows. The reaction is $2Pb_3O_4(s) = 6PbO(yellow) + O_2$. Reinders and Hamburger represent their results accurately by the equation

$$\log p_{mm.} = -\frac{35{,}926}{4.5717T} + 11.8976$$

where it is evident that they have used for the gas constant, R = 4.571/2.303 instead of 1.9885, the value accepted here. If 1.9885 is used, their data may be equally well represented by

$$\log p_{,,} = -\frac{35{,}987}{4.57787T} + 11.8976$$

Calculation by means of the approximation $d \ln p/d(1/T) = -\Delta H/R$ gives for their reaction, $\Delta H = -35{,}987$. Heat capacity equations for the substances involved are now required in order to calculate ΔH_0.

From the determinations of Regnault[31] and of Magnus[32] the heat capacity of lead monoxide is 11.4 at 330°K. and 11.7 at 417°K., whence for PbO, $C_p = 10.26 + 0.0034T$. At room temperature the heat capacity of lead orthoplumbate is 3.06 times that of lead monoxide. Assuming that this ratio holds through the region of Reinders and Hamburger's measurements, for Pb_3O_4, $C_p = 31.41 + 0.0106T$. For oxygen Lewis and Randall[33] give O_2, $C_p = 6.50 + 0.0010T$. For the decomposition of two moles of lead orthoplumbate, $\Delta C_p = 5.24 + 0.0005T$. Taking, at the average temperature of the measurements, $\Delta H_{823} = 35{,}987$, ΔH_0 becomes 31,505. The standard free energy change at the temperature of each of the 16 experiments was calculated by means of the equation $AF^{\circ} = -RT \ln P$, where P is the experimentally determined pressure of the oxygen in atmospheres. By substitution of these values of ΔF°, ΔH_0, and the coefficients of the equation for ΔC_p in the free energy equation in the usual way, 16 values of the integration constant I were calculated which varied from —0.77 to —0.31, most of them being grouped closely about the average, I = —0.52. Then for

$$2Pb_3O_4(s) = 6PbO(yellow) + O_2;\quad AF^{\circ} = 31{,}505 - 5.24T \ln T - 0.00025T^2 - 0.52T;$$
$$\Delta F^{\circ}_{298} = 22{,}430;\quad \Delta H_{298} = 33{,}090 \qquad (10)$$

From Equations 1 and 10, $AS''_{„} = 35.76$, and by the use of the entropies of Pb_3O_4 and O_2, PbO(yellow), $S^{\circ}_{298} = 17.94$.

---

[29] Reinders and Hamburger, *Z. anorg. Chem.*, 89, 71 (1914).

[30] Lewis and Randall, ref. 27, p. 173.

[31] Regnault, *Ann. chim. phys.*, [3] 1, 129 (1841).

[32] Magnus, *Physik. Z.*, 14, 5 (1913).

[33] Lewis and Randall, ref. 27, p. 80.

Combining Equations 2, 3 and 10

$$3Pb(s) + 2O_2(g) = Pb_3O_4(s);\ \Delta F^{\circ}_{298} = -145{,}870$$

and with the entropies of Pb_3O_4, Pb and O_2

$$\Delta H_{298} = -171{,}050 \qquad (11)$$

On returning to Equations 10 and 11, it may be noted that

$$Pb(s) + 1/2O_2 = PbO(\text{yellow});\ \Delta H_{298} = -51{,}500$$

and with 2

$$PbO(\text{yellow}) = PbO(\text{red});\ \Delta H_{298} = -860;\ \Delta S^{\circ}_{298} = -2.35 \qquad (12)$$

From Equations 1 and 2, PbO(red), $S^{\circ}_{298} = 15.62$. Smith and Woods in their paper noted the large discrepancy between their value of the entropy of red lead monoxide and the value of the entropy of lead monoxide, 16.3, which Lewis and Randall[34] calculated from measurements of its heat capacity by Nernst and Schwers.[7] The writer has recalculated the entropy from the same data and obtained 16.41, whereas Miething,[35] using the same data, obtained 17.04. Nernst and Schwers, although they say nothing concerning their sample, probably used the yellow form.

The entropy of yellow lead monoxide which was calculated from Reinders and Hamburger's results, 17.94, is undoubtedly too high, due probably to the assumptions regarding the heat capacities of lead monoxide and orthoplumbate above room temperature. For the present, then, the free energy of lead orthoplumbate which was calculated from Glasstone's data will be accepted, together with the corresponding heat of formation calculated from the entropies of this substance and of lead and oxygen. Thus

$$3Pb(s) + 2O_2(g) = Pb_3O_4(s);\ \Delta F^{\circ}_{298} = -147{,}270;\ \Delta H_{298} = -172{,}440$$

Likewise, from Equations 2 and 3, the entropy of yellow lead monoxide, 16.41, and the entropies of lead and oxygen

$$Pb(s) + 1/2O_2(g) = PbO(\text{yellow});\ \Delta F^{\circ}_{298} = -44{,}887;\ \Delta H_{298} = -51{,}960$$

Summary

The heat capacities of stannous and stannic oxide, lead dioxide and lead orthoplumbate have been determined from 70 to 300°K. and their entropies at 25° have been calculated.

The following table contains the results of calculations from these data and others found in the literature.

	S°_{298}	ΔF°_{298}	ΔH_{298}
$SnO(s)$	13.56	....	....
$SnO_2(s)$	12.51	−123.540	−137,800
PbO(red)	15.62	− 45,050	− 52,360
PbO(yellow)	16.4	− 44,887	− 51,960
$Pb_3O_4(s)$	60.53	−147,270	−172,440
$PbO_2(s)$	18.27	− 52,010	− 65,960

THE HEAT CAPACITIES AT LOW TEMPERATURES OF "FERROUS OXIDE," MAGNETITE AND CUPROUS AND CUPRIC OXIDES[1]

BY RUSSELL W. MILLAR[2]

RECEIVED OCTOBER 8, 1928 PUBLISHED JANUARY 8, 1929

The thermodynamic properties of the important and interesting substances "ferrous oxide," magnetite and cuprous and cupric oxides, have been the subject of an enormous amount of experimental investigations and of an even greater amount of speculation. No attempt will be made here to review the accumulated data relating to the equilibria of these oxides with oxygen and the corresponding metals; most of the data are only approximations which fail to agree. The measurements presented here leave something to be desired with regard to ferrous oxide, which has never yet been prepared pure in quantities greater than a gram, and with regard to the entropy of cuprous oxide, which has at the lowest temperatures at which measurements were made, 75°K., the abnormally high heat capacity of over 8 calories per mole.

Materials.—A sample of crude ferrous oxide, kindly supplied by the Fixed Nitrogen Research Laboratory, was separated magnetically according to the method of Wyckoff and Crittenden.[3] The analysis, according to the method of Sims and Larsen,[4] which agrees with theirs as well as could be expected, was as follows: total iron, 77.24%; free iron, 0.80%; ferrous iron, 68.46%; and ferric iron (by difference), 7.98%. If we assume that all of the ferric oxide is combined with ferrous oxide as magnetite, Fe_3O_4, the material contained free iron, 0.80%; ferrous oxide, 83.05%; and magnetite 16.15%. Although Wyckoff and Crittenden conclude, as a result of their crystallographic measurements, that the purity of the material was much greater, large errors in the analysis do not seem probable in view of the care used to prevent oxidation during dissolution of the sample.

Although many attempts to secure pure ferrous oxide have been made, none has been successful, if we except those of Hilpert and Beyer,[5] Wohler and Balz,[6] and Wohler and Günther,[7] who prepared samples of 98–100% purity, but only in quantities of less than 1 g. Attempts to produce larger quantities are now being made in this Laboratory, but so far with indifferent

[7] Wohler and Günther, *ibid.*, 29, 276 (1923).

success. One embarrassing characteristic, as found by Chaudron,[8] is that the reaction 4FeO = Fe + Fe_3O_4 tends to take place below 570°, so that all preparations made above that temperature must be cooled to room temperature as rapidly as possible. Such a procedure is objectionable because a quenched material has internal strains which cause variations from the thermodynamic properties of the stable form.

The magnetite, from the deposit at Mineville, N. Y., was kindly lent for these measurements by Dr. Sosman of the Geophysical Laboratory of the Carnegie Institution of Washington, The ore was similar to that used by Sosman and Hostetter,[9] whose analysis was: Fe_3O_4, 99.0%; Fe_2O_3, 0.63%; and impurities, largely quartz, 0.37%. A correction was made for the heat capacity of the quartz.

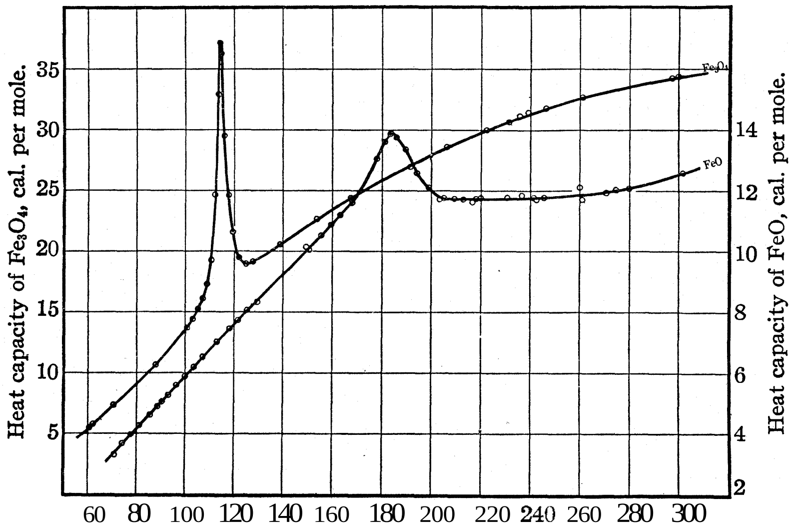

Fig. I—The molal heat capacities of FeO and Fe_3O_4.

The cupric oxide was made by heating No. 28 copper wire in a muffle at 700° until oxidation was apparently complete. Analysis by reduction with hydrogen showed 79.90 and 79.91% copper, whereas the theoretical percentage is 79.89; this corresponds to 0.60% cuprous oxide, but the sample was completely soluble in 4% sulfuric acid without the deposition of metallic copper. The wire was probably completely converted to cupric oxide, but contained the residual impurities of the original copper.

The cuprous oxide was prepared from the cupric oxide by decomposition at about 0.002 mm. pressure in a silica tube, as described by Maier.[10]

[8] Chaudron, *Ann. chim. phys.*, [9] 16,271 (1921).

[9] Sosman and Hostetter, THIS JOURNAL, 38,812 (1916).

[10] Maier, *ibid.*, 51, 194 (1929).

After heating at about 700° until a layer of cuprous oxide, which does not seriously attack fused silica ware below 1100°, had been formed on the outside, the temperature was raised to 1000° and maintained until no more oxygen was evolved. Reduction by hydrogen showed 88.82% of copper, which is the theoretical proportion.

In calculating the heat capacity of the ferrous oxide, it was assumed that the specific heat of the sample was the same as that of pure ferrous oxide. The magnetite and iron are in solid solution in the ferrous oxide, as is shown by the lack of magnetism of the sample and by the normal course of the heat capacity curve near 114°K., where the curve for pure magnetite shows a sharp maximum. Consequently a correction could not be made for the magnetite as if it were a separate phase, and although our knowledge of the properties of pure ferrous oxide may be none the greater, the procedure adopted seemed the only feasible one. Moreover, it seems improbable that the heat capacity of pure ferrous oxide at 25° is as high as 12.5, the value given, since the heat capacity of manganous oxide, 10.30, is very nearly that predicted by Kopp's law, 10.2.

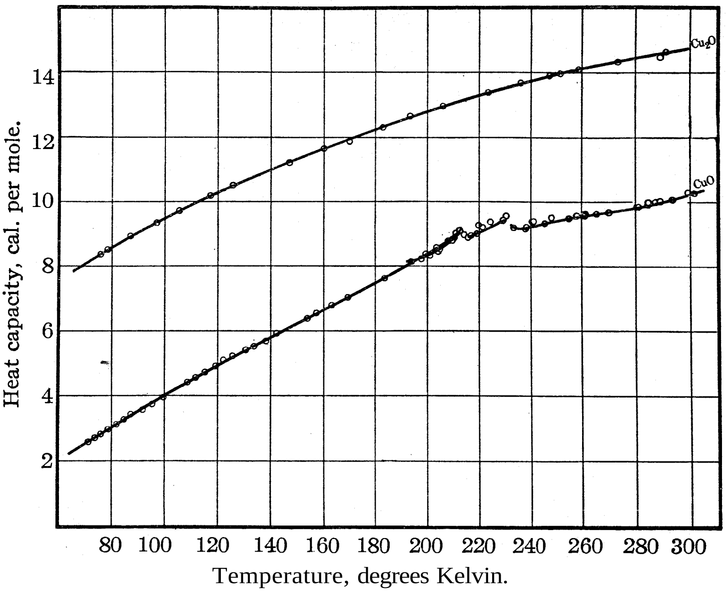

Fig. 2.—The molal heat capacities of Cu_2O and CuO.

In the following tables, heat capacities are expressed in gram calories (15°) per mole. One calorie is equal to 4.185 absolute joules. The calculations were made on the basis of O = 16, Cu = 63.57 and Fe = 55.84.

The measurements of the heat capacity of magnetite agree with those of Parks and Kelley[11] at the lowest temperatures, but gradually become

the magnetite, which they did not make, and part by a correction for loss of heat during the measurements.

A plot of the heat content–temperature curve shows that the heat capacity never becomes infinite, but reaches a maximum of 37.1 at 114.15°K The maximum is undoubtedly due to a change in the magnetic properties.

The first 46 points for cupric oxide, determined in October, 1926, were satisfactory below 200°K., but the measurements made above that temperature were inaccurate because the current through the resistance thermometer varied, due to the rapidly changing temperature of the room. In April of this year it was decided to repeat the measurements above this temperature. Fig. 3 shows all of the points between 180 and 270°K. taken at both times, with numbers corresponding to those in Table IV. It was surprising to find that two discontinuities in the heat capacity curve existed within a narrow range of temperature, and that the runs of the first series were not as inconsistent as was at first supposed. According to expectations the heat capacity in the neighborhood of 220°K. varied with the history of the sample, as will be seen by a comparison of the first and second series. The former was taken after cooling to liquid-air temperatures and heating step by step, and the latter after cooling to 190°K. and proceeding in the same manner, beginning with Run 47, and to 200°K., beginning with Run 62. It may be noted, however, that similar experiments[12] with mangano-manganic oxide and manganese dioxide showed the heat capacity of each of these substances to be independent of its history. Some preliminary measurements of the heat capacity of magnetite, made with an unsatisfactory calorimeter—later discarded—led to the conclusion that its history likewise did not affect this quantity. It will be noted that for manganous oxide, manganese dioxide, and magnetite the discontinuities of the heat capacity curves were very large in comparison with those of cupric oxide, and apparently took place with much greater ease and rapidity.

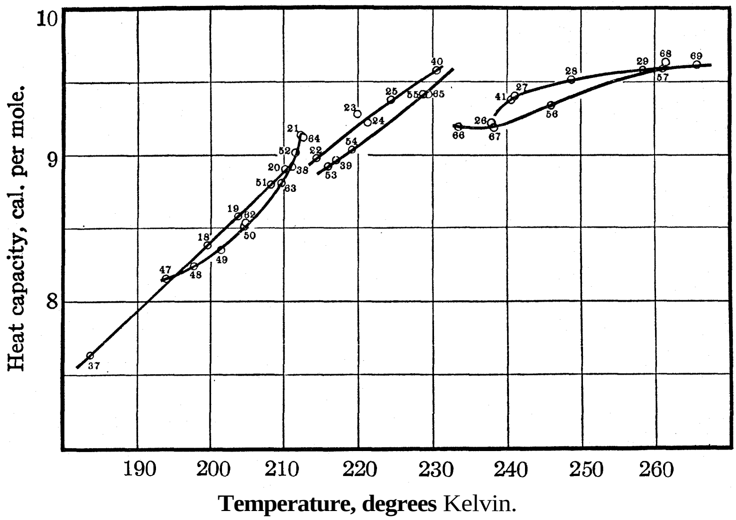

Fig. 3.—The molal heat capacity of CuO.

The Calculation of Entropy.—Obviously no sum of the theoretical equations so far devised, representing heat capacity as a function of the temperature, can be made to fit the data for ferrous oxide, magnetite and cupric oxide. However, if the upper and lower portions of the curve on the C_p–log T axes are connected by a curve representing the probable values of C_p, if no maximum were present, a combination of theoretical curves can be made to represent the interpolated curve with considerable accuracy and the entropy at some temperature below the interpolation can be calculated from the theoretical function.

In the following the Debye function is represented by $D(\beta\nu/T)$, and the Einstein function by $E(\beta\nu/T)$. For ferrous oxide the interpolation is rather large—from 89 to 282°K. The function

$$C_v = D\left(\frac{311}{T}\right) + E\left(\frac{387}{T}\right) + E\left(\frac{1265}{T}\right)$$

---

[12] Millar, This Journal, 50, 1875 (1928).

reproduces the lower portion of the experimental curve and the interpolation within 0.1% to 200°, and within 0.5% to 250° K. The total entropy at 25° is 12.7. Although this value exceeds the entropy of iron—6.71, calculated by Lewis, Gibson and Latimer[13]—more than the entropy of a monoxide usually exceeds that of the metal, yet it was found[12] that the entropy of manganous oxide was 14.92, whereas that of metallic manganese has been found by the above authors to be 7.3. The value for FeO, $S^\circ_{298} = 12.7$, is probably accurate within 2 units.

The interpolation under the peak in the curve representing the heat capacity of magnetite extends from 93 to 158°K. The function

$$C_v = 3D\left(\frac{346}{T}\right) + 4E\left(\frac{574}{T}\right)$$

represents the interpolation and the data above and below within 0.1% to room temperature. Calculation from the Debye function gives $S^\circ = 0.969$ at 44.7°K., and graphical integration above that temperature gives for Fe_3O_4, $S^\circ_{298} = 34.69$. Parks and Kelley[11] give 35.1, of which only 0.17 unit is due to their higher values of the heat capacity near room temperature. The agreement is excellent in view of the difficulty which they must have experienced in using the method of Lewis and Gibson[14] to obtain the entropy at 90°K., the lowest temperature at which they made a measurement, which is almost within the irregular portion of the curve. The present value is probably correct to 0.2 entropy unit.

An accurate calculation of the entropy of cuprous oxide is impossible, since the heat capacity is still over 8 at the lowest temperature. Furthermore, the four lowest points seem too high. The temperature scale may be in error at the lower end, although no uncertainty was anticipated before the calculation of the heat capacity, or these points may lie on the upper portion of an irregularity in the curve. However, the data can be well represented by the function $D(92/T) + E(235/T) + E(825/T)$, which represents the data within 0.3% up to room temperature, with the exception of the four lowest points. Calculation from the Debye function gives $S^\circ = 1.83$ at 25.1°K., and for Cu_2O, $S^\circ_{298} = 21.7 \pm 1.0$. It is hoped that the heat capacity of cuprous oxide at much lower temperatures will be obtained at a later date and thus permit a more satisfactory calculation of its entropy.

For cupric oxide the interpolation extends from 135 to 288°K. The function $D(443/T) + E(671/T) + E(1265/T)$ represents the data and the interpolation within 0.1% to 126° K., and within 0.5 to 224°K. The entropy calculated from the Debye function is 0.69 at 76.2°, and graphical integration over the remaining range gives for CuO, $S^\circ_{298} = 9.75 \pm 0.05$.

No reliable determinations of the heats of formation of the oxides of

---

[13] Lewis, Gibson, and Latimer, THIS JOURNAL, 44, 1008 (1922).

[14] Lewis and Gibson, *ibid.*, 39,2554 (1917).

iron have been made. Since such measurements will, it is hoped, be made in this Laboratory at a later date, calculations of the free energy of these substances will be deferred.

Although the data for the oxides of copper are of sufficient accuracy to permit calculations of their free energies, their consideration is most profitable in connection with the measurements of the e.m.f. of cells reported in the paper by Maier.[10]

Summary

The heat capacities of "ferrous oxide" and of cuprous and cupric oxide have been measured from 70 to 300°K., and of magnetite from 60 to 300°K.

Their entropies are:

	FeO	Fe_3O_4	Cu_2O	CuO
S°_{298}	12.7 ± 2.0	34.69 ± 0.2	21.7 ± 1.0	9.75 ± 0.05

BERKELEY, CALIFORNIA

NOTES

A Simple Apparatus for the Determination of Carbon Dioxide.—The following method has been worked out for the accurate determination of carbon dioxide in limestone. The originality, we believe, lies in the simplification of the apparatus and in the arrangement to minimize contamination with atmospheric carbon dioxide.

No special apparatus is required; two ordinary 1-liter Pyrex flasks, a small rubber balloon, two rubber stoppers and some large glass tubing are all that is necessary.

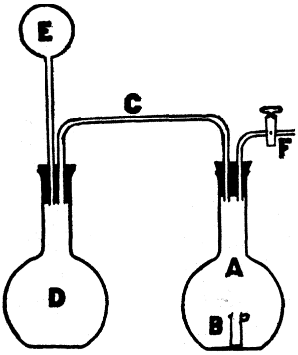

Fig. 1.

Chromic acid is used to liberate the carbon dioxide, and this is absorbed in a carefully standardized solution of barium hydroxide. The excess barium hydroxide is then titrated with standard hydrochloric acid, using phenolphthalein as indicator.

Procedure.—Set up the apparatus as shown in the figure and make sure that it is air tight. Weigh out 0.1000 g. of carbonate into B, place 100 cc. of a 1% aqueous solution of chromic anhydride in A and 50 cc. of water in D. Heat the contents of both A and D to boiling, remove both flames and add 25 cc. of a 0.2 N barium hydroxide solution to D. Carefully lower the bottle B containing the charge into A with a copper wire without letting the acid come in contact with the carbonate. Quickly stopper both A and D, which are thus connected by the tube C. Shake flask A to overturn B, place D in cold water and boil the contents of A. The balloon E serves as a safety valve, pressure regulator and pressure indicator. After boiling for about thirty minutes, remove the flame from beneath A and admit carbon dioxide-free air through F. The flask D should be now at about room temperature. Disconnect it and titrate the excess barium hydroxide with standard hydrochloric acid, using phenolphthalein as indicator.

The advantages of the method are that no train is necessary and the apparatus is cheap and easy to set up. It is likewise easy to clean. The results obtained are quite accurate. In the case of pure calcium carbonate 44.08 and 43.93 instead of 44.00% were obtained. With sodium carbonate the results were likewise accurate.

Note on the Determination of the Activity of One Substance from that of Another by a Cell with a Liquid Junction.—In connection with work done in this Laboratory it was desired to know the activity coefficient of perchloric acid over a range of concentrations. On investigation of the literature, an article by Schuhmann[1] was found in which he states that the activity coefficient of perchloric acid is the same as that of hydrochloric acid of the same molality, at all concentrations up to 1.1 molal. His conclusions are based upon measurements of the cell H_2, $HCl(c)$, $HClO_4(c)$, H_2, since he obtains electromotive forces which are the same as those given by the Lewis and Sargent formula for this kind of liquid junction.

MacInnes and Yeh[2] have given a simple and reasonable derivation of this formula. When the cell operates, certain dilutions and concentrations will occur with respect to Cl^- and ClO_4^- in the composition gradient portion of the cell. (This composition gradient was of course set up by diffusion.) These effects are accompanied by the free-energy changes always involved in diluting or concentrating a substance. The "liquid potential" is the summation of these free energies, in joules per coulomb, when the cell operates reversibly. When the cell operates in a given direction, the relative speeds of Cl^- and ClO_4^- during current flow determine the extent to which the dilutions outweigh the concentrations, or the reverse, and this in turn determines the magnitude and sign of the "liquid potential," since dilution occurs with a decrease and concentration with an increase in free energy. MacInnes and Yeh derive the Lewis and Sargent formula, which involves the ion mobilities, by employing the ordinary equation for the free energy of dilution, assuming that the mobility and activity coefficient of each ion are constant over the entire gradient,

---

[1] Schuhmann, THIS JOURNAL, 46, 58 (1924).

[2] MacInnes and Yeh, *ibid.*, 43, 2563 (1921).

but not that the activity coefficients of all the ions are the same. They assume also a constant composition gradient. The assumption of a constant activity coefficient for a given ion is in accordance with experiment and with the well-known "principle of the ionic strength" of Lewis and Randall and the Debye-Hückel interionic attraction theory. They integrate the free energies of changes in concentration from a point beyond which no Cl^- ever enters to a point beyond which no ClO_4^- ever enters (using the above case as an example). The only reaction in the above cell not accounted for by these assumptions is the formation and disappearance of H^+ at the electrodes and its transport through the cell. If Schuhmann obtains the electromotive force given by the Lewis and Sargent formula, the formation and transport of H^+ must occur with no free-energy change. What these experiments seem to prove, then, is that the activity of H^+ in HCl solutions is the same as that of H^+ in $HClO_4$ solutions of the same molality, but not that the activity of Cl^- in aqueous HCl is the same as that of ClO_4^- in aqueous $HClO_4$ of the same molality. The experiments, therefore, do not prove that the mean activity of the ions, or the activity coefficient of the electrolyte, is the same for HCl and $HClO_4$ of the same molality. In fact, the use of mean activities is a mathematical device to avoid the use of individual ion activities, and is only exact for reactions which can be written in molecular form without arbitrary assignment of positive ions to negative ions, that is, reactions for which the product of the ion activities occurs in the equation connecting free energy with concentration. Practically all the cells used in activity determinations have been such as to involve the formation of the given compound from substances other than ions.

It is possible, of course, that Cl^- and ClO_4^-, because of the symmetrical electronic structure of both these ions, have the same activities in equimolal solutions of the two acids, up to 1.1 molal. Their mobilities are, in fact, nearly the same. It should be noted, however, that the individual ion activity of ClO_3^- is noticeably less than that of Cl^- in solutions of the same ionic strength, according to the table of Lewis and Randall. Other experiments of this type, or the determination of the activity of perchloric acid by freezing-point methods, might prove enlightening. Possibly the method could be used for the determination of individual ion activities. Meanwhile it is felt, in view of the above considerations, that the method used by Schuhmann is not evidence for equal mean activity coefficients in equimolal solutions of two electrolytes with a common ion.

THE ACTION OF SULFURIC ACID IN THE PREPARATION OF CERTAIN ALKYL HALIDES

BY ROGERS MCCULLOUGH[1] AND FRANK CORTESE[2]

RECEIVED JULY 6, 1928 PUBLISHED JANUARY 8, 1929

During the course of our work, we had occasion to prepare alkyl halides of higher purity than ordinarily obtained. Michael and his co-workers[3] came to the conclusion that the purest halides were made by heating the corresponding alcohols with aqueous hydrobromic acid, according to Norris'[4] suggestion. They removed the small amount of unsaturated materials formed with potassium permanganate.

However, sulfuric acid is commonly used in the preparation of these halides.[5] While we have suspected for a long while the detrimental effects attending the use of this acid, we now have definite experimental proof that halides prepared by its aid tend to spoil more easily on keeping, developing colors and free halogen acid. We have shown that sulfuric acid splits out halogen acid, forming small quantities of olefins, which are then polymerized, the polymers adding on halogen acid to form unstable products and violet colors.

We have found that distilling the halide from a mixture containing sulfuric acid results in a decided increase in high-boiling products, particularly in the case of sensitive bromides, such as *iso*propyl, *sec.*-butyl and *iso*butyl. Except in the cases of *sec.*- and isobutyl bromides, all the bromides from ethyl to n-amyl contained very little high-boiling products when they were prepared by slowly distilling the alcohol from hydrobromic acid alone, according to Norris'[4] procedure. The amount of such products was greater for *iso*butyl than for *sec.*-butyl bromide. If the bromide obtained from the first distillation in the Norris method was returned to the acid flask and redistilled to improve the yield, as sometimes recommended, the additional time of heating resulted in an increase in polymers and other undesirable materials.

Allyl chloride and allyl bromide are commonly prepared by the aid of heat, and also by the use of sulfuric acid.[5] These halides, as ordinarily prepared, soon develop an extremely pungent odor, becoming lachrymators, and the bromide also develops a color. A simple cold process has been worked out for preparing these halides. The high-boiling residue

is very small in this process. Furthermore, one distillation gives a product which remains for months water-white and maintains a perfectly clean odor, without any trace of sharpness, when stored in the dark in an ordinary bottle. The yields are poorer than those obtained in "Organic Syntheses,"[5] but our process is recommended when one wishes to sacrifice yield for quality, in making these halides for special work. The process also involves a minimum of apparatus and hardly any attention, although it requires a few days' time.

Experimental

Allyl Alcohol.--Solid potassium carbonate is added to Eastman practical allyl alcohol. The upper layer is removed and given the same treatment. After twenty-four hours it is filtered and used without distillation.

Allyl Chloride.—The alcohol is mixed with **8** times its volume of commercial hydrochloric acid (sp. gr., **1.19)** in a suitable well-corked bottle. After ten days the upper layer is washed once with **10%** sodium hydroxide and twice with **15%** sodium chloride, which minimizes emulsion formation. It is dried over calcium chloride and distilled. The yield of material boiling from 45–47° is from 55–65%. As an example: **204** cc. of crude alcohol with **1632** cc. of acid gave **144** g. of chloride.

If a small amount of halide is wanted in a hurry, the reaction is carried out in a sealed Pyrex bottle immersed in hot water **(60°).** Most of the yield, over 80%, is obtained in three hours.

Allyl Bromide.—A similar process is used. The alcohol: 48% acid ratio in cc. is **1:7.** The yields are 60–65%. Example: **410** cc. of crude alcohol with **2870** cc. of acid gave **478** g. of bromide, boiling from **69–73°.** The excess acid is recovered by distillation.

Allyl Iodide.—The alcohol: acid (sp. gr. **1.7)** ratio in cc. is **1:6.** The time is five days and the yield is 75–80%. Example: ten cc. of crude alcohol gave **10.3** cc. of iodide boiling from 99–103°.

Washing the Crude Halides.—In preparing *sec.*-butyl and *sec.*-amyl bromides by the Norris[4] method, the final products were extracted several times with concentrated sulfuric acid before washing. In some cases the halides were distilled from sulfuric acid. Invariably they turned pink on drying over calcium chloride. During distillation, hydrogen bromide was evolved, the material in the flask gradually assuming colors from pink through lavender to violet-red. The higher the temperature and the longer the contact with sulfuric acid, the worse were the colors and acid evolution. Repeated distillation tended to decrease these evils. We have found Norris' original recommendation of washing with concentrated hydrochloric acid a much better way of getting out the unchanged alcohol. By washing alkyl chlorides in this way and alkyl bromides with 48% hydrobromic acid, the troubles mentioned were reduced to a minimum.

In preparing pure bromides for the determination of their physical properties, to be reported by one of us in a forthcoming paper, the crude samples made by the Norris method were washed repeatedly with small portions of 48% hydrobromic acid until no volume change occurred. All alcohol and possibly some unsaturated products were thus removed. On returning the washings to the preparation flask and redistilling, a further quantity of bromide of a somewhat poorer quality was obtained. Bromides washed in this way gave no emulsion difficulties and on distillation gave very small light colored residues. Washing with sulfuric acid gave emulsions and highly colored residues with a disagreeable odor in the case of bromides easily attacked, e. g., *sec.*-butyl, particularly if the time of contact was long, even in the cold.

Careful fractionation of the products dried after the hydrobromic acid washing gave good yields of bromide of excellent purity. Constant boiling isopropyl bromide was obtained in 42% yields and *sec.*-butyl bromide, boiling over a 0.05" range, in 18% vielcls These pure bromides gave no test for unsaturated materials.

The Formation of Olefin and the Polymerizing Action of Sulfuric Acid.—Fifty cc. of secondary butyl bromide was made according to Norris' procedure and washed with hydrobromic acid. The colorless distillate had no odor of hydrogen bromide, but smelled somewhat unsaturated. The residue in the flask amounted to **3** cc. and had a deep violet color. On redistiliation, the first **3** cc. smelled highly unsaturated and used up 1.5 cc. of a 10% bromine solution in carbon tetrachloride. A fraction of a cc of the colored residue was diluted with chloroform until the color just faded. On adding 1 cc. of acetic anhydride and then one small drop of concentrated sulfuric acid (Burchard test)[6] a faint violet color appearing in one-half minute, developed to a distinct color in a few minutes. A fraction of a cc. was diluted with chloroform to a light pink. Thr Burchard test gave an immediate blue-violet tint and increased depth of color. In ten minutes it was fairly deep greenish violet. After two days the color had faded badly and a ring of purplish red resin had formed around the surface of the liquid. This substantiates the theory proposed by one of us (to be published later) that the Burchard test reagents and similar reagents cause polymerization to form colloidal particles. The color effects are then understood by applying Wo. Ostwald's colloidal theory of color.[7]

In making secondary butyl bromide, by heating the alcohol with acid in a sealed tube at 60°, the amount of unsaturation found was 1%, calculated as dibutene. Five cc. of secondary butyl bromide containing 2% of *sec.*-butyl alcohol was shaken with 5 cc. of concentrated sulfuric acid at room temperature. The volume change indicated that the alcohol had been extracted but even after a few minutes' shaking a small amount of emulsion had formed. After standing for two hours the attack on the bromide was pronounced and standing overnight gave a viscous, dark brown mixture. The use of 70% sulfuric acid reduced the trouble but a small amount of viscous oil also was formed after standing overnight.

Isopropyl, *sec.*-butyl and *sec.*-amyl bromides, especially after sulfuric acid treatment, on drying with calcium chloride assume delicate light blues, pinks, violets and lavenders and become opalescent, the degree of opalescence depending on the depth of the shade of red. Experiment showed that these effects are chargeable to the sulfuric acid treatment.

Three cc. of pure isopropyl bromide was added to 2 cc. of chloroform. One cc. of acetic anhydride and one drop of concentrated sulfuric acid were then added. In forty-eight hours a dark violet color resulted.

One drop of a 2,4-hexadiene dimer was dissolved in 5 cc. of chloroform. One drop of concentrated hydrochloric acid was added and the whole was shaken. Within half a minute the solution had assumed the typical pink color developed by ordinary *sec.*-butyl bromide on standing over calcium chloride, showing that the colors also could be produced by the action of the halogen acid on the unsaturated polymers.

Not all bromides are noticeably attacked by sulfuric acid. n-Butyl bromide seems to be the most stable of all those studied by us. When washed with either sulfuric or hydrobromic acid, it gave an equally good product. The residues from the distillations show only a faint color. Ethyl and n-propyl bromides are more sensitive. In fact, they are sufficiently sensitive for us to recommend only the hydrobromic acid treatment. Isobutyl bromide is quite sensitive and the secondary bromides are so easily attacked that we feel it is very undesirable to use sulfuric acid when pure products are desired.

Summary

1. Convenient methods for making allyl halides are described. Allyl bromide and allyl chloride made in this way do not develop objectionable odors and colors on standing.

2. Sulfuric acid is to be condemned in the preparation of pure alkyl halides.

3. In the preparation of pure alkyl halides, even by the Norris method, a small amount of unsaturated materials is formed.

4. Sulfuric acid not only polymerizes these materials but attacks sensitive halides to form more unsaturated materials.

5. The colors of decomposing halides are caused by the action of sulfuric acid and halogen acid on the unsaturated materials.

6. The Norris procedure gives the purest products.

OXIDATION OF UNSATURATED COMPOUNDS. I. OXIDATION OF CROTONIC AND ISOCROTONIC ACIDS, OF THE LACTONE OF 3-HYDROXY-ISOCROTONIC ACID AND OF MALEIC ANHYDRIDE

BY GÉZA BRAUN[1]

RECEIVED JULY 13, 1928 PUBLISHED JANUARY 8, 1929

I. Oxidation of Crotonic and Isocrotonic Acids

According to the van't Hoff-Wislicenus theory there are two isomeric 2-methylacrylic acids, the cis and trans. In the opinion of Auwers[2] the cis form represents isocrotonic and the trans form crotonic acid. Since this pair of acids has active double bonds and has been thoroughly studied from the point of view of cis-trans isomerism, these acids are very well suited for the study of the addition of hydroxyl groups.

Several different methods for the oxidation of crotonic acid are reported in the literature. MelikoE[3] oxidized it with hypochlorous acid and prepared a dihydroxybutyric acid (m. p. 80°) through the intermediate formation of 2-methylglycidic acid. Fittig and Kochs[4] used barium permanganate, Glatffeld and Woodruff[6] potassium chlorate; in both cases the identical dihydroxybutyric acid, m. p. 74–75", was obtained.

The pure, crystallizable isocrotonic acid had not previously been used for oxidation. Melikoff and Petrenko-Kritschenko[6] succeeded in pre-

paring crystallized dihydroxybutyric acid (m. p. 45°) by the oxidation of Geuther's[7] crude isocrotonic acid, which contained crotonic and tetrolic acids.[8] Fittig and Kochs[4] and later Morrell and Bellars[9] failed to get crystallized products with barium permanganate. They obtained only sirups which did not crystallize or which occasionally contained a few crystals.

The whole situation was rather confused in many respects. The yields of pure dihydroxybutyric acids were cut down by side reactions and isomerizations to such an extent that they were not higher than 20–25%. It was therefore necessary to work out new methods which would show the relation between the crotonic acids and the dihydroxybutyric acids and which would give sufficiently high yields for the study of the addition of hydroxyl groups.

This paper is a report of (A) perbenzoic acid oxidations of crotonic and isocrotonic acids for the *trans* addition of the hydroxyl groups. The method gave a yield of 63% of dihydroxybutyric acids from both crotonic and isocrotonic acids. (B) Chlorate oxidations of these two acids for the cis addition of the hydroxyl groups. The yields were as high as 82% in both cases.

(A) Oxidations by Means of Perbenzoic Acid

(a) Oxidation of Crotonic Acid (m. p. 72°).—In one of his recent papers, Böeseken[10] states that crotonic acid cannot be oxidized with perbenzoic acid. Although the reduction of the per-acid is so very slow as to be easily overlooked, as a matter of fact the oxidation of crotonic acid proceeds very well in both aqueous and non-aqueous solutions.

Among the various methods for the oxidation in the presence of water, Bergmann's[11] method was found to be the best: crotonic and perbenzoic acids were dissolved in chloroform and this solution was shaken with much water. The oxidation takes place in the chloroform phase and the water removes the oxidized product immediately. The yield was about 88% of a viscous sirup which yielded from ethyl acetate 63–64% of crystals, m. p. 81.5°. This product was a dihydroxybutyric acid. Its melting point did not change when the substance was mixed with the acid obtained by the oxidation of isocrotonic acid with silver chlorate (see later). The molecular weight, according to titration, was 121. This corresponds to a formula $C_4H_8O_4$.

The mother liquor from the crystals melting at 81.5° was a non-crystallizable sirup. According to titration it was a mixture of the dihydroxy-

butyric acid and perhaps its lactide. Probably both of the theoretically possible *dl*-1,2-dihydroxybutyric acids were present. As there is at present no known method for the separation of these acids or their derivatives, the sirup was not further investigated.

It is an interesting fact that crotonic acid even in pure water solution can be oxidized with perbenzoic acid. However, the yields were not higher than 30–40% of crystallized product, m. p. 81.5°, when either concentrated or diluted solutions of the per-acid were used.

(b) Oxidation of Isocrotonic Acid (m. p. **15.5°**).—The oxidation was carried out under conditions which had been found to be most favorable in the treatment of crotonic acid. The yield of crude product was 90% of the theoretical; that of crystalline product, m. p. 74–75', was 62–63% of the theoretical. A mixture of this acid (75") with the acid obtained by the oxidation of crotonic acid with chlorate (75°) showed no depression of the melting point.

The oxidation of isocrotonic acid in aqueous solution was more successful than that of crotonic acid but very slow. The yield of dihydroxybutyric acid, m. p. 74°, was about 65% of the theoretical.

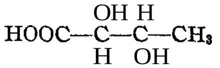
The oxidation of both crotonic and isocrotonic acids in non-aqueous solution is now in progress.

Discussion of the Results

The perbenzoic acid oxidation of crotonic acid gave a dihydroxybutyric acid, m. p. 81.5°, which is identical with the acid obtained from isocrotonic acid by oxidation with chlorate and which must be the same as Melikoff's acid, m. p. 80°.

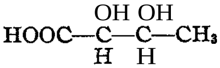
The perbenzoic acid oxidation of isocrotonic acid gave a dihydroxybutyric acid, m. p. 74–75'; this is the same acid that was obtained from crotonic acid with chlorates and permanganate.[5]

According to theory there are two *dl*-1,2-dihydroxybutyric acids. It is suggested that the prefixes *threo* and erythro be attached to the names of these substances to distinguish them and to show their relations to the well known threonic and erythronic acids



$$\mathrm{HOOC{-}\underset{H}{\overset{OH}{C}}{-}\underset{OH}{\overset{H}{C}}{-}CH_3}$$

dl-threo-1,2-Dihydroxybutyric acid



$$\mathrm{HOOC{-}\underset{H}{\overset{OH}{C}}{-}\underset{H}{\overset{OH}{C}}{-}CH_3}$$

dl-erythro-1,2-Dihydroxybutyric acid

One of these dihydroxybutyric acids melts at 74–75", the other at 81.5°; but which of these is the threo form and which the erythro form cannot be decided so satisfactorily as in the case of the tartaric acids, where one form is internally compensated and the other is not. However, if the configuration of the crotonic acids is assumed[2,12] and advantage is taken of the experience of other workers in regard to the manner of addition of hydroxyl

---

[12] For objection see Kuhn and Ebel, *Ber.*, 58, 925 (1925).

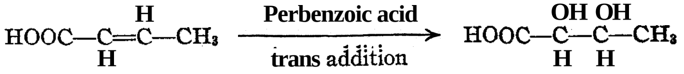
groups at a double bond, it is possible to assign configurations to the two acids in question with a considerable degree of assurance.

It has been shown[11,13] many times that in the oxidation by perbenzoic acid the first step is the formation of an ethylene oxide ring,  $R{-}\underset{\diagdown O \diagup}{CH{-}CH}{-}R$.[2] In the presence of water this ring opens and the compound is converted into the 1,2-glycol. In both steps there is a possibility of formation of both cis or trans compounds.

The oxidation of crotonic and isocrotonic acids with perbenzoic acid gave the dihydroxybutyric acids, isomeric with those obtained in the chlorate oxidations; that is, crotonic acid with perbenzoic acid yielded the *dl*-1,2-dihydroxybutyric acid, m. p. 81.5°, and with silver chlorate the *dl*-1,2-dihydroxybutyric acid, m. p. 75°. Assuming that the configurations ordinarily assigned to maleic and fumaric acids are correct, then it may be said that no case of inversion has ever been observed in a chlorate oxidation. On later pages of this paper will be found evidence supporting this statement. Hence the acid obtained by oxidation with perbenzoic acid is not the same as the acid obtained by chlorate oxidation, and therefore the oxidation with perbenzoic acid must involve a single inversion—either trans formation or trans splitting of the ethylene oxide ring.

There is no work reported in the literature to show whether the direct formation of the ring by oxidation of a double bond is cis or trans; but the trans splitting of the ring in the presence of water seems very probable from the work of Böeseken.[14] According to Kuhn and Ebel,[12] this trans splitting of the oxide rings is a general occurrence and in one case it was definitely proved: the hydrolysis of the internally compensated *cis*-ethylene-oxide-dicarboxylic acid yielded exclusively racemic tartaric acid. The proof in this case is based on the optical properties of both starting and end products. It seems, therefore, to be free from objections. So it seems probable that in the perbenzoic acid oxidations there is a *cis* formation of the oxide ring and then, in the presence of water, a trans splitting of the ring; this means a trans addition of the hydroxyl groups to the double bond.

Now if it be assumed that the oxidations of crotonic and isocrotonic acids by perbenzoic acid run in the same way as in the cases cited, then the two reactions may be written as follows:



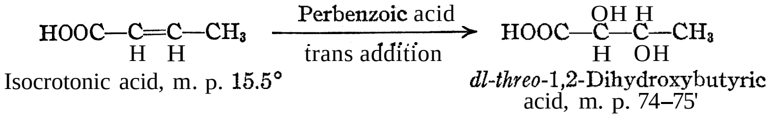
$$HOOC{-}\underset{H}{C}{=}\overset{H}{C}{-}CH_3 \xrightarrow[\text{trans addition}]{\text{Perbenzoic acid}} HOOC{-}\overset{OH}{\underset{H}{C}}{-}\overset{OH}{\underset{H}{C}}{-}CH_3$$

Crotonic acid, m. p. 72° *dl-erythro*-1,2-Dihydroxybutyric acid, m. p. 81.5°

---

[13] Prileschajew, *Ber.*, 42, 4811 (1909).

[14] Böeseken, *ibid.*, 56, 2409 (1923).



$$HOOC-\underset{H}{C}=\underset{H}{C}-CH_3 \xrightarrow[\text{trans addition}]{\text{Perbenzoic acid}} HOOC-\underset{H}{\overset{OH}{C}}-\underset{OH}{\overset{H}{C}}-CH_3$$

Isocrotonic acid, m. p. 15.5°

dl-threo-1,2-Dihydroxybutyric acid, m. p. 74–75'

This means that the acid of m. p. 74–75' is the *threo* form and the acid of m. p. 81.5' is the *erythro* form.

(B) Oxidation of Crotonic and Isocrotonic Acids with Barium and Silver Chlorates with Osmic Acid as a Catalyst

(a) Oxidation of Crotonic Acid with Barium Chlorate.—The oxidation of crotonic acid by means of potassium chlorate with osmic acid as catalyst was recently carried out by Glattfeld and Woodruff.[5,15] A more careful study of this oxidation showed that there was a strong decrease in the initial acidity. This must be due to side reactions, since simple addition of hydroxyl groups to crotonic acid would not change its total acidity, and lactone formation cannot be assumed in this case. In order to clarify the mechanism of this reaction barium chlorate was used instead of potassium chlorate because it may be removed quantitatively from the reaction mixture.

Even under the most favorable conditions used—when the oxidation was carried out in dilute solution at room temperature—there was found a decrease of about 24% in the total acidity after the oxidation was complete. After all of the inorganic matter had been removed, there was found to be a large amount of organically bound chlorine in the solution. This chlorine proved to be present as a chlorohydroxybutyric acid, the formation of which may be explained only by the addition of the *free* hypochlorous acid to the crotonic acid. This is also the reason for the decrease in the acidity; the decrease in acidity is directly proportional to the absorption of hypochlorous acid.[16]

In the most successful of the oxidation experiments carried out, about 20% of the crotonic acid was chlorinated, so that in the reaction mixture in these experiments there were present the dihydroxybutyric acid and chlorohydroxybutyric acid as chief products. The separation of the two acids was very simple: the water was completely removed by distillation at reduced pressure and the dihydroxybutyric acid was separated by crystallization from ethyl acetate as completely as possible. The mother liquor contained the chlorohydroxybutyric acid. The yield of dihydroxybutyric acid (m. p. 74°) was 38% of the theoretical.

The mother liquor was shaken two or three times with water in order to remove the rest of the dihydroxybutyric acid; the ethyl acetate was removed by distillation, leaving the crude chlorohydroxybutyric acid as a

[16] Formation of lactides, of course, also decreases the acidity.

sirup which was identified by analysis but which could not be rendered crystalline. The crystallized acid (m. p. 76°) could be prepared only from the crystallized zinc salt. That this acid was a chlorohydroxybutyric acid was shown by analysis for chlorine and by titration. On account of the small quantity its structure could not be determined.

The addition of hypochlorous acid to crotonic acid in the oxidation experiments with chlorates is then a fact. This chlorination could not be avoided although the oxidation was carried out under various conditions. It was a little lower when the barium chlorate was added gradually during the oxidation and considerably lower (about 3%) when the neutral barium crotonate was oxidized. But the oxidation of barium crotonate is not a practicable method because it is extremely slow: after one year about 30% of the crotonic acid was still present under circumstances in which the oxidation in acid solution was complete in ten days. That the chlorate oxidations do not proceed in neutral solution was recently observed also by Milas.[17]

(b) Oxidation of Crotonic Acid with Potassium **Chlorate.**—The results of the oxidations with potassium chlorate were exactly the same as those with barium chlorate. A potassium-acid double salt was separated in this case as an intermediate product. According to analysis it had the approximate formula $C_4H_7O_4K \cdot C_4H_8O_4$. The product is very soluble in water and hot absolute alcohol, from which it may be recrystallized; it is insoluble in ethyl acetate. For identification it was dissolved in water and the calculated amount of sulfuric acid was added. The dihydroxybutyric acid (m. p. 74°) was obtained with 80% yield. The product was not further investigated.

(c) Oxidation of Crotonic Acid with Silver **Chlorate.**—We have just seen that oxidation with barium and potassium chlorates does not proceed without the simultaneous addition of hypochlorous acid, whether the free crotonic acid or barium crotonate is used. When silver chlorate was used, however, hypochlorous acid addition was reduced to a minimum. This advantage of the silver chlorate is due to the following facts. The silver chloride precipitates as soon as formed; the silver hypochlorite is a very unstable compound and decomposes immediately according to the equation $3AgOCl = AgClO_3 + 2AgCl$. The addition of the hypochlorous acid to the double bonds is therefore greatly reduced.

Two sets of experiments were carried out with silver chlorate: in one set the necessary amount of chlorate (30% excess over the theoretical) was added in one operation at the beginning of the oxidation; in the other set the chlorate was added gradually in order to keep its concentration during the oxidation as low as possible.

In the first set the yield of dihydroxybutyric acid (m. p. 74°) was about

---

[17] Milas, This Journal, 49, 2010 (1927).

60% of the theoretical; about 5% of the crotonic acid was chlorinated under these conditions. The silver salt of the dihydroxybutyric acid (m. p. 74°) was separated as an intermediate product. This silver salt crystallized out when the purified water solution of the dihydroxy acid was concentrated at reduced pressure and could be isolated with absolute alcohol. (One should handle the alcoholic silver precipitates in the presence of chlorate very carefully.)

When the silver chlorate was gradually added in small portions (the second set), practically no chlorination occurred. The osmic acid itself was used as indicator for the course of the oxidation: when the silver chlorate was used up, the color of the solution became brown due to the formation of the lower oxides of osmium. The color disappeared in a short time (even at 0°) after addition of more chlorate. The yield of oxidized product was about 92% and that of crystallized product (m. p. 74°) 70% when the oxidation was carried out at room temperature. When the oxidation was carried out at 0°, the yield of desired product was almost quantitative. Only a small quantity of oxalic and volatile acids was formed. The yield of the crystallized dihydroxybutyric acid (m. p. 74°) was as high as 82% of the theoretical. Investigation of the non-crystallizable sirup—which contained a great deal of dihydroxybutyric acid—is now in progress,

A complete summary of the oxidations carried out with crotonic acid' in 2% aqueous solution is given in Table I.

TABLE I

SUMMARY OF OXIDATIONS

Ag	Gradually	.5	4	0	1.5	96	82	....

(d) Oxidation of Isocrotonic Acid (m. p. 15°) with Silver Chlorate.—The oxidation was carried out by the gradual addition of silver chlorate at 0° in exactly the same manner as with crotonic acid. The yield of oxidized product was 97%; this gave 82% of the theoretically possible amount of crystalline product (m. p. 81.5'). The mixture of this acid with the acid obtained by the oxidation of crotonic acid with perbenzoic acid showed no depression of the melting point.

II. Oxidation of the Lactone of the 3-Hydroxy-isocrotonic Acid with Silver and Barium Chlorates

The lactone was prepared by Lespieau[18] and oxidized with alkali chlorates by Glattfeld and Cohen[19] with good yield. The oxidation was repeated with silver and barium chlorates at room temperature. The yield of erythronic lactone (m. p. 89–90°) in the silver chlorate oxidations was as high as 75% of the theoretical; in the barium chlorate oxidation it was a little lower, 64% of the theoretical. The recrystallized erythronic lactone melted at 92°. For identification it was oxidized with dilute nitric acid according to Anderson[20] and yielded, except for a small amount of oxalic acid, exclusively mesotartaric acid.

In no case was there found any chlorinated compound; the lactone has a very inactive double bond and shows great resistance to the addition of hypochlorous acid.

III. Oxidation of Maleic Anhydride

The oxidation of maleic anhydride and of maleic and fumaric acids with perbenzoic acid was attempted under various conditions but in no case did oxidation occur. This agrees with the observation of Böeseken[10] and Kuhn.[12]

The oxidation of maleic anhydride with barium chlorate in dilute aqueous solution was as successful as that of maleic and fumaric acids described by Milas and Terry.[21] A great difference between the barium and silver chlorate oxidations was observed, while the oxidation with barium chlorate was almost quantitative; the oxidation with silver chlorate under the same conditions gave only a 70% yield of mesotartaric acid. The ratio of the yields with the two chlorates in question, when maleic and fumaric acids were oxidized, was found to be the same. Silver chlorate in these cases is therefore not suitable for the oxidations.

No chlorination was observed in the chlorate oxidations; maleic anhydride (as well as maleic acid in water solution) has an inactive double bond and adds hypochlorous acid only slowly in acid solution.

Discussion of the Results

Hofmann first used activated chlorates for the oxidation of unsaturated compounds.[22] He states that the action of chlorates on ethylene double bonds in the presence of osmic acid in neutral solution, in solutions slightly

---

[22] Hofmann, Ehrhart and Schneider, Ber., 46, 1657 (1914).

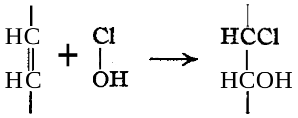
alkaline with bicarbonate or in weakly acid solutions, is exactly the same as that of potassium permanganate, and the reduction of chlorates to chlorides does not pass through the lower oxides of chlorine; the potassium chlorate is reduced directly to potassium chloride. So Hofmann writes the equation for the reaction as follows: $2OsO_4 = Os_2O_5 + 3O$ and $Os_2O_5 + KClO_3 = 2OsO_4 + KCl$.

Milas and Terry [21] recently investigated the oxidation of fumaric and maleic acids by alkali chlorates; they state that the principal reduction products of chlorate in the reaction are chlorite and chloride, principally the latter. The presence of traces of hypochlorous acid and free chlorine was shown by qualitative tests.

Now, the work on the oxidation of crotonic acid by chlorates reported in the present paper shows that: (1) when the crotonic acid is oxidized with barium or potassium chlorate—whether the chlorate is added at the beginning in one operation or added gradually during the oxidation—about 20% of the crotonic acid is chlorinated by the addition of hypochlorous acid; (2) if barium crotonate is oxidized in *neutral* solution, about 3% of the crotonic acid is chlorinated; (3) even in the presence of silver chlorate there occurs 5% chlorination, when the concentration of the silver chlorate is great; and (4) practically no chlorination occurs if the concentration of the silver chlorate is kept as low as possible.

As mentioned before, the addition of hypochlorous acid is an established fact. For the source of the hypochlorous acid which is added there are two possibilities.

1. "Status nascens" Addition.—According to the law of mass action, free chloric acid must be present when a metal chlorate is added to a water solution of an acid: $RCH{=}CHCOOH + MeClO_3 \rightleftarrows RCH{=}CHCOOMe + HClO_3$. The chloric acid will be reduced by the catalytic action of the osmic acid: $HClO_3 \longrightarrow HClO_2 \longrightarrow HClO$. When the reduction has proceeded to the hypochlorous acid stage, two reactions occur simultaneously: one part of the hypochlorous acid is further reduced to hydrogen chloride and another part adds "status nascens" to the double bond



$$\begin{array}{c} | \\ HC \\ \| \\ HC \\ | \end{array} + \begin{array}{c} Cl \\ | \\ OH \end{array} \longrightarrow \begin{array}{c} | \\ HCCl \\ | \\ HCOH \\ | \end{array}$$

If the concentration of the chloric acid, and therefore of the hypochlorous acid, is very low, then there is sufficient osmic acid present to reduce the hypochlorous acid almost completely, and the addition of the hypochlorous acid to the double bond will occur practically not at all. This may be the explanation of the fact that there was very little chlorination when the oxidation of crotonic acids was carried out with silver chlorate and when the concentration of the chlorate was kept as low as possible, while 5% chlorination occurred when the silver chlorate was used in excess.

2. "Secondary" Addition.—After a certain amount of chloric acid has been reduced to hydrogen chloride, these compounds react with the formation of chlorine: $HClO_3 + 5HCl \longrightarrow 3Cl_2 + 3H_2O \longrightarrow 3HCl + 3HClO$, and the hypochlorous acid thus formed adds to the double bond.

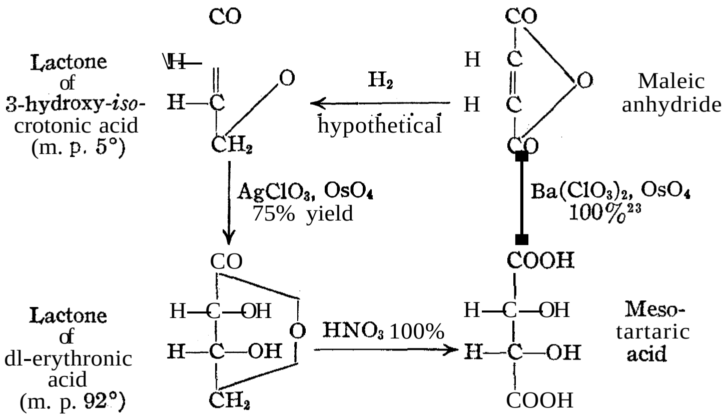
The chlorination of the neutral barium crotonate and chlorination in the presence of silver chlorate point to the "status nascens" source of the hypochlorous acid; in these cases the concentration of the hydrogen chloride is very low and the "secondary" source is not probable. However, if chlorates which give soluble chlorides, such as barium, potassium chlorate, etc., are used, then it is very probable that the hypochlorous acid added comes from both sources, for only a slight difference was observed when the crotonic acid was oxidized by the addition of barium chlorate in one operation at the beginning or by gradual addition of the barium chlorate throughout the oxidation. If the "status nascens" source of the hypochlorous acid were the only source, then in the latter case there would have been much less chlorination, just as in the case of silver chlorate oxidations; but the results of the oxidation with barium chlorate under the two sets of conditions were almost identical, showing that hypochlorous acid was produced by both methods.

In conclusion, it seems to be very probable that in every case the reduction of chlorates passes through the lower oxides of chlorine and some of the hypochlorous acid added is generated by the "status nascens" process; and not only in strong acid solution, as Hofmann stated, but even in weakly acid solution, there is a reaction. between the chloric and hydrochloric acids with the formation of hypochlorous acid.

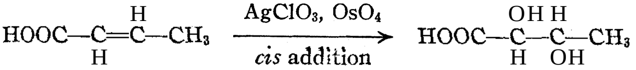
The mechanism of the catalytic action of osmic acid will not be treated at the present time.

The Manner of Addition of Hydroxyl Groups to Double Bonds in Chlorate Oxidations

It has been shown many times in the literature that in the case of chlorate oxidations with osmic acid—when an unsaturated compound was oxidized—just as in case of potassium permanganate oxidations, there is a cis addition of the hydroxyl groups. Milas and Terry[21] improved Hofmann's method and obtained an almost quantitative yield when fumaric acid was oxidized to *racemic* tartaric acid and maleic to mesotartaric acid, and, recently, Glattfeld and Cohen oxidized "maleic"—the lactone of 3-hydroxy-isocrotonic acid, to dl-erythronic lactone. All of the above oxidations were now repeated but under the same conditions that were used with crotonic acid; the results of these experiments are given below and show that the addition of the hydroxyl groups is *cis*.



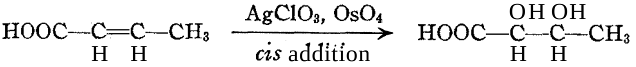
The silver chlorate method of oxidation of crotonic acid yielded *dl*-1,2-dihydroxybutyric acid (m. p. 74–75') and isocrotonic acid yielded by the same method *dl*-1,2-dihydroxybutyric acid (m. p. 81.5°). Now if it is assumed that the oxidations of crotonic and *iso*crotonic acids proceed in the same way as in the former cases, these reactions may be indicated as follows



$$\mathrm{HOOC{-}\underset{H}{C}{=}\overset{H}{C}{-}CH_3} \xrightarrow[\textit{cis}\ \text{addition}]{\mathrm{AgClO_3,\ OsO_4}} \mathrm{HOOC{-}\underset{H}{\overset{OH}{C}}{-}\underset{OH}{\overset{H}{C}}{-}CH_3}$$

Zrotonic acid (m. p. 72°) *dl-threo*-1,2-Dihydroxybutyric acid (m. p. 74–75')

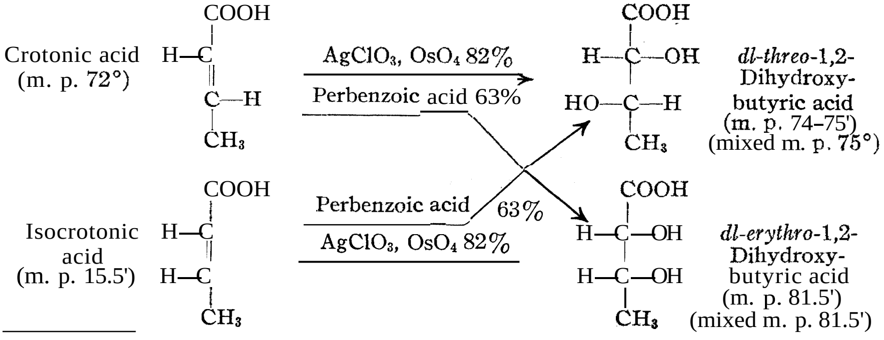
and



$$\mathrm{HOOC{-}\underset{H}{C}{=}\underset{H}{C}{-}CH_3} \xrightarrow[\textit{cis}\ \text{addition}]{\mathrm{AgClO_3,\ OsO_4}} \mathrm{HOOC{-}\underset{H}{\overset{OH}{C}}{-}\underset{H}{\overset{OH}{C}}{-}CH_3}$$

Isocrotonic acid (m. p. 15.5°) . *dl-erythro*-1,2-Dihydroxybutyric acid (m. p. 81.5')

These results are in perfect harmony with those obtained in the perbenzoic acid oxidations, which makes the configurations assigned to the



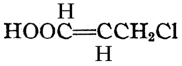
---

[23] By 100% in yield is meant that the isomer indicated was formed exclusively with very high yield. (For instance, in the oxidation of maleic anhydride with barium chlorate there was obtained exclusively mesotartaric acid with an actual yield of 91% and no trace of racemic tartaric acid.)

dihydroxybutyric acids above still more probable. A complete summary of all the oxidations carried out with chlorates and perbenzoic acid is given above.

A better means of determining these configurations would be the oxidation of the two acids to the corresponding tartaric acids, but this unfortunately appears to be impossible. There does, however, seem to be a possibility of obtaining better evidence by an indirect method. If the two 3-chloro acids[24] were prepared, their relation to crotonic and isocrotonic

3-Chloro-crotonic acid



$\mathrm{HOO}\overset{\mathrm{H}}{\mathrm{C}}{=}\underset{\mathrm{H}}{\mathrm{C}}\mathrm{CH_2Cl}$

$\mathrm{HOOC}\overset{\mathrm{H}}{\mathrm{C}}{=}\overset{\mathrm{H}}{\mathrm{C}}\mathrm{CH_2Cl}$

3-Chloro-isocrotonic acid

acids could be demonstrated by reduction with sodium amalgam. The oxidation of these chloro acids should yield a *threo* and an *erythro* 3-chloro-dihydroxybutyric acid. Hydrolysis of these two acids should yield threonic and erythronic acids; oxidation should give mesotartaric and racemic acids; reduction should yield the two dihydroxybutyric acids. Work on these reactions is now in progress.

Experimental Part

Materials

Crotonic Acid.—The commercial product may be used without further purification. The best method for its preparation has been recently described by Auwers.[25]

Isocrotonic Acid.—This was prepared from the commercial product and from Geuther's crude isocrotonic acid according to the method of Wislicenus.[26]

Lactone of 3-Hydroxy-isocrotonic Acid.—The lactone is a by-product in the preparation of *dl*-2,3-dihydroxybutyric acid and may be prepared according to Glatffeld's method[18] with good yield. The crude product was recrystallized twice from one and a half parts of absolute ether, cooled in ice and salt, and the crystals were dried at 0° over phosphoric anhydride in a vacuum desiccator. The melting point of the product was 5.0 to 5.3° (thermometer in the substance).

Perbenzoic Acid.—This was prepared according to Baeyer and Villiger,[27] except that chloroform was used instead of ether as a more suitable solvent for the benzoyl-peroxide. One has to be very sure that all of the materials used in the preparation of the peracid are pure because the oxidations require a long time and an impure peracid decomposes before the oxidations are complete.

Silver Chlorate.—The best method for the preparation of this substance consists in the solution of silver oxide in a slight excess of 10% chloric acid[28] at 30°. The filtrate is concentrated at reduced pressure and the concentrated solution of silver chlorate cooled in ice. The chlorate of silver is just as stable a compound as the chlorates of alkali metals.

The precipitate obtained in the silver chlorate oxidations is almost pure silver

---

[24] The trans compound is known; Lespieau, *Bull. soc. chim.*, [3] 33, 466 (1905); Auwers and Wissebach, Ber., 56, 732 (1923).

chloride. In order to purify it one has to wash it with warm dilute hydrochloric acid and then with water so as to remove oxalic acid and other impurities. It is dried as completely as possible by suction filtration. The pure, moist silver chloride thus obtained (containing about 6–8% of moisture) is suspended in five times its weight of water and, while the mixture is being violently stirred, a 50% excess of zinc dust is rapidly added. The solution becomes hot; the stirring is continued until the solution has cooled to room temperature and then the excess of the zinc is dissolved with 20% sulfuric acid without interrupting the stirring. The gray-brown precipitate is separated by filtration and washed thoroughly. The precipitate still contains a considerable amount of silver chloride and the operation must be repeated with a small amount of zinc dust in order to obtain pure silver, which may be used in the making of silver chlorate. The yields are almost quantitative.

Control of the Oxidations

The best control of the oxidations is the quantitative determination of the unsaturated compounds in the reaction mixture. No general method for this purpose has been published in the literature, as the behavior of unsaturated compounds differs very widely according to the reagents used in the determinations. Bromine water seems to be the most suitable reagent. When this reagent is used the acidity of the reaction mixture is very important; one group of unsaturated compounds—those having *active* double bonds—may be brominated quantitatively even in the presence of mineral acids, while another group—those having *inactive* double bonds—can be brominated only in neutral solution.

In order to find a reliable method for the control of the oxidations, many experiments were carried out for the determination of double bonds of unsaturated acids.

In every case a stock solution was made of such concentration that 25 cc. contained about 0.1 g. of unsaturated substance. In using Winkler's method,[29] there was added to 25 cc. of the stock solution 2 g. of potassium bromide, then 20 cc. of 10% sulfuric acid and 50 cc. of 0.1 N potassium bromate solution of known titer (organic solvent was not used). After two hours' standing in the dark the excess of bromine was measured iodimetrically. When the determinations were made with saturated bromine water, the procedure was as follows: 25 cc. of the stock solution was used

TABLE II

RESULTS OF DETERMINATIONS

Acid	Calculated iodine number	Found with Winkler's method	Free acid	Found with satd. bromine water	
				Potassium acid salt	Neutral salt
Crotonic	295	297			
Isocrotonic	295	297	...	...	...
Fumaric	218.8	7	106	193	216.7
Maleic	218.8	23	178	200	217.2
Lactone of 3-hydroxy-isocrotonic	302	trace	trace	...	187.0

---

[29] See Meyer, "Analyse und Konstitutionsermittlung organischer Verbindungen," 1922.

either as such (free acid) or after neutralization with 0.1 *N* alkali (without indicator). To this was added 10 cc. of saturated bromine water of known titer, the solution was left to stand for two hours in the dark and the excess bromine then titrated (Table II).

The lactone of the 3-hydroxy-isocrotonic acid has a very inactive double bond; it seems to be a heterocyclic compound. It suffers a complicated rearrangement with alkali and has maximum ability to absorb bromine only immediately after saponification.

As a result of this preliminary study the following procedures for the control of oxidations of the acids listed above were adopted.

In the oxidation of fumaric and maleic acids two samples are taken out from time to time: one is neutralized in the presence of indicator for the determination of the acidity and the other is titrated with bromine water after it has been neutralized without using indicator.

In the oxidation of the 3-hydroxy-isocrotonic lactone a sample is taken and heated with an excess of 0.1 N alkali for five minutes on the water-bath; after the solution has been cooled, the excess of alkali is titrated with 0.1 N sulfuric acid, using a very small amount of phenolphthalein, and the solution is then titrated immediately with bromine water.

In the oxidation of crotonic and isocrotonic acids the samples are titrated with alkali for the acidity and with bromine water without neutralization.

If there is silver in the solution, it must be precipitated with sodium chloride solution before testing.

The presence of osmic acid in the bromine titrations does not give any trouble as it does not oxidize hydrogen bromide in weakly acid solutions.

In the perbenzoic acid oxidations the amount of the peracid is measured iodimetrically. If it is necessary to titrate with bromine water, the samples are very much (at least ten times) diluted, as the peracid quickly oxidizes hydrobromic acid.

Oxidation of Crotonic Acid with Perbenzoic Acid

(a) Oxidation in Chloroform Solution.—Ten g. of crotonic acid was dissolved in 500 cc. of water, and 84 cc. of chloroform which contained 24 g. of perbenzoic acid (50% excess) was added. The mixture was shaken at room temperature in the dark.

Time	Start	2 weeks	4 weeks	5 weeks
$CHCl_3$ soln., cc.	0.2	0.2	0.2	0.2
0.1 N $Na_2S_2O_3$ soln., cc.	6.95	4.40	2.80	2.40

Both aqueous and chloroform solutions now required a negligible amount of bromine water.

The chloroform layer was then separated from the aqueous layer and the former was washed with 100 cc. of water. The united aqueous solutions were concentrated at reduced pressure to 300 cc., extracted three times with 50 cc. of chloroform and the water completely removed by further distillation. The residue was dried at a temperature of 40° and a pressure of 2 mm. for several hours. The pale yellow, viscous sirup weighed 12.2 g. (88% of the theoretical). The sirup was dissolved in 14 cc. of ethyl acetate and cooled to 0°. Crystallization took place as soon as the glass wall was scratched and the solution was transformed into a white semi-crystalline mass. After six hours' standing in ice, the mass was subjected to suction filtration and the crystals washed with cold ethyl acetate and dried at 40°, finally in a vacuum desiccator over phosphorus pentoxide. A yield of 8.65 g. of white crystals (m. p. 80.5°) was obtained.

From the mother liquor there was obtained **0.2** g. more of pure crystals, making a total yield of **8.85** g. or **63.5%** of the theoretical.

The crystals were dissolved in **15** cc. of hot ethyl acetate, the solution treated with bone black and filtered hot by suction. The filtrate deposited as it cooled **7.4** g. of white crystals (m. p. 81.5°). A mixture of this acid with the acid obtained by the oxidation of isocrotonic acid with silver chlorate showed no depression of the melting point.

Titration. Subs., 0.3141, 0.3011: 25.85, 24.93 cc. of 0.1 N alkali (phenolphthalein). Calcd. mol. wt. for $C_4H_8O_4$: **120.06.** Found: **121.5, 120.7.**

The acid was found to be very soluble in water, alcohol, acetone and hot ethyl acetate, slightly soluble in cold ethyl acetate and ether, insoluble in chloroform and ligroin.

(b) Oxidation in Aqueous Solution.—Ten g. of crotonic acid was dissolved in **500** cc. of water which contained **4** g. of perbenzoic acid. The solution was allowed to stand at room temperature. During the course of two months a total of 20 g. of crystallized peracid was added from time to time, and after six weeks 100 cc. of ether. Even after two months there was still present about 20% of the crotonic acid. The oxidation was interrupted and the reaction mixture worked up as before. The yield was **8.5** g. of sirup. which gave **5.5** g. of crystals (m. p. **80.5")** in two crops, **40%** of the theoretical.

Oxidation of Isocrotonic Acid with Perbenzoic Acid

(a) Oxidation in Chloroform Solution.—Ten g. of pure, crystallizable isocrotonic acid (m. p. 15.5°) was dissolved in **200** cc. of water and **125** cc. of chloroform which contained **30** g. of perbenzoic acid was added. The mixture was shaken at room temperature in the dark.

After three weeks both aqueous and chloroform solutions required only a negligible amount of bromine water.

The reaction mixture was worked up in exactly the same manner as described above under the oxidation of crotonic acid. Thirteen g. of pale yellow sirup was obtained; 93% of the theoretical. This gave in two crops **8.75** g. of crystals (m. p. 73.5–74°) or 62.5% of the theoretical.

The crystals were recrystallized from hot ethyl acetate; **7.5** g. of crystals (m. p. **74–74.5°**) was obtained. A mixture of this acid with the acid obtained by the oxidation of the crotonic acid with chlorates showed no depression of the melting point. The solubility of the product is almost the same as that of the acid of m. p. **81.5".**

(b) Oxidation in Water Solution.—Three and a half g. of isocrotonic acid (m. p. **15.0")** was dissolved in **175** cc. of water which contained **1.5** g. of perbenzoic acid. The solution was allowed to stand at room temperature. During the course of three months a total of **10.5** g. of peracid was added from time to time. After six weeks **50** cc. of ether was added. The yield was **4.0** g. of sirup which gave **3.22** g. of crystals (m. p. 73.5–74°) in two crops, or **65%** of the theoretical.

Oxidation of Crotonic Acid with Chlorates. I. Barium Chlorate Oxidations

(A) Addition of Total Quantity of Chlorate in One Operation.—Twenty g. of crotonic acid was dissolved in one liter of water which contained **15.6** g. of barium chlorate (25% excess) and **2.5** cc. of a **1%** solution of osmic acid. The solution was kept at room temperature in the dark.

Time	Start	2 days	4 days	6 days
Solution, cc.	2	2	2	2
0.1 N alkali, cc.	4.65	4.30	3.75	3.50
Satd. bromine water, cc.	3.2	2.3	1.1	0.2

No pressure developed in the bottle. The solution was then separated by filtration from a small amount of crystals, which proved to be barium oxalate.

Anal. Subs., 0.3276: loss in weight at 150–160°, 0.0444; $BaSO_4$, 0.2917. Calcd. for $C_2O_4Ba\cdot 2H_2O$: H_2O, 13.78; Ba, 52.54. Found: H_2O, 13.56; Ba, 52.40.

The filtrate from the barium oxalate was extracted twice with 200 cc. of benzene; the water solution was then concentrated to a thin sirup at reduced pressure. The sirup was dissolved in one liter of water and the solution again subjected to distillation in order to remove all of the volatile acids. The residue of the second distillation was dissolved in 300 cc. of water and the excess of barium chlorate was reduced with sulfur dioxide gas. The barium sulfate was separated by filtration and the filtrate concentrated to two-thirds of its volume at reduced pressure. Then the sulfuric and hydrochloric acids were completely removed with barium hydroxide and silver oxide.

The purified solution, which contained the dihydroxybutyric acid and about 20% of the crotonic acid as chlorohydroxybutyric acid, was evaporated to a thick sirup and finally dried at a temperature of 40° and a pressure of 10 mm. for several hours. The yield was 22 g. of pale yellow sirup. This was dissolved in 20 cc. of absolute ethyl acetate and the solution cooled in ice. Crystallization began as soon as the glass walls were scratched. After twelve hours' standing in ice the crystals were separated by filtration, washed carefully with cold ethyl acetate and dried at 40°: Crop I, 8.4 g. of white crystals (m. p. 73.5°); Crop II (see later), 2.0 g. of white crystals (m. p. 72.5°); total, 10.4 g. of white crystals (m. p. 73°), or 38% of the theoretical.

These crystals were recrystallized from hot ethyl acetate and 9.0 g. of crystals (m. p. 74–74.5°) was obtained.

Titration. Subs., 0.2945, 0.3845: 24.31, 31.70 cc. of 0.1 N alkali. Calcd. mol. wt. for $C_4H_8O_4$: 120.06. Found: 121.1, 121.3.

The mother liquor from Crop I was diluted with ethyl acetate to 50 cc. and was shaken once with 50 cc. of water. The two solutions were treated separately.

(a) Water Solution.—The solution was evaporated at reduced pressure and the residue dried and crystallized from ethyl acetate in the usual manner. Two g. of crystals (m. p. 72.5") was obtained (Crop II). They were united with Crop I.

(b) Ethyl Acetate Solution.—This was shaken twice with 20 cc. of water and the ethyl acetate layer dried with sodium sulfate, evaporated and the residue dried at 70° for several hours at reduced pressure. The yield was 1.75 g. of sirup, which did not crystallize. A sample of 0.1745 g. required 12.24 cc. of 0.1 N alkali and after saponification with 0.1 N alkali 11.47 cc. of 0.1 N silver nitrate; calcd. for chlorohydroxybutyric acid, $C_4H_7O_3Cl$: mol. wt., 138.5; Cl, 25.6. Found: mol. wt., 142; chlorine, 23.3.

About 20 g. of this crude chlorohydroxybutyric acid obtained from different experiments was dissolved in 50 cc. of water and the solution extracted twice with 150 cc. of ether. The residue obtained from the ethereal solution was dissolved in 50 cc. of water and the solution neutralized with zinc carbonate. The concentrated solution of the zinc salt deposited 2.0 g. of crystals after standing for three days in ice. A sample of 1.8 g. of the crystallized zinc salt was dissolved in 30 cc. of water, 20 cc. of 10% sulfuric acid was added and the solution extracted with ether, etc. The residue of the ether solution weighed 1.1 g. This was dissolved in 1 cc. of ether and crystallized in ice: 0.3 g. of white crystals (m. p. 76°) was obtained.

Anal. Subs., 0.0991: 6.98 cc. of 0.1 *N* alkali for free acid; 7.18 cc. of 0.1 *N* alkali and 7.22 cc. of 0.1 N silver nitrate for organically bound chlorine after saponification on the water-bath for fifteen minutes. Calcd. for $C_4H_7O_3Cl$: mol. wt., 138.5; Cl, 25.6. Found: mol. wt., 142; Cl, 25.8.

(B) Gradual Addition of Chlorate During Oxidation.—Twenty g. of crotonic acid was dissolved in one liter of water which contained 5 cc. of a 1% osmic acid solution.

Then in the course of three weeks 15.6 g. of barium chlorate was added in about 0.4-g. lots whenever the solution became brown. After four weeks the crotonic acid had entirely disappeared. The decrease in the initial acidity was about 24%. The reaction mixture was worked up as before. The yield of the oxidized product was 24.9 g. and that of the dihydroxybutyric acid (m. p. 72°) 13.5 g. or 48% of the theoretical. The amount of the chlorinated compound was a little less than under (A).

II. Oxidation with Potassium Chlorate

Twenty g. of crotonic acid was dissolved in one liter of water which contained 5 cc. of a 1% solution of osmic acid. Then in the course of three weeks 12 g. of potassium chlorate was added in about 0.3-g. lots whenever the solution became brown. After four weeks the oxidation was complete. There was a 24% decrease in the acidity. The solution was extracted with benzene and the excess of potassium chlorate was reduced with sulfur dioxide gas in the usual manner. The sulfuric acid was precipitated with barium hydroxide; the potassium chloride remained in solution. The residue from the distillation of the water solution was dissolved in 20 cc. of absolute alcohol and absolute ethyl acetate was added until no more precipitation occurred (about 600 cc. of ethyl acetate).

(a) Precipitate.—This was treated with 150 cc. of hot absolute alcohol and the potassium chloride removed by filtration in the hot. The filtrate contained only a trace of chlorine and deposited on cooling 10.9 g. of white crystals (m. p. about 104–106°, not sharp). The product was easily soluble in hot absolute alcohol, from which it may be recrystallized; it is insoluble in ethyl acetate.

Anal. Subs., 0.5121: 17.0 cc. of 0.1 N alkali; $KClO_4$, 0.2537. Calcd. for $C_4H_7O_4K \cdot C_4H_8O_4$: acid, 43.3; K, 14.05. Found: acid, 40.0; K, 13.98.

Three g. of the double salt was dissolved in 400 cc. of water and 11 cc. of N sulfuric acid was added. The solution was then distilled to dryness at reduced pressure, the residue was dissolved in ethyl acetate, etc., in the usual manner. Two and six-tenths g. of a crystalline mass was obtained which yielded 2.0 g. of crystals (m. p. 74°) in two crops.

(b) Ethyl Acetate Solution.—The residue obtained by the removal of the ethyl acetate at reduced pressure weighed 14.8 g., which gave 3.2 g. of crystals (m. p. 73") from ethyl acetate. The mother liquor of the crystals contained about 20% of the crotonic acid as chlorohydroxybutyric acid.

III. Oxidation of Crotonic Acid with Silver Chlorate

(A) Silver Chlorate in Excess.—Twenty g. of crotonic acid was dissolved in one liter of water which contained 18.3 g. of silver chlorate and 2.5 cc. of a 1% solution of osmic acid. The reaction mixture stood at room temperature. The precipitation of the silver chloride began immediately and the solution turned milky.

After 5 days a sample required only a negligible amount of bromine water. At the end of the oxidation there was a slight pressure in the flask. The silver chloride was separated by filtration. According to analysis it contained a small amount of silver oxalate.

The filtrate from the silver chloride was extracted with' benzene and evaporated at reduced pressure. A large amount of crystals appeared. These were dissolved in water and the distillation was repeated. The residue was treated with 100 cc. of absolute alcohol and the crystals were separated by filtration.

(a) Crystals.—These proved to be the silver salt of the dihydroxybutyric acid (m. p. 74°); weight, 4.5 g.

Anal. Subs., 0.9420, 0.4905: 41.40, 21.62 cc. of 0.1 *N* KCNS. Calcd. for $C_4H_7O_4Ag$: Ag, 47.54. Found: Ag, 47.4, 47.56.

Eight g. of this salt from different experiments was dissolved in water and the calculated amount of hydrochloric acid was added, etc.; yield, 4.0 g. of sirup, which gave 3.1 g. of crystals (m. p. 74°).

(b) Alcoholic Solution.—This was evaporated at reduced pressure, the residue treated with ethyl acetate, the solution filtered and the filtrate distilled to dryness. The pale yellow sirup which remained weighed 23 g. and gave 12.8 g. of crystals (m. p. 74°) in two crops from ethyl acetate; total yield (acid and silver salt) was 54% of the theoretical. The mother liquor of the crystals contained about 5% of the crotonic acid as chlorohydroxybutyric acid.

In other cases, when the silver salt was not separated and the oxidation lasted for about two weeks and somewhat more silver chlorate was used (20 g. of silver chlorate for 20 g. of crotonic acid), the yields of dihydroxybutyric acid (m. p. 74°) averaged 60% of the theoretical.

(B) Oxidation by Gradual Addition of Silver Chlorate.—Twenty g. of crotonic acid was dissolved in one liter of ice water which contained 10 cc. of a 1% osmic acid solution and little by little 18.0 g. of crystallized silver chlorate was added in about four weeks, while the solution was kept in ice water. The oxidation was rapid at the beginning; 0.5 g. of chlorate was added as a first portion; the solution became milky within a few minutes and turned brown in three hours. Then on every succeeding day for about two weeks, one g. of chlorate was added in 0.5-g. portions; the oxidation then became slower and 0.5 g. of chlorate was added whenever the solution turned yellow. Finally, the reaction mixture was removed from the ice-bath and allowed to stand at room temperature for a few days. After 18.0 g. of chlorate had been added, the solution remained colorless, showing that no more oxidizable substance was present.

There was no change in the initial acidity and no trace of crotonic acid, but a trace of chlorinated compound was found. The silver precipitate was separated by filtration and washed with dilute hydrochloric acid, giving 13.15 g. of silver chloride. A very small amount of oxalic acid was separated from the hydrochloric acid filtrate.

The filtrate from the silver chloride was distilled at reduced pressure, the excess of silver chlorate (about 0.5 g.) was reduced with sulfur dioxide gas, etc., in the usual manner. The residue from the water solution was a colorless, very viscous sirup which weighed 26.7 g.; 96% of the theoretical. The yield from ethyl acetate in three crops was 23.05 g. of crystals (m. p. 74°) or 82.5% of the theoretical.

The crystals were recrystallized from 40 cc. of ethyl acetate and yielded in two crops a total of 20.8 g. of crystals (m. p. 74.5–75°).

The non-crystallizable residue of the crude crystals weighed 2.7 g.

When the oxidation was carried out at room temperature in the manner described above and when half the amount of osmic acid was used, the yield was 92% of sirup and 70% of the dihydroxybutyric acid (m. p. 74°).

Oxidation of Isocrotonic Acid by Gradual Addition of Silver Chlorate

Six g. of pure isocrotonic acid (m. p. 15.0°) was dissolved in 300 cc. of ice water which contained 2.5 cc. of a 1% osmic acid solution. Then in four weeks 53 cc. of a 10% silver chlorate solution was added in 1.5-cc. portions while the solution was kept in an ice-bath in the dark, etc., as described in the silver chlorate oxidation of crotonic acid under (B). There was no change in the acidity and only a trace of chlorinated compound was found. The yield was 8.05 g. of colorless sirup or 96% of the theoretical. The sirup gave from ethyl acetate in two crops 6.88 g. of crystals (m. p. 81°) or 82%

of the theoretical. The product was recrystallized from 20 cc. of ethyl acetate; 6.0 g. of crystals (m. p. 81.5°) was obtained.

Oxidation of the Lactone of 3-Hydroxy-isocrotonic Acid with Silver and Barium Chlorates

(A) Silver Chlorate.—Ten g. of the lactone (m. p. 5.0°) was dissolved in 100 cc. of water which contained 5 cc. of a 1% osmic acid solution, and ten g. of silver chlorate was added in the course of two months. The reaction mixture stood at room temperature. In the first three additions 2 g. of chlorate was added; thereafter 0.5 g. of chlorate whenever the solution turned brown. At the end of the oxidation there was a slight pressure in the bottle. The titration showed that about 60% of free acid and 40% of lactone was present.

The silver chloride was separated by filtration (the silver precipitate did not contain any oxalate), the filtrate diluted to 250 cc.. extracted with benzene, distilled at reduced pressure to a thick sirup and finally the residue was dried at a temperature of 50° and a pressure of 2 mm. for several hours. The sirup contained only a trace of organically bound chlorine.

This sirup (13.3 g.) was dissolved in 15 cc. of absolute acetone and the solution cooled in ice. During six hours the solution deposited 7.1 g. of crystals (m. p. 89–90°).

The mother liquor was concentrated to a thick sirup, which was dried at a pressure of 2 mm. and a temperature of 70° for two hours. The residue gave 2.2 g. of crystals from absolute acetone. A third crystallization in the same way yielded 1.0 g. of crystals.

The final mother liquor was subjected to distillation at a temperature of 130–150° and a pressure of 1 mm. but suffered partial decomposition. The distillate gave 0.2 g. of crystals from absolute acetone. The total yield of crystallized product was 10.5 g. or 75% of the theoretical.

The crystals were dissolved in 100 cc. of hot absolute acetone, the solution was subjected to filtration in the hot and the filtrate concentrated to 30 cc. This solution deposited after ten hours' standing in ice 8.0 g. of crystals (m. p. 92°).

Two g. of crystals (m. p. 92°) was dissolved in 10 cc. of dilute nitric acid (sp. gr., 1.22) and the solution was kept at 60° for forty-five hours, that is, until evolution of brown fumes had ceased. The nitric acid was removed by distillation at reduced pressure in the usual manner. The crystalline residue was dissolved in 300 cc. of water, the solution neutralized with alkali, heated to boiling and a small amount of calcium acetate solution added until no more precipitation occurred. After ten minutes the calcium oxalate was removed by filtration in the hot. The calcium oxalate was dissolved in dilute hydrochloric acid and again precipitated in the usual manner. The precipitate was washed with hot water and then dried at 105° to constant weight; 0.34 g. of substance was obtained.

Anal. Subs. 0.3393: CaO, 0.1294. Calcd. for $CaC_2O_4 \cdot H_2O$: CaO, 38.34. Found: CaO, 38.14.

The filtrate of the calcium oxalate was acidified with dilute hydrochloric acid and concentrated to 75 cc. at reduced pressure. Then the solution was heated, neutralized and the calcium mesotartrate precipitated with an excess of calcium acetate. After twenty-four hours the precipitate was separated by filtration, washed with warm water and dried in the air for eighteen hours. Three g. of air-dried calcium salt was obtained.

Anal. Subs., 0.2329: loss in weight at 180°, 0.0521; ash, 0.0538. Calcd. for $C_4H_4O_6Ca \cdot 3H_2O$: H_2O, 22.32. Found: 22.37. Calcd. for $C_4H_4O_6Ca$: CaO, 29.81. Found: CaO, 29.76.

This shows that the oxidation yielded, except for a small quantity of oxalic acid, exclusively mesotartaric acid.

(B) Barium Chlorate.—Ten g. of lactone (m. p. 5.0') was dissolved in 100 cc. of water which contained 5 cc. of a 1% solution of osmic acid and 9.2 g. of barium chlorate was added during two months, etc., in just the same manner as described under (A). The yield was 12.7 g. of sirup, which gave 9.1 g. of crystals (m. p. 90°), or 64% of the theoretical. There was found only a trace of organically bound chlorine.

Oxidation of Maleic Anhydride with Barium and Silver Chlorates

(A) Barium Chlorate.—Ten g. of maleic anhydride (m. p. 54°) was dissolved in 500 cc. of water which contained 12.0 g. of barium chlorate and 2.5 cc. of a 1% osmic acid solution. The mixture stood at room temperature. At the beginning the solution became yellow; the color later disappeared. The oxidation was complete in two months; the solution required only a negligible amount of bromine water. There was no change in acidity.

The solution was then extracted with benzene, the excess of barium chlorate reduced with sulfur dioxide gas and the sulfuric and hydrochloric acids were removed in the usual manner. The purified water solution was evaporated at reduced pressure and the crystallized residue dried at a temperature of 40° and a pressure of 8 mm. for three hours. The yield was 15.0 g. of white crystals which contained, according to titration, 13.9 g. of mesotartaric acid or 91% of the theoretical.

The water solution of the acid did not give a precipitate with calcium sulfate water, showing the absence of racemic tartaric acid. The product did not contain a trace of chlorine and required only a trace of bromine water after neutralization.

The oxidation of the maleic anhydride therefore gave exclusively mesotartaric acid.

(B) Silver Chlorate.—Ten g. of maleic anhydride was dissolved in 500 cc. of water which contained 12.0 g. of silver chlorate and 2.5 cc. of a 1% solution of osmic acid. The oxidation was complete in two months, the solution requiring a negligible amount of bromine water. There was a 26% decrease in the acidity. The reaction mixture was worked up as described under (A). The pure solution of the oxidized product did not give a precipitate with calcium sulfate water and contained, according to titration, 10.3 g. of mesotartaric acid or 67% of the theoretical.

The author wishes to thank Dr. J. Stieglitz, Dr. J. W. E. Glattfeld and Dr. J. K. Senior for help in the prosecution of this work and the International Education Board for the financial support which made it possible.

Summary

1. The oxidation of crotonic and isocrotonic acids with perbenzoic acid is described. Crotonic acid gave a *dl*-1,2-dihydroxybutyric acid (m. p. 81.5°) with a yield of 63.5% of the theoretical. Isocrotonic acid gave a *dl*-1,2-dihydroxybutyric acid (m. p. 74–75') with a yield of 62.5%.

2. The oxidation of crotonic and isocrotonic acids with silver chlorate in the presence of osmic acid as a catalyst was carried out. Crotonic acid gave a *dl*-1,2-dihydroxybutyric acid (m. p. 74–75') with a yield of 82.5%. Isocrotonic acid gave a *dl*-1,2-dihydroxybutyric acid (m. p. 81.5°) with a yield of 82.5%.

3. A study of the results of the oxidation of crotonic acid with various chlorates in the presence of osmic acid is described. It was shown that in the chlorate oxidations the reduction of chlorates proceeds through the lower oxides of chlorine and the mechanism of these oxidations is discussed.

4. The most probable structure of the two theoretically possible *dl*-1,2-dihydroxybutyric acids is suggested.

5. A modified procedure for the oxidation of the lactone of 3-hydroxy-isocrotonic acid with silver and barium chlorates is given.

6. The results of a comparative study of the oxidation of maleic anhydride with silver and barium chlorates are given.

ELECTRON DISPLACEMENT IN CARBON COMPOUNDS. V. THE ADDITION OF HYDROGEN CHLORIDE TO 3-ETHYL-2-PENTENE[1]

BY HOWARD J. LUCAS

RECEIVED JULY 23, 1928 PUBLISHED JANUARY 8, 1929

In order to account for the products formed when strong acids add to derivatives of ethylene, investigators have proposed different hypotheses. Markownikoff[2] many years ago laid down the rule that when hydrogen bromide or other similar compound adds, the negative atom goes to that unsaturated carbon atom which is joined to the larger number of other carbon atoms. But there are many exceptions to this rule, the best recognized being acrylic acid, which with hydrogen bromide forms β-bromo-acrylic acid instead of a-bromo-acrylic acid.

An extension of the Lewis theory of molecular structure[3,4] offers another explanation for these phenomena based upon the electron attraction of radicals.

Making use of the formula diagrams, it is evident that a comparison of these values for H, CH_3 and C_2H_5 is all that need be considered. If the usually accepted order of electron attraction, *viz.*, $H > CH_3 > C_2H_5$, is correct,[4] then carbon atom C—2 must have a stronger attraction for the four electrons of the double bond than C—3, since its other four electrons are attracted more strongly by H and CH_3 than are the other four electrons about C—3.[5] Thus C—2 is negative with respect to C—3 (b) and when

[5] From their work on the polarization of the isomeric heptanes, Smyth and Stoops, THIS JOURNAL, 50, 1889 (1928), conclude that any electron shifts existing in these hydrocarbons are so small that they have no appreciable effect upon properties. They also maintain that these and other results provide strong evidence against the assumption

hydrogen chloride adds the halogen should go largely to *C—3,* producing 3-chloro-3-ethylpentane.

(a) Electron displacement structure (b) Polarity due to electron displacement

Polarity and electron structures of 3-ethyl-2-pentene

The hypothesis of alternate polarity would predict that the isomeric 2-chloro-3-ethylpentane would be the principal product.

Hydrogen chloride was selected as the addendum because (a) the aliphatic chlorides are more stable than the bromides and iodides, a very important factor when dealing with easily dissociated secondary and tertiary halides,[6] and (b) the bromides of the higher alcohols boil at temperatures close to those of the alcohols themselves, whereas the chlorides boil considerably lower.

In order to obtain the desired chlorides it was first necessary to prepare the corresponding alcohols, 3-ethyl-2-pentanol and 3-ethyl-3-pentanol (triethylmethanol). The former was obtained from 3-ethyl-2-pentanone by reduction with sodium according to the procedure used for other alcohols[7] and the latter from ethyl bromide and diethylketone by the Grignard method. In carrying out the synthesis of these two alcohols the author was assisted by W. P. Baxter, whose valuable aid is hereby gratefully acknowledged.

The preparation of the two chlorides, 2-chloro-3-ethylpentane and 3-chloro-3-ethylpentane, was accomplished at room temperature by stirring the corresponding alcohol with concentrated hydrochloric acid and zinc chloride and removing the acid layer every few hours. This process resembles the method of Norris and Taylor,[8] who heat the reacting substances, but is a modification which seemed desirable in order to avoid elevated temperatures at which isomeric change would be more rapid. Such a change has been observed in the case of certain alkyl halides.[9] Zinc chloride is a necessary catalyst for the reaction between hydrochloric acid and 3-ethyl-2-pentanol, which undergoes only a 75% conversion

---

of any considerable variation in the position of the electron pairs even in other series of compounds. See also Smyth, *ibid.,* 46, 2151 (1924); Krchma and Williams, *ibid.,* 49, 2408 (1927).

[6] Whereas the chloride obtained from 3-ethyl-2-pentanol could be distilled at atmospheric pressure with only slight decomposition, the bromide evolved hydrogen bromide strongly when heated.

[7] Wislicenus, *Ann.,* 219,309 (1883).

[8] Norris and Taylor, THIS JOURNAL, **46,753** (1924).

[9] Wischnegradsky, *Ann.,* 190,342 (1878), observed that in the reaction of secondary iso-amyl alcohol with hydrochloric and hydriodic acids, the products are tertiary halides, not secondary. Michael and Zeidler, ibid., **393,** 81 (1912), and Michael, Scharf and Voigt, THIS JOURNAL, 38, 653 (1916), observed that pure isobutyl bromide slowly changed to the tertiary compound.

after forty hours without zinc chloride, but is completely converted after sixteen hours in the presence of zinc chloride. Although no attempt was made to determine the minimum time necessary for complete conversion, it is probable that a shorter time would suffice. In view of the fact that tertiary butyl alcohol reacts readily with concentrated hydrochloric acid alone,[10] it is probable that the tertiary heptyl alcohol would have behaved in a similar fashion. However, in order to obtain complete conversion the tertiary chloride was prepared in the same way as the secondary, that is by the use of zinc chloride at room temperature. The attempt to extend the method to primary *iso*butyl alcohol was unsuccessful, no chloride resulting even after several days.

The unsaturated hydrocarbon, 3-ethyl-2-pentene, is readily obtained from the tertiary alcohol, 3-ethyl-3-pentanol, by heating at 100° under a reflux cooler with anhydrous oxalic acid. It combines with hydrogen chloride dissolved in glacial acetic to give a quantitative yield of a heptyl chloride, the properties of which are given in Table I.

In Table I are listed the two heptyl alcohols, the heptene, the two heptyl chlorides, the reaction product and some of the physical properties of these compounds. The boiling points, taken with short Anschiitz thermometers, needed no correction and are given as read; the densities were determined on small samples by the plummet method and are corrected for buoyancy; the refractive indices were determined with an Abbk re-

[10] Davis and Murray, *Ind.* Eng. Chem., 18,844 (1926).

fractometer which was checked at frequent intervals against the standard prism,

The close agreement in the properties of the reaction product and of 3-chloro-3-ethylpentane indicates that this substance constitutes 95–100% of the **material** formed when hydrogen chloride in glacial acetic acid adds to 3-ethyl-2-pentene. The reaction therefore follows the course predicted on the assumption that the electron attractions of the atoms and radicals attached to the unsaturated carbon atoms are in the order $H > CH_3 > C_2H_5$. The course is similar to that between this heptene and sulfuric acid, the product of which was assumed to be the tertiary alcohol, since it was completely decomposed on repeated distillation at atmospheric pressure.[11]

Experimental Part

3-Ethyl-2-pentanone (Unsymmetrical Diethylacetone).—This was obtained in 30% yield by passing a mixture of acetic and diethylacetic acids over thorium oxide at 410–430° and in 31% yield through the acetoacetic ester synthesis in which the diethylacetoacetic ester first produced was decomposed by barium hydroxide according to the general method of Wislicenus.[12] A modification was introduced by using, in place of the 0.25 N solution of barium hydroxide, one approximately twice as concentrated. The material obtained by the pyrolysis method boiled at 136–140" and had a refractive index, n_D^{20}, of 1.4076; that by the decomposition of the ester boiled at 136–137° under a pressure of 745 mm.[13] and had a refractive index. n_D^{20}, of 1.4073.

3-Ethyl-2-pentanol.—This has been obtained, along with other products, by the action of chloro-acetone upon ethylmagnesium bromide.[14] The reduction of 3-ethyl-2-pentanone by means of metallic sodium according to the method used for the reduction of other ketones[7] using, however; twice the amount of sodium necessary for the reaction and diluting the ketone with four times its volume of ether in order to decrease the amount of pinacol produced, gave the desired alcohol in 70% yield and the corresponding pinacol in 8% yield. Complete reduction of the ketone can be brought about by using the excess of sodium recommended. The alcohol, 48 g., distilled at 82.0–82.5° (corr.) under a pressure of 50 mm. and at 151–151.5° (corr.) under 743 mm. without decomposition. It has a pronounced camphor-like odor.

4,5-Dimethyl-3,6-diethyl-4,5-octanediol.—The pinacol obtained in the reduction of 3-ethyl-2-pentanone after two crystallizations from alcohol melted at 100.7–101.2° (corr.). Three determinations of its molecular weight by the micro method of Smith and Young[15] gave 235,[16] which agrees well with 230, the value calculated from $C_{14}H_{30}O_2$.

3-Ethyl-3-pentanol.[11,17]—From 86 g. (1 mole) of diethyl ketone, b. p. 101.2–103.2°,

110 g. (1 mole) of ethyl bromide and 24.5 g. (1 mole) of magnesium in 200 cc. of absolute ether, there was obtained 70 g. (63% yield) of crude 3-ethyl-3-pentanol distilling at 68–72° under 49 mm. The material from two batches was fractionally distilled under a pressure of 50 mm. to prevent decomposition. The fractionation was performed six times, the refractive index being used as a check on the purity. During the last three distillations this value was practically constant. The boiling point of the final product, which has a pronounced camphor-like odor much resembling that of the isomeric alcohol, was 72.5–73.5' (corr.) at 50 mm., 83.5–84.0° (corr.) at 90 mm. and 140.5–141.5° (corr.) at 743 mm. It had refractive indices as follows: n_{D}^{20}, 1.4305 and n_{D}^{25}, 1.4281.

2-Chloro-3-ethylpentme.—The chlorides were prepared at room temperature of approximately 22° in order to decrease the possibility of isomeric change.[9] This chloride was prepared by stirring 10 g. (0.09 mole) of 3-ethyl-2-pentanol with 3 successive portions of 21 g. (0.2 mole) of concentrated hydrochloric acid and 22 g. (0.2 mole) of anhydrous zinc chloride over a period of fourteen hours, renewing the acid at approximately five-hour intervals. The product was shaken with small quantities of water in order to remove most of the acid and dried with anhydrous potassium carbonate. Two fractional distillations, the first at 90 mm. over a range of 70–77° and the second at 50 mm. over a range of 62.0–62.5° (corr.), gave 3.7 g. (35% yield) of product. The two fractions of each distillation differed but slightly in refractive index, the best values being n_{D}^{20}, 1.4318 and n_{D}^{25}, 1.4299. At the end of both distillations there was no tendency for the thermometer thread to rise, indicating absence of any higher boiling material such as the alcohol. The density, d_{25}^{25}, was 0.8911. After standing over phosphorus pentoxide for twenty-four hours, n_{D}^{25} was 1.4295.

When the alcohol was stirred for forty hours with concentrated hydrochloric acid in the proportions given above with replacement every six or seven hours but without the zinc chloride, the product after shaking out with water and drying over potassium carbonate was by weight only 75% converted and had a refractive index, n_{D}^{20}, 1.4293. When distilled at 50 mm. the temperature was slightly higher than before, *viz.*, 63–65', and the indices of the different fractions differed by 0.0011. It was evident that the reaction had not gone to completion even after forty hours.

3-Chloro-3-ethylpentme.—This was prepared by stirring at room temperature 11.6 g. (0.1 mole) of 3-ethyl-3-pentanol with four successive portions of 21 g. (0.2 mole) of concentrated hydrochloric acid and 22 g. (0.2 mole) of anhydrous zinc chloride over a period of eighteen hours, renewing the acid at approximately five-hour intervals. After separating the heptyl chloride, washing five times with water and drying over potassium carbonate, the weight of the crude product was 12.6 g., a yield of 94%. In the operations which followed, drying over phosphorus pentoxide, distilling under a pressure of 100 mm. at 83.0–83.5° (corr.) and drying again over both drying agents, the refractive index was not changed, n_{D}^{25} being 1.4311. Standing for twenty-four hours over phosphorus pentoxide did not change the value.

After the chloride had been distilled at reduced pressure, distillation at atmospheric pressure could be carried on with but slight decomposition. Without a previous distillation the undistilled material evolved hydrogen chloride copiously when heated, probably due to the catalytic influence of suspended matter.[18]

3-Ethyl-2-pentene.—This was obtained by heating equal weights of 3-ethyl-3-pentanol and anhydrous oxalic acid on a boiling water-bath under a reflux cooler for five hours.[11,17d] The hydrocarbon was distilled over, separated from the water, refluxed with metallic sodium and finally distilled from the sodium, coming over at 95–96°.

---

292 (1910); (f) Mazurewitsch, J. *Russ. Phys.-Chem. Soc.*, 42, 1582 (1910); *Chem. Cent.*, 1911, *I*, 1500; (g) Davies and Kipping, J. *Chem. Soc.*, 99, 298 (1911).

[18] Rice, THIS JOURNAL, 48, 2099 (1926).

After refluxing again with sodium, the material distilled at 95.0–95.5° (corr.) at 745 mm. The yield was 84%.

Hydrogen Chloride and 3-Ethyl-2-pentene.—Dry hydrogen chloride was passed into 30 g. of glacial acetic acid, the solution was then cooled by ice and water and the gas was passed in until saturation was reached, 3 g. (0.08 mole) dissolving. To this was added 10.0 g. (0.10 mole) of 3-ethyl-2-pentene and additional hydrogen chloride was passed in until a total of 5 g. (0.14 mole) had dissolved. The mixture stood overnight at 8-10', ice and water were then added and the chloride layer was washed five times with cold water. The weight of the undried chloride layer was 13.3 g., theoretical yield, 13.2 g. This indicated that addition was practically quantitative. After drying over anhydrous potassium carbonate the refractive index, n_D^{25}, was 1.4311 and the density, d_{25}^{25}, was 0.8951. The material distilled completely at 78-79' under 90-91 mm. pressure. The refractive index was unchanged and the density was 0.8948. After standing for twenty-four hours over phosphorus pentoxide the refractive index was still 1.4311.

The refractive index of the reaction product was identical with that of 3-chloro-3-ethylpentane, but the density was too high, being slightly above the value for this chloride. The three materials were allowed to stand for about a month over phosphorus pentoxide, the densities then being, 2-chloro-3-ethylpentane, 0.8874, 3-chloro-3-ethylpentane, 0.8917, and the reaction product, 0.8916. This brought all of the densities down and left the value for the reaction product slightly less than that of 3-chloro-3-ethylpentane. The refractive indices were not again determined although it is possible. that they may have changed. The properties of the reaction product are thus practically identical with those of 3-chloro-3-ethylpentane.

Summary

The heptyl chlorides, 2-chloro- and 3-chloro-3-ethyl pentane have been prepared in a pure state from the corresponding alcohols at room temperature by stirring with concentrated hydrochloric acid and zinc chloride. Some physical properties have been determined.

Hydrogen chloride in glacial acetic acid reacting with 3-ethyl-2-pentene gives a heptyl chloride which is practically pure 3-chloro-3-ethylpentane.

The product formed agrees with the prediction made on the assumption that the electron attractions of hydrogen, methyl and ethylene are in the order $H > CH_3 > C_2H_5$, and not with the hypothesis of an alternately polarized carbon chain.

RESEARCHES ON HYDANTOINS. XLVII. SYNTHESIS OF POLYPEPTIDE HYDANTOINS FROM 2-THIOHYDANTOIN-3-ACETIC ACID[1]

BY ALICE G. RENFREW[2] AND TREAT B. JOHNSON

RECEIVED JULY 26, 1928 PUBLISHED JANUARY 8, 1929

In the study of new organic principles applicable for internal antisepsis we inaugurated three years ago a new feature by introducing into our researches on germicides an investigation of some phenolic derivatives of hydantoin. Having reliable knowledge of the fact that the hydantoin cycle is a non-toxic organic construction and one which is also very resistant to the action of ferments and bacterial enzymes,[3] we concluded that it would be of special interest to determine whether it would be feasible to utilize the hydantoin nucleus as a vehicle for transporting antiseptic groupings in the body. Johnson and Coghill[4] prepared, in the preliminary work, a series of mono- and di-phenol derivatives of hydantoin with the phenolic grouping —C_6H_4OH substituted on both carbon and nitrogen atoms of the hydantoin cycle. A preliminary bacteriological examination of several of these derivatives has already been reported. None thus far examined exhibited an antiseptic activity comparable to phenol. The new combinations did not prove of practical utility as germicidal agents on account of their insolubility in water. The toxicity of the aromatic phenol group, however, was reduced by coupling the benzene nucleus with the hydantoin.

In continuing this work we sought to incorporate changes in constitution which would be expected to increase the solubility of our compounds and at the same time lead to constructions favorable for pharmaceutical application. We therefore turned our attention to a study of certain simple, phenolic constructions combined with the polypeptide hydantoin nucleus. It was felt that a study of the effect of introducing acid groupings on nitrogen would be beneficial; we therefore undertook the preparation of new combinations of this type. The grouping which we selected to increase the solubility of our phenolic compounds was the acid radical —H_2CCOOH. This has been incorporated by substitution in positions

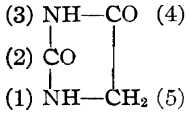
1 and 3 of the hydantoin cycle. In this paper we shall confine our discussion to some derivatives of hydantoin-3-acetic acid, I, and its corresponding sulfur analog, II. The results of our study of derivatives of hydantoin-1-acetic acid will be reported in a later paper.[5]

It has been the experience of this Laboratory that aldehyde condensations are more readily effected with 2-thiohydantoins than with the oxygen analogs. Regarding the influence of sulfur in position 4 or in dithiohydantoins on the course of such condensation reactions we have no knowledge. Johnson and his co-workers have made comparative studies of both hydantoin and 2-thiohydantoin in condensations with various aldehydes[6] The greater activity of the thiohydantoin also characterizes the condensation of hydantoin cycles containing substituents in the 1- and 3-positions of the ring. 1-Phenyl-2-thiohydantoin and 1,3-diphenyl-2-thiohydantoin were condensable with aldehydes without difficulty.[7] Using the corresponding oxygen derivatives, Wheeler and Hoffmann[8] were unsuccessful in effecting similar condensations, although Johnson and Hadley[9] later actually succeeded in condensing 1,3-diphenylhydantoin with benzaldehyde. Thus far no successful condensations of 1-phenylhydantoin with aldehydes have been reported.

The condensations that have been applied successfully with hydantoin-3-acetic acid and its sulfur analog are described in detail in the Experimental Part of this paper, and are illustrated structurally herewith. The three aldehydes used were p-anisaldehyde, salicylaldehyde and piperonal. By inspection of the formulas it will be observed that all of these new products have been represented structurally as cyclic methylene condensation reactions. This is an important conclusion of our work as both the 2-thiohydantion-3-acetic acid, II, and its oxygen analog, I, contain two methylene radicals theoretically capable of condensing with aldehydes. In no case, however, have we obtained any evidence that the methylene radical in the acyclic acetic acid group undergoes a condensation reaction with an aldehyde. Also in no aldehyde condensation reaction did we succeed in revealing a single new case of geometric

---

[5] The system used for numbering the positions of the hydantoin ring, as represented, will be adopted throughout this and following papers. It is in accord with the system of classification in use in Beilstein's "Handbuch der Organische Chemie," and in the subject index of *Chemical Abstracts.* A method of numbering which has been widely used in the past is one in which the numerical assignments to the two nitrogen atoms of the cycle are reversed.



$$\begin{array}{lll} (3)\ NH & - & CO\ (4) \\ (2)\ CO & & \\ (1)\ NH & - & CH_2\ (5) \end{array}$$

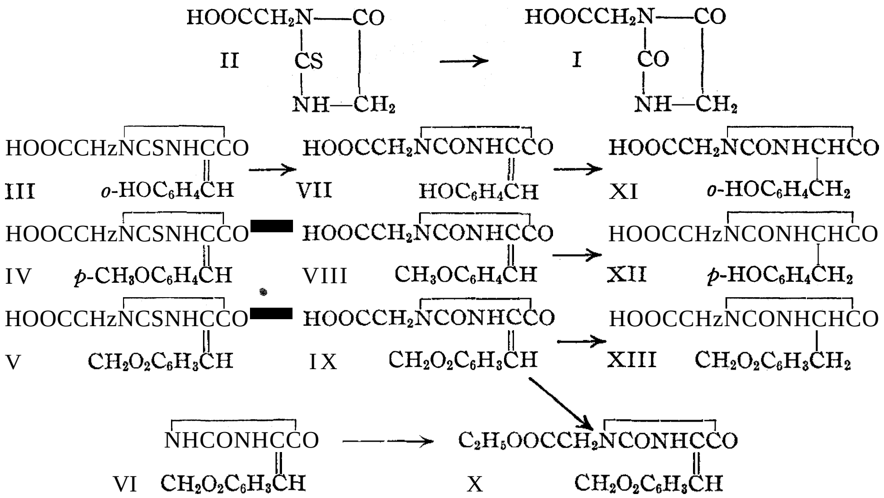
[9] Johnson and Hadley, THIS JOURNAL, 37,171 (1915).



isomerism, despite the fact that the reaction products were carefully studied.

An interesting result worthy of special mention is the fact that most of the condensations applied with the three aldehydes and the hydantoin-3-acetic acids, I and II, in the presence of sodium acetate gave the sodium salts of the condensation products, notwithstanding the fact that all the condensations were carred out in glacal acetic acid solution. The two exceptions were the reaction products resulting from condensation of anisaldehyde and piperonal with 2-thiohydantoin-3-acetic acid. Here the free substituted hydantoin-acetic acids were obtained.

The condensations between 2-thiohydantoin-3-acetic acid, II (or its oxygen analog, I), with aldehydes serve also another useful purpose in that they make it possible to establish conclusively the structure of alkylation products of simple aldehyde-hydantoins when the alkylation method is used in the preparation of polypeptide hydantoin configurations. For example, the structure of the alkylation product X is established by the fact that the same derivative is formed by esterification of the hydantoin IX. It is a common experience that hydantoins of Type VI undergo substitution first in position 3 when subjected to the conditions of an alkylation reaction.

Experimental Part

2-Thiohydantoin-3-acetic acid, $HOOCCH_2NCSNHCH_2CO$.—The acid is easily obtained in a yield of 85–90% of the theoretical according to the method of Johnson and **Renfrew.**[10]

2-Thio-5-panisalhydantoin-3-aceticAcid, $HOOCCH_2NCSNHC{=}(CHC_6H_4OCH_3)CO$.—This hydantoin is formed by digesting thiohydantoin-3-acetic acid (5 g.) with *p*-anisal-

---

[10] Johnson and Renfrew, THIS JOURNAL, **47,** **240** (1925).

dehyde (5.5 g.) in the presence of 6 g. of anhydrous sodium acetate, 10 cc. of glacial acetic acid and 3 cc. of acetic anhydride. After heating the above mixture in an oil-bath for ten minutes at 250–260°, the fluid changed to a magma of the solid hydantoin. A further 10 cc. of glacial acetic acid was then added and the heating continued for two hours, when the condensation was apparently complete. The hydantoin was separated by filtering the reaction mixture while hot and washing with water and alcohol to remove impurities. A yield of 6.7 g. was obtained, corresponding to 80% of the theoretical. The hydantoin is purified by crystallization from alcohol or acetic acid and melts at 280–282°.

Anal. Calcd. for $C_{13}H_{12}O_4N_2S$: N, 9.59. Found: N, 9.63, 9.67.

5-*p*-Anisalhydantoin-3-acetic acid, $\mathrm{HOOCCH_2\overline{NCONHC{=}(CHC_6H_4OCH_3)C}O}$.—This hydantoin-acetic acid has been described previously by Johnson and Hahn,[11] and recently by Granacher and Landolt.[12] The same hydantoin is also obtained by desulfurizing the above 2-thiohydantoin with chloro-acetic acid. A mixture of our product with a specimen of the original hydantoin showed no change in melting point, namely, 269–271°.

In an effort to accumulate further comparative data on the reactivity of the methylene group in nitrogen-substituted hydantoins, this hydantoin was also synthesized by a third method, namely, by condensing anisaldehyde with hydantoin-3-acetic acid. Reaction was brought about by digesting in a mixture of glacial acetic acid and acetic anhydride in the presence of anhydrous sodium acetate. The reaction was complete after refluxing in an oil-bath for three hours. After cooling, the acetic acid solution was diluted with water, when the condensation product separated. This was identified as the sodium salt of anisalhydantoin-3-acetic acid, corresponding in yield to 41% of the theoretical. The salt was initially colorless but after recrystallization from water it separated in green plates which deposited an alkaline residue when burned on platinum foil. This salt was not very soluble in water. These properties characterize the monosodium salt of this hydantoin, which has been studied by Hahn and Burt,[13] thus excluding the possibility of the condensation product being an acyclic hydantoin acid derivative. An excess of hydrochloric acid added to an aqueous solution of the sodium salt produced a heavy precipitate of the corresponding acetic acid. The acid showed a melting point in accordance with that already recorded. With recovery of some salt from filtrates, the total yield of condensation product was 51% of the theoretical. With slight variations in technique this same synthesis has been reported recently by Granacher and Landolt[12] as giving a yield of 57%. This unsaturated hydantoin is reduced smoothly to *p*-hydroxybenzylhydantoin-3-acetic acid when digested with hydriodic acid and red phosphorus.[11]

Salicylalhydantoin-3-Acetic Acid Derivatives

2-Thio-5-salicylalhydantoin-3-acetic Acid, $\mathrm{HOOCCH_2\overline{NCSNHC{=}(CHC_6H_4OH)C}O}$.—This compound is easily formed by applying a condensation reaction with salicylic aldehyde and thiohydantoin-3-acetic acid. The reagents required are used in the following proportions: thiohydantoin-acetic acid, 10 g., salicylaldehyde, 10 g., sodium acetate 12 g., and glacial acetic acid, 30 cc. After heating this mixture for ten to fifteen minutes at 150–155°, the liquid became completely saturated with the condensation product and finally completely solidified. Water was then added to bring it to a volume of

[13] Hahn and Burt, THIS JOURNAL, 39, 2468 (1917).

50 cc. and the insoluble condensation product was separated by filtration. This was identified as the sodium salt of 2-thio-salicylalhydantoin-3-aceticacid and we obtained a yield of 14 g. The salt crystallizes from hot water and is converted into its corresponding acid by the action of hydrochloric acid. The yield of hydantoin was 96% of the theoretical. It was purified by crystallization from glacial acetic acid and melted with decomposition at 253–254°.

Anal. Calcd. for $C_{12}H_{10}O_4N_2S$: N, 10.07. Found: N, 10.12, 10.20.

Salicylalhydantoin-3-acetic acid, $HOOCCH_2\overline{NCONHC{=}(CHC_6H_4OH)C}O$.—Ten grams of the above 2-thiohydantoin compound was suspended in a solution containing 30 g. of chloro-acetic acid in 30 cc. of water. After boiling for five hours, the reaction was complete and the hydantoin had separated. This compound is very insoluble in acetic acid, 120 cc. dissolving less than 2 g. of the hydantoin. It crystallized from boiling acetic acid in light yellow, prismatic crystals melting at 273–274° with decomposition.

Anal. Calcd. for $C_{12}H_{10}O_5N_2$: N, 10.68. Found: N, 10.50, 10.56.

Esterification of this hydantoin-acetic acid with ethyl alcohol gives an ester melting at 164° (uncorr.). An attempt was made to prepare this compound by alkylation of salicylalhydantoin[14] with ethyl chloro-acetate, but the reaction does not take place smoothly and a gummy product is formed from which it is very difficult to separate the ethyl ester.

o-Hydroxybenzylhydantoin-3-acetic Acid, $HOOCCH_2\overline{NCONHCH(CH_2C_6H_4OH)C}O$.—This polypeptide hydantoin was first approached by heating salicylalhydantoin-3-acetic acid with hydriodic acid and red phosphorus. This treatment led to the formation of a gummy product which was extremely difficult to purify. It was found that the reduction could be accomplished by using hydriodic acid alone. The unsaturated hydantoin was suspended in five times its weight of hydriodic acid and the mixture carefully heated, but never allowed to boil. After complete solution the mixture was allowed to stand for a few minutes and the acid then diluted with water. Part of the polypeptide hydantoin crystallized directly from this diluted solution; the remainder was obtained by allowing the filtrate to concentrate in a vacuum over sodium hydroxide. The yield of crude reduction product was about 75% of the theoretical. The hydantoin was purified by crystallization from hot water and separated in the form of rosets melting at 189–190°.

Anal. Calcd. for $C_{12}H_{12}O_5N_2$: N, 10.60. Found: N, 10.59, 10.60.

As would be expected this polypeptide hydantoin gives a positive Jaffé picric acid reaction. A red-brown layer develops very rapidly when the test is performed by the modified method of Brand and Sandberg.[15]

2-Thio-5-piperonal-hydantoin-3-aceticAcid, $HOOCCH_2\overline{NCSNHC{=}(CHC_6H_3O_2CH_2)C}O$.—This compound was obtained in a yield of 90% of the theoretical by condensation of piperonal with 2-thiohydantoin-3-aceticacid. The acid, which was the initial reaction product in this case, crystallizes from boiling acetic acid in small, glistening, yellow crystals which melt with decomposition at 291°.

Anal. Calcd. for $C_{13}H_{10}O_5N_2S$: N, 9.02. Found: N, 8.83, 8.97.

5-Piperonalhydantoin-3-acetic acid, $HOOCCH_2\overline{NCONHC{=}(CHC_6H_3O_2CH_2)C}O$.——The above sulfur hydantoin was desulfurized by refluxing for about thirty hours with

---

[14] Johnson and Scott, THIS JOURNAL. 37, 1846 (1915).

[15] Brand and Sandberg, J. *Biol. Chem.*, 70,381 (1926).

a 50% solution of chloro-acetic acid. The solid never completely dissolved but it gradually became lighter in color and formed hard, compact crystals which settled to the bottom of the flask. The hydantoin separated from acetic acid in the form of lemon-yellow rosets which melted at 275–276°.

Anal. Calcd. for $C_{13}H_{10}O_6N_2$: N, 9.65. Found: N, 9.78, 9.94.

To prove that this compound was a derivative of piperonal-hydantoin rather than a possible condensation product involving a reaction of the methylene radical in the acetic acid group of the hydantoin-3-acetic acid, the acid was esterified with ethyl

$$H_2CO_2C_6H_3CH{=}C(COOH)NCONHCH_2CO$$

alcohol. This ester was found to be identical with the hydantoin-ester formed by direct alkylation of the sodium salt of piperonalhydantoin with ethyl chloro-acetate.

Ethyl **5-Piperonal-hydantoin-3-acetate**,

$$C_2H_5OOCCH_2NCONHC{=}(CHC_6H_3O_2CH_2)CO$$

.—Ten grams of piperonal-hydantoin[5] was suspended in 100 cc. of absolute alcohol containing in solution 1.3 g. of metallic sodium. After digesting for forty-eight hours, two molecular equivalents of ethyl chloro-acetate was added and the digestion continued for two days. The solution was filtered hot and the insoluble residue was triturated with dilute hydrochloric acid, when a small quantity of crystalline material was obtained having the properties of piperonylic acid. From the alcohol solution the above ester separated in the form of prisms melting at 159–160°. It was insoluble in alcohol. When mixed with the ester prepared by esterification of piperonalhydantoin-3-acetic acid, the melting point was not changed.

Anal. Calcd. for $C_{15}H_{14}O_6N_2$: N, 8.80. Found: N, 8.81.

Summary

1. It has been shown that hydantoin-3-acetic acid and its sulfur analog both condense with aldehydes.
2. The cyclic methylene group is the reactive position in the hydantoin.
3. The sulfur hydantoin reacts more favorably with aldehydes than the hydantoin-3-acetic acid.
4. The three aldehydes, anisaldehyde, salicylaldehyde and piperonal gave condensation products which do not exhibit geometric isomerism.
5. The polypeptide hydantoins containing free phenolic groups are being examined to determine their germicidal value and toxicity.

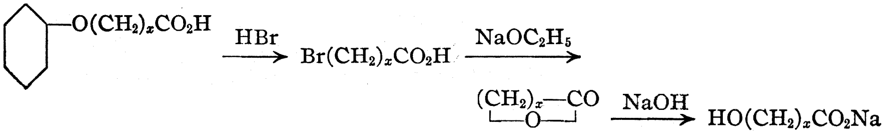
THE PREPARATION OF THE SODIUM SALTS OF OMEGA-HYDROXYBUTYRIC, -VALERIC AND -CAPROIC ACIDS

BY C. S. MARVEL AND E. R. BIRKHIMER

RECEIVED JULY 30, 1928 PUBLISHED JANUARY 8, 1929

Several studies have been made of the hydroxy and amino acids in an attempt to find whether or not they give the same end products in metabolism in the animal organism. In order to gain further information concerning this problem, the preparation of the salts of some w-hydroxy acids was undertaken so that they might be compared with the w-amino acids which have recently been studied by Corley.[1]

The general procedure which was used for the preparation of these compounds can be illustrated by the following reactions



Although these reactions are not essentially new, the methods have not been described in sufficient detail to make possible the easy production of any considerable amounts of these compounds.

y-Phenoxybutyric acid was prepared by the method of Lohmann[2] except that the hydrolysis was carried out under a reflux condenser and not in closed tubes. y-Bromobutyric acid was obtained from it by the method devised by Merchant, Wickert and Marvel[3] for converting phenoxy acids to the corresponding bromo acids. The bromo acid was converted to y-butyrolactone by the method which Cloves[4] has described for the preparation of 6-valerolactone from 8-bromovaleric acid. The lactone was saponified in the usual way with dilute sodium hydroxide solution.

8-Valerolactone was prepared by the same series of reactions, starting with 6-phenoxyvalericacid, and then hydrolyzed to give sodium δ-hydroxyvalerate. However, when Cloves' method of preparing a lactone was applied to ϵ-bromocaproic acid, a very poor yield of ϵ-caprolactone was obtained. This material was apparently a compound of the type $[O(CH_2)_5COO(CH_2)_5CO]_x$, since on hydrolyzing with aqueous hydroxide solution it gave a salt which by analysis agreed with sodium hydroxycaproate.

Experimental Part

γ-Phenoxybutyric Acid.—A mixture of 500 *g.* of phenoxypropyl cyanide and 2500 cc. of concentrated hydrochloric acid (sp. gr., 1.19) was boiled under a reflux condenser for about five hours. The phenoxybutyric acid was extracted with benzene, the benzene evaporated and the product distilled under reduced pressure. The yield was 340 g. (61% of the theoretical amount) boiling at 192–197° (18 mm.).

y-Bromobutyric Acid.—A mixture of 340 g. of γ-phenoxybutyric acid and 550 cc. of 48% hydrobromic acid was placed in a 1-liter round-bottomed flask attached to a 1-meter fractionating column by means of a mercury seal. The reaction mixture was heated to such a point that the temperature of the vapors at the top of the column was about 120°. After about five hours no more phenol was distilling. The reaction mixture was diluted with water and the y-bromobutyric acid was extracted with ether. The product was distilled under reduced pressure. The yield was 220 g. (70% of the theoretical amount) of γ-bromobutyric acid, b. p. 124–127° (7 mm.).

γ-Butyrolactone.—To a solution of 7.8 g. of sodium in 500 cc. of absolute alcohol was added 60.5 g. of γ-bromobutyric acid. The reaction mixture was boiled under a reflux condenser for about five hours. During this time sodium bromide separated. The alcohol was distilled from a steam-bath and the lactone was separated from the sodium bromide by extraction with ether. The ether was evaporated and the lactone distilled under ordinary pressure. The yield was 21.2 g. (67% of the theoretical amount) of a product boiling at 202–206°; sp. gr. $^{28}_{28}$, 1.1054; $n^{26.5}_{\mathrm{D}}$, 1.4343.

Sodium **γ-Hydroxybutyrate.**—A mixture of 16.3 g. of γ-butyrolactone and 7.4 g. of sodium hydroxide dissolved in 30 cc. of water was boiled under a reflux condenser for about three hours. At the end of this time more water was added to dissolve the salt and the solution was filtered and evaporated to dryness under reduced pressure. The salt was recrystallized from alcohol. The yield was 11.5 g. (40% of the theoretical amount).

Anal. Subs., 0.2106: Na_2SO_4, 0.1171. Calcd. for $C_4H_7O_3Na$: Na, 18.25. Found: Na, 18.02.

δ-Valerolactone.—δ-Valerolactone was obtained in 58% yield from δ-bromovaleric acid by the method of Cloves." It boiled at 215–220° at atmospheric pressure; sp. gr. $^{20}_{20}$, 1.1130; n^{20}_{D}, 1.4600.

Sodium **δ-Hydroxyvalerate.**—This material was prepared by the method used for the corresponding butyric acid derivative. From 11 g. of lactone and 4 g. of sodium hydroxide in 20 cc. of water there was obtained 6.6 g. (47% of the theoretical amount) of product.

Anal. Subs., 0.2140: Na_2SO_4, 0.1085. Calcd. for $C_5H_9O_3Na$: Na, 16.43. Found: Na, 16.42.

Sodium **ε-Hydroxycaproate.**—To a solution of 9 g. of sodium in 500 cc. of absolute alcohol was added 77 g. of e-bromocaproic acid. The solution was boiled under reflux for about five hours and then the alcohol was distilled and the residue in the flask extracted with ether. The ether was evaporated and an attempt was made to distil the residue. About 10 g. of material which seemed to be slightly impure e-caprolactone was obtained, boiling at 135–140° (35 mm.). It gave a slight test for bromine; sp. gr. $^{24}_{24}$, 1.0306; n^{24}_{D}, 1.4481.

There was considerable residue (25–30 g.) left in the distilling flask which did not distil when heated to about 200° under 35 mm. pressure. This residue was hydrolyzed by boiling with an aqueous solution of about 6 g. of sodium hydroxide. This solution was decolorized with decolorizing carbon (Norite), filtered and evaporated to dryness. The residue was recrystallized from alcohol. In this manner 14.5 g. of the sodium salt was obtained.

Anal. Subs., 0.2012: Na_2SO_4, 0.0943. Subs., 0.1987: CO_2, 0.3126; H_2O, 0.1277. Calcd. for $C_6H_{11}O_3Na$: Na, 14.93; C, 46.75; H, 7.14. Found: Na, 15.05; C, 46.81; H, 7.14.

Summary

Convenient procedures for the preparation of the sodium salts of the ω-hydroxy derivatives of butyric, valeric and caproic acids have been described.

URBANA, ILLINOIS

SALTS OF AROMATIC NITRILES. II. POTASSIUM PHENYLACETONITRILE

BY MARY M. RISING, IRVING E. MUSKAT AND EDMUND W. LOWE

RECEIVED AUGUST 3, 1928 PUBLISHED JANUARY 8, 1929

There appeared recently a paper[1] by one of the present authors and Dr. Tsoh-Wu Zee in which were discussed the method of preparation and the behavior of sodium phenylacetonitrile, $[(C_6H_5)HC{=}C{=}N]Na$ and $[(C_6H_5)(CN)HC]Na$, and of sodium α-phenylbutyronitrile,[2] $[(C_6H_5)(C_2H_5)C{=}C{=}N]Na$ and $[(C_6H_5)(C_2H_5)(CN)C]Na$. The paper was accompanied by a statement to the effect that the purity and identity of these salts, which were obtained a number of times by Rising and Zee, were established conclusively from the analytical data and the reactions of the compounds, but that since the departure of Dr. Zee for China it had proved so far impossible to repeat his work and obtain the salts again in pure form.

In view of the experimental difficulties encountered in obtaining the sodium salts by the workers who followed Zee, a study of the potassium salts of phenylacetonitrile and α-phenylbutyronitrile was undertaken, and the present paper describes the preparation of potassium phenylacetonitrile, $[(C_6H_5)HC{=}C{=}N]K$, and $[(C_6H_5)(CN)HC]K$, and its conversion into a-phenylbutyronitrile in fairly good yield by treatment with ethyl iodide. The method used by Zee to obtain the sodium salts has been modified slightly and a method of purification of the potassium salt has been developed which will undoubtedly prove useful for other salts of this variety.

A few weeks after the publication of our last report on the sodium salts, the attention of one of the present authors was called by F. W. Upson and T. J. Thompson to a paper of theirs[3] which appeared in 1922 upon

---

[1] Rising and Zee, THIS JOURNAL, 50, 1699 (1928).

[2] This salt was described in an earlier paper by Rising and Zee, *ibid.*, 49, 541 (1927).

[3] Upson and Thompson, *ibid.*, 44, 181 (1922).

"The Preparation and Properties of Several Phenyl Alkyl Succinic Acids," at the end of which these authors describe, incidentally to the main theme of their work, the interesting behavior of a substance, not obtained by them in pure form, produced by the reaction of sodium amide upon phenylacetonitrile in ether. The properties of this substance led Upson and Thompson to conclude that it was sodium phenylacetonitrile, of nitride structure, $(C_6H_5)HC{=}C{=}NNa$. It is a source of great satisfaction to us to find that the conclusions of these workers regarding the structure of the salt are thus in agreement with our own. The results of their work and of ours present striking confirmation of the theory first proposed by Nef and Hesse[4] with regard to the structure of salts of organic nitriles. Upson and Thompson also suggest that an imide form of phenylacetonitrile, $(C_6H_5)HC{=}C{=}NH$, is an intermediate compound in certain condensation reactions, undergoing "rearrangement" to the nitrile form, $(C_6H_5)H_2C(CN)$, in the course of these reactions. An analogous rearrangement of the imide form of the dinitrile of malonic acid, $(CN)HC{=}C{=}NH$, to the nitrile form, $(CN)H_2C(CN)$, was previously proposed by Nef and Hesse. We regret that we failed to give credit in our previous papers to Upson and Thompson for their work in this field. Their paper had escaped our notice due to the two facts that no reference to their observations was included in the title of their paper, and that the indexes of Chemical *Abstracts* and other literature contained no reference to this part of their work.

Rising and Zee obtained sodium phenylacetonitrile in pure form;' they found interesting evidence for the Nef theory of bivalent carbon in the nature of the decomposition products of the salt with acid, and explained the behavior of this salt and of its homolog, sodium α-phenylbutyronitrile, in the reactions studied, upon the assumption of nitride–carbide tautomerism, obviously an extension of the Nef theory with regard to the tautomerism of hydrocyanic acid, the parent substance of nitriles; they also made suggestions regarding the role of sodium phenylacetonitrile in the aldol-like condensations described by von Meyer[5] and others.6 Work along these lines is being continued by Rising, the results to be reported in due time.

Experimental Part

Potassium Phenylacetonitrile $(C_6H_5)HC{=}C{=}NK$ and $(C_6H_5)(CN)HCK$.—This salt was prepared by the treatment of potassium powder with phenylacetonitrile in dry ether in an atmosphere of nitrogen, according to the equation

$$2(C_6H_5)CH_2CN + 2K \longrightarrow 2(C_6H_5)HC{=}C{=}NK + H_2 \qquad (1)$$

The salt can be obtained in pure condition only when the most rigorous precautions are

taken to exclude moisture and carbon dioxide; hence it has seemed best to describe the procedure used in some detail.

Apparatus.—The reaction vessel was a 200-cc. flask carrying a reflux condenser; in the top of the condenser was placed a stopper carrying a tube of calcium chloride, an inlet tube for nitrogen reaching to the bottom of the reaction flask and a dropping funnel closed by means of a tube of calcium chloride. It is of the utmost importance that this apparatus be thoroughly dried. For this purpose a stream of dry nitrogen was drawn through it for forty-eight hours, the apparatus being heated during this time.

Reagents.—The nitrogen used for drying all apparatus was purified by being drawn first through two vessels of alkaline pyrogallol, then over calcium chloride, next through concentrated sulfuric acid and finally over phosphorus pentoxide. The ether which served as the reaction medium was washed with water, placed once over calcium chloride and then twice over bright sodium. After the ether was distilled from the sodium the last traces of water were removed by treatment with sodium-lead alloy. Kahlbaum's phenylacetonitrile, of boiling point 230–231° (uncorr.), and of known purity, was used. Potassium powder was prepared as follows: small squares of freshly cut potassium, weighed under dry xylene, were placed in the reaction flask already described, which contained 30 cc. of xylene (thiophene-free, and dried over sodium-lead alloy). The flask, loosely stoppered, was warmed until the potassium melted; the flask was then tightly closed, and shaken vigorously with a vertical movement until the molten metal was converted into an exceedingly fine powder. The xylene was decanted, the metal was washed very thoroughly with dry ether and finally covered with a layer of dry ether.

Preparation of Potassium Phenylacetonitrile.—Potassium dust (4.2 g.), covered with 30 cc. of ether, was placed under the reflux condenser described. The reaction apparatus was then swept out with nitrogen. Phenylacetonitrile (14 g.), used in 11% excess of the calculated amount to force all of the potassium to react and dissolved in ether to make 60 cc., was allowed to drop slowly into the reaction flask from the dropping funnel. As the reaction began, hydrogen was evolved, a bulky yellow precipitate formed and the ether boiled. When no more hydrogen was evolved, the reaction mixture was warmed for half an hour. The product of the reaction was sticky and could not be readily removed from the flask; the ether was therefore decanted from it, and the residue was washed rapidly several times with ether. The flask and contents were then placed in a vacuum desiccator over phosphorus pentoxide and the last of the ether was drawn off by suction. As the ether was removed the salt swelled and became brittle. The crude product sometimes contained unused potassium metal. Usually, however, the potassium content was somewhat low, due probably to the fact that the excess of nitrile used was not completely removed from the sticky mass. The yield of the salt obtained was 10 g., or 60% of the theoretical. Some loss of product occurred because it could not be removed completely from the reaction flask; the yield was also somewhat lowered due to the fact that some of the potassium dust was lost in the process of washing it with ether.

Purification of Potassium Phenylacetonitrile.—The crude salt was purified as follows: 10 g. of it was treated with 150 cc. of dry benzene in a dry flask in an atmosphere of nitrogen, whereupon much of the crude product dissolved. The benzene solution of the salt was separated from the residue by filtration, a stream of nitrogen being meanwhile allowed to play over the surface of the solution. Following filtration, the benzene solution was treated with dry, low-boiling ligroin to reprecipitate the salt, which was separated by filtration through silk, being kept in an atmosphere of nitrogen during the filtration. The salt was washed several times with ligroin and quickly put into a desiccator over phosphorus pentoxide. The salt, now pure, was kept in an atmosphere of nitrogen until analyzed.

Anal. Subs. 0.1025, 0.1298: K_2SO_4, 0.0571, 0.0721. Subs., 0.3444, 0.2476: N_2, 27.70, 20.20 cc. (22°, 746.5 mm.) (over 50% KOH). Subs., 03073, 0.3594: CO_2, 0.6963, 0.8141; H_2O, 0.1080, 0.1255. Calcd. for KC_8H_6N: K, 25.19; N, 9.03; C, 61.86; H, 3.89. Found: K, 24.97, 24.92; N, 8.95, 9.06; C, 61.79, 61.77; H, 3.90, 3.88.

Behavior of Potassium **Phenylacetonitrile.**—The crude salt is a dark yellow, crystalline substance, becoming a lighter yellow after recrystallization. It is exceedingly sensitive to traces of water and acids, which decompose the salt with the formation of hydrocyanic acid It reacts with ethyl iodide to form a-phenylbutyronitrile, as follows

$$(C_6H_5)HC{=}C{=}NK \rightleftarrows (C_6H_5)(CN)HCK \qquad (2)$$

$$(C_6H_5)(CN)HCK + C_2H_5I \longrightarrow (C_6H_5)(CN)HC(C_2H_5) + KI \qquad (3)$$

For the preparation of a-phenylbutyronitrile by this method the salt was prepared in the usual way, the quantities of reagents being those previously specified, and was treated, without being separated from the reaction mixture, with ethyl iodide (18 g.), a 7% excess. The procedure and course of the reaction resemble that described in a previous paper[1] for the preparation of a-phenylbutyronitrile from sodium phenylacetonitrile. In the present case, however, the yield of nitrile was much better, being 10 g., or 64.4% of the theoretical yield calculated from the amount of potassium used.

Summary

1. The preparation of potassium phenylacetonitrileis reported.
2. The identity of the salt was established by analysis and by its reactions.
3. Its decomposition by acid into hydrocyanic acid indicates a nitride structure for the salt $[(C_6H_5)HC{=}C{=}N]K$.
4. Its conversion into α-phenylbutyronitrile by treatment with ethyl iodide indicates that the salt also exists in a carbide form (tautomeric with the nitride), $[(C_6H_5)(CN)HC]K$.

CONCENTRATION OF HYDRAZINE HYDRATE SOLUTIONS

BY CHARLES D. HURD AND C. W. BENNETT

RECEIVED AUGUST 3, 1928 PUBLISHED JANUARY 8, 1929

Usually, aqueous solutions of hydrazine contain less than 30% of available hydrazine (40–45% hydrazine hydrate), since this concentration may be realized by refluxing[1] a mixture of water (75 parts), hydrazine sulfate (200 parts) and sodium hydroxide (160 parts), and then distilling. For many purposes such a solution of hydrazine hydrate is satisfactory. When more concentrated solutions are desired, the expedient is usually adopted of starting similarly but with less water, or with a minimum volume of water and considerable alcohol.[2] Such devices are far from satisfactory owing to poor yields.

---

[1] "Organic Chemical Reagents," 3, 40 (1921), University of Illinois Bulletin, Vol. 19, No. 6, Oct. 9, 1921.

[2] Vanino, "Handbuch der Präparativen Chemie," F. Enke, Stuttgart, 1913, Vol. I, p. 114.

In recent years, many substances have been satisfactorily dehydrated by distilling them in the presence of an immiscible liquid. It seemed not unlikely that a solution of hydrazine hydrate might be concentrated by such distillation methods and, indeed, such was found to be the case. The method is extremely simple and any degree of concentration up to about 95% of hydrazine hydrate is attainable. It is necessary merely to add a definite quantity of xylene to the dilute hydrazine hydrate solution in a distilling apparatus and heat it until the xylene has distilled away. The residue in the distilling flask, which contains most of the original hydrazine hydrate in concentrated form, may be distilled to a water-clear liquid if desired. The xylene and water which comprise the original distillate are easily separated. The aqueous portion contains varying amounts of hydrazine, which is readily recoverable; as would be expected, the xylene portion contains almost no hydrazine. Toluene may be used instead of xylene, but it is somewhat less efficient. Benzene effects but slight concentration and, therefore, is not to be recommended. Undoubtedly, other immiscible liquids with vapor pressures comparable to that of xylene would be found equally satisfactory and perhaps some would be preferable.

Some of the results may be briefly summarized. With equal parts (150 g. each) of xylene and a 41.8% solution of hydrazine hydrate, one distillation was found to effect a concentration (in 87% yields) to a hydrazine hydrate solution of about 65% strength. By taking 200 g. of xylene (with 150 g. of 41.8% hydrazine hydrate solution), one distillation brought about a change in concentration, in 64% yield, to a hydrazine hydrate solution of 82.7% strength. The latter boiled at 116–119°. The aqueous distillate which was removed by the xylene in the first experiment weighed 62.5 g. and contained 10% of hydrazine hydrate; in the second case it weighed 85 g. and contained 13% of hydrazine hydrate. Concentrations beyond 83% were effected by continued distillation with xylene, but in no case was it found possible to exceed 95–96% by this method. To obtain the latter concentration from a 33% hydrazine hydrate solution in one operation, 5 parts of the latter was distilled with 13 parts of xylene. The residual material, which represented only 12% of the original hydrazine content, boiled at 118–119° and analyzed for 95.4–95.8% of hydrazine hydrate. Although there was some loss, most of the remaining hydrazine was to be found in the aqueous layer of the distillate.

Metathetic Methods for the Liberation of Hydrazine

To liberate hydrazine from a salt such as hydrazine hydrochloride, two modifications of the double decomposition reaction have been recorded. The more customary of these two utilizes sodium hydroxide in water solution, and the alternative procedure makes use of sodium methylate[3] in methanol solution: $NaOCH_3 + N_2H_5Cl \longrightarrow N_2H_4 + CH_3OH + NaCl$. Water and methanol, respectively, contaminate the hydrazine in these two processes. With the purpose of producing uncontaminated hydrazine by a simple procedure, the following three metathetic methods were studied.

$NaNH_2 + N_2H_5X$ into $N_2H_4 + NaX + NH_3$
$CaC_2 + 2N_2H_5X$ into $2N_2H_4 + CaX_2 + C_2H_2$
$Al_4C_3 + 12N_2H_5X$ into $12N_2H_4 + 4AlX_3 + 3CH_4$
(In these reactions X represents chloride or sulfate)

Calcium carbide and hydrazine sulfate failed to interact up to 260°, except for a slight decomposition of the sulfate into free sulfur. The dihydrochloride (of hydrazine) made an explosion, and yielded a very small amount of liquid with an acetylene odor. The only apparent reaction between the dihydrochloride and aluminum carbide was the thermal decomposition of the hydrazine salt, apparently into hydrogen chloride, ammonium chloride, nitrogen and hydrogen. The reaction of sodamide with hydrazine salts under widely varying conditions was found to proceed with explosive violence[4] if undiluted. The use of the hydrocarbons "Nujol" (mineral oil) or xylene as reaction media effectually did away with the explosions, but failed to effect anything but trivial yields of hydrazine. It is quite possible that good results would have been obtained in liquid ammonia as solvent, but we did not try this.

Experimental Part

Solutions of hydrazine hydrate were prepared by the method given in Organic Chemical Reagents.' The hydrazine content of the solutions was determined by titration in acid solution (containing bromide ion) at 60° with 0.1 N potassium bromate solution according to the method of Kurtenacker and Wagner.[5] Three drops of a sulfuric acid solution of indigo was used as an indicator, the color changing from blue through green to yellow at the end-point.

Distillation of Hydrazine Hydrate Solution with Benzene

A mixture of 100 cc. of hydrazine hydrate solution (24% N_2H_5OH) and 200 cc. of benzene was distilled in the manner later described under toluene and xylene. The temperature of the vapors was 69–71° throughout the distillation. When all the benzene had distilled, it was found that only 8 cc. of water of 1.66% hydrazine hydrate content was also in the distillate. The residue of hydrazine hydrate solution in the distilling flask was found to contain 27% of hydrazine hydrate by weight. The benzene was also analyzed but was found to contain practically no hydrazine.

Concentration of Hydrazine Hydrate Solutions with Toluene

A mixture of 95 g. of hydrazine hydrate solution containing 24.6% of hydrazine hydrate by weight and 100 cc. of toluene was distilled using a 500-cc. flask fitted with a

[4] Possibly due to sodium hydrazide. See Stollé, *J. prakt. Chem.*, **83,** 200 (1911); Ebler, *Ber.*, 43, 1690 (1910).

[5] Kurtenacker and Wagner, *Z. anorg. Chem.*, 120, 265 (1921).

cork and a Hempel column of beads. The dimensions of the column were 35 mm. diameter and 17 cm. length. Prom the top of this column a side arm led through a condenser into a receiver. Wherever corks were exposed to hydrazine vapors, they were protected by tin foil. In the distillation the mixture came over at 85–86°, and when all of the toluene had distilled, there was about 20 cc. of water with it. This aqueous layer contained 2.7% of hydrazine hydrate by weight, and the aqueous residue contained 30.6%. The analytical data in these typical cases are given for reference.

Anal. 0.4570 g. of substance consumed 10 cc. of $KBrO_3$ solution, 1 cc. of which was equivalent to 0.00125 g. of N_2H_5OH. Pound: 2.7% of hydrazine hydrate. Subs., 0.1242; $KBrO_3$ solution, 30.4 cc. Found: hydrazine hydrate, 30.6.

The toluene was returned to the flask and the distillation repeated. Again 20 cc. of water was obtained with the same percentage of hydrazine hydrate, namely, 2.7%; the residue was nearly 40%. Again repeating this process, the residue of 25 g. analyzed for 61–61.5% of hydrazine hydrate and the aqueous distillate contained 2.8%. Again the toluene was returned and the distillation repeated. This time the mixture distilled at 89–90". In this case, the aqueous distillate weighed 12 g., and analyzed for about 12% hydrazine hydrate content. The residue was 68% hydrazine hydrate. By returning the toluene and redistilling, it was found that the next distillation temperature of the toluene–water–hydrazine mixture was 94–95°. The distillate (aq. layer) contained 47.6% of hydrazine hydrate by weight, and the residue (5 g.) 86% of hydrazine hydrate. This residue, on fractionation, gave 2.25 g. of a clear liquid which boiled at 117–119°. Analysis before and after fractionation gave values which were almost identical.

It will be shown directly that xylene effects this concentration, and even a greater concentration much more readily, and, therefore, is to be recommended in preference to toluene.

Concentration of Hydrazine Hydrate Solutions with Xylene

Preparation of 65% Hydrazine Hydrate.—A mixture of 150 g. of 41.8% hydrazine hydrate solution and 150 g. of xylene was distilled in the same apparatus as with the benzene and toluene. The distillation consumed only fifteen minutes and the vapors came over from 92–100°. All of the xylene and 62.5 g. of water came over. The watery portion of the distillate analyzed 10.5% by weight of hydrazine hydrate, whereas the residual solution in the flask, which weighed 85 g., analyzed for 65.2%. In other words, about 87% of the original hydrazine hydrate still remained in the concentrated residue.

Preparation of 82% and of 95% Hydrazine Hydrate Solutions.—The only difference from the preceding method was that a greater quantity of xylene was employed. These results are listed in Table I.

[a] The 53 g. of material was redistilled without xylene. The first small portion, which was oily, was discarded. Forty-eight g. of a water-clear liquid, b. p. 116–119°,

was obtained. Its hydrazine hydrate content was 82.7%. This concentrated solution represents about two-thirds of the original hydrazine content. Although there is some loss, much of the remaining third is readily recoverable from the first aqueous distillate.

values not determined because the distillation was uninterrupted until a temperature of **107.5**" was reached.

[c] The 15 *g.* of **94.77,** concentration was redistilled without xylene to obtain 10.5 g. of a fraction which boiled at 118–119°, and which analyzed for nearly **96%** of hydrazine hydrate **(95.4** and **95.4% in** two determinations). The yield of **10.5** *g.* of this high concentration represents about **12%** of the quantity of hydrazine hydrate that was in the original dilute solution. Although there is some loss by retention in the column of beads, and some actual loss, much of the remaining hydrazine is to be found in the "aqueous distillate."

Other attempts to obtain higher than 95–96% hydrazine hydrate by this method were not successful.

Summary

Dilute hydrazine hydrate solutions may be readily concentrated to solutions of 65% strength by distilling them with an equal weight of xylene until all the hydrocarbon is removed. By beginning with more xylene and distilling similarly, concentrations up to 95–96%, but apparently not higher, may be effected in a single operation. Toluene is considerably less efficient than xylene, and benzene is quite unsatisfactory for this purpose.

A few experiments are described wherein hydrazine salts are treated in turn with sodamide, calcium carbide and aluminum carbide. The latter two substances fail to react but sodamide reacts violently if undiluted. Hydrocarbons are unsatisfactory diluents for the purpose of preparing anhydrous hydrazine by this method.

BENZOIN-ANIL-ANILIDE AND BENZOIN-PARA-TOLYL PARA-TOLUIDE AS AMMONO BENZOIN ACETALS

BY HAROLD H. STRAIN

RECEIVED AUGUST 22, 1928 PUBLISHED JANUARY 8, 1929

Introduction

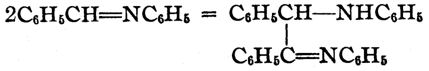
Upon carrying out a series of reactions to support the view that the Schiff's bases are aldehyde-acetals of an ammonia system of compounds, the writer found[1] that both benzylidene-aniline and benzylidene-*p*-toluidine undergo the benzoin condensation reaction, forming benzoin-anil-anilide and benzoin-p-tolyl-toluide, ammono compounds which are analogous to benzoin.[2]

---

[1] Strain, THIS JOURNAL, 50, **2218 (1928).**

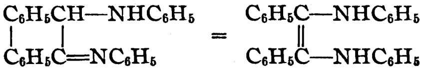
[2] For an explanation of the ammonia system of compounds cf. Franklin, ***Am. Chem.*** **J., 47, 285 (1912);** THIS JOURNAL, **46, 2137 (1924).**

This reaction, as well as the probable structure of these ammono benzoins, is illustrated by the following equation.



$$2C_6H_5CH{=}NC_6H_5 = \begin{array}{l} C_6H_5CH{-}NHC_6H_5 \\ \quad\ \ | \\ C_6H_5C{=}NC_6H_5 \end{array}$$

In addition to being analogous to the aquo benzoins, the ammono benzoins are also analogous to the aquo esters or acetals in that they have organic radicals attached to the nitrogen atoms. In this respect they resemble the ammono aldehyde acetals from which they are prepared and may therefore be regarded as ammono benzoin acetals. Furthermore, the ammono benzoin acetals may also be considered as substituted ammono glycolic aldehydes and should therefore exhibit the familiar enediol tautomerism characteristic of aquo glycolic aldehyde and other α-hydroxy aldehydes, as shown herewith.



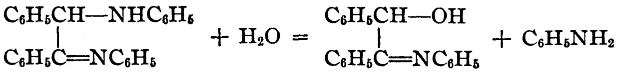
$$\begin{array}{l} C_6H_5CH{-}NHC_6H_5 \\ \quad\ \ | \\ C_6H_5C{=}NC_6H_5 \end{array} = \begin{array}{l} C_6H_5C{-}NHC_6H_5 \\ \quad\ \ \| \\ C_6H_5C{-}NHC_6H_5 \end{array}$$

(keto form) (enediol form)

If the above analogies are real, then the ammono benzoins should undergo all of the reactions characteristic of aquo benzoin and aquo acetals. Upon hydrolysis they should form aquo benzoin and ammono alcohols, while upon ammonolysis they should form ammono benzoin and ammono alcohols. Nitridizing agents should convert them into ammono compounds analogous to the oxidation product of benzoin, that is, benzil. The ammono benzils thus formed should in turn be hydrolyzed to aquo benzil. The ammono benzoins should also be easily converted into indole derivatives, since they represent the intermediate compounds assumed to be formed when indole derivatives are prepared by the action of aniline hydrochloride on benzoin-anilide.[3]

As a matter of fact, all the foregoing predictions have been justified by the experimental work described in this paper.

Upon treatment with water, the ammono benzoins are partially hydrolyzed, forming aquo ammono benzoins and ammono alcohols. Thus benzoin-anil-anilide gives rise to benzoin-anilide and aniline



$$\begin{array}{l} C_6H_5CH{-}NHC_6H_5 \\ \quad\ \ | \\ C_6H_5C{=}NC_6H_5 \end{array} + H_2O = \begin{array}{l} C_6H_5CH{-}OH \\ \quad\ \ | \\ C_6H_5C{=}NC_6H_5 \end{array} + C_6H_5NH_2$$

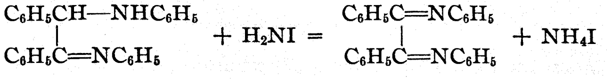
while benzoin-p-tolyl-p-toluide forms benzoin-p-toluide and *p*-toluidine.[4]

---

[3] Bischler and Fireman. Ber., 26, 1336 (1893).

[4] According to Voigt [(a) J. *prakt. Chem.*, (2) 31, 544 (1885), and (b) (2) 34, 2 (1886)] and (c) Japp and Murray [Ber., 26, 2638 (1893)] the structure of benzoin-anilide should be represented by Formula I, below. (d) Lachowicz [*Monatsh.*, 15, 402

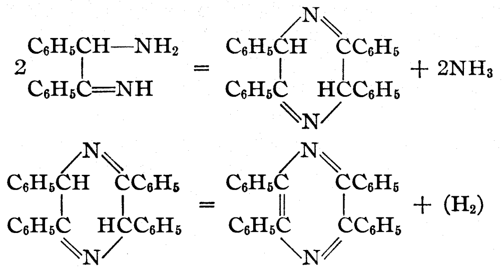
Nitridizing agents convert benzoin-anil-anilide into the corresponding ammono benzil, benzil-dianil, as illustrated by the following equation



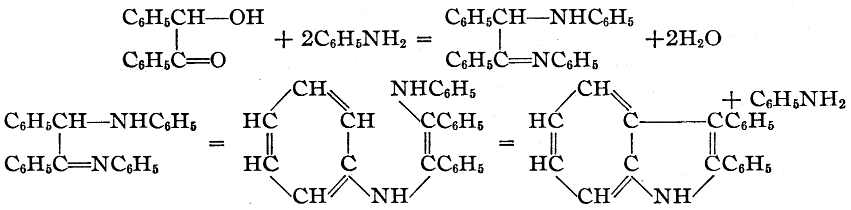
$$\begin{array}{l} C_6H_5CH{-}NHC_6H_5 \\ | \\ C_6H_5C{=}NC_6H_5 \end{array} + H_2NI = \begin{array}{l} C_6H_5C{=}NC_6H_5 \\ | \\ C_6H_5C{=}NC_6H_5 \end{array} + NH_4I$$

while benzoin *p*-tolyl-*p*-toluide is nitridized to benzil-di-*p*-tolyl.

When ammonolyzed, the ammono benzoin acetals form tetraphenylpyrazine in rather poor yields. This reaction probably takes the course illustrated by the following equations, although no free hydrogen has been observed as a reaction product.

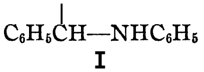


In studying the action of aniline upon benzoin at 200°, Lachowicz[4d] found that, in the presence of hydrogen chloride, benzoin and aniline reacted to form 2,3-diphenylindole.[3,4c,5] In order to explain the reaction Bischler and Fireman proposed the following mechanism, although they were unable to isolate the benzoin-anil-anilide as an intermediate product.



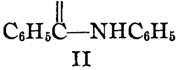
This mechanism has been verified by the writer by the conversion of the

(1894)], on the other hand, thinks that this compound has the structure represented by Formula III.



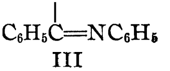
$$\begin{array}{l} C_6H_5C{=}O \\ | \\ C_6H_5CH{-}NHC_6H_5 \end{array}$$

I



$$\begin{array}{l} C_6H_5C{-}OH \\ \| \\ C_6H_5C{-}NHC_6H_5 \end{array}$$

II



$$\begin{array}{l} C_6H_5CH{-}OH \\ | \\ C_6H_5C{=}NC_6H_5 \end{array}$$

III

As a matter of fact, Formulas I and III are related to each other in a manner which may be shown by writing the transition compound, Formula II. Any one of the three formulas written above is derived from the other by the shift of a hydrogen atom analogous to that which takes place in the keto-enol isomerism of acetoacetic ester. However, no evidence is at hand to show that the stable form of the compound may be represented by any particular one of the above formulas.

[5] Japp and Murray, *J. Chem. Soc.*, 65,892 (1894).

ammono benzoins into the corresponding substituted indoles, as illustrated by the last reaction written above.

Experimental

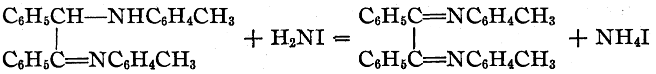
Hydrolysis of the Ammono Benzoins.—Benzoin-anil-anilide was hydrolyzed to the aquo ammono benzoin, benzoin-anilide, when boiled with 80% alcohol containing some hydrochloric acid. The benzoin-anilide obtained by this reaction melts at 99°. It was identical with benzoin-anilide prepared by the writer by the action of aniline on benzoin as described by Voigt,[4b] both compounds having the same crystalline form and the same solubility in alcohol, water and acids. A mixture of the two compounds melted at 99°.

Benzoin-*p*-tolyl-*p*-toluide was hydrolyzed by alcoholic hydrochloric acid to benzoin-*p*-toluide and *p*-toluidine. The mixed aquo ammono benzoin was found to be identical with that prepared by Voigt, both in melting point and solubility in acids and alcohol.[6]

Nitridation of the Ammono Benzoins.—Three-tenths g. of the ammono benzoin was dropped into a solution of 0.6 g. of iodine in liquid ammonia contained in a Faraday tube, which was then sealed and placed in an ice-bath until all of the iodine color had disappeared (about eight hours). At the end of this time, the deep yellow crystals of the benzoin-anil-anilide had completely dissolved, while light yellow crystals were found covering the walls of the tube. These crystals were washed several times and dried in a vacuum. They melted at 144°. The melting point given for benzil-dianil, prepared from benzil and aniline, by Lachowicz[7] is 142" and that by Siegfeld[8] is 141–142°. This difference in melting point must have been due to impurities contained in the previous preparations because both compounds had the same solubility in alcohol, water, ether and benzene. The writer repeated the work of Lachowicz and Siegfeld and found that it was impossible to obtain a compound which looked as pure as that obtained by the nitridation reaction. The melting point of the crystals thus prepared was 142°, but it was not changed when mixed with the crystals melting at 144°. Both compounds were hydrolyzed to benzoin and aniline as described by Lachowicz.

The writer also nitrized (oxidized) benzoin-anil-anilide to the ammono benzil by passing a current of air through a solution of the former in toluene or benzene. However, if the air is saturated with water vapor, a small quantity of benzanilide is formed, proving that the carbon to carbon bond is broken, a reaction which indicates that benzoin-anil-anilide may exist in the enediol form discussed above.

Benzoin-*p*-tolyl-*p*-toluide is only slowly nitridized by ammono hypo-iodous acid, due possibly to the slight solubility of this ammono benzoin in liquid ammonia. On the other hand, the reaction takes place very readily when carried out in benzene solution using air as the de-electronizing agent.



$$\begin{array}{l} C_6H_5CH—NHC_6H_4CH_3 \\ \;| \\ C_6H_5C{=}NC_6H_4CH_3 \end{array} + H_2NI = \begin{array}{l} C_6H_5C{=}NC_6H_4CH_3 \\ \;| \\ C_6H_5C{=}NC_6H_4CH_3 \end{array} + NH_4I$$

The benzil-di-*p*-tolyl obtained by the above reaction melted at 162° and was identical in every respect with that prepared by Lachowicz.[9]

Ammonolysis of the Ammono Benzoins.—Upon heating benzoin-anil-anilide or benzoin-*p*-tolyl-*p*-toluide with liquid ammonia in a sealed tube at 130° for ten hours, the ammono benzoins were found to dissolve while a few colorless, needle-shaped crys-

---

[6] Voigt, ref. 4 b, p. 15.

[7] Lachowicz, *Monatsh.*, 14, 283 (1893).

[8] Siegfeld, Ber., 25, 2601 (1892).

[9] Lachowicz, ref. 7, p. 289.

tals were formed. These crystals proved to be tetraphenylpyrazine. They dissolve in concentrated sulfuric acid, forming a deep red solution from which the pyrazine compound could be recrystallized upon dilution with water.

The melting point of the tetraphenylpyrazine obtained from the ammono benzoins was 252°, while that given by earlier investigators,[10] who used other methods of preparation, is 245–246°. The writer then repeated the work of Japp and Wilson and found that it was possible to prepare tetraphenylpyrazine by the action of ammonium acetate on benzoin, which melted at 252°. The crystals thus obtained showed no depression in melting point when mixed with those obtained by the ammonolysis reaction.

The liquid ammonia decanted from the crystals of tetraphenylpyrazine contained free aniline, or p-toluidine. No other pure compounds could be separated although the yield of tetraphenylpyrazine amounted to only a few per cent. of the weight of the ammono benzoins used in the reaction.

Formation of Substituted Indoles.—Benzoin-anil-anilide does not break down when heated to its boiling point. However, if it is dissolved in benzene or toluene which is saturated with dry hydrogen chloride and the resulting solution heated in a sealed tube for two hours at 180–200°, the reaction products are found to be 2,3-diphenylindole and aniline hydrochloride The latter is insoluble in the hydrogen chloride solution while the former is very soluble so that the two are easily separated. The yield is almost quantitative.

Benzoin-*p*-tolyl-*p*-toluide is converted into 2,3-diphenyl-5-methylindole and *p*-toluidine hydrochloride when heated with benzene and hydrogen chloride. One-half g. of the ammono benzoin formed 0.3 g. of the indole derivative and 0.13 g. of p-toluidine hydrochloride. The 2,3-diphenyl-5-methylindole melted at the recorded temperature and formed a chocolate brown picrate melting at 154°, as described by Bischler and Fireman.[11]

The experiments described in this paper were carried out under the direction of Dr. E. C. Franklin, to whom the writer is greatly indebted for the many helpful suggestions received during the course of the work.

Summary

Benzoin-anil-anilide and benzoin-*p*-tolyl-*p*-toluide are ammono benzoin acetals. As ammono acetals they can be ammonolyzed and hydrolyzed. As ammono benzoins they can be nitridized to ammono benzils.

The ammono benzoins are converted into indole derivatives by hydrogen chloride.

The structure of benzoin-anilide and the ammono benzoins has been discussed.

[COMMUNICATION NO. 367 FROM THE KODAK RESEARCH LABORATORIES]

THE ACTION OF FATTY ACIDS ON CELLULOSE[1]

BY C. J. MALM AND H. T. CLARKE

RECEIVED AUGUST 27, 1928 PUBLISHED JANUARY 8, 1929

When cellulose is heated with acetic acid, no obvious change in the external appearance of the fibers takes place, but esterification occurs and the resulting product contains combined acetyl. While an analogous action has been observed with anhydrous formic acid,[2] none appears to have been recorded in the cases of its homologs. We have found esterification to take place on boiling cellulose not only with acetic acid, but with the higher members of the series up to heptylic. The rates of esterification in these cases are lower than with acetic acid, apparently decreasing with rise in molecular weight.

The esterification of native cellulose fibers in this way tends to a limit expressed by the formula $C_{24}H_{39}O_{20}(COR)$, which in the case of acetic acid and propionic acid is reached after about one hundred hours of boiling under atmospheric pressure. The same result is reached in a shorter time by heating to a higher temperature, either under pressure or in the superheated vapor of the acid. On continuing the action for a prolonged time after this point is reached, esterification ceases, or occurs to only a very slight extent and very slowly (an effect which we incline to attribute to incipient decomposition of the cellulose under the drastic conditions of temperature). This approximate limit is observed with all forms of native cellulose and appears to be independent of the state of aggregation (indicated by the cuprammonium viscosity of the starting material).

When, on the other hand, the native cellulose is replaced by hydrated cellulose, such as rayon prepared from viscose, from cuprammonium solutions or by denitration of nitrocellulose, esterification tends toward a limit expressed by the formula $C_6H_9O_5(COR)$. The same is observed for mercerized cellulose and for cellulose obtained by saponification of precipitated cellulose acetate.

From these observations it must be concluded that, firstly, in native cellulose one hydroxyl group out of every twelve is chemically different from the rest, being capable of esterification without the intervention of acid anhydrides or of catalysts. The fact that one hydroxyl group out of twelve displays distinctive chemical properties is, in our opinion, an argument for regarding native cellulose as a multiple of the unit $C_{24}H_{40}O_{20}$.

---

[1] The results here described form the subjects of U. S. Patents 1,668,944 and 1,668,945 of 1928 and of pending applications.

[2] See E. C. Worden and L. Rutstein, *Kunststoffe*, 2, 325 (1912), for a summary of work on this subject.

Secondly, in hydrated cellulose four such hydroxyl groups are chemically different from the remaining eight.

The introduction of acyl groups to this limited extent causes no substantial alteration in the general appearance of the cellulose treated, beyond a tendency of the fibers to become weaker and more friable. Apart from the fact that they are hydrolyzed by alkali, the low esters are indistinguishable in chemical and physical properties from cellulose, being insoluble in organic liquids, but soluble in Schweitzer's reagent, in concentrated sulfuric or phosphoric acid, and in concentrated zinc chloride. The only marked difference which has been observed is concerned with the action of dyes, and is restricted to the more highly esterified products which are obtained from hydrated cellulose. Thus prolonged boiling with acetic acid confers upon rayon fibers the ability to retain basic dyes, such as Fuchsin and Malachite Green, which are quite inactive toward cellulose in its ordinary forms.

Investigation of saponified cellulose acetates indicates that fibers regenerated (by saponification) from cellulose which has been acetylated heterogeneously yield, on boiling with acetic acid, a series of esters, the limiting composition of which appears to be considerably lower in acetyl than that of those obtained from cellulose regenerated from acetates which have been produced in solution. This difference in chemical behavior is in harmony with the observation of Herzog[3] that the same two types of regenerated cellulose differ in their Roentgen spectra, which correspond, respectively, to that of native cellulose and that of hydrated cellulose. Owing, no doubt, to partial hydration of the cellulose during the heterogeneous acetylation, the fibers regenerated from the acetate so prepared take up higher proportions of acetyl than do the fibers of pure native cellulose, but the amounts are much lower than with cellulose regenerated from acetate which has been in solution.

Experimental

The general procedure adopted in the boiling experiments was as follows: the air-dried cellulose was immersed in 20 to 30 times its weight of glacial acetic acid in a round-bottomed pyrex flask, and gently boiled on an air-bath under reflux. The upper end of the condenser was fitted with a calcium chloride tube to prevent the access of atmospheric moisture. After a few hours of boiling, the heating was discontinued and as much of the acid as possible drained from the cellulose in order to remove soluble impurities as well as moisture originally present and formed by reaction. Fresh acid was added and boiling continued. Samples were periodically removed, thoroughly washed with distilled water and dried for analysis.

When operating with the higher acids, the reflux condenser was replaced by a fractionating column by means of which the water could be removed from the mixture. This system was also occasionally applied to the case of acetic acid.

For analysis, 1-g. samples were suspended in 20 cc. of 75% ethyl alcohol and warmed

---

[3] R. O. Herzog, Ber., 60,600 (1927).

for half an hour at 50–60°, then treated with 20.0 cc. of 0.5 *N* aqueous sodium hydroxide. After holding at 50–55° for fifteen minutes, the mixture was allowed to stand, well stoppered, for forty-eight hours at room temperature. The excess alkali was then titrated with 0.5 *N* acid, using phenolphthalein. It was found possible, in the case of the acetic esters, to reduce the time to twenty-four hours, but for the esters of higher acids the full forty-eight hours were found necessary.

The following experiments are typical of a very large number.

Surgical Cotton (High Viscosity) Boiled with Acetic Acid

Time, hours	0	1	2	4	8	16	24	48	72	96
Acetyl, %	0.6	0.8	1.3	2.4	2.9	3.7	4.5	5.5	6.0	6.2

The formula $C_{24}H_{39}O_{20}(COCH_3)$ requires $CH_3CO = 6.2\%$.

Surgical Cotton Boiled with Acetic Acid

Time, hours	24	48	96	200	300	400	500
Acetyl, %	4.6	5.5	6.0	6.6	6.5	6.8	6.4

At the end of 500 hours, the cotton had become considerably disintegrated.

Linters (Medium Viscosity) Boiled with Acetic Acid

Time, hours	24	48	96	144	200	300
Acetyl, %	4.0	4.9	5.1	5.5	6.2	6.4

Linters (Low Viscosity) Boiled with Acetic Acid

Time, hours	24	48	96	200	300
Acetyl, %	4.4	5.0	5.6	6.9	6.8

Commercial Sulfite Pulp Boiled with Acetic Acid

Time, hours	24	48	96	200	300
Acetyl, %	5.1	5.6	6.7	7.6	7.5

This sample of sulfite pulp contained about 90% of a-cellulose and some colored impurities soluble in hot acetic acid.

Surgical Cotton Boiled with Propionic Acid

Time, hours	24	48	96	160	200
Propionyl, %	4.7	5.7	6.4	7.9	8.0

The cotton had become badly degraded after 200 hours. The formula $C_{24}H_{39}O_{20}(COC_2H_5)$ requires $C_2H_5CO = 8.1\%$.

Linters (Medium Viscosity) Boiled with Propionic Acid

Time, hours	24	48	96	144	200
Propionyl, %	6.7	7.4	7.8	8.0	8.2

Linters (Medium Viscosity) Boiled with n-Butyric Acid

Time, hours	24	48	96	144	200
Butyryl, %	5.0	5.9	8.6	10.2	10.9

The formula $C_{24}H_{39}O_{20}(COC_3H_7)$ requires $C_3H_7CO = 9.9\%$.

Surgical cotton was also heated with acetic acid in sealed glass tubes to 140–145°.

Time, hours	8	16	24	48
Acetyl, %	4.6	5.7	7.4	7.5

The last two samples were somewhat degraded.

Surgical cotton was heated to 150–155° in a current of acetic acid vapor.

Time, hours	6	7	20
Acetyl, %	3.8	4.0	6.0

In the following four experiments, commercial samples of artificial silk, prepared by different processes, were employed. They show very clearly that the acetyl content tends to a limit not far removed from the 21.1% required by the formula $C_6H_9O_5(COCH_3)$.

Viscose Rayon Fibers Boiled with Acetic Acid

Time, hours	24	48	96	200	300	400	500
Acetyl, %	10.2	11.6	14.5	20.0	21.2	22.2	22.3

Cuprammonium Rayon Fibers Boiled with Acetic Acid

Time, hours	24	48	96	200	300	400	500	600	700
Acetyl, %	8.2	10.8	14.6	19.0	20.9	22.0	22.2	22.4	22.1

Denitrated Nitrocellulose Rayon Fibers Boiled with Acetic Acid

Time, hours	24	48	96	200	300	400	500
Acetyl, %	9.1	11.0	13.2	18.5	20.6	21.6	22.0

The same effect is found with cellulose after mercerization. Surgical cotton was soaked for twenty-four hours at 20° in 18% and in 40% sodium hydroxide solution, well washed with water, finally with acetic acid and boiled with acetic acid.

Cellulose Mercerized with 18% NaOH Boiled with Acetic Acid

Time, hours	24	48	96	200	300	400	500	600
Acetyl, %	9.3	11.6	13.5	17.5	19.2	20.9	21.6	21.9

Cellulose Mercerized with 40% NaOH Boiled with Acetic Acid

Time, hours	24	48	96	200	300	400	500	600
Acetyl, %	10.2	13.0	14.8	17.6	19.5	22.2	22.6	22.6

A sample of surgical cotton, mercerized with 18% sodium hydroxide for twenty-four hours at 20°, was heated to 150–155' in a current of acetic acid vapor.

Time, hours	6	12
Acetyl, %	6.7	9.5

Cellulose acetate was prepared by a standard method, using acetic anhydride and a mineral acid catalyst in acetic acid. The resulting solution **was** poured into water and the amorphous precipitate thoroughly washed. It contained 44.5% of acetyl. It was then completely saponified by the process (described above) for the determination of acetyl, well washed with water and finally with acetic acid, and boiled with acetic acid.

Time, hours	0	24	48	96	200	300	400	500
Acetyl, %	0.0	10.0	12.0	14.2	17.8	20.2	22.3	22.2

Surgical cotton was acetylated by a standard method employing acetic anhydride and a mineral catalyst in carbon tetrachloride. The resulting product, which preserved the original fibrous structure of the cotton, contained 43.6% of acetyl. It was completely saponified by the same method as above, well washed with water and finally with acetic acid, and boiled with acetic acid.

Time, hours	24	48	96	200
Acetyl, %	6.7	7.6	9.8	10.8

After 300 hours of boiling, the fibers had become completely disintegrated.

Acknowledgment is due to T. F. Murray, Jr., and A. W. Crane for carrying out the analytical work.

Summary

1. Native cellulose is esterified on heating with acetic acid, the reaction coming to an end when the resulting product contains 6–7% of acetyl. This corresponds to the composition $C_{24}H_{39}O_{20}(COCH_3)$. An analogous effect is produced with propionic acid and butyric acid.

2. Hydrated cellulose, prepared by regeneration of cellulose from its nitrate, from viscose, from its solution in Schweitzer's reagent or from dissolved cellulose acetate, yields, on heating with acetic acid, esters having a limiting composition expressed by the formula $C_6H_9O_5(COCH_3)$.

3. Mercerized cellulose behaves in the same way as hydrated cellulose.

4. Cellulose regenerated from cellulose acetate which has preserved its original fibrous structure behaves, in this reaction, more like native cellulose than hydrated cellulose.

5. In view of the definite limit of esterifiability of native cellulose by acids alone, it is concluded that the constitution of cellulose must be expressed as a multiple of the unit $C_{24}H_{40}O_{20}$.

ROCHESTER, NEW YORK

[COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

THE RELATIONSHIP OF THE CONSTITUTION OF CERTAIN ALKYL HALIDES TO THE FORMATION OF NITROPARAFFINS AND ALKYL NITRITES

BY ROBERT B. REYNOLDS AND HOMER ADKINS

RECEIVED AUGUST 30. 1928 PUBLISHED JANUARY 8, 1929

The reaction of alkyl halides with metallic nitrites results in the formation of varying proportions of the isomeric nitroparaffins and alkyl nitrites. It has been shown by various investigators that the ratio of the isomers in the reaction mixture is dependent upon the nature of the particular alkyl radical and metal used.[1]

Despite the very considerable interest in the subject, as shown by the list of publications, there has been no systematic or accurate determination of the proportions of isomers produced in the reaction of any extensive list of reagents. A summary of the previous observations made upon the reactions of various alkyl halides with silver nitrite is given in Table I.

TABLE I

FORMATION OF ALKYL NITRITES AND NITROPARAFFINS FROM VARIOUS ALKYL HALIDES WITH SILVER NITRITE

Alkyl halides	Yield of isomers, %	Nitroparaffin, %	Alkyl nitrite, %	Observers
Methyl iodide	?	90	None	Meyer and Stuber
Methyl iodide	63	52.6	47.4	Ray and Neogi
Ethyl iodide	?	"50"	"50"	Meyer and Stuber
Ethyl iodide	83	52.9	47.1	Ray and Neogi
n-Propyl iodide	?	Mainly	?	Meyer and Rilliet
*Iso*propyl iodide	80.7	44.1	55.9	Ray and Neogi
Allyl iodide	Poor	?	?	Meyer and Chojnacki
Allyl bromide	34	Mostly	Small	Schiff
Allyl bromide	?	Mostly	Small	Brackebusch
n-Butyl iodide	?	53	?	Züblin
Isobutyl iodide	?	"50"	"50"	Demole
Sec.-butyl iodide	58	?	?	Meyer and Locher
Tert.-butyl iodide	?	Small	Mainly	Tscherniak
Iso-amyl iodide	34.7	79.5	20.5	Ray and Neogi

The present investigation was undertaken in order to ascertain the facts with regard to the proportion of isomers formed from various alkyl halides and silver nitrite, in the hope that ultimately some light would

be shed upon the relationship between the constitution of the reactants and the relative rates of the simultaneous reactions.

Preparation of **Alkyl Halides.**—*n*-Propyl, isopropyl, n-butyl and *iso*butyl iodides were prepared through the reaction of the corresponding alcohol with a mixture of red and white phosphorus and iodine as described by Adams, Kamm and Marvel.[2] It was found that a better product was obtained in the case of *sec.*-butyl iodide if the older method of adding iodine to red phosphorus contained in the alcohol was used. The method of Norris[3] was used for the preparation of *tert.*-butyl iodide and that of Freunder and Damond[4] for the preparation of cyclohexyl iodide. The sodium bromide method[5] was used for the preparation of n-propyl and n-butyl bromide. The method of Norris[6] was used for the preparation of *sec.*-propyl bromide. *Iso*butyl, *sec.*-butyl, *tert.*-butyl, iso-amyl, n-heptyl and *sec.*-octyl bromides were prepared through the reaction of the corresponding alcohol with phosphorus tribromide. The latter was prepared by the method of Schorlemmer.[7] In the preparation of the alkyl halide the tribromide was allowed to drop slowly into the alcohol held in an ice-bath. The reaction mixture was allowed to stand for an hour or so after the addition of the last of the tribromide and then gently warmed. The halide was then separated, washed with water (then with sulfuric acid in the case of isobutyl bromide) then with a 10% solution of sodium carbonate and repeatedly with water. The product was dried over calcium chloride and fractionated. The yields were from 80 to 85% of the theoretical. Benzyl bromide was prepared through the reaction of the alcohol with constant boiling hydrobromic acid in the molecular ratio of 1:3. The yield was 92%. Allyl and β-phenylethyl bromide were obtained from the Eastman Kodak Company.

Reaction of **Silver Nitrite with Various Alkyl Halides.**—The reaction of an alkyl halide with silver nitrite was in general carried out as by Victor Meyer except that the silver nitrite was not mixed with sand. The desired amount of silver nitrite was placed in a round-bottomed flask which was connected by a ground-glass joint to a dropping funnel and a spiral condenser. The alkyl halide was then slowly dropped onto the nitrite, the flask being cooled in an ice–salt mixture. If the reaction was too rapid, more or less decomposition took place with the evolution of oxides of nitrogen. The reaction mixture was allowed to stand for two or three hours in the ice-bath after the addition of the last of the alkyl halide. The mixture was then gently refluxed in a water or oil-bath for four or five hours. The mixture of alkyl nitrite and nitroparaffin was removed from the reaction mixture by distillation, first at atmospheric and then under reduced pressure. If the distillate showed a test for a halide (as it usually did), the mixture was refluxed with a further quantity of silver nitrite. The distillate from this second treatment with silver nitrite was analyzed for nitrogen by the Dumas method. If the result of this analysis indicated that the distillate was a pure mixture of the isomeric alkyl nitrite and nitroparaffin, the mixture was analyzed as described below for the percentage of nitroparaffin.

In the case of one of each of the two preparations from n-butyl iodide, n-propyl and n-heptyl bromide, the method was changed in that the silver nitrite was slowly added

(two to three hours) with shaking to the alkyl halide. This modification in the procedure had no effect upon the yield or proportion of the isomers formed. This procedure was used in both of the preparations for *sec.*-octyl bromide, *tert.*-butyl bromide and allyl bromide. In the case of the first of these the reaction mixture was not refluxed but merely heated to 120–125° for two or three hours. *Tert.*-butyl bromide at first reacted rather slowly with silver nitrite but after a little had reacted the reaction became so vigorous that ten hours was consumed in adding 60 g. of silver nitrite. Allyl bromide was so reactive that it was necessary to add the 35 g. of silver nitrite in very small portions during an interval of twenty hours.

The distillates from the reactions of *tert.*-butyl iodide and cyclohexyl iodide with silver nitrite represented yields of less than 50% of the theoretical amount. The determination of nitrogen showed that these distillates were very far from being a mixture of only the nitro compound and the nitrite. Rather considerable amounts of benzaldehyde were formed in the reaction of benzyl and β-phenylethyl bromides. Attempts to purify the mixture of isomers from the benzaldehyde were unsuccessful. The reaction products of these four alkyl halides therefore were not analyzed for nitroparaffins.

Analysis of Reaction Mixtures.—All previous investigators have attempted to determine the proportion of the isomers in the reaction product by fractional distillation, but in this case a more accurate method was desired. Various methods were rather thoroughly examined and discarded for one reason or another before an accurate but laborious method of analysis was adopted. Attempts were made to saponify the ester and determine the nitrous acid through its reaction with urea to form carbon dioxide and nitrogen. Attempts were also made to titrate the nitrous acid in the presence of the nitroparaffin. Attempts also were made to determine the nitrous acid iodometrically, but all of these methods failed to give accurate results when used for the analysis of mixtures.

The method finally adopted for the analysis involved the addition of an *alcoholic* solution of sodium hydroxide to a weighed sample of a mixture of isomers. The salt of the nitro compound was thereby formed and the alkyl nitrite saponified. The solution was then evaporated and the residue, consisting of the sodium salt of the nitro compound and sodium nitrite,[8] analyzed by a wet combustion method for carbon. From these data it is possible to calculate the percentage of nitro compound in the mixture of isomers.

The apparatus used for the analysis was arranged as follows. [illegible] supply of pure oxygen was led into the top of a 125-cc. dropping funnel whose stem passed through a ground-glass joint to the bottom of a 300-cc. Kjeldahl type of flask. A tube led from the top of this flask through a spiral condenser to a U-tube filled with pumice and chromic anhydride. The products of combustion then passed through two U-tubes containing glass wool plugs saturated with anhydrous sulfuric acid and a layer of acid partially filling the space at the bottom of the U. The gases then passed into a combustion tube supported in a gas furnace. Copper oxide was placed for a length of 5 inches in

---

[8] White and Holben, *Ind.* Eng. *Chem.*, **17**, 83 (1925); Desgrez and Venario, *Compt. rend.*, **180**, 886 (1925).

the center of the tube, while reduced copper spirals were placed on each side. After leaving the combustion furnace, the gases passed through two sulfuric acid drying tubes and then into a Geissler potash bulb properly provided with guard tubes containing soda lime and calcium chloride.

The procedure for the analysis of the mixture of isomers was as follows. A sample of from 0.15 to 0.5 g. was weighed into previously weighed, thin-walled glass vials and immediately sealed off. The vial was placed in the combustion flask and 10 cc. of a 0.1 *N* alcoholic solution of carbonate-free sodium hydroxide added. (The latter was prepared from absolute alcohol and sodium hydroxide.) The vial was broken and the mixture allowed to stand for a few minutes. The volatile material was then removed by distillation from a bath, first at atmospheric pressure until all the visible liquid had distilled, and then under a pressure of a few millimeters. It was found necessary to take great care at this point in order to prevent spattering. The temperature was finally raised to 135–140° during three or four hours. In the case of the heptyl and octyl compounds the temperature was raised to 180° for an hour or two and then maintained at 155° overnight.

After the volatile material was thus expelled, the combustion flask was attached to the rest of the combustion apparatus. Ten to 15 cc. of a chromic acid solution (100 g. of chromic anhydride in 200 cc. of water) was then added under a slight pressure of oxygen followed by 100 cc. of sulfuric acid which had been previously boiled for two hours. Fifteen to 20 cc. of the acid was allowed to remain in the dropping funnel during the combustion. The combustion flask was slowly heated with a Bunsen burner so that there was a steady flow of gas into the potash bulb. Finally the oxidation mixture was boiled for a few minutes. After the flask had cooled somewhat, the system was swept out with a slow stream of purified oxygen. A correction was applied of 0.0327 g. of carbon dioxide.

That the method gives reasonably accurate results is shown by the results of analyses carried out on pure nitrobutane and mixtures of it with n-butyl nitrite. Representative analyses are given in Table II.

TABLE II

ANALYSES FOR NITROBUTANE IN MIXTURES WITH *n*-BUTYL NITRITE

$C_4H_9NO_2$, present, g.	C_4H_9ONO, present, g.	$C_4H_9NO_2$, found, g.	$C_4H_9NO_2$, present, %	$C_4H_9NO_2$, found, %

The method of analysis just described is not applicable to those nitro compounds in which the nitro group is attached to a tertiary carbon atom. The only compound of this type investigated was 2-nitro-isobutane. Mixtures of this compound with *tert.*-butyl nitrite were analyzed in two ways. The amount of the ester present was determined by hydrolyzing the mixture in the presence of standard acid and also by saponifying in a standard solution of sodium hydroxide. The average of three determinations by each method agreed to within less than a tenth of a per cent. The percentage of nitro compound was calculated by difference.

A summary of the data obtained in this investigation of the iodides and bromides is given in Tables III and IV. The name of the alkyl halide undergoing reaction with silver nitrite is given in Col. 1 of Table III, the boiling range of the alkyl halide in Col. 2 and the weight of alkyl halide used in each preparation in Col. 3. The weight of silver nitrite used is given in Col. 4. In Col. 5 are given the boiling-point ranges of the mixture of isomers. The weights of the mixture of isomers are given in Col. 6 for each of two preparations. The percentages of nitrogen found by Dumas determinations in the mixture of isomers are given in Cols. 7 and 8. The percentages of nitrogen theoretically present in the nitrite and nitro compound concerned are given in Col. 9.

*Iso*butyl	74.9	40.0	77.2	57.8
Sec.-Butyl	70.0	31.9	68.3	30.0
Tert.-butyl	..	..	60.0	48.3
Iso-amyl	..	..	78.2	67.5
n-Heptyl	..	..	94.3	71.0
Sec.-octyl	..	..	82.1	34.3

From three to five combustions were carried out on samples of each of the two preparations for each of the alkyl halides. Combustions on the same preparation never varied more than 1.7% from the average and in the great majority of cases the variation was not more than 0.5%. Combustions on different preparations never varied more than 1.1% from the average and rarely more than 0.7%. The averages of all these data are given in Table IV along with the average (two or more preparations) yield of mixed isomers.

n-Butyl chloride apparently does not react at its boiling point with silver nitrite as do the bromide and iodide. Iso-amyl chloride reacted but not at all completely when it was refluxed with silver nitrite. When 25 g. was heated with 45 g. of silver nitrite in a sealed tube at the boiling point of toluene for twenty-four hours, the product, weighing 22 g., contained 10.1% of chlorine calculated as iso-amyl chloride. The percentage of nitrogen in a mixture of the isomers with this percentage of the alkyl halide would be 10.77%. Actually 10.47 and 10.62% of nitrogen was found by analysis by the Dumas method. The analysis of the mixture showed that the isomers were present in the ratio of 30.1% of the nitro-*iso*pentane to 69.9% of the iso-amyl nitrite. The yield of the mixture of isomers was calculated to be 81.1% of the theoretical after allowance had been made for the unreacted *iso*-amyl chloride. Attempts to secure complete reaction of the iso-amyl chloride were unsuccessful.

Discussion of Results

The experimental results may be considered from several points of view.

I. A Comparison of Alkyl Iodides and Bromides as to the Amounts and the Proportions of Nitro Compound and Nitrite Formed.—A larger percentage of nitro compound was produced from the alkyl bromides than from the alkyl iodides, except in the case of *sec.*-butyl bromide. The percentage of 2-nitrobutane formed from *sec.*-butyl bromide was 1.3% less than that formed from *sec.*-butyl iodide.

The yields of mixtures isolated were from 10 to 17% higher with the bromides than with the iodides, except in the case of *sec.*-butyl bromide. *Sec.*-butyl iodide gave 1.7% higher yields than did *sec.*-butyl bromide.

II. The Relation of the Branching of the Chain as to the Proportion of the Isomers Formed.—The primary halides containing a branched chain did not give as high a proportion of nitro compound as did the straight chain compounds. For example, isobutyl bromide gave 57.9% of the nitro compound while n-butyl bromide gave 77.9% of nitro compound. The effect of the *iso* grouping in lowering the proportion of nitro compound apparently becomes less pronounced as it is further removed from the halogen. Isopentyl bromide gave 67.5% of the nitro compound, a proportion which approaches, although it is distinctly lower than, that for a straight chain bromide.

III. The Relation of the Position of the Halogen to the Proportion of the Isomers Found.—If the halogen in the alkyl halide is on a *sec.*-carbon atom, the proportion of nitro compounds is materially less than it is for the corresponding primary alkyl halide. In the case of the propyl and butyl compounds the proportion of the nitro compounds from the *sec.*-halides is in the vicinity of one-half the percentages in the case of the primary halides. It was rather surprising to find that with a branched chain and with the halogen on a *tert.*-carbon atom the proportion of nitro compound was higher than it was for the corresponding *sec.*-halide. *Tert.*-butyl bromide showed 48.3% of nitro compound as contrasted with 30% for the *sec.*-butyl and 57.9% for the isobutyl. Sidgwick states that tertiary halides gave almost entirely the nitrite and very little of the nitro compound. Tscherniak found that by the interaction of *tert.*-butyl iodide and silver nitrite, very little 2-nitro-isobutane was formed, but a larger percentage of the *tert.*-butyl nitrite was formed, no figures being reported.

IV. The Effect of Lengthening the Chain as to Proportion of the Isomers Formed.—It cannot be stated that there was in general either an increase or a decrease in proportions of nitro compound with increasing molecular weight of the alkyl group. n-Butyl iodide gave 5% lower than n-propyl iodide while n-butyl bromide gave 0.5% higher than the n-propyl bromide. n-Heptyl bromide gave only 6% less than the butyl compound. In the case of the iodides there was no difference between *sec.*-propyl and *sec.*-butyl, while in the case of bromides the percentage of nitro compounds dropped from 40.3 to 30%. Going higher in the secondary series to *sec.*-octyl, there is a slight increase in the proportion of nitro compound. As has been noted above in the case of the iso-compounds, there was a considerable increase in the proportion of nitro compound with increasing molecular weight. Sidgwick[9] states that all halides con-

---

[9] Sidgwick, "The Organic Chemistry of Nitrogen," The Clarendon Press, Oxford, 1910, p. 140.

taining more than 4 carbon atoms give very low yields of the nitro compound.

V. The Effect of **Unsaturation** as to Proportion of the Isomers Formed.—The porportion of nitro compound formed from allyl bromide as compared with that of n-propyl bromide indicates that unsaturation has little or no effect on the relative proportions of nitro compound and alkyl nitrite formed.

VI. Relation between Constitution of the **Alkyl** Halide and Yield **of** the Mixture of Isomers.--The highest yields of the mixed isomers were isolated from the reaction of normal alkyl halides, the yield increasing with lengthening of chain in the case of alkyl bromides. *n*-Butyl iodide gave an 0.8% lower yield than did n-propyl iodide. With the exception of the *sec.*-butyl halides, the *sec.*-alkyl halides gave better yields than did the iso-alkyl halides. *Sec.*-butyl iodide gave a 70% yield and the corresponding bromide a 68.3% yield, while *sec.*-octyl bromide gave an 82% yield. *Sec.*-propyl iodide and isobutyl bromide gave an 82% yield. *Sec.*-propyl iodide and isobutyl iodide gave 71.8 and 74.9% yields, respectively, while the corresponding bromides gave 78.5 and 77.3% yields, respectively. Allyl bromide gave a yield of 74%. A yield of only 60% was obtained from *tert.*-butyl bromide.

VII. Relation between Constitution of **Alkyl** Halides and Rapidity of Reaction.—The reaction was more rapid with the branched chain alkyl halides and with the secondary halides than it was with the straight chain. normal alkyl halides. *Tert.*-butyl bromide was the most active of all the saturated alkyl bromides used. The secondary alkyl bromides were more active than the corresponding iso-alkyl halides. Allyl bromide was the most active of all the bromides used. The alkyl iodides react much more rapidly than do alkyl bromides, but the relative reactivities of the various iodides were about the same as with the bromides.

WI. A Comparison of **iso-Amyl** Chloride and Bromide.—The proportion of nitro compound was much less in the case of the reaction of *iso*-amyl chloride than it was for *iso*-amyl bromide. The chloride reacts less rapidly but the yield of the mixture of isomers is about the same as for the bromide.

IX. Mechanism of Reaction.—There seems to have been no adequate hypothesis advanced to account for the differences in the ratio of alkyl nitrites and nitroparaffin produced by the reaction of different alkyl iodides.[10] (Apparently it has not been previously realized that the nature of the halogen also played an important role in determining the proportion of the

isomers formed.) It seems probable to the authors that the two reactants form an addition compound, as suggested by Nef for the cyanides and isocyanides, although it may well be questioned whether a molecular compound is not formed instead of definite primary valences being set up as postulated by Nef. Each component of this molecular compound, alkyl group, metal and halogen, would then exert its influence in determining the relative rates of the two modes of decomposition whereby nitroparaffin and alkyl nitrite are formed.[11] This hypothesis is vague; it explains nothing and predicts nothing, yet it seems that at least for the present it is not possible to advance a more specific one without going far beyond experimental justification.

Summary

A quantitative study has been made of the amount and proportion of isomeric nitroparaffins and alkyl nitrites simultaneously formed through the reaction of silver nitrite and the following list of alkyl halides: n-propyl, isopropyl, n-butyl, isobutyl and *sec.*-butyl iodides, and n-propyl, isopropyl, n-butyl, isobutyl, *sec.*-butyl, *tert.*-butyl, iso-amyl, n-heptyl, *sec.*-octyl and allyl bromides and iso-amyl chloride.

It was found that a larger proportion of nitro compound was produced from the bromides than from the iodides except in the case of *sec.*-butyl bromide. Iso-amyl bromide gave over twice as large a percentage of the nitro compound as did the iso-amyl chloride. The yield of the isomers isolated was from 10 to 17% higher from the bromides than from the iodides, except in the case of *sec.*-butyl bromide. Primary halides containing a branched chain did not give as high a proportion of nitro compound as did the straight chain compounds. If the halogen in the alkyl halide is on a secondary carbon atom, the amount of formation of the nitro compound is materially less than it is for the corresponding primary or tertiary alkyl halide. It cannot be said that there is in general either an increase or a decrease in proportion of nitro compounds with increasing molecular weight of the alkyl group. The results obtained with allyl bromide indicate that unsaturation has little or no effect on the ratio of isomers formed. The highest yields of the mixed isomers were isolated from the reaction of normal alkyl halides, the yield increasing with lengthening of the chain in the case of the bromides. The order of increasing reactivity of the alkyl halides is allyl, *tert.*-butyl, *sec.*-halides, *iso*-alkyl, and n-alkyls. The iodides are more reactive than the bromides.

Attempts to prepare mixtures of the isomers sufficiently pure for analysis were unsuccessful when *tert.*-butyl iodide, cyclohexyl iodide, benzyl bromide or 2-phenylethyl bromide was used.

THE IDENTIFICATION OF ALKYLBARBITURIC ACIDS

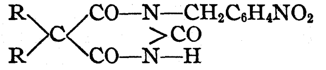
BY EDWARD LYONS AND ARTHUR W. DOX

RECEIVED AUGUST 30, 1928 PUBLISHED JANUARY 8, 1929

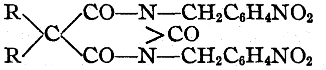
The use of *p*-nitrobenzyl bromide as a reagent for the identification of acids was proposed by Reid.[1] Nearly one hundred acids were tested of which about 90 gave solid esters melting at convenient temperatures. Although Reid had in mind the carboxylic and sulfonic acids, among other acids tested were saccharin, uric and cyanuric acids.[2] Of these the last two gave compounds which melted above 280° or not at all.

Barbituric acid and its derivatives, in which the acidic hydrogens are capable of replacement by sodium, offered a good chance to see if the reagent could find application here. Especially of interest was the possibility of directly substituting an organic radical in the place of the imide hydrogens, the success of which has, to our knowledge, been recorded in only one instance. Fabre[3] showed that veronal (5,5-diethylbarbituric acid) condenses with two molecules of xanthydrol in the presence of acetic acid to form an insoluble 1,3-disubstituted veronal. We have now succeeded in effecting a similar condensation with *p*-nitrobenzyl chloride in the presence of sodium carbonate (or equivalent base). Acids of the veronal type (both imide hydrogens present) readily give compounds containing one or two nitrobenzyl groups. These are easily soluble in alkali if only one imide hydrogen is replaced or insoluble when both hydrogens are substituted by nitrobenzyl groups.

The compounds formed may be represented by the following probable structural formulas: (A) for the mono-substituted derivative, and (B)



(A)



(B)

for the di-substituted derivative (R = alkyl).

Procedure

The procedure is essentially as described in the previous papers. With compounds suspected of having 2 replaceable hydrogens, *i. e.*, those of the veronal type, about 0.5 g. (approx. 1 equivalent) is taken. To this, in a small round-bottomed flask, is added about 0.25 g. of sodium carbonate and 5 cc. of water. The mixture is warmed to dissolve the acid compound and 0.85 g. of *p*-nitrobenzyl chloride, or equivalent amount of bromide (hereafter designated as reagent), and 10 cc. of alcohol are added. These proportions also hold for compounds of the type where only one methylene hydrogen and one N-hydrogen are still replaceable, and are the proportions generally used for

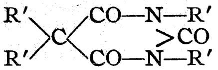
[2] Lyons and Reid, *ibid.*, 39, 1749 (1917).

[3] Fabre, *J. pharm. chim.*, 26, 241 (1922).

totally unknown substances. However, if the compound is suspected of having only 1 replaceable hydrogen the amounts of carbonate and reagent taken are only half of that given above and when there are 3 replaceable hydrogens the amounts of carbonate and reagent are increased by one-half. The mixture thus obtained is refluxed for about an hour. If the p-nitrobenzyl derivative precipitates during the course of the reaction, it is filtered hot on a Büchner funnel. If no precipitate forms, a small sample is cooled. If it still does not precipitate, hot water is added until a cloudiness persists. Cooling then usually gives the desired substance slightly contaminated with some unreacted reagent. The precipitate is washed with water, and more carefully with alcohol and ether and recrystallized as described below.

The various crops of crystals are designated as 1st 1st, 1st 2nd and 2nd 1st, meaning first crystallization first crop and first crystallization second crop, etc. The 2nds were in most instances discarded since high purity rather than quantitative yield was desired. All melting points recorded are uncorrected.

***p*-Nitrobenzyl** Derivatives of Barbituric Acid.—There are four replaceable hydrogens in barbituric acid, making it possible, at least theoretically, to prepare derivatives containing 1, 2, 3 or 4 nitrobenzyl groups. Using 4 equivalents of reagent to one of the acid gave a yellow substance which had no melting point; it charred and burned up. The substance is insoluble in alcohol and ether but is somewhat soluble in chloroform. It is also insoluble in alkali. It probably contains 4 p-nitrobenzyl groups and may be represented by the following structural formula



R' = (—$CH_2C_6H_4NO_2$)

Using less than 4 equivalents of reagent, a mixture of substances was obtained. Besides an insoluble substance having no melting point, a substance soluble in alkali which melted at about 265° was obtained from the mother liquor.

1,3,5,5-Tetra-*p*-nitrobenzylbarbituric Acid.—0.82 g. of barbituric acid dihydrate (1 equivalent) was dissolved in 5 cc. of water containing 0.8 g. of sodium hydroxide (does not dissolve in sodium carbonate solution unless large volume is used). To this were added 10 cc. of alcohol and 3.4 g. (4 equivalents) of reagent. The mixture was refluxed for one hour. It was cooled and the insoluble lemon yellow precipitate was filtered, washed with water, alcohol and ether. The weight was 2 g. It charred when heated. From the mother liquor, on concentration, only some reagent was obtained.

Below are given in tabular form all data relating to the preparation of the p-nitrobenzyl derivatives of barbituric acid and 15 of its alkyl derivatives, and the analyses of several such compounds.

Anal. 3,5-Di-*p*-nitrobenzyl-1-methyl-5-hexylbarbituric acid. Subs., 0.1618: 13.10 cc. of 0.1 N acid. Calcd. for $C_{25}H_{28}O_7N_4$: N, 11.30. Found: N, 11.39.

Summary

p-Nitrobenzyl chloride is a useful reagent for the identification of alkyl barbituric acids. It reacts with these acids, in the presence of sodium carbonate, to form crystalline substitution products with definite melting points. It reacts not only with the imide hydrogens but also with the methylene hydrogens to give completely substituted derivatives.

FACTORS INVOLVED IN THE PREPARATION OF MERCURY DI-ISOBUTYL BY THE REACTION OF FRANKLAND AND DUPPA

BY HARRY F. LEWIS AND EUNICE CHAMBERLIN

RECEIVED SEPTEMBER 11, 1928 PUBLISHED JANUARY 8, 1929

In connection with an investigation involving the preparation of the sodium alkyls, it became necessary to make a large quantity of mercury di-isobutyl.[1] The mercury dialkyls have been known since the time of Frankland and Duppa,[2] who prepared mercury dimethyl and mercury diethyl by the action of dilute sodium amalgam on the alkyl iodide in the presence of ethyl acetate. The preparation of mercury di-isobutyl by this reaction has been studied in some detail and the results are given in this paper.

Other dialkyls prepared by the same reaction include the di-*iso*butyl,[3] the di-octyl,[4] the di-*n*-butyl,[5] and the dipropyl and di-isopropyl derivatives.[6] More recently, Marvel and Gould[7] have prepared the methyl, ethyl, n-propyl, isopropyl and n-butyl mercury di-alkyls through the use of the Grignard reagent with the mercuric halide, and Marvel and Calvery[8] the di-*sec.*-butyl, di-*sec.*-octyl, di-*tert.*-butyl and di-*tert.*-amyl derivatives.

Discussion of Experimental Work

In developing the best conditions for the preparation of mercury di-isobutyl by the Frankland and Duppa reaction, a number of variables

---

[1] It is needless to add that mercury di-isobutyl is extremely poisonous. The compound is volatile and ill effects are not noticed at the time. Symptoms of poisoning include severe headaches, disorder of the digestive tract and a sensitivity both toward the odor and taste of the compound in the atmosphere of the laboratory. Continued exposure to the action of the mercury alkyls may result in a degeneration of the central nervous system and brain.

were studied. These include the influence of time of reaction and temperature, relative concentrations of alkyl halide, amalgam and ethyl acetate, the replacement of iodide by bromide and of ethyl acetate by other esters and other compounds containing the carbonyl group.

Standard Procedure

The standard procedure developed as best for the preparation of mercury di-isobutyl is as follows.

A 2-liter round-bottomed flask is set up in an ice-bath and equipped with a 150-cc. dropping funnel, thermometer, reflux condenser and mechanical stirrer. The non-condensable gases are passed through cold concentrated sulfuric acid and then through a spiral condenser at –10°. In the flask are placed 0.294 mole (31 cc.) of isobutyl iodide and 0.147 mole (14.3 cc.) of ethyl acetate. When the mixture cools to the temperature of the ice-bath, a 0.25% sodium amalgam made by adding 0.591 mole (13.6 g.) of sodium to 27.2 moles (5440 g. or 400 cc.) of mercury is run in at such a rate that the temperature of the mixture does not go above 15°. The amalgam in the dropping funnel is protected from moisture in the air by means of a calcium chloride tube.

When the amalgam is added (this takes about forty-five minutes), the flask is disconnected, a layer of ether added and the excess sodium in the amalgam destroyed by the addition of water. The layers are separated in a thick-walled separatory funnel, the ether layer is dried with calcium chloride and fractionally distilled. Mercury di-isobutyl is collected between 202 and 206°.

Variables

Time.—The desired reaction appears to proceed rapidly and is complete as soon as the last of the amalgam has been added. Under the standard conditions a yield of 56.5% of mercury di-isobutyl is obtained. Refluxing the mixture until the total reaction time is two hours does not increase this yield.

Temperature.—Low temperatures favor the formation of the mercury di-isobutyl to a slight extent. With temperatures between 0–5° the yield is 56.5%, between 15–20°, 49% and at the reflux temperature (75–85°) it falls off to 45%.

Molecular Ratio of Reagents

Sodium.—A variation in quantity of sodium, the other factors being kept constant, is permissible to a certain degree. In the standard procedure, two moles of sodium to one of isobutyl iodide are used. Doubling the quantity of sodium to increase the ratio to 4:1 brings the yield down from 56.5 to 50.7%. When the ratio is decreased from 2:1 to 1.1:1, the yield is 48.7%. This is about the lowest ratio to give good results and indicates that a molar concentration of 1:1 moles of sodium may be used when the concentration of the amalgam is approximately 0.14% by weight.

Molar Ratio of Mercury.—Considerable decrease in yield is noted when the volume of mercury is doubled while the weight of sodium is constant. When 800 cc. of mercury is amalgamated with the standard amount of sodium, the weight concentration of the amalgam becomes 0.125%; this amalgam gives but 38.3% of mercury di-isobutyl.

Nature and Amount of Catalyst.—A half mole of ethyl acetate referred to the iodide (ratio 1:2) gives the optimum yield of 56.5%. A molar ratio of 1:1 gives but 48.7%; on the other hand, a ratio of 1:10 (cf. Tiffeneau, ref. 5) forms but small quantities of the desired product.

In the absence of ethyl acetate, mercury di-*iso*butyl is not formed.

A 1:1 ratio of ethyl butyrate with isobutyl iodide gives a 45% yield, while the i:2 ratio forms but 20.4%.

Catalysts Other than Esters.—Other substances containing the tarbonyl radical may be used as catalysts in place of the esters. Such substances include aldehydes, ketones and anhydrides.

Acetone.—A 1:1 molar ratio of acetone to *iso*butyl iodide gives a 50% yield of mercury di-isobutyl, while a 1:2 ratio forms 42.7%.

Isovaleraldehyde.—*Iso*valeraldehyde will also act as a catalyst in the production of the desired compound but the formation of condensation products interferes with the separation of the mercury di-isobutyl.

Stnaller amounts of mercury di-isobutyl result when the ester is replaced by acetic anhydride.

It would thus appear that the carbonyl radical plays an important part in the formation of mercury di-isobutyl from the action of sodium amalgam on isobutyl iodide. This enlarges the statement found in the literature to the effect that "the reaction takes place only in the presence of an ester like methyl or ethyl acetate."[9]

The function of the carbonyl compound is uncertain. In many cases it is apparently used in the reaction and may not be entirely recovered.

Use of **Isobutyl** Bromide.—When the iodide is replaced by the bromide and the reaction carried out as usual, either for forty-five minutes or for a much longer period, only traces of mercury di-*iso*butyl are obtained; the bromide in these cases may be recovered unchanged.

It makes very little difference whether the amalgam is added to the mixture of catalyst and iodide or whether the reverse procedure is used. The yield is the same in either case. The standard procedure is preferred since it is easier to stir the mixture when it is added in this order.

In the original method as proposed by Prankland and Duppa, the reagents were all shaken together in a separatory funnel. This is difficult to accomplish when large quantities of amalgam are used. It is also hard to control experimental conditions and so the yields are found to vary.

The principal by-product in the reaction is di-isobutyl formed as the result of the Wurtz reaction. There is no evidence of the formation of isobutane and very little for the presence of isobutene among the reaction

products. A purple color in the sulfuric acid wash bottle suggests that the iodide is being carried over.

Conclusions

1. A convenient method has been described for preparing mercury di-isobutyl by the method of Frankland and Duppa. Yields of 50–55% may be obtained.
2. Other esters may be used in place of ethyl acetate. The discovery has been made that carbonyl compounds other than esters can be used as catalysts in the reaction.
3. The principal by-product is di-isobutyl formed by the Wurtz reaction between sodium and isobutyl iodide.
4. Bromide may not replace iodide under the experimental conditions described.
5. Optimum yields are obtained when the following molar concentrations are used: one mole of isobutyl iodide, two moles of sodium, one half mole of ethyl acetate or one mole of acetone and forty six moles of mercury.

THE DISRUPTION OF THE CORN STARCH GRANULE AND ITS RELATION TO THE CONSTITUENT AMYLOSES[1]

BY T. C. TAYLOR AND C. O. BECKMANN

RECEIVED SEPTEMBER 11, 1928 PUBLISHED JANUARY 8, 1929

In some earlier work in this Laboratory, a method for separating the amyloses in corn starch was devised[1a] and the amount of the insoluble or α-amylose and the soluble or β-amylose determined for corn and other starches. This separation, like all other separations, has as its first step the disruption of the granule in water in order to make available the constituent amyloses in the resulting paste. The completeness of the disruption in this case was gaged by the absence of the characteristic granules under the microscope. To obtain the proper type of paste it was necessary to pre-treat the starch with alcoholic hydrogen chloride and then use an effective swelling agent like ammonium thiocyanate to break open the granules when water was added subsequently.

The primary purpose of this paper is to show that the amount of the amyloses in a given starch, such as that of corn, is not dependent on any specific chemical action of the above reagents but only on their effective-

The work covered in this paper is taken from a part of a dissertation presented by C. O. Beckmann to the Faculty of Pure Science of Columbia University in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[1a] Taylor and Iddles, *Ind. Eng.* Chem., 18,713 (1926).

ness in causing complete rupture of the granule. Other swelling agents or mechanical abrasion give starch pastes from which the amyloses may be separated in the same proportion as found previously, whenever such pastes contain no unbroken granules. It is taken for granted that in all methods hydrolytic decomposition or dextrinization must be avoided.

Proof of correctness of this point of view comes from a detailed study of the constitution of a starch paste as a function of swollen granules and of constituent amyloses after their liberation through rupture of these granules. Discrepancies in the literature with regard to the amount of amyloses can be accounted for and avoidance of these difficulties made possible, it is felt, by the results of the investigation. As will be seen, a combination of microscopic examination, viscosity and amylose determination is used to **fix** the properties of the paste and give the picture we have drawn.

Before proceeding it might be well to set down briefly for purposes of reference two current interpretations of the mechanism of paste formation. It is believed by many[2] that the mechanism of paste formation consists of the imbibing of water by the granule, usually by heating, the swelling of the granule, its bursting, the leaching out of the inner substance and, upon cooling, the setting of this material to a viscous gel.

This gel is generally supposed to consist of two parts, separable because of their different solubility in water, but here is where the difficulty begins, for even with the same starch, for example, potato, the amount of insoluble material is reported as varying from 80% down to 2% (the soluble material by difference).[1a,3]

On the other hand, there are those[4] who apparently regard starch as a single chemical individual which in water becomes soluble to a greater or less extent due to hydration. According to this view a starch paste would consist of an equilibrium mixture of more or less hydrated forms of the one substance. The discrepancies in the ratio of insoluble to soluble portions can be explained as a shifting of the equilibrium point due to the imposed conditions.

That there are at least two fairly well defined constituents of the starch granule has been repeatedly demonstrated and is now generally accepted by most investigators[6] While these amyloses probably do hydrate to a

different degree, the following observations indicate that the explanations for the discrepancies in the ratio of the amyloses, at least in corn starch, come from a consideration of the physical condition of the paste from which they are separated rather than from differences in degree of hydration or the presence of a large number of amyloses mutually transferable one into the other. In this respect our results bear out quantitatively the observations and conclusions of Alsberg on the properties of a starch paste.[6]

In this Laboratory it has always been noticed that when amyloses were separated from a paste of high viscosity the amount of insoluble material (classed as a-amylose) was high and whenever pastes of the same concentration were made that were limpid (low viscosity) the insoluble portion was low. Since under the microscope the highly viscous pastes as well as the separated, insoluble material from them showed large quantities of unbroken granules, it was concluded that the amount of so-called α-amylose so determined was fictitious. Contrariwise, in the limpid pastes as used by Taylor and Iddles,[1a] no characteristic granules can be observed under the microscope and the amount of insoluble material is relatively low (amount of soluble or β-amylose is correspondingly high).

Apparently, high paste viscosity, non-availability of the soluble amylose and swollen granules are definitely interrelated. That this is so is borne out by some quantitative measurements given later. It will be shown that the viscosity of pastes made from separated amyloses in a given concentration is only slightly greater than that of water, while that of pastes of the same concentration made by gelatinization[7] is relatively high.

These observations lead logically to another picture[6] of a starch paste, namely, that in the gelatinization of whole starch by hot water some granules only swell while others rupture. The number swelling and the number rupturing depend on the previous treatment given the raw starch or on treatment of the paste. On this basis the viscosity would be due almost entirely to whole but swollen granules[S] which still contain their quota of constituent amyloses. As will be seen, complete rupturing or even partially complete rupturing of the granules is not easily accomplished."

---

[6] Alsberg, *Ind. Eng. Chem.*, *18,* 190 (1926).

[7] The term "gelatinization" should not be confused with disruption of the starch granule. Frequently the terms are used interchangeably. In the course of this research it was found that, although related, they are by no means the same thing. To differentiate between them, therefore, gelatinization will be defined simply as the swelling of the granules, while disruption will mean the actual breaking up of the granule.

[8] Harrison, *J. Soc. Dyers Colourists*, *27,* 84 (1911).

[9] Pastes made in the usual way by boiling the starch with water either at atmospheric pressure or in an autoclave at 15 pounds above atmospheric (to get the corresponding increased temperature) contain swollen granule.; in large quantities. Long treatment under these conditions causes the granules to swell to such an extent that their index of refraction becomes almost that of water and they can be observed only after staining with iodine or gentian violet.

Experimental Part

Effect of Swelling Agents.—Repetition of the work of Taylor and Iddles[1a] on corn starch but omitting the pre-treatment with alcoholic hydrogen chloride gave a stiff paste, instead of the limpid one they describe, on the addition of ammonium thiocyanate. The acid apparently contributes to the process of rupturing also. Substitution of potassium iodide[10] for the ammonium thiocyanate in the Taylor-Iddles''' method gave the same amount of the amyloses as found by them.

A good grade of alkali-washed corn starch was treated with an alcoholic-hydrochloric acid solution according to the method.''' Sixty grams of this sample was treated with a solution of 46 g. of potassium iodide, 46 g. of water and 37 cc. of 95% alcohol. The starch was added to this solution in small portions with constant stirring and rubbing until a homogeneous suspension was formed. Alcohol was added to precipitate the starch after microscopic observation showed that no more whole granules existed. The precipitated, gelatinous mass was ground in a mortar with portions of alcohol until it became granular. It was then washed repeatedly with hot alcohol to remove the potassium iodide, which gave the starch a slight yellow color. It was found impossible to remove the potassium iodide completely. Refluxing the sample in a Soxhlet extractor with alcohol for seventy-two hours failed to remove it. About 10–14% of potassium iodide was absorbed by the starch. The determinations of p-amylose by ultrafiltration made on these samples were corrected, therefore, for absorbed salt: β-amylose found, 85%.

Other swelling agents such as ammonium nitrate or zinc chloride, although effective, were disregarded either because they could not be removed or corrected for subsequently or else because they had a tendency toward the promotion of amylose hydrolysis. The latter reaction is the one that must be avoided. Even the pre-treatment with alcoholic hydrogen chloride gives some substances that reduce Fehling's solution[8] and causes the liberation of some of the associated fatty acids.[11] The amount of the starch so affected is very small and in the light of the subsequent work may generally be neglected.

Mechanical Rupture of Granules in Paste.—If the viscous paste made by heating 5 g. of dry, untreated corn starch with water in the usual way is shaken[4b] or ground in a pebble mill,[12] it becomes more limpid. This may be interpreted as a breaking of some of the swollen granules. Other and perhaps more strenuous methods ought to bring about rupture of all the granules. Accordingly, a similar paste was passed six times through an homogenizer[13] where at a pressure of 4000 lb. per square inch it was discharged through a small outlet orifice.

[13] A Colony homogenizer used for making emulsions was employed. The authors wish to thank Pease Laboratories, Inc., New York City, for the use of this machine and also Messrs. Knoll and Stone for their assistance.

Under the microscope even on stained samples no characteristic granules could be seen in this paste, but the striations so characteristic of the whole granule were very much in evidence. The insoluble or α-amylose as determined by the electrophoretic method of Taylor and Iddles[1a] was 62.5%, while they report 15%. A comparison of the viscosities of this paste with that of raw starch and of the two amyloses under identical conditions and at the same concentrations (see Table I) shows the homogenized paste to be nearer that of raw starch. Apparently this treatment distorts but does not rupture a large number of the already swollen granules, hence the striations, high viscosity and large amount of insoluble "α-amylose." Of course some of the swollen granules are broken and whatever soluble material (β-amylose) is in solution would come, according to our point of view, from these disintegrated starch particles. Further work corroborates this hypothesis.

Disintegration of Dry Granules by Grinding.—It was evident from the results of the previous attempts that breaking swollen starch granules in a paste is not so easily accomplished. Grinding dry starch with sand and subsequently leaching out the soluble material (β-amylose) has been practiced.[14] Alsberg and Perry[15] report that pastes made from dry wheat starch ground in a pebble mill are less viscous than those from unground starch. Prom these ground samples, moreover, much more soluble material was obtained than from the unground by extraction with water at room temperature. They note also that after grinding in a pebble mill for a certain period there are still grains which like the whole starch are birefringent and show the characteristic black cross under the polarizing microscope.[16]

This method of pre-treatment of corn starch seemed to offer great promise in the present problem for it would eliminate completely the necessity for using chemical swelling agents in making the pastes. Suspicion of possible chemical changes in the amyloses would then be removed and the significance of viscosity measurements made more sure. Therefore a series of experiments was made substituting grinding in a ball mill for the use of swelling or gelatinizing agents in the Taylor-Iddles[1a] method. Comparisons were made of the viscosities of pastes from whole starch, with those from samples after various periods of grinding. These results were correlated with the microscopic appearance and with the amount of β-amylose which could be extracted with cold water from the sample or separated from it by electrophoresis. Later the viscosity of the amyloses themselves which had been separated by the electrophoretic method of Taylor and Iddles[1a] from a paste made from a completely ground sample was determined.[17]

[17] In a strict sense it is incorrect to speak of the viscosity of a starch paste because

The ground samples were prepared finally as follows. Three hundred g. of dry corn starch was put in a four-gallon ball mill with about the same volume of quartz balls averaging about $^3/_4$ inch in diameter. The mill was rotated at 45–55 r.p.m. for the periods of time indicated. Twelve-hundred-g. starch loads were used at first but the load was reduced to 300 g. and the grinding continued. If 300 g. is the initial load birefringence disappears and the value for β-amylose reaches 85% after about 172 hours of grinding.

Soluble β-amylose was determined as follows: 2–3 g. of dry starch is shaken with water in a graduated flask and the volume made up to 500 cc. A small amount of toluene is added to prevent the growth of molds. The insoluble part settles out. When a clear supernatant liquid is obtained, an aliquot portion is removed with a pipet to a weighed evaporating dish almost filled with dry sand. This is put into an oven at 105° and evaporated to constant weight, which usually takes three hours.

After grinding the 1200 g. of starch for 130 hours, microscopic examination showed whole granules in large quantities and extraction gave 51.3% β-amylose. After 225 hours' total grinding, no characteristically shaped granules were apparent but birefringence, as evidenced by black crosses in the polarizing microscope, were still plainly visible. The β-amylose (soluble material by extraction) had risen to 63.1%. To cut down the time of treatment, 300 g. of this starch and the same ball load were ground an additional 325 hours, making the total period of 600 hours. In this sample there were no birefringent granules noticeable and the soluble β-amylose (fatty acid free) was 84.1%.

It is interesting to note that when birefringence disappears the amount of soluble or β-amylose is the same as that found by Taylor and Iddles.[1a] Before that point the granules, although no longer characteristically shaped (due no doubt to the effects of the beating in the mill), still hold in a coherent form from their quota of amyloses.[4b] By an electrophoretic separation about 11% of the a-amylose was found in the paste of the 600 hour sample by Taylor-Iddles.[1a] Continued grinding led to the formation of highly opalescent solutions which contained nearly 2% of silica from abrasion of the balls. While not significant in this connection the effect of long grinding on the insoluble a-amylose is being studied.

TABLE I

RELATION BETWEEN PRE-TREATMENT, AVAILABLE β-AMYLOSE AND VISCOSITY

Pre-treatment of corn starch	β-Amylose, %	Relative viscosity at 35°; 1% paste
(a) None	...	2.09
(b) Alc.-HCl and NH_4CNS according to ref. 1a	85.0	1.05
(c) Orig. ground 130 hours	51.3	1.39
(d) Orig. ground 225 hrs.	63.1	1.32
(e) Orig. ground 600 hrs.	84.1	1.09
(f) β-Amylose from (b) by electrophoresis	100.0	1.07
(g) β-Amylose from (e) by electrophoresis	100.0	1.08

---

of its heterogeneity, but it will be shown that settling has no appreciable effect on the values of viscosity relative to water in the concentration used.

Passing to a study of the viscosities of these pastes the results shown in Table I were obtained.

One-tenth of a gram (for a 1% paste or solution) of dry powdered sample was put into an ordinary test-tube and 10 cc. of distilled water added. The tube was then immersed in a beaker of boiling water. After one and one-half minutes the tubes were removed, shaken for ten seconds and re-immersed. After three minutes this was repeated and at the end of five minutes the tube was removed to a thermostat and allowed to come to temperature at 35°. After having attained the temperature of the thermostat, 5 cc. of the paste was removed to an Ostwald viscometer (of the ordinary type with a capillary 10 cm. long and a time value for water at 35° of about sixty seconds). Five to seven readings were taken on each sample. The time for a complete determination is from twenty to thirty minutes from the time of heating. Settling, which would obviously change the time of flow through the capillary, is negligible, since it can be noticed only after fifteen to twenty hours of standing. Moreover, deviations in a set of readings seem to be entirely independent of time.

Precision of Viscosity Measurements

Each value for relative viscosity is the average of those obtained on at least two samples. Each sample was run through the Ostwald viscometer 5 to 6 times. The average deviation for these 5 to 6 runs was 1–2%. The average deviation between two samples prepared (for viscosity measurements) independently was 3–4%.

This accuracy was not obtainable for relative viscosities above 7 or 8. The average deviation in these cases was about 6–7%.

The temperature at which the viscosities were run was 35 ± 0.05°. The change of viscosity due to temperature over this small range was found to be negligible.

In every case the a-amylose which carried the associated fatty acids is equal to (100 − β). When extraction is used the β- is determined directly but in (b) and (d) it was easier to determine the *a*- directly. In (e) a direct current potential of 1200 volts was used to hasten the migration. This gave a clear, supernatant liquid which contained all of the β-amylose **(g).** A layer of toluene on the surface of the liquid prevented mold formation. Incidentally, a similar sample in water under toluene showed no signs of settling after standing for three months. This illustrates how the application of the direct current potential facilitates separation.

Dry samples of β-amylose were obtained by precipitation, on the addition of alcohol to the clear water solutions. The α-amylose was removed from the bottom of the electrophoretic cell[1a] and partially dehydrated by the addition of alcohol. In both cases, to remove the remains of water and obtain a granular mass, a mixture of benzene and alcohol was added in successive portions with mechanical stirring after each portion, forming the ternary mixture (water–benzene–alcohol), boiled off at 60°. The final treatment leaves the white, amorphous material behind in absolute alcohol, from which it is recovered by filtration and evaporation of the adhering alcohol at room temperature.

It should be noted that only when the viscosity has dropped to almost that of the amyloses themselves does the total β-amylose become available for separation from the paste. Of course the rather slimy, insoluble α-amylose contributes something to the viscosity of more concentrated pastes, but it is present in corn starch only to the amount of 15%. In mixtures of α- and β-amyloses in the proportion in which it exists in corn starch in pastes containing 1% total solids, the viscosity was practically that of β- alone and did not approach that of a heat-gelatinized whole starch of the same concentration. These results support the contention that the viscosity of an ordinary starch paste is due to the undisintegrated granule. More significant for the present purpose, however, is the fact that a paste made from a completely ground starch when subjected to the Taylor-Iddles[1a] method gives the same ratio of amyloses with the same general properties as that obtained from their ammonium thiocyanate treatment.

In these measurements it must be remembered that corn β-amylose has a solubility of 7 g. per 100 cc. at 25° and 10 g. per 100 cc. at 35°. These solutions are perfectly clear, but above the concentrations at the respective temperatures there is cloudiness and settling. This, of course, makes viscosity determinations of little quantitative use in this range. In the following table there are summarized the results of the observation.

TABLE II

VARIATION OF VISCOSITY WITH CONCENTRATION AT 35°

Concn. %	Raw starch	Ground starch (63.1% sol.)	β-amylose (from ground starch)
0.25	1.14	..	...
0.50	1.35	..	...
1.00	2.09	1.31	1.078
2.00	7.24	1.71	1.182
3.00	38.95	2.43	1.277
4.00	paste	3.39	1.396
5.00	too	4.77	1.512
6.00	stiff	6.41	1.667
7.00	..	..	1.807
8.00	..	..	1.986
9.00	..	..	2.117
10.00	..	..	2.308

From the above table it is evident that it takes about ten times as much β-amylose (in solution) as it does gelatinized raw starch to obtain the same viscosity. Because of the insolubility and rapid settling of the *a*-amylose, there is no way by this method of measurement, to tell how much this substance contributes to the viscosity of a partially ruptured paste (as in third column). For comparison in a qualitative way, however, these results are interesting.

Summary and Conclusions

1. It has been shown that the a- to β-amylose ratio in corn starch as determined previously[1a] is not dependent upon the method of treatment.

2. Complete rupture of the starch granule may be accomplished also by grinding. The product of this method yields amyloses of high purity.

3. Additional proof is brought forward that the viscosity of a starch paste is directly connected with the number of swollen granules (gelatinized) in that paste.

4. The structure of starch pastes has been discussed and it has been shown that its characteristic properties in the case of corn are functions more of the physical nature of the starch granules than of the chemical nature of the amyloses.

5. The results indicate that before a separation of the constituent amyloses in corn starch can be made, all of the granules must be ruptured. This is evidenced by a drop in the viscosity of starch pastes. Any attempts at separation before this point result in fictitiously high results in insoluble material. Although a few granules rupture easily, the great bulk do so only with great difficulty when a paste is made in the ordinary way.

STUDIES ON THE REACTIONS RELATING TO CARBOHYDRATES AND POLYSACCHARIDES. XX. PREPARATION, PROPERTIES AND IDENTIFICATION OF GLYCEROL BETA-METHYL ETHER

BY HAROLD HIBBERT, MYRON S. WHELEN[1] AND NEAL M. CARTER[2]

RECEIVED SEPTEMBER 13, 1928 PUBLISHED JANUARY 8, 1929

The important role played by glycerol esters and ethers in animal metabolism, industrial processes and organic research has led various investigators to point out the necessity for a reliable characterization of a series of readily identifiable, simple derivatives of glycerol containing substituents definitely located in the a-, β- and a'-positions.

For reasons defined later in this paper, the glycerol ethers are probably the most suitable for the preparation of such a series. Thus Irvine, Macdonald and Soutar[3] proposed the use of glycerol α,β- and α,α'-dimethyl ethers and a- and 8-monomethyl ethers for the identification of mixed glycerides. Controlled hydrolysis of glycerides followed by methylation and further hydrolysis, with the aid of the above reference types, would serve to identify the configuration of the original glyceride substituents.

The authors desire to express their appreciation of the facilities afforded them in carrying out this work, on the one hand to the Canadian National Research Council for the gift of a Bursary (M. S. W.) and on the other to The Forest-Products Laboratory of Canada and the Canadian Pulp and Paper Association for valuable assistance.

[3] Irvine, Macdonald and Soutar, J. Chem. *Soc.*, 107, 342 (1915).

Later, Gilchrist and Purvis[4] attempted to prepare such a series for the identification of the products obtained by the hydrolysis of methylated glycerol glucosides, but were unable to prepare the α,α′-dimethyl and the β-monomethyl ethers. Of the five possible glycerol methyl ethers, the trimethyl,[5] the α,β-dimethyl,[5] a,α′-dimethyl[6] and α-monomethyl[7,8] have been described.

The recent preparation in this Laboratory[9] of the missing member of this series, glycerol β-methyl ether, is thus of considerable interest as it is believed to be the first preparation of a pure @-ether of glycerol. For purposes of ready identification, three crystalline derivatives of this have been prepared, the properties of which are summarized in the following table. The corresponding derivatives of the isomeric a-methyl ether are added for comparison.

Derivative	Of glycerol a-methyl ether, m. p., °C.	Of glycerol @-methylether, m. p., °C.	Crystallizing medium
Di-*p*-nitrobenzoate.	108	155	Ethyl acetate
Di-phenylcarbamatc.	118–119	102	Benzene-ligroin
p-Nitrobenzylidene acetal......	42; 47	106; 139	Methyl alcohol

The di-benzoates appear to be liquids. In the following table a comparison is given of the properties of the glycerol a- and β-methyl ethers.

	Glycerol a-ether	Glycerol @-ether
Boiling point...................	110–111° (13 mm.)	122–123° (13 mm.)
Refractive index$^{17°}_{D}$..............	1.4463	1.4505
Density$^{17°}_{4°}$.....................	1.1197	1.1306

Both ethers are readily soluble in water and most organic solvents The constants of the a-ether are those found by Irvine and co-workers,[8] while those of the β-ether are the results obtained in the preparation of the β-ether by three different processes in this Laboratory.[9,10]

Various *β-esters* of glycerol have been described in the literature,[11] such as the β-nitrate,[12] β-phosphate,[13] β-margarate,[14] β-palmitate,[15] β-benzo-

ate[16] and others, and many methods have been advanced for the synthesis of mixed glycerides with substituents in various positions for comparison with natural products.[14,17] Recent papers,[18] however, cast considerable doubt on the validity of any method involving the intermediate use of halohydrins, and particularly the α,α'-dichloro- or dibromohydrin utilized in the preparation of most of the above compounds, since the products obtained proved to be not the β-derivative but the corresponding a-isomer, in other words a "group wandering" had occurred.

Thus the failure of Gilchrist and Purvis[5] to obtain α,α'-dimethyl and β-monomethyl ethers of glycerol by methods analogous to those used in preparing the above glycerides and other representatives of the series of ether was attributed by them[4] to a wandering of the halogen or methyl group. Similar wandering of acyl groups has been reported[17b,19] in the interesting investigation carried out by Grün and co-workers.

All of these facts focus attention upon the importance of using glycerol ***ethers*** as reference compounds for the determination of configuration, since a wandering of an alkyl group has not been observed in this connection. The authors believe that the methods used for the preparation of glycerol 0-methyl ether described in this paper are generally applicable for the detection of all β-glycerol ethers and glucosides.

Experimental Part

Preparation of Di-p-nitrobenzoate of Glycerol or-Methyl Ether.—The glycerol a-methyl ether used in this experiment was prepared by two methods: *(a)* hydrolysis of 1,2-*iso*propylidene glycerol 1'-methyl ether;[8] and (b) interaction of glycerol α-chlorohydrin (Kahlbaum) with a methyl alcoholic solution of sodium methylate. Both preparations yielded an identical di-p-nitrobenzoate.

Seven-tenths of a g. of the pure glycerol a-methyl ether was dissolved in 5 g. of dry pyridine and after first heating slightly to start the reaction, 6.5 g. of p-nitrobenzoyl chloride was added in small portions; finally, the whole was heated until the product liquefied. It was then allowed to stand at room temperature for eighteen hours. The pasty mass was well stirred with 250 cc. of $N/10$ sulfuric acid solution at 30° to remove the excess pyridine, washed with dilute sodium bicarbonate, finally with water and dried at 100°. Crystallization from hot toluene first deposited a very small amount of a brownish, amorphous powder, m. p. 188°.[20]

The main product was a definite crystalline compound which on recrystallization from hot toluene separated as yellow needles of m. p. 108"; yield practically theoretical.

Preparation of **Di-*p*-nitrobenzoate** of Glycerol **β-Methyl** Ether.—The glycerol ether used was obtained by the hydrolysis of 1,1′-*p*-nitrobenzylidene glycerol 2-methyl ether, m, p. 106°.[10b] Another sample prepared by hydrolysis of 1,1′-benzylidene glycerol 2-methyl ether yielded an identical di-p-nitrobenzoate.

Six-tenths of a gram of the glycerol ether was treated in an exactly similar manner to that above, using 5 g. of dry pyridine and 6 g. of *p*-nitrobenzoyl chloride. Only one product was obtained, which on recrystallization from hot toluene separated as small clusters of orange needles, m. p. 155"; yield almost quantitative.

Anal. Subs., 0.1799: CO_2, 0.3548; H_2O, 0.0661. Subs., 0.2299: N, 13 cc. at 25" and 756 mm Calcd. for $C_{18}H_{16}O_9N_2$: C, 53.48; H, 3.99; N, 6.93. Found: C, 53 71; H, 4.11; N, 6.74.

Preparation of the Di-phenylcarbamate of Glycerol a-Methyl Ether, C_6H_5NHCOO-$CH_2CH(OCONHC_6H_5)CH_2OCH_3$.—One and two-tenths g. of pure glycerol a-methyl ether, b. p. 110–111° (13 mm.), (obtained from the hydrolysis of 1,2-benzylidene glycerol 1'-methyl ether) was mixed with 2 moles of phenyl isocyanate, warmed in a water-bath at 60° for a short time and then allowed to stand for several days at room temperature. The liquid reaction mixture changed to a glassy mass. On further standing white crystals were deposited and the whole mixture became solid. This was dissolved in warm benzene and recrystallized from a mixture of benzene and ligroin, b. p. 80–90" (equal parts), yielding very fine white needles, m. p. 118–119°.

Anal. Subs., 0.1430: CO_2, 0.3279; H_2O, 0.0737. Calcd. for $C_{18}H_{20}O_5N_2$: C, 6283; H, 5.82. Found: C, 62.53; H, 5.76.

Glycerol a-methyl ether obtained by the hydrolysis of 1,2-*iso*propylidene glycerol 1'-methyl ether, as well as by the action of sodium ethylate on a-monochlorohydrin, yielded the same product with phenyl isocyanate.

Di-phenylcarbamate of Glycerol **β-Methyl** Ether, $C_6H_5NHCOOCH_2CH(OCH_3)$-$CH_2OCONHC_6H_5$.—One g. of pure glycerol β-methyl ether, b. p. 123° (13 mm.), (obtained from the hydrolysis of 1,1′-benzylidene glycerol 2-methyl ether) was treated with the equivalent amount of phenyl isocyanate in a similar manner. This yielded fine, white needles from benzene-ligroin solution, m. p. 102°.

Anal. Subs., 0.1340: CO_2, 0.3072; H_2O, 0.0722. Calcd. for $C_{18}H_{20}O_5N_2$: C, 62.83; H, 5.82. Found: C, 62.52; H, 6.02.

A mixed melting point determination made with approximately equal quantities of these two di-phenylcarbamates gave a melting point of 90°, showing the non-identity of these two substances.

Preparation of the ***p*-Nitrobenzylidene Acetals** of Glycerol ***a*- and** &Methyl Ethers.—This condensation is probably more readily and quickly carried out than that of either of the above two types of derivatives. Full details and an explanation of the existence of the two pairs of melting points are found in a previous paper.[10b] **A** brief description of the method employed, sufficing for a ready recognition of the two glycerol monomethyl ethers, is given below..

One g. of the glycerol methyl ether is heated with 1.5 g. of pure *p*-nitrobenzaldehyde (1:1 molecular proportions) and a small drop of 40% sulfuric acid (as catalyst) for fifteen to twenty minutes at 110–120°, the container being meanwhile connected to a water suction pump giving approximately 15 mm. pressure. The resulting product is dissolved at 20° in 3.5 cc. of methyl alcohol and allowed to cool overnight at 0° or lower.

Glycerol a-methyl ether when thus treated yields a pasty mass which redissolves in the methyl alcohol on warming to room temperature, but which may be obtained in crystalline form by filtering the pasty mass from the solvent at a low temperature and recrystallizing. The product is a mixture of the two isomeric 1,2-*p*-nitrobenzylidene glycerol 1'-methyl ethers. The isomer melting at 47° always tends to crystallize out first in characteristic short, yellowish prisms, while the second isomer (m. p. 42') separates as white nodules on further cooling.

From the *β*-methyl ether, on the other hand, the methyl alcohol deposits a mixture of the two markedly crystalline isomeric 1,1'-*p*-nitrobenzylidene glycerol 2-methyl ethers (m. p. 139 and 106°). Recrystallization usually first deposits the higher-melting isomer as gray-white needles but, depending on the amount of solvent used, the lower-melting isomer may simultaneously crystallize as short, white prisms. Although these may be readily separated and identified, the melting point of the mixture (approximately 90°) serves to differentiate the product from that obtained from glycerol *α*-methyl ether.

Summary

1. The properties of and methods for identifying glycerol 0-monomethyl ether are described.

2. The importance of the product as a "type substance" in organic analyses and syntheses is indicated.

THE REDUCTION OF PHENYL NAPHTHYL KETONES BY THE BINARY SYSTEM MAGNESIUM + MAGNESIUM IODIDE

BY W. E. BACHMANN AND R. V. SHANKLAND[1]

RECEIVED SEPTEMBER 28, 1928 PUBLISHED JANUARY 8, 1929

Aromatic ketones[2] are reduced by magnesium + magnesium iodide to free radicals, ketyls, which associate to pinacolates. Addition of water to the pinacolate gives the pinacol. By this method various classes of ketones have been reduced to pinacols. We have now studied the reaction between the binary system and ketones containing a naphthyl group.

We have found that both phenyl a-naphthyl ketone and phenyl P-naphthyl ketone are reduced to the corresponding ketyl pinacolate systems. During the reduction green and brown colors are engendered in the solution. These colors disappear when the solution is exposed to air and reappear when air is prevented from entering. Water likewise removes the color, with concomitant formation of the pinacol.

The pinacol produced from phenyl a-naphthyl ketone by Mg + MgI_2 is different from the pinacol produced from the same ketone by zinc + acetic acid.[3] However, we found that the latter isomer (I) may be trans-

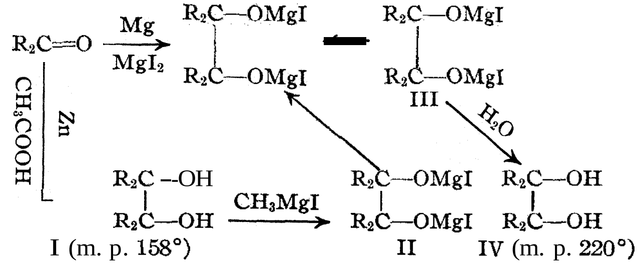
[3] Compare the reduction of benzaldehyde which gives rise to mesohydrobenzoin (m. p. 134") and racemic hydrobenzoin (m. p. 119°).

formed into the former (IV) by converting it to its pinacolate (II) by means of a Grignard reagent. Dissociation into radicals takes place[4] and these radicals become identical with those formed by the addition of Mgf to the C=O group of the ketone, and associate to the new pinacolate (III).



Only a single pinacol was produced when phenyl β-naphthyl ketone was reduced by the two different reducing agents.

The pinacols prepared through the agency of the binary system were rearranged to the corresponding pinacolins, and it was found that the naphthyl group wandered in preference to the phenyl group.

Experimental

Reduction of Phenyl α-Naphthyl Ketone

Reduction of the Ketone by Mg + MgI_2.—A colorless mixture of Mg + MgI_2 was prepared from 4.0 g. of magnesium powder and 12 g. of iodine in 75 cc. of anhydrous ether and 75 cc. of dry benzene. To this mixture 10.0 g. of phenyl α-naphthyl ketone was added and the flask was then stoppered and shaken. Almost instantly the solution became olive-green in color and later the color changed to brown. After half an hour the color was a clear green and reduction was considered complete. On exposure to air the green color was quickly destroyed but when the solution was protected from air the green color reappeared. The solution was filtered from the excess of magnesium and was decomposed with ice and ammonium chloride. Experiments in which a rod of magnesium was employed for reduction showed that the magnesium loss was equivalent to 108% of the calculated value, and that the magnesium hydroxide produced on hydrolysis corresponded to 105%. The organic solution was washed with water and dried over sodium sulfate. Evaporation of the solvents at room temperature left an oily residue. The oil was extracted with warm petroleum ether (40–60°) in order to remove unchanged ketone; however, only traces of ketone were found in this extract. During this treatment the oily mass usually solidified. The crude pinacol (9.2 g.) was recrystallized by dissolving it in the minimum amount of hot chloroform, adding twice that volume of hot alcohol and evaporating the solvents until crystallization began. In this way 4.6 g. of pure diphenyl-di-α-naphthyl pinacol was obtained, which represents a yield of 46%. The pinacol crystallizes in glistening prisms, melting at 220° with decomposition.

Anal. Calcd. for $C_{34}H_{26}O_2$: C, 87.52; H, 5.62. Found: C, 87.32; H, 5.60. Mol. wt., calcd.: 466. Found: 469.

Measurement of the gas evolved when the pinacol was treated with methylmagnesium iodide showed the presence of two hydroxyl groups.

---

[4] Ref. 2, p. 247.

The low yield of pinacol is attributed to difficulty in crystallization. The crude reduction product was shown to be mostly pinacol by rearranging it to the pinacolin. The crude pinacol from 5.0 g. of ketone gave 4.2 g. (87%) of pure pinacolin.

Rearrangement of the Pinacol to the Pinacolin.—The pinacol readily undergoes dehydration when it is warmed with acetic acid containing a small amount of iodine[6] or when it is treated with acetyl chloride. The pinacolin remaining after the solvent had been evaporated was recrystallized from chloroform–alcohol; yield, practically quantitative; m. p. 216–217°. By its reaction with alcoholic potassium hydroxide the pinacolin was proved to be benzoyl-di-a-naphthylphenylmethane $(C_6H_5)(C_{10}H_7)_2CCO(C_6H_5)$.

Anal. Calcd. for $C_{34}H_{24}O$: C, 91.04; H, 5.40. Found: C, 90.94; H, 5.25. Mol. wt., calcd.: 448. Found: 441.

One gram of the pure pinacolin, heated with alcoholic potassium hydroxide for eight hours, gave 0.260 g. (96%) of benzoic acid.

Reduction of the Ketone by Reagents Other than Mg + MgI_2.—The reduction of phenyl α-naphthyl ketone has been studied by a number of investigators.[6] Though many reducing agents were employed, only one method, that of Cohen using zinc and acetic acid, gave a pinacol. No directions, however, were given for carrying out this reduction. We dissolved 10 g. of phenyl a-naphthyl ketone in 175 cc. of cold glacial acetic acid and added 20 g. of zinc dust. After three days the mixture was diluted with water and the insoluble material was filtered off, washed with water and with alcohol. From the insoluble residue the pinacol was extracted by hot benzene. The pinacol obtained after evaporation of the benzene was recrystallized from a mixture of chloroform and alcohol and was obtained in the form of needles of melting point 158°; yield, 4.0 g. Our melting point, analysis and molecular weight were the same as those reported by Cohen for the pinacol. The presence of two hydroxyl groups in the compound was proved by its reaction with methylmagnesium iodide.

We found that the same substance is the product of the action of zinc and ammonium chloride on the ketone.

Rearrangement of the pinacol by warming with acetyl chloride or with acetic acid containing a trace of iodine gave a colorless solid which melted at 232° after it had been recrystallized from chloroformalcohol. The same compound resulted from the action of zinc and acetyl chloride on phenyl α-naphthyl ketone, a method that usually reduces a ketone to the pinacolin.[7]

Anal. Calcd. for $C_{34}H_{24}O$: C, 91.04; H, 5.40. Found: C, 90.88; H, 5.34. Mol. wt., calcd.: 448. Found: 449.

Unlike a pinacolin, the compound is very resistant to hot alcoholic potassium hydroxide. Even after thirty-six hours of boiling with a saturated solution of potassium hydroxide in alcohol, 70% of the compound was recovered unchanged.

Conversion of the Low-Melting Pinacol into the High-Melting Pinacol.—A benzene solution of 2.0 g. of the low-melting pinacol (158°) was added to a filtered ethereal solution of ethylmagnesium iodide. A vigorous evolution of ethane took place and the solution of the pinacolate became dark green in color. The bottle was stoppered and allowed to stand for twenty-four hours at room temperature. The solution was then

decomposed with ice and ammonium chloride in the usual manner. The pinacol was recrystallized and was obtained now in the form of prisms having the melting point 215–217°. This new pinacol was found to be identical with the pinacol produced by reduction of the ketone by Mg + MgI_2. For further verification the pinacol was treated with hot acetic acid containing iodine, whereupon the expected pinacolin of melting point 216° resulted.

Reduction of Phenyl β-Naphthyl Ketone

Diphenyl-di-β-naphthyl Pinacol.—2.32 g. of phenyl-β-naphthyl ketone was reduced by 1.0 g. of magnesium and 3.0 g. of magnesium iodide in 30 cc. of ether–benzene (1:1). During the process of reduction the solution became reddish brown in color. This color was instantly destroyed when the solution came in contact with oxygen of the air, but it was restored when the air was prevented from entering. The loss of magnesium corresponded to 105% of the theoretical value and the magnesium hydroxide produced on hydrolysis was equivalent to 102%. The crude pinacol was recrystallized from chloroform–alcohol and was obtained in the form of needles; m. p. 175°; yield of pure pinacol, 91%.

Anal. Calcd. for $C_{34}H_{26}O_2$: C, 87.52; H, 5.62. Found: C, 86.90; H, 5.68. Mol. wt., calcd.: 466. Found: 461.

An identical pinacol resulted from the reduction of the ketone by zinc and acetic acid.

A quantitative yield of the pinacolin $(C_6H_5)(C_{10}H_7)_2CCO(C_6H_5)$, resulted on dehydration of the pinacol. After being recrystallized from a mixture of benzene and acetic acid, the pinacolin melted at 181–182°.

Anal. Calcd. for $C_{34}H_{24}O$: C, 91.04; H, 5.40. Found: C, 90.83; H, 5.24. Mol. wt., calcd.: 448. Found: 450.

One-half gram of this pinacolin heated with alcoholic potassium hydroxide for six hours gave 0.130 g. (96%) of benzoic acid.

Summary

Both phenyl α-naphthyl ketone and phenyl β-naphthyl ketone are reduced by the binary system, Mg + MgI_2 to ketyls, RR′C—OMgI, which associate to pinacolates, RR′C(OMgI)(IMgO)CRR′. Hydrolysis of the pinacolates gives the corresponding pinacols.

On rearrangement of the pinacols to the pinacolins, the naphthyl group wanders in preference to the phenyl group.

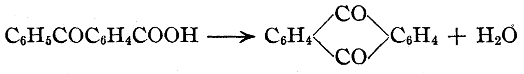
A STUDY OF THE DEHYDRATION OF ORTHO-BENZOYLBENZOIC ACID

BY A. H. GLEASON AND GREGG DOUGHERTY

RECEIVED OCTOBER 1, 1928 PUBLISHED JANUARY 8, 1929

Introduction

It was first noted by Liebermann[1] that anthraquinone could be formed by the elimination of water from o-benzoylbenzoic acid.



$$C_6H_5COC_6H_4COOH \longrightarrow C_6H_4{<}\genfrac{}{}{0pt}{}{CO}{CO}{>}C_6H_4 + H_2O$$

This process has come to have considerable technical importance because it is the principal step in the manufacture of synthetic anthraquinone. In addition, the reaction has certain unusual features which make it interesting from a purely theoretical point of view. For example, it is one of the few condensation reactions involving the use of strong dehydrating reagents such as sulfuric acid in which the yields are very high and side reactions negligible. In fact, under the proper conditions, o-benzoylbenzoic acid is converted apparently quantitatively into anthraquinone. This reaction should lend itself well to kinetic studies which might throw light on the mechanism of such processes in general.

In the synthetic method for producing o-benzoylbenzoic acid from phthalic anhydride and benzene in the presence of aluminum chloride, it is possible, by using substitution products of benzene and the anhydride, to prepare various substituted o-benzoylbenzoic acids which in turn can be condensed to the corresponding anthraquinones. This would seem to be a convenient way, therefore, of ascertaining the influence of different substituents in the benzene ring on this type of reaction. It has been our purpose, first to make a general study of the transformation using the unsubstituted acid, and then to attempt measurements showing the influence of substituents on the rate of reaction. The results of the first investigation are given in this paper.

The Dehydration of o-Benzoylbenzoic Acid under Various Conditions.—It has been found that the acid, when heated alone, yields small amounts of anthraquinone; the reaction temperature is quite high, 220°, and numerous by-products are formed, among them benzophenone.[2] Catalysts such as aluminum chloride, the sulfates of mercury, copper, tin, magnesium and silver and other anhydrous salts which might be expected to accelerate this type of reaction had little or no effect. Thallium chloride, however, had a marked influence on the reaction temperature and, in the

---

[1] Liebermann, *Ber.*, 7, 805 (1874).

[2] Dougherty, THIS JOURNAL, 50, 571 (1928).

presence of traces of this salt, a strong positive test for anthraquinone was obtained at 180°.

It is known that phosphorus pentoxide will cause this condensation,[3] but the yields are not good. With meta- and pyrophosphoric acids the yield of anthraquinone is negligible even with prolonged heating at 100°. The o-benzoylbenzoic acid dissolves very slowly in these acids and hence would make accurate velocity measurements difficult even if the acids were good condensing agents.

Concentrated sulfuric acid proved to be a better condensing agent than the literature implied. That is, most preparation directions for forming anthraquinone from o-benzoylbenzoic acid call for fuming sulfuric acid. It was found that a solution containing ten parts of concentrated sulfuric acid to one of pure o-benzoylbenzoic acid gave a quantitative yield of anthraquinone when heated for two hours at 100°. Even at room temperature the reaction proceeds at a measurable rate with a yield of approximately 4% of the theoretical in one hundred hours. The addition of contact agents such as metallic sulfates to the sulfuric acid reaction mixture had no apparent effect on the rate of condensation. It would seem, from our experiments, that sulfuric acid is almost a specific in this condensation, and while o-benzoylbenzoic acid can be dehydrated by other means, side reactions occur and the yields are never good.

Reaction Velocity Measurements.—When solutions of one part of *o*-benzoylbenzoic acid and ten parts of 96% sulfuric acid were heated for varying lengths of time at a definite temperature, and the resulting amounts of anthraquinone determined (see Experimental Part), the rate of conversion, calculated as a monomolecular reaction, was found to give a good constant over the whole range.

t, hours	6	8	10	12	17	20	22	26	30	36
K at 65°	0.076	0.075	0.078	0.074	0.079	0.074	0.076	0.076	0.078	0.076

t, hours	2	3	4	5	6	7	8	10	12	15
K at 75°	0.242	0.257	0.272	0.255	0.256	0.263	0 256	0.272	0.256	0.272

The velocity constant at 85° was 0.838 and at higher temperatures the reaction was so rapid that accurate measurements could not be made by the method employed. It may be noted that the velocity constant is more than tripled for a 10° rise in temperature. These are rather remarkable results in view of the fact that water is eliminated during the reaction as the sulfuric acid is diluted. Frequently, reactions which proceed in the presence of sulfuric acid are markedly retarded when even small amounts of water are added, as the negative catalytic effect increases exponentially. This is true of the decomposition of oxalic acid by sulfuric acid, and has been explained[4] by the assumption that the

---

[3] Behr *and van* Dorp, *Ber.*, 7,578 (1874).

[4] Bredig *and* Lichty, *J. Phys.* Chem., 11, 225 (1907).

reaction is dependent on the preliminary formation of an addition compound of sulfuric and oxalic acid; the addition of water results in a diminution in the amount of this complex formed.[5]

Since in the oxalic acid decomposition an addition of 0.05% of water, added at 25°, reduces the speed of reaction to one-sixth of that when no water is present, it would appear probable that the o-benzoylbenzoic acid condensation differs fundamentally from reactions of the oxalic acid type.

It might be thought that a monomolecular constant was obtained simply because an excess of the condensing agent was used, but experiments using much smaller ratios of reactant to condensing agent, down to 1:6, gave a good constant (K = 0.238, average deviation 1%, at 75°). When acids (sulfuric) of strength varying from 86–96% were used in the condensation, constants were also obtained. The results from runs with different acid concentrations were compared by plotting the amount of anthraquinone produced in a given time against acid concentration. It may be seen from Curve I, which is a straight line within the experimental error, that the condensing power of the acid solution is directly proportional to the sulfuric acid content. The conclusions to be drawn from these experiments are: the one molecule of water produced during the formation of anthraquinone from o-benzoylbenzoic acid has little or no retarding effect on the reaction velocity and does not cause deviation from the monomolecular order as the reaction proceeds; water added to the sulfuric acid does have a retarding action and in direct proportion to the amount added, but the effect is not as great as in reactions of the oxalic acid type.

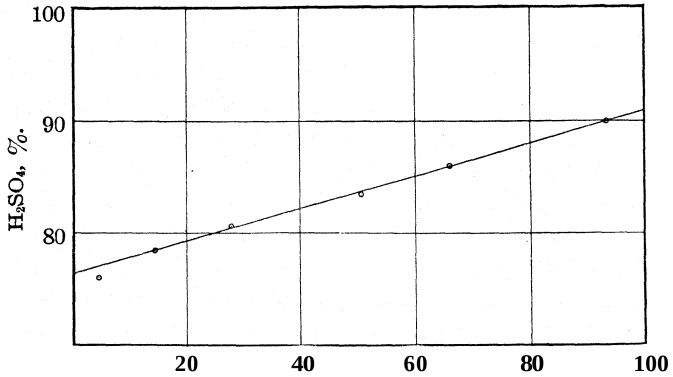


Fig. 1.—Theoretical yield when heated for 4 hours at 75°, %.

Formation of Anthraquinone from Esters and Acyl Derivatives.—It has been found that esters of o-benzoylbenzoic acid, which presumably have the formula $C_6H_5COC_6H_4COOR$, may be condensed by

[5] Taylor, *J. Phys. Chem.*, 27, 322 (1923).

sulfuric acid to anthraquinone, and in the ease of the methyl, ethyl and *iso*propyl compounds the reaction is clean-cut and the yields are nearly as high as with the free o-benzoylbenzoic acid. Here, of course, the alcohols are eliminated instead of water. With esters containing alkyl groups of higher carbon content the reaction is complicated by the formation of unidentified by-products and the yields are not good. This is true of the normal butyl ester, which is a viscous liquid.

When equimolecular quantities of the methyl, ethyl and isopropyl esters are treated with concentrated sulfuric acid under the same conditions, the yields of anthraquinone are almost identical, but are smaller than with the free o-benzoylbenzoic acid: methyl ester 1.25 g., ethyl ester 1.23 g., isopropyl ester 1.28 g. of anthraquinone. Apparently the velocity of the ester reaction is independent of the particular alkyl group present and lower than that of the free acid due to a reaction between the alcohol and sulfuric acid which diminishes the concentration of the latter.

o-Benzoylbenzoic acid may be acylated, and it undoubtedly reacts with acetylating reagents in the enolic form, so that the structure of the acetyl derivative is 
. It was interesting to find out whether this compound could be condensed to anthraquinone and to compare the rate of the reaction with that of the free acid and the esters. The results indicated that the condensation took place with even greater ease than that of the esters and, in fact, is comparable with that of the free acid: acetyl derivative 1.40 g., o-benzoylbenzoic acid, 1.39 g. of anthraquinone. It was previously determined that glacial acetic acid and acetic anhydride did not effect the condensation of o-benzoylbenzoic acid.

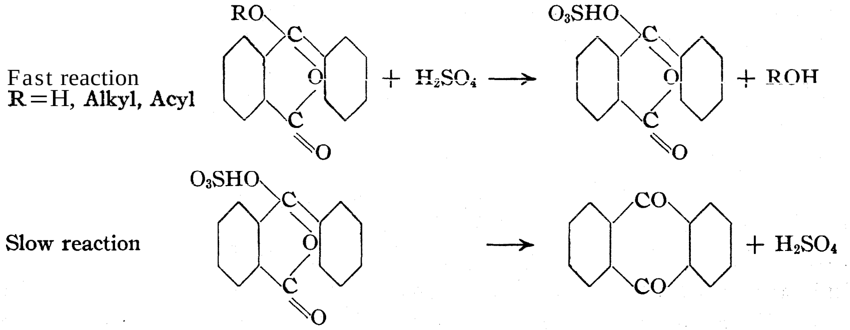
Mechanism of the Reaction.—In order to account for the fact that this condensation, under our experimental conditions, gives a constant for a monomolecular reaction over the whole range, we must either assume an hypothesis in which two opposite effects just balance each other and the results are more or less due to chance, or that the reaction proceeds in such a way that all of the water is eliminated at the start and rapidly as compared to the subsequent reaction which we measure. As regards the first possibility, Francis,[6] from a study of certain ionic reactions, concludes that "the reactivity of a dissolved substance is increased by a change in environment in a direction which will tend to throw it out of solution." We have this condition in the o-benzoylbenzoic acid con-

---

Francis, THIS JOURNAL, 48,662 (1926).

densation: water is eliminated and the solubility of the organic acid is appreciably lowered. On the other hand, the water dilutes the sulfuric acid and diminishes its efficiency as a condensing agent. In order that a monomolecular curve may be obtained, based on the concentration of the o-benzoylbenzoic acid, it is necessary that these two opposing effects be equal. It seems to us unlikely that such an explanation is the true one and we are inclined to believe that our experimental results point to a somewhat less complicated mechanism.

The similarity in the rates of condensation of the three esters indicates that the actual elimination of alcohol is not the reaction which is measured but that the o-benzoylbenzoic acid ester first reacts rapidly with the sulfuric acid and afterwards there is a slow decomposition of the resulting compound. It would seem probable that the free o-benzoylbenzoic acid behaves similarly. The equality of rates when the free acid and the acetyl derivative are condensed points to the same thing and suggests further that the two are in the same tautomeric condition during the reaction, that is, in the enolic form. The steps in the process are indicated by the following equations:



The elimination of water during the fast reaction explains why it has no retarding effect in the process as measured, although when water is actually added to the sulfuric acid beforehand, the rate is lowered. However, the formation of sulfuric acid during the slow reaction would seem to reverse the difficulty since the increased acid concentration should accelerate the reaction. That it does not do so may be explained by the formation of an addition compound of one molecule of sulfuric acid and one of anthraquinone, which prevents the acid eliminated from being effective in the condensation. There is ample evidence for the formation of such addition complexes between concentrated sulfuric acid and organic compounds containing oxygen.[7]

An attempt was made to show directly by the freezing-point method the existence of the addition compound. This was not successful due to

---

[7] Kendall and Carpenter, THIS JOURNAL, 36, **2498** (1914).

the fact that at the high melting points encountered, with even moderate concentrations of anthraquinone, there was decomposition and probably sulfonation. The formation of addition compounds is used frequently to explain reactivity, but in this case there is no appreciable reverse reaction and the only effect of the addition compound is to prevent the eliminated sulfuric acid from functioning as a condensing agent.

Experimental Part

For the qualitative determination of anthraquinone the anthraquinol test was used: heating with zinc dust and dilute sodium hydroxide solution produces a red color. In the preliminary experiments the depth of color was used as a rough estimation of the amount formed.

In determining the anthraquinone quantitatively use was made of the fact that it is insoluble in water and sodium hydroxide solution, while the o-benzoylbenzoic acid is soluble both in hot water and alkali solutions. The reaction mixtures, contained in large test-tubes fitted with rubber stoppers and calcium chloride tubes, were heated in a constant-temperature bath for definite lengths of time. The solutions were poured into cold water, stirred, heated to 80–90° and allowed to settle for five minutes. The more or less clear liquid was decanted off through a small Büchner funnel. To the precipitate in the beaker 2 N sodium hydroxide solution was added to definite alkalinity, the mixture was stirred and warmed and the precipitate collected on the funnel used above. After washing with hot water until the washings gave a neutral reaction with litmus, the anthraquinone was dried on the funnel for four hours at 110°. It was finally carefully removed to a clock glass, dried and weighed to constant weight. The average experimental error was less than 1%.

Summary

Attempts have been made to form anthraquinone by the elimination of water from o-benzoylbenzoic acid by various methods.

The reaction in which-sulfuric acid is used as the condensing agent has been studied, and an explanation of the mechanism of this type of reaction has been offered.

It has been found that the esters and acyl derivatives of *o*-benzoylbenzoic acid form anthraquinone under the same conditions as the free acid.

DIRECT SUBSTITUTION ON THE NITROGEN OF 5,5-DIALKYLBARBITURIC ACIDS

BY ARTHUR W. DOX AND EDWARD G. JONES

RECEIVED OCTOBER 8, 1928 PUBLISHED JANUARY 8, 1929

On account of the high dissociation constant of barbituric acid as compared with that of the 5,5-dialkylbarbituric acids, Wood and Anderson[1] concluded that the unsubstituted barbituric acid exists in solution in the tautomeric enol form representing a migration of hydrogen from the methylene to an adjacent carbonyl. As a further proof of this structure they synthesized the sodium salt of barbituric acid from ureidomalonamide and sodium hydroxide, the reaction, according to their view, consisting in hydrolysis of the amide with formation of a sodium salt, migration of a hydrogen from the methylene to carboxyl and ring closure with loss of water.

If, however, the sodium salt of barbituric acid is actually the enolic form, as postulated by Wood and Anderson, it is rather surprising that alkyl derivatives prepared therefrom are not known to occur in this form. Treatment of sodium barbiturate with alkyl halides yields apparently only derivatives in which alkyl has replaced the methylene hydrogen. Thus, 5-allyl- and 5,5-diallylbarbituric acids may be prepared from barbituric acid and allyl bromide in the presence of sodium acetate.[2] Since barbituric acid is a stronger acid than acetic, it may be assumed that sodium barbiturate is first formed in this reaction. A somewhat more direct reaction is described by Volwiler,[3] where n-butylallylbarbituric acid is prepared from allyl bromide and the sodium salt of *n*-butylbarbituric acid. The less reactive alkyl halides, *e.* g., ethyl bromide, however, give a poor yield of alkylbarbituric acids, and the preparation of such derivatives by direct alkylation has not been developed commercially. All derivatives thus far prepared in this way are identical with the corresponding derivatives prepared by condensation of alkylmalonic esters with urea; that is, the tautomeric alkyl derivatives of barbituric acid are not known.

Further substitution to yield tri- and tetra-alkylbarbituric acids has not hitherto been performed by direct alkylation. Fischer and Dilthey[4] prepared N-methyl- and N-phenyldiethylbarbituric acids by condensation of ethyl diethylmalonate with methylurea and phenylurea, respectively, and tetra-ethylbarbituric acid from diethylmalonyl chloride and

[4] Fischer and Dilthey, Ann., 335, 334 (1904).

sym.-diethylurea. The series of 1,5,5-trialkylbarbituric acids was recently extended by Dox and Hjort[5] and that of 1-aryl-5,5-dialkylbarbituric acids by Hjort and Dox.[6] All of these derivatives were obtained by condensation of the ethyl dialkylmalonate with the appropriate alkyl- or arylurea.

In view of the ease with which the 5,5-dialkylbarbituric acids react with p-nitrobenzyl chloride in the presence of alkali, as shown by Lyons and Dox,[7] to give further substitution on one or both of the imide hydrogens, it seemed probable that other reactive halides might yield analogous products. Here the possibility of tautomeric forms again arises, since the imide groupings are adjacent to carbonyls and the alkali salts of 5,5-dialkylbarbituric acids are believed by some to exist in the enolic form. The question of tautomerism was definitely disposed of in the case of 1-benzyl-5,5-diethylbarbituric acid. This derivative was prepared by both methods, *viz.*, direct benzylation of sodium veronal and condensation of ethyl diethylmalonate with benzylurea. Both products were identical.

Alkylation on the nitrogen apparently does not occur until both methylene hydrogens have been substituted. For example, we treated the sodium salt of isopropylbarbituric acid with the molecular equivalent of benzyl chloride and obtained an isopropylbenzylbarbituric acid identical with that prepared by Dox and Yoder[8] from ethyl isopropylbenzylmalonate and urea. Both products melted at 229°.

The method used in preparing N-substituted derivatives of 5,5-dialkylbarbituric acids consisted simply in dissolving the dialkylbarbituric acid in one equivalent of normal sodium hydroxide and refluxing for several hours with one equivalent of the alkyl halide. The halides used in this work were benzyl chloride and allyl bromide. The product in most cases separated as an oil which became crystalline on standing overnight. Occasionally a by-product insoluble in alkali was obtained which had the properties of a dialkylacetylurea. This is known to result from certain dialkylbarbituric acids when treated with alkali, the reaction consisting in hydrolysis of the pyrimidine ring and loss of carbon dioxide The trisubstituted barbituric acids invariably melted lower than the parent dialkylbarbituric acid. They were purified by recrystallization from dilute alcohol or by acidifying the solution in dilute alkali.

In the following table eight such derivatives are described.

The purification of the trialkylbarbituric acid thus formed involves a fractional crystallization. Even though molecular proportions of the

TABLE I

BARBITURIC ACID DERIVATIVES

N-Benzyl deriv. of	M. p., °C.	Nitrogen, % Calcd.	Nitrogen, % Found
Diethylbarbituric acid	127	10.22	10.19, 10.24
Ethyl iso-amylbarbituric acid	90	8.88	8.96, 8.97
Ethylphenylbarbituric acid	113	8.69	8.48, 8.66
Diallylbarbituric acid	116	9.39	9.29, ...
Allyl *sec.*-butylbarbituric acid	90–91	8.92	9.13, 9.14
N-Allyl deriv. of			
Diethylbarbituric acid	75	12.50	12.66, 12.61
Diallylbarbituric acid	68–69	11.29	11.40, 11.38
Dipropylbarbituric acid	73	11.11	10.90, 10.71

reactants are used, some tetra-alkyl derivative is simultaneously formed and a corresponding amount of the original substance remains unreacted. The former is readily removed by means of its insolubility in dilute alkali, but for the separation of tri- and dialkylbarbituric acids several crystallizations are necessary. In only one case was the tetra-alkyl derivative isolated and identified, *viz.*, diallyldipropylbarbituric acid, which melted at 62–63°; N found, 9.50, calcd., 9.59.

Summary

The sodium salts of 5,5-dialkylbarbituric acids react with such halides as benzyl chloride and allyl bromide to give further substitution on the nitrogen. A trialkyl- or even a tetra-alkylbarbituric acid can thus be obtained. This further substitution results in a marked lowering of the melting point.

NEW BOOKS

The Physics of Crystals. By ABRAM F. JOFFE, Ph.D., D.Sc., D.Eng., LL.D., Director, Roentgen Institute; Director, Physical Technical Institute, Leningrad, Russia. Edited by Leonard B. Loeb, Associate Professor of Physics in the University of California. McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York City, 1928. xi + 198 pp. 61 figs. 15 X 23.5 cm. Price $3.00.

When the reviewer first read the publisher's announcement of this book he was at once prejudiced against it. The story in that announcement of the way in which the author's results had first been treated looked too much like the efforts of a newspaper sob-reporter. After having studied the book (it deserves study, not merely reading), the reviewer's prejudice has been entirely overcome and he has even pasted the publisher's announcement on the flyleaf as a permanent record of some of the difficulties which the author overcame.

The first two chapters give a highly compressed account of the electrical theory of crystal lattices. After these two introductory chapters the author takes up in fifteen chapters the investigations of himself and his staff on the mechanical and electrical properties of crystals. These experiments show such unusual ingenuity and skill that many of them make as fascinating reading as a detective story. He shows that elastic after-effect, and elastic fatigue are properties of polycrystal materials, but are absent in single crystals; he explains clearly what goes on when a crystal is permanently deformed (as in plastic flow of solids); he accounts satisfactorily for the discrepancy between the values of tensile strength as calculated from crystal theory and the values ordinarily found by experiment. He proves that even the crystals of insulating substances like quartz obey Ohm's Law if only polarization is taken into account. It appears that ordinary "pure" individual crystals of insulators have specific conductivities which differ considerably from specimen to specimen, and extreme precautions must be taken in purification to get successive crystals to give identical results. The conductivity increases about 10% per degree centigrade. Strangely enough no increase in conductivity is produced by the presence of water of crystallization. Faraday's laws of electrolysis were checked in solid crystals with an accuracy of 0.1%. The reviewer would interpret Joffe's results on electrolysis by saying that if an ionic crystal is composed of ions of considerably different packing radius, the only one to migrate appreciably in electrolysis at ordinary temperatures is the one with the smaller packing radius. The degree of dissociation in quartz is found (7×10^{14} at 17°) and the order of magnitude of mobility of the ions has been calculated (10^{-6} cm. per sec.). It is hard to think of ionization by collision in solids, but Professor Joffe not only makes it look plausible, but he goes further and discusses the distribution of space charges in crystals. In fact the gap between the electrical properties of gases and solids seems to be pretty well bridged. Dielectric losses are largely explained by Joule's law of heating. The book closes with some interesting speculations on the maximum possible electric field in a dielectric and a statement of the effects to be expected.

The book is worth more than a single edition. That the English of the first edition is as smooth as it is, is evidently due to the efforts of the editor. The reviewer offers the following suggestions, not in the spirit of criticism, but in the hope that they will not only smooth the path of readers of the present edition, but also help in the preparation of a second edition.

1. The bottom of p. 38 should be interpreted in terms of the middle of p. 45.
2. On the fifth line of p. 70, "of" should read "between."
3. On the fifth line of p. 78, "of" should read "with."
4. The thirteenth and fourteenth lines of p. 106 would be more easily understood if the phrase "or cells deprived of positive ions" were in parentheses.

5. The use of "especially true" in the eleventh line of p. 105 is unfortunate.

6. In most places in the book "crystal" means "crystal of rock salt." Unless the reader discovers this, he may interpret some statements as generalizations which appear to apply strictly to sodium chloride, and which apply to other crystals only by inference.

7. The figures would be more readily understood if they had titles. The lack of titles is especially disturbing in Pig. 17 (p. 41) where the reader is left in doubt as to Curve IV until pp. 56 and 58, and where no explanation is given of squares, circles and crosses. Fig. 26 (p. 61) is a plot of log π against log S. The reader must infer from the text what these symbols mean, for they are nowhere explicitly defined. In Fig. 34 (p. 103), no explanation is given of the dots and circles. Apparently they merely serve to distinguish between curves. If so, it would have been easier for the reader if one curve had been full-line and the other dotted.

8. On p. **33** reference is made to an expansion which was said to have been made in a previous chapter in a series in Δr. The ordinary reader would appreciate a more adequate preparation for this statement.

9. Some of the equations are not accompanied by an adequate explanation of symbols. On p. 54, E and α are not defined. Equations 33 and 34 (p. 110) evidently follow the custom of using t for °C. and T for °K., but the fact is not so stated.

10. At the bottom of p. 33, $f_0' Ar$ should read $f' Ar$.

11. In Equation **32** (p. 109), σ^{100} should read σ_0^{100}.

WHEELER P. DAVEY

Organische Chemie. (Organic Chemistry.) By Prof. CARL OPPENHEIMER, Dr. Phil. et Med. (Berlin). Second, revised edition. Georg Thieme, Leipzig, Germany, 1928. xiv + 471 pp. 7 **figs.** 17 × 24.5 cm.

The chief novelty of this work is that the author has sought not only to present a clear and interesting account of the principles of organic chemistry, but to indicate the applications and extensions of this subject to the neighboring field of biology and to technology. The book is addressed to two groups: to those who are already fairly well grounded in the principles of organic chemistry as a pure science but who seek a first, orienting survey of the intensely interesting applications of the science to the study of life processes, and, secondly, to those specialists in fields other than that of organic chemistry who desire a comprehensive account of the present status of this subject. It is thus designed for the use of advanced readers.

The first six chapters, covering 93 pages, are devoted to a thorough and critical exposition of the general characteristics of the compounds of carbon, and of the modern theoretical conceptions regarding their reactions and properties. This is followed by a special part in which representatives of the different types of compounds are described. In this part of the book the author gives particular attention to the physiology and pharmacology of the substances and to their technical preparation and uses wherever the opportunity arises, The average organic chemist will find in these sections, and in the interesting descriptions of some of the more important biochemical processes, a wealth of information and a suggestive presentation of theory. The carbohydrates, the proteins and the alkaloids are treated more comprehensively than in most textbooks of organic chemistry, and one finds, in addition to the usual chapters, sections dealing with the relationship between structure and pharmacological action, chemotherapy, depsides, tannins, polyterpenes, sterols and bile acids, blood and leaf dyestuffs, ferments, antigens.

This second edition will be valued particularly for the inclusion of a large amount of work completed within the last few years. It may be noted, by way of example, that some account is given of the recent contributions to stereochemical theory of Weissenberg, Wohl and Freudenberg, Fajans, Kuhn, Ruzicka, Hückel and of Levene, of the views of the different German investigators in the field of the polysaccharides, of the investigations of Windaus on ergosterol, of Hans Fischer's porphyrin syntheses, of Scheibler's studies of bivalent carbon compounds, of Warburg's work on the respiration ferment. Furthermore, the author makes repeated use of the important Werner-Pfeiffer conception of the nature of complex compounds, and of the extensions to this general theory which we owe to Hantzsch and to Dilthey. The possibility of applying these new ideas to a wide variety of phenomena has been suggested throughout the book. Wieland's theory of the nature of oxidation processes likewise receives considerable attention. Dr. Oppenheimer, in addition to his wide experience in biochemistry, is thus in close touch with modern organic chemical theory, and he has written with enthusiasm a book which is highly useful and stimulating.

While the reviewer considers that the merits of this unusual text far outweigh the faults, he would like to call attention to certain shortcomings from the point of view of the organic chemist. It should be realized that the book is not well suited to the needs of the student who seeks to predict the properties of an unknown compound, or to devise a suitable method for its preparation. Thus one fails to find a statement regarding the directive influence of substituents in the benzene ring, and little is said regarding the effect of one group on the reactivity of other groups. β-Hydroxypropionic acid is dismissed with the remark that "(sie) kommt biologisch nicht vor und bietet kein weiteres Interesse." More serious than such omissions is the tendency of the author to adopt a too positive attitude with regard to debatable questions. It is stated, for example, that the C-alkylation of β-ketonic esters is dependent upon a tautomeric process, and no mention is made of the addition theory. Anthraquinone and phenanthrenequinone are regarded as entirely lacking in the properties of true quinones. The mechanism given for substitution in the benzene nucleus was probably intended to conform to the current theories, but the exposition is ambiguous and incorrect. The views of a large number of chemists have been disregarded in the failure even to mention the Erlenmeyer formula for naphthalene or the bridge-bond structure for anthracene.

Finally, it may be observed that the effort to condense the book by the liberal use of small type and abbreviations, and by omitting many important formulas and all references to the literature, appears somewhat unfortunate. The same object might have been achieved more happily had the author avoided the constant repetition of certain passages.

L. F. FIESER

Hormone und Innere Sekretion. (Hormones and Internal Secretions.) By FRITZ LAQUER, Lecturer at the University of Frankfort. Theodor Steinkopff, Dresden-Blasewitz, Germany, 1928. viii + 136 pages. 15.5 × 22 cm. Price, unbound, RM. 8.50; bound, RM. 10.

In the present plethora of monographs on the endocrine organs and hormones in health and disease, it is refreshing to read this little volume of Dr. Fritz Laquer because Dr. Laquer has succeeded in condensing the essential facts, biochemical, physiological and clinical, in a few pages with remarkable clearness, accuracy and critical judgment. No essential facts appear to be left out on any topic and wherever the author expresses his own judgment on controversial points this judgment appears unusually sound. In many cases, however, the individual authors' findings and conclusions are merely presented parallel with findings of opposite results. In separate chapters Dr. Laquer discusses the pancreas and insulin, the thyroid and thyroxin, the parathyroids, the hypophysis, the adrenals, the ovaries and testes and the thymus. In a final chapter the author briefly summarizes the claims and theories for endocrine functions and hormone character of other substances and organs such as pineal gland, choline, etc.

This little monograph by Dr. Fritz Laquer appears to be one of the briefest and at the same time most comprehensive, readable and reliable guides in the endocrine field in any language. 1218 separate literature references are given in connection with each subject under discussion.

A. J. CARLSON

The Journal of the American Chemical Society

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE UNIVERSITY OF CALIFORNIA]

HEAT CAPACITIES IN AQUEOUS SALT SOLUTIONS

BY MERLE RANDALL AND FREDERICK D. ROSSINI

RECEIVED JUNE 22, 1928 PUBLISHED FEBRUARY 5, 1929

Whenever two substances, A and B, are mixed together the heat capacity of the mixture will be the sum of the heat capacities of the separate substances if the temperature function of the energy state of A, and of B, is the same in the mixture as for each substance separately. It is possible also for their heat capacities to be additive if the deviation of the heat capacity of A, in going from the pure state into the mixture, is exactly negative that of B. If, however, molecules B exert some special influence upon molecules A, then their heat capacities usually will not be additive.

It has been known for a long time that the heat capacity of a given amount of water is greater than that of the same amount of water plus a small amount of any substance which is a strong electrolyte.[1] This behavior can be explained in the following manner. Suppose we have a system consisting of 1000 g. of water, whose heat capacity is G calories. If we add to this water one single molecule of sodium chloride we shall have a system consisting of 1000 g. of water, one sodium ion, and one chloride ion. The heat capacity of this system we find to be $(G - a)$ calories. Then $(-a)$ calories is, apparently, the heat capacity of one sodium ion plus one chloride ion. Since we are dealing with an infinitely dilute solution,[2] Φ° and also $\bar{C}_{p_2}^\circ$ for one gram mole of sodium ion plus one

---

[1] Thomsen, "Thermochemistry," Longmans Green and Co., London, 1908, p. 165, says, "When an aqueous solution is diluted with water the molecular heat of the solution formed is less than the sum of that of the original solution together with that of the water." This is true in every case only if the solute is a strong electrolyte. It is possible also that it is not always true for very concentrated solutions.

[2] The symbols which are pertinent to the main discussion of this paper are defined as follows: m, the molality, the number of moles of solute per 1000 g. (or 55.508 moles) of water *in vacuo*. C_p, the heat capacity of that amount of solution, of molality m, which contains 1000 g. of water plus m moles of solute. $\bar{C}_{p_2}$, the partial molal heat capacity of the solute. This is dC_p/dm, and is the change in the heat capacity of a very large amount of solution on the addition of 1 mole of solute. (Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co.,

gram mole of chloride ion equals $-a \times 6.06 \times 10^{23}$ cal. The presence of the two ions has so affected the water molecules that their heat capacity has been decreased by an amount equal to a calories plus the intrinsic heat capacity of one sodium ion and one chloride ion.

Methods of Determining and Calculating the Apparent and Partial Molal Heat Capacities and the Specific Heat

The method employed in this work to determine these quantities is to measure the difference in the heat capacity of the two systems, (A) 1000 g. of water (heat capacity is 55.508 $\bar{c}_{p_1}{}^\circ$); (B) 1000 g. of water plus m moles of salt (heat capacity is C_p). Then ΔC_p, the apparent heat capacity of the added salt, is given by the equation

$$\Delta C_p = C_p - 55.508\ \bar{c}_{p1}{}^\circ \qquad (1)$$

The apparent heat capacity of the added salt per mole of the added salt is

$$\Phi = \Delta C_p/m \qquad (2)$$

If Φ is plotted against $m^{1/2}$, as in Fig. 3, then

$$\bar{c}_{p2} = \Phi + {}^1/_2 m^{1/2}(\mathrm{d}\Phi/\mathrm{d}m^{1/2}) \qquad (3)$$

That this is true can be shown as follows. From Equations 1 and 2

$$\Phi = (C_p - 55.508\ \bar{c}_{p1}{}^\circ)/m \qquad (4)$$

Differentiating9 with respect to $m^{1/2}$, we find

$$\mathrm{d}\Phi/\mathrm{d}m^{1/2} = m(\mathrm{d}C_p/\mathrm{d}m^{1/2}) - (C_p - 55.508\ \bar{c}_{p1}{}^\circ)2m^{1/2}/m^2 \qquad (5)$$

But $C_p - 55.508\ \bar{c}_{p_1}{}^\circ = m\Phi$, and $m(\mathrm{d}C_p/\mathrm{d}m^{1/2}) = 2m^{3/2}(\mathrm{d}C_p/\mathrm{d}m) = 2m^{3/2}\bar{c}_{p_2}$. Making these substitutions and multiplying by ${}^1/_2 m^{1/2}$, we have Equation 3. Or, the partial molal heat capacity of the solute is equal to the apparent molal heat capacity plus ${}^1/_2$ the product of $m^{1/2}$ times the slope of the curve of Fig. 3.

When Φ and $\bar{c}_{p_2}$ are known, $\bar{c}_{p_1}$ can be calculated as follows.[2] By definition

$$C_p = m\bar{c}_{p2} + 55.508\ \bar{c}_{p1} \qquad (6)$$

then

$$\bar{c}_{p1} = (C_p - m\bar{c}_{p2})/55.508 \qquad (7)$$

From Equations 1 and 2

$$C_p = m\Phi + 55.508\ \bar{c}_{p1}{}^\circ \qquad (8)$$

Hence

$$\bar{c}_{p1} = (m\Phi + 55.508\ \bar{c}_{p1}{}^\circ - m\bar{c}_{p2})/55.508 = (m/55.508)(\Phi - \bar{c}_{p2}) + \bar{c}_{p1}{}^\circ \qquad (9)$$

The specific heat of 1 gram of a solution of molality m is

$$\text{Specific heat} = (m\Phi + 55.508\ \bar{c}_{p1}{}^\circ)/W \qquad (10)$$

New Pork, 1923, p. 83.) $\bar{c}_{p2}{}^\circ$, the value of $\bar{c}_{p2}$ when m is zero. $\bar{c}_{p1}$, the partial molal heat capacity of the water. This is the change in the heat capacity of a very large amount of solution on the addition of 1 mole of water. Specific heat, the heat capacity of one gram of solution. $\bar{c}_{p1}{}^\circ$, the value of $\bar{c}_{p1}$ when m is zero. Φ, the apparent molal heat capacity of the solute, is $(C_p - 55.508\ \bar{c}_{p1}{}^\circ)/m$. It is the change in heat capacity per mole of solute, caused by the addition of m moles of solute to 1000 g. of water. $\Phi^\circ = \bar{c}_{p2}{}^\circ$, the value of the apparent molal heat capacity at $m = 0$.

where W is the weight of the amount of solution which contains 1000 g. of solution.

From the foregoing it is seen how all the four quantities, Φ, $\bar{c}_{p_2}$, $\bar{c}_{p_1}$ and specific heat can be calculated if the ΔC_p of Equation 1 is measured.

In this investigation, the method suggested by Randall and Bisson[3] and used by Randall and Ramage[4] is employed: given two calorimeter units identically alike, and containing like resistance heating units connected in series.

Charge both Units 1 and 2 with the same amount of water, say 1000 g. Pass a current in series through the two units for such a time as to cause a temperature rise in Unit 1 of Δt_1. If Unit 2 were identically the same as Unit 1 in every respect, its temperature rise would also be Δt_1, but there will be some small physical difference between the two units, so that actually the temperature rise in Unit 2 will be $\Delta t_1 + \Delta t_2$, where Δt_2 is the difference in temperature rise between Units 1 and 2 and is very small compared with Δt_1. Now *m* moles of salt are added to Unit 2 and again a current is passed through Units 1 and 2 in series until the temperature rise in 1 is again Δt_1. The temperature rise in Unit 2 **will** now be $\Delta t_1 + \Delta t_2'$. The heat capacity of Unit 1 is the same for both runs; the same amount of electrical energy must have gone into Unit 1 in both runs. Since the two units are in series and have like heating resistances, the energy that has gone into Unit 2 is the same in both runs. Hence for Unit 2

$$(C_p, \text{Unit } 2 + C_p, \text{H}_2\text{O})(\Delta t_1 + \Delta t_2) = (C_p, \text{Unit } 2 + C_p, \text{solution})\,(\Delta t_1 + \text{At,'}) \qquad (11)$$

or

$$(\Delta t_1 + \Delta t_2)/(\Delta t_1 + \text{At,'}) = (C_p, \text{Unit } 2 + C_p, \text{solution})/(C_p, \text{Unit } 2 + C_p, \text{H}_2\text{O}) \qquad (12)$$

Subtracting one from both sides, we have

$$(\text{At,} - \Delta t_2')/(\Delta t_1 + \Delta t_2') = (C_p, \text{solution} - C_p, \text{H}_2\text{O})/(C_p, \text{Unit } 2 + C_p, \text{H}_2\text{O}) \qquad (13)$$

Hence

$$\Delta C_p = [(\Delta t_2 - \Delta t_2')/(\Delta t_1 + \Delta t_2')](C_p, \text{Unit } 2 + C_p\text{H}_2\text{O}) \qquad (14)$$

The Calorimeter

The calorimeter of Randall and Ramage[4] was rebuilt. A nickel-plated brass plate fitted the guide frame on the vertical runways of the thermostat case of Randall and Bisson.[3,4] This plate was laid out so that three nickel-plated brass cylinders A, 15 cm. X 27 cm., could be bolted to it from the lower side, and so that the three leg multiple thermel case would fit from above, one leg into each cylinder. Above each cylinder were sets of holes with extension tubes to provide for the entry of stirrer, heating coil leads and cooling coil leads. The 20-junction and 50-junction thermel of Randall and Bisson[3,4] and their mechanism for propelling the stirrers in the three units were slightly altered and used in this assembly.

As recommended by Randall and Ramage,[4] the Dewar flasks containing the water or solution were placed within cylinders and the whole assembly was submerged in the

---

[3] Randall and Bisson, This Journal, 42, 347 (1920).

[4] Randall and Ramage, *ibid.*, 49, 93 (1927).

oil-bath of the thermostat. In this manner the slight variation in the temperature of the oil-bath was ironed out before reaching the liquid in the Dewar flasks. The air in the enclosed space above the bath was always in temperature equilibrium with the oil.

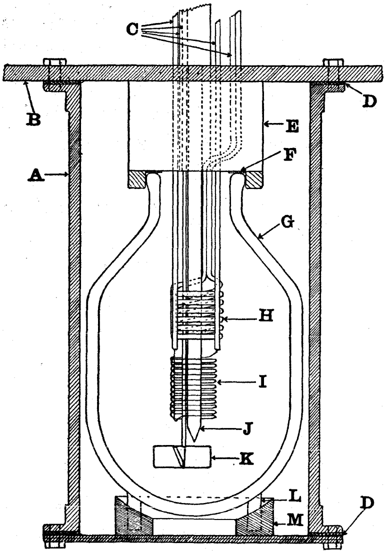

Fig. 1.—One unit of calorimeter.

A cross section of one of the three calorimeter units ($^2/_7$ of actual size) is shown in Pig. 1. The nickel-plated brass cylinder, **A,** was bolted to the nickel-plated brass main plate, B, with the various extension tubes, C, leading to above the surface of the oil in the bath. The gasket, D, made of Garlock sheet rubber packing was shellacked to the cylinder. The vacuum flask, G, was supported on the rubber pieces, L, which were held in the circular piece of balsa wood, M. The flask was tightly held against the rubber gasket, P, which was shellacked to the balsa wood block, E, through which run the stirrer, thermel, entry opening, heating coil leads and cooling coil leads. The protecting tube, J, of the copper-constantan thermel was of Pyrex glass. The cooling coil, H, was of 0.32 cm. copper tubing, joined to leads of thin-walled German silver tubing, and K was a three vane all glass stirrer with 0.3 cm. glass shaft, which was joined to the driving mechanism with rubber tubing.

The heating coil, I, was made by drawing fine silver tubing over double silk covered manganin resistance wire, having a thin coating of bakelite. This silver tubing was coiled and then joined to 0.32 cm German silver tubing leading out of the unit. A cross section of one of the tubing junctions of the heating coil is shown in Fig. 2. The silver tubing P, whose outside diameter was about, 0.064 cm., was tightly drawn over the No. 38 D.S.C. manganin resistance wire, Q. The double silk insulation, S,S,S, has a thin coating of bakelite. The small silver tubing, P, was soldered, R,E, to a larger piece of silver tubing, which in turn fitted snugly into a brass bushing, U, in the 0.32-cm. German silver tubing, V. The lead, T, was No. 28 copper, and the lead, W, was No. 24 copper wire.

This type of heating coil has a very low heat capacity and the interchange of heat between the resistance wire and the solution is very rapid. About 120 cm. of wire was used in the coil and its resistance was about 70 ohms. The first coils used were of No. 30 D.S.C. manganin wire and had a resistance of about 10 ohms. The heating unit was silver plated and then gold plated; the cooling unit was heavily gold plated.

A 10-junction thermel gave the difference in temperature between the bath and Unit 3; the 20-junction thermel gave the temperature difference between Units 1 and 3; while the 50-junction thermel showed the difference in temperature between Units 1 and 2.

When the entire calorimeter assembly was submerged, the extension tubes, C, extended about 2.5 cm. above the surface of the oil. In this manner every part of the calorimeter proper, including the multiple thermel case, was completely immersed in the constant temperature oil-bath. The thermel case was screwed to the main plate of the calorimeter with rubber as gasket material and then shellacked to prevent dissolution of the rubber.

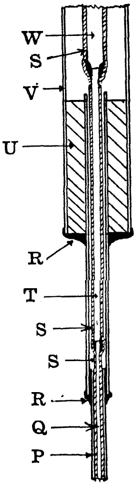

Fig. 2.—Detail of heating coil.

A Leeds and Northrup, White Double Potentiometer, with a range of 100,000 microvolts, and a Leeds and Northrup high sensitivity galvanometer were used to measure the potentials of the three thermels, the potential drop across and the current through the heating coils. These latter two were read only in the direct heat capacity runs.

To supply the working current in the potentiometer, two batteries of two each of Type B6H Edison alkaline cells were used. The entire electrical system was doubly shielded according to the recommendations of White.[5]

Calibration of the Apparatus

Two Meylan stop watches, for use in measuring the time in the direct heat capacity runs for determining the heat capacity of the flasks, were checked against the Observatory time signals and against the Howard Mean Time clock in the Observatory of the Astronomy Department. We thus found the factor (mean solar seconds) to be 1.0000 for the 0.2-sec. watch and 1.0002 for the 0.1-sec. watch.

Since the potential drop across the heating coils was much greater than the capacity of the potentiometer, a fraction $R_a/(R_a + R_b)$ was measured. The value of $(R_a + R_b)/R_a$, found by measuring the current through and the potential drop across known standard resistances, was 181.50, 181.50, 181.52, 181.50; mean 181.50.

The standard cell used for balancing the working current in the potentiometer was a saturated cell of the Weston type which was kept in the thermostat at 25.25°. The cell was placed in a metal can and the leads were brought out through a bakelite plate. The potential was checked against two new Weston and four new Eppley cells over the period of the investigation and was found to be 1.01808 ± 0.00002 v. at 25.25°. This agrees well with the value of 1.01807 v. calculated from the value 1.01830 v. for a saturated Weston cell at 20°, when corrected for the temperature difference.

The insulation resistances on all the thermels were checked and found to be greater than ten million ohms.

The energy current, furnished by lead storage batteries, was found to be non-fluctuating if the batteries were maintained at the proper charge.

The temperature of the oil in the thermostat was maintained at 25.25 ± 0.010°. The period of the fluctuations in the oil-bath temperature was from ten to eighteen minutes, depending upon the temperature of the room. The oil in the bath was kept well stirred with a four-vane, 8-cm. fan stirrer, running at about 630 r.p.m. Two special thermostat thermometers, which could be read to 0.005°, and which had been calibrated at the Bureau of Standards, were placed at different points in the oil-bath and indicated practically uniform temperature throughout the bath.

The high sensitivity galvanometer used was a Leeds and Northrup, Catalog No. 2285. with a period of six sec., an internal resistance of 37 ohms and an external critical damping resistance of 380 ohms. The galvanometer scale was placed 6.7 meters from the galvanometer, and with a telescope having a very high magnification one could estimate 0.2 mm. on the scale. Table I gives the approximate sensitivity of the galvanometer (in mm. on the scale) with the various thermels in the circuit.

TABLE I

---

[5] White, THIS JOURNAL, 36, 2011 (1914).

The 20-junction and the 50-junction thermel had been calibrated by Randall and Bisson[3] against a 4-junction thermel calibrated by the Bureau of Standards. Then the equation for the e.m.f. per junction was

$$\text{E.m.f.} = 40.8751 + 0.05075t^a - 0.0000613t^3 \qquad (15)$$

when one junction was at 0° and the other at a temperature of t°.

The e.m.f. produced on the thermel when one leg was at 0° and the other at the sodium sulfate triple point, 32.383°, was determined for all three thermels.

TABLE II

CALIBRATION OF THERMELS

Thermel	Measured e.m.f., microvolts	E.m.f. calcd. in microvolts	Ratio e.m.f. measured / e.m.f. calcd.
10-jc.	13,753.6	13,789.6	0.99738
20-jc.	27,504.3	27,579.1	.99729
50-jc.	68,759.9	68,947.8	.99727

The factors to be applied to the e.m.f.-temperature equation were 0.9973 for the 20- and the 50-junction thermels and 0.9974 for the 10-junction thermel. In this calibration the figures in the second column show the e.m.f. reading when it was constant to 0.3 microvolt for thirty minutes, with one leg in a mixture of clear cracked ice and conductivity water and the other in a solution of sodium sulfate in equilibrium with the two solid forms Na_2SO_4 and $Na_2SO_4 \cdot 10H_2O$, which has a temperatures of 32.383°. Conductivity water and thrice recrystallized sodium sulfate were used in making the solutions.

The optimum rate for the stirrers in the flasks was found to be 130 r.p.m. This produced good mixing of the water or the solution without developing an excessive amount of stirring energy. The stirring energy was found to be about 0.025 cal. per min. for the above rate with the stirrers used. This was determined by running the stirrers in Units 1 and 2 with the flasks containing water at the temperature of the bath. The only change in temperature occurring in the two flasks, 1 and 2, was then that due to evaporation and stirring. Readings on the 50-junction thermel joining these two flasks were taken for thirty minutes. Stirrer 2 was stopped for ten minutes and then again started. Then readings were again taken after equilibrium had been established. An extrapolation gave the reading which would have been found if Stirrer 2 had not been stopped. The difference in this and the actual observed reading was translated from microvolts to degrees to calories per minute by a simple calculation.

The heat leak from the bath into one of the vacuum flasks containing about 1200 g. of water was found to be about 10^{-5} cal. per sq. cm. per sec. per deg. This is an average for the entire surface of the Dewar flask, although actually most of this leak occurred through the thermel, stirrer, heating coil, and cooling coil leads. With the above amount of water in the vacuum flask, the heat flow into the flask (when its temperature was below that of the bath) from the bath was such as to cause a temperature rise in it of 0.00037 deg. per min. per deg. difference in temperature. Since at the start of an experiment the flask was 0.5° below the temperature of the bath, and was brought to the temperature of the bath in eight minutes, the total temperature rise due to the Newton flow of heat was $0.5 \times 8 \times 0.00037 = 0.00148°$, or about 0.003 of the total rise.

The stirring and evaporation difference between Flasks 1 and 2 as registered by the 50-junction thermel, and between Flasks 1 and 3, as registered by the 20-junction

---

[6] (a) Richards, Am. J. Sci., 6, 201 (1898); (b) Richards and Wells, *Proc.* Am. *Acad. Sci.*, 38,431 (1902); (c) Dickinson and Mueller, THIS JOURNAL, **29**, 1381 (1907).

thermel, varied slightly from run to run but was practically constant for a given run. Great precision in the determination of the stirring and evaporation difference between Flasks 1 and 2 was neoessary, and in most of the runs the stirring and evaporation difference was such as to cause a temperature difference in Units **1** and **2** of about 0.000010° per min. In some runs this was zero and in some as much as **0.000025**" per min.

Most of the stirring and evaporation difference between Flasks **1** and **2,** which is of great importance in a differential run, was due to a difference in evaporation from the two flasks. This evaporation was reduced by preventing gaseous connection between the inside of the flask and the air space between the flask and the cylinder. The only opening from the interior of the flask to the air space in the thermostat case was along the stirrer tube. This was reduced with some packing. **All** the other tubes were packed tightly. The 2.2 cm. cylindrical entry tube was neatly fitted with a removable cylinder of balsa wood.

The cooling of the calorimeters to the starting temperature, if they were above it. was accomplished by running compressed air, under a pressure of **0.5** atm. gage through coils of **0.6** cm. copper tubing immersed in liquid air and thence through rubber tubing to the cooling coil of a unit. The air from the exit tube of the cooling coil in each unit was discharged into the air above the bath. With this cooling system, each unit having *a* heat capacity when charged of about 1200 cal. could be cooled **0.5** deg. in about forty minutes. The moisture and carbon dioxide in the compressed air were removed with calcium chloride, soda lime and a liquid-air trap.

The lag of the rise in temperature of a solution, as registered by the e.m.f. of the thermel, behimd the electrical energy input was found to be about twenty-two seconds for an energy input of 75 cal. per min.

Heat Capacity of a Unit

By the capacity of a unit we shall mean the heat capacity of the vacuum flask plus the thermel, stirrer, heating unit and cooling unit within the flask.

Before any differential runs were made, the heat capacity of Unit **2** was determined. **A** weighed amount of water was placed in Flask **2** and brought to 24.75'. Units **1** and **3** contained water at 25.25°, the temperature of the bath. An amount of energy was put into Unit **2** such that its temperature rise was **0.5** deg. From the energy input and the temperature rise the heat capacity of the unit plus the contained water was calculated. The heat capacity of the unit alone was found by subtracting the heat capacity of the water.

In these direct heat capacity runs the heating time was made about 1000 sec. as the time was measured with a tenth-second stop watch. The energy input was found by taking the average value of potential times current over the period of the run (not the average value of potential times the average value of current) from appropriate plots of the observed value. The method of operation and method of calculation is indicated in Table III, which gives a condensed log of Run 19.

A plot of the temperature (in microvolts) of Unit **2** against the time during the run shows that from the tenth minute to the thirtieth minute

[a] Zero, 84.65. [b] Energy on. [c] Zero, 84.65; e.m.f., 1155.80. [d] Energy off. [e] Zero, 84.40; sensitivity, 18.00 (50); e.m.f., 14.80. [f] Sensitivity, 29.90 (20). [g] Zero, 84.20.

Fore period, 50-jc., 0.97 cm./min. at 1158 microvolts. After period, 50-jc., 0.15 cm./min. at 1158 microvolts. U is the constant stirring and evaporation difference between Units 1 and 2. K is the heat leak constant.

$$1158\,K - U = 0.97 \qquad U = 0.15 \text{ cm./min.}$$
$$10\,K - U = 0.15$$
$$1148\,K = 0.82 \qquad K = 0.00071 \text{ cm./min./microvolt}$$

of the run Unit 2 was 9760 microvolt-minutes below the bath. Therefore the rise in temperature of Unit 2 during the run, due to the heat leak, was 9760 X 0.00071 = 6.90 cm. (scale deflection). The rise in temperature of Unit 2 due to the stirring and evaporation difference between Units 1 and 2 was 20 X 0.15 = 3.00 cm.

The total temperature rise not due to the energy input is then 6.90 + 3.00 or 9.90 cm., which is 5.50 microvolts. From the tenth minute to the thirtieth minute the actual temperature rise was 1155.80 − 14.80 or 1141.00 microvolts. The temperature rise due to the energy input alone was 1141.00 − 5.50 or 1135.50 microvolts, or 1135.50/(2165.8 × 0.9973) deg. The average input for the heating period, obtained by plotting the current and potential drop, was 0.016011 X 181.50 watts. The potential drop across the heating unit was obtained by multiplying the reading (P. D. in Table 111), in microvolts, by 181.50 and dividing by 10^6. The current is the reading (Current in Table III) of the potential drop in microvolts across a standard 0.1 ohm, multiplied by 10 and divided by 10^6. The time was 972.8 sec. The energy input = (972.8)(0.016011 X 181.50) – (0.9989) = 2823.10 joules. The factor correcting for the resistance of the leads to the heating unit is 0.9989. The total heat capacity is then 2823.10 × (2165.8 × 0.9973)/1135.50 = 5370.07 joules per deg. The heat capacity of the water at 25° is (1244.62)(1.00106) X 4.1728 = 5199.06 joules per deg., whence C_p for Unit 2 = 171.01 joules per deg., or 40.89 cal. per deg.

Runs 17, 18 and 19 gave 40.76, 40.96 and 40.89 cal. for the heat capacity of Unit 2, with Flask 387.

By making some differential runs, as explained in the next section, the change in the heat capacity of Unit 2 with volume of liquid was found to be as recorded in Table IV.

TABLE IV

CHANGE IN HEAT CAPACITY OF UNIT 2 (FLASK 387) WITH VOLUME OF SOLUTION

Vol. of liq., cc.	1180–1200	1200–1220	1220–1240	1240–1260	1260–1280	1280–1300
Change in C_p in cal./cc. (Unit 2)	0.005	0.006	0.007	0.008	0.009	0.010

These values were calculated from the results of eighteen runs.

The Differential Heat Capacity Run

The procedure followed in measuring ΔC_p was to charge Units 1 and 2 with water at 24.75' and Unit 3 at 25.25°, the temperature of the bath. An amount of energy sufficient to heat Units 1 and 2 to 25.25° was passed through the heating units in series. The temperature rise of Flask 2, $\Delta t_1 + \Delta t_2$, for a given temperature rise in Flask 1, Δt_1, was measured. Then Δn_2 moles of salt were added to Flask 2, and $\Delta t_1 + \Delta t_2$ was found for the rise of Δt_1 in Flask 1. In this way measurements of Δt_1 and Δt_2 were made after successive additions of salt and the ΔC_p between the original amount of water in Flask 2 and any given solution following it is

$$\Delta C_p(m) = (\Delta t_2(m = 0) - \Delta t_2(m))\,(C_p, \text{Unit } 2 + C_p, \text{H}_2\text{O})(m = 0)/(\Delta t_1 + \Delta t_2(m)) \quad (16)$$

The method of operation and of calculation is shown in Table V, which gives a condensed log of Run 64.

Materials, Constants, Molecular Weights, etc.

The salts used in this work were anhydrous C. P. samples thoroughly dried in an oven at 105°—Kahlbaum's sodium and potassium chlorides, and sodium and potassium nitrates; Merck's potassium sulfate; Baker and Adamson's sodium sulfate and bromide, and potassium bromide and Mallinckrodt's "Reagent Quality" potassium iodide.

The molality of a given solution is calculated from the weight of the water and the weight of the salt added. The water in the flask is weighed to 0.01 g. and the added salt to 0.001 g. All weighings are reduced to vacuum. The molecular weights of the salts are calculated from the International Atomic Weights for 1927.

The unit calorie was taken as the amount of energy required to raise the temperature of 1 g. of water from 15 to 16°. The ratio of the heat capacity of water at 25° to that

[7] See résumé of Lewis and Randall, ref. 2.

in the sub-heading of each section of the table; Col. 2 gives the molality of the solution; Cols. **3** and 4 give Δt_2 (in duplicate experiments), the temperature rise in microvolts of Unit 2 above Unit 1 for a rise of 1000 microvolts in Unit **1**; Col. 5 gives $\Delta t_2^\circ - \Delta t_2$ or the mean of the differences between Δt_2 for the runs when m is zero and the runs of the given molality; Col. *6* gives (ΔC_p) or the uncorrected change in heat capacity of the system due to the total added salt; Col. **7** the true ΔC_p of the system found by correcting the value of the previous column for the change in the heat capacity of the unit with the change of the volume of solution in the **flask** (see Table IV), and the last column the apparent molal heat capacity, Φ, which is found by dividing the value in Col. 7 by the molality. Two or more series of runs were made on each salt and the runs of different series are distinguished on the plots.

[a] **Similar data for the other salts worked with may be found in a manuscript thesis by the Junior Author, filed in the University of California Library, May,** 1928.

The rounded values of the apparent molal heat capacity for the usual rounded values of m are given in the third column of Table VII. The values of the partial molal heat capacity of the solute calculated by means of the plots of Figs. **3** and 4 and the method of Equation **3,** are found in Col. 4. The values of the partial molal heat capacity of the water calculated by means of Equation 9 are given in Col. 5, and the specific heat of the solution referred to water as 0.9979 is calculated according to Equation 10 and is given in the last column.

Discussion

In Figs. 3 and 4 are shown plots of the experimentally determined values of the apparent molal heat capacity, 9, for the ten salts. Since Φ is equal to $\Delta C_p/m$, a given error (in cal.) in the measurement of ΔC_p will appear as a larger or smaller error in 9 (in. cal.) on the plot, depending upon whether m is less than or greater than unity. For very small values of m this error becomes large and for the smallest measured concentration, m = 0.043, the error in Φ is about 23 times that in the actual measurement of ΔC_p. Nevertheless, the extrapolation of the data to m = 0 is fairly certain, as is shown in an examination of the plots. The average error in any given measurement of ΔC_p for all the runs is found to be 0.10 cal. For sodium chloride the average error in a given determination of ΔC_p is 0.06 cal.

The data for sodium and potassium chlorides, sodium sulfate, potassium sulfate, nitrate, bromide and iodide were obtained in the order named. The value of Φ when m is zero is identical with $\bar{c}_{p_2}°$. We find

$$\bar{c}_{p_2}°(\mathrm{KCl}) - \bar{c}_{p_2}°(\mathrm{NaCl}) = \bar{c}_p°(\mathrm{K}^+) - \bar{c}_p°(\mathrm{Na}^+) = -5.2 \text{ cal.} \qquad (17)$$

and

$$\bar{c}_{p_2}°(\mathrm{K_2SO_4}) - \bar{c}_p°(\mathrm{Na_2SO_4}) = 2\bar{c}_p°(\mathrm{K}^+) - 2\bar{c}_p°(\mathrm{Na}^+) = -10.6 \text{ cal.} = 2 \times (-5.3 \text{ cal.}) \qquad (18)$$

Within the limits of error of the extrapolation to zero concentration, these two results are identical and show that the partial heat capacities of ions at infinite dilution are additive.

Given the difference in $\bar{c}_p°$ for Na^+ and K^+, then, if $\bar{c}_{p_2}°$ is found for potassium bromide, iodide and nitrate, $\bar{c}_{p_2}°$ for sodium bromide, iodide and nitrate is known. This relation was utilized in extrapolating the curves for these latter salts on which relatively few measurements were made.

In Fig. 4 is plotted $\bar{c}_{p_2}$ against $m^{1/2}$ for sodium and potassium sulfates, while Fig. 5 gives $\bar{c}_{p_2}$ against $m^{1/2}$ for sodium and potassium chlorides, bromides, iodides and nitrates. The limiting values of the partial molal heat capacity of the various salts are given in Table VIII.

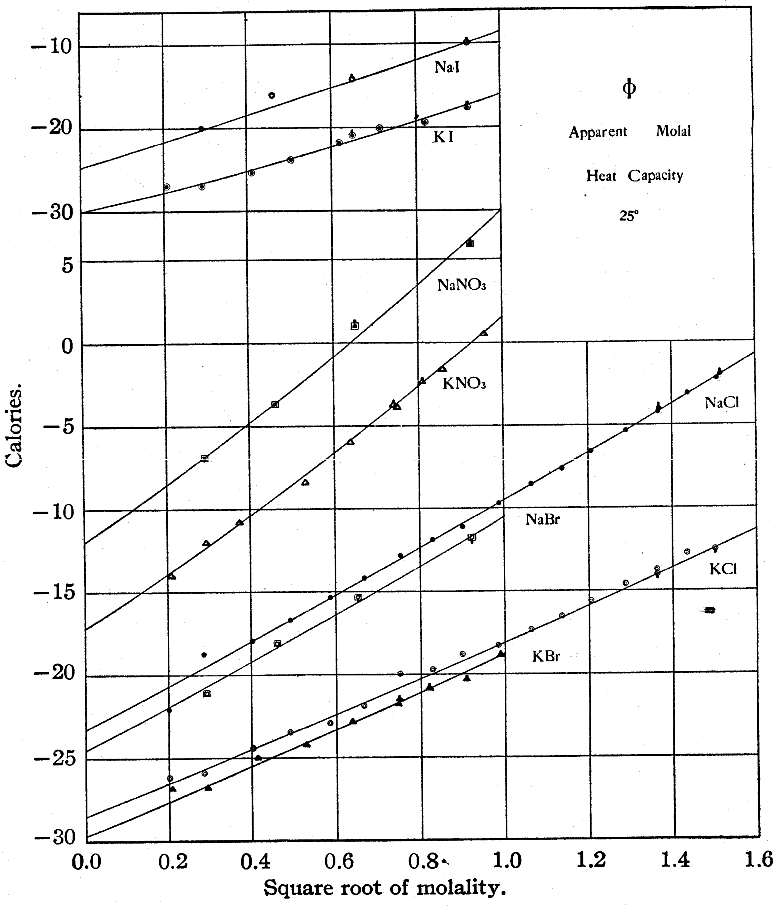

Fig. 3.

Table VIII

Summary of Values of $\bar{c}_{p_2}°$ (25°)

$NaNO_3$	−12.0 cal.	KNO_3	−17.2 cal.	$K^+ - Na^+$	− 5.2 cal.
NaCl	−23.3 cal.	KCl	−28.5 cal.	$SO_4^{--} - I^-$	− 0.2 cal.
NaBr	−24.5 cal.	KBr	−29.7 cal.	$I^- - Br^-$	− 0.3 cal.
NaI	−24.8 cal.	KI	−30.1 cal.	$Br^- - Cl^-$	− 1.2 cal.
Na_2SO_4	−50.0 cal.	K_2SO_4	−60.6 cal.	$Cl^- - NO_3^-$	−11.3 cal.

The values of the differences in the partial molal heat capacities of certain indicated ions at infinite dilution are given in the last column of Table VIII. They are found by subtracting the values for a pair of salts having a common ion.

$\bar{C}_{p_2}{}^\circ$ becomes increasingly negative for the positive ions in the order Na^+, K^+, and for the negative ions in the order NO_3^-, Cl^-, Br^-, I^-, SO_4^{--}. The value of $\bar{C}_{p_2}$ seems to increase to remarkably high values as the concentration is increased. For sodium sulfate at $m = 1.96$, $\bar{C}_{p_2}$ is 66.9 cal. This is more than twice the molal heat capacity of solid sodium sulfate, at the same temperature. At higher concentrations we should expect the value of $\bar{C}_{p_2}$ to become even larger.

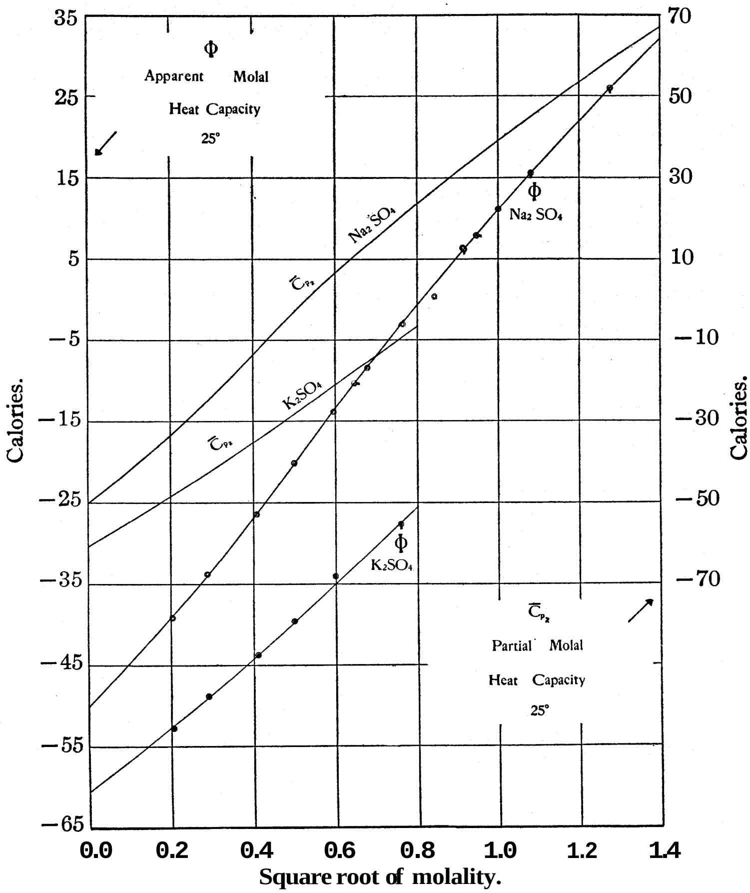

Fig. 4.

The Rate of Change of $\bar{C}_{p_2}$ with Molality

The introduction of a charged particle, as one sodium ion, into an atmosphere of electrical dipoles, as water molecules, changes the energy–temperature relations of all the water molecules within the sphere of influence of the ion in such a manner as to decrease the capacity of these water molecules to take up heat energy. The presence of the charged particle has restricted and damped the kinetic motion (and its temperature coefficient) of the dipoles. Then, too, there may be a direct attachment of a number of the dipoles to the charged body. These effects all make for a considerable decrease in the total number of degrees of freedom in the system, resulting in a diminution of the energy content and of the heat capacity. From these considerations it is easily seen why the apparent heat capacity of a strong electrolyte at infinite dilution is abnormally low, and in nearly every case negative.

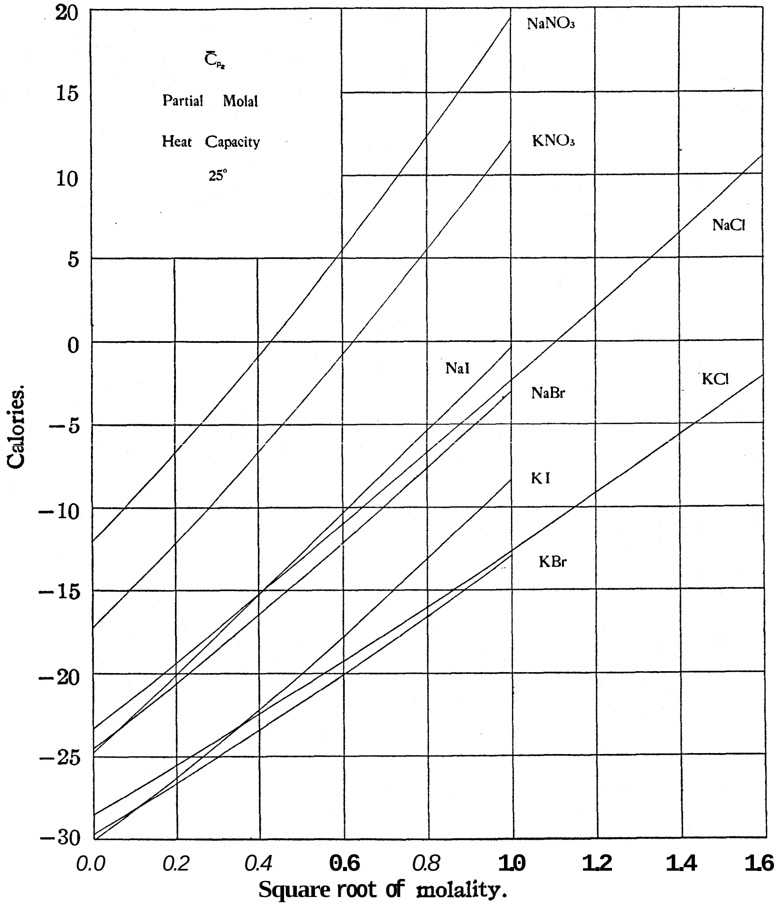

Fig. 5.

Zwicky[8] has attacked the problem of the heat capacity of electrolytic solutions by considering the electrolytic polarization of the water, the ionic atmosphere about a given ion, the compression of the solvent about the ion and the hydration of the ion. Bennewitz[9] considered the change in the intermolecular forces in seeking a theoretical solution of this problem.

Since at infinite dilution a given ion. can have within its sphere of influence only a definite number of water molecules, the effect which a given ion has upon the heat capacity of the water molecules will be independent of the source of the ion. The apparent heat capacity of a sodium ion, at infinite dilution, will be the same whether we obtain it from sodium chloride or from sodium sulfate. In other words, the apparent or partial molal heat capacities of ions at infinite dilution will be additive.[10] The effect that a given ion will have upon the capacity of the neighboring water molecules to absorb heat energy will depend upon the charge of the ion, the size of the ion and the configuration of the ion, if it is a polyatomic ion, such as nitrate or sulfate ion.

Randall and Ramage[4] found $\bar{C}_{p_2}$ to rise linearly with the square root of the molality. Their result is verified in the present measurements. We shall consider how the presence of other ions will affect the influence which a given ion has upon the water molecules. On the basis of the Debye-Hückel[11] theory of strong electrolytes one predicts that, in the dilute region, where the theory has been shown to be applicable, $\bar{C}_{p_2}$ should vary linearly with the square root of the concentration.[12]

Consider two systems, A consisting of an infinitely dilute solution, and B consisting of a solution of molality m. In going from State **A** to State B the change in the free energy of one mole of solute is $\bar{F}_2 - \bar{F}_2^\circ$. Following Debye and Hückel,[11a] we may separate this free energy change into two **parts,** the first of which is that due to the particles considered as solute molecules of **a** perfect solution, in which case the activity of the solute is equal to the concentration, and the second of which is the free energy change due to the fact that the particles are charged ions.

$$\Delta F = [\bar{F}_2\ (\text{class.}) - \bar{F}_2^\circ\ (\text{class.})] - [\bar{F}_2(\text{elec.}) - \bar{F}_2^\circ(\text{elec.})] \tag{19}$$

We can substitute for the second parenthesis the value given by Debye and Hiickel,

$$\bar{F}_2(\text{elec.}) - \bar{F}_2^\circ(\text{elec.}) = -\frac{Ne^2\Sigma\nu_i z_i}{2D}\,\frac{\xi}{1 + \xi\alpha} \tag{20}$$

---

[9] Bennewitz, Z. *Elektrochem.,* 33, 540 (1927).

[10] **A** statement which leads to this result **was** made by Lewis, THIS JOURNAL, 35, 15 (1913).

[11] (a) Debye and Hiickel, ***Physik.*** Z., 24, 185 (1923); (b) Debye, *ibid.,* 25, 97 (1924).

[12] Lange and Messner, *Z.* ***Elektrochem.,*** 33, 431 (1927), applied the Debye-Hückel theory in deriving the variation of $\bar{C}_{p_1}$ in the dilute region.

where $\xi^2 = 4\pi Ne^2\Sigma c_i z_i^2/1000\mathbf{D}kT$, and e is the electronic charge, D the dielectric constant of the medium, N Avogadro's number, k Boltzmann's constant, T absolute temperature, c concentration of solute in moles per liter, c_i concentration of i^{th} kind of ions in moles per liter, z_i charge on the $\mathbf{i}^{\text{th}}$ kind of ions, ν_i the number of the i^{th} kind of ions per molecule, and α a constant of the order or magnitude of the radius of the ion.

For $\bar{F}_2$ (class.) $-$ $\bar{F}_2°$ (class.) Debye and Hiickel write RT ln c, whence

$$\Delta F = -\frac{Ne^2\Sigma\nu_i z_i^2}{2\mathbf{D}}\,\frac{\xi}{1+\xi\alpha} + RT\ln c \tag{21}$$

But

$$T(\delta^2(\Delta F))/\delta T^2 = -\Delta C_p = -(\bar{c}_{p2} - \bar{c}_{p2}°) \tag{22}$$

Substituting Equation 21 in Equation 22, we find

$$\bar{c}_{p2} - \bar{c}_{p2}° = -T\frac{\delta^2}{\delta T^2}\left[-\frac{Ne^2\Sigma\nu_i z_i^2}{2\mathbf{D}}\,\frac{\xi}{1+\xi\alpha}\right] - T\frac{\delta^2\,(RT\ln c)}{\delta T^2} \tag{23}$$

Performing this differentiation and making the slight assumption that $\mathrm{d}c/\mathrm{d}T$ and $\mathrm{d}^2c/\mathrm{d}T^2$ are zero, we obtain

$$\bar{c}_{p2} - \bar{c}_{p2}° = \frac{3}{4}\left(\frac{\pi N}{1000k}\right)^{1/2}\frac{Ne^3}{(\mathbf{D}T)^{3/2}}f(\mathbf{D},\,T)(\Sigma\nu_i z_i^2)^{3/2}\frac{c^{1/2}}{(1+\xi\alpha)^2} \tag{24}$$

where

$$f(\mathbf{D},\,T) = 1 + 2\frac{T}{\mathbf{D}}\frac{\mathrm{d}\mathbf{D}}{\mathrm{d}T} + 5\left(\frac{T}{\mathbf{D}}\frac{\mathrm{d}\mathbf{D}}{\mathrm{d}T}\right)^2 - 2\frac{T^2}{\mathbf{D}}\frac{\mathrm{d}^2\mathbf{D}}{\mathrm{d}T^2} \tag{25}$$

In evaluating D, $\mathrm{d}\mathbf{D}/\mathrm{d}T$ and $\mathrm{d}^2\mathrm{D}/\mathrm{dT}^2$ we can take the values for pure water (which will not be very different from that of a very dilute solution) as taken from the equation of Adams[13] $\mathrm{D} = 400{,}000T^{-3/2}$ deduced from the measurements of Kockel.[14] For $\mathrm{T} = 298.1°K$, $\mathrm{D} = 77.75$; $\mathrm{d}\mathbf{D}/\mathrm{d}T = -0.3914$; $\mathrm{d}^2\mathrm{D}/\mathrm{dT}^2 = 0.003283$; $(T/\mathbf{D})(\mathrm{d}\mathbf{D}/\mathrm{d}T) = (\mathrm{d}\ln\mathbf{D})/(\mathrm{d}\ln\mathbf{T}) = -3/2$; $\mathrm{f}(\mathbf{D},\,\mathrm{T}) = 1.75$. Evaluating

$$\bar{c}_{p2} - \bar{c}_{p2}° = 2.14(\Sigma\nu_i z_i^2)^{3/2}[c^{1/2}/(1+\xi\alpha)^2] \tag{26}$$

In the dilute region $(1 + \xi\alpha)$ closely approaches the value of 1, and the concentration in moles per liter is very nearly the same as the concentration in moles per 1000 g. of water. Hence

$$\bar{c}_{p2} = 2.14(\Sigma\nu_i z_i^2)^{3/2}\,m^{1/2} + \bar{c}_{p2}° \tag{27}$$

The values of the valence factor $(\Sigma\nu_i z_i^2)^{3/2}$ (and 2.14 times the valence factor) for various types of solute are given in Table IX.

TABLE IX

SLOPE OF PARTIAL MOLAL HEAT CAPACITY AGAINST SQUARE ROOT OF MOLALITY

Valence type	1–1	2–1	2–2	3–1	3–2
$(\Sigma\nu_i z_i^2)^{3/2}$	2.82	14.7	22.6	41.6	165
$2.14(\Sigma\nu_i z_i^2)^{3/2}$	6.0	31	48	89	353

Equation 27 shows that in the dilute region in which the Debye-Hückel theory of strong electrolytes is applicable, $\bar{c}_{p_2}$, when plotted against the

---

[13] Adams, THIS JOURNAL, 48, 625 (1926).

[14] Kockel, *Ann. Physik*, [4] 77, 417 (1925).

square root of the concentration, should be a straight line whose slope will depend upon the charge and the number of the ions making up a solute molecule. This slope is the same for solutes of the same valence type and is greater for the higher valence types. It must be remembered that Equation 27 gives only the values of $\bar{c}_{p_2} - \bar{c}_{p_2}{}^\circ$. The value of $\bar{c}_{p_2}{}^\circ$ for any given pair of ions must be sought in some other manner.

The slopes of the curves of partial molal heat capacity against $m^{1/2}$ given in Figs. 4 and 5 at $m^{1/2} = 0$ are approximately as given in Table X.

TABLE X

APPROXIMATE LIMITING SLOPE OF PARTIAL MOLAL HEAT CAPACITY AGAINST SQUARE ROOT OF MOLALITY

Salt	NaCl	NaBr	NaI	Na_2SO_4	$NaNO_3$	KCl	KBr	KI	K_2SO_4	KNO_3
$\bar{c}_{p_2}/m^{1/2}$	19	18	23	76	25	15	15	18	62	25

In all the curves for the uni-univalent salts the slope is increasing somewhat with increase in $m^{1/2}$. For the sulfates there appears a point of inflection, at $m^{1/2} = 0.7$ for potassium sulfate and $m^{1/2} = 0.5$ for sodium sulfate.

According to Equation 27 and Table IX the value of the slope of $\bar{c}_{p_2}$ against $m^{1/2}$, in the dilute region, should be about 6 for a 1–1 and 31 for a 2–1 salt. The slopes given in Table X show an average of about 18 or 20 for the 1–1 and about 70 for the 2–1 salts. These values show the proper order of magnitude and about the right variation with change in the valence types of the salt. A closer agreement might possibly be obtained with a more precise knowledge of the true values of dD/dT and d^2D/dT^2, which are used in Equation 27, and by the non-neglect of the terms dc/dT and d^2c/dT^2. These results seem further to emphasize the validity of the assumptions underlying the Debye-Hückel theory of strong electrolytes as applied to dilute aqueous solutions.

The slopes of these curves of $\bar{c}_{p_2}$ increase in the order of Cl^-, Br^-, I^-, NO_3^- for the negative ions with a common cation and K^+, Na^+, for the positive ions with a common anion.

Other Ions

A complete review of all the available data on the specific heats of aqueous solutions of electrolytes was made to see if some values of $\bar{c}_{p_2}$ could be obtained on salts other than those measured in this work. In order that the data may be used to calculate Φ and by extrapolation to $m = 0$ find $\bar{c}_{p_2}$, the specific heat measurements must not only be reported to 1 in 10,000, but they must be precise to that extent. In comparatively few cases was the first requirement satisfied, and in these few there was lack of precision except in one or two cases. This, coupled with the fact that where the measurements were satisfying there were not enough of them in the dilute region to permit certain extrapolation to zero concentration, resulted in the securing of qualitative instead of quantitative information on values of $\bar{c}_{p_2}^\circ$ for additional salts.[15]

Using the data of Richards and Rowe,[15c,16] together with those here obtained, we find that the univalent positive ions can be arranged in the following order of decreasing (more negative) $\bar{c}_p^\circ$: Li^+, Na^+, K^+, H^+, Rb^+, Cs^+.

Combining the data of this work with those of Jauch[17] on potassium fluoride, we find the univalent negative ions in the following order of decreasing $\bar{c}_p^\circ$: F^-, Cl^-, Br^-, I^-.

The Jauch data also furnish the following qualitative information. In order of decreasing $\bar{c}_p^\circ$ we find Na^+, Mg^{++}, Al^{+++}. We also find $\bar{c}_p^\circ$ for Mg^{++} more negative than that for Be^{++}.

From the data of Cohen, *et al.*,[18] we find that $\bar{c}_p^\circ$ for Cd^{++} is more negative than for Zn^{++}.

The above information tells us that in any given group of the elements $\bar{c}_p^\circ$ becomes more negative as the atomic number increases and, in any given period, $\bar{c}_p^\circ$ becomes more negative as the charge on the ion increases.

The fact that H^+ does not fall into the regular order of the univalent positive ions indicates that it has some unique effect on the water molecules.

An ion at infinite dilution in water can be pictured as having oriented about it a number of water molecules (considered as electrical dipoles), some of which will be directly attached to the ion.[19] On this picture the partial molal heat capacity of the ion at infinite dilution will be the sum of three effects: $\bar{c}_p^\circ = A + B + C$, where A is the intrinsic heat capacity of the ion and has a positive value; B is the effect due to the breaking up of the ion hydrate (ion plus the directly attached water molecules) on the absorption of heat in the reaction: ion hydrate = ion + water molecules (for this reaction heat is absorbed and ΔH is positive; B has a positive value) and *C* is the effect that the charged body has on the heat capacity

---

[15] An example of the inadequacy of some of the specific heat data in giving proper values of $\bar{c}_{p_2}^\circ$ is the following: (a) Lewis and Randall (ref. 2, p. 86) give $\bar{c}_{p_2}^\circ$ for H_2SO_4 in aqueous solution as calculated from the specific heat data of (b) Biron, J. *Russ. Phys.-Chem. Soc.*, 31, 190 (1899), as 10.4 cal. From the specific heat data of (c) Richards and Rowe, THIS JOURNAL, 42, 1621 (1920), and of (d) Wrewsky and Kaigorodoff, Z. *physik. Chem.*, **112,** 83 (1924), and the heat of solution data at various temperatures of (e) Wrewsky and Sawaritzky, *ibid.*, 112, 92 (1924), one finds that $\bar{c}_{p_2}^\circ$ for HCl is about -34 cal. But $\bar{c}_{p_2}^\circ$ for NaCl is -23.3 cal. Hence $2\bar{c}_p^\circ(H^+) - 2\bar{c}_p^\circ(Na^+) = -21$ cal. Since $\bar{c}_{p_2}^\circ(Na_2SO_4)$ is -50 cal., $\bar{c}_{p_2}^\circ(H_2SO_4)$ should be about -71 cal.

[16] Richards and Rowe, THIS JOURNAL, 43, 770 (1921).

[18] (a) Cohen and Moesveld, Z. *physik. Chem., 95,* 305 *(1920);* (b) Cohen, Helderman and Moesveld, *ibid.,* 112, 135 (1924).

[19] Ghosh, *Trans. Faraday Soc.,* 15, 159 (1919).

of the water dipoles due to the restriction it places upon their motion, decreasing their capacity to absorb heating energy. (C has a negative value.)

Since $\bar{c}_p^{\circ}$ for all the ions here investigated is negative, A + B is less than C. Since $\bar{c}_p^{\circ}$ for K^+ is less than that for Na^+, and since A is very nearly the same for both Na^+ and K^+, then B + C is algebraically less (more negative) for K^+ than for Na^+. Since we should expect *C* to be more negative for the ion exerting the greatest electrical force upon the water molecules, then for ions of like charge *C* will be more negative for the smaller ion. Hence B must be greater for Na^+ than for K^+. This means that the temperature coefficient for the heat absorbed in the reaction

$$Na^+(H_2O)_{n_1} = Na^+ + n_1H_2O \tag{28}$$

is greater than that for the reaction

$$K^+(H_2O)_{n_2} = K^+ + n_2H_2O \tag{29}$$

This may be explained by assuming that n_1 is greater than n_2. This is in qualitative agreement with the data on the hydration of ions as given by various investigators.

Reverting to the unique effect observed in the case of H^+, we may postulate the formation of hydronium ion, H_3O^+, for which there is very good evidence from other sources. Effect *C* for H^+ will be large since it is reasonable to suppose that the intrinsic heat capacity of H_3O^+ is less than the sum of the intrinsic heat capacity of H_2O and that of H^+. This need not be a necessary argument in proving why $\bar{c}_p^{\circ}$ (H^+) is more negative than that for K^+ or Na^+, because Effect B will be less in the case of H_3O^+ since it will be larger and hence less hydrated than K^+ or Na^+.

Any consideration of the existence of $(H_2O)_2$ and $(H_2O)_3$ molecules as the molecular state of the water will not invalidate the foregoing arguments.

In the case of polyatomic ions, such as NO_3^- and SO_4^{--}, the configuration, as well as the charge and size, will play a predominant part in determining the value of $\bar{c}_p$".

Let us now consider the cause of the rapid increase in $\bar{c}_{p_2}$ with the concentration. This is obviously due to the fact that Effect C is becoming less negative as the concentration is increased because each ion is affecting fewer water molecules, or the effect per ion is less.

Another point to be considered is the almost linear relationship between $\bar{c}_{p_2}$ and $m^{1/2}$ throughout all the concentrations measured. For an electrolyte the logarithm of the activity coefficient can be approximately expressed in terms of the first two powers of $m^{1/2}$

$$\ln \gamma = Am^{1/2} + Bm \tag{30}$$

also

$$RT \ln \gamma = \bar{F}_2 - \bar{F}_2^{\circ} \tag{31}$$

Since $-(\bar{c}_{p_2} - c_{p_2}^{\circ})$ is $T\,\delta\,(\bar{F}_2 - \bar{F}_2^{\circ})/\delta T^2$ and if $\bar{c}_{p_2} - \bar{c}_{p_2}^{\circ}$ very nearly varies as $m^{1/2}$, this means that probably d^2B/dT^2 is zero. In other words, the physical properties which determine the value of B in the above equation have a temperature coefficient which is itself independent of the temperature.

For the data of Wrewsky and Kaigorodoff,[15d] who measured the specific heat of hydrochloric acid at various temperatures, and comparing Richards and Rowe's[16] 18° data with our 25° data we find that approximately $d\bar{c}_{p_2}°/dT$ is about 0.2 cal. per deg. around 25" for a uni-univalent electrolyte.

This agrees with the results of Randall and Ramage,[4] who found that in a dilute solution of sodium chloride, $\bar{c}_{p_2}$ increased with the temperature. This is in complete accord with the arguments presented here, since the polarizing and orienting effect of the ion upon the water molecules will decrease with increase in the kinetic energy of the dipoles.

From the values of $\bar{c}_{p_2}°$ obtained in this research, it can be stated definitely that for the reaction of dissolving one mole of a substance which is a strong electrolyte in a very large amount of water, AH will decrease with increase in temperature.

Given the reaction

$$MX(s) + n_1H_2O = M^+(m) + X^-(m) + n_1H_2O \qquad (32)$$

If n_1 is taken so large as to make the molality practically zero, we may write

$$MX(solid) = M^+(m = 0) + X^-(m = 0) \qquad (33)$$

Now we have shown that $\bar{c}_p°$ (M^+) + $\bar{c}_p°$ (X^-) is negative. Then $\Delta C_p = d\Delta H/dT$ is negative. Of course ΔC_p will be negative even though $\bar{c}_p°$ (M^+) + $\bar{c}_p°$ (X^-) be positive, provided the latter sum be less than the heat capacity of the solid.

In the case of a substance giving polyatomic ions, $\bar{c}_{p_2}°$ may be positive but will be less than the heat capacity of the pure substance. For very weak electrolytes, such as mercuric chloride and cadmium iodide, $\bar{c}_{p_2}°$ has a positive value which may be greater than the heat capacity of the solid.

In conclusion, we wish to express our thanks to Messrs. Jack Sherman, Albert Sherman and Bernard Weidenbaurn for their assistance in drawing Figs. 1 and 2, and in recalculating the specific heat data of other investigators; and to Mr. G. F. Nelson for building much of the apparatus.

Summary

The assembly of a calorimeter having a precision of greater than 0.1 per mille in measuring differentially the heat capacities of aqueous salt solutions is described, and a description of its calibration and method of operation for direct and for differential heat capacity measurements is given.

Methods of determining and calculating Φ, the apparent molal heat capacity of the solute, $\bar{C}_{p_2}$, the partial molal heat capacity of the solute, $\bar{C}_{p_1}$, the partial molal heat capacity of the solvent and the specific heat of the solution are given.

Tables and plots of the experimental data and tables of rounded values of Φ, $\bar{C}_{p_2}$, $\bar{C}_{p_1}$ and specific heat are given for the nitrates, chlorides, bromides, iodides and sulfates of sodium and potassium in aqueous solution from infinite dilution to 1.0 molal, and in some cases to 2.5 molal.

A theoretical equation for $\bar{C}_{p_2} - \bar{C}_{p_2}^{\circ}$ is derived on the basis of the Debye-Hückel theory of strong electrolytes in aqueous solution, and is compared with the experimentally determined values. ($\bar{C}_{p_2}^{\circ}$ refers to infinite dilution.)

The partial molal heat capacity of a given ion is shown to depend upon the charge, the size and the configuration of the ion. The partial molal heat capacities of ions are shown to be additive at infinite dilution.

The relation of the results obtained to hydration of ions and the temperature coefficient of the heat of solution of a strong electrolyte in a large amount of water is discussed.

THE REDUCTION OF PERMANGANATE ION BY CHROMIC ION IN ACID SOLUTION

BY H. A. FALES AND P. S. ROLLER[1]

RECEIVED AUGUST 8, 1928 PUBLISHED FEBRUARY 5, 1929

The peculiar nature of the reduction of permanganate ion in acid solution has long interested chemists. As early as 1866 Harcourt and Esson[2] in their study of the reduction of permanganate by oxalic acid observed that the reaction was autocatalytic and catalyzed by manganous ion, and that in the presence of the latter excess of oxalic acid slowed down the rate of oxidation. They imputed the catalytic effect to the formation of manganese dioxide in solution.

In 1903 the study of the reduction by oxalic acid was again undertaken by Schilow,[3] who endeavored to show that the autocatalysis was due to the interaction between the permanganate and a trivalent manganic oxalate complex, the primary reduction product.

The same reaction was next studied by Skrabal,[4] who observed a period

[1] This paper is constructed from a dissertation submitted by P. S. Roller in partial fulfilment of the requirements for the degree of Doctor of Philosophy at Columbia University.

[2] Harcourt and Esson, *Phil. Mag.*, 201 (1866).

[3] Schilow, *Ber.*, 36, 2735 (1903).

[4] Skrabal, *Z. anorg. Chem.*, 42, 1 (1905).

of comparatively rapid reduction which he called the induction period. In this period the interaction between the manganous ion which had been liberated in the so-called incubation period and the permanganate ion *induced* a rapid oxidation of the oxalic acid. In the presence of excess manganous ion, this author discovered the reaction to be unimolecular. This result was imputed to the unimolecular decomposition of the trivalent manganic ion complex already postulated by Schilow.

The work of Krutweig[5] shows that the reduction of permanganate by tartaric acid is exactly similar to that by oxalic acid; that the same holds true for lactic and citric acids is indicated by the recent work of Dey and Dhar.[6]

The tendency of trivalent manganic ion to enter into a complex compound with anions, particularly of organic acids, has been frequently affirmed. Salts of the manganic complex with malonic and oxalic acids have recently been prepared by Meyer and Schramm,[7] the compositions of the complex acids being $H_3[Mn(C_3H_2O_4)_3]$ and $H_3[Mn(C_2O_4)_3]$.

In order to obtain a clearer understanding of the mechanism of the reduction of permanganate ion, it seemed desirable to study the reduction in a medium free from the disturbing influence of complex compound formation between the trivalent manganic ion and the reductant. Chromic ion, which reduces permanganate ion in acid solution slowly at 25°, was chosen because as a metallic cation it met this requirement of non-complex formation.

Method of **Experiment and Analysis of Reaction Mixture.**—Experiments were conducted at 25.1°. After coming to temperature potassium chrome alum solution was rapidly pipetted into a prepared permanganate solution, which contained sulfuric acid and any other reagents whose effect was to be determined. (In the experiments with "MnO_2 dissolved in H_2SO_4," the MnO_2 in solution was formed by allowing $MnSO_4$ to interact with the prepared $KMnO_4$ solution for sixteen minutes before the addition of the chrome alum.)

The chrome alum and the sulfuric acid were in excess. The concentrations were: MnO_4^-, 0.00144 *M;* Cr^{+++}, 0.0227 *M;* H_2SO_4, 2.92 *M.* All other concentrations are expressed as a ratio of these.

At definite intervals of time, 25 cc. of the reaction mixture was rapidly pipetted into a solution consisting of 60 cc. of 1.2 M sulfuric acid and 25 cc. of 0.5 M potassium bromide. Free bromine was instantly liberated by the MnO_4^-, and was extracted by carbon disulfide purified according to the method of Allery.[8] The $Cr_2O_7^{--}$ which had been formed in the reaction was titrated electrometrically with 0.01 N ferrous sulfate.

---

To avoid reduction of the $Cr_2O_7^{--}$ by Br^- or by carbon disulfide, all analytical operations had to be carried out in the absence of sunlight.

The platinum electrode was steamed between titrations and occasionally immersed in cold cleaning mixture. All vessels were steamed before use.

The electrometric titration had to be completed with little delay and one might not run past the end-point, as the back titration was inaccurate.

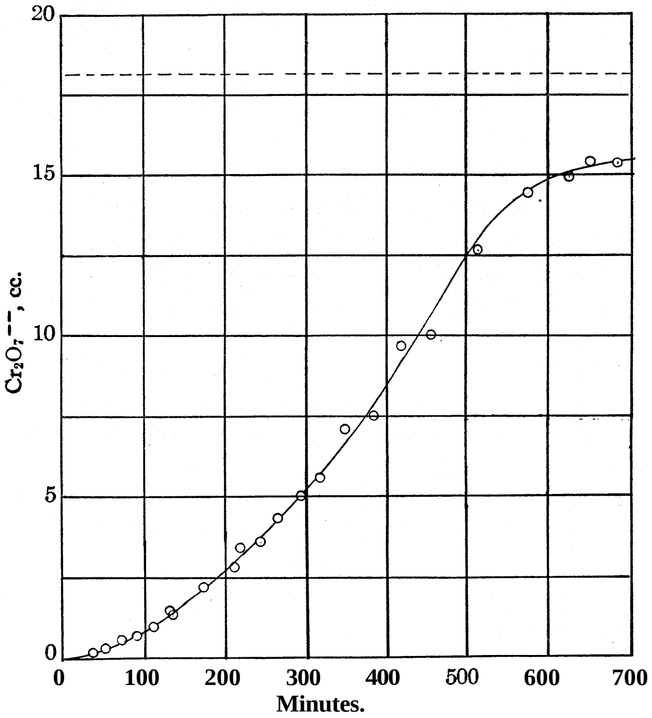

Fig. 1.—Reduction of MnO_4^- by Cr^{+++} in sulfuric acid solution at 25.1°.

The analysis of a series of prepared reaction mixtures showed the method to be accurate to ±0.05 cc. Check was frequently made on the analytical method.

It later occurred to the authors that it might be labor-saving to sweep out the dissolved bromine with air but this modification was not adopted in any of these experiments.

Reduction of MnO_4^- by Cr^{+++} in 2.92 M Sulfuric Acid Solution at 25.1°.—In Table I are given the results obtained in the direct reduction of MnO_4^- by Cr^{+++} ion. In the first column is the time in minutes from the instant that the chrome alum was added; in the second column is given the cc. of $Cr_2O_7^{--}$ (0.01 N) produced at the end of the corresponding time. The results of this table are plotted in Fig. 1.

Table I

Reduction of MnO_4^- by Cr^{+++} at 25.1°

Initial concentrations: MnO_4^-, 0.00144 *M*; Cr^{+++}, 0.0227 *M*; H_2SO_4, 2.92 *M*.

Minutes	$Cr_2O_7^{--}$, cc.	Minutes	$Cr_2O_7^{--}$, cc.	Minutes	$Cr_2O_7^{--}$, cc.
30.92	0.18	217.3	3.40	444.7	9.94
51.42	.30	241.1	3.65	513.2	12.70
71.42	.59	263.8	4.30	575.2	14.40
89.70	.72	293.2	4.97	625.5	14.78
110.1	.98	318.0	5.56	649.5	15.38
130.0	1.46	348.9	7.10	683.2	15.28
134.2	1.30	383.0	7.49	712.4	15.35
173.2	2.23	418.4	9.68	∞	18.20
209.9	2.78				

From the figure it is seen that the initial slow oxidation is rapidly autocatalyzed to an almost linear rate of oxidation. This rate finally falls off rather abruptly to a slow retarded rate of reaction at a point several cc. below the maximum degree of oxidation. There is a close resemblance between the results here obtained and those of Schilow[3] on the oxidation of oxalic acid.

From the change in the magnitude of the initial rate of oxidation with a change in the MnO_4^- and Cr^{+++} concentrations, the order of this reaction may be determined. A number of points were determined in the neighborhood of the origin, a smooth curve was drawn and the time required for a given degree of oxidation read off from the curve. The results for different initial MnO_4^- and Cr^{+++} ion concentrations are shown in Table II.

Table II

Order of the MnO_4^-–Cr^{+++} Reaction in Sulfuric Acid Solution

Relative MnO_4^- concentration	1	2	1
Relative Cr^{+++} concentration	1	1	0.5
$Cr_2O_7^{--}$, cc.	Minutes	Minutes	Minutes
0.1	23	11	40
.2	36	18	70
.4	58	32	113
.6	77	44	148

It is seen from Table II that doubling the MnO_4^- concentration doubles the initial rate of oxidation, while decreasing the Cr^{+++} concentration by one-half produces a corresponding decrease in the initial rate. The order of the reaction between MnO_4^- and Cr^{+++} with the latter in excess is therefore bimolecular and, since the oxidation of the Cr^{+++} is presumably to the hexavalent state, the reaction may be represented by the following equation, in which the reduction of MnO_4^- is to the tetravalent Mn.

$$MnO_4^- + Cr^{+++} = CrO_4^{--} + Mn^{++++} \qquad (1)$$

The effect on the reaction between MnO_4^- and Cr^{+++} of changing the concentration of the sulfuric acid was determined in the same way. The results are shown in Table III.

TABLE III

EFFECT OF SULFURIC ACID ON THE MnO_4^--Cr^{+++} REACTION

Relative sulfuric acid concentration	1	0.6
$Cr_2O_7^{--}$, cc.	Minutes	Minutes
0.1	23	21
.2	36	30
.4	58	44
.6	77	54

From Table III it is seen that reducing the sulfuric acid concentration by one-half produces little effect on the rate of oxidation initially. Neglecting the purely ionic effects of changing the sulfuric acid concentration, this result is in accordance with the reaction expressed by Equation 1, since the hydrogen-ion concentration does not enter. As the oxidation proceeds, the effect of decreasing the acidity becomes more and more marked, resulting in an increase in the rate of oxidation. This is due to the strong effect of acid on the autocatalysis.

Oxidation of Cr^{+++} by Manganese Dioxide Dissolved in Sulfuric Acid.—As already indicated, by manganese dioxide dissolved in sulfuric acid we mean the mixtures obtained on adding Mn^{++} to MnO_4^- in acid solution. In the course of the oxidation of Cr^{+++} by MnO_4^- the products of the interaction between MnO_4^- and Mn^{++} will be present in solution. Since the oxidation rate of these products exceeds that of the permanganate itself, it was important, in order to obtain an insight into the nature of the permanganate reduction by chromic ion, to study their oxidation properties. To do this we measured the oxidation rate of mixtures of MnO_4^- and Mn^{++}, obtained by adding the latter to the former contained in sulfuric acid solution, such as would virtually be present in the course of the reduction of the MnO_4^- ion.

20.27	5.58	111.9	11.20		

The results which were obtained for different ratios of Mn^{++} to MnO_4^- are shown in Tables IV, V and VI, and are also plotted in Fig. 2 as Curves A, B and C, respectively.

In Curves A, B and C of Fig. 2, where the ratios of Mn^{++} to MnO_4^- are 0.42, 2.11 and 4.22, respectively, the initial rate of oxidation of the Cr^{+++} is seen to increase with increase in the ratio. On the contrary, the extent of oxidation after a sufficient period of time is greater in inverse order. This is seen to be due to the fact that the initial rate of oxidation falls off more rapidly the higher the ratio of Mn^{++} to MnO_4^-. Indeed, at a ratio 0.42 the curve is linear up to 14 cc. of $Cr_2O_7^{--}$, and at a ratio of 2.11 it is linear up to 6 cc. of $Cr_2O_7^{--}$.

An interpretation of these results throws considerable light on the question of the relationship of MnO_4^- to its ions of lower valence and their relative oxidizing characteristics.

Interaction between MnO_4^- and the Mn^{++} which has been added leads to the formation in acid solution of the trivalent Mn^{+++} ion and the tetravalent Mn^{++++} ion. Since these oxidize Cr^{+++} more rapidly than MnO_4^- itself, the reason for the increase in the initial rate of oxidation with increase in the ratio (up to 4.22) is understood.

The presence of excess MnO_4^- accounts for the initial linear rate of oxidation shown in Curves A and B. In the course of the oxidation the excess MnO_4^- interacts rapidly with the Mn^{++} which has been liberated to regenerate the reactive Mn^{+++} and Mn^{++++} and, indeed, since the rate is linear, in practically the same proportions in which they had originally been present.

The proportion of Mn^{+++} and Mn^{++++} may be estimated from the degree of linearity of the Curves A and B. Considering the latter, where the ratio of Mn^{++} to MnO_4^- is 2.11, the linearity extends over a period of 6 cc. of $Cr_2O_7^{--}$. Since this corresponds to the excess MnO_4^-, we find that the fraction of the total MnO_4^- which has been unacted on by the Mn^{++} added is, since 18.2 cc. of $Cr_2O_7^{--}$ corresponds to the complete reduction of the MnO_4^- to Mn^{++}, $^6/_{18.2}$, or close to $^1/_3$.

Let x be the number of moles of Mn^{+++} which has been formed, and a the initial total number of moles of MnO_4^-. The ratio of Mn^{++} to MnO_4^- being 2.11, and $^2/_3$ of the total MnO_4^- having interacted, the concentration of the Mn^{++++} which has been formed is $(2.78\,a - x)$. Since 5 Mn^{+++} is formed per mole of MnO_4^- and 5 Mn^{++++} for every 2 moles of MnO_4^- which have interacted, the follawing equation which accounts for the loss of MnO_4^- holds true

$$\frac{1}{5}x + \frac{2}{5}(2.78\,a - x) = 0.63\ a \tag{2}$$

Solving this equation for x, we obtain $x = 2.20$ a, $(2.78\,a - x) = 0.58$ a. Consequently, in this solution the Mn^{+++} is present to the extent of 79%, the Mn^{++++} to the extent of 21%.

Grube and Huberich[8] have measured the equilibrium between Mn^{++}, Mn^{+++} and Mn^{++++} in sulfuric acid solution. Mn^{+++} dissociates into Mn^{++++} and Mn^{++} according to the following equation

$$2\,Mn^{+++} = Mn^{++++} + Mn^{++} \tag{3}$$

The degree of dissociation is found to be augmented by a decrease in acidity due to the hydrolysis of the Mn^{++++} to MnO_3^{--}. Extrapolation from the results of these authors shows that at 2.92 M sulfuric acid the dissociation should be perhaps 80%. In the presence of MnO_4^- it should indeed be greater.

The preponderance of Mn^{+++} which we have shown to be present indicates that the interaction between MnO_4^- and Mn^{++} at a ratio of 2.11 leads to the initial formation of a large percentage of the trivalent Mn^{+++}, which having been formed dissociates but slowly into Mn^{++++}. This slow dissociation is probably due at least partly to the reversing action of the Mnf +++ present.

The Oxidation Properties of Mn^{+++} and Mn^{++++}.—To determine which of these ions oxidizes Cr^{+++} more rapidly, it is necessary to measure the initial rate after a known change in the proportion of the Mn^{+++} to Mn^{++++}. Now decreasing the acidity causes a shift to the formation of Mn^{++++}, manganese dioxide eventually being precipitated during the course of the oxidation if the acidity has been sufficiently decreased, say from 2.92 M sulfuric acid to 1.46 M sulfuric acid.

Under conditions corresponding to the results expressed in Table V and Curve B, Fig. 2, but with the acidity decreased by a fraction, the initial linear rate of oxidation was measured. The results are shown in Table VII, where the usual sulfuric acid concentration, 2.92 *M*, is expressed as unity.

TABLE VII

EFFECT OF CHANGING THE SULFURIC ACID CONCENTRATION ON THE OXIDATION BY MANGANESE DIOXIDE DISSOLVED IN SULFURIC ACID

Relative sulfuric acid concentration	1	0.8	0.65	0.5
Linear rate of oxidation, cc. of $Cr_2O_7^{--}$/min.	0.238	0.332	0.348	0.396

---

[9] Grube and Huberich, *Z. Elektrochem.*, **29**, 8 (1923).

That the tetravalent Mn^{++++} oxidizes the Cr^{+++} more rapidly is seen from the fact that decreasing the sulfuric acid concentration results in an increase in the rate of oxidation.

The slow but continuous dissociation of Mn^{+++} into Mn^{++++} in its approach to the equilibrium concentration is demonstrated by increasing the period of incubation between the MnO_4^- and Mn^{++} previous to adding the Cr^{+++}. The results are shown in Table VIII, where it is seen that increasing the incubation period results in an increase in the rate of oxidation.

Table VIII

Effect of Changing the MnO_4^-–Mn^{++} Incubation Period

Incubation period, minutes	4	16	24	32
Linear rate of oxidation, cc. of $Cr_2O_7^{--}$/min.	0.228	0.238	0.250	0.268

The tendency of Mn^{+++} to enter into complex ion formation with anions is well known. If it exists in complex formation with sulfuric acid, so that the dissociation of the Mn^{+++} into Mn^{++++} and Mn^{++} is preceded by its liberation from the complex, this should be reflected in a greater increase in the initial rate for a given increase in the incubation period when the sulfuric acid concentration is diminished.

Table IX

Effect of Changing the MnO_4^-–Mn^{++} Incubation Period—Sulfuric Acid Concentration Reduced by One-Half to 1.46 M

Incubation period, minutes	8	18
Linear rate of oxidation, cc. of $Cr_2O_7^{--}$/min.	0.294	0.396

Comparing the results of Table IX with those of Table VIII, it is seen that at the lower acidity the effect of changing the incubation period is considerably more marked.

Müller and Koppe[10] and Holluta and Obrist[11] have shown that in the presence of fluoride ion the reaction between MnO_4^- and Mn^{++} goes completely to the formation of a trivalent manganic fluoride complex. In Table X are given the results obtained in the oxidation of Cr^{+++} by this complex formed by adding NaF to the MnO_4^- before the addition of excess Mn^{++}.

Table X

Effect of Fluoride Ion on the Oxidation of Cr^{+++} Ion by Manganese Dioxide Dissolved in Sulfuric Acid

$Mn^{++}/MnO_4^- = 4.22$. $F^-/Mn^{+++} = 4.04$

Minutes	10.62	20.62	40.73
$Cr_2O_7^{--}$ cc.	2.19	3.56	5.48

---

[10] Müller and Koppe, *Z. anorg. Chem.*, 68,160 (1910).

[11] Holluta and Obrist, *Monatsh.*, 41, 555 (1920).

Comparing the results of this table with those of Table VI, where the Mn^{++}/MnO_4^- ratio is also 4.22, it is seen that the rate of oxidation due to the fluoride ion complex is two-thirds that in the absence of fluoride ion. Such a small diminution in the rate leads again to the conclusion that in a 2.92 *M* sulfuric acid solution we have present primarily the $Mn^{+++}\cdot H_2SO_4$ complex rather than the free Mn^{+++}.

The Relative Proportion of Mn^{+++} and Mn^{++++} in Manganese Dioxide Dissolved in Sulfuric Acid.—In 2.92 M sulfuric acid, the addition of 2.11 moles of Mn^{++} per mole of MnO_4^- at 0.00144 M concentration leads as we have seen to the formation of 79% Mn^{+++} and 21% Mn^{++++}. How this proportion is affected by a change in the ratio can be determined by reference to Curve C, Pig. 2, where the ratio is only 0.42.

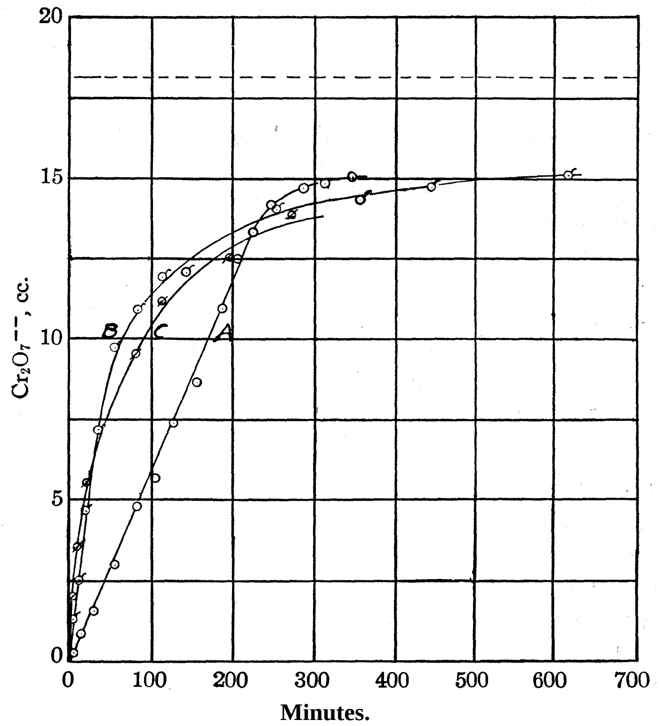

Fig. 2.—Oxidation of Cr^{+++} by manganese dioxide dissolved in sulfuric acid at 25.1°. Curve A, Mn^{++}/MnO_4^- = 0.42; Curve B, Mn^{++}/MnO_4^- = 2.11; Curve C, Mn^{++}/MnO_4^- = 4.22.

Here the curve is linear up to 14 cc. of $Cr_2O_7^{--}$. By the same method of calculation previously employed, it is found that the percentages are here, 22% Mn^{+++}, 78% Mn^{++++}. Thus it is seen that with a decrease in the ratio of Mn^{++} to MnO_4^- there is a large increase in the proportion of Mn^{++++} to Mn^{+++}.

The Interaction between Mn^{++} and Mn^{++++}, and the Mechanism of the Oxidation by Mn^{+++}.—The magnitude of the interaction between Mn^{++} and Mn^{++++} to give Mn^{+++} may be inquired into by determining the effect of excess Mn^{++} on the rate of oxidation of Cr^{+++} by MnO_2 in sulfuric acid. For if Mn^{++} reduces the Mn^{++++} to the less reactive Mn^{+++} ion, its effect in excess would be to diminish the rate of oxidation of the Cr^{+++} to $Cr_2O_7^{--}$.

We will first set down the results obtained on the addition of Zn^{++} and Fe^{+++} ions. Zinc sulfate and ferric sulfate were added to the MnO_4^- in sulfuric acid previous to the addition of the Mn^{++}, the Cr^{+++} then being added in the usual way.

TABLE XI*a*

EFFECT OF Zn^{++} ON THE OXIDATION OR Cr^{+++} ION BY MANGANESE DIOXIDE DISSOLVED IN SULRURIC ACID

$Mn^{++}/MnO_4^- = 2.11$

Ratio of Zn^{++}/Mn^{++++}	0.0	0.063	0.31	0.92
Linear rate of oxidation, cc. of $Cr_2O_7^{--}$/min.	0.238	0.315	0.285	0.290

TABLE XI*b*

EFFECT OF Fe^{+++} ON THE OXIDATION OR Cr^{+++} ION BY MANGANESE DIOXIDE DISSOLVED IN SULFURIC ACID

$Mn^{++}/MnO_4^- = 2.11$

Ratio of Fe^{+++}/Mn^{++++}	0.0	0.023	0.24
Linear rate of oxidation, cc. of $Cr_2O_7^{--}$/min.	0.238	0.280	0.300

In Tables XI*a* and XI*b* the concentrations of the Zn^{++} and Fe^{+++} are expressed as their ratio in moles to the Mn^{++++} that would be present if the latter alone were formed by interaction between MnO_4^- and Mn^{++}. It is seen that a slight addition of Zn^{++} or Fe^{+++} cation produces an increase in the linear rate of oxidation. Further addition of these cations produces but little increase in the rate.

Having thus determined what the effect of Mn^{++} should be in its capacity as a cation, we set down in Tables XIIa and XIIb the results which

TABLE XIIa

EFFECT OB EXCESS Mn^{++} ON THE OXIDATION OF Cr^{+++} ION BY MANGANESE DIOXIDE DISSOLVED IN SULFURIC ACID

MnO_4^- concentration, 0.000576 *M*

Ratio of Mn^{++}/MnO_4^-	2.1111	7.38/1	15.8/1
Cc. of $Cr_2O_7^{--}$ after ten minutes	0.626	0.473	0.306

TABLE XIIb

EFFECT OF EXCESS Mn^{++} ON THE OXIDATION OR Cr^{+++} ION BY MANGANESE DIOXIDE DISSOLVED IN SULFURIC ACID

MnO_4^- concentration, 0.000288 M

Ratio of Mn^{++}/MnO_4^-	2.11/1	10.5/1
Cc. of $Cr_2O_7^{--}$ after ten minutes	0.225	0.108

were obtained with Mn^{++} in excess. The degree of oxidation after ten minutes is recorded against the ratio of Mn^{++} to MnO_4^-.

The effect of Mn^{++} in ratio greater than 4, contrary to the effect of the Zn^{++} and Fe^{+++} cations, is a progressive decrease in the oxidation rate as the ratio is increased.

We have already seen that the apparent oxidation rate of Mn^{++++} is greater than that of Mn^{+++}. The above results with Mn^{++} ion in excess can be explained then on the basis of a greater interaction between Mn^{++++} and the excess Mn^{++} to give the Mn^{+++} ion, as expressed in Equation 3.

Whence does the Mn^{++++} ion arise? This question is pertinent since we have seen that the greater the initial ratio of Mn^{++} to MnO_4^- the greater the proportion of Mn^{+++} which is formed. At a ratio exceeding 4, we should expect the formation solely of Mn^{+++}.

On this basis, the Mn^{++++} which interacts with the excess Mn^{++} comes from the subsequent dissociation of the Mn^{+++} initially formed. It thus appears that the oxidation of Cr^{+++} by Mn^{+++} is at least in part indirect, taking place in virtue of its dissociation into the reactive Mn^{++++}. The apparent oxidation rate of the Mn^{+++} decreases in the presence of excess Mn^{++} due to the greater reversal of this dissociation.

The potential of Mn^{+++} against Mn^{++} in 4.55 M sulfuric acid, decreasing with the acidity, is given by Grube and Huberich[8] as 1.503 v. Landolt-Bornstein "Tabellen," 1923, cite the normal electrode potential of $HCrO_4^-$ against Cr^{+++} as 1.3 v. The closeness of these values makes it appear likely that the oxidation of Cr^{+++} by Mn^{+++} is entirely indirect. Assuming this to be the case, the mechanism of the oxidation by the trivalent manganese is as follows.

$$\text{I} \quad Mn(HSO_4)_3 \text{ [complex]} \rightleftarrows Mn^{+++} + 3HSO_4^-$$

$$\text{IIa} \quad Mn^{+++} + Mn(HSO_4)_3 = Mn^{++++} + Mn^{++} + 3(HSO_4)^-$$

$$\text{IIb} \quad 2\,Mn^{+++} = Mn^{++++} + Mn^{++}$$

$$\text{III} \quad Mn^{++++} + Mn^{+++} + Cr^{+++} + 4H_2O = CrO_4^{--} + 2Mn^{++} + 8H^+$$

In Stage I we have the disengagement of the Mn^{+++} from its complex with the sulfuric acid. In Stages IIa and IIb the Mn^{+++} dissociates to form Mn^{++++}. In the third stage the Mn^{++++} oxidizes the Cr^{+++}, in conjunction with Mn^{+++}.

Skrabal[4] assumed that the rate of oxidation of oxalic acid in the presence of excess Mn^{++} was determined by the rate of dissociation of the Mn^{+++} ion from its oxalic acid complex. This rate of dissociation he found to be unimolecular. Dey and Dhar[6] found the oxidation of lactic and citric acids by the trivalent manganese also to be unimolecular.

If in accordance with these results we assume the rate of oxidation of Cr^{+++} in excess to be determined by the rate of the unimolecular disengagement of Mn^{+++} from its sulfuric acid complex we have

$$\frac{dx}{dt} = k_1 (a - x) \tag{4}$$

x is here the equivalent concentration of $Cr_2O_7^{--}$, a is the initial equivalent (or molar) concentration of Mn^{+++}, while $(a - x)$ is the molar concentration of the trivalent manganese at any instant.

Now the above equation is strictly true only when the tetravalent manganese, whose concentration is negligible against the trivalent manganese, is used up solely in its reduction by the Cr^{+++}. However, a fraction of it is reduced to Mn^{+++} by the excess manganous ion according to **(3)** as we have shown.

Let b represent the initial molar excess of Mn^{++}, so that $b + x$ is the concentration of Mn^{++} at any instant.

The rate of reduction of Mn^{++++} by Mn^{++} is given by the equation

$$R_1 = k_3\, Mn^{++++} (b + x) \tag{5}$$

The rate of reduction of Mn^{++++} by the Cr^{+++} in excess is, according to Stage III above, given by

$$R_2 = k_2\, Mn^{++++} (a - x) \tag{6}$$

From (5) and *(6)* the fraction of the Mn^{++++}, formed by the dissociation of the Mn^{+++}, which is reduced by the Cr^{+++} as against reduction by the Mn^{++} is

$$F = \frac{kt\,(a - x)}{(k_3b + k_2a) + (k_3 - k_2)x} \tag{7}$$

To take this reducing action of Mn^{++} into account a correction must be made to Equation 4 such that it is multiplied by the fraction F. We thus obtain finally for the rate of formation of $Cr_2O_7^{--}$

$$\frac{dx}{dt} = \frac{k_a\,(a - x)^2}{(k_b + x)} \tag{8}$$

where

$$k_a = \frac{k_1k_2}{k_3 - k_2} \tag{9}$$

$$k_b = \frac{k_3b + k_2a}{k_3 - k_2} \tag{10}$$

This equation may be integrated and reduced to the form given by (11), where K_2 and K_1 represent a bi- and unimolecular velocity constant, respectively

$$(k_b + a)K_2 - Kt = k_a \tag{11}$$

If we plot K_1 against K_2 we should by Equation *11* obtain a straight line whose slope is $(k_b + a)$ and whose intercept is k,. From the smoothed data of Table VI, K_2 and K_1 were calculated and plotted against each other as shown in Fig. **3.** **A** straight line is obtained with a slope of **23.0** and intercept *—0.0088.* With a = 18.2 cc., this gives $k_a = 0.0088$ and $k_b = 4.8$. Solving for k_3/k_2 and for k_1 by Equations 9 and *10,* with $b = 0.73$, we obtain $k_3/k_2 = 5.61$ and $k_1 = 0.0406$. The specific rate of reduction of Mn^{++++} by Mn^{++} is thus 5.61 times as great as that by Cr^{+++} in excess, while the constant for the unimolecular decomposition at 25° of the complex, $Mn(HSO_4)_3$, is 0.0406.

At 35.0' the results obtained in the oxidation of Cr^{+++} by Mn^{+++} are shown in Table XIII.

TABLE XIII

OXIDATION OR Cr^{+++} BY MANGANESE DIOXIDE IN SULFURIC ACID AT 35.0°

Ratio of Mn^{++}/MnO_4^- = 4.22. MnO_4^- = 0.001440 M

Minutes	4.00	9.55	19.90	35.00	56.95	89.42	149.3
$Cr_2O_7^{--}$, cc.	4.90	7.62	10.11	12.11	13.69	14.78	15.70

Calculation from the straight line obtained in plotting K_1 against K_2 (Fig. 4) shows that at 35.0' k_3/k_2 = 4.37, k_1 = 0.163. The temperature coefficient of the unimolecular decomposition of the complex $Mn(HSO_4)_3$ is therefore 4.01.

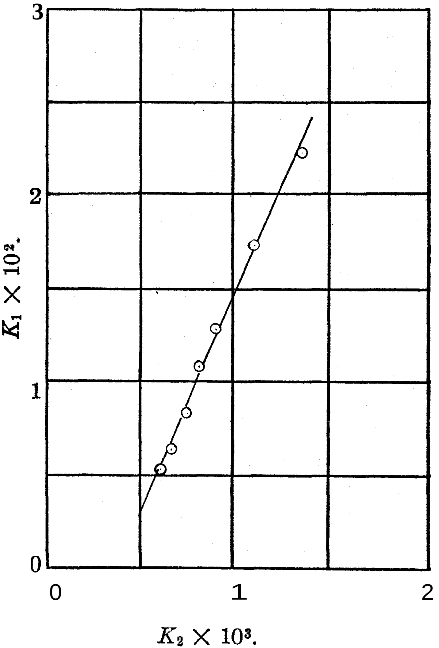

Fig. 3.—Oxidation of Cr^{+++} by manganese dioxide dissolved in sulfuric acid at 25.1°. Mn^{++}/MnO_4^- = 4.22.

Order of the Oxidation by Manganese Dioxide Dissolved in Sulfuric Acid.—In the oxidation by manganese dioxide in sulfuric acid solution the order of the reaction with respect to Cr^{+++} is unity as is seen from the data of Table XIV.

The initial linear rate of oxidation is here 0.011 cc./min. as against 0.024 cc./min. when the Cr^{+++} concentration is twice as great (Table V).

In the presence of a mixture of tri- and tetravalent manganese we should expect in accordance with Stage III of the above reaction a bimolecular oxidation of the Cr^{+++} (in excess). Keeping the ratio constant at 2.11, where, at MnO_4^- = 0.00144 *M*, we have 79% of Mn^{+++}, 21% of Mn^{++++}, the initial linear rate of oxidation was measured with varying MnO_4^- concentration. The results are shown in Table XV.

TABLE XIV

OXIDATION OR Cr^{+++} BY MANGANESE DIOXIDE IN SULFURIC ACID AT 25.1°

Cr^{+++} concentration reduced by $^1/_2$. Ratio of Mn^{++}/MnO_4^- = 2.11

Minutes	6.25	18.12	38.08	69.62	140.2	221.9	328.8	442.4
$Cr_2O_7^{--}$, cc.	0.60	1.84	4.74	7.94	10.48	11.97	13.10	13.80

TABLE XV

INITIAL LINEAR RATE OF OXIDATION WITH CHANGE IN THE MANGANESE DIOXIDE CONCENTRATION

Relative manganese dioxide concentration	2.0	1.0	0.4	0.2[a]
$Cr_2O_7^{--}$, cc./min.	0.665	0.238	0.060	0.021

[a] The Mn^{++} remained in contact with the MnO_4^- for forty-five instead of the usual sixteen minutes.

If we plot the log of the rate of oxidation against the relative concentration, we obtain very closely a straight line whose slope is 1.5. This is therefore the apparent order of the oxidation of Cr^{+++} in excess by a mixture of the tri- and tetravalent manganese.

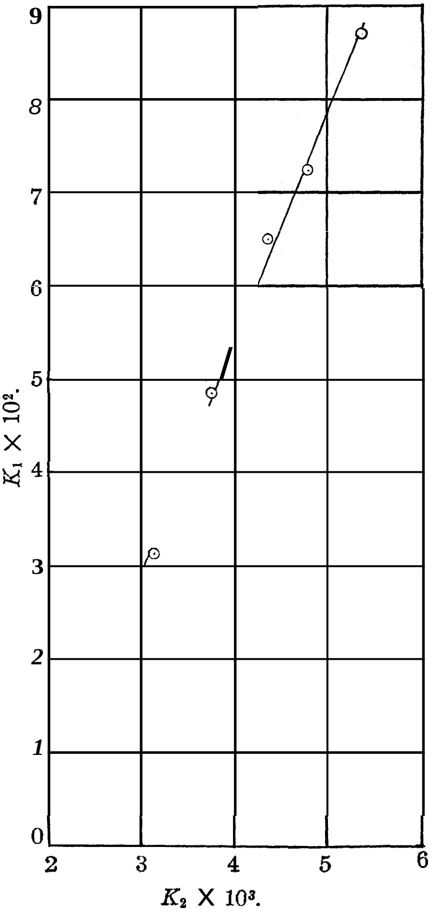

Fig. 4.—Oxidation of Cr^{+++} by manganese dioxide dissolved in sulfuric acid at 35.0°. $Mn^{++}/MnO_4^- = 4.22$.

Now we have already observed that decreasing the concentration of Mn^{++} relative to MnO_4^- results in a shift in the proportion of Mn^{++++} to Mn^{+++} in favor of the tetravalent ion. The apparent fractional order of reaction found above can be explained on the basis of a similar shift with a decrease in the initial Mn^{++} concentration, though here the MnO_4^- concentration also changes.

Properties of the Reduction of MnO_4^- in Acid Solution.—We have shown that the oxidation by MnO_4^- in acid solution is accompanied by the oxidation due to the direct action of the tetravalent and the indirect action of the trivalent manganese. MnO_4^- itself oxidizes Cr^{+++} very slowly at 25°; Mn^{++++} oxidizes it rapidly. The action of Mn^{+++} takes place in virtue of its unimolecular disengagement from a complex compound with sulfuric acid with subsequent dissociation into Mn^{++++}. The latter is responsible for the oxidation of the Cr^{+++}. Mn^{++} reduces Mn^{++++} to the trivalent state. Thus the oxidation of Cr^{+++} by Mn^{+++} is retarded in proportion to the excess Mn^{++} present.

Since, ultimately, only Mn^{+++} in its usual complex form and an increasing excess of Mn^{++} are present, the marked end retardation observed in the oxidation of Cr^{+++} by MnO_4^- is explained.

We have shown that the interaction between Mn^{++} and MnO_4^- in 2.92 *M* sulfuric acid leads initially to the formation of Mn^{+++} and Mn^{++++}. The proportion of the latter is increased at a fixed MnO_4^- concentration by decreasing the Mn^{++} concentration.

On this basis, in the course of the oxidation of Cr^{+++} by MnO_4^-, the Mn^{++} which is first liberated forms the reactive Mn^{++++}. As the concentration of Mn^{++} tends to build up relative to the MnO_4^-, more and more of the trivalent manganese is formed, thus slowing up the autocatalysis until finally, since it alone is present, its own slow oxidation rate is measured.

The results obtained here in the reduction of MnO_4^- by Cr^{+++} show in several respects a striking similarity to the reduction by oxalic, tartaric and citric acids, etc. The chief difference lies in the fact that here the Mn^{+++} forms a complex with sulfuric acid, while there it forms a complex which is probably more stable with the reducing agent itself. By assuming as above an indirect oxidation by the Mn^{+++} complex and a very rapid oxidation by the Mn^{++++}, the properties of the permanganate reduction by these organic acids may be readily explained. In particular the so-called induction observed by Skrabal[4] in the oxidation of oxalic acid can be accounted for by the formation in the presence of slight amounts of Mn^{++} of the highly reactive Mn^{++++} by interaction between MnO_4^- and Mn^{++}.

Summary

The reduction of MnO_4^- by Cr^{+++} at 25.1° in sulfuric acid solution is autocatalytic and resembles closely the reduction by numerous organic acids, such as oxalic acid.

A study of the mechanism of the reaction reveals the presence of Mn^{++++} and of Mn^{+++} which is contained in a sulfuric acid complex. Oxidation by the latter is indirect in virtue of its unimolecular disengagement from the complex and its subsequent decomposition into Mn^{++++}, which oxidizes Cr^{+++} rapidly. The temperature coefficient between 25 and 35° of the unimolecular reaction is 4.01. Mn^{++++} also reacts with Mn^{++}, thus reverting to the non-reactive Mn^{+++}.

In the interaction between Mn^{++} and MnO_4^- in acid solution, the relative proportion of Mn^{++++} to Mn^{+++} increases with decrease in the ratio of Mn^{++} to MnO_4^-.

THE SOLUBILITY OF CALCIUM SULFATE FROM 0 TO 200°

BY EVERETT P. PARTRIDGE[1] AND ALFRED H. WHITE[2]

RECEIVED AUGUST 11, 1928 PUBLISHED FEBRUARY 5, 1929

The Literature on the Solubility of Calcium Sulfate

A search of the literature, complete up to May, 1928, covering references to the solubility of any of the various forms of calcium sulfate, was made and the original data abstracted from these articles were compared. Such as seemed significant have been utilized in conjunction with the determinations described in the present paper.

For the purposes of this paper all concentrations have been expressed in parts of $CaSO_4$ per million parts of solution. Conversion from original data has been carried out with the use of the density measurements of Hulett and Allen[3] on calcium sulfate solutions, although in view of the low solubilities encountered this is a refinement well within the experimental error.

The Solubility of Gypsum.—The lower curve of Fig. 1 represents the solubility of gypsum as determined by the values of Raupenstrauch,[4] Hulett and Allen,[3] Melcher,[5] and Cavazzi.[6] The excellent agreement of the four sets of data is checked by individual determinations at various temperatures made by other recent investigators.

It should be noted here that Raupenstrauch has never received the credit due him for the first accurate determination of the gypsum solubility curve. His article antedates the well-known and equally excellent work of Hulett and Allen by seventeen years but it has been quite generally ignored.

The Solubility of Calcium Sulfate Hemihydrate.—Marignac,[7] Potilitzin[8] and Cavazzi[6] found the solubility of dehydrated gypsum at room temperature to be approximately five times that of fully hydrated gypsum. That these values represent the solubility of calcium sulfate hemihydrate

calcium sulfate exist and that "soluble anhydrite," long a mystery, possesses the crystal structure of calcium sulfate hemihydrate. Evidence confirming this statement will be presented in the near future by Ramsdell and Partridge in a crystallographic study of the forms of calcium sulfate produced at various temperatures between 100 and 200° in contact, respectively, with water and with dry air. Additional circumstantial evidence will be shown in the present article from the fact that the solubility curve for hemihydrate below 100° found by Chassevent is continuous with the solubility curve above 100" previously ascribed to "soluble anhydrite."

Fig. 2.—Solubility of gypsum, hemihydrate and anhydrite from 100 to 220° C. expressed in parts per million of $CaSO_4$.

When gypsum is the initial solid phase in contact with water, the solubility at temperatures above 100" is shown by the upper curve of Fig. 2, which is determined by the data of Boyer-Guillon,[12] Melcher[5] and Hall, Robb and Coleman[13] on "soluble anhydrite," and of the authors of this paper on calcium sulfate hemihydrate. The less accurate values of Tilden and Shenstone[14] are also shown.

This solubility curve for hemihydrate intersects that for gypsum at a temperature of approximately 98°, which is in excellent accord with the observation made by Davis,[15] and checked by the authors of this paper, that gypsum crystals in contact with water at 100° are gradually converted to hemihydrate.

The **Solubility of Anhydrite.**—Melcher[5] calculated the solubility of anhydrite at **100, 156** and 218° from conductivity measurements carried out with solutions of calcium sulfate in a platinum-lined bomb, using as solid phase either an initial addition of anhydrite or anhydrite formed from an initial addition of gypsum by maintaining the bomb at 218° for several hours. Hall, Robb and Coleman[13] made a series of direct determinations in a small laboratory boiler, using solutions of calcium sulfate in contact with a solid phase of anhydrite prepared by burning gypsum at a dull red heat in a muffle furnace for several hours. The dotted line of Fig. **2** is determined by the average values of the individual determinations of the latter investigators, while the bottom curve, determined by the authors of this paper, passes through the points found by Melcher.

Experimental Work

General Method.—Solubility values at intervals in the temperature range 100–200° were obtained by analysis of the sulfate content of samples removed from an experimental boiler housed in a thermostat which could be maintained for any desired period of time at a temperature constant to within **0.5".** This boiler was initially charged for each series of determinations with **10** liters of **a** solution of calcium sulfate saturated with gypsum at room temperature, to which solution was added **10** g. of precipitated gypsum powder. Solution samples were removed through a filter within the boiler and were cooled to **14–16'** in a cooling coil while still subjected to boiler pressure. The sulfate concentration of these samples was found gravimetrically by precipitation as barium sulfate.

Apparatus.—A photograph of the experimental boiler unit used in the authors' work is shown in Fig. 3. **This was used for the solubility work here described and also for a series of scale formation tests which will be described in the future. For the determinations of solubility the unit consisted essentially of the *boiler* proper, suspended within an *air thermostat,* fed by *a* small pump, and equipped with an *internal filter* connected to a *cooling coil* outside of the thermostat.**

The *boiler* was a two-foot length of six-inch steam pipe. fitted with companion flanges. The boiler feed line and an exhaust line were tapped into the top flange, while the bottom flange carried a special plug which served to introduce the internal filter and to make connection between this filter and the external cooling coil.

The *air thermostat* was made of sheet steel with two spaced linings of transite to cut down heat radiation. It was heated by Chromel A resistance coils and rapid circulation of the air was maintained by a motor-driven fan. The temperature of the thermostat was controlled by a mercury column, the expansion of which operated a relay controlling the current through the heating coils. The fluctuation of the thermostat air temperature was rapid and was less than 0.5°. Such a fluctuation was considered negligible in view of the relatively great heat capacity of the boiler and its contents.

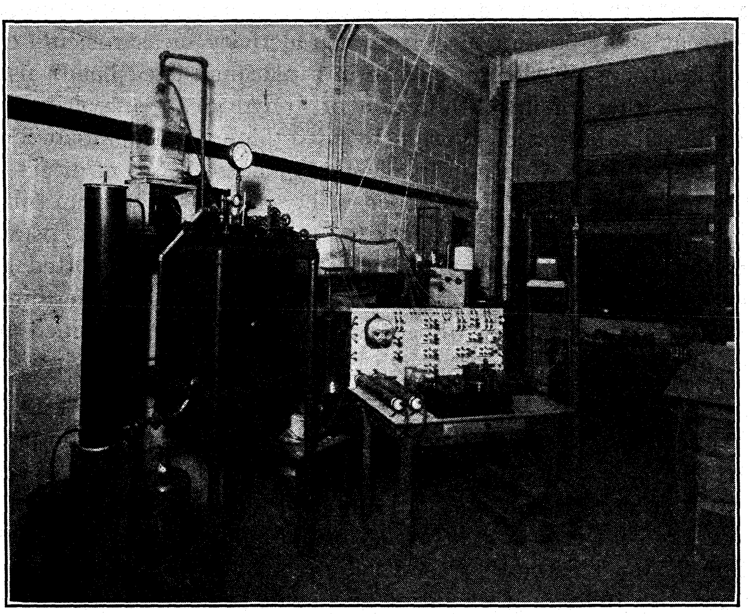

Fig. 3.—Equipment used in determining solubilities of calcium sulfate at temperatures above 100°C.

The *pump,* used for introducing solution into the boiler under pressure during an extended series of determinations, was loaned to the authors by Dr. R. E. Hall. It has previously been described by him elsewhere.[16]

The *internal filter* consisted of fifteen layers of very finely-woven cotton cloth supported between fine copper gauze and perforated metal plates and mounted in a cylindrical cup. Since this was mounted vertically within the boiler, a deposit of solid material accumulated in the cup during each run and served not only as an additional filter medium but also as a safeguard against the passage of supersaturated solution.

The *cooling coil* was made from twenty feet of $^1/_8''$ galvanized iron pipe bent in a spiral and suspended in a container through which tap water was rapidly circulated. The flow of solution samples was continuously downward from the internal filter to the discharge from the cooling coil. This discharge was regulated by a small needle valve just above the outlet.

[16] R. E. Hall and others, *Carnegie Inst. of Tech. Bull.,24,* 145 (1927).

The measurement of temperatures was carried out with copper–nickel thermocouples, since it was necessary to use this pair of elements in the scale formation tests also conducted in this boiler. For the solubility work the temperatures of the solution within the boiler and of the air thermostat were measured with a Leeds and Northrup Type K potentiometer and a galvanometer of the enclosed lamp-and-scale type, using ice in a thermos bottle for a cold junction. The thermocouples used were calibrated directly against a standardized thermometer in the vapor of boiling liquids. Distilled water, ethylene bromide, bromobenzene, aniline and nitrobenzene were used to establish the calibration curve between 100 and 200°. This curve was almost a straight line, with a slight concavity downward.

Experimental Procedure.—During the early part of the solubility determinations it was discovered that hemihydrate remained apparently stable for periods up to forty-eight hours when held at temperatures between 100 and 130° but at temperatures above the latter value the solubility values gradually dropped toward the anhydrite curve. In the neighborhood of 200" this change took place within a few hours. Advantage was taken of this natural establishment of equilibrium with anhydrite in determining the solubility curve for this form, instead of using a solid phase of anhydrite prepared by the ignition of gypsum.

At the start of each series of determinations, the boiler was filled with 10 liters of a solution saturated with respect to gypsum at room temperature, with a concentration very close to 2000 parts per million of $CaSO_4$. Ten grams of gypsum powder was introduced with the solution. The air thermostat was heated up to the temperature at which the first sample was to be taken and temperature readings were taken at occasional intervals until the boiler solution had become constant at this value. The first samples were taken at from two to twelve hours after this attainment of the steady state, longer intervals being used in the later series of determinations. Second samples were taken after a similar interval and in some cases third samples after another interval. The temperature of the air thermostat was then changed and the same procedure repeated at the new temperature. When the solution level in the boiler had dropped to that of the internal filter, a fresh charge was pumped in. During the early runs the stock solution of saturated calcium sulfate solution was used for refilling; during the later runs, distilled water, because it was found by experience that less time was lost in coming to equilibrium from a condition of undersaturation than from one of supersaturation. This was particularly noticeable in the case of determinations with anhydrite, so that points for this curve were obtained with successively decreasing temperatures in order to prevent the possibility of supersaturation.

Duplicate 250-cc. portions of solution were obtained at each sampling. The temperature of the cooled sample was measured and always fell between 14 and 16°. From this temperature and the calibration for the volumetric flask used in measuring the samples, the mass of the sample was obtained. The sample and the washings from the volumetric flask were acidified with 0.5 cc. of concentrated hydrochloric acid, and were evaporated on a hot-plate to a volume of approximately 200 cc. The sulfate was then precipitated with 20 cc. in excess of the calculated amount of a solution of barium chloride containing 20 g. per liter of $BaCl_2 \cdot 2H_2O$. The solution then was returned to the hot-plate and again evaporated to 150–200 cc. (one to two hours). It was then filtered through an alundum crucible and the precipitate was washed thoroughly with hot water. The crucible was ignited in an electric muffle furnace at approximately 850° for one hour and was cooled in a desiccator

Experimental Data and Discussion

The experimentally determined solubilities are given in Table I. Values representing pre-equilibrium conditions at various temperatures have been omitted, as have been values representing transition from hemihydrate to anhydrite in the range above 130°. The data of Table I are presented also in Fig. 2 as the solid circles. From Fig. 2 it is readily evident that the data of the authors for the hemihydrate curve check excellently with

the previously published values of Boyer-Guillon, Melcher, and Hall, Robb and Coleman. In the case of the anhydrite curve, however, the authors' points check identically with those of Melcher and determine a curve which falls 200 parts per million below that of Hall, Robb and Coleman at 100°, approaching the latter as the temperature increases, until they attain an identical value at 200°.

It is the belief of the authors that the lowest points obtained by Hall, Robb and Coleman at each temperature for the solubility of anhydrite represent the most accurate determinations, and that the higher values indicate that complete conversion to anhydrite was not obtained in the preliminary burning of gypsum for their experiments. The variation between different determinations at the same temperature is easily accounted for by the assumption that varying amounts of hemihydrate were still present in the anhydrite added to their experimental boiler as the solid phase. This assumption is supported by the note appearing in their data to the effect that crystallographic examination of the solid phase from their boiler during one experiment showed material with refractive indices between 1.550 and 1.600. The alpha index of hemihydrate has been determined as 1.550, while the alpha index for anhydrite, its lowest index, is 1.571.[17]

At this time it is not possible to define with certainty the equilibrium diagram for the various forms of calcium sulfate in contact with water. The authors suggest the system shown in Fig. 4, in which the solubility curves of Figs. 1 and 2 are combined. Use has here been made of a solubility value for anhydrite at 33° given by Haddon and Brown,[18] which indicates the course of the anhydrite curve below 100°. This portion of the curve requires accurate determination before the intersection of the anhydrite and gypsum curves can be known with any certainty, but at present it appears to be at 38–39", which is the maximum of the gypsum solubility curve.

The transition temperature from gypsum to anhydrite given by van't Hoff[19] is 66". This value was obtained by two separate methods, one depending on vapor pressure and dilatometer measurements on concentrated salt solutions containing calcium sulfate, the other depending on a thermodynamic treatment of solubility data. The latter method is in error, since the solubility data of Boyer-Guillon were used under the misconception, common at the time, that they referred to anhydrite. The former method presents experimental difficulties which made van't Hoff consider it less certain than the latter. This transition temperature of 66°, therefore, is not securely founded.

From work of the authors on calcium sulfate scale formation, which will be described in the future, it appears that while anhydrite should apparently be the stable solid phase formed from solution over the whole range of boiler temperatures, hemihydrate is actually formed in the range of 100–130°. This apparent anomaly requires further study, as does the fact that gypsum is not converted to anhydrite when in contact with water between 39 and 98" but does change rapidly to hemihydrate at some temperature between 98 and 100°. Incomplete experiments indicate that hemihydrate is converted very slowly to anhydrite at this latter temperature.

Conclusions

The solubilities of hemihydrate and of anhydrite have been studied in the temperature range 100–200°. The values for the solubility of hemihydrate check those of earlier investigators commonly referred to as the values for the solubility of "soluble anhydrite." The values found for anhydrite are lower than the accepted values up to 200°, approaching the latter with increase in temperature and coinciding with them at 200°.

The solubility curve previously designated as that of "soluble anhydrite" between 100 and 200" has been shown to be a prolongation of the solubility curve for hemihydrate below 100°. Evidence that "soluble anhydrite" is identical in crystal structure with calcium sulfate hemihydrate has been advanced by other investigators and support of this view will be presented in a future paper by L. S. Ramsdell and E. P. Partridge.

A tentative equilibrium diagram for the system calcium sulfate–water is proposed, which indicates that the temperature of transition from gypsum to anhydrite lies slightly below 40° and that the temperature of transition from gypsum to hemihydrate lies at 98°.

Hemihydrate exists in contact with water only as an unstable phase over the entire temperature range 0–200°. In the range 90–130°, however, it is apparently metastable for periods up to forty-eight hours. Incomplete experiments indicate that gypsum is converted into hemihydrate in less than one day when in contact with water at 100°, and that the hemihydrate thus formed is subsequently transformed into anhydrite over longer periods of time.

Summary

Values for the solubility of calcium sulfate between 100 and 200° have been redetermined. The whole system of calcium sulfate and water up to 200° has been reviewed, with the conclusion that gypsum and anhydrite are the only stable phases within this range. The transition temperature of gypsum into anhydrite lies near 40°. Hemihydrate is the only other

form of calcium sulfate which has existence in the range 0–200°. "Soluble anhydrite" is identical in crystal form with hemihydrate, and the solubility curve formerly given as that of "soluble anhydrite" is the curve for hemihydrate. Hemihydrate is metastable in the approximate range 90–130°, showing decreasing stability with decrease of temperature below 90° and with increase of temperature above 130°.

OXIDATIONS PROMOTED BY ULTRASONIC RADIATION

By F. O. Schmitt,[1] C. H. Johnson and A. R. Olson

Received August 13, 1928 Published February 5, 1929

During the course of an investigation of the effects of ultrasonic radiation on certain photosensitive reactions, it was found that iodine was liberated from an aqueous solution of potassium iodide by such radiation. It was subsequently discovered that other reactions were sensitive to this agency; indeed Richards and Loomis,[2] using a 2-kilowatt oscillator, have reported two cases in which they observed some stimulation.

Experimental Methods

The high-frequency mechanical vibrations were generated in a manner already described.[3] The electrical oscillations were produced by a single 250-watt tube tuned to the natural frequency of the quartz crystal, which was about 750 kilocycles per second. In the cases of almost all reactions reported in the present paper, the reactants were contained in a test-tube dipping into the liquid dielectric immediately over the crystal. In this way the energy was transmitted to the solution in the test-tube, resulting in vigorous cavitation of any dissolved gas, the escaping bubbles being momentarily caught in the nodes of the standing wave system. In certain reactions it was desirable to render the liquid free, to all practical purposes, of dissolved gases before radiation. This was accomplished by boiling for three or four minutes in a test-tube fitted with a valve. On cooling the tube the valve closed, excluding the air indefinitely. In other reactions in which the presence of only one gas was desired, the liquid was rendered air-free in the manner already described; the valve was removed and a layer of mineral oil laid over the surface; the gas to be dissolved was then bubbled in from a fine jet. The use of oil had certain disadvantages and it was never employed unless absolutely essential. In order to ascertain whether electrical oscillations were responsible for the observed effects, a test-tube containing the reactants was placed above

the dielectric, another test-tube within the induction coil and a small receptacle containing potassium iodide and starch solution was inserted between the electrodes and the circuit tuned. In none of these experiments was any reaction observed, although the solutions within the induction coil, and between the electrodes, became hot.

Reactions Involving Gases

I. Oxidation of Halide Ions.—The oxidations of halide ions in neutral solutions by atmospheric oxygen in the dark are extremely slow reactions. If a 1 N aqueous solution of potassium iodide saturated with air under atmospheric pressure is subjected to ultrasonic radiation, iodine is liberated. When potassium iodide–starch reagent is added to aqueous solutions of potassium bromide and potassium chloride which have been radiated in the same way, the starch–iodine color appears immediately; if distilled water is radiated and tested in this manner no color appears until after a lapse of four or five minutes. Either the bromide and chloride ions are oxidized in these experiments or some other substance is produced in the presence of these salts which oxidizes the iodide ion instantaneously. To test the influence of positive ions 1 N potassium nitrate and 1 N potassium sulfate solutions were treated as above. Both of these solutions behaved essentially like distilled water but the rates of development of color were noticeably faster. To test further the influence of the positive ions, the above experiments were repeated with 1 N solutions of sodium and lithium salts and precisely similar results were obtained. Since Li^+ is considered to be highly hydrated in solution, the effect of hydration appears not to be important. It was also demonstrated that the hydrogen-ion concentration has a marked influence upon the rate and extent of color production. Although the halides showed an immediate color upon adding the starch–iodide reagent, the intensity of color developed by these solutions on standing in the dark for half an hour was as follows: $I^- > NO_3^- > SO_4^{--} > Cl^- >$ water $> Br^-$.

The depth of color produced by a three-minute period of radiation of potassium iodide solution is of the same order of magnitude as that produced by one part in a million of hydrogen perioxide. To test for the formation of hydrogen peroxide, titanium sulfate reagent was irradiated. Positive results were obtained in the majority of the trials; all of these solutions were sensitive to one part of hydrogen peroxide in three million parts of water. The formation of ozone was also suspected and it was tested for with manganous sulfate in acid solution. The tests were negative, but it is likely that this method is not sufficiently sensitive to justify the conclusion that no ozone was formed.

It is well known that the presence of ions influences the sensitivity of the starch–iodide test. Very dilute solutions of hydrogen peroxide were therefore added to starch–iodide reagent containing potassium salts. When potassium iodide was the salt added, a distinct color appeared immediately; with other salts a lapse of from one to three minutes occurred before color developed. The relative rates of color production in these experiments, under comparable conditions, were as follows: $I^- > NO_3^- > SO_4^{--} > Cl^- >$ water $> Br^-$. On standing in the dark for half an hour these solutions showed approximately the same depth of color although exhibiting some differences in shade.

The influence of the sulfate and nitrate ions in the case of the radiated solutions may merely have been upon the sensitivity of the starch–iodide test; but the immediate apppearance of color with bromide and chloride, on addition of the reagent after radiating, indicates some additional factor. This may be the production of free bromine and chlorine by oxidation of the halide ions.

2. Oxidation of Hydrogen Sulfide.—Aqueous solutions containing. hydrogen sulfide and air, when radiated for a few minutes, become strongly opalescent due to the oxidation of the hydrogen sulfide to sulfur, the latter appearing in the form of a colloidal precipitate. An attempt was made to estimate the amount of hydrogen sulfide which was oxidized under the influence of a three-minute period of radiation, by determining the strength of a solution of sodium thiosulfate required to react with sulfuric acid and yield a solution of the same degree of opalescence as an average radiated sample. The assay indicated that three minutes' radiation caused the oxidation of about 0.2 cc. of hydrogen sulfide gas, under standard conditions, from 5-cc. samples of solution. In this case, again, the rate of oxidation of an aqueous solution of hydrogen sulfide to sulfur by air alone is a reaction which even over a period of days does not proceed to any appreciable extent. A mixture of equal volumes of a 3% solution of hydrogen peroxide and of the aqueous solution of hydrogen sulfide produced opalescence at a much slower rate than that observed under the influence of ultrasonic radiation.

3. Oxidation of Organic Halogen Compounds.—A very striking result was obtained when a clear aqueous solution of carbon tetrachloride was radiated in the presence of starch and potassium iodide. The blue color of the starch iodide compound developed immediately; at the end of one minute of radiation the tube was practically opaque and the color many times deeper than that obtained by three minutes' radiation of potassium iodide and starch alone. Air and water must both be present for this reaction to occur.

If a two-phase system, carbon tetrachloride and aqueous potassium bromide solution, is radiated, the aqueous phase quickly becomes yellow due to the liberation of bromine. A number of other experiments involving organic compounds are now in progress and the results will be communicated in a later paper.

4. Reduction by Gaseous Hydrogen.—A solution of ferric ion through which hydrogen had been passed for a sufficiently long time to remove the dissolved air was radiated for five minutes. The resulting solution was tested for ferrous ion by potassium ferricyanide, and also for a change in the ferric-ion concentration with ferrocyanide and thiocyanate. In the most carefully controlled experiments no reduction could be detected. Had the amount of reduction been comparable to the amount of oxidation found in the former experiments, these tests would have been sufficiently delicate to detect the change.

Reactions not Involving Gases

Having succeeded in inducing reactions involving oxidations by oxygen under the influence of ultrasonic radiation, it next became necessary to determine whether slow reactions which proceed in the absence of oxygen could similarly be accelerated. Two reactions have already been studied by Richards and Loomis,[2] namely, the hydrolysis of dimethyl sulfate, and the iodine "clock" reaction, and the conclusion drawn that; after controlling the reactions as carefully as possible for differences in integral temperatures, there was a residual difference in rates which indicated that the radiation produced a 10% acceleration.

In certain of our experiments along quite different lines, in which Brom Thymol Blue was used and apparently positive results were obtained, it was suspected that the indicator itself was affected rather than that the reaction had been stimulated. Subsequent tests showed that when a dilute aqueous solution of Brom Thymol Blue (to which sufficient sodium hydroxide was added to produce a blue-green color) was radiated, the solution changed to yellow in a very short time. It was easy to demonstrate that comparatively few of the dye molecules were destroyed in the process of radiation, for addition of alkali caused a prompt return of the blue color. Other indicators, such as Brom Phenol Blue and litmus were affected in a similar manner. Whatever the process may be, there is no doubt that dye molecules were altered by the radiation and gave rise to hydrogen ions.

In the experiments of Richards and Loomis on the hydrolysis of dimethyl sulfate, Brom Thymol Blue was used to indicate the course of the hydrolysis. Since, during radiation, a sufficient amount of this indicator is decomposed to affect the color of the remaining indicator molecules, it follows that their results are not yet complete enough to justify their conclusions. We have shown above that if an aqueous solution con-containing dissolved oxygen is radiated, hydrogen peroxide or something analogous to it is formed. This must contribute to the acceleration of the iodine "clock" reaction observed by Richards and Loomis. Since the solutions employed by them were acid, any hydrogen peroxide produced by the radiation would transform the iodate to iodine independently of the mechanism of the "clock" reaction.

It will be shown in a later section of this paper that considerable importance must be attached to the cavitation of a gas from the reacting solutions. Consequently, all solutions at present under consideration were kept free of gases during the course of the reaction. In order to maintain the same sensitivity of test as in the previous experiments, all the reactions chosen involved the oxidation of iodide ion. Briefly, starch–iodide solution was added to three oxidizing agents, chlorate, arsenate and nitrite ions, respectively, in acid solution. Manipulation of the ionic concentrations and of P_H values permitted suitable regulation of the rates of oxidation. After mixing, the solutions were rendered free of gases and subjected to radiation, a control tube similarly treated but not radiated being kept in each experiment. The results can be summarized as follows. The oxidation of iodide ion proceeded slowly in all cases but in none of the experiments was it possible to state definitely that an increase in the reaction rate occurred, as a result of from five to fifteen minutes of radiation. Moreover, cavitation of nitrogen from solution during the course of the reactions produced no appreciable acceleration, It is evident that if any stimulation of these reactions occurred, the amount of such stimulation was small compared to that observed when oxygen was present.

The Effect of Pressure.—It is probably significant that the reactions which have been accelerated by ultrasonic vibrations have involved at least one gas. The oxidation of hydrogen sulfide presents the most striking example of stimulation and in this case both reactants are gases under normal conditions. To ascertain whether the oxidation occurred during the process of cavitation, on the assumption that the formation of an interface is essential to the activation of the oxygen molecules, experiments were carried out with aqueous solutions of potassium iodide containing very small amounts of dissolved air. Iodine was liberated although no bubbles were seen. Moreover, bubbling oxygen in a fine stream during radiation through an aqueous solution of potassium iodide and starch, which originally was gas-free, did not give rise to color, apparently since none of the oxygen dissolved. If an aqueous solution of potassium iodide and starch is saturated with oxygen gas under four or five atmospheres of pressure and then released, no oxidation of iodide ion occurs. It seems necessary to assume that every phase of bubble formation is realized in this process, and it must be concluded, therefore, that the mere formation of bubbles in the absence of ultrasonic vibrations is unable to effect the oxidation.

On the other hand, if solutions of potassium iodide or of hydrogen sulfide containing air were radiated for the same time at a series of increasing pressures, applied from an oxygen tank, it was found that the amount of reaction as measured by the depth of color or opalescence, respectively, slowly increased up to a certain pressure; above this critical pressure there was a sudden diminution in the reaction rate. The depth of color produced by three minutes' exposure increased somewhat with pressure, so that at a pressure of thirty-five pounds per square inch the color was definitely darker than at atmospheric pressure. Under these conditions no visible cavitation occurred during radiation. At fifty-five pounds the depth of color was still maintained, but on increasing the pressure pound by pound, a series of fainter and fainter colors was produced until at sixty-five pounds per square inch no color could be detected after three minutes' radiation. The critical pressure above which no measurable reaction takes place is an arbitrary figure depending chiefly upon the amount of dissolved gas and upon the intensity of radiation. In a series of experiments with very dilute hydrogen sulfide–air solutions, it occurred at twenty-seven pounds per square inch.

The fact that the color intensity increases slightly with pressure up to a certain point is to be expected. Increased pressure, the prevention of loss of reactants by cavitation, and the consequent minimizing of disturbances in the standing wave system produced by the larger bubbles all tend to augment the amount of reaction taking place during the period of radiation. The fact that higher pressures inhibit the reaction completely is a powerful argument against the hypothesis that individual oxygen molecules in solution can be activated directly by ultrasonic energy. A possible explanation of the phenomenon is that there exists a critical bubble size below the limits of visibility which is essential for the activation of the oxygen. Application of pressure beyond a certain amount prevents the cavitation of bubbles of this size and consequently inhibits the reaction. A pressure of seventy pounds per square inch does not affect the rate of oxidation of potassium iodide by hydrogen peroxide. The effect of pressure, therefore, must be on the rate of formation of hydrogen peroxide if this be the active agent.

It may be mentioned that the rise in temperature caused by exposing a test-tube containing 10 cc. of water at room temperature to three minutes of radiation was about 5°, both under atmospheric pressure and under an applied pressure of seventy pounds per square inch. In the latter case cavitation of air was prevented, and the piling up of the water at the meniscus noticeably increased. Yet, as stressed above, oxidations did not occur under these circumstances.

Summary

A number of substances in the presence of oxygen and water have been oxidized by subjecting them to ultrasonic radiation under such conditions that gas bubbles might be formed in the liquid.

GRAVIMETRIC METHOD FOR MICRO DETERMINATION OF MOLYBDENUM

By Joseph B. Niederl and Edith P. Silbert

Received August 17, 1928 Published February 5, 1929

Introduction.—As the necessity arose for determining molybdenum micro-analytically in organic compounds, it has been found that Pregl's method for the quantitative micro determination of metals in organic substances[1] can be used in principle for the gravimetric micro determination of molybdenum as molybdenum trioxide.

Apparatus.—While the apparatus and manipulations in the course of the analysis remained the same, the following changes were necessary in the analytical procedure to give satisfactory results.

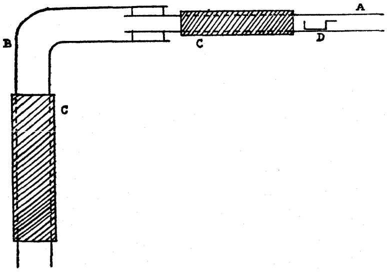

Fig. 1.—Micro muffle, according to Pregl. A, combustion tube; B, bent tube; C, wire gauze; D, combustion boat.

Method.—Three to five mg. of the substance is weighed in a micro porcelain combustion boat (a platinum boat cannot be used since partial reduction of the molybdenum trioxide may occur) on a micro-analytical balance (Christian Becker micro-analytical balance proved to be satisfactory). To this a drop of concentrated nitric acid is added. The boat is then brought into the combustion tube of the micro muffle (as shown in the diagram above) and heating begun over a small wire gauze with a Bunsen burner at about 30 mm. distance from the combustion boat.

Within a few minutes the nitric acid and the fumes of the oxides of nitrogen will be driven off and the wire gauze and flame are moved directly under the boat. After heating the boat in this manner for about five minutes, the wire gauze is removed and the heating continued at the same spot under the combustion boat for exactly five minutes longer. Since the molybdenum trioxide is volatile at temperatures above 450°,[2] the temperature of the flame is important. The flame should be non-luminous and so adjusted that it burns quietly, with an outer cone of about 7 cm. and an inner cone of about 3 cm. in length.

The material in the combustion boat should now appear yellow while

hot and grayish-white when cold. At this point the operation is finished and the boat containing the molybdenum trioxide is weighed.

This method, which requires only a short time for completion, is applicable for organic and inorganic substances provided they contain no other non-combustible or non-volatile constituents.

Results.—Some of the results obtained are as follows.

Molybdic Acid. 56.67% of Molybdenum. Macro Analysis.

Sample taken, mg.	3.105	2.275	2.442	3.250
MoO_3, mg.	2.642	1.934	2.075	2.758
Molybdenum found, %	56.71	56.68	56.62	56.58

Ammonium Molybdate. 53.87% of Molybdenum. Macro Analysis.

Sample taken, mg.	4.155	5.675	3.786	2.667
MoO_3, mg.	3.339	4.576	3.045	2.144
Molybdenum found, %	53.57	53.75	53.53	53.59

Histamine Molybdate. Calcd., 48.24% of Molybdenum.

Sample taken, mg.	3.936	5.017	4.406

I. PURIFICATION OF METHYL FLUORIDE
II. QUANTITATIVE GAS ANALYSIS BY HIGH DISPERSION INFRA-RED SPECTROSCOPY

BY WILLARD H. BENNETT

RECEIVED AUGUST 20, 1928 PUBLISHED FEBRUARY 5, 1929

Besides the interest in a ready method for preparing pure methyl fluoride, it is thought that this investigation will be of interest inasmuch as an application of infra-red spectroscopy is made in determining the purity of an organic compound with greater accuracy than is available through the usual chemical methods.

The best method for the preparation of methyl fluoride which a search of the literature revealed was that of E. Moles and T. Batuecas.[1] They prepared silver fluoride by recrystallization and warmed with methyl iodide, purifying the vapors by repeated warming with silver fluoride. Their test of purity consisted of bringing the methyl fluoride gas to constant density by purification. They also tried the method of heating

---

[1] Moles and Batuecas, *J. chim. phys.*, 17,537 (1919).

potassium methyl sulfate with potassium fluoride and found that by the density determination method, they obtained 95% methyl fluoride at first, and then successively less methyl fluoride with each preparation, so the method was abandoned. It was stated that in all probability the impurity was methyl ether.

This investigation began with an attempt to find a method for the elimination of the methyl ether from the methyl fluoride prepared by the latter method, since the crystallization of silver fluoride is such a time-consuming operation.

Erlenmeyer and Kriechbaumer[2] give a method of preparation of methyl ether. Methyl alcohol is heated with concentrated sulfuric acid and the gas evolved is passed into concentrated sulfuric acid, which absorbs 600 volumes of methyl ether. This sulfuric acid solution is run into an equal volume of water, when 92% of the methyl ether is recovered. It was thus thought that concentrated sulfuric acid would be a good absorbent of methyl ether.

Potassium fluoride hydrate, $KF \cdot 2H_2O$ (Baker), was heated until the water of crystallization had boiled off, leaving a white mass of anhydrous potassium fluoride, KF. This was pulverized. Potassium methyl sulfate, crystalline KCH_3SO_4 (Eastman), was pulverized and mixed with the pulverized potassium fluoride in the ratio of two parts of KF to five parts of KCH_3SO_4. The mixture was heated to 140–200°. The gas evolved was passed (1) through concentrated sulfuric acid in a spiral wash bottle with a gas path of about 65 cm., (2) through a concentrated solution of potassium hydroxide, (3) through a drying tube of soda lime and two drying tubes of calcium chloride (fused), and (4) into a condenser submerged in liquid air.

Methyl fluoride is solid at the boiling point of liquid air, so care had to be exercised to keep solid methyl fluoride from plugging the entrance tube to the condenser bulb. The middle fraction was taken from the methyl fluoride boiling out of the condenser on lifting the latter from the liquid air.

The impurities to be expected from reactions occurring in heating $KF + KCH_3SO_4$ are CO_2, H_2O, $(CH_3)_2O$, C_2H_4 and SO_2. The KOH is known to absorb CO_2 and SO_2 quantitatively, and $CaCl_2$ absorbs the H_2O.

Three samples of methyl fluoride were prepared. Sample A was prepared by removing the sulfuric acid bottle from the purification train, the gas being passed into the spectroscopic absorption cell without condensing with liquid air. Sample B was made without the sulfuric acid bottle also, but it was fractionated from liquid air. Sample C was prepared pure as above described.

The spectra of these three samples were measured on the high dispersion spectrometer in this Laboratory. A fairly large range of wave length of the radiation from a Nernst glower was selected by a fore-prism spectrometer. This radiation was passed through the gas cell and allowed to fall on the entrance slit of the grating spectrometer. A Michigan echelette grating ruled on a solder surface with 1440 lines per inch was used to further disperse the beam. The exit slit selected a narrow range of wave length of radiation which fell on a junction of a Pfund thermopile. The current from the thermopile was amplified by means of a Moll-Burger thermo-relay. The current from this relay was measured by means of a high sensitivity Leeds and Northrup galvanometer.

---

[2] Erlenmeyer and Kriechbaumer, *Ber.*, 7,699 (1875).

The gas cell was built of brass and was provided with rock salt windows. It was sealed so that the rise of pressure, after evacuation, was about 0.1 mm. in the course of two days. A pump, a manometer and a McLeod gage were used for controlling and measuring the pressure of gas used in each spectroscopic measurement.

A more detailed description of the apparatus and of the method of observation is being published concurrently with this.[3]

A preliminary inspection of the spectra when plotted showed that samples A and B contained methyl ether but that sample C contained practically none of the ether. The spectra of none of the samples showed any similarity to the spectrum of the band in this region for ethylene, so it was definitely concluded at the outset that none of the latter gas was present.

In a previous communication[4] the variation of infra-red absorption in liquids with cell thickness was studied and it was found experimentally that for small cell thicknesses the absorption is approximately proportional to the thickness. Since the fine structure of the spectrum of the methyl ether is not resolved with the slit width used, the absorption of the gas will vary with gas concentration in the cell in the same manner that it does with cell thickness in the case of liquids, and the percentage absorption will be porportional to the gas concentration for small percentage absorptions, to within the accuracy of these measurements. The validity of this assumption was checked by measuring the spectrum of pure methyl ether at 2 cm. and 4 cm. pressure, and the respective absorptions were found to differ by a factor of 2, to within the experimental error stated later.

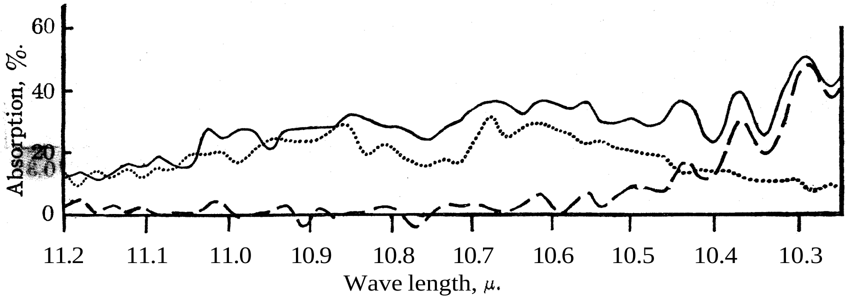

Fig. 1.

Fig. 1 shows the absorption spectra in the region 10.3 μ to 11.2 μ of these samples. No essential difference was found in the spectra of samples A and B and these, with the absorption cell filled at 73.6 cm. pressure, are shown as the full line. The spectrum of sample C at 73.7 cm. pressure

is shown as the broken line and the spectrum of methyl ether at 2.0 cm. pressure is shown as the dotted line. Fig. 2 shows that part of the 10-p

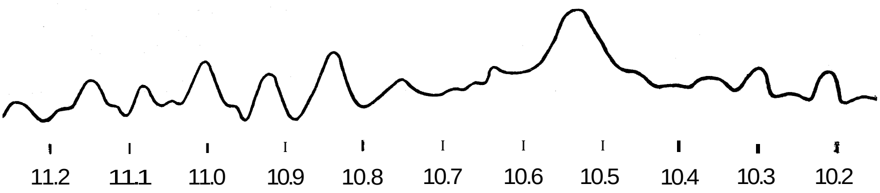

Fig. 2.

band for ethylene at a low pressure which lies in this region.[5] In Fig. 3, the full line represents the observed absorption percentages for the purified methyl fluoride at 73.7 cm. pressure. The dotted line represents the absorption of the empty cell.

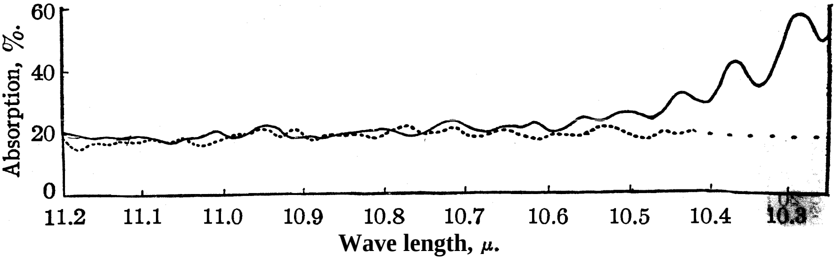

Fig. 3.

From data compiled in Table I, the percentages of methyl ether present in samples A and B were determined. The range of wave length from 10.8 μ to 11.2 μ was deemed the most representative. Readings were taken at 2' intervals of circle setting as given in Col. 1. Cols. 2, 3 and 4 give the percentages of absorption of samples A and B and methyl ether, respectively. Cols. 5 and 6 give the ratios of the absorption of methyl ether to the absorptions of samples A and B, respectively. By the method of least squares, the value of the ratios for samples A and B are 118 ± 4% and 123 ± 4%, respectively. Since the methyl ether spectrum was measured with the gas at 2.0 cm. pressure, while the spectra of samples A and B were both taken at 73.6 cm. pressure, the molar concentrations of methyl ether in samples A and B are

$$\frac{2.0}{73.6}\,(1.18 \pm 0.04) \text{ and } \frac{2.0}{73.6}\,(1.23 \pm 0.04)$$

or 3.08 ± 0.10% and 3.21 ± 0.10%, respectively. Hence fractionation from liquid air has not removed methyl ether to within the probable experimental error, which is 0.10%.

50	28.0	29.0	22.5	124	129

Table II gives the data used in the computation of methyl ether present in sample C. As seen in Fig. 3, some values of the percentage absorption for the cell empty are greater than those for the cell filled with sample C. This is due to the experimental error in each reading. Giving the values in the same order as in Table I, Col. 1 gives the circle setting, Cols. 2 and 3 the absorption percentages for sample C and methyl ether, respectively, and Col. 4 the ratios of the corresponding percentages in Col. 3 to those in Col. 2. The value of the ratio by the method of least squares is 7.9 ± 3.0% and the molar concentration of methyl ether in sample C is 0.20 ± 0.08%. It is thus seen that it is possible but not probable that all of the methyl ether has been removed by washing with concentrated sulfuric acid.

TABLE II

OXIDATION–REDUCTION POTENTIALS. I. THE FERRIC–FERROUS ELECTRODE

BY STEPHEN POPOFF AND ADOLF H. KUNZ

RECEIVED AUGUST 23, 1928 PUBLISHED FEBRUARY 5, 1929

The two outstanding difficulties in the interpretation of oxidation–reduction potential half-cells are the incomplete elimination of liquid junction potentials and the lack of precise data on the activity of one electrolyte in the presence of one or more others. According to Gerke[1] the published data in this field abound with unnecessary liquid junction potential corrections which cannot be precisely computed.

In the present study of the oxidation–reduction potential of the ferric–ferrous half-cell the foregoing difficulties were reduced to a minimum. Electromotive force measurements were made of the cell

$$\mathrm{Pt, H_2 \mid HCl \mid HCl + FeCl_3 + FeCl_2 \mid Pt}$$

The liquid junction potential was kept constant by a Lamb and Larson[2] flowing junction. In each series the acid concentration was the same throughout the cell. In all cases the ratio of the concentrations of the ferric and ferrous chlorides was kept as nearly as possible equal to one.

With decreasing concentration of ferric and ferrous chlorides, within each series, both sides of the cell approach identity and the liquid junction potential approaches zero. By plotting a function of the potential against the concentration of the ferrous chloride and extrapolating to zero concentration, the liquid junction potential disappears.

To obtain the normal oxidation–reduction potential a correction must be made for the presence of the hydrochloric acid. This was accomplished by plotting the values derived from the graphs at various acidities against the acid concentration and again extrapolating to zero.

Special Equipment

1. Electrode Vessel.—An all-glass electrode vessel[3] shown in Fig. 1 was used for the potential measurements. A is the oxidation–reduction chamber in which were placed the mixtures of ferrous and ferric chlorides and hydrochloric acid. T is a platinum foil, 8 × 18 *mm.*, sealed into a glass holder which is filled with mercury for contact. S is a stirrer with a liquid seal in which was put some of the same solution as in A. L was not used in this problem. B is the hydrogen electrode chamber. E are duplicate platinum electrodes. F is the hydrogen inlet and G the outlet. In G was placed acid of the same concentration as in B. The two chambers are connected by a Lamb and Larson flowing junction H. C contained the same solution as A and C the same as B.

---

[1] Gerke, Chem. Reviews, 1, 388 (1925).

[2] Lamb and Larson, THIS JOURNAL, 42, 229 (1920).

[3] Much credit for the design of this and other apparatus used is due to J. A. Riddick who was working on a similar problem.

The rate of flow is regulated by the overflow N. K and K' are stopcocks to prevent diffusion.

2. Constant Temperature Bath.—"White Rose" oil was used as the liquid in the bath. The temperature was easily kept at 25 ± 0.01°. The temperature was determined by a 0.1° thermometer which was compared with a similar thermometer calibrated by the Bureau of Standards. A Beckmann thermometer in the bath served as indicator for temperature changes.

3. Potentiometer and Galvanometer.—A Leeds and Northrup Type K potentiometer was used in conjunction with a Leeds and Northrup galvanometer, 2339a, and a lamp and scale reflector. A small lead storage cell was used for the working battery. The potentiometer and galvanometer were put on an equipotential base with the bath.

4. Standard Cell.—An Eppley standard cell of the unsaturated type was used. This was checked indirectly with a cell calibrated by the Bureau of Standards.

5. Oxygen Remover.—A 100-watt tungsten filament electric light bulb with sealed-in inlet and outlet tubes served to remove any possible traces of oxygen from the hydrogen used. The bulb was attached to a 110-volt circuit in series with a lamp-bank containing two 100-watt carbon bulbs in parallel.

Materials

1. All water used was redistilled from alkaline permanganate.

2. All hydrochloric acid was distilled twice from C. P. acid after dilution to a specific gravity of about 1.1.

3. Ferrous Chloride.—J. T. Baker's C. P. anhydrous salt was recrystallized twice from hydrochloric acid. Baxter and Hoover[4] found that two recrystallizations are sufficient to eliminate the predominating metallic impurities.

4. Ferric Chloride.—Chlorine was passed through a hot concentrated solution of the recrystallized ferrous chloride in hydrochloric acid. The ferric solution showed only a very faint and negligible test for ferrous iron. The chlorine was prepared in an all-glass vessel by adding redistilled hydrochloric acid to C. P. potassium permanganate.

5. Potassium permanganate was recrystallized twice for making the analyzing solutions.

6. Hydrogen was generated electrolytically from a concentrated solution of sodium hydroxide, using nickel electrodes. The gas was passed in order through a solution of potassium permanganate, an oxygen remover and three wash bottles (the last one was in the bath) containing acid of the same concentration as that in the hydrogen electrode vessel.

7. Silver nitrate, stannous chloride, mercuric chloride and preventive solutions were made from the best C. P. grade chemicals obtainable.

Analytical Methods

1. **Standardization of** 0.1 N Potassium Permanganate **Solution.**—Both iron wire and sodium oxalate were used. In the former case several lengths of bright iron wire containing 99.858% of iron were dissolved in 5 cc. of concentrated hydrochloric acid and 35 cc. of water and the solution boiled for five minutes to expel carbides. A drop of stannous chloride solution was added while hot. After cooling, 10 cc. of saturated mercuric chloride and 20 cc. of preventive mixture were added. After a short in-

---

[4] Baxter and Hoover, THIS JOURNAL, 34, 1660 (1912).

terval it was titrated electrometrically with potassium permanganate. In this and all other analyses titrations were made with weight burets. Results were also obtained without adding stannous chloride. In the sodium oxalate method the conditions of McBride[5] were followed. The results are presented in Table I.

It is evident that the titer increases with the amount of iron wire used, and that the value is higher when stannous chloride is used. Since subsequent work showed that the presence of mercurous chloride is objectionable the method without stannous chloride is probably the better, especially since it compares quite favorably with the sodium oxalate method.

TABLE I

THE STANDARDIZATION OF $KMnO_4$

	With Stannous Chloride			
G. of Fe	0.22590	0.22650	0.25460	0.25700
Fe titer	0.005802	0.005800	0.005824	0.005826
	Without Stannous Chloride			
G. of Fe	0.06310	0.06400	0.12580	0.12730
Fe titer	0.005765	0.005757	0.005781	0.005796
G. of Fe	0.12830	0.22150	0.22680	
Fe titer	0.005800	0.005807	0.005808	
	Using Sodium Oxalate			
Sodium oxalate titer	0.006974	0.006984		
G. of Fe per g. of soln.	0.005815	0.005815		

The absolute value of the iron titer of the potassium permanganate was not really required in this study as it deals principally with the ratio of the concentrations of the ferrous and ferric iron. Therefore it is only necessary that the permanganate be used under identical conditions in all iron titrations, ferrous as well as total.

2. Standardization **of** 0.01 N Potassium **Permanganate.**—This was accomplished by diluting to 0.01 N a solution of ferrous chloride whose total iron content had been previously determined with 0.1 N potassium permanganate. The 0.01 N ferrous chloride (after reduction of the ferric iron present) was titrated electrometrically with the dilute permanganate. No satisfactory electrometric end-point could be obtained when mercurous chloride was present so it was filtered off through asbestos before titrating. To be sure that no appreciable oxidation of iron takes place in filtering and transferring the ferrous solution, three drops of stannous chloride were added to 28 cc. of one molal hydrochloric acid containing 10 cc. of mercuric chloride solution. Twelve cc. of ferrous chloride solution in one molal acid was then added, the mercurous chloride filtered off and, after adding 20 cc. of preventive mixture, the solution was titrated. Fer-

---

[5] McBride, THIS JOURNAL, 34, 393 (1912).

rous chloride solution was titrated in the usual way at the same time. The results are shown in Table II.

TABLE II

OXIDATION OF Fe^{++} BY FILTERING

	G. of Fe per g. of soln.	Average
Filtering	0.019205, 0.019213	0.019209
Not filtering	0.019209, 0.019197, 0.019213	0.019206

3. Standardization of Silver Nitrate Solution.—This was done electrometrically using a silver chloride electrode with hydrochloric acid *as* the standard.

4. Standardization of Hydrochloric Acid Solution.—A carbonate-free solution of sodium hydroxide was prepared by adding a slight excess of barium hydroxide to an approximately 0.4 *N* solution of sodium hydroxide. This was filtered through asbestos out of contact with carbon dioxide and then standardized with benzoic acid and by hydrochloric acid diluted from constant boiling acid prepared by the method of Foulk and Hollingsworth.[6] The two methods agreed to within 0.05%. An error of 0.1% in the standardization of one molal acid will make an error of 0.06 mv. in the potential of the hydrogen electrode. The solution was kept in a paraffined bottle. After two months it showed no change. The acid solutions were standardized with this base, using phenolphthalein as the indicator.

5. The Determination of Ferrous Iron.—As the iron titer of a solution varies with the amount of acid present, enough acid was added in every titration to make a total of approximately 40 cc. of one molal hydrochloric acid. Twenty cc. of preventive mixture and enough water were added to make the volume at the close of the titration 200 cc. The titration was performed electrometrically.

That no appreciable oxidation of ferrous iron takes place during the time of titration is shown in Table III by comparing values obtained by titrating a solution containing ferrous iron (and about the same concentration of ferric iron) in one molal hydrochloric acid with 0.01 *N* potassium permanganate. As all titrations were made under these conditions, the air was not excluded.

TABLE III

COMPARISON OF Fe TITRATION IN AIR AND CO_2

G. of Fe per g. of soln.	In air	0.00052061	0.00052062
	In CO_2	0.00052061	0.00052074

When the ratio of ferrous and ferric iron is nearly one and the concentration of acid is about one molal, there is very little oxidation when left standing in a bottle half full of air. In one case there was no appreciable

---

[6] Foulk and Hollingsworth, THIS JOURNAL, 45,1220 (1923).

decrease in ferrous iron concentration overnight and less than 1% decrease in a week.

When the ratio of ferrous to ferric iron is greater than one, oxidation is slightly more rapid in one molal acid and considerably more rapid in solutions of lower acid concentration.

6. The Determination of Total Iron.—This was done in a similar fashion after reduction with stannous chloride and filtering off the mercurous chloride. The total iron content for the solutions employed (Tables II and IV) was about the same. That the filtering of the mercurous chloride is necessary is shown by the results in Table IV.

TABLE IV

INFLUENCE OF Hg_2Cl_2 ON TITRATION OF IRON

G. of Fe per g. of soln.	Filtered	0.016303	0.016298
	Not filtered	0.016320	0.016324

The difference of 0.15% between the filtered and non-filtered will cause a difference of 0.3% in the ratio of the concentration of ferrous to ferric iron. An error of 0.4% in the ratio will make an error of 0.1 mv. in the potential of the cell.

7. Determination of Total Chlorides.—This was done electrometrically with a silver chloride electrode as in the standardization of the silver nitrate solution. Table V shows a comparison between the chloride content of one solution determined by the electrometric method and by the Volhard method.

TABLE V

COMPARISON BETWEEN ELECTROMETRIC AND VOLHARDT METHODS FOR THE DETERMINATION OF CHLORIDES

Method	Volhard	Electrometric
G. of Cl per g. of soln.	0.05697, 0.05688	0.05704, 0.05706

The better agreement of duplicates and the rapidity of the electrometric method are strong arguments in its favor. Here again the exact value for the chloride content is not so important, for any error is minimized by dilution with accurately standardized acid.

Experimental Methods and Calculations

1. Hydrochloric Acid Solution.—The stock solution of acid was analyzed and the value recorded as grams of vacuum weight hydrogen chloride per gram of air weight of solution. This was diluted to the required molality by weighing out a definite quantity and adding the calculated weight of water, using the proper buoyancy correction factors. After dilution the solution was checked by another analysis and readjusted if not within 0.1% of the desired molality.

2. Ferrous Chloride Solutions.—The stock solution of ferrous chloride in hydrochloric acid was analyzed for ferrous iron, total iron and total chlorides. The ferric iron content was taken as the difference between the total and ferrous iron. The amount of water required to dilute the solution to the proper molality of acid was calculated and then added.

3. Ferric Chloride Solutions.—These were diluted to the same molality as the ferrous chloride solution and in the same manner.

4. Mixing Solutions to 1 : 1 Ratio of Ferric and Ferrous Iron.—The total iron content of the ferrous and ferric chloride solutions was calculated from dilution data. The ferrous content of the ferrous chloride solution was determined by titration just before mixing.

The ferrous-ferric mixture was made in the ratio of 0.998:1 in order to take care of a small amount of oxidation which takes place in the mixing and standing before use.

In Series V the 1:1 mixture was made up for each run and then diluted to the desired concentration of ferrous iron with one molal hydrochloric acid. After completing the potential measurements of the cells the ferrous iron of the solution of the cell was determined and the ratio of ferrous to ferric iron calculated. In all cases the ratio was within a few tenths of one per cent. of the value calculated for dilution.

In the other series a larger quantity of the I:1 mixture was made up, analyzed and kept in an atmosphere of carbon dioxide. The solution was analyzed before using for dilution and again the following day. Typical results are given in Table VI.

TABLE VI

THE STABILITY OR MIXTURES OR FERROUS AND FERRIC CHLORIDE IN AN ATMOSPHERE OR CO_2

G. of Fe per g. of soln.	Before use	0.011096	0.011095
	After use (one day)	0.011085	0.011093

That there is no appreciable oxidation of ferrous iron during the process of dilution is shown in Table VII.

TABLE VII

COMPARISON OF ANALYZED AND CALCULATED AMOUNTS OF Fe^{++}

G. of Fe per g. of soln.	Calculated	0.00023872
	Analyzed	0.00023870, 0.00023850

5. Calculation of Potentials.—There are three sources of potential in the cell

$$\mathrm{Pt, H_2} \underset{E_1}{\mid} \mathrm{HCl} \underset{E_2}{\mid} \mathrm{HCl + FeCl_2 + FeCl_3} \underset{E_3}{\mid} \mathrm{Pt}$$

E_1 is the potential of the hydrogen electrode, which is given by the equation

$$E_1 = -0.05915 \log a_{H^+}/a_{H_2} \qquad (1)$$

or

$$E_1 = 0.05915 \left(\tfrac{1}{2} \log p_{H_2} - \tfrac{1}{2} \log 760 - \log a_{H^+}\right) \qquad (2)$$

in which p is the partial pressure of the hydrogen of a solution of hydrochloric acid whose hydrogen-ion activity is a.

The values of Randall and Young[7] for the activities of hydrochloric acid were used. The partial pressure of the hydrogen was taken as the barometric pressure (corrected for temperature of barometer) minus the vapor pressure of the acid used. Values for the vapor pressures were calculated from data in "International Critical Tables."[8]

---

[7] Randall and Young, THIS JOURNAL, 50, 995 (1928).

[8] "International Critical Tables," 1928, Vol. III, p. 293.

E_2 is a liquid junction potential which cannot be computed at finite concentrations of ferrous and ferric chlorides. In the method of extrapolation used it disappears; hence it is included with E_3. E_3 is the potential of the ferric–ferrous electrode given by equation

$$E_3 = E_1 - E_{\text{cell}} \tag{3}$$

6. Experimental Details.—The hydrogen electrode vessels (Fig. 1) were filled to a level so that half of the platinized platinum electrode was immersed in the acid and the other half exposed to the hydrogen gas. The electrodes were platinized by the method of Popoff, Kunz and Snow[9] except that the treatment with nitric acid was omitted. Electrodes prepared with and without treatment with nitric acid agreed to within 0.01 mv. All duplicate electrodes prepared were within this agreement.

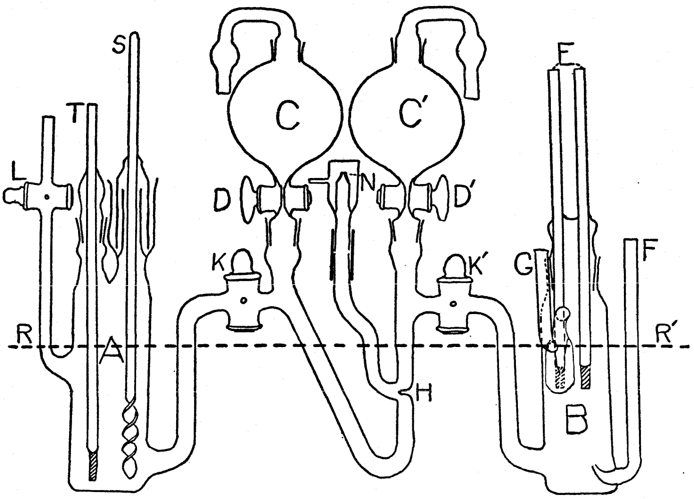

Fig. 1.—Electrode vessel.

In the previous investigation thinly and thickly plated electrodes were found to give the same potential to within 0.1 mv. The present study showed that the agreement is within 0.01 mv. However, the thickly coated electrode requires a longer time to attain equilibrium.

The oxidation–reduction half-cells were completely filled with the mixture of ferrous and ferric chlorides in hydrochloric acid. That no oxidation of the ferrous iron takes place in the cells was proved by analyzing the solution from duplicate cells, one at the end of one day and the other the following day. The variations of the results were within the limits of the experimental precision.

The cells were immersed in the oil of the bath up to line RR'. The rate of overflow from the flowing junction was about 300 cc. per hour.

Measurements of the electromotive forces of the cells were made about two hours after the hydrogen was admitted. Readings were then made about every half hour. After the cell readings did not differ for two hours the cells were assumed to be at equilibrium as cells left in overnight did not change their potential. In the fifth series Potential measurements were recorded to 0.01 mv. At the lower (0.2 to 0.05) concentration of acid the readings could only be obtained definitely to 0.05 mv. All observa-

tions were made with stopcocks K and K′ closed. These were greaseless. No change in potential was caused by stirring the solution in the oxidation-reduction chambers.

Experimental Data and Discussion

1. The Oxidation–Reduction Potential at Various Acid Concentrations.—In Table **VIII** are presented the potentials of the ferric–ferrous electrode at various acid concentrations and with the ratio of the concentrations of the ferric and ferrous ion nearly equal to one. The data from which the potentials were calculated are also given. In every case there is a liquid junction potential (E_l) which decreases with dilution. The potential of the electrode, then, is expressed by the equation

$$E = E_0 - 0.05915 \log (a_{\text{Fe}^{+++}}/a_{\text{Fe}^{++}}) \pm E_l \qquad (4)$$

or

$$E_0 = [E + 0.05915 \log (C_{\text{Fe}^{+++}}/C_{\text{Fe}^{++}})] + 0.05915 \log (\gamma_{\text{Fe}^{+++}}/\gamma_{\text{Fe}^{++}}) \pm E_l \qquad (5)$$

D	2.2022	.76945	− .72183				

The values of the terms in the parentheses ([ ]) are called E_a in the tables. The factor 0.05915 log $(C_{\text{Fe}^{+++}}/C_{\text{Fe}^{++}})$ corrects for the small departure from a one to one ratio between the ferric and ferrous iron concentrations. Since the difference is very small it will not appreciably affect the ratio of the activity coefficients.

Fig. 2 shows the results of plotting the values of E_a at each acidity against the concentration of the ferrous iron and extrapolating to zero concentration at which E_l is eliminated. The extrapolated values (E_0') read from the graph are presented in Table IX.

Table IX

The Oxidation–Reduction Potential at Various Acid Concentrations

Series	I	II	III	IV	V
Molality of HCl	0.05	0.1	0.2	0.5	1.0
E_0'	−0.7386	−0.7311	−0.7222	−0.7098	−0.7000

It is suggested that these values of E_0' are of greater practical importance than the theoretical value of E_0 since in actual practice oxidation–reduction reactions involving iron are usually carried out in acid solution. Therefore in making predictions based on Equation 4 these values should be used.

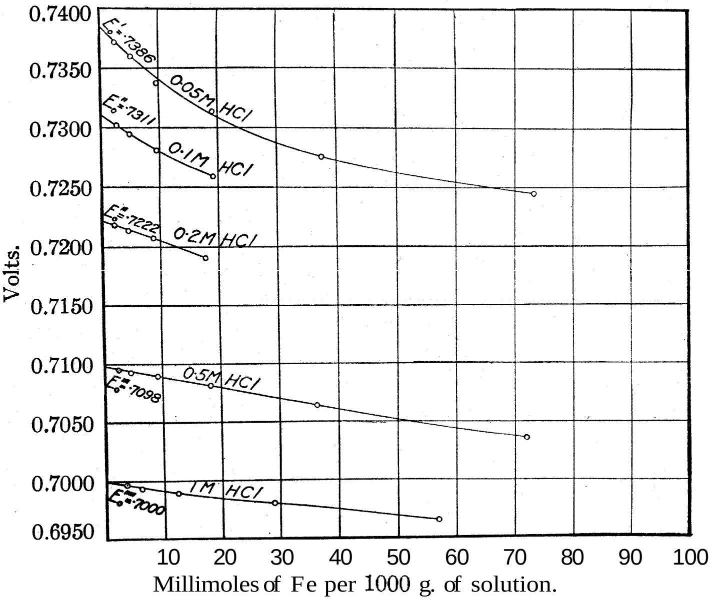

Fig. 2.—The oxidation–reduction potentials at various acid concentrations and with decreasing iron concentrations.

2. The Normal Oxidation–Reduction Potential.—In Fig. 3 the values of E_0' are plotted against the concentration of acid and the curve extrapolated to zero concentration. This corrects for the effect of the hydrochloric acid upon the activities of the ferrous and ferric ions and the normal oxidation–reduction potential of the ferric–ferrous electrode is found to be —0.7476 volt.

In Fig. 4 the logarithms of the values of E_0' are plotted against the acid concentration and extrapolated in the same way. This gives a somewhat better curve for extrapolation. The extrapolated value is 8.8737–10, whose antilogarithm is 0.7477.

3. Comparison between Results from Equilibrium and Electromotive

Force Methods.—Noyes and Brann[10] determined equilibrium constants at 25° for the reaction

$$Ag + Fe(NO_3)_3 = AgNO_3 + Fe(NO_3)_2 \qquad (6)$$

at an acid concentration of 0.05 M nitric. By plotting the values obtained against the total nitrate concentration and extrapolating to zero concentration, they obtained 0.128 for the true equilibrium constant of the above reaction.

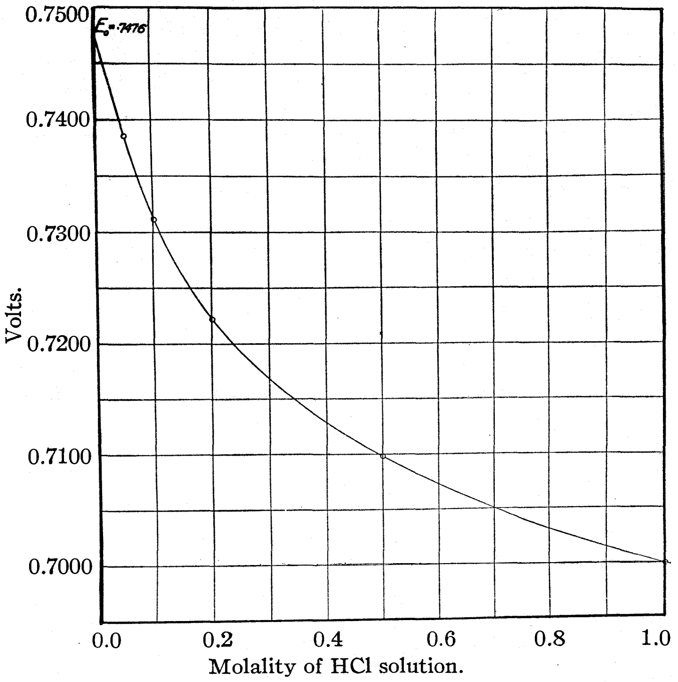

Fig. 3.—The oxidation–reduction potentials plotted against the acid concentrations.

Using −0.7995 for the potential of the silver electrode and the foregoing equilibrium constant, the normal oxidation–reduction potential of the ferric–ferrous electrode was calculated as −0.7467.

At the same time they determined the potential of the ferric–ferrous electrode to be −0.738 volt by direct e.m.f. measurements and a similar plotting of results. In the latter case, however, a salt bridge of saturated potassium chloride solution was used to eliminate liquid junction potentials. According to Lewis and Randall,[11] it is now certain that this method by no means eliminates and sometimes may even increase the

---

[10] Noyes and Brann, THIS JOURNAL, 34, 1016 (1912).

[11] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, p. 399,

liquid potential. In view of this Lewis and Randall accept their equilibrium data as the more precise determination of the normal electrode potential. This value (—0.7467) compares quite favorably with the value determined in this study (—0.7477). Being cognizant of the errors of extrapolation we are inclined to believe that the final value of —0.7477 is uncertain by 0.5 mv.

4. The Normal Oxidation–Reduction Potential Calculated from the Principle of Total Ionic Strength.—The total ionic strengths (one-half of the sum of the molalities of each ion times the square of its valence) of the solutions used in cells of Series I were calculated. Cells E and F have a total ionic strength of less than one-tenth at which the principle of ionic strength might be expected to hold. Therefore E_0 was calculated from these cells by Equation 4. The activity coefficients of the ferrous iron were interpolated from the values given by Lewis and Randall[12] for any bivalent ion. The ferric ion activity coefficients are similarly obtained from the values given for lanthanum. The values of E_0 calculated in this manner are given in Table X.

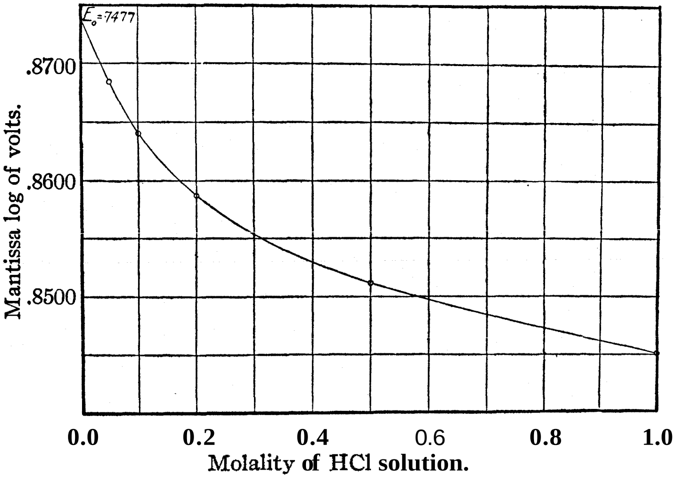

Fig. 4.—The mantissa of log of oxidation–reduction potentials plotted against the acid concentrations.

TABLE X

E_0 CALCULATED FROM IONIC STRENGTH

Cell	E	F
Total ionic strength	0.097956	0.073998
E_0	−0.7487	−0.7497

In view of the admitted uncertainties in the values for the activity

---

[12] See ref. 11, p. 382.

coefficients used the agreement with the value obtained by extrapolation in this study (−0.7477) is as good as may be expected.

In the calculation of E_0 from ionic strength the liquid junction potential was not considered. The latter was not considered because an uncertainty of one in the second decimal place of the activity coefficient of iron causes a variation of 1.3 mv. in the value of E_0.

Influence of Variation of Concentration of Iron and Acid.—The effect of decreasing the concentration of iron and acid is to increase the oxidation–reduction potentials. This is to be expected when one considers that ferric chloride forms complex salts with hydrochloric acid while ferrous chloride does not, and that the activity coefficients of a trivalent ion must increase much faster with dilution than those of a divalent ion since both become equal to one at infinite dilution. It is not safe therefore to assume, as some[13] have, that the activity coefficients of ferric and ferrous chlorides are the same.

The decrease of the oxidation–reduction potential (not the normal) with increase of the concentration of acid is in agreement with Carter and Clews[14] findings and tends to throw light (at least on half of the story) on the fact that ferrous chloride is oxidized by sulfur dioxide in strong acid solution but that ferric chloride is reduced by sulfur dioxide in dilute acid solution.

Use of Salts without Recrystallization.—It is reasonable to suppose that in the present study the salts employed need not necessarily be of "atomic weight" purity since in the extrapolations the effect of impurities will also be extrapolated to zero. J. T. Baker's best grades of ferrous and ferric chlorides were employed in one molal hydrochloric acid. The potentials coincided very closely with those obtained with the recrystallized salts. In the dilute solution the values practically coincided.

Summary and Conclusions

1. A method has been devised for the precise determination of oxidation–reduction potentials, consisting of the use of a special electrode vessel, suitable procedure, and mathematical and graphical treatment which eliminate uncertainties in former methods regarding liquid junction potentials and the activity of one electrolyte in the presence of others.

2. Methods of analysis which lead to greater precision in the determination of iron are given. A method was chosen for each analysis which gave results within 0.1% of those obtained by a widely different method. The errors of analysis were smaller than the corresponding errors in the electromotive force measurements.

[13] Peters, *Z. physik. Chem.*, **26**, 193 (1895). Getman, "Outlines of Theoretical Chemistry," John Wiley and Sons, New York, 1927, p. 581.

[14] Carter and Clews, *J. Chem. Soc.*, **125**, 1880 (1924).

3. The treatment with nitric acid of hydrogen electrodes which had been plated in solutions containing lead was found to be unnecessary. Thinly platinized electrodes give practically the same potentials as thickly coated ones.

4. The oxidation–reduction potentials of the ferric–ferrous electrode have been determined at various acid concentrations. It is to be emphasized that these values are of practical importance in attempting to make predictions.

5. The normal oxidation–reduction potential determined in this study compares favorably with the potential calculated from equilibrium measurements by Noyes and Brann.

6. The principle of ionic strength was applied to the calculation of the normal potential employing data obtained in 0.05 molal hydrochloric acid. The values thus calculated are in fair agreement (considering the uncertainty of activity coefficients now available) with that derived by extrapolation.

7. The value for the normal oxidation–reduction potential of the ferric–ferrous electrode determined in this study is −0.7477. The uncertainty is probably of the order of ±0.5 mv.

THE DETERMINATION OF TRACES OF IODINE. II. IODINE IN VEGETABLES[1]

BY J. F. McCLENDON AND ROE E. REMINGTON[2]

RECEIVED SEPTEMBER 13, 1928 PUBLISHED FEBRUARY 5, 1929

In the first paper of this series[3] the general principles of a method for the determination of traces of iodine were outlined. The statement was made that an apparatus for feeding in milk powder was used. This apparatus is also useful for vegetables and consists of a steel tube with water-cooled open end and piston in the other end which is advanced by means of a screw similar to the piston of an "Alemite gun." Vegetables are made into a stick, placed in the steel tube, and advanced slowly by means of the screw and thus fed into a silica tube furnace and burned in oxygen.

---

[2] With the technical assistance of F. B. Culp.

[3] McClendon, THIS JOURNAL, 50, 1093 (1928).

Original Procedure

An outline of the apparatus is given in Fig. 1. The steel tube is of 24 mm. bore and 50 cm. long. The walls are 1 mm. thick and the threads on the screw are 2 mm. apart (pitch). Around the open end is coiled 10 turns of lead pipe, 3 mm. bore for cooling-water. The steel tube is clamped rigidly in a horizontal position. Its open end is applied to the open end of a horizontal silica tube of 36 mm. bore and 60 cm. long with an elbow extending downward of the same bore and 30 cm. long.

The horizontal portion of the silica tube is heated by five large Méker burners. Around the junction of the steel tube with the silica tube is a pyrex glass adapter of 38 mm. bore with a side neck admitting oxygen and allowing the oxygen to go into a small crack between the steel and silica tubes. The elbow of the silica tube extends downward into an absorption flask made of three 500-cc. pyrex globe flasks. In the absorption flask is placed 0.25 g. of sodium hydroxide and enough water to extend into the middle section or second globe. Some of this solution is run into the 4 Milligan wash bottles (connected in parallel) by tilting the flask. The space between the elbow and the lip of the absorption flask is stoppered with wet asbestos. The absorption flask and Milligan wash bottles stand in a tank full of ice water. The side neck of the absorption flask passes to the Milligan wash bottles and then through a small Cottrell precipitator (described in the first paper) and to a rapid air pump (Cenco rotary No. 1400) which exhausts the air at the rate of 1.25 cu. ft. per minute and causes the oxygen to flow into the open end of the silica tube.

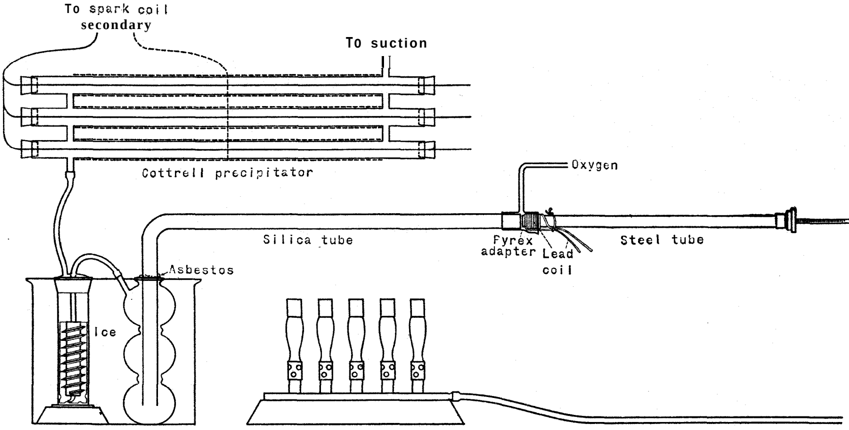

Fig. 1.

About 5 to 10 kg. of the fresh vegetables to be analyzed are ground in a suitable mill and the pulp partially dried on sheets of tin, or cheap dinner plates, in an electric oven at about 100". When the pulp reaches the consistency of putty, it is made into sticks about 50 mm. long and 24 mm. in diameter and replaced in the oven. The sticks shrink in length and diameter during further drying. In starting the combustion a stick is placed in the steel tube and the screw advanced until a few mm. of the stick extends out of the steel tube. The oxygen is turned on, the Méker burners are lighted, the pump is started and the Cottrell precipitator operated. The oxygen adapter is slid to one side and a gas flame is applied to the crack between the steel tube and the silica tube until the stick of vegetable material is ignited. The adapter is quickly replaced so that the stick burns with a white heat in oxygen. The stick is advanced by means of the screw at such a rate that it burns without the evolution of soot and tarry material. It is usually possible to advance it about 0.5 mm. per second unless it contains a great deal of fat or oil, in which case it may not be possible to advance it so rapidly. The rate of advance depends also on the rapidity of the pump, it being understood that oxygen is fed in as fast as it is sucked through by means of the pump. The ash is drawn a few cm. into the tube by the current of flue-gas. After the completion of the burning of one stick, another one is placed in the steel tube without stopping the rest of the apparatus and burned in the same way, this process continuing until the whole sample has been burned.

At the end of the combustion the contents of the large absorption flask and the wash bottle and washings of the Cottrell precipitator are evaporated in a pyrex beaker. The ash is scraped out of the silica tube and ground with the washings of the tube in *a* small ball mill using Jasper balls (from the Jasper Stone Company, Jasper, Minnesota). After grinding for several hours and until the ash is reduced to an impalpable powder, it is removed from the ball mill to a centrifuge tube or beaker, allowed to settle or centrifuged and the soluble portion transferred quantitatively by several decantations to the beaker containing the contents of the absorption flask. When the contents of the beaker have evaporated to a small volume, they are transferred to an evaporating dish, dried in an electric oven to dryness and then scraped out with a steel spatula, ground in a mortar and placed on a curved piece of sheet nickel which is placed in a pyrex combustion tube of about 30 mm. bore and 40 mm. long with an elbow which is drawn out to a much smaller bore, 20 mm. long and extends down into a side-necked test-tube. In the test-tube are placed a few milligrams of sodium hydroxide and 10 cc. of distilled water. The space between the lip of the test-tube and the elbow is plugged with wet asbestos. A suction pump is attached to the side neck. The region under the nickel boat is heated with a large, flat gas burner with the air vent opened just enough to prevent the flame from being luminous or, in other words, the pyrex tube is heated just below its softening point while air is drawn through the tube. The open end of the tube is loosely plugged with a ball of dry asbestos or glass wool so as to prevent convection currents. The heat is continued until the traces of organic matter which have escaped the first combustion are entirely burned. It is rarely necessary to redissolve the ash, filter it and burn the carbon separately. The heat of the tube should not be high enough to fuse the ash, as that will stop the combustion.

At the end of the second combustion the ash is placed in a small beaker or an evaporating dish and dissolved in the sodium hydroxide solution from the side-necked test-tube. Into it is run, drop by drop, a mixture of 90 parts of sirupy phosphoric acid and 10 parts of a solution of sulfurous acid (0.1 N or stronger and titrated recently). The addition of acid is continued until effervescence ceases. The solution is then boiled for about five minutes to expel the sulfur dioxide. It is tested with indicator paper (made by evaporating an alcoholic solution of brom phenol blue on ash-free filter paper) by removing a small drop on a glass needle and touching it to the paper. If the indicator paper does not change quickly from blue to yellow, concentrated sulfuric acid should be added drop by drop until it does change the paper as indicated.

This solution is now run into a 12-cc. separatory funnel which has an etched mark at a volume of 10 cc. and made up to the mark with distilled water. A small crystal (about 1 mg.) of sodium nitrite is added, the stopper inserted and the nitrite dissolved by agitation. One cc. of purified carbon tetrachloride (see first paper) is introduced into the separatory funnel, gently agitated or inverted 200 times so as to bring about partition-equilibrium between the iodine in the water and the carbon tetrachloride. If the carbon tetrachloride is at all cloudy, it is run into a 1 cc. centrifuge tube and centrifuged until clear. It is then placed in the left cup of a Bausch and Lomb micro-colorimeter and set at 20 mm. In the right cup of the colorimeter is placed about 1 cc.

of carbon tetrachloride containing 0.1 mg. of iodine per cc. and a color match made. An average of ten readings on the right side in mm. divided by 20 and multiplied by 0.1 (the concentration of the standard) gives the milligrams of iodine in the carbon tetrachloride, and this multiplied by 1.118 gives the milligrams of iodine in the sample analyzed. As a check on the extraction, 0.1 cc. of the water in the separatory funnel is run into a small vial containing a minute crystal of potassium iodide. A drop of carbon tetrachloride is added and the vial agitated. If the carbon tetrachloride does not become pink, a drop of conc. sulfuric acid is added to the separatory funnel and the process is repeated. If the pink color appears this time, 1 cc. of carbon tetrachloride is added to the separatory funnel, the extraction and reading are made and the yield is added to that of the first extraction.

At the end of the combustion it will be found that some ash has adhered to the silica. This is only enough to cause a slight error in the analysis but is sufficient to shorten the life of the silica tube, due to the difference in expansion of silica and ash. The life of the tube may be prolonged by rubbing off as much of the ash as possible with sand paper and then dissolving the remainder first with hydrochloric and then with hydrofluoric acid before heating the tube again. If the tube cracks off at the end it may be cut off or used for burning oils (to be described in the third paper). An elbow made by bending the silica tube is much less liable to break than an elbow that is fused on. Hence the larger tubes described in the first paper are not economical.

If the vegetables contain much chloride the wires in the Cottrell precipitator must be sealed in glass tubes run through the rubber stoppers in order to preserve the insulation.

The percentage of the total iodine caught by the Cottrell precipitator varies with the nature of the vegetable that is burned. If this percentage is determined for one sample of vegetable and found to be low it may be desirable to omit the Cottrell precipitator in analyzing similar samples, its place being taken by 4 or more Milligan wash bottles connected in parallel and a tube of 25 mm. bore 500 mm. long packed with moist glass wool. If no soot is formed the smoke is largely alkali chlorides.

In the second combustion (in the pyrex combustion tube) the material is alkaline and only a small percentage of iodine is volatilized and caught in the side-necked test-tube. This method of combustion is almost as convenient as combustion in an open crucible, however, and since some form of furnace is necessary to prevent overheating of the crucible, the pyrex tube forms a convenient type of furnace as regards visibility. If the ash fuses it may be necessary to add potassium nitrate to it for complete combustion, in which case the liability of loss of iodine from an open crucible is increased.

Some chemists have had difficulty with the method due to the material to be burned adhering to the open end of the steel tube. This is due to the tube becoming too hot or the material being in powdered form. The steel tube should not be inserted *inside* of a silica tube in which the combustion takes place. If the material is not made into sticks it may be burned in a sheet iron "boat" about 6 inches long with a handle or empty portion 18 inches long. About 30 g. of the ground vegetable or vegetable compressed into tablets is spread over the bottom of the boat, ignited and burned. The boat is withdrawn and another 30 g. added and the. process repeated until the whole is burned. Since a similar method was described in the first paper, no special details are added here except to suggest that the silica tube herein described is more economical than the larger one described in the first paper. In using the boat an oxygen inlet tube may be held up by an independent support and inserted into the silica tube as far as the most advanced end of the boat so that combustion begins at this end first and only gradually spreads over the material in the boat. The use of the boat is very unsatisfactory if the vegetable has a high fat content.

Extraction of Ash Containing Large Quantities of Soluble Salts.—The ash is extracted repeatedly in a ball mill with 95% alcohol (recently distilled over sodium hydroxide), or enough alcohol to cover the ash is added, and allowed to stand for fifteen minutes with occasional gentle stirring with a glass rod. The alcohol is decanted through a small ashless filter, the residue being retained in the dish. A second portion of alcohol is now added, and the residue rubbed with a small porcelain pestle. The ash contains considerable alkali carbonates, which extract water from the alcohol, forming a 3-phase system and the mass is at first gummy and adheres to the pestle, but later becomes pasty, so that trituration with the alcohol becomes easy. The residue is washed with a third portion of alcohol, triturating it thoroughly, and the alcohol is passed through the same filter as before.

TABLE I

ANALYSES BY THE METHOD

Potassium iodide was added to 50 g. of iodine-free starch with the following results:

Added	0.200 mg.	Found by analysis	0.194 mg.

Iodine in Vegetables from South Carolina

	Field peas	Okra	Potatoes	Sweet potatoes	Peaches
Dry matter, %	90.6	8.9	19.7	31.0	11.1
I_2, dry basis, parts per billion	197	412	333	115	192

California Vegetables

	Asparagus	Beets	Carrots	Celery	Peas	Spinach	Tomato
I_2, dry basis, parts per billion	12.0	8.0	8.0	14.0	9.0	32.0	20.0

Alternative Method Using Low-Temperature **Ashing.**—If the sample is of cereal grain (which gives an acid ash), it should be moistened with 50 cc. of 2% calcium lactate solution followed by 50 cc. of 2% sodium carbonate solution. The sample is dried, coarsely ground and heated in an evaporating dish over a small flame until the vegetable matter begins to smolder. The heat is now withdrawn so that the sample will continue to smolder and burn at low temperature, without flame. If smoldering ceases the dish may be heated again until ignited.

After this preliminary ignition, during which the sample will be completely converted into a black char, the dish is placed in a muffle and maintained at a temperature which must not exceed 450° until ashing is practically complete and the ash is light gray in color. It is not usually practicable to carry the ignition to complete whiteness of ash. This ignition in the muffle will require from twelve to fifteen hours.

TABLE II

ANALYSES BY THE LOW-TEMPERATURE METHOD

Sodium iodide was added to half of a sample of dried, ground potatoes and not to the other half and the halves were analyzed separately, with the following results:

Dry sample	Iodine, mg.
100 g. of potatoes—0.1 mg. of iodine	0.129
100 g. of potatoes	.034
Added iodine recovered	0.095 = 95%

South Carolina potatoes	Sample 1	Sample 2	Sample 3
I_2, parts per billion	338	348	369

Summary

A method has been described for the rapid combustion of vegetables for iodine analysis which necessitates the use of oxygen and special stoking to prevent soot and tar formation and results in volatilization of chlorides and iodides. These are not all caught by ordinary wash bottles. A simple form of Cottrell precipitator will precipitate all the smoke (largely alkali chlorides) provided it is large enough for the rest of the apparatus. The precipitator and mechanical stoking apparatus are shown in Fig. 1.

Low-temperature burning in open dishes requires about fifteen hours for 100-g. dry samples and does not result in large losses of iodides if the ash is alkaline and temperature never above 450°. Combustion is never complete if the ash fuses. Calcium lactate must be added to vegetables with an acid ash (cereals) in order to make the ash alkaline and prevent fusion of the ash.

THE ATOMIC WEIGHT OF COPPER FROM THE LAKE SUPERIOR REGION AND FROM CHILE[1]

BY THEODORE W. RICHARDS AND ARTHUR W. PHILLIPS

RECEIVED SEPTEMBER 18, 1928 PUBLISHED FEBRUARY 6, 1929

Examination of the atomic weights of elements from different geographical and geological sources is of importance because of the bearing on the genesis of the elements. None of the comparisons,[2] except for products of radioactive disintegration and possibly boron, has shown any segregation of isotopes. The results here presented confirm this conclusion for the case of copper. Furthermore, they contribute to the determination of the atomic weight of this element by the analysis of yet another compound. Most of the work on the atomic weight of copper for thirty years was from the point of view of the electrochemical equivalent, which Clarke in his excellent critical review[3] shows to be inferior to the chemical method.[4]

Copper was chosen for investigation because it could be obtained from different known geological ages and from regions widely separated, because it was known to have at least two isotopes and because its atomic

[4] Since the completion of the research here recorded, Ruer and Bode [*Z. anorg. allgem. Chem.,* **137, 101** (1924)] employed the copper oxide method and found a value **63.546,** which they have defended against the criticisms of the German Atomic Weight Commission [Ruer and Bode, *Ber.,* **58A, 852 (1925);** *ibid.,* **59B, 1698** (1926)].

weight needed confirmation. One sample was obtained from the Lake Superior region and another from the Chile ore deposits.

The former, from the Calumet and Hecla Mines, contained equal parts from the upper and lower lodes. There is reason to believe that this deposit was formed not later than the Cambrian.[5] The deposits at Chuquicamata, Chile, from which the second sample came, are said to consist of a series of lodes in granitic rock, intrusive in Jurassic strata.[6]

Methods previously used for the determination of the atomic weight of copper were based on analyses of CuO, $CuSO_4$ or $CuBr_2$, and by comparison with silver, directly as well as electrolytically. For the purpose of confirmation of the atomic weight it was deemed advisable to analyze some other compound by means primarily chemical.

Tests were conducted on both cuprous and cupric chlorides to determine their suitability for analysis in the anhydrous condition. Samples of each chloride were fused in an atmosphere of chlorine in a bottling apparatus and nitrogen was used to displace the chlorine. Both cupric and cuprous chloride yielded bluish black crystals, which were partially soluble in water, giving a blue solution and a white precipitate. Under available conditions the equilibrium between cuprous chloride, cupric chloride and chlorine did not give a suitable salt.[7]

A simpler method was adopted based upon work done with cupric bromide.[8] This method, in brief, consisted in determining the copper electrolytically and the chloride content by comparison with silver in a solution of recrystallized hydrated cupric chloride.

Purification of Materials

Water, nitric acid and sulfuric acid were carefully purified and before use all were proved to be free from chloride by nephelometric tests. All alcohol and hydrochloric acid used were carefully distilled. All other reagents were also purified before use.

Pure silver was prepared from residues of silver bromide resulting from previous atomic weight work. The bromide was reduced with pure zinc, the resulting silver being washed with sulfuric acid and water before solution in nitric acid. After three crystallizations of the nitrate the silver was reduced with freshly prepared ammonium formate. The silver was thoroughly washed, fused into buttons and electrolyzed, and the crystals were again fused on lime in a hydrogen atmosphere. The resulting buttons were etched with nitric acid, washed twenty times and dried in a vacuum

at 400°. A few of the buttons were electrolyzed again to provide small crystals used in adjusting weights of silver required in analysis. The silver was kept in a desiccator over fused potassium hydroxide.

Purification of cupric chloride was accomplished by repeated crystallization as $CuCl_2 \cdot 2H_2O$. The copper from Calumet and Hecla, Sample A, was a block of pure copper weighing about 1500 g. The center of this block was turned out on a lathe. For the first series of crystallizations 500 g. of shavings was taken; for the second series (A II) 300 g. A third series (A III) was obtained by recrystallization of the mother liquor from the first two series.

The copper turnings, washed with alcohol to remove grease, were dissolved in hydrochloric acid to which had been added a small amount of nitric acid. The cupric chloride was recrystallized four times in pyrex dishes with evaporation over the steam-bath and with centrifugal drainage. Any insoluble matter was removed by filtration after the first crystallization. Tests for iron were negative after the first crystallization. Two more crystallizations of the cupric chloride were performed in quartz dishes, evaporation in these cases taking place in vacuum desiccators over sulfuric acid. The solution was filtered after the fifth crystallization. Care was taken not to reach a high vacuum which would cause bumping and splashing. As an emergency precaution to prevent formation of hydrogen chloride by splashing solution into the concentrated sulfuric acid, watch glasses were placed beneath the quartz dishes. Since usually the crystals, forming on the surface, made a crust, the desiccator was opened from time to time and the crystals were pushed down with a glass rake. In this way was avoided the appearance of any brownish color due to the presence of anhydrous cupric chloride.

At each stage of crystallization tests were made for free hydrochloric acid. Such tests were at the best comparative. However, since each sample was purified until the same acidity was reached, the atomic weights of the different samples should be entirely comparable.

The method used in these tests was similar to that used in the analysis of cupric bromide.[8] One cubic centimeter of a concentrated cupric chloride solution was diluted to 10 cc. and one drop of methyl orange solution was added. The resulting color was purple if the solution was acidic and yellowish-green if basic. The turning point in color was marked. In order to obtain a standard for comparison the change in acidity was carefully followed in a series of nine crystallizations. These experiments showed that during the first three crystallizations all excess acid was eliminated. During the next five crystallizations the shade of purple was almost constant. The standard chosen was the purple thus produced. After the ninth crystallization the turn in color was observed. The standard purple color was restored by the addition of less than four milligrams of hydrochloric acid to a solution containing 60 g. of cupric chloride. In the crystallization of Sample A there was a slight loss of color during the first three crystallizations, but during the next three the color remained practically constant.

The Chile copper, Sample B, was received in the form of small ingots of about 200 g. each. An ingot and a half were taken for the first series of crystallizations (B I and B II). The same method of purification was followed for Sample B as for Sample A except that three crystallizations over sulfuric acid were necessary to give the normal acid test. A second set of crystallizations was performed with the mother liquors from the last four crystallizations of the first series (B III).

Analysis of Solutions

About 40 **g.** of the cupric chloride crystals was dissolved in 1100 cc. of best water in a "Non-Sol" bottle. Samples of 100 cc. each were withdrawn with a pipet using a suction pump and these samples were placed in weighed Florence flasks, which were provided with stoppers consisting of short sections of glass tubing, fitting into the neck of the flasks and supported by a small section of rubber tubing resting on the lip of the flask. The solutions were then weighed to one milligram. In half the samples the copper content was determined and in the other half the chlorine was precipitated with silver. In certain cases it was found necessary to apply a correction for the formation of atacamite. This correction will be discussed below in detail.

Determination of Copper.—The weighed sample was carefully transferred from the flask to a quartz evaporating dish and the flask rinsed many times. The solution was then evaporated on the steam-bath to dryness. The residue was taken up in a small amount of water and sulfuric acid added to convert the chloride to sulfate. The solution was again evaporated, treated with water, and evaporated to make certain of expelling all of the hydrochloric acid. The copper sulfate was dissolved in 10 *cc.* of water and transferred to a scrupulously clean, weighed platinum crucible. The evaporating dish was washed repeatedly with small portions of water and the washings were stirred into the main solution. The crucible was then made the cathode in an electrolytic stand. All the usual precautions were taken in the electrolysis. The washings were collected and tested for copper. The crucible was dried at 85° before the first weighing and at 120° before reweighing. In every analysis the deposit of copper was smooth, firm, even, coherent and of bright, uniform color. No flakes and no crystalline character were observed.

The washings were evaporated to about 10 cc., made alkaline with ammonium hydroxide, evaporated and heated gently to drive off ammonium sulfate. The residue was taken up in 5 cc. of water and tested for copper with potassium ferrocyanide. In every case a faint coloration resulted, The amount of copper which would cause this coloration was ascertained by comparison with known amounts of copper. The amount of undeposited copper was quite uniform in the washings from different analyses and amounted to 0.00006 g. This correction was applied to all analyses.

Determination of Chlorine.—A weighed sample of cupric chloride solution was transferred to a 3-liter precipitation flask. With fifteen or more rinsings of the Florence flask the solution was diluted to 500 cc. From the previous copper determination the equivalent amount of silver was calculated (assuming 63.565 as the atomic weight of copper) and weighed out with proper allowance for weight corrections and for the buoyancy of air. The silver was dissolved in nitric acid in a flask with a bulb tower and the resulting solution diluted to 500 cc. The silver solution was then added to the cupric chloride solution in a dark room, in which all further work with the solution was conducted. By the usual nephelometric tests over a period of several months the exact end-point was measured.

Correction for Atacamite

After solution **A I** had stood for a few days a slight precipitate was observed at the bottom of the container. Upon examination this precipitate was found to consist of small clusters of fine, light-green rhombic crystals which had grown from the solution. Their form and color indicated that they might be cupric oxychloride or atacamite, sometimes written $CuCl_2{\cdot}3CuO{\cdot}4H_2O$. In the early work on cupric bromide a similar precipitate had been found and made the subject of a short paper.[9]

Solution A I was filtered and kept for six months. No further growth of crystals was observed. The second solution A II was carefully watched. Seven days after the recrystallized cupric chloride had been dissolved crystals were observed. This solution was left for four months before being filtered. The crystals were then analyzed and the solution was used for atomic weight determinations. In the meantime solution A III was prepared, but with the addition of one cubic centimeter of nitric acid (40%) to a concentrated solution of the crystals before dilution. As no crystals grew in solution A III in forty days, the solution was analyzed.

Solution B I yielded crystals in five days. After fifteen days the crystals were collected on a Gooch-Munroe crucible. This solution stood for four months without any more crystals appearing. Solution B II was prepared from the same crystals as solution B I. However, in this case one cubic centimeter of nitric acid was added to the first concentrated solution before final dilution. In the case of solution B III crystals were found on

---

[9] Richards, *Proc. Am. Acad. Arts Sci.*, *25*, *215 (1890)*.

the fourth day. This solution was filtered after twenty-one days, the crystals were investigated and the solution was analyzed.

Apparently the growth of crystals was complete in a week. It is significant that the weights of the crystals were practically the same in solutions B III and A II.

The precipitates from these two solutions were washed with distilled water and dried at 120° to constant weight. They were then dissolved in nitric acid and the chlorine was determined as silver chloride. Excess silver was removed with hydrobromic acid, and after conversion to the sulfate the copper was determined electrolytically. The results of the analyses are given in Table I.

TABLE I

ANALYSIS OF PRECIPITATES

Soln.	Precipitate, g.	AgCl, g.	Chlorine, g.	Copper, g.	Copper, %	Chlorine, %
A II	0.02262	0.01572	0.00389	0.01294	57.2	17.2
B III	.02277	.01540	.00381	.01305	57.3	16.7

The copper content of atacamite should be 57% according to the formula usually assigned it. The chlorine content was likewise slightly higher than theoretical, but since the ratio of chlorine to copper was similar to that for atacamite, it was concluded that the crystals consisted of this compound,

It was necessary to investigate the method of formation of this precipitate, because in it the weight of chlorine was much smaller on the basis of the copper present than in pure cupric chloride. If this difference of chlorine had'been retained in solution in the formation of the atacamite, there would be an excess of chlorine in the solutions from which the precipitate had been removed. On the other hand, if in some way the chlorine had escaped from solution, no correction for excess chlorine would be necessary in the case of removal of the precipitate. But in the cases where the atacamite was held in solution with nitric acid, a loss of chlorine would mean an excess of copper or a deficiency of chlorine, and a correction need be added to the chlorine found in the analysis of the solution. For example, in the atacamite from solution A II the weight of chlorine found was 0.00389 g., whereas the weight of chlorine required for an equivalent amount of $CuCl_2$ is 0.01443 g. This difference of 0.01054 g. of chlorine corresponds in the chloride analysis to 0.03207 g. of silver for the whole solution or 0.00291 g. of silver for each 100-cc. sample analyzed. Similarly for solution B III the difference in silver would be 0.00297 g. for each 100-cc. sample.

It became important then, to find out whether the chlorine left the solution or not. This problem was attacked in several ways. The acidity of the solutions was carefully followed before and after precipitation of the oxychloride. Since acidity was no greater after precipitation of atacamite than before, it appeared that the atacamite was not formed by hydrolysis.

If cuprous chloride had been present in the crystals of cupric chloride, oxidation of the cuprous chloride to cupric would have formed the oxychloride.[10] Both cuprous chloride and atacamite are soluble in concentrated cupric chloride. Growth of crystals from solution would require some time. On this conjecture, to test for loss of chlorine, a solution of purest cupric chloride was placed in a vacuum desiccator for evaporation over chloride-free sulfuric acid. Ten cubic centimeters of saturated potassium hydroxide solution was placed within the desiccator. After one month the potassium hydroxide was tested. Compared with a blank test with a similar unexposed solution of potassium hydroxide, an increase in chloride content of the hydroxide was found.

A second test was conducted in a similar manner except that the cupric chloride solution was treated with a little potassium hydroxide. This solution could not have contained excess acid or chlorine. Again the potassium hydroxide gained chlorine.

In order to determine whether this loss during crystallization was chlorine or hydrochloric acid, pure cupric chloride crystals, moistened with water, were placed in a desiccator over chloride-free sulfuric acid with all the precautions previously employed. A strip of starch-iodide paper was suspended within the desiccator. Although the strip was moistened when introduced it quickly became dry. In two months the paper was distinctly purple, whereas in a blank test the paper did not change in color.

Since this test with dry starch-iodide paper was not entirely convincing, a more delicate method was tried. In accordance with a method proposed by Ganassini[11] a strip of chlorine-free filter paper was moistened with a 10% solution of potassium bromide, dried, then dipped into a 0.04% ammoniacal alcoholic solution of fluorescein and again dried. When this paper was left in a vacuum desiccator with moist cupric chloride crystals, it gradually became pink, due to conversion of fluorescein into eosin. The first coloration was observed in seven days. The color developed for about one month, after which no increase in intensity was observed. Blank tests with fluorescein-bromide paper showed no change in color.

It appeared, then, that chlorine was lost in the crystallization of the cupric chloride, undoubtedly from formation of cuprous chloride. The atacamite resulted, not from hydrolysis, but most probably from oxidation of cuprous chloride and crystallization of this rather insoluble complex on dilution and long standing. It seems probable from Henry's Law that all of the free chlorine left the solution. The chlorine lost was undoubtedly represented by the precipitate on account of the insolubility of the atacamite. Agreement of analyses with and without atacamite in

---

[10] Cf. Gröger, *Z. anorg. Chem.*, **28, 154 (1901).**

[11] Ganassini, ***Chem. Zentr.*, I, 1172 (1904).**

the solution further corroborates the hypothesis. The experience with cupric chloride is quite comparable with that with the bromide.[12]

In the analyses, therefore, a correction was added of silver equivalent to the chlorine lost in the cases of solutions A III and B II where the precipitate was dissolved in nitric acid. The correction was based upon the analysis of atacamite from the other solutions and could be legitimately applied because of the similarity of treatment accorded the different series of crystallizations, because all samples gave identical tests for acidity and because the weights of precipitates in the other solution were similar, No correction was applied for solutions A II and B III where the precipitate was removed from the solution.

In Tables II to V are recorded the results of all the successful analyses with the exception of several preliminary ones performed only for practice. Solutions A I and B I were used in the investigation of atacamite.

All values given have been corrected to vacuum. In calculating the necessary corrections the following densities were used: weights, 8.4; $CuCl_2$ solutions, 1.02; silver, 10.49. The atomic weight of copper is referred through chlorine directly to the atomic weight of silver, which was taken as 107.880.

The atomic weights of the samples of copper from Calumet and Hecla and from Chile are identical within the limit of accuracy of the present methods. Neither the correction for atacamite nor the question of acidity influences this comparison. It is a striking case of identity of isotopic constitution of a chemical element taken from sources differing greatly in geological age and geographical distribution.

4	101.881	1.28720	+0.00006	1.26350
5	101.941	1.28794	+ .00006	1.26348
6	101.927	1.28748	+ .00006	[1.26321]*
			Average	1.26349

Chlorine Analyses

Sample	Corr. wt. of sample, g.	Corr. silver weighed out, g.	Nephelometer correction	Corr. silver equiv. for sample, g.	Corr. silver equiv. per 100 g. of soln., *g*.
1	101.897	4.37043	+0.00021	4.37064	4.28926
2	101.974	4.37377	− .00005	4.37372	4.28905
3	101.929	4.37153	+ .00052	4.37205	4.28931
				Average	4.28921

From 4.28921:1.26349 = 215.760:X, X = 63.557, the atomic weight of copper.

*Since the third copper analysis is widely divergent from the other two it is omitted in computing the average. If included the atomic weight of copper found from solution B III becomes 63.554.

The value found by the analysis of cupric chloride adds valuable evidence to the atomic weight of copper. The condensed results of **all** accepted analyses are listed in Table VI.

As a result of fifteen copper determinations and fourteen chlorine determinations the atomic weight of copper is found to be **63.557.**

This value does not seem to be influenced perceptibly by the formation of atacamite, since identical values are obtained whether the atacamite is removed or dissolved and due allowance made for it. The relative acidity, while not affecting the comparison of the samples, since all gave the same indicator test, might have caused a slight deviation from **a** true value. From experimental evidence the total change from a distinctly acidic to a distinctly basic reaction would correspond to **0.006** unit in atomic weight. If it is assumed that the true acidity for the cupric chloride solutions was midway between these conditions, the atomic weight found would be about **0.003** unit low.

TABLE VI

ATOMIC WEIGHT OF COPPER

From solution A II	63.557
From solution A III	63.557
From solution B II	63.557
From solution B III	63.557
Grand average	63.557

Acknowledgment for generous financial assistance in this research is made to the Carnegie Institution of Washington and to an anonymous benefactor of this Laboratory.

Summary

No difference was found in the atomic weights of specimens of copper from the Calumet and Hecla mines in the Lake Superior region in Michigan and from Chuquicamata, Chile.

The ratio of the atomic weight of copper to that of silver was determined by analysis of pure, recrystallized cupric chloride. The copper was determined electrolytically and the chlorine by nephelometric titration with pure silver. On the basis of Ag = 107.880 the atomic weight of copper was found to be **63.557.**

THE SURFACE TENSION OF LIQUID SULFUR DIOXIDE

BY VERNON M. STOWE

RECEIVED OCTOBER 1, 1928 PUBLISHED FEBRUARY 5, 1929

The surface tension of liquid sulfur dioxide has been determined once only and that at a single temperature. At −25° Grunmach[1] found the surface tension of the liquid to be **33.5** dynes per cm. The author has been interested for several years in the work of Dr. Bond[2] of the University of Iowa on solubility. Now Hildebrand[3] recounts the relation between surface tension and solubility. Therefore, it seemed very desirable to determine the surface tension of liquid sulfur dioxide at several temperatures in order that comparisons might be made with other liquids. The problem of the solubility relations of liquid carbon dioxide has already been attacked in this same manner by Quinn.[4]

Experimental

The capillary tube method was used. **A** large number of capillary tubes were drawn from a variety of soft glass tubes and of these six were chosen for uniformity of bore, determined by means of a micrometer. They were washed with a mixture of potassium dichromate and sulfuric acid for over twenty-four hours. They were thoroughly rinsed with tap water, then with distilled water and finally with conductivity water. They were dried by drawing air through them briefly and were placed in a desiccator over phosphorus pentoxide for more than a week. From the time they were removed from the cleaning solution they were handled with carefully cleaned hands and only at one end. This end was broken off immediately to prevent impurities from

spreading down onto the cleaned portion. The capillaries were loaded into tubes of heavy pyrex glass **1.35** cm. in diameter, sealed at one end. These tubes had been thoroughly cleaned and dried in the same manner as the capillaries. The capillaries were held in a position along the axis of the "jacket" tube by means of two platinum wires bent into a bracket shape, with a loop in the middle. The upper part of the jacket tube **was** constricted to make subsequent sealing easy.

Liquid sulfur dioxide was prepared by the method mentioned by Bond and Beach" except that no mercury seal was used. The apparatus was well swept out by preparing several portions of the liquid. It boiled at −9.8° at 736 mm. pressure, leaving no residue. The jackets were filled about one-fourth full and sealed off at a length of about **10** cm.

A thermostat was constructed of a quart size unsilvered wide-mouthed Dewar flask. This was cooled to **−90** and −50° by pouring liquid air into a long test-tube and inserting this tube into the thermostat liquid. Ethyl alcohol was used at the low temperatures. The slcohol would congeal about the tube and furnish a fairly even temperature for some time as it thawed. Ice and calcium chloride were used for the temperature −20°, and salt and ice for **−10** and −5°. Ice water and much ice were used for the 0° point. Water at 4° was used to cool tap water to achieve temperatures between 0 and 25°. Temperatures of **30** to 50° were attained by inserting a long narrow lamp commercially used for illuminating showcases. This was turned off and on by means of a home made thermoregulator containing toluene and a mercury contact column. The temperature could easily be controlled within one-tenth of one degree. The light was turned on and off several times per second even when all vibration was eliminated. The bath was stirred efficiently at all temperatures.

The thermometers were checked against one or two standard thermometers recently calibrated by the U. S. Bureau of Standards. At sub-zero temperatures it was necessary to check against freezing and sublimation points. Carbon dioxide, mercury, chloroform, chlorobenzene and carbon tetrachloride were used.

Tubes were kept at the required temperature for thirty minutes to one hour before readings were taken. When working at temperatures somewhat removed from room temperatures, they were placed in a crude cooling bath or warming bath in order that they might come quickly to equilibrium when used.

Readings of the height of the column in the capillary were made by means of a good heavy cathetometer. At least five readings checking within ±0.01 cm. were made. These readings were made with the tube suspended in the thermostat in at least two different positions and at different levels to eliminate errors due to distortion of light by the Dewar flask and the jacket tube. Discrepancies due to this cause were rare. The averages of these readings are recorded in Table II.

After reading the height of the liquid in the capillaries at the various temperatures the tubes were opened. When the sulfur dioxide had completely evaporated, they were rinsed out with some carbon tetrachloride which had been purified by freshly distilling in a tin–glass–air system followed by fractional crystallization. The tubes were now charged with some of the purified carbon tetrachloride, which has a surface tension very close to the value for sulfur dioxide at 20°. The tubes were now suspended in the thermostat and readings were made of the capillary rise. Assuming Richards and Carver's[5] value for the surface tension of carbon tetrachloride to be correct, the radii of the capillaries were calculated

---

[5] Richards and Carver, THIS JOURNAL, 43, **845 (1921).**

from the equation $r = 2\gamma/hdg$, where r is the radius of a capillary, h is the capillary rise corrected as shown below, d is the density of carbon tetrachloride at 20°, g is the acceleration due to gravity and γ is the surface tension of carbon tetrachloride at 20°. The values so found for the radii are listed in Table I.

A second method was employed to determine the radii. A thread of mercury was introduced into each capillary tube and the length of the thread was measured by a micrometer in conjunction with a steel decimeter scale. Incidentally, a check on the uniformity of bore of the capillaries was made by moving the thread along. The length remained practically constant in all cases. The radii were calculated in the obvious manner, after using a microbalance to weigh the mercury by difference. These values are given in the third column of Table I.

The radii were determined finally by breaking the capillaries off squarely and examining them under a microscope fitted with a micrometer. These results are listed in the fourth column of Table I. The mercury method was probably the most exact and these values are used. The fifth and sixth columns give the percentage of deviation from the mercury values. The author did not examine the probable error of these methods. The agreement between the sets was considered very satisfactory.

TABLE I

RADII OF THE CAPILLARY TUBES IN CENTIMETERS

Tube	Method 1st, CCl_4	 2d, Hg	 3d, ocular	Deviations 1st, %	 3d, %
1	**0.01978**	**0.01950**	**0.01995**	+1.4	+2.3

4	.01692	.017117	.01736	−1.2	+1.4
5	.02677	.02737	.02729	−0.5	−0.3
6	.01409	.014222	.01430	−0.9	+0.6

Results

The calculations were made in the same manner as those performed by Quinn in the article mentioned. Table II lists the temperature, the tube number, the observed height, the height after two corrections had been made, the densities of the liquid and of the gas, the difference between these values, the surface tension and the average of these numbers at each temperature. The corrections were for volume of the meniscus, and a correction for the effect of the outer tube, made in the same manner as Quinn made them. The densities were read from a large graph upon which had been plotted all the data of densities listed by "International Critical Tables." They were extrapolated mechanically where necessary. Tube No. 3 was thrown out entirely because it was not properly filled with the liquid.

Discussion

The equation of de Block mentioned by Quinn was applied to the data between −20° and +50° and found to fit within 0.5%. This equation states that $\gamma = K(t_c - t)^n$, where t is the temperature concerned, in degrees centigrade, t_c is the critical temperature, γ is the surface tension and K $= \gamma_0/(t_c)^n$. Here γ_0 is the surface tension at 0° and n is *a* constant, equal to 1.2 for most normal unassociated liquids. In the present work n was determined for each experimental datum and the values were averaged, yielding 1.19. However, the median value seemed more desirable on inspection. This value for n is 1.20. The surface tension was therefore

TABLE III

CALCULATED RESULTS

t, °C.	n	$\gamma_{\text{obs.}}$	$\gamma_{\text{calcd.}}$ (n = 1.2)	Diff.	$\gamma_{\text{calcd.}}$ (n = 1.19)	Diff.
−20	1.17	30.68	30.70	+0.02	30.74	+0.06
−10	1.13	28.59	28.70	+ .11	28.69	+ .10
− 5.8	1.06	27.70	27.84	+ .14	27.83	+ .13
+ 5	1.28	25.58	25.65	+ .07	25.66	+ .08
+ 9.9	1.27	24.54	24.66	+ .12	24.68	+ .14
+15	1.20	23.64	23.64	0	23.67	+ .03

24.5	1.22	21.61	21.69	+ .08	21.73	+ .12
30	1.19	20.73	20.69	− .04	20.73	0
40	1.20	18.77	18.76	− .01	18.81	+ .04
50	1.20	16.85	16.86	+ .01	16.92	+ .07

calculated from both equations, $y = 0.061534(157.5-t)^{1.2}$ and $\gamma = 0.06473(157.5-t)^{1.19}$. The results are entered in Table III, with the deviations of each from the experimental values. The value $n = 1.20$ appears to fit slightly better than $n = 1.19$, although the latter yields smaller maximum deviations. The critical temperature was taken from the work of Cardoso and Fiorentina.[6]

The functions mentioned by Hildebrand,[3] in which E_σ = the total energy of surface formation and v = molal volume, were evaluated as follows: $E_\sigma = 79$ at 20°; $\gamma/v^{1/3} = 6.33$ at 20°; $E_\sigma/v^{1/3} = 22$ at 20°. The second function classifies sulfur dioxide between chloroform and benzene in the Hildebrand solubility table.

Numerical values were substituted in the equation of Ramsay and Shields.[7]

$$\frac{\gamma_1\,(M/d_1)^{2/3} - \gamma_2\,(M/d_2)^{2/3}}{t_2 - t_1} = k$$

The data for -20 and $+50°$ place the value of k at 2.134. Non-polar liquids average about 2.12.

This work represents a repetition and an extension of crude experiments reported before the North Dakota Academy of Science on May 4, 1928. The author wishes to express his thanks to Dr. S. C. Lind, Director of the School of Chemistry of the University of Minnesota, for his courtesy in placing facilities of the School at his disposal.

Summary

1. Measurements of the surface tension of liquid sulfur dioxide are reported at temperatures from +50 to $-20°$ with less accurate measurements down to $-80°$ in the undercooled region.
2. The equation of de Block in the form $\gamma = 0.061534(157.5-t)^{1.2}$ is found to fit the experimental data excellently over a 70° range.
3. Several constants depending upon the value of the surface tension are calculated. Results classify liquid sulfur dioxide with benzene and chloroform in its solubility relations.

THE ELECTROMOTIVE FORCES OF UNI-UNIVALENT HALIDES IN CONCENTRATED AQUEOUS SOLUTIONS

BY HERBERT S. HARNED

RECEIVED OCTOBER 5, 1928 PUBLISHED FEBRUARY 5, 1929

Measurements of flowing amalgam cells of the type

$$Ag \mid AgX \mid MX(m_2) \mid M_xHg \mid MX(m_1) \mid AgX \mid Ag$$

in which MX is an alkaline halide, have been made by a number of investigators.[1] Accurate results of this character are of fundamental importance since they measure the partial free energy of the solute relative to a given concentration directly, and thus afford a means of computing the activity coefficients. Further, these electromotive forces are of considerable use for the calculation of other quantities, as, for example, the dissociation of water in salt solutions.[2] For these reasons, a more searching, precise and thorough study than heretofore made of the cells containing potassium and sodium chlorides and bromides will be presented, as well as results of less accuracy with cells containing lithium chloride and bromide. Certain experimental difficulties which were encountered will be pointed out and the concentration range in which these measurements may be expected to be valid will be indicated.

Materials and Electrodes.—The mercury employed was distilled three or more times. All the salts were purified by recrystallization of high grade analyzed chemicals. The sodium and potassium chlorides were precipitated by hydrochloric acid gas and then fused. The recrystallized sodium and potassium bromides were dried for two days or more at a temperature of 200–250°. Solutions of these salts were made by direct weighing of both salt and water. Concentrated solutions (approximately 12 M) of lithium chloride and bromide were made from the recrystallized salts and analyzed gravimetrically. These stock solutions were diluted to the desired strength by mixing with the required weight of water.

The amalgams of potassium and sodium were made by the method described by Harned[3] and always contained approximately 0.01% of the alkali metal. Lithium amalgam of approximately 0.003% as recommended by Harned and Swindells[4] was employed. It was made by the electrolysis of a solution of the hydroxide. We have never encountered serious difficulties in the use of sodium or potassium amalgams. Lithium amalgam, however, is much more difficult to control and consequently results obtained with it are considerably less reliable than those obtained with the sodium and potassium amalgams.

Three kinds of silver-silver chloride electrodes have been employed. **Type 1.**

A platinum spiral filled with a paste of silver oxide was heated to 450°. The silver electrode thus obtained was surrounded by crystalline silver chloride, obtained by the slow evaporation over sulfuric acid of an ammoniacal silver chloride solution. This type of crystalline silver chloride was recommended by Giintelberg[6] for this purpose. Type 2. A platinum spiral which held silver obtained from heating the oxide paste was made the anode in a normal hydrochloric acid solution and the chloride was formed by slow electrolysis at low current densities (20 ma. per cc. electrode for two hours). Type 3. These electrodes were the same as recommended by Noyes and Ellis,[6] and were the same as Type 2 with the exception that a layer of electrolytic silver was deposited upon the spiral by electrolysis of a potassium silver cyanide solution before the silver oxide paste was put on.

Apparatus and Methods of Measurement.—The cell finally employed (Fig. 1) was of a very simple design. It could be filled readily through the tubes DD with solutions which had been previously boiled *in vacuo*. It also could be completely emptied by suction through the outlets OO. This method of filling and emptying the apparatus has been sufficiently described elsewhere.[7] A Type 1 electrode is represented by C. A small ball of glass wool at the narrow opening in the tube was used to hold the crystalline silver chloride. Electrodes of Types 2 and 3 are represented by A. In the actual measurements, electrodes of the same type were used in each of the two cell compartments. The stopcocks SS which had to be manipulated during the course of a measurement are shown to contain grease cups at the two ends. By filling these with a rubber–vaseline–paraffin mixture, they could be manipulated under the water in the thermostat without danger of electrical leakage. The amalgam reservoirs, B, were of the design used by MacInnes and Beattie. In the cases of potassium and sodium chlorides and bromides, and lithium bromide, three amalgam reservoirs were employed. A measurement would be made with the first, then the cell emptied and refilled with the same solution. The second amalgam reservoir was then introduced and another measurement obtained. This manipulation was repeated until all three amalgam reservoirs were used. Reservoir No. 1 delivered 1 cc. of amalgam in fifteen seconds from the left capillary and 1 cc. in twenty-five seconds from the right capillary. Reservoir No. 2 delivered 1 cc. in fifteen seconds from both capillaries. Reservoir No. 3 delivered 1 cc. in twenty-five seconds from the left and the same amount from the right capillary in fifteen seconds. Two ways of forming the amalgam electrodes were employed when using potassium and sodium amalgams. One was to allow the jets of amalgam from the capillaries to break in the solution. This could be done by removing the amal-

[7] Åkerlöf, *ibid.*, 48, 1160 (1926).

gam quite rapidly through the stopcocks SS. The second way was to form pools of mercury in the electrode vessels by removing the amalgam comparatively slowly at first through SS. The jets from the capillaries were allowed to flow without breaking into the pools of amalgam. This allowed a large amalgam surface. When using potassium and sodium amalgams *both these methods of manipulation gave identical results.* Owing to the high reactivity of lithium amalgam, the pool method was never successful. The first method of the free flowing jet was always employed, but even this was difficult because of the manner in which the lithium amalgam stuck to the sides of the glass walls. Although results were obtainable which could be reproduced to within ±0.3 mv., they were always somewhat erratic. Other forms of amalgam reservoirs with specially designed capillary delivery tubes were tried but none of these was sufficiently applicable to warrant further description. Such a specially designed apparatus was used in the case of some of the lithium chloride cells.

Experimental Results

1. Potassium Chloride.—The most extensive series of measurements was obtained with the cells containing potassium chloride. The three amalgam reservoirs as well as the three types of silver–silver chloride electrodes were employed. In Table I are given the results with the crystalline silver chloride electrodes of Type 1. Two series were obtained without changing the silver chloride electrodes. One compartment of the cell was filled with 0.1 *M* potassium chloride and the other compartment contained the solutions of varying strengths. The first series was started

with the solutions of the lowest concentration and three measurements were taken with the three different amalgam droppers (denoted by Nos. 1, 2 and **3)**. The solution of the next concentration was then introduced and three measurements were taken. This was repeated through Series I, Then the process was reversed and measurements were taken first with the most concentrated and then with the solution of the next lower strength. The second, third and fourth columns contain the electromotive forces of Series I and the next column the total deviation of this series. Series 11 is exactly similar. The columns headed M_{I} and M_{II} are the mean values of the first and second series, respectively, and A is the total deviation of these mean values. The next to last column contains the mean of all the results.

The results of cells containing the 0.01 or 0.02 molal solutions were much more difficult to obtain. The electromotive force of the 0.01–0.1 M cell checked the values obtained by MacInnes and Parker fairly closely. There is considerable doubt as to whether these results are correct. Indeed, Lewis and Randall thought that unavoidable side reactions caused difficulties with these cells, and this opinion has been borne out by more recent investigations. Care therefore should be exercised in attempting to employ these results. On the other hand, the entire cell mechanism works more steadily with solutions of 0.05 M and above so that this series is reliable at concentrations of 0.1 M and higher. The average deviation between Series I and II in the concentration range of from 0.02 to 4 M is 0.04 mv. This is good if it is possible to obtain the same result with other types of silver-silver chloride electrodes.

Table II contains the electromotive forces of the same cells obtained with Type 2 and Type **3** electrodes as well as the mean values of the results with Type 1 electrodes. Those with Type 3 electrodes were obtained by Harned and Douglas and were only single measurements. The measurements obtained with Type 2 electrodes are recent and were made with the

three different amalgam droppers. A freshly prepared spiral electrode which had been equilibrated with the cell solution for about two hours was used for each measurement. In Col. 3 the number of results obtained with electrodes of Type 2 are given and in Col. 5 their total deviation in millivolts. It is to be observed that the difference in millivolts between the series with Type 1 and Type 2 silver–silver chloride electrodes is 0.11, 0.06, 0.07 and 0.07 mv. in the cells containing the 1, 2, 3 and 4 M solutions, respectively. The results with Type 2 electrodes are all slightly lower than those with Type 1. Further, the agreement with the Noyes and Ellis electrodes (Type 3) is very good.

2. Potassium Bromide, Sodium Chloride and Sodium Bromide.—Cells containing potassium bromide have been previously measured by Pearce and Hart[1d] and Harned and Douglas.[1e] A few results of less accuracy were obtained by Allmand and Polack[1c] from measurements of cells containing sodium chloride. Harned and Douglas also measured the cells containing sodium bromide. The measurements given in Table III are far more extensive and accurate than those previously obtained. Spiral electrodes of Types 2 and 3 were employed. Type 2 electrodes were employed in the case of all three salts. Type 3 or the Noyes and Ellis type were employed in the case of some of the sodium chloride results. This is indicated in the table. A freshly made silver–silver chloride or silver–silver bromide electrode was used in each run of three results.

These electrodes were placed in the cells and in the cell solutions for periods of from three to five hours before readings were taken. In the case of the silver-silver chloride electrodes constant and reproducible values were obtained within two to three hours. Silver–silver bromide electrodes took somewhat longer to equilibrate. For example, cells of the type

$$H_2 \mid HBr \mid AgBr \mid Ag$$

take about four hours to reach a constant and reproducible electromotive force. This remains constant for from four to ten hours and then slowly decreases. In the present investigation the solution and electrode were kept in contact from four to five hours before the first measurement. Removal of the solution and immediate refilling could be carried out without considerably affecting the electromotive force. Consequently, the second and third measurements were carried out within ten to twenty minutes after the first one.

The first column of the table gives the molal salt concentrations, the columns headed "No." contain the number of determinations, the columns E contain the mean electromotive forces and those headed A (mv.) the total deviations in millivolts. In the case of potassium bromide these results check those obtained by Harned and Douglas well at the lower concentrations. Thus they obtained —0.0324, 0.0746, 0.1068, 0.1266 and 0.1410 at concentrations of 0.05, 0.5, 1, 1.5 and 2 molal, which compare favor-

ably with those given in Table III. In the case of the cells containing sodium bromide, they obtained 0.0773, 0.1123, 0.1345, 0.1505, 0.1659 and 0.1779 at 0.5, 1, 1.5, 2, 2.5 and 3 molal salt concentrations, which agree fairly well with the later results. The total deviations of the results are seen to be within 0.3 millivolt. We regard this as very good since the cell mechanism is complicated, since the conditions of flow of the amalgam were varied in each case and since new silver–silver halide electrodes were made for each run of three or less results. It has been our experience that results of very high consistency may be obtained by performing each operation in exactly the same manner. We do not believe that results thus obtained are necessarily the correct reversible electromotive forces. We have, therefore, preferred to sacrifice consistency by varying the cell mechanism in the ways previously described.

3. Lithium Chloride and Bromide.—In Table IV are given the results obtained with lithium amalgams. Since we were never able to obtain as steady readings with these as with the sodium or potassium amalgams, we regard the results as having approximately an accuracy of ± 0.2 mv. up to 2 molal. In the case of cells containing salt at higher concentrations than this, the accuracy decreases. We obtained 0.1168 and 0.1958 volt with cells containing lithium chloride at 1 and 3 molal concentrations, respectively, which agree fairly well with 0.1165 and 0.1954 previously determined by MacInnes and Beattie. Since all the electrodes were prepared in an entirely different manner from that employed by these investigators, the result is encouraging.

One possible source of error which is independent of the mechanism and operation of these cells remains to be discussed. In concentrated

In the lithium chloride series the results in parentheses were found with Type 2 silver–silver chloride electrodes. All others were made with Type 1 electrodes. All lithium bromide results were obtained with Type 2 electrodes.

salt solutions the solubility of the silver halides increases rapidly with the salt concentration. The solubility of silver chloride in potassium, sodium and lithium chlorides is not sufficient to cause any error greater than the experimental error of these measurements. On the other hand, the solubility of silver bromide in the corresponding salt solutions is sufficient to cause an error in the solutions of 2 M salt concentration and higher. Thus, from the data of Hellwig,[8] we find that in a 3 M potassium bromide solution enough silver bromide will be dissolved to cause a maximum error of 0.3 mv. either by reason of its adding bromide ion to the solution or removing bromide ion due to complex formation. This error will be greater in the cases of sodium and lithium bromides. We do not believe that the amalgam electrodes were affected by any silver which may have diffused into the amalgam compartment of the cells. This was shown by the fact that the solution could be removed from the cell, a fresh one introduced and the same result obtained from a measurement taken before diffusion could have taken place. The effect of the solubility of silver iodide in the iodide solutions upon the electromotive force of such cells was pointed out by Harned and Douglas to be of such a magnitude as to render the result uncertain when the iodide solutions were more concentrated than 1 molal.

A Discussion of the Electromotive Forces of Halide Solutions.—In Table V, Part I, the electromotive forces of concentration cells without liquid junction containing the electrolyte at 0.1 M and 1 M concentrations in the two compartments are compiled.

As a first attempt to consider these results, MacInnes[g] and Harned[10]

proposed a tentative postulate which was the equivalent of the assumption that the electromotive forces of the cells under discussion referred to a given concentration should be additive. We are now able to show that this postulate is only a rough approximation, and point out the character of the departure from this postulate. In Part II of Table V are given the differences in millivolts of the cells containing the different salts. Although the differences between bromides and chlorides, sodium and potassium salts, etc., are of the same order of magnitude, there appears to be a uniform deviation from a strict additive relationship.

On the other hand, the deviation is not uniform in the cases of the more concentrated solutions, if we can rely on the results obtained for the cells containing lithium salts. This is illustrated by Part III of the table. Thus it is seen that the difference between lithium and sodium chlorides is greater than that between the corresponding bromides.

The Activity Coefficients of Halides.—In order to obtain the activity coefficients of potassium and sodium chlorides and bromides from the results in Tables II and III we have made use of the method of extrapolation employed by Hückel.[11] By means of the equation

---

[11] (a) Hückel, *Physik. Z.*, **26**, 93 (1925); (b) Scatchard, THIS JOURNAL, **47**, 2098 (1925); (c) Harned, *ibid.*, **48**, 326 (1926); (d) Harned and Åkerlöf, *Physik. Z.*, **27**, 411 (1926).

$$\log \gamma = -\frac{0.356\sqrt{2c}}{1 + A\sqrt{2c}} + B \times 2c - \log (1 + 0.036\ m) \qquad (1)$$

where c is the concentration in normality, m the molal concentration and A and B are constants, it is possible to extrapolate to infinite dilution the data at higher concentrations with a considerable degree of certainty. Having evaluated the constants A and B, the activity coefficients, γ, obtained by Equation 1 may be compared with those obtained from the electromotive force data according to the thermodynamic equation of the cells. Since the results were all obtained by the use of the 0.1 M reference solution, this latter equation is

$$E = 0.1183 \log \frac{\gamma m}{\gamma_{0.1} \times 0.1} \qquad (2)$$

where $\gamma_{0.1}$ is the activity coefficient in 0.1 M solution. The results obtained by the use of these two methods are compiled in Table VI. The values, $\gamma_{\text{obs.}}$, are the activity coefficients computed directly from the electromotive force data by Equation 2, employing the reference values in parenthesis at 0.1 M, and $\gamma_{\text{calcd.}}$ are those computed by Equation 1. The values of A and B employed are given in the lower part of the table.

[a] **Harned** and Douglas, **ref.** le.

In our previous computations these constants were obtained from the electromotive forces of the cells at 0.1, 1 and 3 molal concentrations. This elaborate calculation has not been repeated. The B constants of the previous calculations have been changed somewhat to meet the requirements of the new experiments in the concentration range from 0.1 to 2 molal. The values for potassium and sodium chloride at 0.001, 0.005 and 0.01 molal taken from the compilation of Scatchard were obtained by him from freezing point data.[12]

Up to a concentration of 2 *M* the agreement between the observed and calculated values is extraordinarily good. The difference between the values obtained is rarely over two in the third place of activity coefficient, which corresponds to a deviation of a little over 0.1 mv. At concentrations above 2 M the values obtained by Hiickel's equation are all somewhat less than the observed values and this difference increases with increasing salt concentration.

In the cases of the less accurate results with lithium chloride and bromide, we have made no further calculation by Equation 1 but have simply computed γ by Equation 2. To this end we employed the reference values at 0.1 M indicated by parenthesis in Table VII. Some of them had been previously obtained by extrapolation by Equation 1.[11a,d] In the case of the less accurate results with the iodides, suitable values were chosen at 0.1 M concentration. In this table we have also included the activity coefficients of hydrochloric acid as recently computed by Randall and Young,[13] hydrobromic acid computed from the results of James[14] and potassium and sodium iodides obtained from the data of Harned and Douglas.[1e]

Comparison of Activity Coefficients Obtained from Electromotive Force and Vapor Pressure Data.—It is a matter of considerable impor-

---

[12] Scatchard, THIS JOURNAL, 47, 648 (1925).

[13] Randall and Young, *ibid.*, 50,989 (1928).

[14] James, unpublished results.

tance to verify the above method for determining activity coefficients by comparing the values thus obtained with values computed by another method which involves a different experimental mechanism. To this end, the vapor pressure measurements of Lovelace, Frazer and Sease[15] of solutions of potassium chloride at 20° are suitable. Since the vapor pressure measures the activity of the solvent, it is possible to compute the activity of the solute by the equation

$$\partial \ln a_2 = -\frac{N_1}{N_2}\partial \ln a_1 \qquad (3)$$

where a_1, N_1 and a_2, N_2 are the activities and mole fractions of the solvent and solute, respectively. If the vapor pressure of the solvent is not great, the gas laws will hold for the vapor, and the vapor pressure, p_1, may be taken as proportional to α_1. Consequently, by substituting p_1 for α_1 and forming a definite integral, we obtain

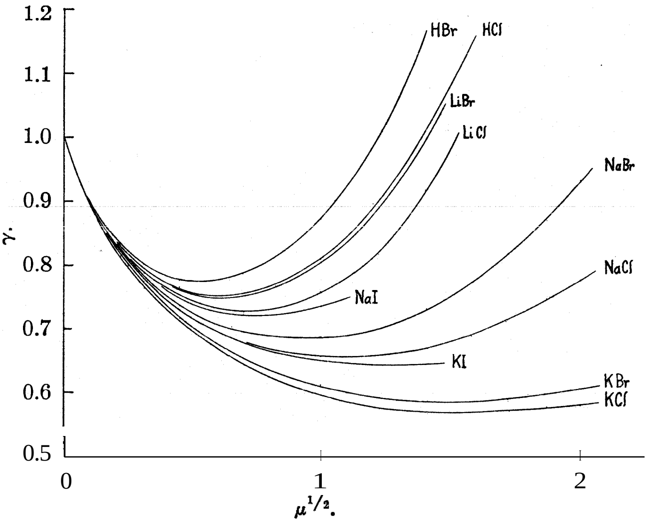

Fig. 2.

$$\int_{\alpha_2'}^{\alpha_2''}\partial \ln \alpha_2 = -\int_{p_1'}^{p_1''}\frac{N_1}{N_2}\partial \ln p_1 \qquad (4)$$

By plotting N_1/N_2 against $\ln p_1$ and evaluating the integral on the right graphically, $\ln \alpha_2''/\alpha_1'$ or $\ln \gamma_2 m_2/\gamma_1 m_1$ may be obtained. From this γ relative to a given concentration may be computed. A similar computation has been made by Scatchard.[16] In Table VIII the result of this calculation is given. The values at 1 M were taken to be identical at the two temperatures. The agreement at 0.2 and 0.5 molal is excellent but

[16] Scatchard, *ibid.*, **47**, 654 (1925).

TABLE VIII

COMPARISON OF ACTIVITY COEFFICIENTS OF POTASSIUM CHLORIDE FROM ELECTROMOTIVE FORCE AND VAPOR PRESSURE DATA

m	0.1	0.2	0.5	1	2	3	4
γ (E.m.f.) 25°	0.764	0.712	0.644	(0.597)	0.569	0.571	0.581
γ (V. P.) 20°	(0.780)	0.713	0.643	(0.597)	0.566	0.562	0.565

at 0.1 molal the result is not good. This is probably due to an error in the vapor pressure method. At 2, 3 and 4 molal the values at 20° become increasingly less than those at 25°. This is to be expected since the partial molal heat of dilution is negative. The magnitude of the difference is of the correct order.[17] We regard this agreement in the concentration range of from 0.2 to 4 molal as excellent confirmation of the method employed.

I take this opportunity to express my appreciation to Dr. Geoffrey M. James and Mr. Robert Robinson for the valuable assistance rendered by them at the time of these measurements.

Summary

1. Measurements at 25° of high accuracy of cells of the type

$$Ag \mid AgX \mid MX(m) \mid M_xHg \mid MX(0.1) \mid AgX \mid Ag$$

containing sodium and potassium chlorides and bromides have been made.

2. Similar but less accurate measurements have been made with similar cells containing lithium chloride and bromide.

3. The electromotive forces of halides have been discussed and considerable departure from additivity is observable.

4. The activity coefficients of sodium and potassium chlorides and bromides have been calculated from the results of the electromotive force measurements and compared with those calculated by Hückel's equation.

5. The activity coefficients of ten halides have been calculated and discussed.

6. The activity coefficients of potassium chloride derived from the electromotive force measurements have been compared with those computed from vapor pressure measurements.

KINETIC STUDIES ON ETHYLENE OXIDES

BY J. N. BRÖNSTED, MARY KILPATRICK AND MARTIN KILPATRICK

RECEIVED OCTOBER 6, 1928 PUBLISHED FEBRUARY 5, 1929

A. Introduction

The ethylene oxides form a group of compounds which is of great interest from the standpoint of both organic and physical chemistry. Their exceptional reactivity in solution already at ordinary temperature offers an inviting field for multifarious kinetic investigations. The "basicity" of these compounds in particular is a striking phenomenon, the mechanism of which does not seem as yet to have been fully understood.

In textbooks of organic chemistry the ethylene oxides are sometimes referred to as "pseudo bases." It is generally recognized that they cannot be classed as bases in the usual sense of this word owing to their lack of electric conductivity in pure aqueous solution. It also seems to be a general opinion that "basicity" of the substances is explicable from their tendency to unite with acids. The precipitation of insoluble metallic hydroxides, e. g., ferric hydroxide, from solutions of the corresponding salts is then looked upon as due to reactions with the acid made free by "hydrolysis."

It will be shown in the present paper that this addition of acids exhibited by the ethylene oxides is kinetically only to a minor extent the reason for their apparent basicity. Regardless of this fact, however, it should be realized that the ability of a substance to add an acid is by no means a feature characteristic of bases. Bases are characterized by adding protons. Taking up the whole of an acid molecule is something quite different from the basic function; it depends upon the anion of the acid in an individual manner and need not have any relation to the strength of the acid added. For instance, the strongest of all electrically neutral acids, perchloric acid, does not react with ethylene oxides in the same way as do the hydrohalogenic acids, although in this group the addition velocity increases with the strength.

Hantzsch[1] was the first to study the reaction between ethylene oxides and acids from a physico-chemical standpoint. He found by conductivity measurements that hydrochloric acid is taken up by ethylene oxide with a considerable velocity, but the reaction came to a standstill long before all of the acid or oxide had disappeared. He did not give any explanation of the incompleteness of the reaction, However, at the same time Henry[2] showed that the oxides in the presence of acids take up water to form

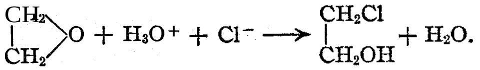
---

[1] Hantzsch and Hibbert, *Ber.*, **40**, 1,514 (1907).

[2] Henry, *Compt. rend.*, **144**, 1404 (1907).

glycols. The part of the oxide reacting in this way is of course prevented from combining with the hydrochloric acid and this easily explains the result of Hantzsch.

The most obvious manner in which hydrochloric acid in dilute aqueous solution may react with ethylene oxide is kinetically as follows



$$\begin{array}{l}CH_2\\ |\;\;\rangle O\\ CH_2\end{array} + H_3O^+ + Cl^- \longrightarrow \begin{array}{l}CH_2Cl\\ |\\ CH_2OH\end{array} + H_2O.$$

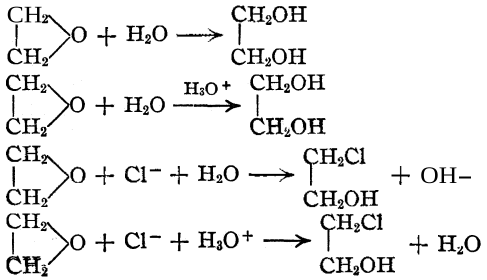
As it stands it presents a reaction between an electrically neutral molecule and two ions of opposite sign and accordingly from the theory of velocity of ionic reactions[3,4] the velocity should be given by

$$h = kc_{Ox}\cdot c_{H_3O^+}c_{Cl^-}f_1^2 \tag{1}$$

the c's indicating the concentrations of the reacting molecules and f the activity coefficient of a univalent ion. A reaction like this might, therefore, be well suited for testing the theory of reaction velocity. In fact, the work described in the present paper was taken up with the primary purpose of providing such a test.

What happens in an aqueous solution of ethylene oxide in the presence of hydrochloric acid is, however, more complicated than the simple addition of the acid. It has already been mentioned that the oxide takes up water when acids are present. This is a hydrogen-ion catalysis. Furthermore, there is a "spontaneous" water addition. Finally, we have found that the oxide combines with the anion of the acid and water, a reaction which is independent of hydrogen-ion concentration. There may also be acid catalysis in the general sense of this term,[5] but this we have been unable to detect with certainty so far,

In other words, ethylene oxide in a solution of hydrochloric acid disappears by four different paths, as follows:



Reaction I $$\begin{array}{l}CH_2\\ |\;\;\rangle O\\ CH_2\end{array} + H_2O \longrightarrow \begin{array}{l}CH_2OH\\ |\\ CH_2OH\end{array}$$

Reaction II $$\begin{array}{l}CH_2\\ |\;\;\rangle O\\ CH_2\end{array} + H_2O \xrightarrow{H_3O^+} \begin{array}{l}CH_2OH\\ |\\ CH_2OH\end{array}$$

Reaction III $$\begin{array}{l}CH_2\\ |\;\;\rangle O\\ CH_2\end{array} + Cl^- + H_2O \longrightarrow \begin{array}{l}CH_2Cl\\ |\\ CH_2OH\end{array} + OH^-$$

Reaction IV $$\begin{array}{l}CH_2\\ |\;\;\rangle O\\ CH_2\end{array} + Cl^- + H_3O^+ \longrightarrow \begin{array}{l}CH_2Cl\\ |\\ CH_2OH\end{array} + H_2O$$

The reactions not only take place with the simple ethylene oxide, but are probably general for the whole group of oxides. In addition to the

simple oxide, we investigated glycid,  $CH_2OHCHCH_2$ and epichlorohydrin,  $CH_3ClCHCH_2$. Furthermore, hydrochloric acid can be replaced by a great number of other acids.

For the sake of simplicity the reactions will henceforth be referred to by the numbers assigned to them above.

B. Preparations

a. Ethylene Oxide.—Ethylene chlorohydrin, CH_2ClCH_2OH, was made from ethylene glycol by the method of Ladenburg.[6] A 25% solution of sodium hydroxide was admitted slowly from a dropping funnel onto ethylene chlorohydrin contained in a distilling flask in a water-bath at 50–60°. The side arm of the distilling flask was attached to a spiral condenser packed in an ice and salt freezing mixture and the tube of the condenser passed into a receiving bulb similarly cooled. The distillation of ethylene oxide proceeded slowly, taking four hours for an 80-g. portion of chlorohydrin; at the end of this time the temperature of the water-bath was raised to 80°. The contents of the receiving bulb were then redistilled directly into a storage tube packed in ice and salt in a Dewar flask. The greater part of the ethylene oxide passed over at 12–13", as recorded by a thermometer, the bulb of which was immersed in the liquid oxide; this was the fraction used. The pure, dry oxide boils at 10.7° according to Maass and Boomer.? For our purpose, however, it was unnecessary to go through the tedious process of entirely removing the water.

b. **Glycid.**—α-Monochlorohydrin, $CH_2ClCHOHCH_2OH$, was made by passing hydrogen chloride into glycerin under the conditions of Smith's "Synthesis 2."[8] Nef's method[9] was used in the preparation of glycid from α-monochlorohydrin. After several fractionations of our product we obtained a quantity of glycid corresponding to 37% of the theoretical yield, free from any chlorine-containing impurity, boiling between 55 and 57° at 8–10 mm. pressure and of specific gravity 1.115^{20}_{4}. The specific gravities previously recorded are[g] 1.111^{22} and[10] 1.165".

c. **Epichlorohydrin.**—For our experiments with epichlorohydrin we redistilled Kahlbaum's epichlorohydrin and took that fraction boiling between 116.5 and 117.5° at 765 mm.

C. Reactions I and II

It was found by Wurtz,[11] Nef[g] and Reboul[12] that the three oxides in question in the presence of water at 100° slowly transform into the corresponding glycols. Reaction I must then be very slow at ordinary temperature. In the case of oxides containing a tertiary carbon atom

the hydration proceeds much faster.[13] Our measurements of the rates are described below.

It has been mentioned that the addition of water to the oxides is accelerated by acids. It is, however, only recently that these reactions have been studied as examples of hydrogen-ion catalysis. After the present investigation was begun, Smith, Wode and Widhe[14] published measurements on the rates of addition of water to ethylene oxide and to epichlorohydrin at 25° in solutions of nitric acid and of perchloric acid of concentration 0.01 to 0.3 M. The reactions were followed by analytical methods and especially in the case of ethylene oxide the experimental errors were large. The authors state that, from their results, they are unable to judge whether the rate of reaction is proportional to the hydrogen-ion concentration or to the hydrogen-ion activity. From their results with nitric and perchloric acids, and from some results (as yet unpublished) with sulfuric acid, Smith, Wode and Widhe conclude that the nature of the anion of the catalyzing acid is unimportant.

1. Experimental Method

A dilatometric method was used in the present investigation for following Reactions I and II. From density data it was calculated that the hydration of ethylene oxides is accompanied by a considerable contraction. This was actually found to be the case also in solution, the contraction during reaction of 50 cc. of a solution originally 0.2 *M* in ethylene oxide being about 10 cm., measured in a capillary tube 1 mm. in diameter. Preliminary experiments showed that the conductivity of a solution 0.01 *M* in perchloric acid, or of a solution 0.01 M in perchloric acid and 0.1 M in sodium perchlorate, remained practically constant during the reaction; there was, therefore, no interference of Reactions III or IV. For this reason it was decided to use perchloric acid as catalyst. With the development of an accurate method of measurement it was thought that k_1, the constant of the "spontaneous" reaction (Reaction I), might be obtained by extrapolation of the velocity constants in dilute acid solution.

The apparatus is shown in Fig. 1. A is a vessel of 150-cc. capacity used as a mixing chamber and as conductivity cell; B and C are platinized electrodes; D is *a* tube through which carbon dioxide-free air may be admitted. The bulb E, of 50-cc. capacity, is the diiatometer. FG, the graduated portion of the capillary, is 0.0086 cm^2. in cross section and 20 cm. in length. It was found that the bore of the capillary was uniform to within 1% throughout the entire length and uniform to 0.5% throughout the upper half; the upper half was the region used. T, a glass chamber filled with mercury, is capped with a steel top through which moves the screw H acting as a plunger. With the screw H in its uppermost position mercury stands in the small reservoir K, and with the screw in its lowest position mercury extends to L and M in the tubes to the left

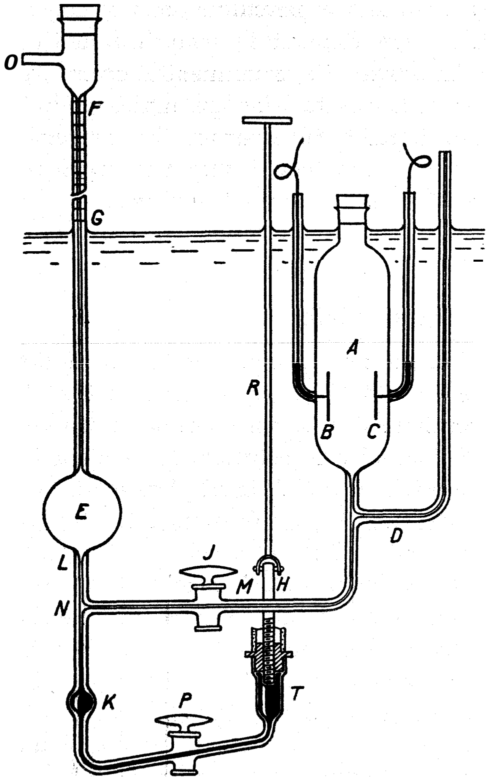
[14] Smith, Wode and Widhe, *Z. physik. Chem.*, **130,** 154 (1927).

and right of the cock I. The upper part of the screw, H, and the connecting rod, R. are enclosed in a rubber tube. The apparatus was mounted and placed in an insulated glass thermostat at 20.00°; the maximum fluctuation in temperature observed in the thermostat during the course of the work was 0.005°.

The procedure was as follows: 150 cc. of a solution of ethylene oxide was placed in the cell A and allowed to come to the temperature of the bath. A given volume of the solution was removed with a pipet and the same volume of 0.1 *M* perchloric acid was added. Mixing was effected by bubbling air through the solution for a few minutes. On account of the electrodes it was not feasible to dry the apparatus between experiments and, after draining, a few drops of water always remained in the tubes connecting A and E. One-third of the solution was therefore allowed to flow over into E and was forced back into A by compressed air applied at Q, before the dilatometer was finally filled. During the filling the mercury stood at N. Experience showed that if the solution was drawn up to G in the capillary, and the cock I closed, by alternately screwing down H (cock P open) and opening I, mercury could be brought to the position I, and M, and the solution D to a convenient position near the top of the graduations on the capillary. Cock P was then closed. The mercury-sealed cock[15] J proved very satisfactory and only an occasional regreasing was necessary. The tightness of J was frequently tested by reading the position of the meniscus of a column of water confined in the apparatus at the beginning and at the end of a period of twelve hours. The process of mixing the solution and filling the dilatometer took approximately ten minutes. No trouble was experienced from the formation of air bubbles.



Pig. 1.

Readings were taken at convenient intervals over a period approximately twice the half time of the reaction, and later a second set of readings was taken at the same intervals. The time elapsing between the two sets of readings was always more than twice the period of. half completion; as a rule it was twenty-four hours. The experiments were calculated by the method suggested by Guggenheim.[16]

For very slow reactions, as Reaction I in the case of ethylene oxide, the rate was determined by measuring the contraction in a sealed dilatometer. The dilatometer was a bulb of 50-cc. capacity, from the top of which extended a graduated capillary tube 0.6 mm. in diameter and 30 cm. long, and from the bottom a short thin-walled

---

[15] Brönsted and Guggenheim, THIS JOURNAL, 49, 2554 (1927).

[16] Guggenheim, *Phil. Mag.*, 1, 538 (1926).

tube. Before filling the dilatometer the lower tube was drawn out each time in the flame. The dilatometer was filled by suction applied through the upper tube, and the lower tube was then sealed off at its narrowest point. If an air bubble formed in the solution during the process of filling or of sealing, it was expelled through the capillary by tilting and tapping while the dilatometer bulb was gently warmed. The solution was protected from the air by a glass cap fitting over the top of the capillary tube and dipping into a mercury-filled cup. The rate was calculated by Guggenheim's method, particularly convenient in the case of very slow monomolecular reactions such as this.

2. Results with Ethylene Oxide

Table I gives the data of a typical experiment to determine the velocity of Reaction II. The concentration of perchloric acid (M here and in the following means molarity, i. e., moles per liter) recorded is the mean of the value calculated from dilution of a standard solution of perchloric acid and the value found by titration of 100 cc. of the residual solution against standard sodium hydroxide at the end of the experiment. The perchloric acid concentration given in all the experiments represents this mean. The difference between the two values was always small, and sometimes positive, sometimes negative. The resistance of the solution was measured at intervals during the course of the reaction. With perchloric acid and perchlorates there was usually an increase in resistance of about 0.5%; the

effect upon the resistance of the change in medium with the progress of the reaction will be discussed in a later section of the paper. The fourth column of the table gives Av or the difference between the reading in the second column and the corresponding reading in the third column. When log *Av* is plotted against the time, recorded in Col. 1, the slope of the best line drawn through the points is **—0.4343** k. The fifth column shows the values of Av, of which the logarithms lie exactly on this line, and *Av* — $\Delta v_{\text{calcd.}}$ gives the deviation of any point from the line.

Experiments were made in solutions of perchloric acid ranging in concentration from **0.003** to **0.02 M.** The velocity constants are given in the sixth column of Table **II,** and in Fig. **2** they are shown plotted against the concentration of perchloric acid.

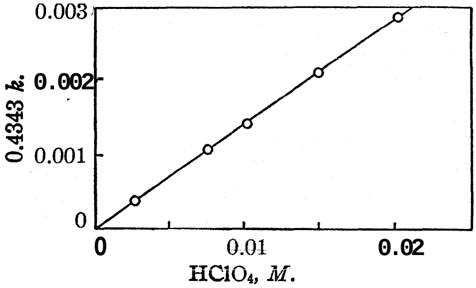

Fig. 2.—Effect of hydrogen ion upon the velocity of addition of water to ethylene oxide (Reaction II).

From **Fig.** 2 it is obvious that the observed velocity constants lie approximately on a straight line. It is evident, therefore, that the rate of reaction is proportional to the hydrogen-ion concentration. From the figure it is also evident that, without carrying out tediously long experiments in very dilute acid solution, it is futile to hope to detect, much less to measure, the spontaneous reaction (Reaction I) by extrapolation of the results in acid solution. It is also evident that the spontaneous reaction can have only a very slight effect upon the rates here measured.

In order to determine the spontaneous reaction the sealed dilatometer was employed, the measurement extending over a period of two months. The solution used was prepared from ethylene oxide and carbon **dioxide-free** water to which a drop of dilute sodium hydroxide solution was added; the resulting solution was **0.2** M in oxide and just alkaline to bromthymol

TABLE II

EFFECT OF HYDROGEN ION UPON THE RATE OF ADDITION OF WATER TO ETHYLENE OXIDE. SALT EFFECT. $t = 20°$. $0.434k_1 = 9.4 \times 10^{-6}$

blue. The velocity constant, $0.434 k_1$, was found to be 9.4×10^{-6}, corresponding to a half time of 23 days at 20°. The effect of any hydrogen-ion catalysis was negligible in our solution, which at the start was 1×10^{-8} molar in hydrogen ion. Experiments in sodium hydroxide solutions up to 0.1 *M* showed the effect of hydroxyl ion to be negligible also.

Knowing k_1 we can now determine exactly k_2, the constant of Reaction II for molar acid, at various salt concentrations.

The sixth column in Table II records the observed velocity constant, and the seventh shows this constant corrected for the spontaneous reaction and divided by the hydrogen-ion concentration, *i. e.*, $k_2 = (k - k_1)/(\text{molarity } HClO_4)$. The fourth column of Table II gives the percentage change in resistance during the reaction. In Fig. 3 $0.4343 k_2$ is plotted against the total equivalent salt concentration, the salt effect of $NaClO_4$ and $HClO_4$ being taken as equal in the first approximation.

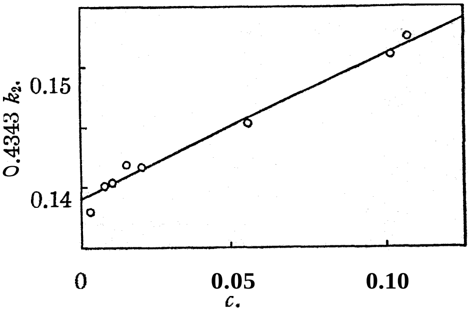

Fig. 3.--Salt effect upon Reaction II. Ethylene oxide, c = total salt concentration $= M_{HClO_4} + M_{NaClO_4}$.

The catalytic constant for ethylene oxide thus may be represented by the linear relationship

$$0.4343 k_2 = 0.1391 4 0.120 c$$

c being the salt concentration. The 9% increase in 0.1 N salt solution is a rather large primary salt effect.

3. Results with Glycid

Reaction I in the case of glycid was followed in a way similar to that described above for ethylene oxide. In Table III are collected the results of experiments in pure water and in various solutions.

TABLE III

THE "SPONTANEOUS" ADDITION OF WATER TO GLYCID. t = 20°

Composition of solution	$0.43 k_1 \times 10^6$
Glycid, 0.1 M, CO_2-free water	6.8
Glycid, 0.1 M, CO_2-free water	6.9
Glycid, 0.1 M, Na_2HPO_4, 0.0025 *M*; KH_2PO_4, 0.0025 *M*	7.6
Glycid, 0.1 *M*, Na_2HPO_4, 0.0050 *M*; KH_2PO_4, 0.0050 *M*	7.0

	Average, 7.4×10^{-6}

The last experiment in Table III was measured over a period of two months and the data were plotted by Guggenheim's method; the reaction, however, was not unimolecular over its entire course, but after the time of half completion decreased in rate, the trend amounting to 20%. Experiments were also made in sodium acetate–acetic acid buffer solution, where the reaction was more rapid, and where the increase in rate was roughly proportional to the acetate concentration. The explanation was later discovered to be addition of acetate ion (Reaction III); this reaction will be discussed at some length for epichlorohydrin. From analogy with experiments on ethylene oxide and epichlorohydrin, it is probable that in the phosphate buffer solutions there was also addition.

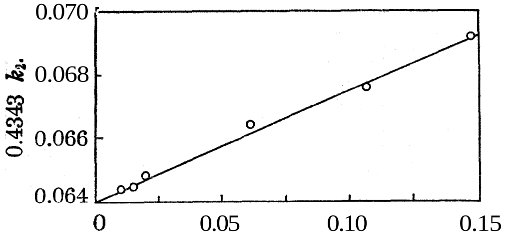

Fig. 4.—Salt effect upon Reaction II. Glycid, c = total salt concentration = M_{HClO_4} + M_{NaClO_4}.

In Table IV are given the results of the experiments in perchloric acid solution. The constant for molar acid, k_2, was obtained as before by subtracting k_1 from the observed velocity constant and dividing the difference by the acid concentration. The correction for the spontaneous reaction is very small as in the case of ethylene oxide. The values of 0.4343 k_2 given in Table IV are shown in Fig. 4 plotted against the total equivalent salt concentration. The salt effect is linear, amounting to 5% in 0.1 N salt solution, as is seen from the equation

$$0.434\ k_2 = 0.0640 + 0.035\ c$$

Experiments were also carried out in solutions of nitric acid, of nitric acid and potassium nitrate, of benzenesulfonic acid, and of benzenesulfonic acid and sodium benzene sulfonate. The results of these experiments are given in Table V.

The first column shows the initial acid concentration as calculated from dilution of a standard solution, the second the acid concentration found upon titration of 100 cc. of the residual solution at the end of the experiment. In the first, second and fourth experiments there was undoubted

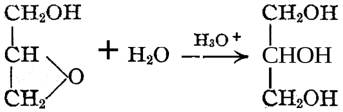
disappearance of glycid due to Reactions III and IV. Definite velocity constants are recorded for the third experiment only, that in benzenesulfonic acid, without salt. In the other cases it was difficult to draw a representative line through the points obtained by plotting log Av against time as the later points lay well above the line through the earlier. The change in resistance during the experiments, recorded in the fourth column, also substantiate this difficulty. Without any addition of the ions of the acid to glycid during the reaction



$$\begin{matrix} CH_2OH \\ | \\ CH \\ | \quad \rangle O \\ CH_2 \end{matrix} + H_2O \xrightarrow{H_3O^+} \begin{matrix} CH_2OH \\ | \\ CHOH \\ | \\ CH_2OH \end{matrix}$$

in perchloric acid solution a slight change in the conductivity of the perchloric acid is expected because of the change in the medium occurring with disappearance of glycid and formation of glycerin. From measurements of the resistance of 0.01000 M perchloric acid in solutions 0.20 M in glycerin and in solutions 0.20 M in glycid, we concluded that an increase of 1% in the resistance is to be expected during the course of the reaction if the initial glycid concentration is 0.20 M. This is qualitatively confirmed by the experiments shown in Table IV.

The increases in resistance in the first, second and fourth experiments of Table V considerably exceed this medium effect.

All these observations tend to confirm the result of the direct titration that acid disappears by the addition Reactions III and IV, these reactions occurring to a greater extent with nitric than with benzene sulfonic acid.

Smith, Wode and Widhe[14] used nitric as well as perchloric acid in measuring Reaction II for ethylene oxide and for epichlorohydrin. They state that the nature of the anion of the catalyzing acid "seems to be of minor importance." Their method of following the reaction was not sufficiently accurate to enable them to detect the complications which we encountered. These complications should, of course, not be neglected when trying to apply the reaction here dealt with for determination of hydrogen-ion concentrations.

4. Results with Epichlorohydrin

The spontaneous addition of water to epichlorohydrin was measured in the same way as the addition of ethylene oxide. Daily readings were taken over a period of a month. The velocity constant, 0.434 k_1, was found to be 2.54 × 10^{-5}, which corresponds to a half time of eight days; Reaction I is therefore approximately three times as fast as in the cases of ethylene oxide and glycid. Two experiments were also carried out in sodium perchlorate solution to determine, if possible, the salt effect upon Reaction I. The results are summarized in Table VI, from which it is evident that there is no detectable salt effect in 0.1 M solution. The solution used in the first experiment was just alkaline to bromthymol blue; the solutions in the second and third experiments were at the change point of bromcresol purple. Hydrogen-ion catalysis was negligible in all experiments. After fourteen days a trace of chloride was detected in the residual portion of the solution used in the first experiment; this was probably due to the hydrolysis of the product of the reaction, $CH_2ClCHOHCH_2OH$, which hydrolyzes much more rapidly than does epichlorohydrin.[17] The reaction showed in no case deviation from unimolecularity.

---

[17] Smith, Z. physik. Chem., 92, 724 (1918).

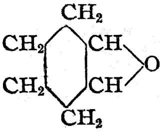
The relationship is evidently linear, k_2 being expressed by the equation

$$0.4343\, k_2 = 0.01059 + 0.0065\, c$$

In 0.1 N salt solution there is, therefore, a 6% salt effect.

5. Results with Cyclohexene Oxide

A few experiments were made with cyclohexene oxide.[18]

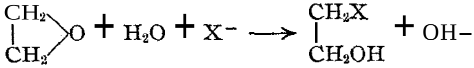


In the presence of perchloric acid this oxide added water very rapidly, the constant for molar acid being $k_2 = 50$.

The constant for the spontaneous reaction is probably small. Dilatometric measurements in acetate and phosphate buffers indicated that the reaction is complicated by Reaction III.

D. Reaction III

Reaction III consists stoichiometrically in an addition of acid to ethylene oxides just as does Reaction IV. Kinetically, however, it is quite different from an addition of acid, the kinetic scheme, as already mentioned, being



$$\begin{matrix} CH_2 \\ | \\ CH_2 \end{matrix}\!\!>O + H_2O + X^- \longrightarrow \begin{matrix} CH_2X \\ | \\ CH_2OH \end{matrix} + OH^-$$

where X^- is the anion of the acid. The reaction is therefore independent of the hydrogen-ion concentration. X^- may represent chloride, bromide, iodide, thiocyanate, formate, benzoate, acetate or trimethylacetate ion. From numerous qualitative experiments it would appear that X^- can also represent other anions, the one exception found being perchlorate.

Smith[19] mentions this reaction in the case of chloride ion and glycid in connection with the preparation of β-monochlorohydrin; however, he makes no distinction between this reaction and the direct addition of hydrochloric acid (Reaction IV), which gives the same products as the above reaction in acid solution. As far as we are aware, Reaction III has in the past always been confused with Reaction IV, the direct addition of acid.[20]

Nevertheless, it is Reaction III, not Reaction IV which imparts to the ethylene oxides their conspicuous apparent basicity. These properties are shown not only in the case of "hydrolyzing" chlorides, where the addition of "free acid" may be made responsible for the precipitation of metal hydroxide.[21] They are exhibited in a no less conspicuous manner, for in-

stance, in a solution of potassium chloride. Adding to a 0.1 M potassium chloride solution phenolphthalein and a little epichlorohydrin or glycid, one very soon finds the solution pink, the color rapidly deepening to indicate a strongly basic reaction. After titrating the hydroxide formed, the reaction proceeds further.

It is easy to show that the reaction here described is much too rapid to be explained kinetically as an addition of hydrochloric acid. Since the addition of hydrochloric acid is roughly proportional to the concentrations, $c_{H_3O^+}$ and c_{Cl^-}, of the two ions, the reaction should be a million times slower in 0.1 KCl than in 0.1 HCl, if it was kinetically a direct addition of acid. This is very far from being the case. The rate in the salt solution is only fifty times slower than it is in the acid solution. An investigation also showed that the reaction in salt solution was independent of the hydrogen-ion concentration over a considerable range, in conformity with the kinetic scheme of Reaction III.

In order to follow Reaction III it must be isolated from Reactions II and IV. If the hydrogen-ion concentration is kept sufficiently low, Reactions II and IV become negligible and Reaction III may then be studied, account being taken of Reaction I. In addition, the solution must not become too alkaline, for then the reverse reaction may come in. The hydrogen-ion concentration must be kept within the limits 1×10^{-4} and $1 \times 10^{-8.5}$ M. In the study of the addition of the anions of weak acids this is a relatively simple matter, but in the case of the anions of the strong acids it is necessary to make and regulate an artificial buffer solution. On the other hand, the determination of the extent of the reaction is easier in the case of strong acids than in the case of weak.

1. Strong Acids

a. Experimental Method.—When an ethylene oxide disappears by Reaction III, for instance, in a potassium chloride solution, an equivalent amount of potassium hydroxide is set free. In order to study this reaction and to have it proceed undisturbed by other influences, the P_H of the solution should be kept within the limits given above (4 to 8.5) and should also be kept constant as far as possible. The double purpose of measuring the speed titrimetrically and keeping the P_H constant can be sufficiently fulfilled by running continuously into the reacting mixture from a microburet such amounts of strong acid that the solution, to which an indicator is added, always matches in color a constant reference buffer solution containing the same indicator. The reaction then proceeds at the P_H characteristic of the indicator and color chosen, which can be varied from one experiment to another. Its extent is directly recorded by the readings on the buret.

The condition necessary for the application of this principle is, first, that a very small amount of acid should give a sufficient change in the color of the solution in which the corresponding potassium salt is present. For this reason the method is applicable only to salts of strong acids.

In order to avoid too much volume change of the reacting solution, the acid added should be rather concentrated. Since one drop of such a solution would change the P_H far outside the permissible limits, the acid is added from the buret through a very fine capillary ending below the surface of the solution. With continuous stirring by air the color then remained practically uniform throughout the solution.

The details of the experimental procedure were as follows. Two cylindrical vessels of 100-cc. capacity and with capillary tubes sealed to their lower ends were mounted vertically in the thermostat and a white porcelain plate was arranged behind them. A bufier solution with a few drops of indicator was placed in one vessel and the solution of the salt to be studied was placed in the other vessel with an equal amount of indicator. Carbon dioxide-free air was bubbled through the solution and when the solution had come to the temperature of the bath, the oxide was added and the initial time was taken. Meanwhile, a special microburet had been filled with 0.5 M perchloric acid. The tip of the buret was 10 cm. in length and of very narrow bore (approximately 0.12 mm.). The graduated portion of the buret was 20 cm. in length and held 1 cc. of acid. As soon as the oxide was added the tip of the buret, extending through a rubber stopper, was set in the solution, the buret was clamped in place and connected to a device by which the pressure above the acid in the buret could be slightly changed so that the flow of perchloric acid from the buret was just sufficient to keep the solution at the desired hydrogen-ion concentration, as shown by a comparison of the color of the reacting solution with the color of the blank. At convenient times buret readings were taken and the time was recorded. The apparatus was arranged in duplicate and two experiments were carried out at the same time.

b. Calculations.—The velocity constants of each experiment were calculated by the velocity equation

$$-\frac{dc_{Ox.}}{dt} = kc_{Ox.}c_{X^-}$$

where X^- is the anion of the salt solution employed. On integration it gives

$$kt = \frac{1}{0.4343(a-b)} \log \frac{b(a-x)}{a(b-x)}$$

a being the initial concentration of the oxide, b that of the salt and x the concentration of both which has disappeared at the time t. Log $(a-x)/(b-x)$ was plotted against the time in minutes and the best line was drawn through the points. The line has an intercept at the initial time of log a/b. The slope of the line divided by 0.4343 $(a-b)$ gives the velocity constant. As it is not convenient to reproduce these plots, the numerical values are given in Col. 5 of Table VIII, which shows the data of a typical experiment.

In calculating the values of x in this table, the effect of the solution being diluted by the strong acid added has not been taken into account. There

is also a small correction to be introduced from the disappearance of the oxide by Reaction I, The slight trend shown by the values of k in the fifth column may be explained in that way. Corrections have been introduced for these effectsin Table IX and the following tables.

c. **Results with Glycid.**—The results of a number of experiments with glycid and iodide are summarized in Table IX. The first six experiments show the effect of the acidity. The acidity seems to–have no

[a] Approximate constants.

influence upon the velocity constant, k_1 within the considerable range of $c_{H_3O^+}$ from 5×10^{-6} to 6×10^{-9}. At higher hydrogen-ion concentration, $c_{H_3O^+} = 6 \times 10^{-5}$, however, the velocity increases, due to Reaction IV, the direct addition of hydrogen iodide. It is here no longer possible to obtain a good velocity constant, because the adjustment of the PH by means of the color of the indicator is not accurate enough when the hydrogen ion enters into the reaction to a considerable extent. At a hydrogen-ion concentration of 6×10^{-10} *M* the calculated values of k decrease as the reaction proceeds; the reaction is probably no longer going to completion. This effect, however, was not investigated further.

Experiments 7–13 were carried out to study the effect of the concentration of the iodide. The rate is very nearly proportional to this concentration. As indicated by the results of these experiments and Expts. 14–17 in which sodium perchlorate was added, there seems to be a small negative salt effect.

The addition of bromide and of chloride is much slower than that of iodide and in the case of the chloride it is necessary to work at higher salt concentrations. As was found with the iodide the reaction is independent of the hydrogen-ion concentration and a negative salt effect is indicated. The results are summarized in Tables X and XI.

It was also found that thiocyanate adds to glycid at a rate comparable to that of iodide.

As is shown in Table XII, the rate was no longer found to be independent of the hydrogen-ion concentration at a hydrogen-ion concentration of

4×10^{-4} M. Thiocyanic acid, therefore, adds to glycid as do the halogen acids.

The salt effect $(1/k_0)(dk/dc)$ in the experiments with chloride, bromide and iodide is on an average -0.30 (k_0 is the velocity constant at zero salt concentration). Taking this to be true also for the thiocyanate, we find that the constants of the four reactions can be represented by

$$k_{\mathrm{Cl}^-} = 150 \times (1 - 0.30c) \times 10^{-6}$$
$$k_{\mathrm{Br}^-} = 103 \times (1 - 0.30\sim) \times 10^{-5}$$
$$k_{\mathrm{Th}^-} = 79 \times (1 - 0.30c) \times 10^{-4}$$
$$k_{\mathrm{I}^-} = 162 \times (1 - 0.30c) \times 10^{-4}$$

d. Results with **Epichlorohydrin.**—The results with epichlorohydrin are quite parallel to those with glycid. The rate of addition is independent of the hydrogen-ion concentration over a considerable range and is proportional to the concentration of the reacting ion. In all cases the reaction is approximately four times as fast as the corresponding reaction with glycid. In studying the addition of iodide to epichlorohydrin, owing to the speed of this reaction, we were able to work at iodide concentrations less than 0.01 M and to follow the reaction practically to completion. In order to avoid the various corrections being greatly magnified with the extent of the reaction, we used, however, only the first part of the reaction, where these corrections are small. The results are given in Table XIII. In the fifth experiment of Table XIII the epichlorohydrin concentration was low and the iodide concentration high, so that the major part of the correction was for the spontaneous reaction.

TABLE XIII

ADDITION OF IODIDE ION TO EPICHLOROHYDRIN. $t = 20°$

The experiments on the addition of bromide, chloride and thiocyanate ion to epichlorohydrin are summarized in Tables XIV, XV and XVI. In Tables XIV and XV, where experiments at widely varying salt concentrations are recorded, the figures show the presence of a negative salt effect as in the case of glycid, but somewhat smaller (0.2 instead of 0.3). If the same salt effect is assumed to exist in all four salt solutions, which

3	.0228	.1000	1×10^{-7}	371

is of course only approximately true, the constants can be given by the following equations

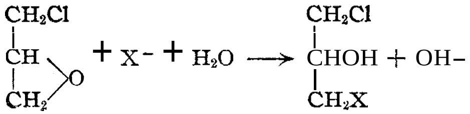
$$k_{\mathrm{Cl}^-} = 69 \times (1 - 0.2c) \times 10^{-5}$$
$$k_{\mathrm{Br}^-} = 37 \times (1 - 0.2c) \times 10^{-4}$$
$$k_{\mathrm{Th}^-} = 38 \times (1 - 0.2c) \times 10^{-3}$$
$$k_{\mathrm{I}^-} = 60 \times (1 - 0.2c) \times 10^{-3}$$

Ethylene oxide is so volatile that it is impossible to obtain quantitative results using this method of following the reaction; qualitative experiments, however, indicate that the rates are approximately the same as with glycid.

2. Weak Acids

In a mixture of acetic acid and acetate ions and in similar buffers the weak acid is added to epichlorohydrin by Reaction III. As the reaction proceeds, the PH of the buffer varies only slightly in the first part of the reaction. The device of artificially maintaining a certain value of the hydrogen-ion concentration, as in the case of strong acids just described, was therefore not necessary. For the same reason, however, also the method used there for following the reaction was inapplicable.

The rate of addition of the anion was determined by titration of the acid from time to time in samples of the reacting solution. Since addition of the anion results in the formation of the hydroxyl ion and consequent neutralization of the acid of the buffer



$$\mathrm{OH^- + HX \longrightarrow H_2O + X^-}$$

the concentration of the anion remains constant. The epichlorohydrin in such a buffer solution disappears by two paths, by Reaction I, the spontaneous, and by Reaction III above. Since the duration of an experiment here was much longer than in the case of strong acids, Reaction I becomes predominant and must be eliminated in order to calculate the constant of Reaction III.

Representing by a the initial concentration of epichlorohydrin, by x the concentration of monochlorohydrin formed at time t and by y the concentration of addition compound formed by Reaction III, one has

$$\frac{dx}{dt} = k_1(a - x - y) \tag{1}$$

$$\frac{dy}{dt} = k'(a - x - y) \tag{2}$$

where k_1 is known (0.434 $k_1 = 2.54 \times 10^{-5}$, *cf.* p. 438) and $k' = k_3c$, c being the concentration of the anion. In order to find k' one divides Equation 1 by Equation 2 and integrates

$$\frac{x}{y} = \frac{k_1}{k'} \text{ or } x + y = y \times \frac{k_1 + k'}{k'}$$

Substituting this value for $x + y$ in (2) and integrating, one has

$$\ln \frac{a}{a - \dfrac{k_1 + k'}{k'}y} = (kt + k')t \tag{3}$$

by which k' is determined, since y equals the concentration of acid which has disappeared, which has been found by the titration. In order to solve for k', we chose a number of arbitrary values of k', plotted the value of the ln of Equation 3 against k', and $t\,(k_1 + k')$ against k', the intersection of the curve representing the logarithmic expression and the line representing $(k_1 + k')\,t$ gave the value of k' satisfying Equation 3. In estimating the acetic acid, enough standard sodium hydroxide solution, 0.02 M, was added to neutralize nine-tenths of the acid; carbon dioxide-free air was bubbled through the solution for twenty minutes and the solution was then titrated to the appearance of the pink color of phenolphthalein. Table XVII shows a typical experiment.

The fourth column contains the arbitrarily chosen values of k', the fifth the corresponding values of the logarithmic expression, and the sixth the corresponding values of $t\,(k_1 + k')$. The seventh column gives the value of k' at the intersection of the curve and the line obtained when $2.30 \log \dfrac{a}{a - y(k_1 + k')/k'}$ and $(k_1 + k')\,t$, respectively, are plotted against k'. The velocity constant, k_3, is obtained by dividing k' by the acetate-ion concentration. Experiments were carried out with acetic, formic, benzoic and trimethylacetic acids. The results of all of the experiments are collected in Table XVIII.

The experiments in formate–formic acid buffer solution are within themselves less accurate than the rest. It was found to be impossible to titrate the formic acid using phenolphthalein as indicator; in the slightly alkaline solution formic acid was regenerated and no end-point could be obtained. The method finally adopted was to add enough sodium hydroxide solution to neutralize nine-tenths of the formic acid, air for fifteen minutes and to remove carbon dioxide and titrate rapidly to the change-point of bromthymol blue,

From Table XVIII it is evident that the rate of reaction is proportional to the anion concentration and independent of the concentration of the acid and of the hydrogen ion over the range studied. In other words, it is actually Reaction III which is responsible for the addition of weak acid. It is also evident that any salt effect amounts to less than 2% in 0.1 N solution.

E. Reaction IV

As mentioned already in the Introduction, the primary purpose of the present work was to study Reaction IV, the direct addition of strong acid to ethylene oxides, from the stand-point of the modern theory of the velocity of ionic reactons.

Only little is known of the kinetics of this addition reaction. Bodfors[20] states that the reaction is probably more rapid with hydrobromic than with hydrochloric acid. With hydriodic acid a simultaneous reduction of the oxide is known to occur.

The addition of hydrochloric acid to epichlorohydrin has recently been found by Smith, Wode and Widhe[14] to be a reaction of the third order. These authors followed the reaction by an analytical method; they worked at comparatively high acid concentrations (0.07–0.13 *M*), they did not recognize the presence of Reactions I and III, and from their results the salt effect upon Reaction IV cannot be determined.

A number of preliminary experiments were carried out in order to determine under what conditions Reaction IV might best be studied. In these experiments the reaction was followed by measurement of the diminution in the conductivity of the solution with addition of acid, the oxide being always present in great excess. An approximate velocity constant was calculated from the equation

$$-\frac{\mathrm{d}c_{\text{Acid}}}{\mathrm{d}t} = kc_{\text{Oxide}}c^2_{\text{Acid}}$$

or

$$\frac{\mathrm{d}\left(\frac{1}{c_{\text{Acid}}}\right)}{\mathrm{d}t} = kc_{\text{Oxide}}$$

by plotting the reciprocal of the acid concentration against time and dividing the slope of the best line through the early points by the oxide concentration. The results of these preliminary experiments are given in Table XIX.

It appears from these figures that the addition of hydrobromic acid is four or five times as rapid as the addition of hydrochloric acid in both the ethylene oxide and epichlorohydrin reaction and also that the reaction with ethylene oxide is about four times as rapid as the reaction with

TABLE XIX

PRELIMINARY EXPERIMENTS ON REACTION IV

[a] The average of the values from four experiments.

epichlorohydrin. For the accurate measurements we decided upon the hydrobromic acid–glycid reaction as probably the most suitable.

1. Description of Experimental Part

The disappearance of hydrobromic acid in the glycid solution was measured by the conductivity of the solution in the conductivity cell shown in Fig. 1. The relation between conductivity and concentration of pure aqueous hydrobromic acid solutions was first determined in the same cell. From this relationship the concentration in the solutions in which the addition took place was calculated on two assumptions; first, that the medium effect of glycid upon the conductivity of hydrobromic acid was the same as the medium effect upon the conductivity of perchloric acid, for which an increase of 1.2% in resistance was found to correspond to a concentration of 0.10 M glycid; and, second, that the medium effect of the glycid, glycerin and bromohydrin present in the solution after the start was the same as the initial medium effect of the glycid. This is certainly not exactly true but may be taken as a sufficient approximation.

The cell constant was obtained by measurement of the conductivity of a *N*/50 potassium chloride solution; the value of Kohlrausch, Holborn and Diesselhorst,[22] was applied for the specific conductivity of *N*/50 potassium chloride solution at 20°.

The acid used was made from Kahlbaum's 25% hydrobromic acid, which was distilled in an all-glass apparatus; the second half of the distillate was redistilled and the middle portion of the second distillate (passing over under a pressure of 764 mm. and containing 47.8% of hydrogen bromide) was taken for the experiments. Solutions ranging from 0.06 to 0.001 M were measured. Excepting the original solution, 0.06173 M, each solution of hydrobromic acid was prepared at room temperature by dilution to one liter of 500 cc. of the preceding solution. No solvent correction was made; it may be mentioned, however, that the specific con-

---

[22] Landolt, Bornstein, Roth, Scheel, "Physikalisch-chemische Tabellen," 5th ed., Vol. II, p. 1098.

ductivity of the water used was 2.4 × 10^{-6} reciprocal ohms. The molecular conductivities are given in Table XX and are shown in Fig. **6** plotted against the square roots of the hydrobromic acid concentration.

Table XX

Molecular Conductivity of Hydrobromic Acid. $t = 20°$

HBr, molarity	Molecular conductivity	HBr, molarity	Molecular conductivity
0.06173	366.8	0.003858	386.4
.03087	374.2	.001929	388.9
.01543	379.6	.000965	389.9
.007717	383.4		

The experimental procedure for determining the rate of addition was the following. A glycid solution was placed in Cell A and allowed to come to the temperature of the thermostat, after which a certain volume was removed with a pipet and an equal volume of hydrobromic acid solution was added. Carbon dioxide-free air was bubbled through the solution in order to mix it and readings of the resistance of the solution were then made at convenient intervals.

The values of the molal conductivity shown in Table XX were plotted against the logarithm of the corresponding resistances. By referring the logarithm of the resistance of the reacting solution corrected for the medium effect, to this graph, the corrected molal conductivity was obtained and from this again the concentration of the hydrobromic acid in the reacting solution was calculated.

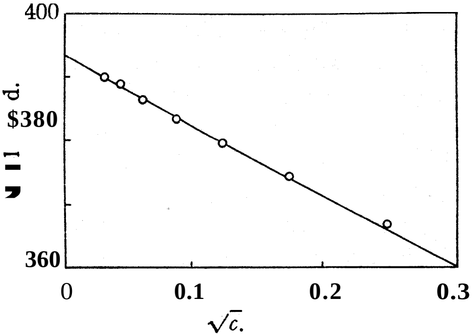

Fig. 6.—Molal conductivity of hydrobromic acid, c = molality of HBr.

2. Calculations

As already pointed out, in an aqueous solution of hydrobromic acid and glycid four reactions occur. Letting x be the concentration of glycid and y the concentration of hydrobromic acid in moles per liter, we may express the kinetic equations of these reactions as follows:

(Reaction I) **Glycid + $H_2O \longrightarrow$ Glycerin**

$$-\left(\frac{dx}{dt}\right)_1 = k_1x \qquad (1)$$

(Reaction II) **Glycid + $H_2O \xrightarrow{H_3O^+}$ Glycerin**

$$-\left(\frac{dx}{dt}\right)_2 = k_2xy = (k_2' + k_2''y)xy \qquad (2)$$

(Reaction III) Glycid + Br^- + H_2O ⟶ Bromohydrin + OH^-

$$-\left(\frac{dx}{dt}\right)_3 = k_3xy; \quad -\left(\frac{dy}{dt}\right)_3 = k_3xy \qquad (3,\ a \text{ and } b)$$

(Reaction IV) Glycid + Br^- + H_3O^+ ⟶ Bromohydrin + H_2O

$$-\left(\frac{dx}{dt}\right)_4 = -\left(\frac{dy}{dt}\right)_4 = k_4xy^2f^2 \qquad (4,\ a \text{ and } b)$$

In setting up these equations the salt effect upon Reaction I and III, which are insignificant, have been neglected. In Reaction II the salt effect has been taken care of by the member k''_2y. The equation developed for Reaction IV is identical with Equation 1 on p. 429 and is the relation to be tested; f indicates the activity coefficient of a univalent ion, for which the equation[23]

$$-\log f = 0.5\sqrt{c} - 0.5c \qquad (5)$$

is supposed to hold.

According to the theoretical Equation 4, the direct addition of hydrobromic acid to glycid is no simple third order reaction. Calculating the reaction constant, k_4f^2, under the presupposition of a simple third-order reaction, we shall expect it to increase steadily during an experiment due to the increase in f as the reaction proceeds.

The constants k_1, k'_2, k''_2 and k_3 are all known from the preceding sections, namely, $k_1 = 2.30 \times 7.4 \times 10^{-6}$; $k'_2 = 2.30 \times 0.0640$; $k''_2 = 2.30 \times 0.035$; $k_3 = 0.00100$. The problem is to decide whether the experiments can be satisfied by a constant value of k_4 and to find its value.

The rate of disappearance of glycid from Equation 1 to 4 is

$$-\frac{dx}{dt} = k_1x + k'_2xy + k''_2xy^2 + k_3xy + k_4xy^2f^2$$

and the rate of disappearance of acid

$$-\frac{dy}{dt} = k_3xy + k_4xy^2f^2$$

We wish to integrate these equations in such a way that from an observed relationship between y and t we are in a position to determine the unknown quantity, k_4. This problem can be solved in a way which has been pointed out by Mr. B. Jessen. We are much indebted to him for this assistance and also for his carrying out a great part of the rather lengthy numerical calculations.

Let

$$k_1 + k'_2y + k''_2y^2 = g \qquad (6)$$

a known function of y, and

$$k_3y + k_4y^2f^2 = h \qquad (7)$$

an unknown function of y. The differential equations then become

$$-\frac{dx}{dt} = (g + h)x \qquad (8)$$

---

[23] Cf. Bronsted, *Trans. Faraday Soc.*, *23*, *416* (1927).

and

$$-\frac{dy}{dt} = hx \tag{9}$$

Subtracting, we have

$$-\frac{d(x-y)}{dt} = gx$$

and letting $x - y = X$

$$-\frac{dX}{dt} = gX + gy$$

Since g and gy are known functions of t, the above equation in X is linear and of the first degree in X and dX/dt can be integrated; the integrated form is

$$X = \frac{1}{S}\left[X_0 - \int_0^t gyS\,dt\right] \tag{10}$$

where S is given by

$$\ln S = \int_0^t g\,dt$$

We now have x or X + y as a function of t, and from the slope of the curve obtained by plotting y against t, the value of the function h may be found at any time. From Equation 2 we have

$$k_4f^2 = \frac{h - k_3y}{y^2} \tag{11}$$

the value of which is now determined by inserting for y and h their proper values. The constancy of k_4 thus determined will furnish a test of the correctness of the equation used for describing Reaction IV.

From Table XXI, in which the results of a typical experiment are given, the procedure of the calculations appears clearly.

The initial values of glycid and hydrobromic acid (x_0 and y_0) were 0.1456 and 0.00991, respectively. The values of the concentration of hydrobromic acid (Col. 2) at the time, t (Col. 1), are smoothed values taken from a graph in which y, determined by the conductivity method as described (p. 451), was plotted against t. The fourth column contains the function g or $k_1 + k_2'y + k_2''y^2$ calculated from the values of the constants given above. The fifth contains S, i. e., the antilogarithm of the integral 0.4343 $\int_0^t$ gdt obtained by graphic integration. The sixth column contains the glycid concentration x, which is equal to

$$\frac{1}{S}\left[X_0 - \int_0^t gySdt\right] + y$$

Here again the integral was evaluated graphically. The seventh column records k_4f^2, the classical velocity constant, calculated by Equation 11; the eighth, its logarithm.

3. Results

In Fig. 7 the velocity constant k_4f^2 from Table XXI is plotted against hydrobromic acid concentration and in Fig. 8 the logarithm of the same velocity constant is plotted against the square root of the acid concentration. From the first plot the increasing change in the constant with decreasing acid concentration predicted by the theory appears. The second plot gives a simple quantitative picture of this change. Since the activity coefficient f is given by Equation 5, the limiting slope for small concentrations in the plot, Fig. 8, should be

$$\frac{d \log (k_4 f^2)}{d\sqrt{c}} = -1$$

The straight line in Fig. 8 is drawn with this slope, to which the measurements are seen actually to conform very well.

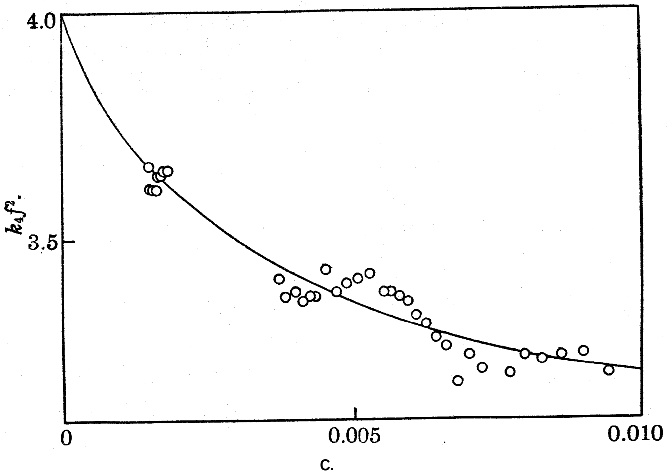

Fig. 7.—Addition of HBr to glycid. Reaction IV, c = HBr concentration.

In addition to the one experiment here described, five other experiments were performed in which the initial glycid concentration ranged from

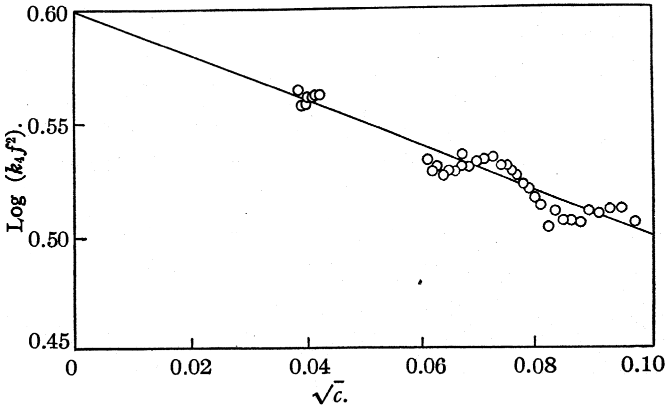

Fig. 8.—Addition of HBr to glycid. Reaction IV, c = HBr concentration.

0.045 to 0.15 M, and the initial hydrobromic acid concentration from 0.0067 to 0,041 M. The series of velocity constants $k_4 f^2$ obtained for all the experiments in quite the same way as above were plotted against the hydrobromic acid concentrations, as is done for a single experiment in Fig. 7, and through the band of points a representative curve was drawn. In Table XXII are shown the velocity constants taken from this curve and corresponding to specified hydrobromic acid concentrations.

TABLE XXII

THE VELOCITY OF REACTION IV

Glycid + Hydrobromic Acid ⟶ Bromohydrin

HBr concn., molarity	Obs. velocity constant (k_4f^2)	**log** k_4 + 2 logf	**HBr** concn., **molarity**	Obs. velocity constant (k_4f^2)	log k_4 + 2 **log**
0.00100	3.72	0.571	0.0100	3.17	0.501
.00200	3.59	.555	.0125	3.10	.491
.00300	3 47	.540	.0150	3.04	.483
.00400	3.41	.533	.0175	2.99	.476
.00500	3.35	.525	.0200	2.95	.470
.00600	3.30	.519	.0250	2.87	.458
.00700	3.27	.515	.0300	2.81	.499
.00800	3.23	.509	.0350	2.75	.439
.00900	3.20	.505	.0400	2.69	.430

The logarithms of the velocity constants, k_4f^2, given in the third column of Table XXII are plotted in Fig. 9 against the square roots of the acid concentrations. The dotted line in the graph indicates the theoretical limiting slope. The full curve is drawn to satisfy the equation

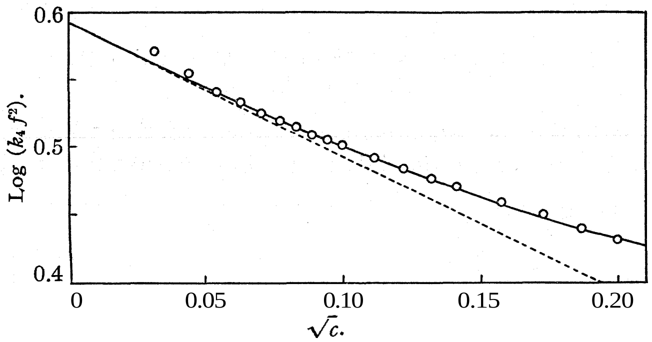

Fig. 9.—Addition of HBr to glycid. Reaction IV, c = HBr concentration.

$$\log (k_4f^2) = 0.592 + \sqrt{c} + c$$

which takes into account the deviations from the limiting slope at higher acid concentrations.

Except for the two points in the most dilute region, where the experimental error is greatest, the experimental points are obviously located very closely on this curve. This means that the experimental points satisfy the two equations $\log k_4 = 0.592$ and $2 \log f = \sqrt{c} + c$, the latter of which is identical with Equation 5. In other words, since f is known to follow Equation 5, the experiments have shown k_4 to be a constant independent of the acid concentration.

In spite of the interference of three other processes, it has thus been possible to show that the direct addition of a strong acid to glycid follows the requirement of the modern theory of velocity of ionic reactions.

F. Discussion

From the results stated in the previous sections it is evident that the "basicity" of ethylene oxides is a property which is exhibited in solutions of these substances only under certain conditions and is not at all inherent in the oxide molecules as in the case of true bases. The oxide molecules are unable—at least to an extent detectable in the ordinary experiment—to exert the basic function which consists in the simple addition of protons. If the oxide molecule takes up a proton it invariably at the same time adds also an anion, and if no suitable anion is available it remains unchanged.

The simultaneous addition of a proton and an anion amounts to the addition of a hydrogen compound. If this hydrogen compound is an acid, for instance, hydrochloric acid, the reaction makes the acidity of the solution decrease and the oxide seems to be basic. The tendency to add an acid may be so strong that the reaction proceeds rapidly even in an aqueous solution which is already "neutral" or "basic" (for instance in potassium iodide). The hydrogen compound in question, however, need not be of acid character. The ethylene oxides, for instance, add basic hydrogen compounds, and the occurrence of this reaction in water solution may cause an increase in acidity. The conclusion on the basis of such phenomena that ethylene oxide is an acid would be justified to the same extent as the conclusion of its being a base on the basis of its adding hydrogen chloride.

The truth, of course, is this, that the ethylene oxides do not possess the character of bases. Applying to them the term of "pseudo-bases" would not even be an adequate description of their nature. Their apparent basicity (and acidity) simply originate in their tendency to combine directly with, and thus to remove from the solution, a multitude of substances, whereby, according to the nature of the substance removed and formed, the acidity of the solution may increase or decrease. Since the reactions by which acids are taken up are the more numerous and conspicuous, the idea generally adopted of a special basicity of these oxides becomes intelligible.

As to the kinetic mechanism by which the basicity in a solution is produced, it has been shown above that two Reactions (III and IV) are effective. While Reaction IV, or the direct addition of acids, takes place in the case of the halide acids, Reaction III seems to occur more generally for both weak and strong acids. Perchloric acid is the only one for which no indication of addition has been found either by Reaction III or IV. It is Reaction III which is essentially responsible for the phenomenon of "basicity" observed in solutions of ethylene oxides under ordinary conditions.

The study of the different reactions in which the ethylene oxides take part has also contributed to the verification of the general theory of reaction velocity.[3,4] For Reaction II, which takes place between the oxide molecule and the hydrogen ion, this theory requires a linear salt effect which has actually been found (Tables II, IV and VII) in the hydrogen-ion catalysis of all three oxides investigated. It is in conformity with this theory that the concentration of the hydrogen ion in these reactions is the factor by which the reaction is mainly controlled. Essentially the same laws hold good in the case of Reaction III. Reaction IV, on the other hand, is a reaction between ions of opposite sign, and should theoretically be characterized by a negative exponential salt effect. As shown above (Section P, 3) this is actually found and the salt effect demonstrated corresponds closely to the requirements of the theory.

In order to compare the velocities of the various reactions, the constants are collected in tables below. Table XXIII contains the unimolecular constants for Reactions I and II for the three oxides investigated.

TABLE XXIII

$t = 20°$

	k_1 (Spont. react.)	k_2 (Hydrogen-ion catal.)
Ethylene oxide	2.16×10^{-5}	$0.320 + 0.28c$
Glycid	1.70×10^{-5}	$0.147 + 0.081c$
Epichlorohydrin	5.84×10^{-5}	$0.0244 + 0.0150c$

The constants seem to depend upon the substance in an individual manner. While in passing from ethylene oxide to glycid both constants decrease somewhat, there is a considerable increase in k_1 and a considerable decrease in k_2 passing from these oxides to epichlorohydrin. The ratios glycid/epichlorohydrin are

$$\left(\frac{k_{\text{Gl}}}{k_{\text{Ep}}}\right)_1 = 0.29 \qquad \left(\frac{k_{\text{Gl}}}{k_{\text{Ep}}}\right)_2 = 6.0$$

The constants for Reaction III are given in Table XXIV.

TABLE XXIV

k_3 AT ZERO SALT CONCENTRATION. $t = 20°$

Ion reacting	Glycid	Epichlorohydrin	$(k_{\text{Gl}}/k_{\text{Ep}})_0$
I^-	1.62×10^{-2}	6.0×10^{-2}	0.27
Th^-	7.9×10^{-3}	3.8×10^{-2}	.21
Br^-	1.03×10^{-3}	3.7×10^{-3}	.28
Cl^-	1.50×10^{-4}	6.9×10^{-4}	.22
Formate	....	2.8×10^{-4}	
Benzoate	....	3.1×10^{-4}	
Acetate	....	3.7×10^{-4}	
Trimethylacetate	....	5.0×10^{-4}	

In this table the anions—except for Th^-, the thiocyanate ion, the strength of which is unknown—are arranged according to basic strength. This factor, however, does not seem to control the reactions, since in the case of the halide ions the velocity increases with decreasing strength, while the converse is true for the anions of the four organic acids. In the cases of the very weak base Cl^- and the relatively strong trimethylacetate ion, the rates are practically the same. As shown by the last column in Table XXIV, the reaction is about 4 times faster with epichlorohydrin than with glycid. The ratio k_{Gl}/k_{Ep} is almost the same for Reactions III and I.

Reaction IV has been extensively studied only for glycid and hydrobromic acid. The preliminary results recorded in Table XIX, however, enable us to obtain an approximate comparison for a number of reactions. From the data in this table at 25 and 18°, the data for 20" have been calculated by the equation $d \log k/dT = 0.045$, which is shown to hold for ethylene oxide.

TABLE XXV

k_4 FOR HALOGENIC ACIDS AT ACID CONCN. 0.01 AND $t = 20°$

Ethylene oxide	HBr	5.2
Ethylene oxide	HCl	1.3
Glycid	HBr	3.3
Epichlorohydrin	HBr	1.3
Epichlorohydrin	HCl	0.27

As in Reaction III, glycid here also reacts somewhat more slowly than ethylene oxide, and epichlorohydrin again more slowly than glycid. For the ratio k_{Gl}/k_{Ep} we find

$$\left(\frac{k_{Gl}}{k_{Ep}}\right)_4 = 2.5$$

It is possible, therefore, to divide the four reactions here dealt with into two groups, one comprising Reactions I and III, in which epichlorohydrin reacts much faster than glycid, and another, comprising Reactions II and IV, in which the converse is true. Furthermore, comparing the constants of the four reactions for each oxide, the following simple relation is found to be approximately true

$$\frac{k_1}{k_2} = \frac{k_3}{k_4}$$

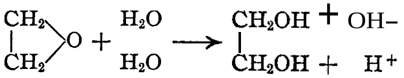
This is shown by the figures in Table XXVI, where the logarithms of the available ratios are tabulated,

TABLE XXVI

LOGARITHMS OF RATIOS

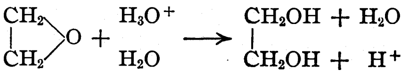
Oxide	Log k_1/k_2	Log k_3/k_4 (Cl)	Log k_3/k_4 (Br)
Glycid	$\bar{4}.1$	....	$\bar{4}.5$
Epichlorohydrin	$\bar{3}.4$	3.4	$\bar{3}.6$

An explanation of this simple relationship is afforded by the assumption of the following mechanism underlying the reactions. If in Reaction I the water molecule taken up by the oxide originates from two molecules of water, the one providing a proton and the other an hydroxyl ion



(I)

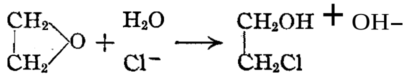
Reaction II may be described in an analogous way by simply exchanging the first water molecule which provides the proton by a hydrogen ion:



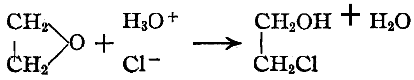
(II)

Since the H_3O^+ ion is much more acid than H_2O, the proton is more easily provided by the former, while the addition of OH^- is not affected by the presence of OH_3^+. Reaction II therefore proceeds much more rapidly than Reaction I.

If now in (I) and (II) the second water molecule is exchanged for an anion, for instance, Cl^-, Reactions III and IV appear



(III)



(IV)

and as in these reactions IV is obtained from III by again exchanging H_2O by H_3O^+, Reaction III is seen to be related to IV in just the same way as I to II. The simple relationship demonstrated by the figures in Table XXVI seems, therefore, to be well justified by the mechanism suggested.

The kinetic similarity found within the two groups of reactions here dealt with also justifies the point of view previously emphasized that catalytic reactions (Reaction II) and ordinary uncatalyzed reactions are intrinsically not different in nature.

Further insight into the reactions of the ethylene oxides may be obtainable by examining their kinetic properties in more alkaline solutions and from the stand-point of the extended theory of acid and basic catalysis. This problem is the subject of further studies in this Laboratory.

The authors are indebted to Rask-Örsted-Fondet, Copenhagen, for a grant which has made this investigation possible.

Summary

1. The ethylene oxides react in aqueous solutions in four different ways. They unite spontaneously with water to form glycols (Reaction I). The same reactions proceed, catalyzed by hydrogen ions H_3O^+ (Reaction II). They react with anions and water taking up acid (Reac-

tion III); and finally add acids directly (Reaction IV). It has been possible to separate and study separately all these reactions, using as material ethylene oxide, glycid and epichlorohydrin.

2. The hydration of ethylene oxides (Reactions I and II) is accompanied by a considerable contraction and can be followed dilatometrically. Reactions III and IV can be followed titrimetrically. A special titrimetric procedure in artificially controlled buffers was devised for following the addition of anions of strong acids (Reaction III). Reaction IV was followed by conductivity measurements.

3. The ethylene oxides exhibit apparently basic properties in certain solutions. They are, however, not bases or pseudo-bases. Their "basicity" is due to their taking up acids, which may occur through Reactions III or IV. Under ordinary conditions Reaction IV is predominant in causing basicity. The oxides may, however, also add bases and this causes acidity.

4. The hydrogen-ion catalysis (Reaction II) is determined by the concentration of the hydrogen ion. There is a considerable positive primary salt effect, which in accordance with the general theory of velocity is linear in character. Reaction III proceeds proportionally to the anion concentration and shows a slight negative primary salt effect. The velocity constant increases in the order Cl^-, Br^-, CSN^-, I^-, and in the order formate, benzoate, acetate, trimethylacetate ion.

5. The direct addition of strong acid was specially studied with glycid and hydrobromic acid. The reaction—in which two ions of opposite sign take part—was shown to follow the theoretical equation for such reactions, exhibiting an exponential negative salt effect of the predicted magnitude.

6. The constants k_1, k_2, k_3 and k_4 for Reactions I–IV satisfy approximately the equation $k_1/k_2 = k_3/k_4$. A plausible reaction mechanism has been suggested, which explains this relation.

THE ACTIVITIES OF MOLTEN ALLOYS OF THALLIUM WITH TIN AND WITH LEAD

BY J. H. HILDEBRAND AND J. N. SHARMA

RECEIVED OCTOBER 22, 1928 PUBLISHED FEBRUARY 5, 1929

The investigation described in this paper represents a continuation of the program begun five years ago by N. W. Taylor[1] under the direction of the senior author for the determination of activities in molten alloys by a study of the e.m.f. of concentration cells. Such measurements give accurate data concerning activities over a large temperature range and are of great interest in connection with theories of solution already presented.[2] Taylor studied the alloys of cadmium with zinc, tin, bismuth and lead, and the alloy of zinc with tin. In the present investigation we have studied alloys of thallium with tin and with lead. The electrolyte used was the eutectic mixture of the fused salts of 60% lithium chloride and 40% potassium chloride, with a small amount of thallous chloride. The alloy constituted one electrode and pure thallium the other. The reaction in the cell may be represented as the transference of thallium from its pure state, where it has a unit activity, to the alloy, where its activity is a_1. The electromotive force is related to the activity by the equation $\mathbf{E}_1 = RT/\mathbf{N}_1\mathbf{F} \ln 1/a_1$, where R, T, **N** and F have the usual significance. All symbols with subscript "1" will be used in the course of this article to represent the more electropositive component of the alloy, thallium.

Materials.—The lithium chloride, potassium chloride and thallous chloride used in this research were found to be free from heavy metals. The lead was from the material purified by Hogness;[3] the tin was of known purity, and was used without further purification. About 500 g. of thallium that was at hand contained perhaps 7% of lead and small amounts of other impurities. The method used for its purification was the one used by Richards and Smyth.[4] This purified electrolytic thallium was placed in an alundum tube, which in turn was placed in a pyrex glass apparatus provided with a small inlet tube for the passage of hydrogen gas. This apparatus was heated by an electric unit and a current of hydrogen passed through. When the metal was melted, the bottom of the alundum tube was broken with the aid of a long glass rod. The pure, clean metal ran into the glass tubing provided for that purpose. Sticks of lead and tin were cast in the same manner.

Apparatus+—The cell was similar to that used by Taylor, with two cups to contain pure thallium and four other cups for alloys of varying composition. The only modification from Taylor's cell was that tungsten electrodes were soldered to heavy gold wires to lead out of the furnace and connect with the potentiometer, instead of to the

oxidizable copper wires previously used. These wires were insulated by short pieces of narrow pyrex glass tubing.

The furnace was the one used by Taylor. Temperatures were determined by two chromel-alumel thermocouples, which were calibrated against the melting points of tin, zinc and antimony. Each calibration was accurate to 1°, corresponding to 0.05 millivolt in e.m.f., which was within the limit of error.

Experimental Procedure.—The metals, whose surfaces were scraped clean and bright, were cut into small pieces. The pure thallium was put into two cups while weighed amounts of both the metals were placed in each of the remaining four cups to give alloys of known composition. The total weight of the alloy varied from about 7 to 8 g. All inlet tubes except two were sealed off and the cell was placed in the furnace. The current was turned on and a stream of hydrogen passed through the cell. In the meantime the electrolyte was prepared by weighing 60% lithium chloride and 40% potassium chloride, together with small amounts of thallous chloride and potassium hydroxide, the latter to insure the absence of hydrogen ion. When the metals in the cell had melted, the stream of hydrogen-was shut off, the clear electrolyte was immediately poured into the cell and the two remaining inlet tubes were stoppered.

The gold leads from the several compartments were connected through mercury cups to the potentiometer. This was a Leeds and Northrup (new) K type instrument, and was used with a working battery of 2 Edison cells. The electromotive force at the beginning changed more or less rapidly, but after about six or seven hours the phases became uniform in composition and the e.m.f. became constant to 0.1 m.v. The temperature of the furnace was controlled by means of the resistance and electromotive force readings were taken at intervals of one-half hour until ten or more readings were obtained. The duration of each run was usually two or three days.

In the beginning of the experimental work measurements were made on zinc–tin systems to develop the technique. The results obtained agreed with those of Taylor within the limits of experimental error.

The System Thallium–Tin.--Four runs were made on this system. The constancy of electromotive force values is illustrated in Table I, giving observed values from Run 4. Table II summarizes the observations for each run. Each e.m.f. recorded is an average of ten or more readings taken at half-hour intervals. In each recorded run, the two compartments containing the pure thallium gave zero e.m.f. against each other.

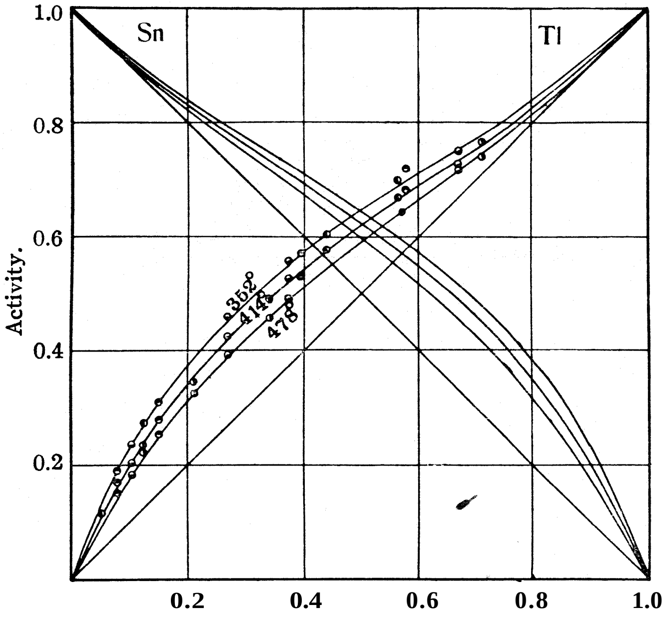
The table also gives values of log γ_1, where γ_1 is the activity coefficient, defined as a_1/N_1, where N_1 is the mole fraction of thallium, that is, the activity is taken as unity in the pure metal and not, as is customary in dealing with aqueous solutions, as the infinitely dilute solution.

The calculated values of a_1 are plotted against N_1 in Fig. 1 to show deviations from Raoult's Law. Log γ_1 is plotted against N_1 in Fig. 2. This latter plot has an important physical significance for, as the senior author has stated,[5] we may regard γ_1 as the ratio of the escaping tendency of a single molecule of thallium in solution to its escaping tendency from the pure liquid thallium. The logarithm of this ratio is zero when Raoult's law is obeyed by the solution, that is, when the intermolecular forces do not change with the composition. Due to the presence of the tin, these forces have become weaker, and hence there are positive deviations from Raoult's law.

---

[5] Ref. 2, p. 43.

The activity of the tin has been calculated by the aid of the Duhem equation, which may be expressed as follows: $N_1 \, d \log \gamma_1 = N_2 \, d \log \gamma_2$. For symmetrical curves such as these, Porter[6] has found. and the senior author has confirmed for many systems, that the relation between activity and mole fraction is often expressed by the simple equation: $\log \gamma_1 = \beta N_2^2$. The application of the Duhem equation gives for the other component: $\log \gamma_2 = \beta N_1^2$.



Mole fraction of thallium, N_1.

◑, Run 1; ◐, Run 2; 8, Run 3; ⊖, Run 4.

Fig. 1.—Activities for the system thallium-tin.

The values of $\log \gamma_1$ for the three temperatures are plotted against N_2^2 in Fig. 3. The slopes of the straight lines that can be drawn through the points give directly the several values of β given in Table III. The variation of β with T is linear and is given closely by the equation $\beta = 1.0763 - 0.00101\,T$, as shown by the excellent agreement between observed and calculated values in Table III.

[6] A. W. Porter, *Trans. Faraday Soc.*, *16*, 336 (1921).

This justifies the calculation of a_1 in this system by the equation $\log a_1/N_1 = (1.0763 - 0.00101T)N_2^2$, and of a_2 by the same equation with subscripts interchanged. Table IV gives values of a_1 so calculated for certain values of N_1. The values of a_2 are given if N_2 and a_2 are read in place of N_1 and a_1.

The table also gives the corresponding values of $\log \gamma_1$, where γ_1 is the activity coefficient, a_1/N_1, also values of the heat of transfer of thallium from pure metal to alloy, $\bar{H}_1 - H_1^{\circ}$, and the free energy of transfer of thallium from an ideal solution to the actual solution of the same concentration, $\bar{F}_1 - \bar{F}_1^i$. The latter is given by $RT \ln \gamma_1$, and the former by the expression $0.00101 \times 2.3026 \times RT^2N_2^2$, which is derived from the

Fig. 3.—Plot of logarithm of activity coefficient of thallium against square of mole fraction of tin.

expression for free energy and its temperature coefficient. We may recall, in this connection, that since there is no heat of solution in forming an ideal solution, the molal heat content of the liquid in the pure state, H_1°, is the same as its partial molal heat content in the ideal solution, $\bar{H}_1^i$; hence $\bar{H}_1 - H_1^{\circ} = \bar{H}_1 - \bar{H}_1^i$.

So far as the variation with N is concerned, this system corresponds perfectly to the definition of a regular system given by the senior author.[7] The simplest equation applying to such a system is $RT \ln a_1/N_1 = bN_2^2$. This would apply to the system under consideration if βT were a constant, b/R. The values of βT given in Table III show that β decreases more rapidly than this. We may see the discrepancy in different but equivalent terms by recalling that a regular solution is defined in part as one which involves no entropy changes in the transfer of a component to it from an ideal solution of the same mole fraction. When this is true, the corresponding free energy and heat changes are identical, but the values in Table IV show that $\bar{F}_1 - \bar{F}_1^i$ is not equal to $\bar{H}_1 - \bar{H}_1^i$ in this case, although the two approach each other as the temperature is lowered.

An explanation of the discrepancy might be found, at least in part, if we knew the volume change involved in forming the mixture. It may prove necessary to consider the specific heat of the electrons in the alloy and in the pure metal. Although this is usually comparatively small, it may occasionally be very considerable. The previous studies of metallic solutions have ignored any influence of the free electrons, and it will be

---

interesting to determine how long this neglect can continue. We hope to make a study, in this connection, of the thermoelectric potentials of liquid alloys against pure metals.

The magnitude of the deviation from Raoult's law has been shown with other systems to correspond approximately to differences in internal pressure. We do not have the data for a close estimate of the internal pressure of thallium but the table published by the senior author shows thallium two places below tin and cadmium two above. This agrees well with the fact that the systems thallium–tin and cadmium–tin deviate to the same extent from Raoult's law, as shown by the following comparison: for the former system at 478°, when the mole fraction of tin is 0.1, its activity is 1.81; in the latter system at 483°, the activity of tin at the same mole fraction is 1.78.

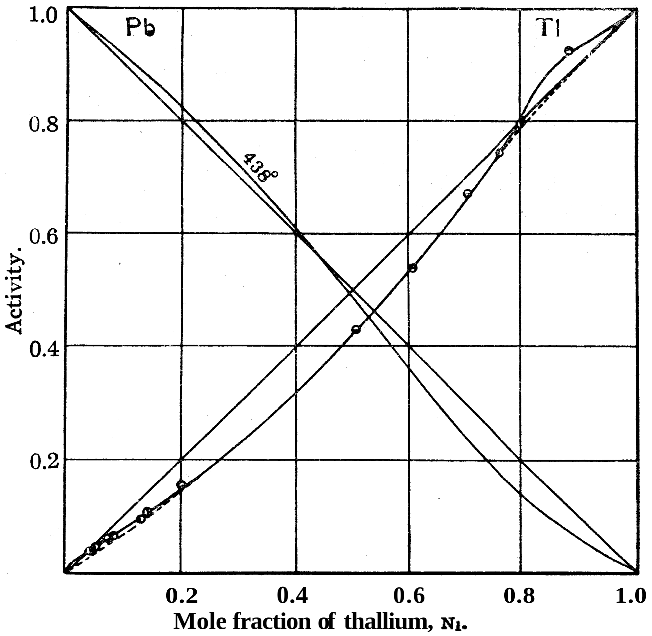
The System Thallium–Lead.—Six successful runs were made on the system thallium–lead. The electromotive forces recorded in Table V are each averages of ten or more individual readings.

The activity of thallium is plotted against its mole fraction in Fig. 4, and log γ_1 is plotted against N_1 in Fig. 5. This system, although not deviating much from Raoult's law, is evidently rather complicated and strongly resembles the system lead–bismuth, investigated by Taylor,[1] showing both positive and negative deviations from Raoult's law. In order to make sure that this complication was not due to any participation of lead in the electrical process, the electrolyte was analyzed after the completion of the run. No trace of lead was found.



————, Observed; – – – –, $PbCl_2$ calcd.; 8, Run 1; 9, Run 2; ◑, Run 3; ◐, Run 4.

Fig. 4.—Activities for the system thallium-lead.

Taylor's investigation showed the possibility of the existence of a weak compound, Cd_3Bi_2, while the freezing-point composition diagram for the present system[8] shows the existence of the compound $PbTl_2$. It is, therefore, not surprising that both of these systems should show positive and negative deviations alike, the latter due to the formation of the compound, the former to differences in internal pressure between compound and pure components.

---

[8] Lewkonja, *Z. anorg. allgem. Chem.*, 52, 454 (1907).

Neglecting the differences in internal pressure, the effect of compound formation may be calculated by methods already developed.[9] Expressing the equilibrium constant for the reaction Pb + 2Tl = $PbTl_2$ in terms of the mole fractions of each molecular species present, we find that by assigning to it the value 2.719, we get the dotted curve shown in Fig. 4, which agrees well with the observed points except at the ends. ences in internal pressure, not taken into account in this calculation, of course diminish the quantitative significance of the above numerical value of K.

The activity of the lead in these alloys was calculated by the aid of the Duhem equation, using a graphic method of integration,[10] since no simple equation could be found to represent this system. The calculated values of a_2 are given in Table VI for certain values of N_1, together with the smoothed-out values for a_1.

Summary

1. The activities of thallium in liquid alloys with tin and with lead have been determined over a range of 125° by the aid of e.m.f. measurements and an equation is given for the activity in terms of mole fraction and temperature for the thallium–tin system.
2. The partial molal heat of transfer of thallium from an ideal solution to the tin solution of the same mole fraction has been calculated over a range of composition and temperature. Comparison with the free energy values calculated for the same process shows disagreement; hence, although the solution behaves as a regular solution with the respect to changes in composition, it is not regular with respect to changes in temperature.
3. The thallium–lead system, although not deviating much from ideality, shows a rather complicated behavior, almost identical with that of cadmium–bismuth alloys and which may be attributed, in part, to the presence in solution of some of the compound $PbTl_2$.

A SIMPLE REFERENCE ELECTRODE FOR POTENTIOMETRIC TITRATIONS

BY H. H. WILLARD AND A. W. BOLDYREFF

RECEIVED OCTOBER 22, 1928 PUBLISHED FEBRUARY 5, 1929

The inconvenience connected with the use of the calomel or silver chloride half-cell as a reference electrode in potentiometric titration has long been recognized. Hostetter and Roberts[1] suggested the use of a palladium wire in place of the usual half-cell. Willard and Fenwick[2] studied a large number of bimetallic systems. Furman[3] proposed an amalgamated gold electrode as a suitable reference electrode in some oxidation–reduction reactions.

[3] Furman, ibid., 50,268,273 (1928).

Kamienski[4] used in technical electrometric determinations, especially of metals, a copper electrode in saturated copper sulfate as reference and a carborundum electrode against gold or platinum electrodes. Ball' proposed as a standard electrode a platinum wire immersed in a 3 N sulfuric acid solution (for oxidation–reduction work) or in N hydrochloric acid (for acidimetry), the electrical connection with the solution titrated being established through a wet asbestos fiber sealed securely in the end of a small glass tube. Müller[6] used in oxidation–reduction titrations an electrode system consisting of a platinum wire sealed inside of a capillary containing a very small volume of the original solution, the other electrode being a platinum wire wound around the capillary.

A very convenient and accurate method for differential potentiometric titrations has been described by MacInnes and Jones[7] and by MacInnes.[8] Modified procedures for this method are found in the papers of Roth,[9] Heckzo[10] and Hall.[11]

Among other recent methods avoiding the use of a standard half-cell in potentiometric titrations, but based on different principles than those noted above, might be mentioned those of Sandved and Backer,[12] Reissaus,[13] Foulk and Bawden[14] and Furman and Wilson.[15]

The electrode described here eliminates the use of the standard half-cell in all types of potentiometric titrations. The principle involved is extremely simple. A clean, bright platinum wire, immersed in any standard solution (oxidizing or reducing agent, acid or alkali, or a precipitating agent) will rapidly assume a perfectly definite potential.

Therefore, a very satisfactory reference electrode can be obtained by sealing a piece of smooth platinum wire into the tip of the buret (below the stopcock). It is thus in contact with the standard solution used in the titration. By dipping the tip of the buret into the solution titrated, an electrical connection is established with the indicator electrode. This "buret electrode" is shown in Fig. 1.

The tip of the buret is bent and drawn out to keep the buret out of the way and to minimize the diffusion at the point of contact of the solutions. The error due to diffusion is negligible as far as reaction inside and at the

tip of the buret is concerned because the tip is flushed out during each successive addition of the reagent, and because the concentration of the ion titrated is being constantly diminished and becomes vanishingly small near the end-point. As far as the change in potential due to diffusion is concerned, it has been shown in a control experiment that during the time between two successive additions of the titrating agent this is less than the error in measurement. The buret was filled with *0.1* N potassium bromate and the tip dipped into a solution $N/40$ with respect to arsenite. The potential between a smooth platinum wire in this solution and **the** buret electrode was measured every minute; the deviation from the initial value during five minutes did not exceed *0.2* mv.

To demonstrate the usefulness of such an electrode and the constancy of its potential, a titration was made of *0.1* *N* potassium dichromate with *0.1* N ferrous sulfate in a solution containing 25 cc. of conc. sulfuric acid in *100* cc. of solution. Three electrodes dipped into the solution: a silver chloride electrode, a bright platinum wire and a "buret electrode." The potential between any two of them could be measured. The results are shown in Table I.

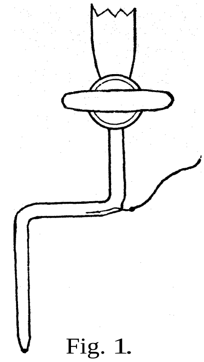

Fig. 1.

, TABLE I

POTENTIALS BETWEEN DIFFERENT ELECTRODES

Titration of approx. 0.1 N $K_2Cr_2O_7$ with 0.1 N $FeSO_4$.

$FeSO_4$ added, cc.	Potential between Pt. AgCl, mv.	Pt/buret electrode, mv.	Buret electrode/AgCl, mv.
0.0	0.8813	0.6610	0.220
4.0	.8896	.6695	.220
8.0	.8911	.6714	.220
12.0	.8930	.6724	.221
16.0	.8935	.6739	.220
20.0	.8905	.6697	.220
24.0	.8994	.6802	.219
24.5	.9000	.6801	.220
24.7	.8969	.6771	.220
24.9	.8946	.6752	.220
25.0	.8812	.6598	.221
25.1	.8418	.6243	.218
25.2	.4594	.2393	.220
25.3	.4344	.2124	.222
25.5	.4123	.1940	.218

The curves obtained by plotting potential against volume have obviously the same shape regardless of which electrode is used, but are displaced vertically from each other by an amount equal to the potential difference between the "buret electrode" and the standard half-cell. A change from the mean value of a few millivolts in the potential of the "buret electrode" is due to polarization in the process of balancing the potentiometer circuit. In some solutions (particularly 0.1 N sodium hydroxide) this polarization can become appreciable unless sufficient care is taken in balancing. A control experiment showed that this was concentration polarization.

A summary of the tests to which this method was subjected is shown in Table II. All solutions were carefully standardized and were approximately 0.1 N. The figures given represent the results of individual titrations.

In the case of permanganate, a trace of manganese dioxide forms on the platinum wire and at the tip of the buret, but the error is negligible.

TABLE II

COMPARISON OF "BURET ELECTRODE" AND AgCl ELECTRODE

Subs. titrated	Titrating soln.	$\Delta E/\Delta v$ at e.-pt. mv./cc. "Buret electrode"	AgCl electrode	Calcd., cc.	Found, cc.
$K_2Cr_2O_7$	$FeSO_4$	3850	3820	25.18	25.15
$FeSO_4$	$KMnO_4$	4270	4240	24.93	24.90
H_3AsO_3	$KBrO_3$	2900	2500	25.00	24.95
HCl	NaOH	1680	1820	18.55	18.55
HQ	$AgNO_3$	490	510	25.08	25.10

Summary

1. A simple reference electrode has been devised, consisting of a platinum wire fused into the tip of a buret.
2. The constancy of the potential of this electrode has been shown by titrations involving oxidation–reduction, neutralization and precipitation reactions.

ANN ARBOR, MICHIGAN

NOTES

A Micro Extraction Method.—For the extraction of very small amounts of material the following method may prove helpful.

A capillary of about 1–2 mm. in inner diameter and 8–10 cm. in length is filled with the liquid material (1 drop) to be extracted and an equal amount of the non-miscible extraction medium. It is then sealed at both ends and centrifuged in such a manner, that the liquid layer with the higher specific gravity is forced through the liquid layer having the lower specific gravity by having the first one at the top in the centrifugal tube and the latter on the bottom. This operation is repeated several times.

The closed capillary is then cut apart under the microscope at the zone of contact. By opening the ends both liquids, the solvent and the extraction medium, become available for examination.

By using ammoniacal aqueous solutions of alkaloids and chloroform as the extraction medium, satisfactory results were obtained by this method.

A Brine Circulator for Cooling Condensers.—In working with low-boiling compounds it has been found advisable at times to circulate cold brine through the jackets of the condensers. Such circulation may be made continuous by the use of a simple modification of the "air lift" pump used in some sulfuric acid plants. The system gives excellent cooling and requires no attention.

The pump consists of an old condenser jacket with the lower side arm plugged up. A piece of glass tubing of about 6 mm. diameter is passed through the stopper in the top of the jacket and reaches almost to the bottom. Through the stopper in the bottom of the jacket a piece of small glass tubing of such size that it will not plug up the 6-mm. tube is passed and reaches about 2 centimeters into the 6-mm. tube. This small tube is connected to an air blast tap by a rubber tube C with a pinchcock on it to regulate the flow of air. The top side arm of the jacket is connected by rubber tubing B to the outlet of the condenser to be cooled, and the 6-mm. tube is connected by a rubber tube D to a piece of bent glass tubing hooked over the edge of a pail. This tube D should be vertical or nearly so throughout its length. The pail is filled with concentrated brine and ice and the siphon A is connected to the inlet of the condenser to be cooled. The height of the water level in the pail should be about four feet above the bottom of the pump, which may be suspended vertically over the edge of the laboratory bench.

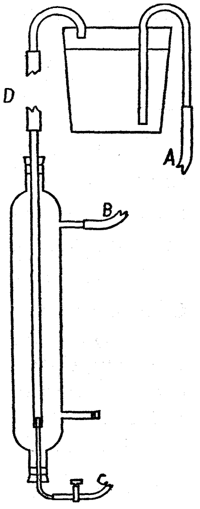

Fig. 1.—A brine circulator for condensers.

In order to start the circulation of the brine both the condenser to be cooled and the pump are filled with brine and the air is then regulated so that a steady stream of bubbles passes up the tube. The condenser jacket can be kept below zero in this manner without any difficulty whatsoever.

MONO-ARYLGUANIDINES. I. ALPHA-PHENYLGUANIDINE[1]

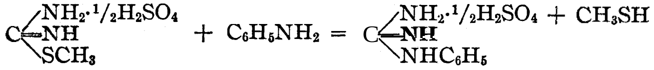
BY G. B. L. SMITH[2,3]

RECEIVED JULY 14, 1928 PUBLISHED FEBRUARY 5, 1929

Introduction

Mono-arylguanidines have received little attention or study, while diaryl- and triarylguanidines are well known and a number are produced commercially. One method only, the ammonation of cyanamide,* has been suggested for the preparation of α-phenylguanidine, the simplest compound of this series.[5]

In considering possible new methods for the preparation of α-phenylguanidine, attention was directed to the synthesis of methylguanidine[6] by the reaction between methyl-isothiourea sulfate and monomethylamine. It has been found that an excess of aniline reacts with methyl-isothiourea sulfate to form α-phenylguanidine sulfate.



$$C\begin{matrix}\diagup NH_2\cdot{}^1/_2H_2SO_4\\ =NH\\ \diagdown SCH_3\end{matrix} + C_6H_5NH_2 = C\begin{matrix}\diagup NH_2\cdot{}^1/_2H_2SO_4\\ =NH\\ \diagdown NHC_6H_5\end{matrix} + CH_3SH$$

This substance is contaminated with aniline sulfate, which cannot be removed by recrystallization from water,' but purification may be accomplished by taking advantage of the relative insolubility of α-phenylguanidine carbonate.

[7] The author contemplates a study of the system α-phenylguanidine–aniline–sulfuric acid–water with a view to ascertaining the exact nature of the product of this side reaction with aniline.

Experimental Part

Materials.—Methyl-isothiourea sulfate was prepared by the method of Arndt,[8] using thiourea of a high grade of purity.[9]

Crude **α-Phenylguanidine** Sulfate.—Four moles (555 g.) of methyl-isothiourea sulfate and eight moles (740 cc.) of redistilled aniline were heated to boiling under a reflux by means of an oil-bath, and the uncondensed vapors were led through a series of three wash bottles containing a 20% solution of sodium hydroxide. The system was placed under reduced pressure and the heating was continued until the solid was completely dissolved (or melted) and there was no further evolution of methyl mercaptan. On cooling the liquid solidified and was intimately incorporated with about one liter of 95% alcohol, allowed to stand with occasional shaking for twenty-four hours, filtered and the remaining solid treated in the same manner with a second liter of alcohol. This solid material when dried was generally a pale lavender in color. Further purification may be effected by decolorizing with vegetable charcoal and recrystallizing, but the sulfuric acid content of the product varies with the concentration of sulfuric acid used in recrystallizing. One speciman recrystallized from water containing 5% of sulfuric acid gave an analysis for sulfuric acid of 29.00 and for nitrogen of 18.20, indicating the presence of about 30% of aniline sulfate.

α-Phenylguanidine Carbonate.—A solution of 50 g. of crude a-phenylguanidine sulfate was neutralized with barium hydroxide and filtered. Barium hydroxide or sulfuric acid was added to the filtrate until neither was in excess and it was filtered a second time. The volume of the solution was now about 500 cc. and carbon dioxide was passed in for about two hours while the solution was cooled in an ice-bath. A granular precipitate formed which was filtered and the filtrate concentrated to half volume and treated with carbon dioxide a second and third time; yield, 30 g.

---

[8] Arndt, *Ber.*, 54B, 2236 (1921).

[9] Obtained from the American Cyanamide Company.

α-Phenylguanidine (Base).—The preparation of the base may be accomplished by treatment of a solution of one of the salts with an alkali and in general the sulfate and barium hydroxide was used. In a typical experiment 30 g. of Pure a-phenylguanidine sulfate in 100 cc. of hot water was treated with crystalline barium hydroxide and digested for one hour. After the barium sulfate was filtered off, the base separated as an oil and crystallized on seeding with a crystal of previously prepared base. The crystals were separated by filtration, washed with 5 cc. of 95% alcohol and dried in *vacuo* over phosphorus pentoxide. This material melted at 67–68° and when crystallized from benzene at 66–67°.

α-Phenylguanidine when exposed to the laboratory atmosphere takes on carbon dioxide and moisture rapidly and the melting point is raised. A sample after standing for several months was analyzed for carbon dioxide and 7.94% was found. A melting point of about 125° was invariably found when the base was dried in the atmosphere or in the oven at 50–60° and such specimens always contained carbon dioxide.

Salts of **α-Phenylguanidine.**—Salts of a-phenylguanidine may be prepared by adding the respective acid to a solution or suspension of the base or carbonate in hot water. The salt may be isolated by chilling the concentrated solution, or in the case of the hydrochloride concentrating to crystallization in a desiccator. The picrate precipitates when picric acid is added to the solutions of any salt. The extremely hygroscopic character of the hydrochloride rendered an accurate melting point determination difficult. A statement of analytical results and properties of a-phenylguanidine and its salts is given in the accompanying table.

Microscopical Notes

Base.—When prepared from the sulfate and sodium hydroxide, droplets of liquid are first formed; these coalesce and crystallize on standing. Seeding or stirring aids the crystallization. The crystals obtained are mostly rhomb-shaped tablets and dendritic forms derived from them. The acute angle of the rhombs is about 63" and is frequently truncated by a small crystal face. The tabular views of the crystals show symmetrical extinction and fairly strong double refraction, with somewhat anomalous polarization colors. They give a biaxial interference figure, the axial plane bisecting the acute angle of the rhombs; 2V is large. Edge views of the tablets exhibit oblique extinction, dispersed at about 40".

Sulfate.—The crystals are elongated tablets and flattened prisms, with symmetrical end faces making an angle of 150" with each other. Double refraction is moderately strong, with parallel extinction shown by tabular and edge views. The end views were not observed. The crystals showed biaxial interference figures, with the plane of the optic axes transverse of the long crystals; 2V large; optically positive; acute bisectrix is not perpendicular to the principal plane of the tablets.

Hydrochloride.—A number of crystallographic forms are represented: prisms, pinacoids, pyramids and domes, in differing degrees of development. The simpler crystals show a rhomb-shaped outline with beveled edges and terminal angles of either 70 or 85°. Double refraction is strong, with symmetrical extinction shown by the rhombs, and oblique extinction shown by edge views; biaxial, with the plane of the optic axis bisecting the acute angle of the rhombs, and the acute bisectrix inclined to the principal plane of the crystals; optically positive.

Nitrate.—Recrystallized from water, the crystals are in the form of oblique prisms with beveled edges, the ends truncated by a pinacoid at about 70° to their axis. The double refraction is strong, with oblique extinction exhibited by all views of the prisms. The extinction angle varies, depending on the orientation, but the maximum is about 35°; biaxial interference figure; 2V large, with plane of optic axis obliquely transverse of the crystals, optically positive,

Picrate.—Spherulites, crosses, dendrites, fine needles, prisms, and small tablets, six-sided in outline and having terminal angles of about 95° may be seen. Double refraction is very strong, with symmetrical extinction; biaxial interference figure; 2V large, with plane of the optic axis transverse of the crystals, optically negative.

Chloroplatinate.—The golden-yellow crystals are sparingly soluble in water and when precipitated show a marked tendency to form a supersaturated solution. The crystals are oblique bi-pyramids, with basal and clino-pinacoids. They show strong double refraction and all views show oblique extinction; biaxial; 2V large; probably optically positive.

Summary

The reaction between methyl-isothiourea sulfate and aniline resulted in the formation of a product consisting of a-phenylguanidine sulfate and aniline sulfate. Pure a-phenylguanidine and a number of its salts were prepared by first converting the a-phenylguanidine sulfate in the crude product to the carbonate. Certain physical and chemical properties of these substances have been described.

MERCURATION OF RESORCINOL AND SOME ALKYLRESORCINOLS

BY REUBEN B. SANDIN

RECEIVED JULY 16, 1928 PUBLISHED FEBRUARY 5, 1929

No trimercurated derivative of resorcinol has been described in the literature and no work has been published on the mercuation of the alkylresorcinols. Dimroth has prepared a chloromercuriresorcinol and a dichloromercuriresorcinol.[1] Leys has prepared a yellow mercury resorcinol compound to which he gives the formula $HgO_2{=}C_6H_3.HgOAc$.[2] Kharasch and Chalkley[3] have examined the reactivity of acetoxymercurire-

---

[1] Dimroth, *Ber.*, 35, 2865 *(1902).*

[2] Leys, *J. pharm. chim.*, (6) 21, 1388 (1905).

[3] Whitmore, "Organic Compounds of Mercury," The Chemical Catalog Co., Inc., New York, 1921, p. 59.

sorcinol and diacetoxymercuriresorcinol dimethyl ether with ammonium sulfide. Raiziss and Prouskouriakoff[4] have prepared 4-acetoxy- and 4-chloromercuri-2-nitroresorcinol.

Regarding the relation between bactericidal power and weight of the side chain, the work of Johnson and Lane[5] and, more recently, the work of Leonard[6] have shown that the disinfectant power of the alkylresorcinols varies directly with the weight of the side chain, up to and including the hexyl group. Henry and Sharp[7] have mercurated some alkylphenols, and in their work on the bactericidal action of mercury compounds[8] it is shown that the monomercurated *p-tert.*-butylphenol apparently is less effective than the corresponding mono-mercurated *p-iso*-amylphenol.

Because it was thought that the mercurated alkylresorcinols might prove to be good bactericidal agents, and also that the study of the effect of the weight of the side chain in these compounds would prove interesting? some mercurated derivatives of ethyl- and hexylresorcinol have been prepared. Hexylresorcinol has been used because of its high phenol coefficient. Ethylresorcinol has been chosen for comparison because it is probably the easiest and cheapest alkylresorcinol to prepare. Incidentally, a trimercurated derivative of resorcinol has been prepared.

The formulas given are only tentative ones. No attempt has been made to determine the position of the mercury groups because very little information, and mostly none at all, concerning the corresponding iodine derivatives is reported in the literature.[10] It is almost certain, however, that the mercury groups are in ortho and para positions, that is, in positions 2 and 6, to the phenolic hydroxyl groups in the dimercurated alkylresorcinols, and in either one of these two positions in the monomercurated alkylresorcinols. An orientation of the mercury meta to phenolic hydroxyl is entirely improbable.[11]

Ethyl- and hexylresorcinol readily react with two molecular proportions of mercuric acetate dissolved in hot alcohol to give practically quantitative yields of the dimercurated derivatives. There is a complete removal of mercuric ion, as shown by the fact that the filtrates give no precipitate with ammonium sulfide solution. From a determination of the mercury and acetate contents and also the yields obtained, it is believed that one mercury group is an acetoxymercuri group, while the remaining mercury

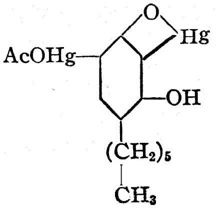
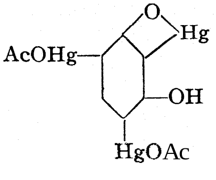
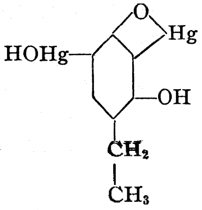
group is an anhydride group formed by the elimination of acetic acid between the phenolic hydroxyl and the acetoxymercuri group ortho to it. It is also believed that the formation of the anhydride takes place with the mercury in position 2, that is, with the mercury which is between the two phenolic hydroxyls. A suggested structure for the dimercurated hexylresorcinol would be Formula I.



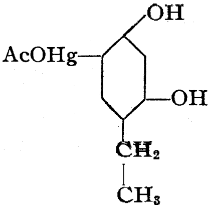
I



II



III



IV

The dimercurated alkylresorcinols prepared by the action of the alkylresorcinols on an alcoholic mercuric acetate solution are insoluble in the ordinary organic solvents, and therefore cannot be purified by crystallization. However, they usually separate in a pure state if care is taken to work with pure starting materials.

The monomercurated alkylresorcinols are prepared by adding one molecular proportion of dry mercuric acetate to two molecular proportions of the alkylresorcinol dissolved in a very small amount of hot glacial acetic acid. The compounds formed in this way are mono-acetoxymercurialkylresorcinols. They, as well as the monochloromercuri compounds, are difficult to obtain in a pure state from solvents because of their tendency to precipitate as yellow, insoluble solids. The latter are probably due to the formation of anhydro monomercurated compounds.

Resorcinol readily forms a trimercurated derivative when one molecular proportion of resorcinol is added to a hot solution of three molecular proportions of mercuric acetate in alcohol. If the proposed formula is correct, the yield is a quantitative one. In this case, too, there is a complete removal of mercuric ion from solution. The suggested formula for this compound is II.

Experimental Part

Mercuration of Alkylresorcinols*

Ethylresorcinol.—The ethylresorcinol used was prepared by the method of Johnson and Hodge.[12] One and four-tenths g. (0.01 mole) of ethylresorcinol dissolved in 10 cc. of alcohol was added to a boiling solution of 6.37 g. (0.02 mole) of mercuric acetate dissolved in 50 cc. of alcohol and 5 cc. of glacial acetic acid. Almost immediately a bright yellow solid separated and care was taken to stop heating as soon as the precipitate appeared, due to the violent "bumping" which always occurred. The reaction mixture was allowed to stand for about twelve hours. The mercurated ethylresorcinol

---

[12] Johnson and Hodge, THIS JOURNAL, 35, 1014 (1913).

was filtered off by suction and washed with hot alcohol. It was air dried and then dried *in vacuo* over sulfuric acid. The yield was **5.80** g. or 97%. The compound is insoluble in all ordinary organic solvents but is soluble in a solution of sodium hydroxide. It darkens on exposure to light and when heated at 180° it darkens but does not melt at 300°.

Anal.[13] Calcd. for $C_{10}H_{10}O_4Hg_2$: Hg, **67.40.** Found: Hg, **67.34, 67.47, 67.04. 66.85.**

On steam distillation, after decomposition by phosphoric acid, it yields **10.20%** of acetic acid ($C_{10}H_{10}O_4Hg_2$ requires **10.08%** of acetic acid), These results indicate that the compound is an anhydromercuri-acetoxymercuri-ethylresorcinol.

The above mercury compound was converted into the dichlorodimercuri-ethylresorcinol by the addition of hydrochloric acid to a suspension (it was necessary to add a few drops of alcohol to cause wetting) of the former in water. It was also necessary to stir vigorously during the addition of hydrochloric acid to prevent a localized high concentration of hydrochloric acid, which tends to break the carbon–mercury bond. The dichloro compound is a white solid and can be crystallized from alcohol. From this solvent it also tends to separate as a yellow solid which is probably an anhydromercuri derivative. The dichlorodimercuri-ethylresorcinol decomposes at 207–209° (corrected).

Anal. Calcd. for $C_8H_8O_2Cl_2Hg_2$: **Hg, 65.96.** Found: Hg, **65.82, 65.74.**

When carbon dioxide was bubbled through a sodium hydroxide solution of the anhydromercuri-acetoxymercuri-ethylresorcinol, a gelatinous precipitate was formed. This was washed repeatedly with water by decantation, then filtered off by suction and finally dried at 100° for two hours. It was obtained as a dark brown solid. The analysis indicates an anhydromercuri-hydroxymercuri-ethylresorcinol, of which the probable structure is Formula III.

And. Calcd. for $C_8H_8O_3Hg_2$: Hg, **72.52.** Found: Hg, **72.68, 72.56.**

In order to obtain a monomercurated ethylresorcinol, one mole of mercuric acetate was added, with heating and stirring, to two moles of ethylresorcinol dissolved in a very small amount of glacial acetic acid. Whiie still hot the solution was poured into water; thereupon a white solid mono-acetoxymercuri-ethylresorcinol separated. Or, if the hot solution was poured into a saturated salt solution, a white solid monochloromercuri-ethylresorcinol was formed. In both cases the compounds were crystallized from alcohol. It has been impossible so far to separate either the mono-acetoxy or the monochloro compound into two isomeric substances. Preference is given to position 6, as far as the orientation of the mercury group is concerned. Formula IV is given as the probable structure The mono-acetoxy derivative melts with charring at 163–**164**" (corrected).

Anal. of mono-acetoxymercuri-ethylresorcinol. Calcd. for $C_{10}H_{12}O_4Hg$: Hg, **50.57.** Found: Hg, **50.32, 50.30.**

The monochloro compound melts to a clear liquid at 145–146° (corrected).

Anal. of monochloromercuri-ethylresorcinol. Calcd. for $C_8H_9O_2ClHg$: Hg, **53.76.** Found: Hg, **53.50, 54.10.**

Hexylresorcinol.—The hexylresorcinol for the work was prepared according to the procedure given by Dohme, Cox and Miller.[14] The mercurated hexylresorcinol

---

[13] The analysis was carried out by decomposing the mercury compound with fuming nitric acid in a sealed tube at a temperature of 200°. The inorganic mercury in the resulting solution was then determined as mercuric sulfide.

[14] Dohme, Cox and Miller, **This Journal,** 48, **1688** (1926).

derivatives were obtained by the method already described for the mercurated ethylresorcinol compounds. In general the properties of these two series of compounds are similar. The anhydromercuri-acetoxymercuri-hexylresorcino was obtained as a bright yellow solid in a practically quantitative yield. In one case 1.94 g. (0.01 mole) of hexylresorcinol and 6.37 g. (0.02 mole) of mercuric acetate gave 6.30 g. of dimercurated derivative, or a yield of 96%. In another case 5.47 g. of hexylresorcinol and 17.95 g. of mercuric acetate gave a yield of 18.30 g., or 100%.

The compound darkens at 200° and does not melt at 300°. It darkens when exposed to light. It is insoluble in the ordinary organic solvents and is difficultly soluble in a golution of sodium hydroxide.

Anal. Calcd. for $C_{14}H_{18}O_4Hg_2$: Hg, 61.60; acetic acid, 9.21. Found: Hg, 61.27, 61.32, 61.29, 60.90; acetic acid, 9.39, 9.40.

The dichloromercuri-hexylresorcinol is a white solid and can be purified from alcohol, from which it also tends to separate as a yellow, insoluble derivative. This difficulty in purification may account for the low mercury results reported below. It melts at 137–138° (corrected).

Anal. Calcd. for $C_{12}H_{16}O_2Cl_2Hg_2$: Hg, 60.40. Found: Hg, 59.66, 59.70.

A mono-acetoxymercuri-hexylresorcinol was prepared. It was crystallized from alcohol. It forms white crystals and melts, with charring, at 177–178° (corrected).

Anal. Calcd. for $C_{14}H_{20}O_4Hg$: Hg, 44.32. Found: Hg, 44.10, 43.80.

Mercuration of Resorcinol

Trimercurated Derivative of Resorcinol.—A trimercurated derivative of resorcinol was obtained by the addition of 1.10 g. (0.01 mole) of resorcinol dissolved in 10 cc. of alcohol to a hot solution of 9.56 g. (0.03 mole) of mercuric acetate dissolved in 75 cc. of alcohol and 5 cc. of glacial acetic acid. The precipitation of the yellow trimercurated compound was almost immediate. Heating was interrupted as soon as the precipitate appeared. It was allowed to stand for twelve hours, then filtered off by suction and washed with hot alcohol. It was dried in *vacuo* over sulfuric acid. The yield was 8.21 g. or practically 100%. There is a complete removal of mercuric ion from solution. It darkens at 210° and does not melt at 300°. It is insoluble in all of the ordinary organic solvents. It is slightly soluble in a solution of sodium hydroxide.

Anal. Calcd. for $C_{10}H_8O_6Hg_3$: Hg, 72.75; acetic acid, 14.53. Found: Hg, 72.50, 72.20; acetic acid, 14.30, 14.40.

Summary

1. The preparation of some mono- and dimercurated derivatives of ethyl- and hexylresorcinol has been described.

2. The preparation of a trimercurated derivative of resorcinol has been described.

ULTRAVIOLET ABSORPTION OF PARA-AMINOBENZOIC ESTERS IN WATER SOLUTION

BY E. RAYMOND RIEGEL AND KENNETH W. BUCHWALD

RECEIVED JULY 28, 1928 PUBLISHED FEBRUARY 5, 1929

Para-aminobenzoic acid and its esters are ordinarily classed among the benzenoid compounds; their water solutions would then be expected to exhibit selective absorption in the ultraviolet with a moderate persistence referable in part to the benzene nucleus, in part to such persistence as might be ascribed to the amino group and to the carboxyl group. Without exception the eight substances which form the main part of this study possess a selective persistence of a much higher order, comparable to that of the quinonoids. The purpose of the study is to establish this fact and to explain it, at least in part. The eight substances are *p*-aminobenzoic acid, its methyl, ethyl, n-propyl and n-butyl esters, butyn, procaine and tutocaine. In the course of the discussion the data for several other substances were required and were therefore included; these are dimethyl-*p*-aminobenzoic acid, aniline and two of its salts, benzoic acid, *p*-hydroxybenzoic acid, guanidine, nitroguanidine and aminonitroguanidine. Since a number of the substances included were local anesthetics, it seemed worth while to add stovaine and alypin, in order to furnish a basis which might be of value in their identification. In the case of butyn, procaine and tutocaine, the free bases as well as the salts were measured. All solutions were water solutions, and in order to avoid the use of any other solvents, a water solution of benzene was prepared and its absorption measured. By ultraviolet we mean the region between the visible and 2100 Å.

Previous Investigations

Methyl, ethyl, n-propyl and n-butyl *p*-aminobenzoates, butyn and butyn base, procaine base, tutocaine and tutocaine base, dimethyl *p*-aminobenzoic acid, guanidine, nitroguanidine, aminonitroguanidine and alypin have not been measured previously, as far as we have been able to find, in any solvent.

Procaine, under the name novocaine, and stovaine have been studied by Brustier;[1] the measurements are reported in terms of logarithms of thickness of solution against wave lengths. A Baly tube was used.

Para-aminobenzoic acid was said by Magini to have a strong absorption band between 300 and 240 mμ which on dilution is drawn together at 260 mμ.[2]

[2] Quoted from Kayser, "Handbuch der Spectroscopie," S. Hirzel, Leipzig, 1905, Vol. III, p. 474.

Aniline in alcohol solutions was originally studied by Hartley[3] while aniline in alcohol with and without hydrogen chloride was studied by Baly and Collie.[4] Benzoic acid and *p*-hydroxybenzoic acid have been measured recently, with high accuracy, but in a solution of hexane with 10% ether.[5]

None of these measurements fitted exactly into our scheme, either because extinction coefficients are not given, or a comparison spectrum for each solution spectrum was not used, or the curve is incomplete, or the solvent was not water, and we have therefore made our own measurements and included them in this report.

Note: Under the curve represents absorption above, transparency.

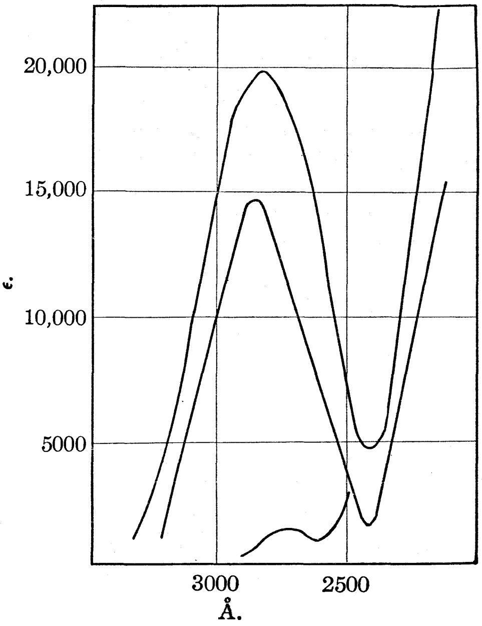

Fig. 2.—Upper curve, methyl-*p*-aminobenzoate; middle curve, ethyl-*p*-aminobenzoate (benzocaine); lower curve, alypin.

Procedure

The procedure was essentially the same as given in a previous publication, to which the reader is referred.[6]

The Schwarzschild constant in $\log t_1/t_0 = k \log I_0/I_{tr}$, the expression which links the fractions of whole revolutions of the sectors to the in-

tensities, was again taken as 1; a recent paper confirms previous workers in setting this constant equal to 1, and establishes that the experimental error in the use of the Hilger sector photometer need not exceed ±2%.[7]

One departure from the previous disposition was made in that the light of the comparison spectrum was allowed to pass through a blank cell containing the same lot of solvent as the solution cell. We were led to do this because of the possible reduction in intensity which the light through the solution cell might suffer by solvent absorption, while that of the comparison spectrum would not suffer the corresponding loss. The statements regarding absorption by water are conflicting. Miller[8] states that water is "ausgezeichnet durchlassig" for the ultraviolet, confirmed by Soret, Hartley, Nichols and others. Kreusler[9] gives figures which show that freshly distilled water kept in Jena glass has very little absorption except for the region of 2000 Å. and shorter waves, but that for distilled

water one-half day old, kept in common glass, the absorption was near 10%. The complete series was run first without the solvent cell for the comparison spectrum, and then repeated with the cell, and observing the caution of keeping the water in pyrex flasks. While the difference in persistence values is not great, there is a difference which makes the latter procedure imperative.[10] Only the values for the measurements with the solvent cell in place are given in this paper. All solutions were at room temperature.

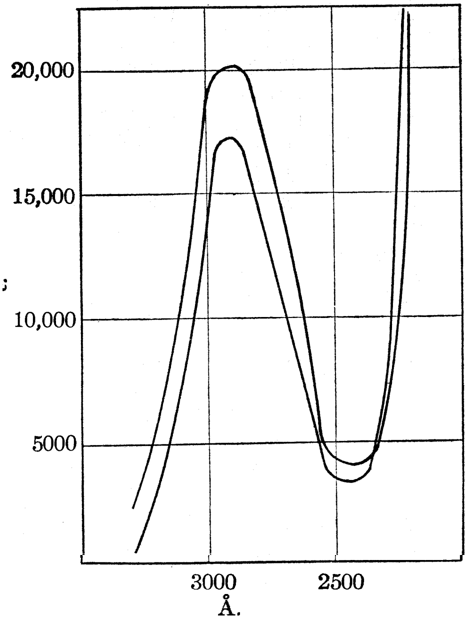

Fig. 5.—Upper curve, procaine; lower curve; tutocaine.

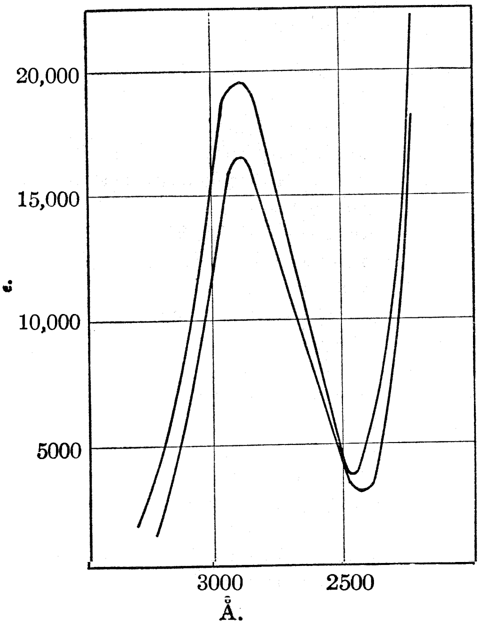

Fig. 6.—Upper curve, procaine base; lower curve, tutocaine base.

Discussion

The absorption curves of the p-aminobenzoic esters and of the free acid are clearly similar and their selective persistence is of the same order of magnitude. The values for selective persistence have been brought together in Table I; they are scaled from the original curve on millimeter paper and represent the numerical difference between the extinction coefficient for the head of the band, which is also the absolute persistence, and the extinction coefficient at the trough, where the transparency is about to cease. As will be seen from the last value in the table, the selective persistence of N-methyl-y-pyridone, a quinonoid, is surpassed by three of the p-aminobenzoic esters and approached by the other three,

---

[10] We are indebted to Dr. Shapiro of the Department of Physics, Cornell University, for this timely criticism.

TABLE I

ABSOLUTE PERSISTENCES AND SELECTIVE PERSISTENCES (WATER SOLUTIONS)

Compound	Head of band. Å.	Absolute persistence	Selective persistence
p-Aminobenzoic acid	2710	11800	9700

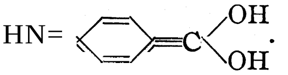
[a] THIS JOURNAL, **48,** 1342 (1926).

as well as by the free acid. This suggests that for each of these substances most of the molecules are in the hemiquinoid form indicated by the formula



Such a view is confirmed by the low absorptive power of dimethyl-*p*-aminobenzoic acid, whose selective absorption is only 5.6% of that of the average of the first 11 items in the table, all with the *p*-aminobenzoic structure. The methyl group is generally assumed to migrate with great reluctance if at all. The absorption for aniline alone, added to that for benzoic acid alone, is insufficient to account for the selective persistence of the *p*-aminobenzoic compounds. *p*-Hydroxybenzoic acid, on the other hand, has a selective persistence about equaling the average of that of the *p*-aminobenzoic substances; like the latter, *p*-hydroxybenzoic acid may be written in hemiquinoid form, , which would explain its high persistence.

Mere para position does endow the molecule with a selective persistence of the magnitude possessed by the p-amino compounds; for example, p-xylene in alcohol has its maximum persistence at 2740 Å., namely 256, while p-cymene in alcohol has its best selective persistence at the band 2730 Å., measuring 540. The latter is the greatest persistence of *p*-substituted alkyl benzenes which we have measured.[11] It is evident that mere para position does not account for the high selective persistences reported.

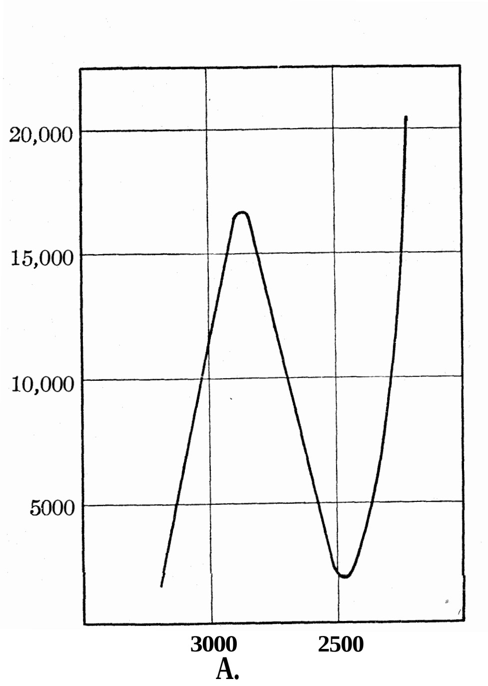


Fig. 7.—Butyn base.

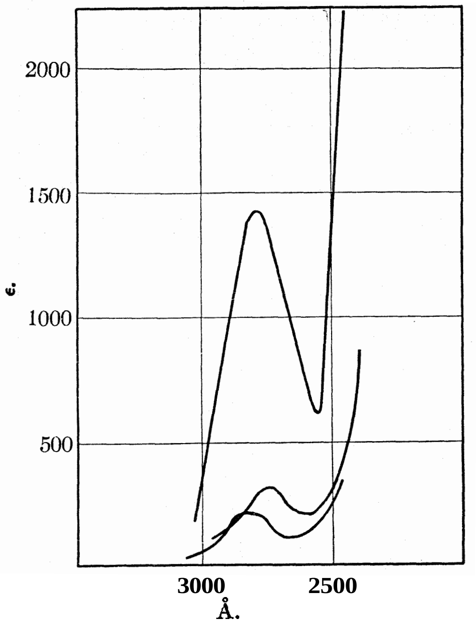

Fig. 8.—Upper curve, aniline; middle curve, aniline hydrochloride; lower curve, aniline hydrobromide.

It was expected that the free base would differ from the respective hydrochlorides or sulfates in a regular manner, but as may be seen from the table, butyn base has a selective persistence considerably lower than butyn, while procaine base has one about equal to that of procaine, and tutocaine base also has essentially the same selective persistence as tutocaine. In the case of aniline, both the hydrochloride and the hydrobromide have a selective persistence about $^1/_8$ of that possessed by the free base.

[11] These results will be embodied in a subsequent paper.

That selective absorption is not limited to ring structures is well shown by the absorption curves for nitroguanidine and aminonitroguanidine. These two substances have not only considerable selective persistence but their curves are similar in shape to that of the p-aminobenzoic compounds. Guanidine carbonate has no selective absorption, so that the selective absorption of its two derivatives must be due to the nitro group and to the disturbance in the stability of the molecule caused by its introduction. Stovaine and alypin have only inconsiderable selective persistence; their molecules contain no grouping susceptible to a hemiquinoid or quinonoid rearrangement. Benzene in water has only slight selective persistence.

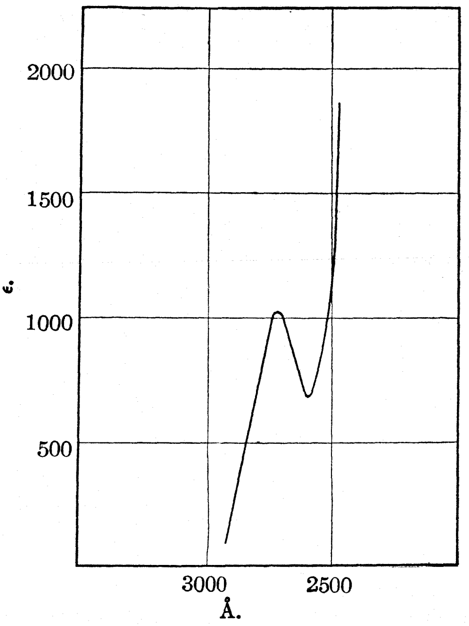

Fig. 9.—Benzoic acid.

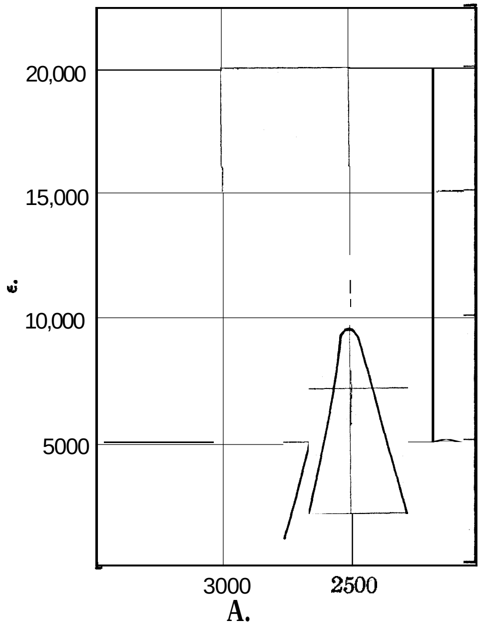

Fig. 10.—*p*-Hydroxybenzoic acid.

Cocaine in the form of hydrochloride in water solution has been measured by Castille,[12] while cocaine base in alcohol had been studied some time before that by Henri.[13] We repeated the study of the salt, using cocaine sulfate in water solution, obtaining values in agreement with those of Castille.

The base dissolved in water was also measured; the curve is not unlike that for the alcohol solution. From our results a band at 2725 Å. has absolute persistence **1400,** selective persistence **600;** while a second band at **2310 Å.** has absolute persistence **13,300** with a selective persistence undetermined because the trough of this band lies below **2100 Å.**

[12] Castille, *Bull. acad. royal med. Belg.* [5], 5, 193–200 (1925); see also ref. 1.

[13] Gompel and Henri, *Compt. rend.,* 156, 1541 (1913).

The head of the band for the *p*-aminobenzoic esters is well toward the red from the position of the head for the free acid, in agreement with the rule of Hartley. The position of the heads of the bands for the several esters with respect to each other does not show absolute agreement with the rule.

Materials

p-Aminobenzoic acid, a by-product in the manufacture of benzoic acid by the nitration of toluene, was recrystallized twice, and the absorption spectrum determined on this sample; m. p. 186° ("International Critical Tables," 187°).

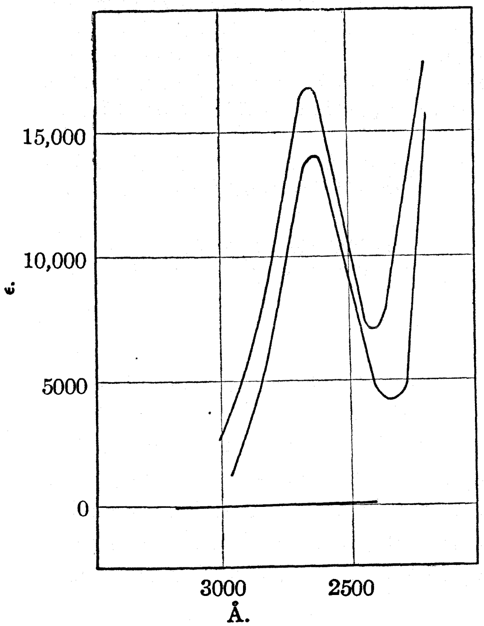

Fig. 11.—Upper curve, aminonitroguanidine; middle curve, nitroguanidine; lower curve, guanidine carbonate.

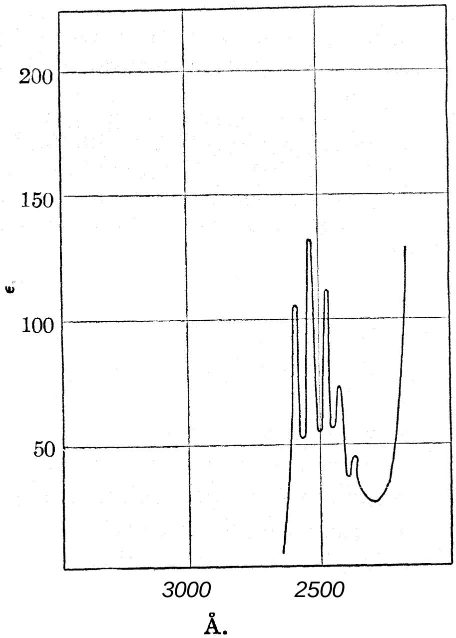

Fig. 12.—Benzene in water.

Methyl p-aminobenzoate was made from the acid by esterification with methyl alcohol in the presence of sulfuric acid; after refluxing for five hours the excess methyl alcohol was removed by distillation. The residual liquid was cooled and neutralized while ice-cold with caustic. A somewhat colored, sweet-smelling precipitate of the ester was formed; it was filtered off, washed with water and recrystallized from alcohol several times. The melting point was 112° ("International Critical Tables," 112°).

Ethyl p-aminobenzoate was the pharmaceutical benzocaine, recrystallized, with melting point 90° ("International Critical Tables," 91°).

n-Propyl p-aminobenzoate was made from the acid by esterification with *n*-propyl alcohol by the same procedure as for the methyl ester, The melting point was 75° ("International Critical Tables," 74–75°).

Butyn, procaine, tutocaine, stovaine and alypin were the pharmaceutical products; they were all recrystallized at least once and their several constants were found to agree with the literature values. The free bases for butyn, procaine and tutocaine were prepared from the salts by treating with ammonia, drying the oil first formed and, after it had hardened, crystallizing. Tutocaine base leaves the oil stage with great difficulty; we were able, however, to use a special sample prepared for this work by the Winthrop Chemical Company, consisting of well-formed crystals with melting point 98–99°. The procaine base melted at 60°, the butyn base at 33°.

Dimethyl *p*-aminobenzoic acid was made from Michler's ketone by mixing it with soda lime and heating the mixture in a retort to 350°; after the dimethylaniline had distilled off, the residue was treated with hot water and acidified with dilute acetic acid. This method is one of the two proposed by Bischoff;[14] the second one involves closed tubes. Both were tried, and the first was found to be very much superior. The crude product was recrystallized twice from 50% alcohol, giving white needles of melting point 235°, essentially the Beilstein value.

Nitroguanidine was made by dissolving guanidine nitrate in cold sulfuric acid and pouring the solution slowly into cold water;[15] long, needle-shaped crystals separate and these were recrystallized; melting point 230° ("International Critical Tables," 231°).

Aminonitroguanidine was supplied by Mr. John F. Williams of the Graduate Department, who prepared it, with Mr. Ross Phillips, for the first time.[16] The substance decomposes with explosive violence at 185°.

The remaining substances are well known and were prepared or purified by standard methods; each was tested for its physical constants, and these agreed with literature values.

Summary

1. The ultraviolet absorption of the water solutions of p-aminobenzoic acid and of seven of its esters has been determined.

2. In order to assist in the discussion, the ultraviolet absorption of several other substances was also determined. These substances are dimethyl-p-aminobenzoic acid, aniline and two of its salts, benzoic acid, p-hydroxybenzoic acid, guanidine, nitroguanidine, aminonitroguanidine, stovaine, alypin, benzene and the free bases of butyn, procaine and tutocaine, all in water solution.

3. The selective absorption of the p-aminobenzoic compounds averages 14,100, with the extremes 9700 and 15,900, while that for benzene in water solution is less than 100; hence the considerable absorption of the *p*-aminobenzoic compounds is not due to the benzenoid nucleus, but rather to a hemiquinoid state. This conclusion is confirmed by a consideration of the selective absorption of the substances listed in 2.

THE OXIDATION OF TRIBROMORESORCINOL[1]

BY TENNEY L. DAVIS AND JULIAN W. HILL

RECEIVED AUGUST 9, 1928 PUBLISHED FEBRUARY 5, 1929

A study of the oxidation of resorcinol and its derivatives is interesting because of the light which it may throw upon the mechanism of the oxidation of phenols in general, a subject already largely illuminated by the researches of Pummerer,[2] Goldschmidt,[3] Hunter[4] and others, and because of the possibility that *m*-quinones may be produced. No m-quinones are known. If products from the oxidation of resorcinol and its derivative are isolated and characterized and found to be not m-quinones, then the results will show us how the molecules have evaded the possibility of *m*-quinone formation and will, to that extent, increase our understanding of the factors which determine stable structures in aromatic and related compounds.

The oxidation of resorcinol does not appear to have been studied. Henrich, Schmidt and Rossteutscher[5] studied the oxidation by air of orcinol in alkaline solution and although they did not establish the structure of the primary oxidation product they showed that it yielded on reduction a substance which was probably pentahydroxyditolyl. Stenhouse[6] oxidized trichloro-orcinol with alkaline potassium ferricyanide and believed that he isolated a *p*-quinone, $C_7H_4Cl_2O_3$, which reduced to a hydroquinone, $C_7H_6Cl_2O_3$. He reported that he had secured corresponding results with tribromo-orcinol, trichlororesorcinol and tribromoresorcinol, but did not describe the experiments or the compounds. We find that alkali has a very destructive effect upon tribromoresorcinol,[7] and have had no success with ferricyanide as an oxidizing agent. Meyer and Desamari[8] attempted by a number of methods to prepare a m-quinone from tribromoresorcinol, but recovered the substance unchanged after shaking it in ether solution with silver oxide and anhydrous sodium sulfate, after boiling in benzene solution with lead dioxide, and after treating with nitric acid in cold glacial acetic acid solution. By the use of nitric acid in

warm glacial acetic acid solution, they converted tribromoresorcinol into 2-bromo-4,6-dinitroresorcinol.

We have isolated three products from the oxidation of tribromoresorcinol with aqueous chromic acid and have established their relationships and probable structure.

The methods described by Benedikt[9] for the preparation of tribromoresorcinol were found to give a poor yield (65% in the best experiment) and recrystallization from dilute alcohol gave pink crystals. We have found that crystallization from chloroform yields a white product and that bromination in that medium gives pure material in practically theoretical yield. The resulting tribromoresorcinol crystallized from chloroform in white needles, m. p. 111°, and was identified by analysis.

The first oxidation experiments were carried out by adding tribromoresorcinol with stirring to a fairly strong aqueous solution of chromic acid. A brick-red crystalline powder formed at once, the mixture soon warmed up with frothing and the reaction was stopped by diluting with a large volume of water. The solid matter, recrystallized from benzene, yielded some red crystals and some unchanged tribromoresorcinol, but mostly a varnish—and the amount of product was small. Much better results were secured by oxidation in a two-phase system. An approximately 10% solution of tribromoresorcinol in benzene was shaken from time to time during three hours with a slightly smaller volume of aqueous chromic acid solution (20% CrO_3) in a bottle cooled by immersion in freshly drawn tap water. Carbon dioxide was evolved and bromine set free. Crystals separated in both phases. Removed by filtration, washed with water and dried, the product consisted of a light red-brown crystalline powder equal to 30–37% of the weight of the tribromoresorcinol which was used. Under the polarizing microscope it was found to be a mixture of a large amount of red crystals with a red-yellow pleochroism and a relatively small amount of light-colored material.

Purification of the product presented many difficulties. It was soluble in benzene, ether and glacial acetic acid, and soluble and apparently stable in cold alcohol, though with hot alcohol it yielded acetaldehyde—and the solutions in ordinary, slightly moist solvents generally yielded varnishes. Perfectly dry benzene, distilled over sodium, was found to yield crystals. By fractional crystallization from this solvent, decantation and mechanical separation of the crystals, the crude material gave splendid red crystals with a blue reflection, about 60% of its weight, and light-colored material, about 8 or 9%. The latter material by crystallization from dry benzene yielded small, white, lustrous crystals and a very small amount of yellow crystalline matter.

The yellow substance melted at 211° and was identified as tribromo-

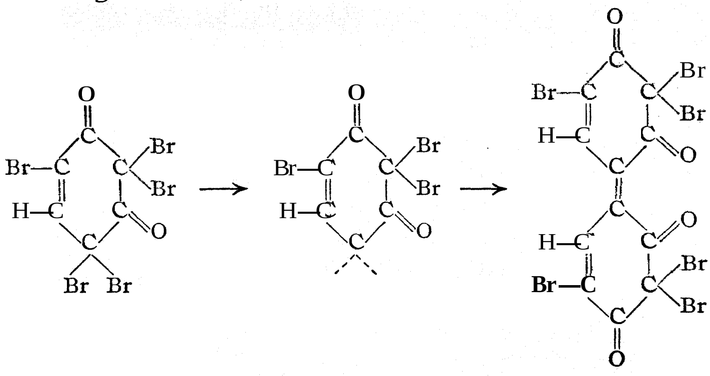
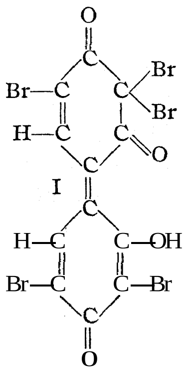
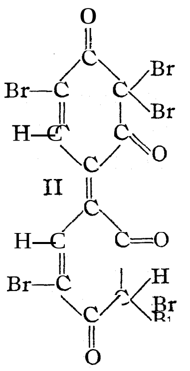
resoquinone by analysis and by comparison with known material prepared according to the method of Liebermann and Dittler[10] by heating pentabromoresorcinol at 157–160° in a current of dry carbon dioxide until bromine no longer came off, thus



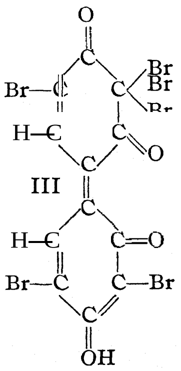
The red-colored substance which is the principal product of the oxidation of tribromoresorcinol crystallized from benzene in crystals containing benzene of crystallization, a circumstance which materially hindered its characterization. It was obtained free from solvent by replacing the benzene with ether and then refluxing with low-boiling petroleum ether, and was found by analysis and molecular weight determination to have the composition, $C_{12}H_3O_4Br_5$. Its chemical properties and transformations indicate that it has one or another of the structures indicated below.



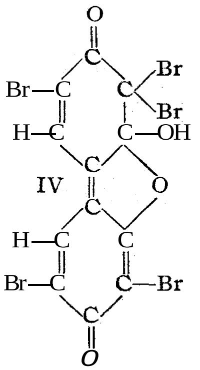
I



II



III



IV

The first three of these formulas may properly be regarded as representing one single tautomeric substance. Whether Formula IV, with the dibenzofuran[11] arrangement, really represents a substance different from this

---

[10] Liebermann and Dittler, *Ann.*, 169, 252 (1874).

[11] Behr, Arno and von Dorp, *Ber.*, 7, 398 (1874), oxidized phenol to dibenzofuran, and Pummerer, ibid., 58, 1808 (1925), obtained a dibenzofuran derivative by the low-temperature oxidation of *p*-cresol by means of alkaline potassium ferricyanide.

one may perhaps be questioned. An attempt to prove the presence of an hydroxyl group by the formation of an acetyl derivative was unsuccessful—and we consider the structure represented by Formulas I, II and III as the more probable. We have named the substance rhodo-(brom)-resoquinone (literally, the red-colored quinone-like substance from the oxidation of brominated resorcinol).

Rhodo-(brom)-resoquinone crystallizes from benzene in deep red crystals which have at first a blue reflection but lose their luster rapidly and give off a portion of their benzene, retaining some of it very tenaciously. In a melting point tube the crystals swell up, give off their benzene at 105° and melt at about 220" with decomposition and blackening. Analysis for carbon, hydrogen and bromine indicated that different batches contained different amounts of benzene. The molecular compound of rhodo-(brom)-resoquinone with ether, $C_{12}H_3O_4Br_5 \cdot C_4H_{10}O$, crystallizes from ether in pyramidal crystals of a somewhat lighter shade of red than the benzene compound. The crystals retain their luster and do not lose ether on exposure to the air. After some months they turn brown and smell of acetaldehyde. On heating they bleach and finally melt with decomposition at about 215°. The molecular compound with carbon disulfide, $C_{12}H_3O_4Br_5 \cdot {}^1/_4CS_2$, was identified by analysis. Compounds with bromoform and carbon tetrachloride were also prepared.

Rhodo-(brom)-resoquinone dissolves in dilute aqueous sodium hydroxide to form a dark green or black solution, and in concentrated sulfuric acid with a deep red color. It oxidizes the usual ketone reagents, hydrazine, semicarbazide, hydroxylamine, phenylhydrazine and dinitrophenylhydrazine, with the evolution of nitrogen. With reducing agents, sulfurous acid, sodium bisulfite, stannous chloride, metal and acid, hydrogen bromide and hydrogen iodide, it yields 3,5,3′,5′tetrabromo-2,4,2′,4′-tetrahydroxydiphenyl, identified by analysis of the substance and of its tetra-acetate for bromine and by mixed melting points of the two with known materials prepared by the reduction of tribromoresoquinone and subsequent acetylation.

In the first experiments rhodo-(brom)-resoquinone was reduced by passing sulfur dioxide into an alcohol suspension of the substance. It later appeared that the same result could be attained more rapidly and more conveniently by bubbling hydrogen bromide through a benzene solution or suspension. Bromine is liberated. Aqueous hydrobromic acid acts in the same way but much more slowly. An alcohol solution of hydrogen iodide acts rapidly, liberating iodine. A determination of the amount of iodine which was liberated supplied a means of ascertaining the oxidizing power of the substance and hence supplied further evidence of its structure.

Tribromoresoquinone was found to be reduced by the same treatment and an experiment was carried out with that substance as a check upon the accuracy of the method. The conversion of tribromoresoquinone into tetrabromotetrahydroxydiphenyl, that is, the change from $C_{12}H_2O_4Br_6$ to $C_{12}H_6O_4Br_4$, involves the addition of four hydrogen atoms and the removal of two bromine atoms, and hence requires six molecules of hydrogen iodide, thus

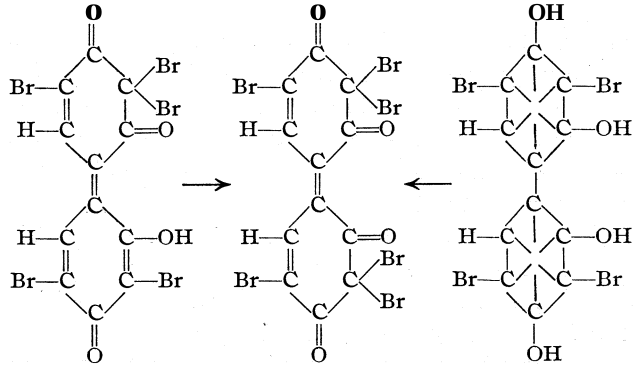
$$C_{12}H_2O_4Br_6 + 6HI \longrightarrow C_{12}H_6O_4Br_4 + 3I_2 + 2HBr$$

Similarly, if rhodo-(brom)-resoquinone has the formula which we suppose it to possess, its reduction by hydrogen iodide would take place as follows

$$C_{12}H_3O_4Br_5 + 4HI \longrightarrow C_{12}H_6O_4Br_4 + 2I_2 + HBr$$

Titrations with thiosulfate of the iodine liberated during the reduction of tribromoresoquinone and of solvent-free rhodo-(brom)-resoquinone (taken for convenience in weighing) gave results in agreement with the above equations. This establishes definitely the number of the hydrogen atoms in rhodo-(brom)-resoquinone, a number which is left in doubt by the elementary analysis. An experiment with rhodo-(brom)-resoquinone containing ether of crystallization gave a result which corresponds to the formula $C_{12}H_3O_4Br_5{\cdot}C_4H_{10}O$ for the molecular compound.

Rhodo-(brom)-resoquinone yields the same reduction product as tribromoresoquinone, and the measurement of its oxidizing power suggests that it is intermediate between tribromoresoquinone and its reduction product. We find indeed that it is converted into tribromoresoquinone by the treatment by which Zincke and Schwabe[12] previously converted tetrabromotetrahydroxydiphenyl into tribromoresoquinone, namely, by the action of bromine in 50% aqueous acetic acid. The formulas show the close similarity between the compounds.



Rhodo-(brom)-resoquinone Tribromoresoquinone

Final proof that rhodo-(brom)-resoquinone is intermediate between tribromoresoquinone and its reduction product was found by producing it by the partial reduction of tribromoresoquinone. The reduction first

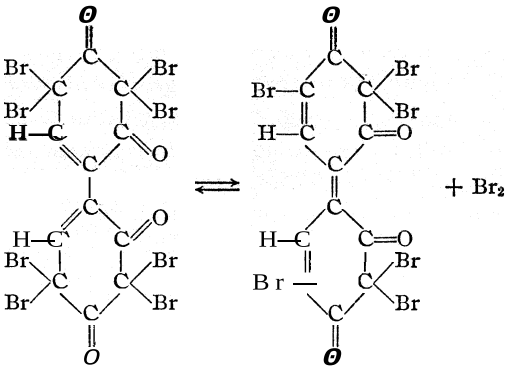
---

[12] Zincke and Schwabe, *Ber.*, 42, 797 (1909).

came about by accident. Tribromoresoquinone was allowed to stand overnight with a solution of bromine in benzene, and crusts of red crystals of rhodo-(brom)-resoquinone were found the next morning on the sides and bottom of the vessel. On longer standing the red crystals disappeared and white crystals of tetrabromotetrahydroxydiphenyl were deposited. Rhodo-(brom)-resoquinone alone was found to yield the same reduction product under like conditions. The reduction of tribromoresoquinone first to rhodo(brom)-resoquinone and finally to tetrabromotetrahydroxydiphenyl was due in this case to hydrogen bromide produced by the action of the bromine on the benzene, for solutions containing these substances did not evolve hydrogen bromide as did a solution of bromine in benzene alone. Tribromoresoquinone is not altered by long contact with a solution of bromine in carbon tetrachloride in a dry vessel closed by a glass stopper. If a cork stopper is used, the cork is attacked by the bromine to produce hydrogen bromide, and the same changes occur as in benzene solution. With hydrogen iodide tribromoresoquinone is reduced at once to tetrabromotetrahydroxydiphenyl; it is not possible, as with hydrogen bromide, to stop at the intermediate stage of reduction which is represented by rhodo-(brom)-resoquinone.

When the molecular compounds of rhodo-(brom)-resoquinone are heated they slowly lose their color and at 160–190° are entirely bleached. The white compound which is thus produced was obtained in larger quantity by heating the benzene compound at 120° for several days—small, white needles from glacial acetic acid, m. p. 228–229°. Analysis gave results which correspond to the formula, $C_{12}H_3O_4Br_5$, indicating that the substance is isomeric or polymeric with rhodo-(brom)-resoquinone. The substance is sparingly soluble in the usual solvents and its molecular weight could not be determined. It dissolves slowly in glacial acetic acid with the production of a yellow color. It liberates much less iodine from alcoholic hydrogen iodide than does rhodo-(brom)-resoquinone and resists all attempts at bromination whether in glacial or dilute acetic acid, in chloroform or carbon tetrachloride, or with undiluted bromine. We have not been able to prove its structure.

The white product from the oxidation of tribromoresorcinol was obtained by the spontaneous evaporation of its benzene solution as small, white, lustrous crystals, m. p. 227–228° with decomposition. Analysis indicated the formula, $C_{12}H_2O_4Br_8$, and its properties and reactions warrant us in assigning it the structure of tetrabromoresoquinone. Boiled with glacial acetic acid it goes into solution; the liquid quickly turns yellow and then deep orange red, bromine is given off and the liquid on cooling deposits crystals of tribromoresoquinone. The heavily brominated tetrabromoresoquinone under these conditions drops off two bromine atoms to produce the more highly conjugated, tribromoresoquinone, thus

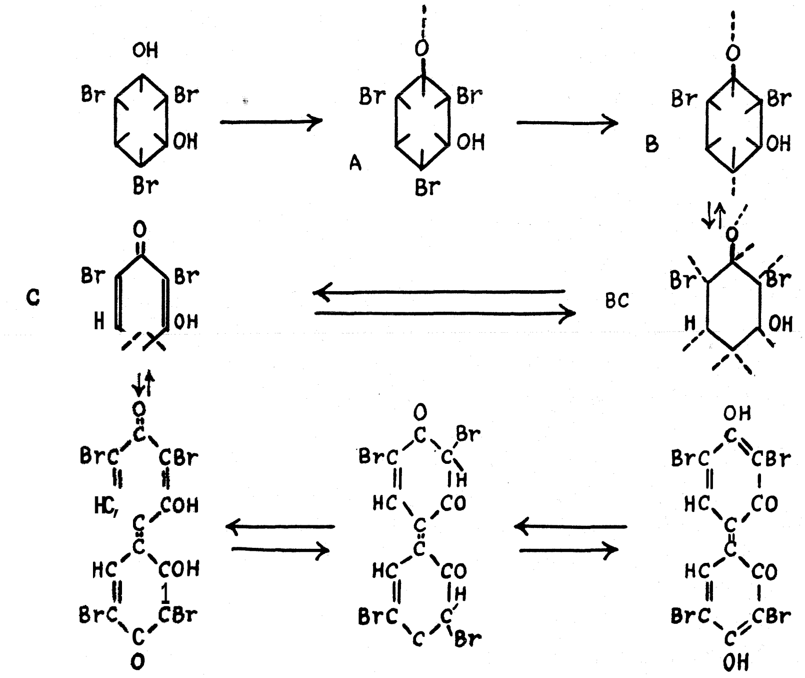


In benzene solution tetrabromoresoquinone shows but little tendency to give off bromine, yet the residues from the evaporation of such solutions to dryness are invariably tinged with yellow. When reduced in alcohol solution with aqueous stannous chloride, tetrabromoresoquinone yields 3,5,3′,5′-tetrabromo-2,4,2′,4′-tetrahydroxydiphenyl. Titration of the iodine liberated by the reaction of tetrabromoresoquinone on hydrogen iodide in alcohol solution showed that the reaction takes place as follows

$$C_{12}H_2O_4Br_8 + 8HI \longrightarrow C_{12}H_6O_4Br_4 + 4I_2 + 4HBr$$

The result served also to fix with certainty the hydrogen content of the substance, otherwise left in doubt because of the errors inherent in the determination of a small amount of hydrogen. Tetrabromoresoquinone is produced from tribromoresoquinone and from rhodo-(brom)-resoquinone when either of these substances is allowed to stand in contact with undiluted bromine. It is produced when tribromoresoquinone is shaken by machine for twenty-four hours with benzene and aqueous chromic acid containing bromine, under conditions similar to those which existed in the original oxidation experiment.

The Mechanism of the Reaction.—The work of Pummerer,[2] Goldschmidt[3] and Hunter[4] has shown it to be probable that the first step in the oxidation of phenols is the removal of hydrogen from the hydroxyl group. leading to the formation, at least momentarily, of a radical in which there is a free oxygen affinity, a radical of the sort which Hunter has designated Type A. Hunter's work has further made it probable that the formation of a radical of this type is followed, in the case of halogenated phenols, by the loss of halogen from the ring with the production of a (Type B) doubly unsaturated radical. Such Type B radicals may under oxidizing conditions yield *p*-quinones, which compounds Stenhouse, Hunter and others have indeed procured. In the absence of oxidizing agents they may combine with themselves, as Hunter found, to form polyphenylene oxides. They may also combine with themselves in another mode to form di-nuclear quinones; a possibility which is perhaps more evident if the radical represented by the Type B formula is formulated in another way (Type C below). Since Types B and C, if written with the partial valencies according to Thiele (BC below), have the same graphical representation, we think that any distinction between them is without a difference in fact and is entirely gratuitous. The action of chromic acid on tribromoresorcinol, in accordance with these hypotheses, would result in the liberation of free bromine and in the formation of a radical which would combine with itself to form the at present unknown dibromoresoquinone.



If dibromoresoquinone were a product of the oxidation of tribromoresorcinol, it would be expected to be brominated further under the conditions of our experiment. The substitution of one bromine atom would yield rhodo-(brom)-resoquinone, which would enter into molecular combination with the benzene which is present, would crystallize out and would to a large extent escape further action. If any of it should brominate, however, it would yield tribromoresoquinone and tetrabromoresoquinone, the substances which we have found. It seems probable that tribromoresoquinone was not present in the crude product of the oxidation and that the small quantity which we found was produced during the fractional crystallization by the spontaneous elimination of bromine from tetrabromoresoquinone.

Experiments

Experiments which are indicated with sufficient fullness in the foregoing are not again described in this section. Experiments are reported in the order in which their results are discussed in the first section of the paper.

Preparation of Tribromoresorcinol.—One hundred grams of resorcinol was suspended in 1500 cc. of chloroform and 432 g. of bromine was added slowly from a dropping funnel while the mixture was mechanically stirred. The clear red liquid was boiled under reflux for about an hour until it had become light yellow in color and hydrogen bromide was no longer evolved. It was treated with decolorizing carbon, distilled to one-third its volume and allowed to cool and crystallize. Concentration of the mother liquors yielded more material and the last crops were of a faint pink color. The product crystallized in handsome white needles, m. p. 111°, and was obtained in practically theoretical amount. Recrystallization from chloroform failed to raise the melting point but removed every trace of color.

Anal. Subs., 0.1964: CO_2, 0.1508; H_2O, 0.0171. Subs., 0.1230: AgBr, 0.2009. Calcd. for $C_6H_3O_2Br_3$; C, 20.69; H, 0.86; Br, 69.12. Found: C, 20.95; H, 0.97, Br, 69.51.

Isolation of the Oxidation Products.—The oxidation of tribromoresorcinol was carried out in batches, in the manner described earlier, 200 cc. of a 10% solution of the substance in benzene (previously treated with chromic acid and washed with water) and 125 cc. of aqueous chromic acid being used for each run. Gases were given off which contained carbon dioxide, as evidenced by turbidity with baryta water. After about forty-five minutes the two phases emulsified and crystalline material began to separate. Experiment showed that the yield of product did not increase after three hours, at the end of which time from 6 to 7.5 g. of crude material was obtained from each batch. The mother liquor contained free bromine, as shown by the production of tribromo-aniline, m. p. 120°, when it was distilled into aniline water.

The crude product contained a small amount of insoluble, dark-colored material which was discarded. One hundred and fifty grams, worked up as already described, yielded 90 g. of red crystals, 12 g. of light-colored material and 25 g. of residues which it was not practicable to work up. The working up of the light-colored material yielded a very small amount of the yellow constituent. The red and yellow substances were purified further by recrystallization from hot dry benzene. The white substance was obtained pure by dissolving it in a large volume of benzene and concentrating slowly. Its solubility varied very little with temperature but it separated in crystals as the volume diminished.

The Yellow Substance—Tribromoresoquinone.—*Anal.* Subs., 0.1194: AgBr, 0.1947. Calcd. for $C_{12}H_2O_4Br_6$: Br, 69.56. Found: Br, 69.40.

Rhodo-(brom)-resoquinone.—The red crystals which resulted from the fractional crystallization from benzene were shown to contain benzene by decomposing 4.5 g. of the material with aqueous potassium hydroxide and distilling into an ice-cooled receiver. The solid portion of the distillate melted at about 7°, occupied a volume of 0.90 cc. at room temperature, boiled at 79°, and on nitration yielded m-dinitrobenzene, m. p. 89.5". Two samples prepared at different times gave analytical results which correspond fairly well to one and to one-half equivalent of benzene, respectively, but the agreement is perhaps fortuitous.

Anal. Subs., 0.1976: CO_2, 0.2437; H_2O, 0.0302. Subs., 0.1916, 0.1867: AgBr, 0.2642, 0.2570. Calcd. for $C_{12}H_3O_4Br_5{\cdot}C_6H_6$: C, 31.35; H, 1.30; Br, 58.05. Found: C, 33.64; H, 1.71; Br, 58.68, 58.58.

Anal. Subs., 0.1726, 0.2001: CO_2, 0.1809, 0.2073; H_2O, 0.0196, 0.0221. Subs., 0.1315, 0.1452, 0.1597: AgBr, 0.1858, 0.2061, 0.2255. Calcd. for $C_{12}H_3O_4Br_5.{}^1/_2C_6H_6$: C, 27.69; H, 0.92; Br, 61.54. Found: C, 28.59, 28.26; H, 1.27, 1.24; Br, 60.13, 60.40, 60.09.

The molecular compound of rhodo-(brom)-resoquinone with ether was prepared by extracting a portion of the benzene compound in a Soxhlet extractor with ether which had been previously distilled over sodium. After a time crystals began to separate from the boiling liquid in the flask. When all of the material had been dissolved from the thimble, the crystals in the flask were removed. Another crop of excellent crystals was obtained by evaporating tho mother liquor almost to dryness in a vacuum over sulfuric acid. Three and five-tenths grams of the substance, decomposed by cold aqueous potassium hydroxide, yielded about 0.3 cc. of a liquid which smelled like ether and boiled at 35–37°. The alkaline liquid on distillation gave no evidence of benzene.

Anal. Subs., 0.1878, 0.2226: CO_2, 0.1916, 0.2286; H_2O, 0.0323, 0.0390. Subs., 0.1195, 0.1243, 0.1444: AgBr, 0.1651, 0,1705, 0,1985. Calcd. for $C_{12}H_3O_4Br_5{\cdot}C_4H_{10}O$: C, 28.03; H, 1.90; Br, 58.40. Found: C, 27.83, 28.01; H, 1.92, 1.96; Br, 58.79, 58.37, 58.50.

The molecular compound with carbon disulfide was prepared from the benzene compound in the same way by the use of a Soxhlet extractor.

Anal. Subs., 0.01617, 0.01670: CO_2, 0.01395, 0.01451; H_2O, 0.00101, 0.00131. Subs., 0.1480: AgBr, 0.2213; $BaSO_4$, 0.0279. Calcd. for $C_{12}H_3O_4Br_5{\cdot}{}^1/_4CS_2$: C, 23.3; H, 0.48, Br, 63.5; S, 2.54. Found: C, 23.5, 23.7; H, 0.69, 0.87; Br, 63.6; *S*, 2.59.

Rhodo-(brom)-resoquinone free from combined solvent was obtained by boiling the ether compound with dry, low boiling, petroleum ether. The temperature of the heating bath did not exceed 45°. At the end of an hour and three-quarters the crystals had entirely disintegrated to a red powder. This was removed and dried in a vacuum.

Anal. Subs., 0.1631, 0.1718: CO_2, 0.1405, 0.1470; H_2O, 0.0088, 0.0102. Subs., 0.1191, 0.1418: AgBr, 0.1830, 0.2265. Calcd. for $C_{12}H_3O_4Br_5$: C, 23.56;' H, 0.49; Br, 65.47. Found: C, 23.50. 23.34; H, 0.60, 0.66; Br, 65.39, 65.22.

Mol. wt. Subs., 0.0756, 0.0736; benzene, 20.32, 20.29; *AT*, 0.032°, 0.031°. Calcd.: 611. Found: 616, 620.

Reduction of Rhodo-(brom)-resoquinone.—Ten grams of rhodo-(brom)-resoquinone with benzene of crystallization was dissolved in a mixture of 140 cc. of alcohol and 40 cc. of water, and sulfur dioxide was bubbled in until the liquid was light yellow. A precipitate separated and a further quantity of crystals appeared when the liquid was diluted with water. The yield of crude tetrabromotetrahydroxydiphenyl amounted to 5 g. of fine, violet-tinted crystals. Recrystallized from dilute alcohol with the use of decolorizing carbon, it yielded the pure product, silky white needles which melted at 277–278° after darkening at 240°.

Anal. Subs., 0.0980, 0.0960, 0.1087: AgBr, 0.1375, 0.1345, 0.1520. Calcd. for $C_{12}H_6O_4Br_4$: Br, 59.90. Found: Br, 59.71, 59.62, 59.51.

Three and one-half grams of tetrabromotetrahydroxydiphenyl was acetylated by boiling for a short time with 10 cc. of acetyl chloride and a few drops of concd. sulfuric acid and yielded 3.5 g. of the tetra-acetate, m. p. 194.5° after recrystallization from alcohol.

Anal. Subs., 0.1210, 0.1224: AgBr, 0.1294, 0.1311. Calcd. for $C_{20}H_{14}O_8Br_4$: Br, 45.58. Found: Br, 45.51, 45.57.

Iodimetric Titration of Tribromoresoquinone and Rhodo-(brom)-resoquinone.—The sample was dissolved as far as possible in 10 cc. of alcohol. Five cc. of 10% sulfuric acid and 1 cc. of 50% potassium iodide solution were then added with swirling, A white, crystalline precipitate of potassium sulfate separated. After standing for a short time, the mixture was diluted with 50 cc. of water. Most of the precipitate dissolved. The diluted solution was then titrated with standard sodium thiosulfate solution. Just before the disappearance of the yellow color, starch solution was added and the liquid was titrated to the disappearance of the blue tint. Experiment showed that if less alcohol was used, the sample blackened when potassium iodide was added. If much more alcohol was used, no blue color was produced on the addition of the starch solution.

Anal. Tribromoresoquinone. Subs., 0.1356, 0.1147: 29.75, 25.32 cc. of 0.0394 N $Na_2S_2O_3$. Calcd.: 1.179, 0.997 cc. of N $Na_2S_2O_3$. Found: 1.172, 0.998.

Anal. Rhodo-(brom)-resoquinone free from solvent. Subs., 0.0752, 0.1458: 11.25, 21.55 cc. of 0.0441 N $Na_2S_2O_3$. Calcd.: 0.493, 0.956 cc. of N $Na_2S_2O_3$. Found: 0.496, 0.950.

Anal. Rhodo-(brom)-resoquinone with ether. Subs., 0.1877, 0.1079: 24.90, 14.40 cc. of 0.0441 *N* $Na_2S_2O_3$. Calcd. for $C_{12}H_3O_4Br_5 \cdot C_4H_{10}O$: 1.096, 0.630 cc. of *N* $Na_2S_2O_3$. Found: 1.098, 0.635.

Bromination of Rhodo-(brom)-resoquinone.—One gram of rhodo-(brom)-resoquinone with benzene of crystallization was suspended in 15 cc. of 50% aqueous acetic acid and 1 cc. of bromine in 2 cc. of glacial acetic acid was added. The solid matter very soon turned yellow. After an hour it was removed, washed with water, dried in a vacuum over phosphorus pentoxide and recrystallized from benzene. The amber-colored crystals darkened at 190° and melted with decomposition at 210°. A mixture with known tribromoresoquinone of similar properties behaved in the same manner on heating.

Anal. Subs., 0.1266, 0.1429: AgBr, 0.2071, 0.2326. Calcd. for $C_{12}H_2O_4Br_6$: Br, 69.56. Found: Br, 69.62, 69.27.

Effect of Heating on Rhodo-(brom)-resoquinone.—A sample of rhodo-(brom)-resoquinone with benzene of crystallization was heated for one day at 95° and then for two days at 120°. The resulting light gray material after several crystallizations from glacial acetic acid yielded white crystals which melted at 228–229°. Although the substance appears to have the same composition as solvent-free rhodo-(brom)-resoquinone, it has only about one-half as much oxidizing power, as shown by iodimetric titration.

Anal. Subs., 0.01059, 0.01566: CO_2, 0.00902, 0.01348; H_2O, 0.00057, 0.00096. Subs., 0.0963, 0.0954: AgBr, 0.1477, 0.1466. Calcd. for $C_{12}H_3O_4Br_5$: C, 23.56; H 0.49; Br, 65.47. Found: C, 23.2, 23.5; H, 0.59, 0.68; Br, 65.27, 65.33. *Iodine Titration.* Subs., 0.01075, 0.01568, 0.02449: 3.40, 5.35, 10.30 cc. of 0.0105 *N* $Na_2S_2O_3$. Calcd.: 0.0705, 0.1028, 0.1606 cc. of *N* $Na_2S_2O_3$. Found: 0.0357, 0.0562, 0.1082.

Tetrabromoresoquinone.—*Anal.* Subs., 0.01718, 0.01303: CO_2, 0.01065, 0.00807; H_2O, 0.00100, 0.00099. Subs., 0.0940, 0.1006: AgBr, 0.1660, 0.1770. Calcd. for $C_{12}H_2O_4Br_8$: C, 16.9; H, 0.24; Br, 75.30. Found: C, 16.9, 16.9; H, 0.65, 0.84; Br, 75.15, 74.87. *Iodine Titration.* Subs., 0.0255, 0.0380: 27.21, 40.51 cc. of 0.00869 N $Na_2S_2O_3$. Calcd.: 0.240, 0.358 cc. of N $Na_2S_2O_3$. Found: 0.236, 0.352.

Conversion of Tetrabromoresoquinone to Tribromoresoquinone.—A small amount of tetrabromoresoquinone was boiled with 10 cc. of glacial acetic acid. The solution, yellow at first, became deep orange on boiling. The vapors turned starch–iodide paper blue. On cooling the liquid deposited orange needles, m. p. 203'. A sample of known tribromoresoquinone, recrystallized from glacial acetic acid, melted at 205°, and a mixture with the material from tetrabromoresoquinone melted at 204.5°. The appearance of the two under the microscope was identical.

Anal. Subs., 0.1263: AgBr, 0.2058. Calcd. for $C_{12}H_2O_4Br_6$: 69.56. Found: 69.34.

Conversion of Rhodo-(brom)-resoquinone and of Tribromoresoquinone to Tetrabromoresoquinone.—A small amount of solvent-free rhodo-(brom)-resoquinone was treated with 3 cc. of bromine, allowed to stand for two days and evaporated to dryness in a vacuum over caustic potash. The resulting material was ground up with carbon tetrachloride, washed with that solvent to free it from any traces of bromine, dried, taken up in benzene and evaporated to dryness at room temperature. The crystalline residue consisted of a mixture of white material with red crystals of rhodo-(brom)-resoquinone with benzene of crystallization. The white material was compared under the polarizing microscope with known tetrabromoresoquinone and found to be identical with it. Tetrabromoresoquinone is uniaxial negative with an w-index of about 1.776 and an e-index of about 1.700.

A similar experiment with tribromoresoquinone yielded a residue which consisted of a mixture of tetrabrnmoresoquinone with unchanged tribromoresoquinone.

A mixture of 1 g. of tribromoresoquinone, 13 cc. of 20% aqueous chromic acid, 20 cc. of benzene and 1 cc. of bromine was shaken by machine for twenty-four hours. The phases were separated and filtered and the residues were combined and recrystallized from benzene. The product consisted of small, white, lustrous crystals, m. p. 215°. A mixture with tetrabromoresoquinone, m. p. 227–228°, melted at 219–220°. A small amount of the material boiled with glacial acetic acid yielded a deep yellow solution. Examination under the polarizing microscope showed it to be tetrabromoresoquinone.

Summary

Tribromoresorcinol has been successfully oxidized by shaking a benzene solution of the substance with aqueous chromic acid.

Three products have been isolated. One of them, tribromoresoquinone, is known, having been prepared heretofore by another method. The other two, rhodo-(bromo)-resoquinone and tetrabromoresoquinone, are new. All three are dinuclear and yield the same tetrabromotetrahydroxydiphenyl on reduction.

The relationships among the three substances have been elucidated. Their oxidizing powers have been measured by titration of the iodine liberated from hydriodic acid and the results have given a precise indication of their hydrogen content.

The action of chromic acid on tribromoresorcinol appears to be first the oxidation of one hydroxyl group and the removal of one bromine atom from the nucleus. The resulting intermediate substance apparently doubles up to form the at present unknown dibromoresoquinone or 2,2′-dihydroxy-3,5,3′,5′-tetrabromodiphenoquinone. The products which have been isolated are brominated derivatives of this substance—rhodo-(brom)-resoquinone being formed by the substitution of one hydrogen atom by bromine, tribromoresoquinone by the substitution of two and tetrabromoresoquinone by the further addition of two bromine atoms.

THE NITRATION OF SUBSTITUTED ANILINES[1]

BY E. RAYMOND RIEGEL, HOWARD W. POST AND E. EMMET REID[2]

RECEIVED SEPTEMBER 17, 1928 PUBLISHED FEBRUARY 5, 1929

As is well known, it is customary to acetylate an aromatic amine to protect it during nitration. In acetanilide and in its substitution products, the nitrogen is trivalent and probably remains so even in the presence of strong acids. It directs an entering group to the ortho or para position. In the case of aniline in sulfuric acid solution, the nitrogen is pentavalent and orients an entering group chiefly to the meta position. The yield of m-nitraniline is only moderate.

The object of the present investigation was to determine the effect of various substituents on the stability of aniline, *i. e.*, the resistivity toward the oxidizing action of nitric acid, during nitration in sulfuric acid solution. Certain substituted anilines give good yields of nitranilines, while others are entirely destroyed by the same nitration mixture. The substituents that have been used are the hydroxyl, carboxyl and sulfonic acid groups, with the nitro group in one case. In all, fourteen substituted anilines were studied. These are arranged in order of decreasing "persistence" of amino. The figures given represent the percentage of original amino present after nitration. We have taken no account of possible formation of nitrous acid during nitration and consequent conversion of amino to hydroxyl. The formulas given are those of probable nitration products, determined by formation of derivatives.

	Compound	%		Compound	
1	p-Aminophenol	72.6	8	m-Amino-p-hydroxybenzoic acid	0.0
2	m-Aminosalicylic acid	42.5	9	m-Amino-p-hydroxytoluene	.0
3	*m*-Amino-*p*-hydroxybenzenesulfonic acid	40.0	10	*o*-Amino-*p*-nitrophenol	.0
4	Sulfanilic acid	34.0	11	Anthranilic acid	.0
5	Metanilic acid	26.7	12	1-Amino-4-phenol-6-sulfonic acid	
6	*p*-Amino-*m*-hydroxybenzenesulfonic acid	4.8	13	m-Aminophenol	
7	o-Aminophenol	0.0	14	1-Amino-2-hydroxy-4-naphthalenesulfonic acid	49.0

Method of Nitration.—The amine was dissolved in 13 to 18 parts by weight of concentrated sulfuric acid (sp. gr., 1.84) and cooled to below 5° and the nitrating mixture of fuming nitric and concentrated sulfuric acids added, drop by drop from a buret. The

[1] Presented at the Detroit meeting of the American Chemical Society, September 1927.

[2] Submitted by the second author to the Board of University Studies of the Johns Hopkins University in conformity with the requirements for the degree of Doctor of Philosophy, June, 1927. The work was begun at the University of Buffalo.

acid mixture was added in 10% excess based on the amount required to yield a mono-nitro derivative. It was made up to contain 0.0083 mole of nitric acid per cc. The system was stirred constantly. The mixture of acids and amine was kept for one hour at 0°, one hour at room temperature and then poured over ice. The resulting precipitate was filtered off and analyzed. Water solutions of nitration products were titrated against standard sodium nitrite in the presence of hydrochloric acid for amino contents, using starch iodide paper as indicator. Nitro groups were determined by titration against standard titanous chloride[8] and chlorine was determined whenever necessary by the Carius method.

Discussion of Results.—Nitrating aniline itself, by our method, gave a nitration product which probably consisted of a number of dinitro derivatives. After repeated extraction with alcohol and ether the product melted between 180 and 200° with decomposition. Further investigations are now being carried on to determine the identity of this material.

As regards the substitution products of aniline, the presence of hydroxyl ortho to amino seems to make the compound extremely susceptible to oxidation, while the same group in the para position gives a molecule which can be nitrated with good yield. This holds true with respect to the pairs above: 1 and 7, 2 and 8, 3 and 6. Again, the effect of the hydroxyl group in the ortho position can be overcome by the introduction of the sulfonic acid group, as witness 3 and 7, but this sulfonic acid group is a better protecting agent, in one case para to the amino (4 and 5) and in another meta (3 and 6). Evidently this is due to the presence of the hydroxyl, as Nos. 4 and 5 are sulfanilic and metanilic acids, respectively, and 3 and 6 are m-amino-p-hydroxybenzenesulfonic acid and *m*-hydroxy-*p*-aminobenzenesulfonic acid. It should be noted that p-hydroxy-aniline sulfonated spontaneously, during the reaction, and its resistance to decomposition may be due in part, at least, to the introduction of the sulfonic acid group.

The question arises as to why there should be such a difference in resistance toward the oxidizing action of nitric acid between ortho and para aminophenols and their derivatives.

Conclusions.—*o*-Aminophenol and its derivatives are unstable in the presence of a strong oxidizing agent such as fuming nitric acid, *o*-aminophenol itself going to pieces. *p*-Aminophenol is capable of giving a good yield of nitro-aminophenolsulfonic acid under the conditions holding in our work. Assuming the most stable configuration of the benzene ring to be that in which alternate carbons are similarly polarized, an electronegative group can be said to direct an entering group to the ortho or para position, while an electropositive group directs meta. This holds qualitatively. p-Aminophenol directs both sulfonic acid and nitro to the positions ortho to hydroxyl, thus giving evidence that hydroxyl is the determining factor. The amino tends in this case to adopt an electro-

---

[8] Thornton and Wood, *Ind. Eng. Chem.*, 19, 150 (1927).

positive character, at least in a relative sense. We assume that the resistivity of the ring in this case is due to the coincidence between the directive effects of the two groups, at least in part, and that the two groups when ortho to each other do not succeed in adopting such distinctly opposite polarity because of their proximity to each other.

Materials

p-Aminophenol was obtained from the Eastman Kodak Co.; NH_2, 14.34%.

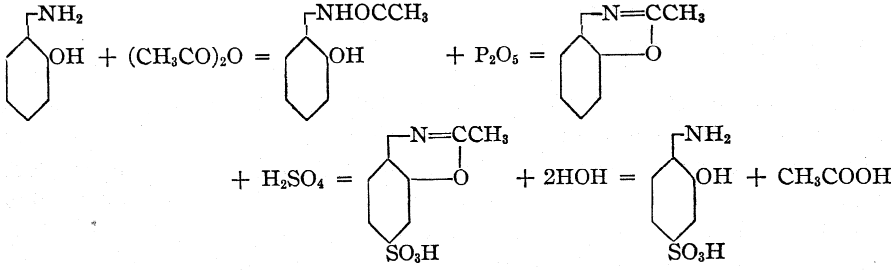
m-Aminosalicylic acid was made by coupling salicylic acid with benzene diazo chloride and reducing the azo compound with stannous chloride and hydrochloric acid.[4] The hydrochloride melted at 236°; Cl, 18.61. The free amine melted at 250–260°; acetyl derivative at 218°.[5]

m-Amino-p-hydroxybenzenesulfonic acid was obtained from the National Aniline and Chemical Co., and from the Wilbur White Chemical Co.; NH_2, 8.52%, S, 15.93; the anilide melted at 203°.[6]

Sulfanilic acid was obtained from the Eastman Kodak Company; NH_2, 9.42%.

Metanilic acid was obtained from the Eastman Kodak Company; NH_2, 9.16%.

1-Amino-6-hydroxy-4-benzenesulfonic acid was made by a method which is outlined in the literature but not in detail. o-Aminophenol, 85 g., was treated with 190 g. of acetic anhydride and the cooled product sucked dry and desiccated. This acetylaminophenol (40 g.) was then distilled off at 200° with phosphorus pentoxide. There was about 20 cc. of oily product.[7] This gave us ethenyl-o-aminophenol, of which 20 g. was placed in a ten-inch test-tube and treated with 24 g. of fuming sulfuric acid ("163%") drop by drop, the test-tube being immersed in a freezing mixture of ice and salt and the system stirred. The entire sulfonation mixture was allowed to stand for one hour and then thrown into ice water. The resulting solid was sucked dry and hydrolyzed by boiling water (400 cc.); yield, 13 g. of blue-black needles, melting after recrystallization from water at 205–210° with decomposition; NH_2, 8.66%.



o-Aminophenol was made by nitrating phenol and reducing, checking with material from the Eastman Kodak Company.

1-Amino-6-hydroxy-3-benzoic acid was made by coupling p-hydroxybenzoic acid with benzene diazo chloride and reducing with tin and hydrochloric acid, then comparing the product with one made by nitrating p-hydroxybenzoic acid and reducing with tin and hydrochloric acid; melting point, 226°; NH_2, 10.72%. In only one run

were we able to do this with the free acid; all subsequent runs were made with the methyl ester.[8]

1-Amino-3-methyl-6-hydroxybenzene was made by dissolving 21.6 g. of p-cresol in 36 g. of sodium hydroxide and 60 cc. of water. To this was added benzene diazo chloride made by titrating a solution of 18.6 g. of aniline in 150 cc. of hydrochloric acid (1:1) with 13.8 g. of sodium nitrite in 35 cc. of water. The precipitated azo compound was reduced by covering with a solution of 113 g. of stannous chloride in 119 g. of hydrochloric acid and gently warming. The product was precipitated by pouring into concentrated hydrochloric acid solution, the process being repeated to eliminate aniline hydrochloride. The free base was obtained by boiling with water; m. p. 129"; NH_2, 12.58%.

I-Amino-3-nitro-6-phenol was made by the reduction of dinitrophenol; m. p. 136°.[9]

o-**Aminobenzoic** acid was purchased from the Eastman Kodak Company; NH_2, 11.71%.

1-Amino-4-phenol-2-sulfonic acid was made by treating phenol with nitrous acid and then with sodium bisulfite; m. p. 270°.[10]

m-Aminophenol was purchased from the Eastman Kodak Company.

1-Amino-4-naphthol-2-sulfonic acid was purchased from the National Aniline and Chemical Co.

Identification of Nitration **Products.**—*p*-Aminophenol gave $C_6H_2(1)NH_2(3)SO_3H$-(4)OH(5)NO_2; derivative with dinitrochlorobenzene a red powder;[11] nitration product: NH_2, 6.82%; NO_2, 19.06%.

1-Amino-4-hydroxy-3-benzoic acid gave $C_6H_2(1)NH_2(3)COOH(4)OH(5)NO_2$; NH_2, 8.91%; NO_2, 21.81%.

1-Amino-6-phenol-3-sulfonic acid gave $C_6H_2(1)NH_2(3)SO_3H(6)OH(5)NO_2$; derivative with *β*-naphthol a brown powder;[12] nitration product: NH_2, 6.79%; NO_2, 18.37%.

p-**Aminobenzenesulfonic** acid gave $C_6H_3(1)NH_2(4)SO_3H(5)NO_2$($NH_2$, 7.34%); **de**rivative with salicylic acid a yellow-green material.

m-**Aminobenzenesulfonic** acid gave probably mostly unchanged amine and some m-phenolsulfonic acid (NH_2, 8.38%); derivative with diazotized benzidene and Gamma **Acid** a trace of black powder.[13]

1-Amino-6-phenol-4-sulfonic acid gave $C_6H_2(1)NH_2(3)NO_2(4)SO_3H(6)OH$; NH_2, 6.71%; NO_2, 18.87%.

Summary

Fourteen substituted anilines have been nitrated with mixed acids under the same conditions. Great differences in stability have been found; some groups seem to stabilize the molecule, *i. e.*, render it more resistant to the oxidizing action of the nitric acid, while others bring about its destruction. The influence of the groups depends on their position—two electronegative groups para to each other seem to make the resultant molecule more resistant to oxidation.

THE POLYHYDRIC ALCOHOL–POLYBASIC ACID REACTION. I. GLYCEROL–PHTHALIC ANHYDRIDE

BY R. H. KIENLE AND A. G. HOVEY

RECEIVED SEPTEMBER 22, 1928 PUBLISHED FEBRUARY 5, 1929

Introduction

The tendency of the organic chemist to discard the tarry residues or resinous products of a reaction and to explain them away by merely mentioning their formation is unfortunate. It is quite probable that in the study of resin formation many new ideas of space chemistry will be brought forth which, although not revolutionary, will simplify our concepts of materials regarded as complex and at the same time bring about a better correlation between organic chemistry, colloidal phenomena and statistical mechanics.

Although the resinous products of the polyhydric alcohol–polybasic acid reactions have been in commercial application for some time, no systematic study of the reactions has been made until the last four years.

It is probably safe to say that a resinous product results whenever *a* polyhydric alcohol and polybasic acid are heated together. This has never failed to happen when such characteristic aliphatic alcohols as glycerol, ethylene glycol and mannite have been heated with characteristic polybasic acids as phthalic anhydride, phthalic, isophthalic, tartaric, malic, succinic, citric, sebacic, diphenic[1] and naphthalic[1] acids.

The properties of the resinous products and the methods of promoting the reactions are so similar that any information obtained on the glycerol–phthalic anhydride reaction is very likely to have useful application to the others.

Historical

Although Berzelius reported the formation of a resin from tartaric acid and glycerol in the early days, it was not until 1901 that the reaction between glycerol and phthalic anhydride was reported by Watson Smith.[2] Between 1910 and 1915, M. J. Callahan[3] performed numerous experiments as a result of which new and useful resins were made which showed possibilities for commercial applications. At the same time, W. C. Arsem, E. S. Dawson, Jr., and K. B. Howell[4] studied the general reaction, substituting other alcohols and acids for glycerol and phthalic anhydride;

and also the effect produced when other ingredients are added. Since 1924 the authors have been performing quantitative experiments which are probably yielding the first kinetic data on the poly-ester reaction.

Materials

Pure phthalic anhydride was obtained by melting C. P. phthalic anhydride (Selden Co.) in an electrically heated glass container over which a current of dry air was passed which conducted the vapors into a cooled bulb, where dusty cobwebs of pure phthalic anhydride were deposited. The final product had a melting point of 131.8°.

The best water-white glycerol available had a density of 1.2561 by pycnometer measurement, which corresponds to a purity of about 97.7% according to the tables of Bosart and Snoddy.[5] This glycerol was vacuum-distilled in air-tight glass apparatus. Wherever a rubber stopper was used it was isolated from the vapors by thick tin foil, so that no distillate could escape from the rubber into the vapors of the glycerol. Anhydrous sodium sulfate was placed in the distilling flask together with some glass beads to prevent bumping. Hydrogen was passed through a capillary jet which served both to prevent oxidation and minimize bumping. Only the distillate between 160 and 200° was used and redistilled. The final product had a d_{25}^{25} of 1.2598, corresponding to a purity of 99.2% according to Bosart and Snoddy.

Experimental

I. Study of the Products of the Reaction.—If the reaction involves no other mechanism than that of simple esterification, there should be no other products than esters and water. In watching the reaction, however, the most readily noticed phenomenon is the evolution of a white sublimate, shown to be phthalic anhydride, which results from the fact that the reaction takes place at a temperature where the vapor pressure of the anhydride is high. Because of the low apparent density of the sublimed phthalic anhydride, it appears that considerable quantities are evolved, but there actually is relatively very little by weight.

The apparatus which was used to study the products of formation is shown in Fig. 1. The Erlenmeyer flask, heated by a Bunsen burner, contained the reaction mixture and was connected to three traps A, B and C, which were to collect solid, liquid and gas, respectively.

Trap A consisted of a tared flask, Trap B a tared flask connected to a water-cooled condenser and Trap C, a tared flask submerged in liquid air. The circulation of the vapors from the reaction mixture was insured by introducing dry air free from carbon dioxide through a calibrated flowmeter (about 2 bubbles per second) into the reaction flask. As a precaution to prevent the collection of material in the glass tube between the reaction flask and Trap A, a small heating unit of nichrome wire was wound around it.

The reaction mixture, consisting of 46 g. of glycerol and 111 g. of phthalic anhydride, was gradually warmed up to 210° in two hours and twenty-two minutes. After cooling the reaction flask, Trap A was found to contain 7.0 g. of material, most of which was a colorless liquid, water, together with white crystals. On opening the flask a sharp odor also was noticed. The contents of the flask was titrated with $N/25$ potassium hydroxide solution, using phenolphthalein as an indicator. There was found the equivalent of 0.085 g. of phthalic anhydride.

---

[5] Bosart and Snoddy, Ind. *Eng. Chem.*, 19, 506–510 (1927).

Any increase in weight of Trap B was found to be less than the order of the accuracy of the experiment Trap C contained approximately *0.5* g. of white crystalline solid which melted at 0° to a clear white liquid, probably water although the sharp odor was noticed in this flask also. The water gave no aldehyde test (rosaniline) until near gelation. The reaction mixture itself gave no aldehyde test until gelation.

This, together with the fact that acrolein and phthalic anhydride do not form a resin, makes very doubtful the suggestion of Barry, Drummond and Morell,[6] that intermediate aldehyde formation is the mechanism for the building up of these resins from the polyhydric alcohol–polybasic acid reaction.

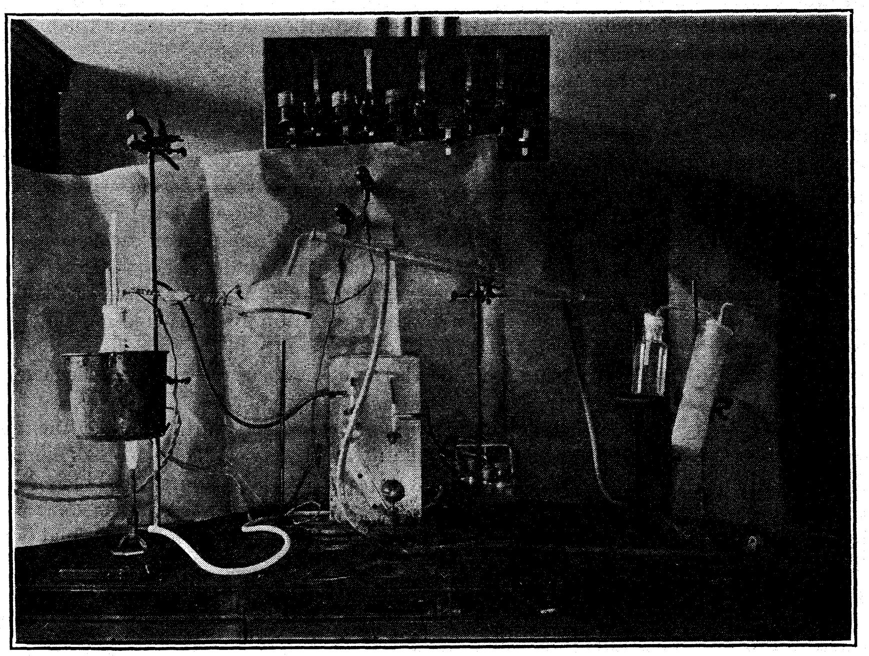

Fig. 1.

II. Kinetic Isothermal Studies of the Reaction **with** Time.—It would be extremely gratifying to be able to determine from time to time during the reaction the exact concentration not only of the phthalic anhydride and glycerol but also of the products, water and resin, as well. With such data the reaction velocities could be studied, and with the constants known it might be possible by comparison with data on the heat of reaction and specific heats to obtain free energy relationships for this unusual

---

[6] Barry, Drummond and Morell, "Natural and Synthetic Resins," D. Van Nostrand Co., New York, p. 164.

type of reaction. However, none of the standard methods for determination of glycerol or free hydroxyl groups has proved satisfactory. The determination of water content is tedious and uncertain; hence the reaction has been followed from the standpoint of free and combined acid.

Preparation of Samples.—The reaction has been followed by allowing it to proceed at atmospheric pressure, keeping it as nearly isothermal as possible, and by taking out samples from time to time. The theoretical proportion of glycerol, 184.2 g., was weighed out into the reaction vessel and warmed up to the temperature at which the reaction was to be carried out. At the same time phthalic anhydride was melted in an Erlenmeyer flask and raised slightly above the temperature at which the reaction was to take place, to allow for cooling when pouring. When it was desired to start the reaction, the molten phthalic anhydride was poured into the reaction vessel on the balance pan until the theoretical proportion, 444.2 g., was weighed out. The most accurate method of taking the time of the start of the reaction was when one-half of the molten anhydride had been poured in. As soon as the molten phthalic anhydride was added and stirred in, the temperature of the reaction mixture rose very rapidly above the point at which it was desired to run the reaction. Because the reaction was strongly exothermic at the start, it was necessary to cool as quickly as possible with a jet of compressed air, and the reaction vessel was not placed in the insulated oil-bath until the temperature was approximately that of the oil-bath. From then on it was necessary to supply heat to the reaction mixture in order to maintain isothermal conditions.

Samples were taken from time to time by pipetting out a small amount of the fluid into numbered containers; these were allowed to cool rapidly, thus freezing the equilibrium at that point. Samples were taken more frequently in the earlier stages of the reaction than in the latter stages, because the reaction was proceeding so much more rapidly.

The viscosity of the liquid reaction mixture kept increasing until suddenly the mass stiffened and became an irreversible gel. It was much more difficult to take samples after gelation. A heat of gelation might be expected, but no appreciable increase in temperature was noticed. A few samples were taken after the transition and some were left in an oven at 200° to react for a time, infinite in comparison, so that a final equilibrium value could be reached.

(a) **Free** Acidity.—The decrease in free acidity was determined and is reported both as percentage of free acidity, calculated as phthalic anhydride, and as acid value (acid number). The tared samples of about 1 g. each were dissolved in 25 cc. of C. P. acetone which had a low acidity "blank" and then titrated with standardized 0.1 *N* potassium hydroxide solution, using phenolphthalein as an indicator.

Table I shows the data obtained on the decrease of free acidity as the reaction proceeded. While this is as was expected, it is perhaps surprising to note that in every case the free acidity was reduced to approximately one-half within one minute after the start of the reaction. For the first instant the reaction is strongly exothermic. The temperature of the reaction mixture rapidly rises from 15 to 44° above the temperature of the substances when they were poured together. The data indicate that the reaction is about half way through at the end of the first minute, after which it proceeds at a greatly diminished rate until gelation occurs.

In Fig. 2 is plotted the decrease in free acidity with time. It is useful to report the acidity both as acid number and as percentage of free phthalic

TABLE I

ISOTHERMS OF FREE ACIDITY CHANGE WITH TIME

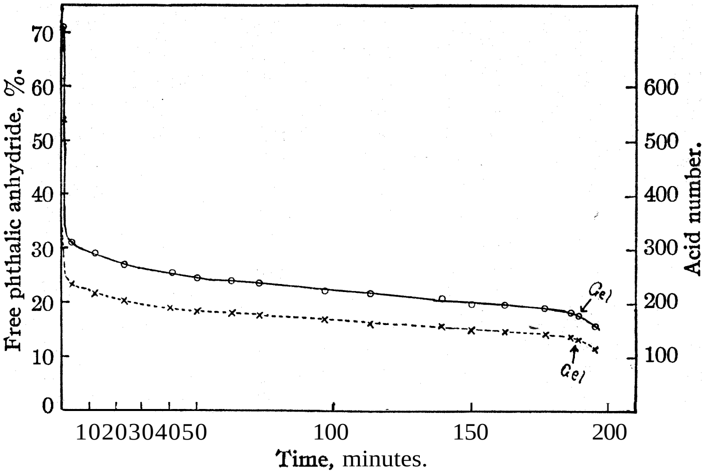
anhydride. The curve illustrates clearly the sudden drop in free acid at the start of the reaction and the subsequent slow continuous change right up to gelation.

(b) Saponification Number.—If the resinous product is an ester, it should be saponifiable just as the less complex esters are. The saponification number should remain fairly constant unless affected by change in density of the resin or by volatilization of some free phthalic anhydride.

For the determination, 1-g. samples were refluxed in Erlenmeyer flasks for one hour with 50 cc. of N alcoholic potassium hydroxide solution. Upon cooling titration was made with 0.5 N hydrochloric acid until the pink color of phenolphthalein disappeared; 0.5 N potassium hydroxide solution then was run in until the pink color reappeared.



——, Free phthalic anhydride; - - - -, acid number.

Fig. 2.—Decrease of free acidity with time. T = 195°.

Fig. 3 shows how the saponification value remains fairly constant with time in contrast to the steady decrease in acid number.

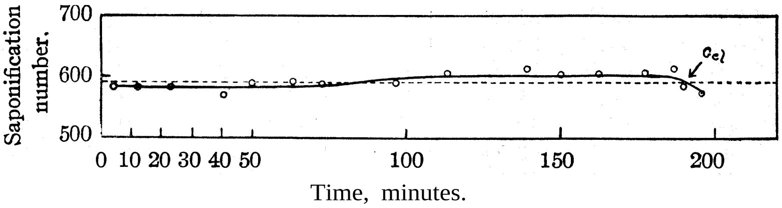


Fig. 3.—Variation of saponification number with time. T = 195°.

(c) **Degree of Esterification.**—The saponification number is useful in that it may be used to calculate the degree or percentage of esterification. When the acid number is subtracted from the saponification number, the resulting value is known as ester number or ester value, which represents the number of milligrams of potassium hydroxide equivalent to the acid which is combined in the ester.

$$\text{Ester number} = \text{saponification number} - \text{acid number}$$

$$\text{Percentage esterification} = \frac{\text{ester number}}{\text{saponification number}} \times 100 = \frac{(\text{saponification number} - \text{acid number})}{\text{saponification number}} \times 100$$

Fig. **4** shows how the percentage of esterification consistently increases with time. Analytical data show that various batches of glycerol–phthalic anhydride resin in manufacture have an esterification of 75–79% just before gelation.

(d) Variation of Other Properties with Time; **1. Flow Point.**—The change in flow point[7] with time was one of the earliest studies made in following the formation of the resinous condensate. The flow point[7] is that temperature at which a small sample of resin (0.50" thick) will flow under gravity a vertical distance of 0.20" when subjected to a gradual increase in temperature of 2–3° per minute. This value is correspondingly lower than the melting point but is more useful and may be more sharply determined. As the reaction proceeds, the flow point gradually increases until it reaches 115–118°, when gelation occurs. After gelation the resin flows only when pressure is applied. Fig. 5 shows the curve of increase of flow point with time.

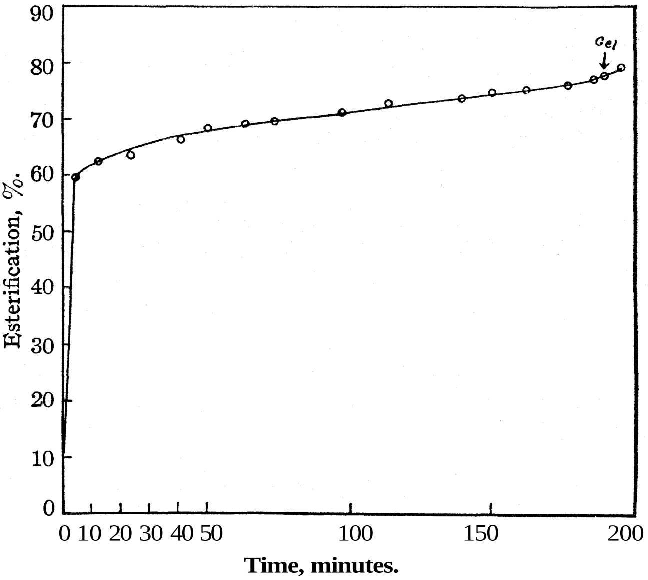

Fig. 4.—Increase of esterification with time. *T* = 195°.

2. Viscosity.—The viscosity of the liquid reaction mixture, which probably influences the flow point, has not been followed quantitatively. It is obvious that the viscosity is quite low at the start of the reaction, then gradually increases until at gelation it approaches an infinite value.

3. Density.—The density at 15.5/15.5°, as determined by a pycnometer with mineral oil for an insoluble liquid, was found to increase in the early stages of the reaction.

[7] **General Electric Standard** Test No. 24.

4. Color.—The color changes but slightly in going from a water white liquid to a very pale straw color at gelation.

5. **Refractive Index.—By** comparing the powdered resin with liquids of known refractive index, this value was found to change but slightly from 1.56 in the early stages of the reaction to 1.58 just before gelation.

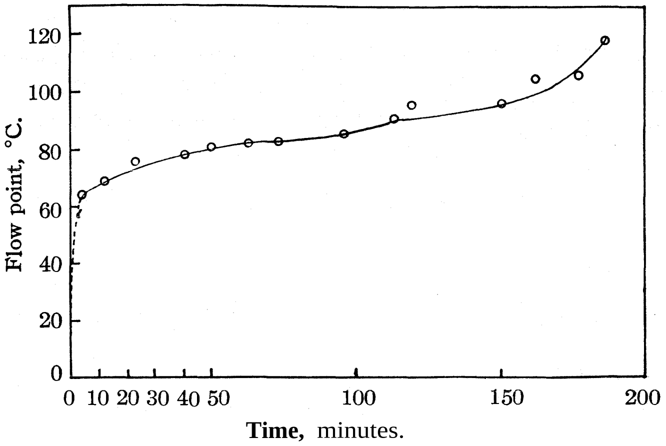

Fig. 5.—Increase of flow point with **time.** T = 195°.

Table II shows a comparison of the variation of the different properties of a set of standard samples taken from time to time, keeping the temperature at 195°.

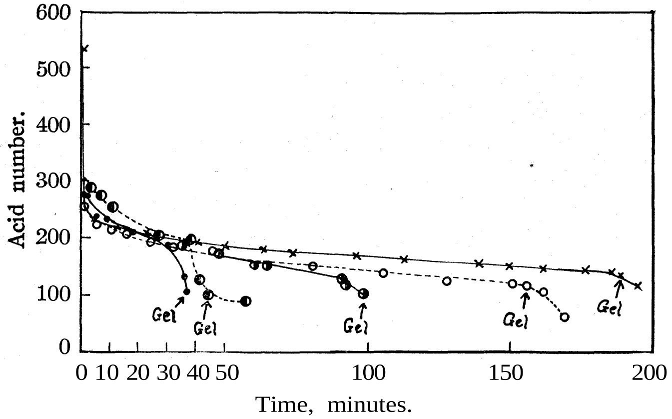
III. Effect of Temperature.—It is interesting to compare the isothermal curves by plotting the free acidity *vs.* time, Fig. 6. All of the curves are much the same for the early part of the reaction, but the isotherms obtained when the reaction was carried out at higher temperatures require shorter paths to reach gelation. This suggests a relationship between time of gelation and the temperature.



0,232°; ◐, 230°; ◑, 215°; O, 200°; X, 195°.

Fig. 6.—Isotherms of free acid *vs.* time, showing effect of temperature.

Fig. 7 shows that when gelation time is plotted against the reciprocal of the absolute temperature, the result is a straight line.

Discussion

The data indicate that as the glycerol–phthalic anhydride reaction proceeds, the changes in the various properties are gradual and continuous. This makes it rather doubtful whether the reaction takes place in certain steps, such as the formation first of a monoglyceride, then a diglyceride and finally a triglyceride. It is more likely that a heterogeneous complexity of esters results, and finally the formation of more complex structures.

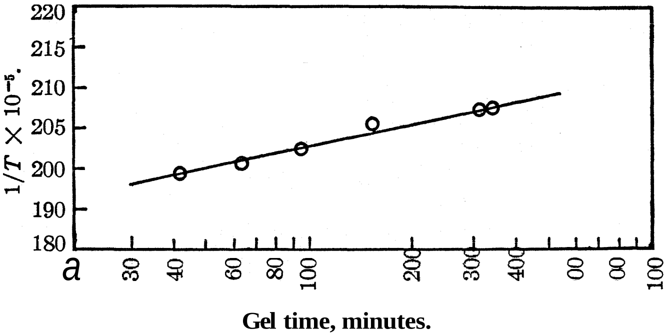


Fig. 7.—Gel time *vs.* reciprocal of absolute temperature.

Increase in temperature promotes the rapidity of this reaction, as in the case of the simpler esters. Regardless of the temperature at which this reaction is carried out, it does not seem possible to carry this reaction to completion, since gelation (with obstruction to mobility) invariably occurs between 75–79% esterification.

In the study of this resin-producing reaction, no evidence was found to indicate that anything but simple esterification occurred. This fact, together with the others just mentioned, must be taken into account in any theory of resinification, which is a problem that the authors hope in the near future to discuss in detail.

Summary

1. The glycerol–phthalic anhydride reaction proceeds by esterification, since water was the only product collected. No intermediate aldehyde was detected until near gelation.

2. The reaction went very rapidly at the start, evolving heat, and was apparently about one-half complete within one minute.

3. As the reaction proceeded under isothermal conditions, the free acidity decreased, the saponification number remained fairly constant and the percentage of esterification increased. The changes in other properties with time were noted.

4. Similar resinous products result if other polyhydric alcohols are substituted for glycerol, or if other polybasic acids are substituted for phthalic anhydride.

5. At whatever temperature the glycerol–phthalic anhydride reaction is carried out, gelation occurs before the esterification has an opportunity to complete itself.

STRUCTURE OF BETA-GLUCOCHLORALOSE[1]

BY H. W. COLES, L. D. GOODHUE AND R. M. HIXON

RECEIVED SEPTEMBER 24, 1928 PUBLISHED FEBRUARY 5, 1929

Two crystalline chloral derivatives of glucose were reported by Heffter[2] in 1889 but were not named. More detailed studies of the chloral derivatives of the various carbohydrates have been made by Hanriot[3] and his associates, by Meunier,[4] by Petit and Polonowski,[5] and by Pictet and Reichel.[6] The most recent formula for the β-glucochloralose is that of Pictet and Reichel (Formula III). Most of the standard handbooks give the older formula of Hanriot (Formula I) or of Polonomski (Formula II).

The evidence regarding the structure of β-glucochloralose is conflicting. The absence of reducing properties, the failure to combine with hydroxylamine and phenylhydrazine and the resistance of the compound to hydrogenation all indicate that the free aldehyde groups of both the glucose and the chloral have been modified in their union. The formation of

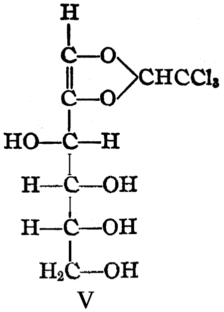
IV



V

Formulas for p-glucochloralose.

tetra-derivatives and the fact that the carbohydrate chain can be oxidized by nitric acid without rupture of the glucose–chloral linkage have been used as evidence for the above formulas. The essential points which these formulas depict are: (a) a carbon–carbon linkage between the chloral and glucose radicals and (b) the presence of four free hydroxy groups.

On the other hand, the chloral condensation products with glycerin' and with the α-hydroxy acids[8] have been considered to have acetal linkages analogous to the other aldehyde and ketone condensation products with the poly-alcohols. Similar structures are also assumed to be present in the dichloral glucoses.[9] The reaction reported by Hanriot and Kling[10] would be highly indicative that this is also the case in β-glucochloralose. The reaction was accordingly duplicated for confirmation. β-Glucochloralose was reduced by means of aluminum amalgam to dechloro-β-glucochloralose (glucose-dichloroacetaldehyde). This compound was hydrolyzed by refluxing with dilute hydrochloric acid. The dichloro-acetaldehyde was distilled out and converted to both the oxime and osazone of glyoxal for identification. The glucose was isolated as the osazone. It seems improbable that the removal of one chlorine atom would render the linkage shown in either Formula I, II or III as labile as this reaction would indicate.

The conversion of β-glucochloralose to two different dichloralglucoses identical with those previously reported in the literature would appear to harmonize with only this acetal type of structure. There would appear to be no logical explanation for the condensation of chloral with β-glucochloralose as represented by any of the proposed formulas containing four free hydroxy groups, to give a dichloralglucose containing but one free hydroxy group. The only formula that suggests itself as being in harmony with these facts is an acetal type of linkage in the p-glucochloralose,

with a keto-enol isomerization similar to that shown in Formulas IV and V to explain the formation of tetra-derivatives.

The linkage shown in IV is that of the 1,2-monochloralglucose. This structure presumably belongs to the compound reported in this paper as being formed by the condensation of chloral with 3,5,6-trimethylglucose obtained from the corresponding mono-acetone glucose. This compound is not identical with the trimethyl-β-glucochloralose obtained by direct methylation of β-glucochloralose. The two isomeric trimethylchloralglucoses are very similar in solubilities. The 3,5,6-trimethylmonochloralglucose gives no reaction for an active hydrogen with the Zerewitinoff test.[11] The trimethyl-β-glucochloralose not only gives this test but forms a monoacetyl derivative.[12]

Evidence regarding the positions of the methyl groups in trimethyl-β-glucochloralose was sought by removing both one and two of the chlorine atoms and hydrolyzing the reduced chloral group to give the free trimethylglucose. The dichloro-acetaldehyde was easily characterized by its oxime and osazone but sufficient monochloro-acetaldehyde was not obtained to be certain of its identity. In both derivatives the strength of acid necessary to hydrolyze the compounds was so strong (about 1 N) that partial decomposition of the methylated sugar resulted. The impure sirup obtained by vacuum distillation resembled the 3,5,6-trimethylglucose in its instability toward acids and in being levorotatory.

Experimental Part

Preparation of β-Glucochloralose.—The following method of preparation of β-glucochloralose was found most satisfactory: 300 g. of chloral hydrate and 400 cc. of concd. sulfuric acid are cooled in running water to 12–15°. As soon as the chloral layer begins to separate, 200 g. of glucose is stirred in using a strong mechanical stirring apparatus, the blades of which should be near the bottom of the beaker to prevent clogging with the floating cakes of material. After stirring for ten to twelve hours at 12–15°, the reddish, viscous mass, which should show no evidence of charring, is poured slowly with violent stirring into 4 liters of cold water. The white precipitate of dichloralglucoses is allowed to settle. The mother liquor is decanted, brought to a boil and allowed to cool slowly. The β-glucochloralose which separates at this point is recrystallized from alcohol, several recrystallizations being necessary for absolute purity; yield, 60 g.

Separation of the Dichloralglucoses.—The precipitate of dichloralglucoses obtained in the above procedure is heated with 500 cc. of water and small portions of sodium hydroxide are added until the excess chloral is driven off and the mixture becomes slightly alkaline. The crude product is filtered off and washed; yield, about 100 g.

A hot alcoholic extract of this product yields the dichloralglucose of m. p. 225° frequently reported in the literature. Only one recrystallization is necessary for purification.

---

[11] Zerewitinoff, Ber., 40,2023 (1907); *Z. anal. Chem.*, 68,321 (1926).

[12] This compound will be reported in a later paper. Attempts to introduce a fourth methyl group have as yet proved negative.

Evaporation of the alcoholic mother liquor leaves a sirup which is taken up in hot carbon tetrachloride and filtered from insoluble materials. Cooling and concentrating this solution yields the dichloralglucose, m. p. 135°, frequently described in the literature. The yield of the two dichloralglucoses is about equal.

It is possible that other dichloralglucoses can be isolated from this mixture, as further information regarding their specific solubilities becomes available. At times a compound of m. p. 188° is obtained with the latter fraction mentioned above.

Conversion of β-Glucochloralose into Two Different Dichloralglucoses.—Twenty g. of β-glucochloralose was treated with 100 g. of chloral hydrate and 100 cc. of sulfuric acid as described for glucose. After the precipitation with water and washing free from acid as in the previous directions, the dichloralglucoses were separated from the unchanged compound by taking up in acetone. The mixture of the two dichloralglucoses is thrown out of the acetone as a white powder by adding water until it is turbid and allowing to stand for two or three hours. The powder (about 10 g.) is dried at 70° until the odor of chloral is no longer noticeable and is then extracted with 200 cc. of hot benzene.

One of the dichloralglucoses (m. p. 268°) is insoluble in benzene and remains as a residue (about 3 g.). Acetylation yielded the mono-acetate (m. p. 198°) as reported by Ross and Payne.[9] Both of these compounds were also checked by chlorine analysis.

Slow evaporation of the benzene solution yields about 6 g. of an isomeric dichloralglucose (m. p. 225°). This compound was checked by a mixed melting point with the dichloralglucose isolated as a by-product in the preparation of the β-glucochloralose. Acetylation yielded the mono-acetate (m. p. 126°), as reported by Ross and Payne.[9]

Trimethyl-β-Glucochloralose.—It was found impossible to methylate β-glucochloralose by either the silver oxide method of Purdie and Irvine[13] or by the original dimethyl sulfate reaction proposed by Haworth.[14] The following modification of the latter method was found quite successful: 5 to 7 g. of finely powdered β-glucochloralose is placed in a three-necked flask provided with a condenser and a mercury-sealed mechanical stirrer; 100 cc. of dimethyl sulfate is added and the mixture is warmed to 60° until nearly all of the compound is in solution. The water-bath is removed and 25 g. of sodium hydroxide in pieces the size of a pea is added. If the mixture is kept dry the reaction is slow but as the reaction proceeds it becomes more rapid and care must be taken to prevent too high temperature. The excess dimethyl sulfate is destroyed by adding sodium hydroxide in 3 g. portions until the reaction mixture becomes basic. Small amounts of water are added as the mixture becomes too thick to stir.

The reaction mixture is extracted repeatedly with chloroform, the chloroform extract concentrated to a sirup, the sirup taken up in methyl alcohol and crystallized by careful addition of water; yield, 4 g. After recrystallization from petroleum ether the melting point remains constant at 109–110°.

Anal. (Carius). Calcd. for $C_{11}H_{17}O_6Cl_3$: Cl, 30.28. Found: Cl, 30.44, 30.42.

The trimethyl-β-glucochloralose showed little or no rotation in methyl alcohol (concd. 2.2% in a decimeter tube). The crystals are soluble in hot water, glacial acetic acid and ethyl acetate. Repeated methylation by the above method did not change the compound.

Trimethyl Monodechloro-β-glucochloralose (Trimethylglucose-dichloro-acetaldehyde).—Seven g. of trimethyl-β-glucochloralose was dissolved in 250 cc. of alcohol containing 5 cc. of concd. hydrochloric acid. The solution was diluted with water until precipitation just began. This solution is held at 50–60° under reflux for twenty-four

[14] Haworth, *ibid.*, 107, 8 (1915).

hours while an excess of aluminum amalgam is added in small portions. If the amalgam is added in one portion, it tends to become inactive. As the reaction becomes alkaline, acid is added. The alcohol is distilled out under reduced pressure and the residue is extracted with ether. The oil obtained from the ether is difficult to obtain crystalline, the best method being to precipitate it carefully from alcoholic solution by slowly adding water; m. p. 68°; yield, 3 g.

Anal. Calcd. for $C_{11}H_{18}O_6Cl_2$: C, 41.63; H, 5.72; Cl, 22.37. Found: C, 41.78, H, 5.75; Cl, 22.33, 22.57.

Acid hydrolysis of 5 g. of this compound in 30 cc. of water and 7 cc. of hydrochloric acid (concd.) at boiling temperatures under reflux for six hours yielded positive tests for the dichloro-acetaldehyde (osazone of glyoxal) but the sugar resinified.

Lower concentrations of acid caused only slight hydrolysis. Several attempts were made to purify the methylated sugar by vacuum distillation but in no case was it possible to free the sirup from chlorine. The sirup was slightly levorotatory.

Trimethylbidechloro-β-glucochloralose (Trimethylglucose Monochloro-acetaldehyde).—The trimethyl-β-glucochloralose was reduced with sodium amalgam under various conditions. The reduced compounds would not crystallize so they were subjected to vacuum distillation. A clear sirup which partially crystallized came over at 155–160° (bath temp.) under 4 mm. The chlorine analysis was slightly low for the monochloro compound (calcd., 12.8; found, 11.72). Hydrolysis of the sirup yielded results similar to those described for the preceding compound.

Mono-acetone glucose has been prepared by partial hydrolysis of diacetoneglucose in water solutions.[15] A more convenient method has been found by taking advantage of the insolubility of the mono-acetoneglucose in ethyl acetate as compared to the solubility of the diacetoneglucose. Fifty g. of diacetoneglucose is dissolved in 400 cc. of ethyl acetate containing 4 cc. of concentrated nitric acid. The solution is heated to boiling and then cooled. The mono-acetoneglucose separates at once and is pure after one recrystallization from either water or neutral ethyl acetate.

3,5,6-Trimethylmonochloralglucose.—Five g. of 3,5,6-trimethylglucose, prepared from mono-acetoneglucose, was added to 40 cc. of sulfuric acid and 30 g. of chloral hydrate cooled in an ice-bath and mechanically stirred. After four hours the solution was stirred into 400 cc. of ice water. The separated gummy mass was taken up in chloroform and washed with sodium hydroxide solution to free it from sulfuric acid. After the evaporation of the chloroform the sirup was allowed to crystallize from alcohol and was then recrystallized from petroleum ether. The melting point gradually changed from 109 to 120° after many recrystallizations; yield, 2 g.

Anal. Calcd. for $C_{11}H_{17}O_6Cl_3$: Cl, 30.28. Found: Cl, 30.54. Rotation. Soln. 0.8413 g.; chloroform, 9.998 cc. (by wt.). $\alpha_D^{25} = -2.44°$ in a decimeter tube; $[\alpha]_D^{25} = -29.01°$.

The compound does not react with methylmagnesium iodide, which would indicate the absence of free hydroxyl groups. The solubilities are about the same as for the isomeric compound obtained by methylation of β-glucochloralose.

Summary

1. Trimethyl-β-glucochloralose is reported from the methylation of β-glucochloralose. Attempts to introduce a fourth methyl group have proved negative although an acetyl group can be introduced.

2. 3,5,6-Trimethylmonochloralglucose is reported from the condensation of chloral with 3,5,6-trimethylglucose.

---

[15] Irvine and Macdonald, *J. Chem. Soc.*, 107, 1701 (1915).

3. β-Glucochloralose condenses with chloral to yield two dichloralglucoses identical with those previously reported in the literature.

4. It is pointed out that the present formulas for β-glucochloralose cannot explain the formation of the dichloralglucoses. The reaction reported by Hanriot and Kling by which both the aldehyde and glucose are identified would indicate an acetal rather than a carbon–carbon linkage.

ORIENTATION IN THE BENZENE RING. THE BROMINATION OF 2-AMINORESORCINOL DIMETHYL ETHER[1]

BY ARTHUR A. LEVINE AND HOOPER LINFORD

RECEIVED SEPTEMBER 25, 1928 PUBLISHED FEBRUARY 5, 1929

It has been shown in preceding papers[2] that the 2,6-dimethyl ether of pyrogallol gives on halogenation in an anhydrous medium a monohalogen substitution product in which the halogen atom has substituted meta to the hydroxyl group. The bromination of 2-aminoresorcinol dimethyl ether, which has an analogous structure, has been investigated in order to determine the mechanism of the reaction. Two courses are open for the entering halogen atom, it may substitute directly in the ring or else replace one of the amino hydrogens and subsequently migrate to the ortho-ortho-para positions as shown by Chattaway and Orton[3] in case of acetanilide. It may be assumed that in 2-aminoresorcinol the bromine atom enters the amino group and subsequently migrates to the para position, but such is not the case, apparently, since the product obtained has the bromine atom in the meta position to the amino group. It has not been possible to prepare the N-bromo derivative and actually determine whether the bromine atom migrates to the meta position. Every effort gave oxidation products.

The acetanilide of 2-aminoresorcinol dimethyl ether was brominated with a calculated quantity of bromine in acetic acid as a solvent. Numerous attempts have been made to brominate the free base in an anhydrous medium. Satisfactory results have been obtained on bromination of the free base in glacial acetic acid containing a small quantity of acetic anhydride. The product obtained, however, was the corresponding monobromo-acetanilide. The formation of the acetanilide is rather unusual, taking place with the utmost ease at room temperature, while Kauffmann

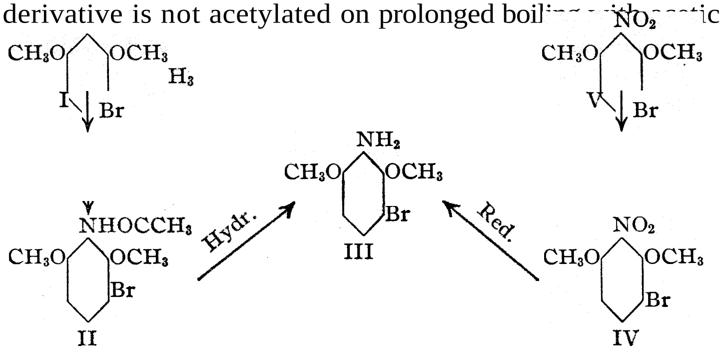
[1] Abstracted from a thesis by Hooper Linford, presented to the Graduate Faculty of the State College of Washington in partial fulfilment of the requirements for the degree of Master of Science.

[2] (a) Levine, THIS JOURNAL, 48, 2719 (1926); (b) 49, 797 (1927).

[3] Chattaway and Orton, Ber., 32, 3573, 3635 (1899).

and Franck[4] found that 2-aminoresorcinol dimethyl ether acetylates with difficulty. It has also been found in this Laboratory that the monobromo derivative is not acetylated on prolonged boiling with acetic anhydride,



Determination of the Position of the Bromine Atom.—The bromoacetanilide (II) was hydrolyzed with alcoholic potassium hydroxide, giving the free base (III). This was compared and found identical with the compound (IV) obtained on bromination of 2-nitroresorcinol dimethyl ether (V) and subsequent reduction of this bromoderivative. It is assumed that the bromine atom enters into the ring in the meta position to the nitro group since the combined effect of the groups already present orient in that position. Efforts to oxidize the bromo derivative to the corresponding quinone have not yielded the desired product, complex oxidation products containing nitrogen being obtained. Likewise, attempts to diazotize and convert the brominated amine to the corresponding phenol, 3-bromo-2,6-dimethyl ether of pyrogallol, whose constitution has been established,[2b] have not been possible.

Experimental Part

Preparation of **2-Aminoresorcinol Dimethyl** Ether.—This was prepared by the method of Kauffmann and Franck.[4] It was used without any further purification in the preparation of the acetanilide and in subsequent brominating experiments.

The acetanilide of 2-aminoresorcinol dimethyl ether was prepared by heating 5 g. of the free base with 50 cc. of freshly distilled acetic anhydride in a sealed tube for about four hours at a temperature of 150–160". If the heating is continued for about ten hours, as recommended by Kauffmann and Franck, the chief product is not the acetanilide but a substance melting at 181°. This substance will be described in a subsequent paper.

Bromination of the Acetanilide of 2-Aminoresorcinol Dimethyl Ether.—Five grams of the acetanilide was dissolved in 50 cc. of glacial acetic acid and 4.5 g. of bromine dissolved in 15 cc. of acetic acid was added. The bromination occurred readily with evolution of hydrogen bromide. After standing for one-half hour the reaction mixture was poured into 300 cc. of water. A precipitate formed, which was filtered off and on crystallization from the glacial acetic acid two substances were obtained, a monobromo derivative melting at 161–162°, and a dibromo derivative melting at 212–213°.

---

[4] Rauffmann and Franck, *Ber.,* 40, 4006 (1907).

Bromination of the Acetanilide with Four Equivalents of Bromine.—Five grams of the acetanilide dissolved in 50 cc. of acetic acid was treated with 9 g. of bromine dissolved in 15 cc. of acetic acid; on pouring the reaction mixture into water and crystallizing the product from acetic acid, a substance identical with the one above melting at 212–213° was obtained as the only product that could be isolated. If the bromination was carried out at the temperature of the steam-bath, either with four equivalents or an excess of bromine, a product melting at 187–188° was formed. This is a dibromo derivative isomeric with the one melting at 213–214°.

Bromination of the Free Base in Glacial Acetic Acid in the Presence of Acetic Anhydride.—To five grams of 2-aminoresorcinol dimethyl ether dissolved in 50 cc. of acetic anhydride was added 5.1 g. of bromine, in 10 cc. of glacial acetic acid. After one hour the resulting mixture was poured into 200 cc. of water. The precipitate was filtered off and recrystallized from alcohol. This product, melting at 161–162°, was identical with the bromo-acetanilide obtained above. If an excess of bromine was used and the reaction carried out at the temperature of the steam-bath, a product identical with the substance melting at 187–188° was obtained as the sole product.

The **Acetanilide** of **4-Bromo-2-aminoresorcinol Dimethyl** Ether.—This was obtained on bromination of the acetanilide of 2-aminoresorcinol dimethyl ether or the free base. It was purified by repeated recrystallization from dilute acetic acid and subsequently from benzene until a constant melting point was obtained. From the former solvent it crystallized in hexagonal plates and from the latter in fine needles. It is soluble in alcohol, acetic acid, benzene and ether but insoluble in water and ligroin. It melts at 161–162°.

Anal. Subs., 0.2090, 0.2140: CO_2, 0.3320, 0.3424; H_2O, 0.0830, 0.0847. Subs., 0.2191. 0.2304: AgBr, 0.1528, 0.1610. Calcd. for $C_{10}H_{12}O_3NBr$: C, 43, 80; H, 4.41; Br, 29.70. Found: C, 43.34, 43.65; H, 4.44, 4.43; Br, 29.68, 29.74.

Hydrolysis of the **Acetanilide.**—Four grams of the above acetanilide was refluxed for two hours with 200 cc. of 2 *N* alcoholic solution of potassium hydroxide. The reaction mixture was acidified with hydrochloric acid and extracted with ether, yielding a small quantity of the original substance melting at 161–162°. The acid solution was made alkaline with sodium hydroxide and extracted with ether. The ethereal extract was dried with anhydrous sodium sulfate and on evaporation gave an oily product (3 g.) which solidified on cooling.

4-Bromo-2-aminoresorcinol dimethyl ether obtained as described above was crystallized from alcohol, forming small scale-like crystals melting at 67–68°. It is quite soluble in the usual organic solvents.

Anal. Subs., 0.0982, 0.1769: AgBr, 0.0785, 0.1426. Calod. for $C_8H_{10}O_2NBr$: Br, 34.44. Found: 34.27, 34.41.

Reduction of **4-Bromo-2-nitroresorcinol Dimethyl** Ether.—Ten grams of 4-bromo-2-nitroresorcinol dimethyl ether prepared by the method of Kauffmann and Franck[5] was refluxed with 15 g. of tin and 50 cc. of concentrated hydrochloric acid for one hour. On cooling enough water was added to keep the tin double salt in solution and enough potassium hydroxide added to make the solution strongly alkaline. The solution was extracted three times with ether and the ether extract was dried with anhydrous sodium sulfate. After evaporation of the ether an oily residue remained which solidified when cold. It was crystallized from alcohol and found to be identical with the bromo-2-aminoresorcinol dimethyl ether obtained on hydrolysis of the acetanilide described above.

Attempts have been made to prepare the acetanilide of 4-bromo-2-aminoresorcinol

---

[5] Ref. 4, p. 4002.

dimethyl ether by refluxing the free base obtained above with acetic anhydride; this has not been possible. The product obtained had lost a methoxy group. This will be discussed further in a subsequent paper.

The Acetanilide of Dibromo-2-aminoresorcinol Dimethyl Ether Melting at 213–214°.—This was obtained by bromination of the acetanilide or the free base in acetic acid and acetic anhydride as described above. It was repeatedly recrystallized from alcohol and subsequently from benzene, forming fine white needle-like crystals.

Anal. Subs., 0.1039: AgBr, 0.1087. Calcd. for $C_{10}H_{11}O_3NBr_2$: Br, 45.15. Found: Br, 45.52.

The isomeric dibromo derivative melting at 187–188° was obtained by brominating the acetanilide of 2-aminoresorcinol dimethyl ether at the temperature of the steam-bath. It was crystallized from benzene.

Anal. Subs., 0.1104: AgBr, 0.1175. Calcd. for $C_{10}H_{11}NBr_2$: Br, 45.15. Found: Br, 45.30.

Summary

It has been shown that the bromine atom enters the meta position to the amino group in 2-aminoresorcinol dimethyl ether.

DERIVATIVES OF MONO- AND DIAMINOHYDROXYPHENYLARSONIC ACIDS

BY BARRETT C. FISHER AND GEORGE W. RAIZISS

RECEIVED SEPTEMBER 27, 1928 PUBLISHED FEBRUARY 5, 1929

The practical significance of 3-amino-4-hydroxyphenylarsonic acid lies in its chemical relationship to such valuable medicinal products as arsphenamine and its derivatives, as well as stovarsol (acetarsone). The first is produced by reduction of 3-amino-4-hydroxyphenylarsonic acid, while the latter is the N-acetyl derivative of the same acid. Recent investigations indicate that 3-amino-4-hydroxyphenylarsonic acid itself is valuable in the treatment of protozoan infections.[1] The purpose of this paper is to describe several new derivatives of the above acid and also of the closely related diaminohydroxyphenylarsonicacid, all of which were synthesized by us in the course of chemotherapeutic research.

Of the halogenated 3-amino-4-hydroxyphenylarsonic acids, the 5-chloro[2] and 5-iodo[3] derivatives are known. We succeeded in preparing 5-bromo-3-amino-4-hydroxyphenylarsonic acid by first brominating the corresponding nitrohydroxyarsonic acid and then reducing the resulting product to the amino derivative. The direct bromination of 3-amino-4-

[1] Levaditi and Navarro-Martin, *Compt. rend. acad. sci.*, 174, 893 (1922); Fourneau, Navarro-Martin and Mr. and Mrs. Trefouel, *Ann. inst. Pasteur*, *37*, 551 (1923); Petzetakis, *Presse Medicale*, March 7, 1925.

hydroxyphenylarsonic acid could not be effected because of the readiness with which the amino acid oxidizes. The bromo-amino product can be obtained in even purer form than its parent amino compound, because it is more stable and crystallizes readily from water in beautiful colorless prisms. We assume that in brominating, as in mercurating, 3-nitro-4-hydroxyphenylarsonic acid the halogen, like mercury, enters position 5 of the benzene ring.[4] Most of the chemical properties and solubilities of 5-bromo-3-amino-4-hydroxylphenylarsonic acid are identical with those of the parent compound (3-amino-4-hydroxyphenylarsonic acid) except that it is soluble in hot water. It reacts with acetic anhydride, forming the corresponding acetyl compound, which is particularly interesting because it is a bromo derivative of the pharmaceutically important 3-acetylamino-4-hydroxyphenylarsonic acid (acetarsone). The halogenated compound, however, is more soluble in water.

3,5-Diamino-4-hydroxyphenylarsonic acid can now be produced with good yields due to improvements in the method of preparation. In a previous article[6] the fact that this compound crystallizes with $^1/_2$ molecule of water was overlooked, so that the analytical results now more closely approximate the theoretical figure. N-acyl derivatives of the 3,5-diamino acid are formed with comparative ease; the formyl compound is obtained at ordinary temperature after twenty-four hours, while the other acyl derivatives result within ten to fifteen minutes. In all cases substitution occurred in both amino groups. Of particular interest is 3,5-di-(chloro-acetylamino)-4-hydroxyphenylarsonic acid; it possesses the property of combining with one molecule of an amine, forming the corresponding mono glycyl derivative of the type formula, $C_6H_2(AsO_3H_2)$-$(OH)(NHCOCH_2Cl)(NHCOCH_2HNR)$. These will be described in a subsequent paper.

3-Acetylamino-4-hydroxyphenylarsonic acid is utilized in therapy as such. We prepared various salts of this acid in order to ascertain whether or not they possess any therapeutic advantages over the parent compound. The alkali salts are soluble in water, while the alkaline earth salts, except that of strontium, are insoluble. They all crystallize with water of crystallization; the only exceptions are the strontium and barium salts.

5-Bromo-3-amino-4-hydroxyphenylarsonic acid, as well as its N-acyl and diacyl derivatives, are not more trypanocidal or spirocheticidal than 3-amino-4-hydroxyphenylarsonic acid itself or its acetyl derivative. The least toxic of all the compounds described in this paper is 3,5-di-(acetylamino)-4-hydroxyphenylarsonic acid. Its maximum tolerated dose for white rats by the intravenous route is 1.4 g. per kilogram of body weight; for rabbits, 0.6 g. per kilo. These figures appear more significant when

[4] Stieglitz, Kharasch and Hanke, THIS JOURNAL, 43, 1185 (1921).

[5] Raiziss and Gavron, *ibid.*, 43, 583 (1921).

compared with those obtained for 3-acetylamino-4-hydroxyphenylarsonic acid under the same conditions, *viz.*, 0.3 g. per kilo for rats.

Experimental Part

Salts of **3-Acetylamino-4-hydroxyphenylarsonic** Acid.—The lithium salt, $Li_2O_3As\cdot C_6H_3(OH)(NHOCCH_3)\cdot 2H_2O$, is prepared by suspending 1 mole of 3-acetylamino-4-hydroxyphenylarsonic acid in a small volume of water, heating to boiling, gradually adding 2 moles of lithium carbonate and heating until the evolution of carbon dioxide ceases. After filtering and cooling, the filtrate is treated with 10 volumes of acetone and the lithium salt separates out immediately. This is filtered off and washed first with acetone and then ether. It is a colorless, amorphous powder soluble in water, methyl and ethyl alcohols; it is insoluble in acetone or ether.

The calcium and barium salts, $CaO_3As\cdot C_6H_3(OH)(NHOCCH_3)\cdot 2H_2O$ and $BaO_3As\text{-}C_6H_3(OH)(NHOCCH_3)$, are prepared like the lithium salt except (1) that the parent arsonic acid is suspended in 50 parts of water, (2) the reaction mixture is boiled for twenty minutes and (3) the salts crystallize out spontaneously from the filtrate when cooled to 15°, without the aid of a prtcipitant. They are washed successively with water, methyl alcohol and ether, and finally air dried. The calcium salt crystallizes in colorless, highly refractive crystals, while the barium compound exists as colorless needles. They are both soluble in hot water but only sparingly so in cold; they are insoluble in methyl or ethyl alcohol, acetone or ether.

The strontium salt, $SrO_3AsC_6H_3(OH)(NHOCCH_3)$, is prepared like the lithium salt except that it is precipitated from the filtrate at 10° with 3 volumes of 95% methyl alcohol. It is allowed to stand at 10° for one hour, then filtered off and washed first with methyl alcohol and ultimately with ether. It forms colorless rhombohedra which are very soluble in cold water but insoluble in organic solvents.

TABLE I

ANALYTICAL DATA

Salt of	Nitrogen, % Calcd.	Nitrogen, % Found	Arsenic. % Calcd.	Arsenic. % Found
Lithium	4.33	4.48	23.23	23.58
Calcium	4.01	4.05	21.48	21.95
Barium	3.41	3.31	18.29	18.79
Strontium	3.88	4.05	20.79	21.39

Bromo Derivatives of Aryl Arsonic Acids

5-Bromo-3-nitro-4-hydroxyphenylarsonic Acid, $H_2O_3AsC_6H_2BrNO_2OH$.—263 g. (1 mole) of 3-nitro-4-hydroxyphenylarsonic acid is suspended in 800 cc. of 95% methyl alcohol, 20 g. of iron added (as a carrier), the flask connected to a reflux condenser and a solution of 160 g. of bromine in 200 cc. of methyl alcohol introduced drop by drop, with frequent shaking. The reaction must not to be permitted to become too violent. After all of the bromine has been added, the reaction mixture is cooled, filtered and the filtrate treated with 10 volumes of water. The yellow bromo derivative precipitates immediately; it is washed with water and then crystallized from the same medium; yield of recrystallized product, 154 *g.*

5-Bromo-3-nitro-4-hydroxyphenylarsonic acid crystallizes in yellow, microscopic plates which are soluble in hot water, but almost insoluble in cold, sparingly soluble in dilute hydrochloric acid, readily in dilute alkalies, acetone, ethyl or methyl alcohol, insoluble in ether and most other organic solvents. When heated it starts to decompose at about 280°, but remains unmelted at 300°.

Anal. Calcd. for $C_6H_5O_6NAsBr$: N, 4.08; As, 21.93. Found: N, 3.63; As, 21.46.

5-Bromo-3-amino-4-hydroxyphenylarsonic Acid, $H_2O_3AsC_6H_2BrNH_2OH$.—Thirty-four and two-tenths g. of the corresponding nitro compound is dissolved in 50 cc. of 4 N sodium hydroxide solution, mixed with a solution of 40 g. of magnesium chloride in 300 cc. of water, the whole cooled to −5° and then stirred mechanically. Ninety-five g. of sodium hydrosulfite is now gradually added in the course of two hours, care being taken that the temperature does not rise above 0°. After all of the hydrosulfite has been introduced, the mixture is stirred for another half hour, when the crude bromo-amino compound precipitates. This is filtered off, washed with a small volume of ice water and purified by dissolving in the least amount of 5% hydrochloric acid, rapidly filtering and neutralizing the cooled filtrate with dilute sodium hydroxide solution until faintly acid to Congo Red. After standing for a short time, the product crystallizes out from solution; it is filtered off, washed with water until free of chlorides and sulfates and then recrystallized from hot water to which Nuchar "W" has been added to decolorize; yield, 14 g. It forms colorless prisms which are soluble in hot water, almost insoluble in cold, insoluble in dilute alkali, dilute hydrochloric acid, ethyl and methyl alcohols, insoluble in acetone, ether and most organic solvents.

Anal. Calcd. for $C_6H_7O_4NAsBr$: N, 4.48; As, 24.04; Br, 25.64. Found: N, 4.35; As, 23.67; Br, 25.30.

5-Bromo-3-acetylamino-4-hydroxyphenylarsonic Acid, $H_2O_3AsC_6H_2BrOH(NHOCCH_3)$.—This acid was prepared from the preceding amino compound (10.4 g.) by suspending it in water (100 cc.) and chopped ice (200 g.) and acetylating with acetic anhydride (6.9 g.) at reduced temperature. The whole is mechanically stirred for one hour and the resulting precipitate filtered off and purified by dissolving in *N* sodium hydroxide, decolorizing with Nuchar "W," filtering, cooling the filtrate and acidifying slightly with hydrochloric acid, using Congo Red as an indicator; yield, 6 g. It gives colorless prisms which are soluble in water, 10% hydrochloric acid, dilute alkalies, ethyl and methyl alcohols, but insoluble in ether. It darkens at 267–270° but remains unmelted at 300°.

Anal. Calcd. for $C_8H_9O_5NAsBr$: N, 3.95; As, 21.18. Found: N, 3.88; As, 21.19.

N-Acyl Derivatives of 3,5-Diamino-4-hydroxyphenylarsonic Acid

3,5-Diamino-4-hydroxyphenylarsonic Acid, $H_2O_3AsC_6H_2(OH)(NH_2)_2 \cdot {}^1/_2H_2O$.—This compound was first described in a German patent.[6] The method of preparation was later modified by Raiziss and Gavron[5] and still further improved by Raiziss and Fisher.[7] It is obtained by reducing 3,5-dinitro-4-hydroxyphenylarsonic acid with sodium hydrosulfite at low temperature, and is purified by dissolving in dilute hydrochloric acid, filtering and neutralizing the filtrate with dilute sodium hydroxide.

Anal. Calcd. for $C_6H_9O_4N_2As \cdot {}^1/_2H_2O$: N, 10.89; As, 29.18; H_2O, 3.50. Found: N, 10.76; As, 29.00; H_2O, 3.10.

3,5-Di-(formylamino)-4-hydroxyphenylarsonic Acid, $H_2O_3As \cdot C_6H_2(OH)(NHOCH)_2$.—A mixture of 10 g. of 3,5-diamino-4-hydroxyphenylarsonic acid and 30 cc. of 85% formic acid is allowed to react at room temperature overnight, then diluted with 300 cc. of water and cooled. The crude diformyl derivative, which precipitates out, is filtered off, washed with water until free from acid, and finally recrystallized from hot water, using Nuchar as a decolorizing agent; yield of recrystallized product, 5 g.

It forms colorless, short, spear-shaped needles which are very sparingly soluble in cold water, soluble in dilute aqueous sodium hydroxide, ethyl or methyl alcohol, in-

---

[6] German Patent 224,953 (1910).

[7] Raiziss and Fisher, to be published in "Organic Syntheses."

soluble in most other organic solvents, and is decomposed by hydrochloric acid. When heated it starts to decompose rapidly at about 200° but remains unmelted at 275°.

Anal. Calcd. for $C_8H_9O_6N_2As$: N, 9.21; As, 24.67. Found: N, 9.21; As, 24.52.

The sodium salt of this compound was prepared by dissolving it in aqueous sodium hydroxide and precipitating with 10 volumes of ethyl alcohol.

3,5-Di-(acetylamino)-4-hydroxyphenylarsonic acid, $H_2O_3AsC_6H_2(OH)(NHOCCH_3)_2$, prepared according to the method of Raiziss and Gavron[5] and recrystallized from water, using Nuchar as a decolorizer, is obtained in clusters of colorless needles. It is soluble in boiling water, but only sparingly so in cold, soluble in cold dilute aqueous alkalies, insoluble in dilute acids and the usual organic solvents. It darkens at 235–240° but does not melt at 275°.

Anal. Calcd. for $C_{10}H_{13}O_6As$: N, 8.43; As, 22.60. Found: N, 8.09; As, 22.48.

3,5-Di-(propionylamino)-4-hydroxyphenylarsonic Acid, $H_2O_3AsC_6H_2(OH)(NHOCCH_2CH_3)_2$.—12.4 g. of 3,5-diamino-4-hydroxyphenylarsonic acid is suspended in 50 cc. of water, 14.3 g. of propionic anhydride added and the whole refluxed for ten minutes. After diluting with 50 cc. of water and cooling, 10 cc. of concentrated hydrochloric acid is added. The resulting precipitate is filtered off, washed several times with 10% hydrochloric acid, then with water until free of chlorine ions and recrystallized from water, using Nuchar to decolorize; yield, 6 g.

The dipropionyl compound crystallizes in long, colorless silky needles, soluble in hot water, sparingly so in cold water, soluble in dilute aqueous alkalies, insoluble in dilute acids or the usual organic solvents except methyl alcohol, in which it is sparingly soluble. When heated it melts at 197–198° to a dark red liquid.

Anal. Calcd. for $C_{12}H_{17}O_6N_2As$: N, 7.78; As, 20.83. Found: N, 7.77; As, 20.53.

3,5-Di-(butyrylamino)-4-hydroxyphenylarsonic Acid, $H_2O_3AsC_6H_2(OH)(NHOCCH_2CH_2CH_3)_2$, is prepared from butyric anhydride like the corresponding propionyl compound, except (1) that 5 g. of copper turnings must be added as a catalyst and (2) after cooling the reaction mixture it is not necessary to dilute with water before precipitating with concentrated hydrochloric acid. It crystallizes from hot water in colorless needles, m. p. 177°, soluble in acetone and methyl alcohol; with other solvents it behaves like the preceding compound.

Anal. Calcd. for $C_{14}H_{21}O_6N_2As$: N, 7.21; As, 19.33. Found: N, 7.08; As, 19.57

3,5-Di-(chloro-acetylamino)-4-hydroxyphenylarsonic Acid, $H_2O_3AsC_6H_2(OH)(NHOCCH_2Cl)_2$.—To a solution of 24.8 g. of 3,5-diamino-4-hydroxyphenylarsonic acid in 200 cc. of *N* sodium hydroxide solution, 22.6 g. of chloro-acetyl chloride is slowly added during fifteen minutes while stirring rapidly. The reaction starts immediately with considerable evolution of heat. The mixture is then cooled, stirred for one-half hour longer and the desired product obtained by the addition of 20 cc. of concentrated hydrochloric acid. It is filtered off, suspended in 10% hydrochloric acid, again filtered and washed, first with 10% hydrochloric acid, then with water until free of chlorine ions. It is finally purified by recrystallizing from 10% acetic acid, using Nuchar to decolorize.

The compound separates as colorless needles, darkening at 200° and melting with decomposition at 210–211°. It is soluble in dilute aqueous alkalies, methyl alcohol and boiling dilute acetic acid, very sparingly so in hot water, practically insoluble in cold water and insoluble in acetone or ether.

Anal. Calcd. for $C_{10}H_{11}O_6N_2AsCl_2$: N, 6.98; As, 18.70. Found: N, 6.77; As, 19.17.

The sodium salts of these 5 acyl derivatives were prepared but not analyzed.

Summary

1. The following compounds have been prepared and described for the first time: (a) The lithium, calcium, barium and strontium salts of 3-acetylamino-4-hydroxyphenylarsonic acid; (b) 5-bromo-3-nitro-4-hydroxyphenylarsonic acid, 5-bromo-3-amino-4-hydroxyphenylarsonic acid and 5-bromo-3-acetylamino-4-hydroxyphenylarsonic acid; (c) 3,5-di-(formylamino)-, 3,5-di-(propionylamino)-, 3,5-di-(butyrylamino)-, 3,5-di-(chloro-acetylamino)-4-hydroxyphenylarsonic acids and their sodium salts.

2. 5-Bromo-3-amino-4-hydroxyphenylarsonic acid is neither more trypanocidal or spirocheticidal than 3-amino-4-hydroxyphenylarsonic acid or its N-acetyl derivative.

3. The least toxic of all the compounds discussed in this paper is 3,5-di-(acetylamino)-4-hydroxyphenylarsonic acid. When injected intravenously into white rats its maximum tolerated dose is 4.6 times greater than that of 3-acetylamino-4-hydroxyphenylarsonic acid.

THE SYNTHESIS OF 6-HYDROXYPIPERONYLIC ACID AND INCIDENTAL COMPOUNDS

BY MARSTON TAYLOR BOGERT AND FRANK ROSE ELDER[1]

RECEIVED OCTOBER 1, 1928 PUBLISHED FEBRUARY 5, 1929

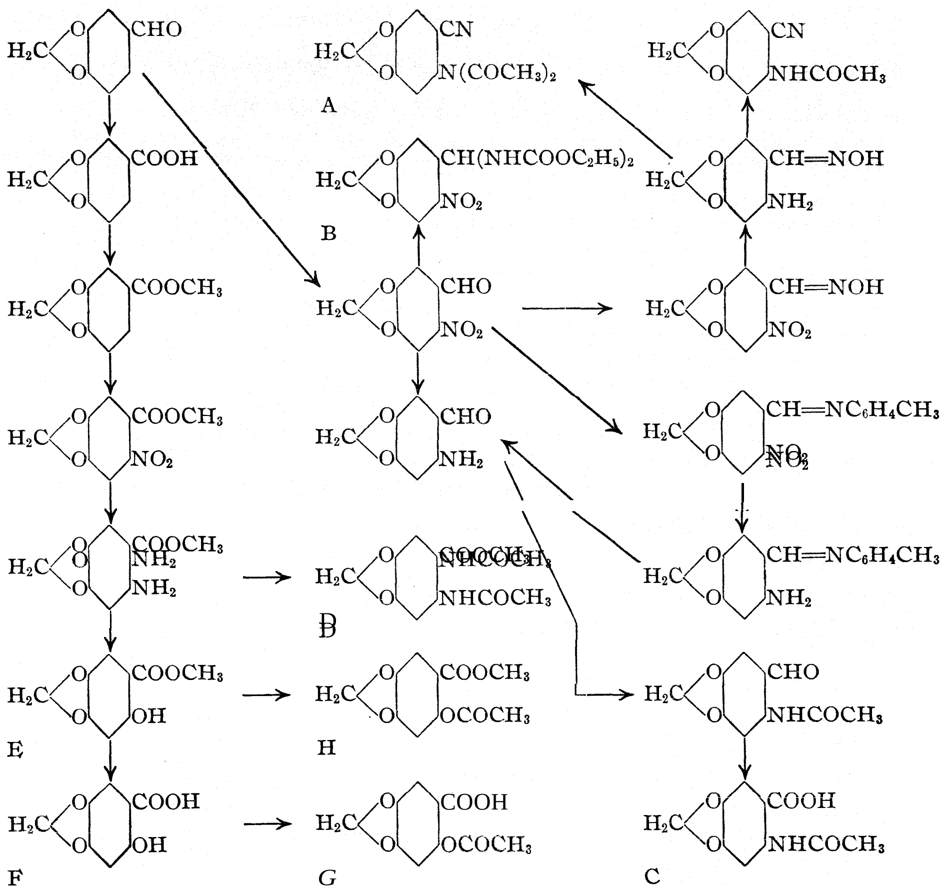
Salicylic acid and its derivatives, notably acetyl-salicylic acid (Aspirin), have proved to be of sufficient therapeutic value to justify additional experimental work for the purpose of gaining more light upon the connection between chemical constitution and physiological effect in the group of the o-hydroxybenzoic acids.

The experimental work which follows describes the synthesis of 6-hydroxypiperonylic acid, some of its derivatives and incidental products. This particular acid was selected because we failed to find any description of it in the literature, because it is structurally the methylene ether of a dihydroxysalicylic acid and because of the fact that the methylene-dioxy grouping is of frequent occurrence in natural products, including certain of the alkaloids.

The various lines of approach to this goal are sufficiently indicated in the flow diagram. The route via piperonylic acid proved most satisfactory, for reasons set forth in the Experimental Part.

---

[1] Based upon the Dissertation submitted by Dr. Elder in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the Faculty of Pure Science of Columbia University, 1927. An abstract of this paper was read before the Division of the Chemistry of Medicinal Products, at the Richmond Meeting of the American Chemical Society, April, 1927.



It is worth noting that methyl 6-hydroxypiperonylate, in contradistinction to methyl salicylate, possessed only an exceedingly faint agreeable odor, without any of the wintergreen character. Similarly, the methyl ester of the 6-aminopiperonylic acid was a colorless and practically odorless crystalline solid, with none of the aroma peculiar to methyl anthranilate.

Of the 6-hydroxypiperonylic acid, and of its acetyl derivative, sufficient material has not been accumulated as yet to proceed with the pharmacological tests.

Heretofore, 6-aminopiperonal has been obtained only indirectly from the 6-nitro compound, through the reduction of the *p*-toluidine derivative of the latter and hydrolysis of the resultant 6-aminopiperonylidene-*p*-toluidine, all attempts at the direct reduction of the nitro-aldehyde itself having failed. We have found that this direct reduction of the nitro to the amino-aldehyde can be accomplished with ferrous sulfate and ammonia, under proper conditions, with a yield of 60%.

Experimental

6-Nitropiperonal was prepared by the process of Salway,[2] with certain modifications which were found to give larger yields, as follows.

To 500 cc. of concentrated nitric acid (sp. gr. 1.42) cooled to 0°, there was added 50 g. of finely pulverized piperonal slowly and with constant stirring, the temperature being maintained below 0° during this addition and for two to three hours thereafter. If some of the piperonal still remained undissolved, the freezing mixture was removed and the mixture allowed to warm gradually, until all was dissolved. The solution was poured immediately into ice water, the yellow precipitate collected, washed free from nitric acid and stirred with sufficient 40% sodium bisulfite solution to make a thick paste. Two volumes of water were added and the mixture filtered. The residue was subjected to the same treatment and this was repeated with the two or three succeeding residues. The combined filtrates were made alkaline with sodium hydroxide, the precipitate collected, washed thoroughly and crystallized from a 1:1 mixture of ethyl acetate and alcohol. The nitropiperonal so obtained formed long, pale yellow needles, m. p. 97–98' (corr.) (Salway gives 98°); yield, 46 g., or 70%. There was recovered also 14 g. of 4-nitro-1,2-methylenedioxybenzene which, taken together with the nitropiperonal, accounts for 96% of the piperonal used. The formation of this by-product, through replacement of the aldehyde group during the nitration, was noted first by Salway.

6-Nitropiperonylidene-diurethan.—In 1913 Bianchi[3] condensed piperonal with ethylurethan and obtained a product in good yield which was easily hydrolyzed. Experiments were conducted therefore with nitropiperonal, for the purpose of preparing a similar urethan condensation, to be reduced to the corresponding amino derivative and the latter hydrolyzed to the 6-aminopiperonal.

A mixture of 5 g. of nitropiperonal and 4.86 g. of ethylurethan was heated at 100–110°. To the clear yellow melt there was added 1 cc. of concentrated hydrochloric acid, the mixture was well stirred and the heating continued until the evolution of vapor ceased. The hydrochloric acid addition caused the mixture to turn first green, then brown and finally black, and nearly solid. It was left overnight, then dissolved in a mixture of alcohol, chloroform and acetone, boiled for several hours with a decolorizing carbon, filtered and the filtrate concentrated. The brownish product which separated was collected, washed with a little cold alcohol, boiled in ethyl acetate solution with a decolorizing carbon and the filtrate concentrated and cooled. There separated a fine, feathery solid, with a faint yellowish-green tinge, which melted with decomposition at 207–208" (corr.); yield, 1 g., or 10%. On long exposure to the light, its color changed to a yellowish brown. For analysis, the product was dried to constant weight at 110–115°.

Anal. Calcd. for $C_{14}H_{17}O_8N_3$: C, 47.32; H, 4.83; N, 11.83. Found: C, 47.10, 46.67; H, 5.27, 4.94; N, 11.98.

Considerable difficulty was experienced in purifying this product through failure to find any satisfactory solvent or mixture of solvents. It dissolved in both acids and alkalies, and when dry was exceedingly light, fluffy and triboelectric. Because of these unpromising results, further work along this line was abandoned.

6-Nitropiperonal **Oxime.**—Haber[4] described this oxime but gave no

---

[2] Salway, J. *Chem. Soc.*, **95,** 1155 (1909).

[3] Bianchi, *Gazz. chim. ital.*, *43,* I, 237 (1913).

[4] Haber, **Ber.,** 24, 625 (1891).

details concerning its preparation or yield. We found that dry potassium carbonate as a condensing agent gave better results than zinc oxide.

To an alcoholic solution of the aldehyde (10 g.) and hydroxylamine hydrochloride (*3.6* g.), there was added dry potassium carbonate (3.6 g.) dissolved in a little water, and the mixture was boiled for three hours. The yellow oxime which separated as the mixture cooled, when recrystallized from alcohol, melted at 201–203° (corr.); yield, 84% (9 g.). Haber gave the m. p. as 203°.

6-Aminopiperonal oxime was prepared from the nitro oxime by reduction in alcoholic solution with ammonia and hydrogen sulfide, essentially as described by Haber.[4] Decolorized and crystallized from alcohol, it formed nearly colorless, glistening needles. m. p. 182–183° (corr.); yield, 81%. Haber recorded the melting point as 175.5°.

6-Acetaminopiperonylonitrile.—Haber[4] reported that when he heated the above amino oxime for a short time with excess of acetic anhydride and sodium acetate, the acetaminopiperonylonitrile, m. p. 216° (corr.) resulted. We found that, depending upon the duration of this heating, the product was either the mono- or the diacetyl derivative.

A mixture of 2 g. of the amino oxime, 1 g. of fused sodium acetate and 20 g. of acetic anhydride was boiled for ten to twelve minutes and then poured into an excess of cold dilute sodium carbonate solution. The precipitate (1 g.) was collected, washed, crystallized from alcohol and then from chloroform. A small amount (0.3 g.) of fine, feathery needles was thus secured, m. p. 215–217° (corr.), which was dried *in vacuo* over concentrated sulfuric acid and analyzed.

And. Calcd. for $C_{10}H_8O_3N_2$: C, 58.82; H, 3.92; N, 13.73. Found: C. 58.78; H, 4.22; N, 13.82.

Briefer heating gave no appreciable quantity of this mono-acetyl derivative. In boiling ethyl or iso-amyl acetate solution, the acetylation failed wholly, and the amino oxime was recovered unaltered.

The yield of mono-acetyl derivative noted did not seem to us sufficient to make this route of approach to our goal a very promising one and the work was discontinued.

6-Diacetaminopiperonylonitrile.—When the amino oxime (2.5 g.), fused sodium acetate (2 g.) and acetic anhydride (15 g.) were boiled together for an hour, the mixture poured into the dilute carbonate solution and the precipitate crystallized from alcohol, thin plates (1.5 g.) were obtained, m. p. 115–122° (corr.). These were dissolved in chloroform (10 cc.) cold. Spontaneous evaporation of the solvent yielded colorless, thin rectangular plates, m. p. 146–147' (corr.), which were dried *in vacuo* over concentrated sulfuric acid and analyzed.

And. Calcd. for $C_{12}H_{10}O_4N_2$: C, 58.54; H, 4.07; N, 11.38. Found: C, 58.64; H, 4.18; N, 11.92, 11.93.

6-Nitropiperonylidene-*p*-toluidine.—Rilliet and Kreitmann,[5] after reviewing the failure of other workers to obtain 6-aminopiperonal by direct reduction of the nitro-aldehyde, succeeded in preparing it indirectly through the *p*-toluidine derivative of the latter.

On repeating this work, we found that the use of a 20% excess of *p*-toluidine gave a much better yield of the condensation product (90% instead of 75%). Since this product is very sensitive to the light, rapidly turning dark red, the condensation and subsequent crystallization were carried out in the dark, and long glistening yellow needles

---

[5] Rilliet and Kreitmann, *Compt. rend.*, 157,782 (1913).

were thus secured, m. p. 121–122° (corr.). Rilliet and Kreitmann gave the m. p. as 121.5°.

6-Aminopiperonylidene-*p*-toluidine was prepared from the nitro derivative by reduction in alcoholic solution with sodium sulfide, as described by Rilliet and Kreitmann.[5] The crude product (yield, 60%) was crystallized twice from alcohol and then once from benzene. Small rosets of fine, silky yellow needles resulted, m. p. 137–138° (corr.); yield, 12%. Rilliet and Kreitmann reported a yield of 54% and a melting point of 134.5°. Our product was dried *in vacuo* over concentrated sulfuric acid and analyzed.

Anal. Calcd. for $C_{15}H_{14}O_2N_2$: C, 70.82; H, 5.60; N, 11.02. Found: C, 70.61; H, 5.85; N, 10.89.

We tried also the reduction method of Cobenzl,[6] using sulfur and sodium sulfide in alcoholic solution, but the yield of amino derivative was less.

6-Aminopiperonal.—Rilliet and Kreitmann[5] stated that they hydrolyzed the p-toluidine derivative by boiling it with dilute sodium hydroxide. Judging by our own experience, they must have meant an alcoholic and not an aqueous alkaline solution, for we found that twenty hours' boiling with a 10% aqueous sodium hydroxide solution was without effect. However, it was easily hydrolyzed as follows.

A solution of 6 g. of the p-toluidine derivative and 15 g. of potassium hydroxide in 300 cc. of alcohol was boiled under a reflux condenser for three to four hours, an equal volume of water added and steam blown through as long as any p-toluidine came over. The residual liquid was filtered hot and as the filtrate cooled yellowish needles of the aminopiperonal separated which were crystallized from water and then melted at 107–108° (corr.); yield, about 50%. Rilliet and Kreitmann gave the m. p. as 107°.

The direct reduction of 6-nitropiperonal has been essayed unsuccessfully by various investigators,[7] and we were equally unsuccessful when we attempted to apply the method used by Bamberger and Demuth[8] for the reduction of o-nitrobenzaldehyde to the amino-aldehyde, by the use of titanous chloride,[9] or by the action of hydrogen sulfide and ammonia. We were more fortunate, however, when we tried ferrous sulfate and ammonia.[10]

To a solution of 100 g. of ferrous sulfate in 500 cc. of boiling water there was added a hot aqueous solution of 10 g. of nitropiperonal, followed by about 100 cc. of concentrated ammonium hydroxide solution in small portions, until the solution was alkaline to litmus. After boiling the mixture for five minutes, it was filtered, the precipitate washed thoroughly with boiling water and the filtrate and washings were combined and cooled. The crude amino-aldehyde which separated was recrystallized from water and then formed long yellow needles, m. p. 107–108° (corr.), identical with that obtained by the Rilliet and Kreitmann method; yield, 5 g., or 60%.

Attempts to replace the amino group by hydroxyl, through the diazo reaction, proved futile.

Acetyl Derivative.—Colorless needles (from water), m. p. 161–162° (corr.). Rilliet and Kreitmann gave the melting point as 160°.

6-Acetaminopiperonylic Acid.—The 6-acetaminopiperonal (3 g.) was oxidized by potassium permanganate in the presence of magnesium sulfate, and the crude product crystallized from dilute alcohol in faintly yellowish, long feathery needles, m. p. 124–125° (corr), soluble in alcohol but difficultly soluble in water; yield, 0.4 g. It was dried in *vacuo* over concentrated sulfuric acid and analyzed.

And. Calcd. for $C_{10}H_9O_5N$: C, 53.81; H, 4.03. Found: C, 52.97, 54.13; H, 4.09, 4.81.

While these analytical results are not very satisfactory, they are sufficiently close, if considered in conjunction with the method of preparation, to support the assumption that the product was the acid stated. No material was left for further analyses and the preparation was not repeated.

Piperonylic acid was prepared most conveniently as follows. To 3 liters of water, there was added 50 g. of finely powdered piperonal and the mixture was heated to 40–50°, stirred mechanically and potassium permanganate solution run in slowly until the odor of piperonal was no longer perceptible. This required generally about 125 g. of the permanganate. Excess of the latter, if any, was destroyed by the addition of a little alcohol, the mixture filtered hot and the filtrate acidified with hydrochloric acid. The piperonylic acid which separated as the solution cooled was practically pure; yield, 36 g., or 65%.

When the oxidation was conducted in acetone, instead of in aqueous solution, the yield was about the same. Oxidation in the presence of magnesium sulfate, however, resulted in considerably lower yields.

Methyl 6-Aminopiperonylate.—Piperonylic acid was converted into its methyl ester, the latter nitrated and the nitro ester reduced to the 6-amino ester, as described by Oertley and Pictet[11] and with similar results.

Acetyl Derivative.—Colorless, fine fluffy needles (from alcohol), m. p. 183–184" (corr.); soluble in alcohol, acetone, chloroform or benzene, less so in ether, and but slightly soluble in water. It was dried *in vacuo* over concentrated sulfuric acid and analyzed.

Anal. Calcd. for $C_{11}H_{11}O_5N$: C, 55.70; H, 4.64. Found: C, 55.63, 55.88; H, 4.83, 4.93.

Methyl 6-Hydroxypiperonylate.—The conversion of the amino into the hydroxy ester proved to be a rather troublesome task. When the diazotized ester was boiled with water, subjected to a current of steam, or dropped into a boiling borax solution, a dark red product resulted from which we were unable to recover any of the desired hydroxy ester. The problem was finally solved as follows.

To a well-cooled solution of 5 g. of the amino ester in 10 g. of concentrated sulfuric acid and 25 cc. of water, there was added 2.15 g. of potassium nitrate in 10 cc. of water and the diazo solution was dropped slowly into a boiling solution of 25 g. of copper sulfate in 25 cc. of water. The resultant solution was poured into 400–500 cc. of water and the mixture left overnight at room temperature. The reddish-brown precipitate was collected, washed thoroughly with water, decolorized in boiling alcoholic solution and the filtrate allowed to cool, There separated colorless rosets, m. p. 97–98° (corr.); yield, 50%. This proved to be a mixture of the desired ester with a small amount of 6-hydroxypiperonylic acid. It was therefore shaken first with a dilute sodium car-

---

[11] Oertley and Pictet, Ber., 43, 1336 (1910).

bonate solution, to remove the free hydroxy acid, and the residue then extracted with dilute sodium hydroxide solution. The use of too strong a caustic alkali solution must be avoided. The caustic soda extracts were acidified, the colorless precipitate was collected, washed, dried, dissolved in a mixture of alcohol and ether and the solvent allowed to evaporate spontaneously. The hydroxy ester crystallized in small colorless rosets, m. p. 99–100° (corr.), which were practically odorless and gave a deep blue color with ferric chloride solution. These crystals were dried *in vacuo* over concentrated sulfuric acid and analyzed.

Anal. Calcd. for $C_9H_8O_5$: C, **55.10;** H, **4.11.** Found: C, **55.19;** H, **4.28.**

The acetyl derivative, from the ester and acetyl chloride, was decolorized in ether solution and then separated in nearly colorless crystals, m. p. 50–60°. Recrystallized from a mixture of alcohol and ether, it formed rosets of nearly colorless needles, m. p. **97–98'** (corr.); yield, **3.5** g. or 60%. For analysis, it was dried *in vacuo* over concentrated sulfuric acid.

Anal. Calcd. for $C_{11}H_{11}O_6$: C, **55.46;** H, **4.20.** Found: **C, 55.29;** H, **4.25.**

6-Hydroxypiperonylic Acid.—The methyl ester was hydrolyzed by boiling it for about an hour in dilute (5%) potassium hydroxide solution until a test portion no longer yielded a precipitate when saturated with carbon dioxide. The slightly reddish solution was acidified with dilute hydrochloric acid, the precipitate collected, washed and dried; yield, 7 g. or 80%. Recrystallized from either chloroform or dilute alcohol, it formed nearly colorless fluffy needles, m. p. **211–212"** (corr.), easily soluble in alcohol, but only slightly in water, ether, chloroform or benzene. For analysis it was dried *in vacuo* over concentrated sulfuric acid; (a) was crystallized from alcohol, and (b) from chloroform.

Anal. Calcd. for $C_8H_6O_5$: C, **52.74;** H, **3.29.** Found: **C,** (a) **52.38,** (b) **52.45;** H, (a) **3.24,** (b) **3.26.**

With ferric chloride solution, this acid gave the same deep blue color as its methyl ester.

6-Acetoxypiperonylic Acid.—Very great difficulty was experienced in the preparation of this aspirin by direct acetylation of the hydroxy acid and no satisfactory method was worked out, although a great deal of experimental work was done and many different processes were tried.

About equal parts of the hydroxy acid and fused sodium acetate were dissolved in acetic anhydride, an excess of acetyl chloride was added, the mixture boiled for six to eight hours, cooled, poured into a large volume of cold water and the precipitate removed, washed and dried. Fractional crystallization of this product from acetic anhydride, repeated **5** or **6** times, washing the crystals each time with a little cold ether, finally yielded a small quantity of nearly colorless needles, which melted at 155.5–156.5° (corr.), with slight preliminary softening, were freely soluble in alcohol, glacial acetic acid or acetic anhydride and dissolved but slightly in water, ether, chloroform or benzene.

Anal. Calcd. for $C_{10}H_8O_6$: C, **53.57;** H, **3.57.** Found: C, **53.77;** H, **3.96.**

Summary

1. 6-Hydroxypiperonylic acid and its acetyl derivative, the former a derivative of salicylic acid and the latter of aspirin have been synthesized from piperonal, for the purpose of pharmacological investigation.

2. It has been shown that 6-nitropiperonal can be reduced directly to the amino aldehyde by the use of ferrous sulfate and ammonia.

3. Other derivatives of piperonal and of piperonylic acid have been prepared and described.

[CONTRIBUTION FROM THE LABORATORY OF PHYSICAL CHEMISTRY OF THE UNIVERSITY OF UPSALA]

THE MOLECULAR WEIGHT OF THE HEMOCYANIN OF LIMULUS POLYPHEMUS

BY THE SVEDBERG AND FRANCIS F. HEYROTH[1]

RECEIVED OCTOBER 2, 1928 PUBLISHED FEBRUARY 5, 1929

Gross differences have been reported by several workers[2] in the copper content, oxygen-combining curves, isoelectric points and various other properties of the hemocyanins obtained from different animals. This investigation was undertaken to determine whether a similar difference could be observed in the molecular weights of the hemocyanins or respiratory pigments of two species, the vineyard snail, Helix *pomatia*, and the horseshoe crab, Limulus polyphemus. Measurements in the ultracentrifuge by Svedberg and Chirnoaga have shown the former protein to have a molecular weight of 5,000,000 in solutions containing 0.05–0.1% of hemocyanin near the isoelectric point, 5.2. The copper contents of the hemocyanins of *Limulus* and Helix are 0.17 and 0.28%, respectively.[3]

Experimental

Preparation of Material.—We are indebted to Dr. A. C. Redfield for a sample of the hemocyanin of Limulus prepared by him at Woods Hole in 1926. He has described its preparation as follows:[3] "The fresh serum from a large number of animals was salted out by the addition of ammonium sulfate to half saturation, and in this condition preserved for some six months. The precipitated hemocyanin was separated by filtration, redissolved in 5% saturated ammonium sulfate containing 0.001 N ammonium hydroxide, filtered free of all insoluble residue, and reprecipitated by adding just sufficient saturated ammonium sulfate. This precipitate was separated by centrifugation. In order to secure a satisfactory separation, it was found desirable to bring the reaction to approximately PH 8.0 by the addition of ammonium hydroxide. The process of redissolving and salting out was then repeated two more times."

The material so prepared was dissolved in 5% saturated ammonium sulfate and further purified by dialysis before beginning this series of experiments. The dialysis was conducted in collodion bags in the ice chest against *N*/10,000 and later *N*/1000

---

[1] Fellow in Medicine of the National Research Council.

[2] References in Svedberg and Chirnoaga, THIS JOURNAL, 50, 1399 (1928), and in the papers of Stedman and Stedman, *Biochem.* J., 20, 938, 949 (1928).

sodium hydroxide. After three weeks the alkali was replaced by distilled water, which was repeatedly changed during a month.

The suspension obtained had a specific electrical conductivity of 1.07×10^{-5} mho. The solubility of the hemocyanin of *Limulus* in electrolyte solutions is not as great as that of *Helix,* a suspension of which may be brought into solution by the addition of but traces of salts. A 2.27% stock solution of the *Limulus* hemocyanin was made from the supension by adding **3** cc. of $M/15$ $Na_2HPO_4 \cdot 2H_2O$ and *1.5* cc. of $M/15$ KH_2PO_4 per *100* cc. of final solution. The reaction of this solution, PH *6.63* (electrometrically determined), permitted the preparation of a sufficiently concentrated solution for the pycnometric determination of the partial specific volume, V, of the protein. At the same time the reaction was judged to be not too **far** from the isoelectric point of the protein. This is not accurately known, Stedman and Stedman[2] merely stating that the method of maximal precipitation indicates it to be somewhat greater than *6.3.* Toluene was employed as a preservative as it is readily removed from the solutions just before use by bubbling nitrogen gas through them.

The partial specific volume was determined by the pycnometric method described for the other proteins studied in this Laboratory. The concentration of the solutions was determined by transferring *1* cc. of the solution to a porcelain crucible, evaporating down to coagulation on a water-bath and then drying to constant weight at 105°. The content of anhydrous salt per cc. of the solution was subtracted from this weight. The mean value of V obtained in three determinations at two protein concentrations was *0.735* at 20°. This is, within the limits of experimental error, the same as that of the hemocyanin of *Helix.*

Preliminary measurements of the visible and ultraviolet light absorption showed the hemocyanin of *Limulus* to possess in general the same type of absorption curve as that obtained from *Helix.* In the experiments here reported the light absorption in the short-waved ultraviolet region only was employed. Chlorine and bromine filters were used as previously described[4] for the isolation of this region of the radiations from a quartz mercury vapor lamp.

Determination of the Molecular Weight

A. Sedimentation Velocity Method.—In this method the molecular weight is given by the equation $M = RTs/D(1 - V\rho)$ in which s is the specific sedimentation velocity or rate of movement of the protein under unit centrifugal field expressed in cm. per second, D is the diffusion constant expressed in cm.^{2} per day, ρ the density of the solution, R the gas constant and T the absolute temperature. The ultracentrifuge designed for low and medium centrifugal fields was employed in all of the runs. A speed of approximately *8400* r.p.m. *(4100* times the force of gravity) was used and each run was continued for seven and a half hours, as this hemocyanin did not move down as rapidly as did that of *Helix.* Since an increase in the concentration of *Helix* hemocyanin solutions has been shown to produce a great depression of the values of the diffusion constant, while affecting but slightly the specific sedimentation velocity, a series of runs with *Limulus* hemocyanin at concentrations varying from 0.03 to 0.98% was deemed necessary. Three different quartz cells were used to secure the necessary thickness of layer of the variously concentrated

---

[4] Svedberg and Nichols, **THIS** JOURNAL, 48, *3081 (1926).*

solutions necessary in order to secure photographs of suitable contrast by means of exposures of from fifteen to forty-five seconds. Thus, the thickness of the layer of solution used was 2 mm. for 0.65 and 0.98% solutions, 8 mm. for the range of 0.09 to 0.12%, and 14 mm. for the more dilute solutions of 0.03 to 0.06%. Imperial process plates were employed. Dilutions of the stock solution into phosphate buffer of PH 6.63 were made immediately before each run. The results of each of the runs are given in Table I, in which Col. 1 gives the concentration of the protein, Col. 2 the specific sedimentation velocity and Col. 3 the diffusion constant. In almost all of the runs fifteen values of each were calculated at successive half-hour intervals. In the case of the diffusion constants the first three values in each series have been omitted and then only the next ten following values have been employed in the calculation of the mean value for each run. The first three values are inaccurate as, since the rate of centrifugation was not great under the centrifugal field employed, no region of pure buffer had yet appeared. The last few values are also in most cases in error because there is then no longer present a region of the solution within which there is no change of concentration with distance from the center of rotation.

[a] This solution was made from the precipitate obtained by dialyzing a 0.03% solution. See section on Reversibility of the Disintegration.

The values of *s* are fairly constant throughout the range studied and show no definite trend with change of concentration. The diffusion values are, however, very irregular and lead to great variations in the molecular weights calculated in each of the runs. Thus the molecular weights vary from 1.31 × 10^6 to 2.05 × 10^6. Such variations point to the possibility that more than one variety of light-absorbing substance may be present in the solutions employed. That such is the case becomes apparent from a consideration of the drift with time which occurs in the successive diffusion constants obtained during the course of several of the runs. Table II gives the values of the diffusion constants obtained at successive half-hour intervals, and these are seen to increase throughout several, but not all, of the runs. As has been previously explained, this excessive blurring of the protein solution–solvent boundary may result from the gradual separation arising from the sedimentation at different rates of two or more proteins of not very greatly different frictional resistances.

The run at the concentration of 0.98% gave no indication of the presence of molecules of varying frictional resistance, but at 0.65 and 0.12% the presence of unlike molecules was clearly indicated. This effect was even more marked in solutions of 0.09%. When, however, the dilution was extended to 0.06%, it tended to disappear. In only one of three runs at this concentration could it be detected with certainty. The presence of such a condition in the two runs at 0.03% cannot be accurately determined as the contrast obtained with reasonable exposures was too small.

That the source of this non-uniformity of the protein molecules may well be a disintegration of the molecules present in the more concentrated solutions may be concluded from measurements of the light absorption in the region between the boundary of the protein and the meniscus of the solution. In the more concentrated solutions, 0.98 and 0.65%, these were never more than traces of light-absorbing material left in this region. The point on the concentration scale corresponding to the galvanometer reading given by the density in the photograph of this portion of the solution is in the following taken as a rough measure of the amount of non-centrifugible material present. The "concentrations" so stated do not give directly the actual concentration of the non-centrifugible material, since the value of $e/$ may conceivably (and in fact does) change as the units are disintegrated. Such "concentration" values have been given in Col. 4 of Table I and show clearly that the amount of non-centrifugible material increases from negligible amounts, 3–5% at 0.65% and over, to 17% upon dilution to 0.09%, and even to very high values in excess of 50% in 0.03% solutions. A possible interpretation of both the time drift in the diffusion constant and the formation of non-centrifugible material is as follows.

Dilution tends to cause a disintegration of the hemocyanin molecules. In the solutions which have been but slightly diluted only a comparatively small amount of non-centrifugible material is formed. This in itself is incapable of producing the drift with time in the diffusion values. At about 0.09 to 0.65% there is present, however, a certain amount of partly disintegrated or highly hydrated material which lowers but slightly the mean specific sedimentation velocity but which is capable of moving at such a rate in the centrifugal field as to produce the observed drift in the diffusion constants. In still more dilute solutions the disintegration process proceeds further, so that there are present fewer of the molecules in the first stage of disintegration (those which are responsible for the drift) and more of the more completely disintegrated and therefore non-centrifugible material. With increasing dilution as the decomposed material becomes more and more non-centrifugible, the drift in the diffusion values tends to disappear. The material which does centrifuge down in these dilute solutions may represent some of the original molecules which have escaped disintegration or may be possibly a more stable denaturation product of the same molecular weight as the protein present in the more concentrated solutions.

The progressive nature of the disintegration change due to dilution is indicated also by an effect noted in the latter part of some of the runs in dilute solutions and not noted in the case of other proteins. In the more dilute runs the successive curves tend to overlap each other in such a way as to indicate that during a given run non-centrifugible material is formed in increasing amounts. In each successive curve the light absorption increases in the region between the protein boundary and the meniscus. That a similar overlapping occurs also in the region in which the concentration is uniform indicates that the sum of the light absorption due to the presence of some large and some small molecules is greater than that due to the same amount of protein when present entirely as large, non-disintegrated molecules. The light absorption experiments reported in a later section point to the same possibility.

If the mean diffusionconstant, 0.0139, of only those runs (two at 0.06% and one at 0.98%) in which no marked drift with time in the values occurred is used, together with mean specific sedimentation velocity obtained from all of the experiments, a molecular weight of 1.90 X 10^6 is found. If only the diffusion constant obtained at 0.98% is used, the value is 2.04 × 10^6.

B. Sedimentation Equilibrium Method.—This method is based upon the attainment of an equilibrium in the cell between the centrifugation of the protein toward the bottom and its diffusion toward the top. A series of values for the molecular weight, M, is calculated by the equation

$$M = \frac{2RT \ln (c_2/c_1)}{(1 - V\rho)\omega^2(x_2^2 - x_1^2)}$$

for a series of portions ($x_2 - x_1$) of the column of liquid. R, T, p and ω have their usual meanings and c_1 and c_2 are the concentrations at the

5.55	5.50	,0790	.0703	9.52 X 10^5

distances x_1 and x_2 from the axis of rotation. If the molecules of the protein solution have uniform frictional resistances, the successive values of M obtained at successive fractions of the way from the top to the bottom of the solution fluctuate irregularly about a mean value. The presence of a second type of molecule makes itself evident by a progressive increase in these values as the bottom of the cell is approached. The indication given by the sedimentation velocity method of the presence of more than one kind of molecule in 0.06–0.09% solutions was confirmed by the finding of a drift in the molecular weight values in an equilibrium run A of Table III. In this run equilibrium was attained in a column of solution, 0.06%, 4 mm. in height after eighty hours of centrifuging at a speed of 1900 r.p.m. The second run in Table III was made by using a 5-mm. column of a somewhat more concentrated 0.15% solution. In this case even after ninety to one hundred hours equilibrium had not been attained, as the concentration–distance curves at seventy-eight, ninety-one and one hundred hours did not coincide. It is probable that as the solution toward the central end of the cell becomes more dilute (0.07%) as equilibrium is approached, a disintegration of the molecules there occurs. Since this continues as the heavier molecules diffuse into this region, new conditions are set up, delaying greatly the attainment of a final state of equilibrium.

The Light Absorption of the Protein.—The light absorption of ***Limulus*** hemocyanin was measured in the visible region by means of a König-Martens spectrophotometer in a 2.86% solution at PH 6.74 and in the ultraviolet region by a modified Judd-Lewis spectrophotometer at a series of concentrations from **0.03** to 0.136%, corresponding to the range employed in the centrifuging experiments. In general the positions of the maxima of the absorption bands agree with those reported for ***Helix*** hemocyanin, although the values of ϵ/c are lower throughout than in the case of the latter protein. This is indicated in Fig. 1, which gives for comparison the light absorption curves of the two proteins. For the *Limulus* hemocyanin the values plotted in the ultraviolet were the mean of determinations at the concentrations 0.09 and 0.136%.

TABLE IV

579	.178	.248	.377	492	.104	.200	.360
556	.176	.249	.395	479	.098	....	.349
538	.165	.238	.401	468	.093	.197	.346

The values of ϵ/c for the visible spectral region are given in Table IV and Fig. 2. It was shown by Svedberg and Chirnoaga that at *PH* **3.8** the maximum for *Helix* was shifted to the red and that the values over the whole region became relatively lower than those obtained at Ph **5.6.**

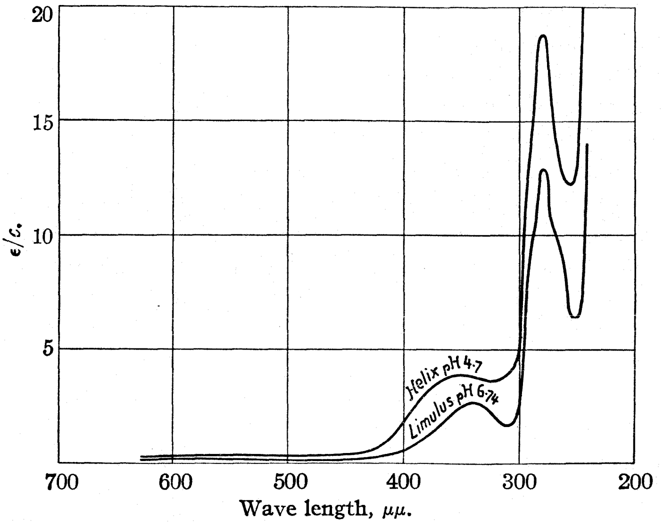

Fig. 1.

These changes accompanied a decomposition of the protein which has since been studied in detail. The values obtained for *Limulus* hemocyanin near its isoelectric point correspond more closely with those for the smaller particles of *Helix* which are present at *Ph* **3.8** than with the values for the larger molecules present at Ph **5.6.** The position of the maximum for *Limulus* hemocyanin also corresponds better with that of *Helix* at **3.8** than at **5.6.**

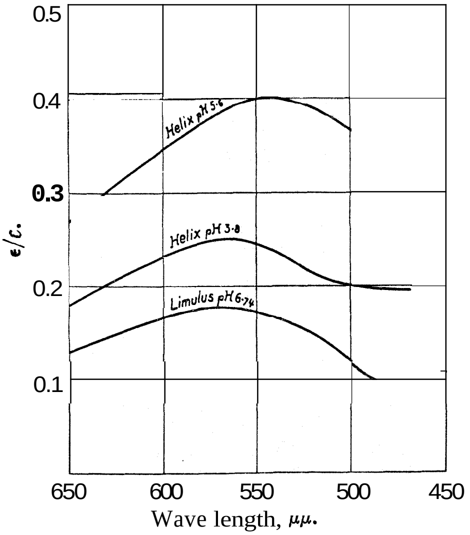

Fig. 2.

Although the accuracy of the measurements made with the Judd-Lewis apparatus in the ultraviolet is not as great as that of those in the visible made with the Konig-Martens spectrophotometer, two curves made at different concentrations of *Limulus* hemocyanin at *Ph* **6.63** are presented in Fig. **3,** as significant differences are shown which are readily reproducible. The measurements plotted indicate that Beer's law does not hold over this concentration range and that the light absorption increases as the concentration is lowered. This change in light absorption occurs in the same concentration range as that in which the sedimentation velocity and equilibrium runs had indicated the protein to undergo a change leading to the production of units of lesser magnitude. This change occurs over the entire ultraviolet region but is most evident on the broad maximum between 360–330μμ. This region is shown on a larger scale in Fig. 4, in which values at several concentrations are plotted. It appears here that the minimum which occurs at about 300–315μμ in the more concentrated solutions is by dilution shifted toward the longer wave lengths.

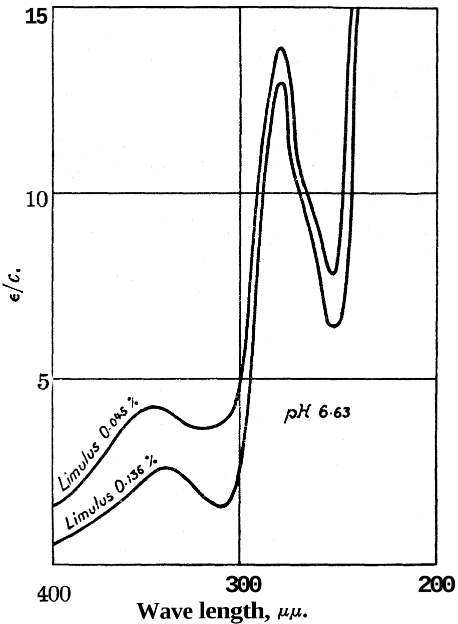

Fig. 3.

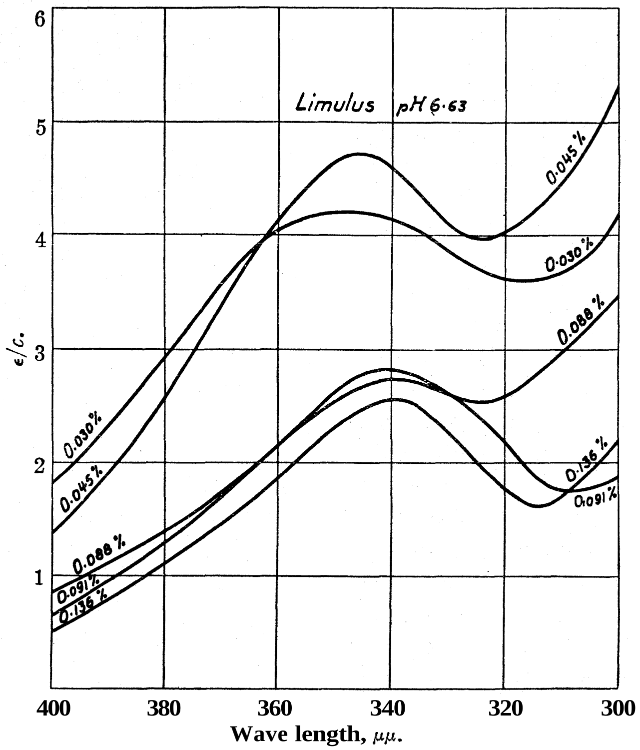
Reversibility of the Decomposition.—The light absorption of a portion of a 0.03% solution of *Limulus* hemocyanin was measured in a 20-mm. cell. After twenty-four hours the remainder of the solution was dialyzed against distilled water until a precipitate appeared. This was then dissolved to form an 0.088% solution at PH 6.63 and the light absorption was again measured. Fig. 4 shows that the light absorption of this solution corresponded to about that which had been previously obtained by using a solution of 0.09%. In a repetition of this experiment the reprecipitated protein was dissolved to form a somewhat stronger solution, 0.13%. In this case the light absorption was that of about a 0.09% solution. The decomposition attending dilution thus appears to be at least in large part reversible.

A similar result was obtained when the reprecipitated, previously diluted hemocyanin was studied in the ultracentrifuge by the sedimentation velocity method. Precipitated hemocyanin obtained by the dialysis of a solution which had been only 0.03% for twenty-four hours was dissolved to form a solution of 0.127%. The light absorption of the non-centrifugible material corresponded to that of a solution about 17.5% as concentrated as that of the solution centrifuged. This was the value previously obtained in a solution of 0.09% (Table I). The effect of dilution was in this case partly reversed by the recombination which occurred during the dialysis, which resulted in the production of a precipitate of the original protein. In the cases in which the reversibility was not entirely complete it is probable that dialysis had not been continued for a sufficient time; the suspension removed from the bag and brought into solution by the addition of phosphate solutions may have been contaminated by some as yet uncombined material.



Pig. 4.

Discussion

Evidence has been presented from sedimentation velocity and equilibrium measurements in the ultracentrifuge and from measurements of the light absorption in the ultraviolet that a decomposition occurs in solutions of *Limulus* hemocyanin when diluted beyond 0.6%. The mechanism of the change (hydrolysis, disassociation or other type of splitting) has not been determined. The occurrence of such an effect of dilution upon the proteins is not unprecedented, for a similar change has been described in the case of serum albumin.[5] That the change occurs within the range of concentrations most suitable for the photographic recording of the motion of the protein in the centrifugal field complicates

---

[5] Svedberg and Sjögren, This Journal, 50, 3318 (1928).

greatly the molecular weight determination. If the mean of all of the diffusion constants obtained in each of the sedimentation velocity runs is employed in determining the molecular weight, a value of 1.60×10^6 results, which multiplied by 3.12 gives 4.99×10^6, a value very close to the molecular weight 5.08×10^6, which has been determined for the *Helix* hemocyanin. Such a comparison is perhaps possible because the error introduced by the mean drift in the diffusion constants with time is about that observed in the sedimentation of *Helix* hemocyanin at *P*H 4.7. It should, however, only be permissible to make such a comparison at either the isoelectric points of the two proteins or at regions so far removed from each of them that the ratio of charged to uncharged molecules is the same in each case. Only by so doing would it be possible to exclude the effects of the charges upon the ions which depress the diffusion constants, making the values of the molecular weights abnormally high. Since the reaction 6.63 employed in this work is probably less than 0.3 of a Sorensen unit alkaline to the isoelectric point, a comparison may be made of the molecular weight of the *Limulus* hemocyanin obtained by using only those diffusion constants free from drift, 2.04×10^6, with the apparent molecular weight of *Helix* hemocyanin at a PH 0.3 unit alkaline to its isoelectric point, or 5.5. If the values 1.90×10^6 or 2.04×10^6 are multiplied by 3.12 the values 5.93×10^6 or 6.36×10^6 are obtained. The apparent molecular weight of *Helix* hemocyanin at 5.62 has been found to be 6.19×10^6. The molecular weight of *Limulus* hemocyanin may then be stated to be, within the limits of experimental error, one-third that of the hemocyanin of *Helix.*

An attempt was made to calculate the diffusion constant for this protein by the aid of the Einstein equation

$$D = \frac{RT}{N} \times \frac{1}{6\pi r\eta}$$

in which R, T and N have their usual meanings and η is the viscosity of water at 20° expressed in absolute units. The radius, r, of the particle is calculated to be 8.398×10^{-7} from the molecular weight and density of the protein on the assumption that the molecules are spherical. As the mean value for the diffusion constant in those runs in which there was no drift with time was 0.0139, while the value obtained by the calculation outlined is 0.0214, it is evident that there is a large discrepancy. It is therefore probable that the assumption upon which the calculation was made, that is, that the molecules are spherical, is without justification. There is thus an analogy between these two hemocyanins and the proteins phycoerythrin and phycocyan. In each case the molecules of greater molecular weight are spherical. Phycocyan with half the molecular weight and the same diffusion constant as phycoerythrin and *Limulus* hemocyanin with one-third the molecular weight of *Helix* hemocyanin and a diffusion constant approximately that of the latter, each have molecules diverging widely from the spherical shape.

Summary

1. Measurements of the molecular weight of the hemocyanin of the horseshoe crab *Limulus polyphemus* have been made in dilute phosphate buffer solution at P_H 6.63 in concentrations of 0.03–0.09% of protein by the sedimentation velocity and the sedimentation equilibrium methods in the ultracentrifuge.

2. Both methods indicate that at concentrations of about 0.06–0.1% the protein undergoes decomposition.

3. The existence of this decomposition has been confirmed by measurements of the ultraviolet absorption, as the values of ϵ/c increase with dilution in this range of concentrations.

4. The decomposition is largely if not completely reversible and a protein of the same molecular weight and ϵ/c as that originally used may be precipitated from the dilute solutions by removing electrolytes by dialysis.

5. The sedimentation velocity method indicates for the hemocyanin of *Limulus polyphemus* a probable molecular weight of 2.04×10^6 under the conditions described.

THE INFLUENCE OF THE HYDROGEN-ION ACTIVITY UPON THE STABILITY OF THE HEMOCYANIN OF HELIX POMATIA

BY THE SVEDBERG AND FRANCIS F. HEYROTH[1]

RECEIVED OCTOBER 2, 1928 PUBLISHED FEBRUARY 5, 1929

The previously reported determinations by ultracentrifugal methods[2] of the molecular weight of the hemocyanin isolated from the blood of the vineyard snail, *Helix pomatia*, were made upon solutions buffered to P_H 4.7, which is not far removed from P_H 5.2, the isoelectric point of the protein. This reaction was adopted to obviate the disturbing variation in the diffusion constant which in preliminary experiments at P_H 8.0 had been found to vary approximately inversely as the centrifugal force applied. As it was also noted that at P_H 3.8 the hemocyanin molecule appeared to break up into smaller units of undetermined size, a further study of this protein was deemed advisable in order to determine the region within which its huge molecules (of molecular weight 5,000,000 at P_H 4.7 in solutions containing 0.09% of protein) are stable. A similar series

[2] Svedberg and Chirnoaga, THIS JOURNAL, 50, 1399 (1928).

of measurements of the molecular weight of carboxyhemoglobin[3] at various hydrogen-ion activities had indicated that protein to be stable over the range from *P*H 6.0 to 9.05.

Experimental

Material Used.—A suspension of dialyzed hemocyanin crystals prepared by Chirnoaga for the previously reported investigation and there described in detail was employed. The crystals were dissolved in 100 cc. of distilled water to form a 1.78% solution by the aid of only 1.5 cc. of an acetic acid–sodium acetate buffer of *P*H 4.7. Just before starting each of the centrifuging experiments, a 1:20 dilution was made from this stock solution into a buffer solution of the desired reaction. The buffers used were sodium acetate–acetic acid mixtures over the range of PH 5.62 and less, and mixtures of the primary and secondary sodium phosphates over the more alkaline range. In the former case the sodium-ion concentration was kept constant at 0.02 molar and the amount of acetic acid varied to give the required *P*H. In the case of the phosphate buffers, the ionic strength of the solution was maintained constant at 0.0225, the relative volumes of *M*/15 solutions of the two salts necessary to give the desired reactions being calculated by the method of Cohn.[4] In most cases the reported *P*H values were, however, determined electrometrically upon additional samples of the solutions prepared as for the actual runs. The concentration of the protein used was 0.089% in all except the runs at *P*H 3.8, in which it was somewhat higher. The value 0.738 at 20° was used for the partial specific volume in those few instances in which values for the molecular weight are reported.

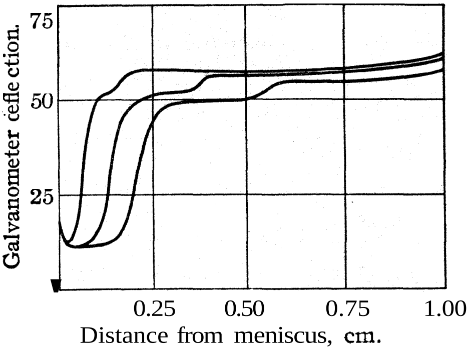

Fig. 1.

The material used contained a small quantity of a substance which moved in the centrifugal field somewhat more rapidly than the hemocyanin proper. This made itself evident by producing a second sedimentation boundary, appearing at the top of the usual concentration–distance curves, as shown in Fig. 1. This contamination in no way altered the sedimentation of the hemocyanin, as the heavier material was centrifuged down during the early part of each run. As may be seen from the results obtained at *P*H 4.7, reported in Table I, the specific sedimenta-

[4] Cohn, *ibid.*, 49, 173 (1927).

tion velocity and diffusion constant (and therefore molecular weight) checked very well with the values previously published and included in the table for comparison. For experiments made some months later upon the reversibility of the disintegration process to be described below, a fresh solution was employed, prepared by redissolving the precipitate obtained by redialyzing what remained of the former solution. This solution was free from the heavier material, so that in a run at P_H 4.7 only one boundary was observed.

The Determination of Molecular Weights.—The sedimentation velocity method was employed exclusively in this work. It is based upon the equation, $M = RTs/D(1 - V\rho)$, in which s is the specific sedimentation velocity or rate of movement of the boundary under unit centrifugal force in cm. per second, D is the diffusion constant of the protein in cm.^{2}/sec., V the partial specific volume of the protein, ρ the density of the solution, R the gas constant, and T the absolute temperature.[5] Except for the runs at P_H 3.8 and **3.9,** which were performed in the oil-turbine centrifuge operated at 42,000 and 25,000 r.p.m. (centrifugal force 102,000 and 36,000 times the force of gravity), respectively, the runs were all made at a speed of approximately 8400 r.p.m. (centrifugal force 4100 times the force of gravity) in a new ultracentrifuge designed for low and medium centrifugal fields.

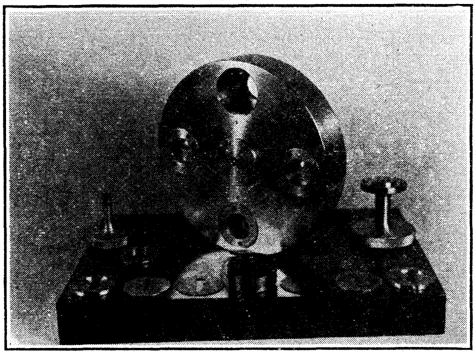

Fig. 2.

The cells employed were each made from two round quartz plates **30** mm. in diameter and **5** mm. thick, cemented to a third plate of the same diameter and 8 mm. thick. This had cut in it a sectorial aperture of 5°. The cell was cemented to a steel collar having an opening coincident with the opening of the sectorial cell. The steel collar containing the cell was supported by a system of sectorial disks and diaphragms in a hole drilled in the rotor of the centrifuge. Actually only a 3° sector was exposed to radiations passing through the cell when supported in the rotor. The latter, 15 cm. in diameter and **3** cm. in thickness, was arranged to receive four cells. In practice, however, only two cells were used at a time, the spaces for the other two being filled by aluminum blanks. Fig. **2** shows the rotor, one of the cells, and the various disks and diaphragms. The rotor was supported upon a vertical rotating shaft carrying two ball bearings, which in its turn was supported by a flexible steel rod. The energy of rotation was delivered by a motor and transferred to the rotating shaft by an endless screw device and a system of special couplings. To prevent heating the rotor was surrounded by hydrogen at atmospheric pressure, confined within a casing about the

---

[5] Svedberg and Nichols, THIS JOURNAL, 49, 2920 **(1927).**

rotor. To further ensure constancy of the temperature during each run the casing within which the rotor turned was immersed in a water thermostat regulated to maintain a temperature of 20° (Fig. **3**).

The casing of the centrifuge was also provided with two quartz windows, each fitted with an electromagnetic shutter. The optical system used is shown diagrammatically in Fig. 4. The ultraviolet radiations from a quartz mercury vapor lamp B, with matte surface for uniformity of illumination, mounted in a water-cooled lamphouse **A** were made to pass a 6-cm, water filter C, an 8-cm. bromine filter D, and an 8-cm. chlorine filter E. The radiations, which were thus restricted to those with wave lengths shorter than $290\mu\mu$,[6] were reflected vertically by the prism F through the cell I carried by the rotor H of the centrifuge G. The quartz lens K, of focal length **64.5** cm. and provided with an aperture of $f/25$, threw an image of the sectorial aperture in double natural size upon a photographic plate (Imperial Process) in a camera mounted in a room above that containing the centrifuge. The length of exposure was thirty seconds, except in two runs at PH *8.2* and **3.4,** in which shorter times were used.

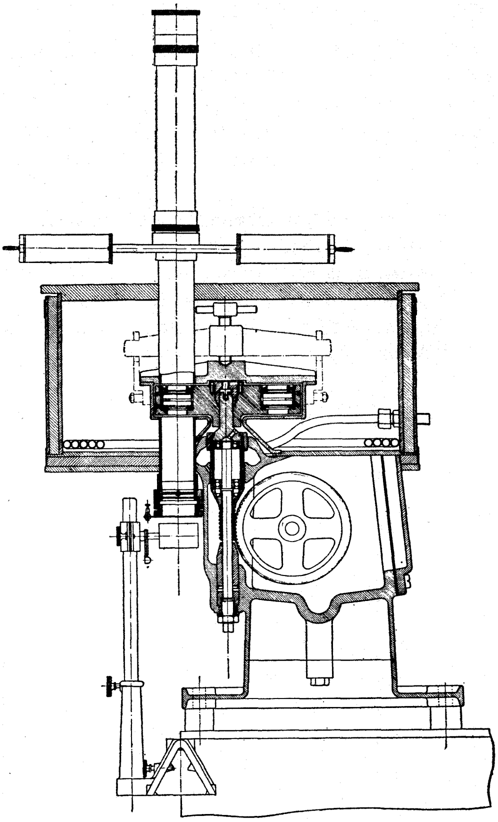

Fig. **3**.

Table I presents the results obtained in each of the runs. In it Col. 1 gives the PH, Col. 2 the specific sedimentation velocity and Col. **3** the diffusion constant, obtained from the blurring of the boundary. In Col. 4 are given molecular weights for those of the runs in which obvious disintegration of the molecules did not occur. The variation of s and D with PH is shown graphically in Fig. 5, dotted lines being employed in the regions in which disintegration is believed to have occurred.

Certain of the values for the "diffusion constant" are enclosed in parentheses to indicate that these values cannot be considered as representing the diffusion of molecules of uniform size. Table II and Fig. 6 illustrate the criterion by means of which it may be determined whether, in a given run, the concentration–distance gradients at the protein solution–solvent boundaries at successive time intervals may be ascribed entirely to the

diffusion of the molecules against the force of centrifugation. If this is true, as is approximately the case, in Table II from P_H 4.5 to 7.46 the successive calculated values of D fluctuate about a mean which may be taken as the diffusion constant. If, however, the concentration-distance gradients at the boundaries are in part due to the increasing separation of molecules of not very different frictional resistances moving toward the bottom of the cell at different rates or moving downward at the same and diffusing backward at different rates, the successive calculated D values increase with some fluctuations throughout the run. It is the mean values of such runs (obtained at P_H values < 4.7 and > 7.46) which have been placed in parentheses, as they cannot be

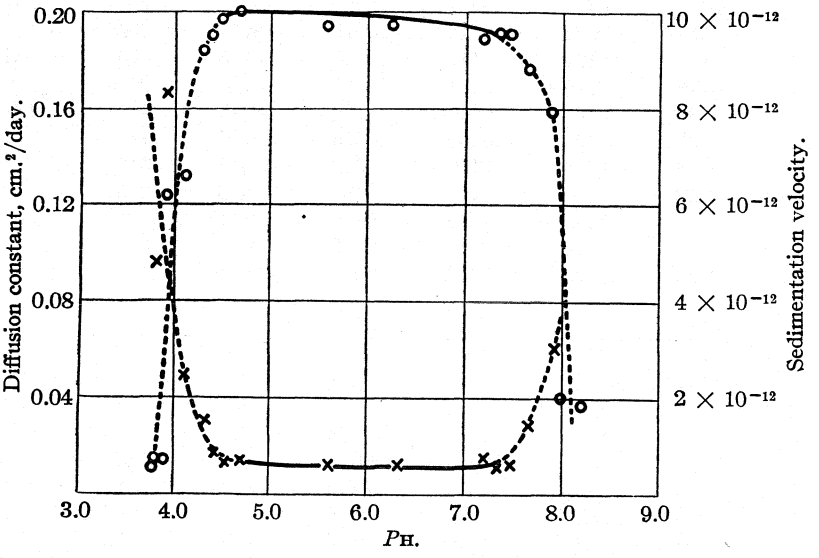
[a] In calculating the mean values the first value of each series was omitted, as during the first thirty minutes sedimentation had not progressed far enough to give a boundary from which the diffusion constant could be accurately obtained.

used for the calculation of molecular weights. In Fig. 6 lines have been drawn through the successive D values in three of the runs plotted on a scale which magnifies any drift: the slopes of the curves, plotting each in this manner (only three are given in Fig. **6** to avoid confusion), indicate a gradual loss of the uniformity of the molecules which exists near the isoelectric point as the solutions are made increasingly acid or alkaline. When the limits of the range **4.7–7.46** are exceeded, the slopes of such lines increase enormously. The increasing D values shown in the dotted portions of Fig. 5 are thus in large part due to this separation of unlike particles and in small part to the greater diffusibility of the smaller ones present.

Discussion of Results

Fig. 5 shows that the specific sedimentation velocity remains approximately constant at **9.61–10.00** × 10^{-12} between **PH 4.5** and **7.36;** at about these limits it decreases at first gradually and then very rapidly. The protein is thus stable between a reaction not greatly acid to its isoelectric point and one which corresponds approximately with that (7.4–7.8) believed to prevail in the snail's blood.[7]

The decrease in the rate of movement in the centrifugal field at reactions acid to PH 4.5 and alkaline to PH 7.36 may be regarded as indicating the presence of increasing numbers of smaller units resulting from a disintegration of the hemocyanin under the influence of the hydrogen or hydroxyl ions. The *s* values given on the descending dotted portions of the curve are therefore only to be regarded as mean sedimentation rates for mixtures in varying proportions of particles of various sizes. In support of the view that molecular disintegration occurs in these regions may be mentioned four experimental facts.



××××, diffusion; ○○○○, sedimentation.

Fig. 5.

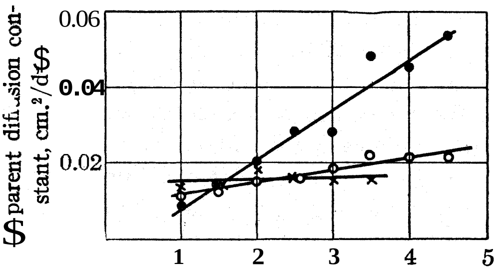


Fig. 6.

1. The previously mentioned drift in the apparent diffusion constants with time becomes enormous here.

2. The concentration–distance curves obtained during the early portion of a run at PH 3.9 and 25,000 r.p.m., shown (uncorrected for the sector shape of cell and for in-

creased acceleration with distance) in Fig. **7**, exhibit two boundaries moving at different rates and corresponding to different particle sizes or to two mixtures each composed of particles not greatly unlike. A similar effect was noted in the two most alkaline runs.

3. Runs made with solutions which had been kept at *PH* 3.8 for differing periods of time give different values for the specific sedimentation velocity. The decrease with time suggests that the acid decomposition which is effected in large part very rapidly, continues at a lower rate. Thus *s* determined immediately after bringing the protein to *PH* **3.8** was **0.739** $\times 10^{-12}$. After nine days at this reaction, it decreased to 0.574 $\times 10^{-12}$.

4. The Tyndall cone is much diminished in intensity in the acid and alkaline solutions.

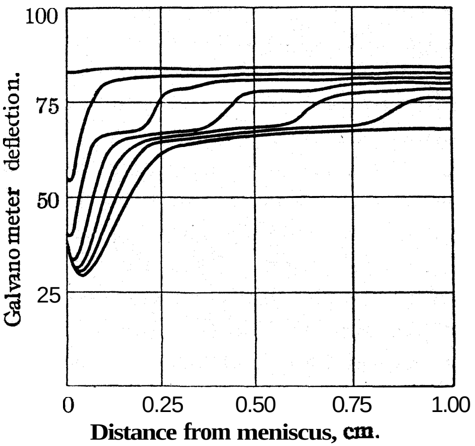

Fig. 7.

Our value of approximately 2.0 for *s* at *PH* 8.0 was much lower than the values **5.63–6.60** $\times 10^{-12}$ found in the previous investigation. An explanation is afforded by the run at *PH* 8.2, in which the form of the sedimentation curves indicated the presence of a small amount of material moving with a velocity *s* (8.24 X 10^{-12}) which is somewhat less than that of the protein, near its isolectric point, together with some material of *s* about 2.2 X 10^{-12}, and a large quantity of material non-centrifugible at 8000 r.p.m. The presence of the latter was indicated by the fact that the light absorption by the liquid between the protein boundary and the meniscus was much greater than that of the buffer solvent photographed in the same cell. It corresponded to that of a protein solution **40%** as concentrated as that (0.089%) used in the experiment. Solutions in the neighborhood of *PH* **8.0** thus appear to contain particles the sizes of which are distributed about three

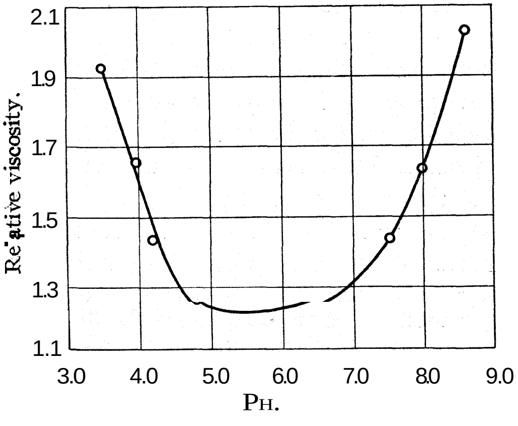

Fig. 8.

values. The relative amounts of the material in each of these magnitudes appears to vary rapidly with time and slight alterations in P_H. The s values on the alkaline side are somewhat less reproducible than those on the acid side of the stability region.

In Fig. 8 is reproduced the curve obtained by Stedman and Stedman[8] for the relation of the viscosity of the dialyzed serum of the snail, *Helix,* to the P_H. The curve shows increases in the relative viscosity amounting almost to double, in exactly those P_H regions in which the specific sedimentation velocity falls off most sharply. These investigators furnish no measurements between P_H 4.7 and 7.3. It might at first be supposed that the increased viscosity retards the movement of the protein under the centrifugal field. It is, however, the viscosity of the solvent and not that of the protein solution as such which is believed to influence the rate of centrifugation. Even though this were not the case, the viscosity changes in the dilute solutions employed would be insufficient to account for the observed drop in the sedimentation velocity.[9] The rising values for the diffusion constant in these regions would be entirely inexplicable upon such a supposition. Sufficient independent evidence has also been presented to indicate that a disintegration of the molecules actually occurs in these regions.

It is therefore possible that, on the other hand, the dispersion of the protein into smaller units may have been in part at least responsible for the increase in viscosity observed by Stedman and Stedman. An increase in the viscosity of sulfur sols attending a diminution in the size of the particles present has been noted by Odén.[10]

To the suggestion of Pauli[11] that the increased viscosity of the solutions of proteins away from their isoelectric points is due to increased hydration accompanying the formation of the protein ions, may be added, at least in the case of hemocyanin, the possibility that it may be in part due to the increase in dispersion resulting from a disintegration of the molecules. The analysis by Smoluchowski[12] of the limits of applicability of the Einstein equation for the variation of the viscosity of a colloidal suspension with its volume concentration indicates that it may only be expected to hold when, among other conditions, the ratio of the particle radius to the distance between the particles is small. As in snail blood the diameter of the hemocyanin molecules is about two-thirds the distance between the

---

[8] Stedman and Stedman, *Biochem. J.,* 21, 541 (1927)

[9] The non-centrifugible material present at P_H 8.0 may, however, be considered to be a portion of the solvent within which the heavier units are moving, and the increase in viscosity which its presence imparts to the buffer solution may aid in lowering the sedimentation rate of the larger unattacked or partly disintegrated molecules.

surfaces of the adjacent molecules, the Einstein equation need not be expected to apply to viscosity changes in the serum studied by Stedman and Stedman, and accordingly its implication that the degree of dispersion of the particles is without influence upon the viscosity need not be binding.

The determination of the magnitudes of the particles formed by the acid or alkaline disintegrations of the hemocyanin must be postponed until greater centrifugal fields are available. The results of sedimentation experiments at 42,000 r.p.m. indicate that even at PH 3.8 all of the light-absorbing material present occurs in particles of size sufficient to move measurable distances in the short times within which runs are completed, since the light absorption in that portion of the liquid between the protein boundary and the meniscus corresponds to that of the pure buffer employed as solvent. This appears to exclude the possibility that the acid decomposition proceeds far enough to result in the formation of amino acids, the motion of which would not be measurable under the conditions described. The light-absorbing units which result from the alkaline disintegration are not, however, as completely removed from that part of the liquid from which most of the protein molecules have been centrifuged. Small amounts of such non-centrifugible material were noted in every run made at a *PH* greater than 7.4, so that it is probable that the disintegration induced by hydroxyl ions proceeds somewhat further than that due to hydrogen ions.

The **Reversibility** of the Disintegrations.—Some months after the conclusion of these experiments a number of additional runs were made to determine whether or not the acid breakdown of the hemocyanin is reversible. Crystals freshly dialyzed from the remainder of the stock solution used in the earlier experiments were dissolved by the addition of a small amount of buffer solution to form a stock solution containing 1.66% of protein at *PH* 4.7. When diluted to 0.087%, this was found free from material non-centrifugible at 8000 r.p.m., and its specific sedimentation velocity checked well with that previously obtained. One of the runs was made at *PH* 3.4, attained by adding only the acid of the acetic acid–sodium acetate buffer required to make a similar dilution at *PH* 4.7. At 8000 r.p.m. only a small fraction of the light-absorbing material present underwent sedimentation, and this at a rate which could be only roughly estimated as 0.8 that of the hemocyanin in its stable region. The light absorption in the region which might be expected to contain only buffer solution corresponded instead to that found in *a* solution containing 52% of the protein present in the solution used. Another sample which had stood at PH **3.4** for about eight hours was brought to *PH* 4.7 by the addition of the requisite amount of sodium acetate. The Tyndall cone, which had not been entirely destroyed by the acid treatment, was markedly increased in intensity and a small amount of a coarse precipitate was produced at the same time. After several hours, a run showed the presence of non-centrifugible material corresponding in light absorption to a solution containing but 19% (21% in a second experiment) of the amount of hemocyanin in the original solution, indicating that the acid decomposition had been partly reversed. In a third experiment, in which the acid treatment was maintained for only one hour before restoring the PH to 4.7, a large proportion of molecules of the original size were reformed, and the amount of non-centrifugible material was correspondingly less, as the light absorption equaled that of a solution of 12% of the original protein concentration. In all three of these experiments the forms of the sedimentation curves indicated the presence of smaller particles in admixture. It thus appears that the first products which result from the acid-induced decomposition of the hemocyanin may reunite when the solution is restored to PH values at which it is stable. Such a process is attended by some loss of material by precipitation and is never quite complete. On maintaining the acid reaction for longer periods a further irreversible splitting appears to ensue.

The Region of Stability.—At PH 4.7[13] both the specific sedimentation velocity and the diffusion constant have maximal values. As the PH is made increasingly acid to this or increasingly alkaline beyond the isoelectric point, both of these values decrease progressively and gradually. This effect may possibly be explained as due to progressively increasing hydration of the protein molecules under the influence of the acid or alkali. The theoretical effect of hydration would be a lowering of both the specific sedimentation velocity and the diffusion constant by the same fraction of their values for material at the isoelectric point. Calculations showed that the new values to be expected were each of the molecules covered by a monomolecular layer of water, would be in the neighborhood of 97.4% of the corresponding values at the isoelectric point. The decreasing values of s (Table I), as the PH values at which decomposition occurs are approached, are, within the limits of accuracy of these measurements, in accord with the supposition that the decomposition of the molecules is preceded by their hydration.

The diffusion constants also diminish from the region of the isoelectric point to the regions of beginning decomposition. The decrease is, however, greater than that of the sedimentation velocity. This discrepancy is somewhat obscured by the fact that even in this region there is a slight and gradually increasing drift in the diffusion values obtained at successive time intervals. Thus each of the mean values plotted in Fig. 5 is slightly too great, the errors increasing as the regions of decomposition are approached. This excess diminution of the diffusion constants over that

---

[13] As this series of measurements was completed before it was learned that the isoelectric point of the protein is *5.2,* no run was performed at that PH.

to be expected as the result of hydration, while apparently slight, is nevertheless sufficient to lead to relatively great errors (20%) in the molecular weights calculated by their aid. The diminution in the diffusion may possibly be explained as due to the mutual interaction of the charges upon the ions which are formed in increasing relative amounts as the reaction is brought away from the isoelectric point. The great size and therefore proximity of the ions would render such an effect likely. Such interionic forces would not alter the rate of sedimentation of the molecules and ions as a group. In this respect they would be analogous to or identical with the forces postulated in the previous communication to account for the diminished diffusion and only slightly diminished sedimentation rate observed in hemocyanin solutions at *P*H 4.7 as the concentration of the protein is increased. The diminution of diffusion resulting from the presence of charged ions in close proximity tends to obscure itself in the graphical records of the sedimentation of the protein, as it may itself be in part responsible for the slight drift with time in the diffusion values obtained in this region. The greater diffusibility of the uncharged molecules over that of the ions would tend to cause an increase in the blurring of the boundary with time.

Summary

1. The variation of the specific sedimentation velocity and the diffusion constant of the hemocyanin of Helix *pomatia* have been measured over the range of PH from 3.8 to 8.2.
2. Hemocyanin in 0.089% concentration in dilute acetate and phosphate buffer solutions from PH 4.5 to 7.4 possesses a molecular weight of five million.
3. As these limits of PH are approached, the protein molecules become hydrated and as the limits are exceeded rapidly undergo disintegration into smaller particles of undetermined magnitude.
4. The acid disintegration is in its earliest stages reversible, but the disintegration of the products first formed continues slowly and is in its later stages irreversible.
5. The *P*H ranges within which the disintegration occurs are the same as those within which the viscosity of snail serum is known to increase rapidly.

A NEW SERIES OF SULFONEPHTHALEINS

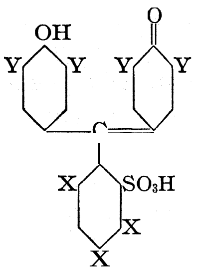
BY WILTON C. HARDEN WITH NATHAN L. DRAKE

RECEIVED OCTOBER 4, 1928 PUBLISHED FEBRUARY 5, 1929

The sulfonephthaleins together with the phthaleins constitute a group of compounds that has long been of much interest. Since the synthesis of the first members of the former class by Remsen and his co-workers,[1] they have been extensively used both as indicators and as diagnostic aids in clinical and experimental medicine. Orndorff and his students,[2] Clark and Lubs,[3] Cohen[4] and others have made important contributions to this field of chemistry.

The sulfonephthaleins, in general, and phenolsulfonephthaleins in particular, have been much used as a means of testing the renal function, since they are eliminated from the blood stream after intravenous injection almost quantitatively through the kidneys.[5] Those phenolphthaleins, on the other hand, which contain four halogens in the phthalic acid residue are eliminated from the blood stream through the liver and hence are used as tests of hepatic function.[6]

Having these facts in mind, it was thought that a study of the chemical behavior and pharmacological action of those sulfonephthaleins having four halogens in the o-sulfobenzoic acid part of the molecule would be of interest. The recent synthesis of the di- and tetra-halogenated o-sulfobenzoic acids and their anhydrides by Twiss[7] has made possible the preparation of such a series of compounds. The purpose of the present paper is to describe a limited number of compounds of this class. Their general formula may be represented as shown in the accompanying diagram, where X is any halogen and Y may be hydrogen or halogen.



No attempt has been made to prepare all the possible members of this class, the authors having been content to limit themselves to the following compounds: phenoltetrachlorosulfonephthalein, phenoltetrabromosulfonephthalein, o-cresoltetrachlorosulfonephthalein, *o*-cresoltetrabromosulfone-

phthalein, tetrabromophenoltetrabromosulfonephthalein, tetrabromophenoltetrachlorasulfonephthdein, dibromo-*o*-cresoltetrabromosulfonephthalein, dibromo-o-cresoltetrachlorosulfonephthalein, dibromophenoltetrabroinosulfonephthalein and o-cresoltetra-iodosulfonephthalein. Phenoltetra-iodosulfonephthaleinhas also been prepared but is not included in the present investigation. In naming these compounds the author has adopted the usual custom, that is, halogen preceding the phenol indicating its presence in the phenolic part of the molecule and halogen following the phenol indicating its presence in the o-sulfobenzoic acid part.

Experimental Part

Preparation of **Phenoltetrachlorosulfonephthalein.**—Eleven g. of phenol was heated to 110° in a small three-necked flask; 16.1 g. of tetrachloro-*o*-sulfobenzoic acid anhydride was then added and the mixture stirred until all had dissolved. Eight cc. of fuming stannic chloride was then added and the temperature raised to 120–130°. Heating was continued at this temperature for eight hours, with mechanical stirring. The melt was then poured into water and steam distilled to remove excess phenol. After distillation the dye solution was made alkaline with sodium carbonate and allowed to stand overnight. It was then filtered to remove the precipitated tin and poured into 1:1 hydrochloric acid with rapid mechanical stirring. The crude dye was thus precipitated as a red or pink amorphous powder. It was filtered off, redissolved in sodium carbonate, filtered and again precipitated with hydrochloricacid; yield, 11 grams (45%). A small portion was then crystallized from hot benzene, in which it is difficultly soluble, dried and analyzed.

Anal. Calcd. for $C_{19}H_{10}O_5Cl_4S$: Cl, 28.85; S, 6.50. Found: Cl, 28.64; S, 6.58.

Preparation of **Tetrabromophenoltetrachlorosulfonephthalein.**—Four and nine-tenths g. of crude phenoltetrachlorosulfonephthalein prepared as described above was suspended in 50 cc. of glacial acetic acid. A slight excess over the calculated amount of bromine dissolved in glacial acetic acid was introduced through a dropping funnel while the suspension was stirred mechanically. The suspended dye slowly dissolved upon addition of the bromine and when all had been added the flask was allowed to stand uncorked at room temperature overnight. A small crop of crystals settled out; these were filtered off, the solution wsa warmed on a water-bath and the hydrobromic and some of the acetic acid removed by passing a current of air through the solution. When the solution had been reduced to about half its original volume, the flask was stoppered and allowed to cool in the ice box. The brominated dye crystallizes as salmon-colored crystals; yield 6.5 (81%). After two recrystallizations from acetic acid a sample analyzed as follows.

Anal. Calcd. for $C_{19}H_6O_5Cl_4Br_4S$: Cl, 17.56; Br, 39.58; S, 3.96. Found: Cl, 17.10; Br, 39.90; S, 3.61.

Preparation of **Phenoltetrabromosulfonephthalein.**—Fifteen *g.* of phenol was heated in an oil-bath for half an hour at 110°, 25.85 g. of the anhydride of tetrabromo-*o*-sulfobenzoic acid was added, the mixture well stirred, 8 cc. of fuming stannic chloride added and the mixture heated to 130–140° for seven hours. The solid melt thus obtained was subjected to steam distillation, treated with sodium carbonate and hydrochloric acid as in the case of the tetrachloro compound, dried and weighed; yield, 20 g. (60%). A small portion was repeatedly recrystallized from hot benzene as before.

Anal. Calcd. for $C_{19}H_{10}O_5Br_4S$: Br, 47.70; S, 4.70. Found: Br, 47.56; S, 4.55, 4.71.

Preparation of **Tetrabromophenoltetrabromosulfonephthalein.**—Six and seven-tenths g. of the phenoltetrabromosulfonephthalein prepared as above was suspended in **50** cc. of glacial acetic acid, and **7** g. of bromine in **20** cc. of glacial acetic acid was added slowly with constant stirring. The solution was allowed to stand at room temperature overnight; hydrobromic acid was then removed by a current of air, the solution cooled, filtered, the cream-colored crystals recrystallized twice from acetic acid, dried at 80° and analyzed.

Anal. Calcd. for $C_{19}H_6O_5Br_8S$: Br, **64.77;** S, **3.23.** Found: Br, **64.68, 64.48; S, 3.41, 3.40.**

Preparation of **o-Cresoltetrachlorosulfonephthalein.**—Twelve g. of o-cresol was heated just as in the previous condensations, and **16.1** g. of the anhydride of tetrachloro-o-sulfobenzoic acid added. No condensing agent was used, previous experience having shown it to be unnecessary in most condensations with o-cresol. The mixture was heated for two hours at **120–130"** and then the temperature was slowly raised (one hour) to 160° and maintained at this point for an additional two hours. Purification was carried out as in previous condensations, the crude dye being crystallized from hot benzene in greenish-red iridescent plates; yield, **19** g. **(73%).** After one recrystallization, analysis gave the following results.

Anal. Calcd. for $C_{21}H_{14}O_5Cl_4S$: Cl, 27.27; S, **6.15.** Found: **Cl, 27.16;** S, **6.14.**

Preparation of **Dibromo-o-cresoltetrachlorosulfonephthalein.**—Six g. of o-cresoltetrachlorosulfonephthalein prepared as above was suspended in **50** cc. of glacial acetic acid and the calculated amount of bromine in glacial acetic acid added as before. In several minutes a large crop of white crystals had formed. On standing overnight in the ice box another portion crystallized out. The portions were united and recrystallized three times from acetic acid.

Anal. Calcd. for $C_{21}H_{12}O_5Br_2Cl_4S$: Br, **23.57; Cl, 20.92;** S, **4.72.** Found: Br, **23.92; Cl, 20.61;** S, **4.74.**

Preparation of **o-cresoltetrabromosulfonephthalein.**—The condensation was carried out as in the case of the o-cresoltetrachloro compound, using **14** g. of o-cresol and **25** g. of the anhydride of tetrabromo-o-sulfobenzoic acid; yield, **28** g. **(82%).** Repeated crystallization from benzene gave a product which analyzed as follows.

Anal. Calcd. for $C_{21}H_{14}O_5Br_4S$: Br, **45.80;** S, 4.58. Found: Br, **45.48;** S, **4.56.**

Preparation of **Dibromo-o-cresoltetrabromosulfonephthalei—Foe** g. of the material just described was suspended in **100** cc. of glacial acetic acid, the calculated amount of bromine in glacial acetic acid added and the mixture treated as in previous brominations. In this case, however, crystallization from acetic acid did not give a pure product, so the crystals were dissolved in a small amount of hot acetone, **5** g. of "Norite" and **2** cc. of acetic acid added and the mixture boiled for one hour under a reflux condenser. The solution was then filtered while hot and concentrated by evaporation on the water-bath. The dye came out as a pink amorphous powder, which was dried and again crystallized from acetic acid. By this method a product giving the following analysis was obtained.

Anal. Calcd. for $C_{21}H_{12}O_5Br_6S$: Br, **56.03;** S, **3.73.** Found: Br, **56.12;** S, **3.65.**

Preparation of **o-Cresoltetra-iodosulfonephthalein.**—Eighteen g. of o-cresol was heated in an oil-bath to 110–120° and **20** g. of tetra-iodo-o-sulfobenzoic acid anhydride was added and the mixture well stirred. Ten cc. of stannic chloride and **0.5** cc. of sulfuric acid were then added and the mixture heated at 120–130° for five hours, being stirred mechanically. The melt was then poured into water and steam distilled to remove excess cresol. The crude dye was then repeatedly dissolved in dilute sodium hydroxide and precipitated by hydrochloric acid. A small fraction was recrystallized several times from acetic acid, in which it is only slightly soluble.

And. Calcd. for $C_{21}H_{14}O_5I_4S$: I, 57.32; S, 3.61. Found: I, 57.25; S, 3.61,

Preparation of Dibromophenoltetrabromosulfonephthalein.—Twenty g. of o-bromophenol (Eastman) was heated at 110° and 26 g. of tetrabromo-o-sulfobenzoic acid anhydride was added. When the anhydride had completely dissolved, 5 cc. of stannic chloride was added and the temperature raised to 120–130° and kept at this point for twelve hours. Excess bromophenol was removed by steam distillation and the dye partially purified by repeated solution in sodium carbonate and precipitation by means of hydrochloric acid. The dye is very soluble in water and appreciably soluble in dilute hydrochloric acid. A small sample was crystallized from acetic acid and analyzed.

Anal. Calcd. for $C_{19}H_8O_5Br_6S$: Br, 58.90; S, 3.86. Found: Br, 58.69; S, 3.91.

Discussion

Since the unhalogenated analogs of all these compounds are useful indicators for the determination of hydrogen-ion concentration, it was thought that a study of the useful P_H range of these compounds would be of value. The method employed in each case was as follows: 0.1 g. of the dye was thoroughly ground in a small glass mortar with sufficient *N*/20 sodium hydroxide to form the monosodium salt. The resulting solution was diluted to 250 cc. to give a 0.04% aqueous solution of the sodium salt.[8] One-half cc. of this solution was then added to 10 cc. of various buffers from P_H 1.0 to 9.6 and the color ranges carefully observed. The indicators were found to have the ranges and colors shown in the accompanying table (Table I).

TABLE I

COLOR CHANGE AND USEFUL Pa RANGE OR TETRAHALOGENATED SULFONEPHTHALEINS

Name	P_H interval	Color change
Phenoltetrabromosulfonephthalein	6.6 to 8.2	Yellow to purple
Phenoltetrachlorosulfonephthalein	6.6 to 8.2	Yellow to purple[a]
o-Cresoltetrabromosulfonephthalein	7.2 to 8.8	Yellow–violet–purple
o-Cresoltetrachlorosulfonephthalein	7.2 to 8.8	Yellow–violet–purple
Tetrabromophenoltetrabromosulfonephthalein	3.0 to 4.6	Yellow–green–blue
Tetrabromophenoltetrachlorosulfonephthalein	3.0 to 4.6	Yellow–green–blue[a]
Dibromo-o-cresoltetrabromosulfonephthalein	5.2 to 6.8	Yellow–green–violet
Dibromo-o-cresoltetrachlorosulfonephthalein	5.2 to 6.8	Yellow–green–violet[a]
Phenoltetra-iodosulfonephthalein (crude)	6.4 to 8.0	Yellow to red
o-Cresoltetra-iodosulfonephthalein	7.0 to 8.6	Yellow to purple
Dibromophenoltetrabromosulfonephthalein	5.6 to 7.2	Yellow to purple

[a] Lighter shades.

Table II shows the useful P_H interval of their unhalogenated analogs. A study of the two tables brings out some very interesting facts. The nature of the halogen in the o-sulfobenzoic acid part seems to affect the color only very slightly. The only difference is that in the case of the chlorine compounds the shades are somewhat lighter. A more important

---

[8] Clark and Lubs, "Determination of Hydrogen Ions," Williams and Wilkins Company. Baltimore, Maryland, 1922, 2nd ed.

observation, however, is that the replacement of four hydrogens in the *o*-sulfobenzoic acid part of the molecule by halogens does not materially change the useful PH range of the compounds. In each case the useful range is practically the same for the two series, although the colors are somewhat different. The halogenated compounds show an additional extremely acid range not measurable by the ordinary buffers. This range might possibly prove useful since in strong acid (N HCl) they are red shading to yellow at *P*H's in the vicinity of 2.0.

TABLE II[a]

COLOR CHANGE AND *P*H RANGE OF THE UNHALOGENATED ANALOGS OF THOSE COMPOUNDS SHOWN IN TABLE I

Name of indicator	Trade name	Concn., %	Interval in *P*H	Color	
				Acid	Alkaline
Phenolsulfonephthalein	Phenol red	0 02	6.8–8 6	Yellow	Red
Tetrabromophenolsulfonephthalein	Brom phenol blue	.04	3.0–4.6	Yellow	Blue
o-Cresolsulfouephthalein	Cresol red	.02	7 2–8.8	Yellow	Red
Dibromo-o-cresolsulfonephthalein	Brom cresol purple	.04	5.2–6 8	Yellow	Purple

[a] Adapted from Kolthoff and Furman, "Indicators," John Wiley and Sons, Inc., New York, 1928.

The effect of halogen and alkyl substitution in the phenolic part of the molecule as shown in Table I is identical with that observed by other investigators.[3a,4c] in the unhalogenated series.

The new compounds show the usual dichromatism found in so many of the sulfonephthaleins and possess no apparent advantage as indicators over those now in general use. No attempt has been made to determine the apparent dissociation constants of these compounds nor any spectrophotometric data regarding them.

The author wishes to express his thanks to Mr. Grant Spurrier of the Research Laboratories of Hynson, Westcott and Dunning for his technical assistance.

Summary

1. The following compounds have been prepared: phenoltetrabromosulfonephthalein, phenoltetrachlorosulfonephthalein, *o*-cresoltetrabromosulfonephthalein, o-cresoltetrachlorosulfonephthalein, *o*-cresoltetra-iodosulfonephthalein, tetrabromophenoltetrabromosulfonephthalein, dibromophenoltetrabromosulfonephthalein, tetrabromophenoltetrachlorosulfonephthalein, dibromo-o-cresoltetrabromosulfonephthalein and dibromo-*o*-cresoltetrachlorosulfonephthalein.

2. Their color change with changing hydrogen-ion concentration has been determined.

3. Their pharmacological and bacteriological action is being investigated and will be reported elsewhere.

4. Further investigation of compounds of this series is in progress.

THE FORMATION OF PRIMARY AMINES FROM GRIGMARD REAGENTS AND MONOCHLORO-AMINE. II

BY GEORGE H. COLEMAN AND CHARLES B. YAGER

RECEIVED OCTOBER 11, 1928 PUBLISHED FEBRUARY 5, 1929

In a recent[1] study of the reaction of monochloro-amine with Grignard reagents, it was found that primary amines and ammonia are formed according to the following reactions

$$RMgX + NH_2Cl = RNH_2 + MgXCl \qquad (1)$$

$$RMgX + NH_2Cl = RCl + MgXNH_2 \qquad (2)$$

The reagents used, with the exception of phenylmagnesium chloride, bromide and iodide, were prepared from primary halogen compounds.

Since some of the methods used for the preparation of primary amines cannot be used for amines in which the amino group is attached to a secondary or a tertiary carbon atom, the monochloro-amine reaction has been studied with Grignard reagents prepared from secondary and tertiary halogen compounds. The course of the reaction and the yields of amines and ammonia are much the same as with the primary reagents. The variation in yields with chlorides, bromides and iodides was again observed. The results obtained with the fifteen reagents thus far used are shown in Table I.

TABLE I

PERCENTAGE YIELDS OF AMINES AND AMMONIA FROM MONOCHLORO-AMINE AND GRIGNARD REAGENTS

	X = Cl % yields		X = Br % yields		X = I % yields	
Reagents	RNH_2	NH_3	RNH_2	NH_3	RNH_2	NH_3

[a] The secondary amyl halides used were the symmetrical compounds prepared from diethylcarbinol.

The monochloro-amine was prepared by a further slight modification of the method of Marckwald and Wille.[2] Instead of distilling the aqueous solution under diminished pressure the monochloro-amine was extracted directly with ether.

Since it was essential to have an excess of Grignard reagent present, the organomagnesium halide solutions were analyzed by titration with

[2] Marckwald and Wille, Ber., 56, 1319 (1923).

acid as described by Gilman, Wilkinson, Fishel and Meyers[3] before adding the monochloro-amine.

The method of carrying out the reaction and isolating the products was very similar to that described by Coleman and Hauser.[1] The products obtained as the amine hydrochlorides and ammonium chloride were analyzed and derivatives prepared.

Work is being continued with other chloro-amines and with nitrogen trichloride with the thought of preparing secondary and tertiary amines. The work of Buylla[4] with iododiethylamine and Strecker[5] with nitrogen trichloride might indicate, however, that Reaction *2* predominates in these cases.

Experimental

Preparation of Monochloro-amine.—Two hundred cc. of cold sodium hypochlorite solution prepared as described by Marckwald and Wille[2] was added slowly with shaking to 200 cc. of 1 *N* ammonium hydroxide cooled to 0° or below. The monochloro-amine was extracted first with a 100-cc. portion of cold ether and then with three 50-cc. portions. The four extractions were combined and dried for a short time with calcium chloride. The yield of monochloro-amine by this method is somewhat less than that obtained by the distillation method described by Coleman and Hauser[1] using carbon dioxide snow around the receiver. The method is, however, much simpler and the yield is better than by the distillation method if the receiver is cooled with only ice and salt.

Analysis of the Monochloro-amine Solution.—The method used was that previously described[1] with a slight modification of procedure in the analysis for nitrogen. After adding the sample to the hydrochloric acid, the flask was stoppered and shaken vigorously for a short time. It was then opened and the chlorine and ether driven off by gentle warming. With the dilute solutions used the results were as satisfactory as those obtained by allowing the hydrochloric acid mixture to stand for several hours. For concentrated solutions of monochloro-amine the method used by Coleman and Craig[6] for concentrated solutions of nitrogen trichloride may be used.

Preparation of the Grignard Reagents.—The methods used in the preparation and analysis of the Grignard reagents were essentially those described by Giman and his co-workers.[3,7]

Reaction of Monochloro-amine with Grignard Reagents

The reactions of monochloro-amine with the Grignard reagents were carried out as previously described.[1] After the excess Grignard reagent had been decomposed with water, however, the basic mixture was always brought into solution with acid before adding alkali and distilling with steam.

The purity of the hydrochloride was determined by analysis and the amines were identified by the preparation of derivatives. Mixed melting points were taken with known compounds when these were available.

FURTHER STUDIES OF SYRINGIC ACID AND ITS DERIVATIVES[1]

BY MARSTON TAYLOR BOGERT AND BERNARD B. COYNE[2]

RECEIVED OCTOBER 13, 1928 PUBLISHED FEBRUARY 5, 1929

In previous articles[3] from these Laboratories, we have described various derivatives of syringic acid and incidental compounds, and the present paper continues and supplements these earlier investigations.

The flow sheet represents the various products prepared in the course of the work and the origin of each.

The nitration of polyhydroxylated benzoic acids is complicated by the tendency of such compounds either to undergo complete decomposition, or to have the carboxyl displaced by the nitro group.[3a,4] These tendencies have been overcome by protecting the carboxyl group by esterification and the hydroxyls by alkylation or esterification.[3a,5] Bogert and Plaut[3a] obtained the dinitropyrogallol dimethyl ether by direct nitration of syringic acid. We have found similarly that when nitrosyringic acid is boiled with tin and hydrochloric acid, the product is the monaminopyrogallol dimethyl ether, but that the aminosyringic acid can be obtained by carrying out the reduction at 40–45° under suitable conditions.

Schiffer[6] encountered similar difficulties when he sought to reduce nitrotriethylgallic acid. We have also ascertained, in line with the above, that acetylsyringic acid can be nitrated easily, in acetic anhydride solution, to give the nitro-acetylsyringic acid without loss of carbon dioxide

The methylene-aminosyringic acid refused to yield the corresponding indigo, under the experimental conditions employed. This recalls the recent unsuccessful efforts of Overmyer[7] to prepare a hexamethoxy indigo from aminotrimethylgallic acid.

---

[7] Overmyer, THIS JOURNAL, 49, 499 (1927).

Experimental Part

Trimethylgallic Acid.—The method adopted for the preparation of this acid was based upon that of Graebe and Marta[8] as modified by Mauthner,[9] but involved a sufficient number of variations to make it seem advisable to describe the procedure.

A 5-liter flask containing 200 g. of gallic acid suspended in 1 liter of water was fitted with a 3-holed rubber stopper carrying thermometer, stopcock funnel tube and guard tube filled with sodium hyposulfite (to exclude oxygen). The acid was dissolved by the addition of a solution of 320 g. of sodium hydroxide and a small amount of sodium bisulfite (to prevent oxidation) in 1 liter of water, and 356 g. of methyl sulfate was then run in gradually and the flask shaken for twenty to thirty minutes while the temperature of the mixture was maintained below 35°. When evolution of heat was no longer caused by the reaction, a further 356 g. of methyl sulfate was added and the temperature of the mixture allowed to rise to 45°, after which it was refluxed for two hours, 80 g. of sodium hydroxide added (to saponify excess of methyl sulfate), the refluxing continued for a further two hours, the solution cooled, acidified with dilute hydrochloric acid, the precipitate collected, washed with cold water and recrystallized from a large volume of boiling water in the presence of a decolorizing carbon. The colorless crystalline product melted at 168" (corr.), in agreement with the literature; yield of crude product, 220 g., or 87%; after one crystallization, 180 g., or 72%, without figuring in that still recoverable from the mother liquor. It did not pay, however, to work over the mother liquor from the precipitation of the original crude acid,

As Overmyer[7] has pointed out, the crude product may be crystallized also from glacial acetic acid.

The use of sodium hydrosulfite, in place of the bisulfite, to prevent oxidation during the methylation of the gallic acid, was not so satisfactory and often imparted a foul odor to the product, possibly due to the formation of traces of mercaptan or sulfide from the methyl sulfate.

Syringic Acid.—Most of this acid required for the experimental work was obtained from the trimethylgallic acid by the method of Bogert and Ehrlich.[3b]

Alimchandani and Meldrum,[10] as well as others, have suggested the use of concentrated sulfuric acid, in place of the fuming acid, for accomplishing this demethylation but, in our experience, unless the reaction was conducted as follows, the product contained some unchanged trimethylgallic acid.

To 300 g. of concentrated sulfuric acid, 60 g. of trimethylgallic acid was added all at once and the solution kept for six hours at 40° with occasional agitation. It was allowed to cool, left overnight at room temperature and then stirred into 300 cc. of water without external cooling. The syringic acid which separated was collected, washed with cold water and crystallized from boiling water in the presence of a decolorizing carbon. From the original mother liquor more syringic acid separated on standing and

[8] Graebe and Martz, *Ann.*, 340,219 (1905).

[9] Mauthner, "Organic Syntheses," John Wiley and Sons, Inc., New York, *6*, 96 (1926).

[10] Alimchandani and Meldrum, *J. Chem. Soc.*, 117,967 (1920).

on concentration. Additional amounts may be recovered from the wash waters and second mother liquor; total yield of crude acid, **45** g., or **80%;** after one crystallization, **35** g., or **63%.** The carefully purified acid was odorless. The melting point varies somewhat depending upon the rapidity of heating and is generally preceded by a sintering or softening. The product obtained as described sintered at 204° and melted at **206.5**" (corr.). Koerner[11] and Gadamer[12] reported the m. p. as **202°,** Graebe and Martz[8] and Bogert and Ehrlich[3b] as **204°,** Alimchandani and Meldrum[10] as **206–207**" and Anderson and Nabenhauer[13] as **209–210".**

The methyl ester was obtained easily and in good yield by the method of Bogert and Ehrlich[3b] and in the anhydrous form melted at **107**" (corr.), as stated by them; yield, 75%.

Acetylsyringic acid was prepared first by Gadamer,[14] by the oxidation of acetylsinapinic acid, and more recently by Anderson and Nabenhauer,[13] by oxidation of the acetyl derivative of the anthocyanidin of Isabella grapes and by the direct acetylation of syringic acid. Our procedure differed somewhat from the latter. A suspension of **10** g. of syringic acid in **30** g. of acetic anhydride was warmed gently until a clear solution was obtained, **0.5** g. of fused sodium acetate was added and the solution left overnight at room temperature. The next morning the solution, including any crystals which had separated, was poured into **100** cc. of water and stirred thoroughly, to insure the hydrolysis of any excess anhydride. As the solution cooled, the crude acetylsyringic acid crystallized in amount essentially equal to that calculated. By a single recrystallization from water the pure acid was secured, m. p. 190.5° (corr.); yield, 78%, without including that recoverable by working over the mother liquors. Gadamer reported a m. p. of **181–183";** Anderson and Nabenhauer, **190–191°.**

When this acid was dissolved in absolute methanol and the solution saturated with dry hydrogen chloride, the acetyl group was removed and the carboxyl simultaneously esterified, with production of methyl syringate.

The methyl ester was prepared similarly, by direct acetylation of methyl syringate. as carried out first by Bogert and Plaut,[3a] and later by Alimchandani and Meldrum;[10] yield of crude product, 97%. Recrystallized from alcohol, the pure ester melted at **131.5**" (corr.). Bogert and Plaut found a m. p. of 129° (corr.) and Alimchandani and Meldrum reported **131°.**

Nitrosyringic Acid.—A suspension of **9** g. of nitro-acetylsyringic acid (see beyond) in **150** cc. of **5%** hydrochloric acid was refluxed until a clear solution was secured (about two hours). As the solution cooled, the nitrosyringic acid separated in long pale yellow needles, carrying one mole of water, some of which was lost even at room temperature; yield, 91%. Recrystallized from water, or from dilute (30%) alcohol, and dried at 110°, it formed colorless crystals which softened at 213° (corr.) and melted with decomposition at 218° (corr.); yield, 78%.

Anal. Calcd. for $C_9H_9O_7N$: C, **44.44;** H, **3.70.** Found: **C, 44.46;** H, **3.74.**

The product was soluble more or less freely in alcohol, ether, acetone or boiling water, but slightly soluble in cold water or in strong hydrochloric acid and practically insoluble in petroleum ether, chloroform or benzene. It dissolved in sodium bicarbonate solution, coloring it red. In contradistinction to the well-known sweet taste of o-nitrobenzoic acid, the taste of this analog was sour and brackish.

The introduction of this nitro group interfered so seriously with the methylation of the hydroxyl group in the meta position that such methylating agents as methyl

---

[11] Koerner, Gazz. *chim. ital.*, **18,215 (1888).**

[12] Gadamer, ***Ber.*****, 30,2330 (1897).**

[14] Gadamer, **Arch.** *Pharm.*, **235, 570 (1897).**

iodide and methyl sulfate were without effect upon it. This is in accord with the experience of Hemmelmayr,[15] who encountered similar difficulties in trying to methylate nitro-β-resorcylic acid.

Methyl Ester.—This was obtained by digesting methyl nitro-acetylsyringate with dilute hydrochloric acid, in practically the same way as just described for the free acid; yield of crude product, **95%.** Recrystallized from alcohol, it formed colorless needles, m. p. 210° (corr.); yield, **83%.**

Anal. Calcd. for $C_{10}H_{11}O_7N$: C, 46.69; H, 4.28. Pound: C, **47.05;** H, **4.50.**

The same product was obtained by dissolving nitrosyringic acid or its acetyl derivative in absolute methanol and saturating the solution with dry hydrogen chloride.

This nitro ester was very stable toward both acids and alkalies and could not be hydrolyzed to the free acid without decomposition. The experience of Schiffer[16] with ethyl nitrotriethylgallate, or of Thorns and Siebeling[17] with methyl nitrotrimethylgallate, was much the same.

Bogert and Plaut[3a] nitrated methyl syringate, in acetic anhydride solution, at low temperature, and reported the formation of a methyl nitrosyringate, melting at 68.3" (corr.), and that the same product was obtained by the action of concentrated (48%) hydrobromic acid upon methyl nitrotrimethylgallate, but we have been unable to check this direct nitration of methyl syringate or obtain the product, m. p. 68.3°, reported by them.

We endeavored to repeat this direct nitration of methyl syringate, but found the crude product very difficult to purify (as did Bogert and Plaut also), and failed to isolate either the compound of m. p. 68.3°, or the one of m. p. 210°. Further work is necessary to explain this discrepancy in results since, as noted beyond, both products seem to yield the same aminosyringate on reduction.

Nitro-acetylsyringic Acid, $(CH_3O)_2(CH_3COO)C_6H(NO_2)COOH$.—A mixture of 10 g. of acetylsyringic acid and **30** g. of acetic anhydride was nitrated with 5 cc. of fuming nitric acid (sp. gr. **1.6)** at −5°, adding the nitric acid very slowly with vigorous mechanical stirring. The acetylsyringic acid used must be pure and dry and the addition of the nitric acid be conducted very carefully, especially at first, or the reaction may proceed with explosive violence. After all of the nitric acid had been added, the stirring was continued for an hour longer, when a mass of minute crystals separated. After this mixture had stood for two hours at low temperature, it was poured into **200** cc. of **ice** water, the mixture well agitated to hydrolyze any excess of acetic anhydride and the insoluble nitro acid collected and orystallized from 50% alcohol. The product formed colorless, minute, diamond-shaped plates which melted with decomposition at **190"** (corr.). It dissolved in sodium bicarbonate solution to a colorless solution. but in aqueous sodium hydroxide a red color developed rapidly; yield of crude product, **92%;** of pure substance, **82%.** It dissolved quite readily in acetone or hot alcohol, less easily in ether or chloroform and was difficultly soluble or insoluble in water, petroleum ether or benzene.

A 1:1 mixture of acetylsyringic and nitro-acetylsyringic acids melted at 158–165°.

Anal. Calcd. for $C_{11}H_{11}O_8N$: C, **46.34;** H, 3.89. Found: C, **46.28;** H, **3.99.**

---

[15] Hemmelmayr, *Monatsh.,* **26, 185 (1905).**

[16] Schiffer, *Ber.,* **25, 727 (1892).**

[17] Thorns and Siebeling, *ibid.,* **44,** 2115 (1911).

The methyl ester was obtained by nitrating methyl acetylsyringate in the manner just described for the acid itself and also by the acetylation of methyl nitrosyringate with acetic anhydride and sodium acetate. The pure ester crystallized from **95%** alcohol in long, colorless needles, m. p. 107.5° (corr.); yield of crude product, 98%, of pure substance **85%.**

Anal. Calcd. for $C_{12}H_{13}O_8N$: C, **48.16;** H, **4.35.** Found: C, **48.09;** H, **4.38**

Aminosyringic Acid.—To a solution of 5 g. of stannous chloride in 10 cc. of concentrated hydrochloric acid, containing a little metallic tin, there was added gradually 5 g. of finely powdered nitrosyringic acid. During the addition of the nitro acid the mixture was stirred mechanically, its temperature was maintained at 40–45°, and tin and hydrochloric acid were replenished from time to time until a total of **10** g. of the former and **250** cc. of the latter had been used. The nitro acid slowly dissolved and the colorless tin double salt of the amino acid separated. Too much nitro acid should not be added at a time, since the separated tin double salt tends to coat it over and protect it from reduction. When the reduction was complete, the double salt was collected, washed with concentrated hydrochloric acid, dissolved in water and de-tinned by hydrogen sulfide. The filtrate from the stannous sulfide was evaporated under diminished pressure, at room temperature first and then at 60°. Colorless, fine needles of the amino acid hydrochloride were obtained, melting with decomposition at 185° (corr.); yield, 59%. It was partly hydrolyzed by pure water, but could be crystallized from dilute hvdrochloric acid.

It was dissolved in water, a slight excess of ammonium hydroxide solution and a little sodium sulfite (to retard oxidation) added, and then dilute acetic acid in slight excess. When the solution was cooled, the free amino acid separated in colorless needles which, after recrystallization from water, melted with decomposition at 169° (corr.); yield of crude acid, **97%;** of pure product, **86%.**

Anal. Calcd. for $C_9H_{11}O_5N$: C, 50.74; H, **5.16.** Found: C, **50.98;** H, **4.97.**

The troublesome tin sulfide precipitation may be avoided and the amino acid obtained more quickly, although in somewhat lower yield, by dissolving the tin double salt in a small amount of water, adding sufficient ammonium hydroxide solution to precipitate all of the tin as hydroxide, neutralizing the filtrate with acetic acid and recovering the amino acid as already described.

The free acid is moderately soluble in acetone, hot water or hot alcohol, only slightly soluble in ether or chloroform and practically insoluble in petroleum ether or benzene. Its hydrochloride was treated with potassium cyanate, for the purpose of getting the corresponding ureido acid, but the results were negative.

Methyl Ester.—Prepared by reduction of the methyl nitrosyringate with tin and hydrochloric acid, essentially as described by Bogert and Plaut,[3a] the hydrochloride was obtained in colorless needles which darkened at 192° and melted with decomposition at 217° (corr.); yield, **65%.** Bogert and Plaut gave the m. p. as 192°.

Anal. Calcd. for $C_{10}H_{14}O_5NCl$: Cl, **13.48.** Found: Cl, **13.80.**

A few crystals of sodium sulfite were added to an aqueous solution of this hydrochloride and the free ester was then precipitated by a slight excess of sodium bicarbonate and crystallized from dilute alcohol in the dark, as recommended by Bogert and Plaut. The colorless granular crystals obtained melted at 126.5° (corr.). Bogert and Plaut reported a m. p. of 110° (corr.).

The same product was secured by dissolving the aminosyringic acid in absolute methanol, saturating the cold solution with dry hydrogen chloride, dissolving the resultant hydrochloride in water and precipitating the solution by the addition of sodium bicarbonate.

Anal. Calcd. for $C_{10}H_{13}O_5N$: C, 52.86; H, 5.73. Found: C, 52.53; H, 5.59.

Attempts to hydrolyze this ester to the free acid all failed, acids or alkalies causing deeper-seated changes.

When this ester was diazotized and the diazo solution treated with cuprous oxide, a vigorous evolution of nitrogen occurred and the product isolated proved to be methyl syringate; yield, 69%. Power and Shedden[18] diazotized ethyl aminogallate and succeeded in isolating a diazo derivative, which lost nitrogen when heated with water at 220" and gave ethyl gallate.

Acetanthranil of Acetylsyringic Acid, $(CH_3O)_2(CH_3COO)C_6HN(COCH_3)CO$.—When a solution of aminosyringic acid (3 g.) in acetic anhydride (9 cc.), containing a trace of fused sodium acetate, was allowed to stand, crystals of this acetanthranil separated, which were recrystallized from acetic anhydride or from dry benzene. The compound then formed colorless needles, m. p. 169" (corr.); yield, 78%.

Anal. Calcd. for $C_{13}H_{13}O_6N$: C, 55.91; H, 4.66. Found: C, 55.82; H, 4.71.

The conversion of this acetanthranil into quinazolones, by the action of amines,[19,20] has not been accomplished as yet. Preliminary experiments with ammonia and aniline seem to indicate that it is less reactive in this respect than acetanthranil itself.

Acetamino-acetylsyringic acid, $(CH_3O)_2(CH_3COO)C_6H(NHCOCH_3)COOH$, was obtained very easily from the above acetanthranil by evaporating its aqueous solution, and was recrystallized from water; m. p. 193° (corr.); yield, 75%.

Anal. Calcd. for $C_{13}H_{15}O_7N$: C, 52.52; H, 5.05. Found: C, 52.23; H, 4.98.

Methyl Ester.—Prepared as described by Bogert and Plaut.[3a] The colorless crystals secured by us melted at 154° (corr.), whereas Bogert and Plaut found a m. p. of 139.9" (corr.).

Anal. Calcd. for $C_{14}H_{17}O_7N$: C, 54.02; H, 5.47. Found: C, 53.91; H, 5.44.

Structurally this acid is of methacetin type but no pharmacological tests have been conducted with it.

Hydrochloride of **3-Amino-2,6-dimethylpyrogallol,** $(CH_3O)_2(HO)C_6H_2NH_2$.—A suspension of 10 g. of nitrosyringic acid in 100 cc. of concentrated hydrochloric acid was heated under a reflux condenser, while 20 g. of tin was added gradually. When solution was complete (about four to five hours), the mixture was cooled, the double tin salt collected, dissolved in water, the tin precipitated as sulfide, the filtrate evaporated to dryness under diminished pressure and the residue crystallized from water. Large. colorless orthorhombic crystals of the hydrochloride resulted, m. p. 198° (corr.) with decomposition; yield, 78%.

Anal. Calcd. for $C_8H_{12}O_3NCl$: Cl, 17.27. Found: Cl, 17.24.

When nitrosyringic acid was boiled with ferrous sulfate and ammonium hydroxide solution, the aminopyrogallol dimethyl ether was again the product.

Benzoyl Derivative.—This was prepared by the action of benzoyl chloride upon the amine, in the presence of a slight excess of sodium bicarbonate and a few crystals of sodium sulfite. It crystallized from alcohol in large colorless flakes, m. p. 158.3° (corr.); yield, almost that calculated.

Anal. Calcd. for $C_{15}H_{15}O_4N$: C, 65.93; H, 5.50. Found: C, 66.06; H, 5.56.

Its alcoholic solution was colored deep red by ferric chloride. It was insoluble in cold dilute hydrochloric acid, or in sodium bicarbonate solution.

Methylene-aminosyringic Acid, $(CH_3O)_2(OH)C_6H(N{=}CH_2)COOH$.—A solution of aminosyringic acid (1 g.) in dilute hydrochloric acid (2 cc. of acid: 10 cc. of water) was cooled to 0° and a 40% formaldehyde solution (3 cc.) added slowly. The colorless crystals which separated were removed, dried and recrystallized from a mixture of chloroform and carbon tetrachloride, when they softened at 191° (corr.), and melted with decomposition at 195° (corr.); yield, 75%. When it was warmed with dilute sulfuric acid, formaldehyde was evolved.

Anal. Calcd. for $C_{10}H_{11}O_5N$: C, 53.33; H, 4.88. Pound: C, 53.40; H, 4.79.

The crystals of methylene-anthranilic acid are luminescent in the dark when rubbed,[21] but these crystals were not.

Experiments conducted for the purpose of converting this methylene derivative into the corresponding glycine nitrile and indigo have proved unsuccessful so far.

Summary

1. The preparation and properties of the following new compounds are described: nitrosyringic acid, nitro-acetylsyringic acid and its methyl ester, aminosyringic acid, its hydrochloride, acetanthranil, diacetyl and methylene derivatives, 3-aminopyrogallol-2,6-dimethyl ether, its hydrochloride and benzoyl derivative.

2. In the case of methyl nitrosyringate, methyl aminosyringate, the hydrochloride and diacetyl derivative of the latter, the melting points found differ from those already in the literature.

SOME OBSERVATIONS ON THE CATALYTIC ACTIVITY OF ALUMINUM CHLORIDE

BY GREGG DOUGHERTY

RECEIVED OCTOBER 13, 1928 PUBLISHED FEBRUARY 5, 1929

Aluminum chloride forms addition compounds with many different types of organic molecules, and in almost every attempt to explain the mechanism of the Friedel-Crafts reaction, the catalytic activity of the aluminum chloride has been connected with the formation of these complexes. Little is known concerning the nature of the addition compounds and no adequate reasons for their catalytic activity have been suggested.

The additive power of aluminum chloride is usually explained electronically on the ground that the aluminum atom in aluminum chloride possesses an outer shell of six electrons, and in order to achieve the more stable arrangement of eight, it will share a pair previously belonging totally to some other atom or molecule. Unless a rearrangement of some sort occurs, this new molecule, according to the ideas of Lowry[1] and Sidg-

---

[1] Lowry, J. *Chem. Soc.,* 123,822 (1923); *Phil. Mag.,* 45,964,1013 (1923).

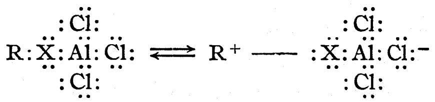
wick,[2] should have a polar character. It would seem likely that the active agents in the Friedel-Crafts synthesis are these polarized or even ionized addition compounds which exist, possibly in very small amount only, in equilibrium with the undissociated or unpolarized molecules. It is a fact that solutions of aluminum halides in alkyl halides, and organic aluminum halide solutions in general, often show considerable conductivity.

An explanation of the mechanism of the Friedel-Crafts synthesis involving in part this idea was advanced by the present author and published as an insert in an article on synthetic anthraquinone by K. H. Klipstein.[3]

Lately H. J. Prins[4] has suggested that under the influence of aluminum chloride benzene polarizes or ionizes in such a way as to give effectively a hydrogen ion and a phenyl ion. In this paper the ideas mentioned above concerning the nature of the Friedel-Crafts reactions are extended and the results of some experimental work bearing on the problem are offered.

Theoretical Part

If one adopts the current ideas of the electronic theory of valence, it is possible to show that if aluminum chloride adds to benzene and there is a subsequent polarization or dissociation, the probable result would be a polarized molecule of the type $(C_6H_5AlCl_3)^-$—H^+ or the ions $(C_6H_5AlCl)^-$ and H^+. Similarly, with an alkyl halide, RX, we would obtain



$$R:\underset{..}{\overset{..}{X}}:\underset{:\underset{..}{Cl}:}{\overset{:\overset{..}{Cl}:}{\underset{..}{\overset{..}{Al}}}}:\underset{..}{\overset{..}{Cl}}: \rightleftharpoons R^+ \text{——} :\underset{..}{\overset{..}{X}}:\underset{:\underset{..}{Cl}:}{\overset{:\overset{..}{Cl}:}{\underset{..}{\overset{..}{Al}}}}:\underset{..}{\overset{..}{Cl}}:^-$$

or R^+ and $(X\ Al\ Cl_3)^-$. The simplest example of the Friedel-Crafts reaction in which the action is truly catalytic, that is, the aluminum chloride is not taken from the system as the process proceeds in the form of a very inert addition compound with one of the resultants, as in a ketone synthesis, would be represented by the following

$$C_6H_6 + AlCl_3 \rightleftharpoons C_6H_6AlCl_3 \rightleftharpoons (C_6H_5AlCl_3)^-\text{—}H^+ \qquad (1)$$

$$RX + AlCl_3 \rightleftharpoons RXAlCl_3 \rightleftharpoons R^+\text{—}(XAlCl_3)^- \qquad (2)$$

$$(C_6H_5AlCl_3)^-\text{—}H^+ + R^+\text{—}(XAlCl_3)^- \rightleftharpoons (C_6H_5AlCl_3)^-\text{—}R^+ + H^+\text{—}(XAlCl_3)^- \qquad (3)$$

$$(C_6H_5AlCl_3)^-\text{—}R^+ \rightleftharpoons C_6H_5R\cdot AlCl_3 \rightleftharpoons C_6H_5R + AlCl_3 \qquad (4)$$

$$H^+\text{—}(XAlCl_3)^- \rightleftharpoons HX\cdot AlCl_3 \rightleftharpoons HX + AlCl_3 \qquad (5)$$

These reactions indicate a situation somewhat similar to that which we have presumably when inorganic ionogens react. There would be displacement in one direction or another if any pair of ions formed an insoluble compound or a very volatile one. In the above a nearly complete reaction results due to the volatility of the hydrogen chloride. As the

[3] Klipstein, *Ind. Eng. Chem.*, 18, 1327 (1926).

[4] Prins, *Chem. Weekblud,* 24,615 (1927).

reactions indicate, the reaction should be reversible and it is a fact that we can de-alkylate alkyl benzenes by means of aluminum chloride and a stream of hydrogen chloride. In actual practice the situation is not so simple as the equations would lead one to believe. This is due to the fact that the C_6H_5R can add to aluminum chloride and become part of a polarized or ionized molecule just as benzene does. The result is a reaction mixture containing various polyalkylated benzenes in addition to the mono-alkyl compound. The former are formed in a proportion depending on the relative tendency to add to aluminum chloride and the extent to which each of the resulting addition compounds is dissociated.

The Action of Aluminum Chloride on Halogen Compounds.—The reactions given above for the formation of alkylbenzenes suggest that if benzene were replaced by another alkyl halide, or a halogen compound of like properties, different from RX, metathetical reactions should occur essentially similar in type to those of Friedel and Crafts. Such reactions would be represented by the following

$$RX + AlCl_3 \rightleftharpoons RX\cdot AlCl_3 \rightleftharpoons R^+\text{—}(XAlCl_3)^- \qquad (6)$$

$$R_1X_1 + AlCl_3 \rightleftharpoons R_1X_1\cdot AlCl_3 \rightleftharpoons R_1{}^+\text{—}(X_1AlCl_3)^- \qquad (7)$$

$$R^+\text{—}(XAlCl_3)^- + R_1{}^+\text{—}(X_1AlCl_3)^- \rightleftharpoons R^+\text{—}(X_1AlCl_3)^- + R_1{}^+\text{—}(XAlCl_3)^- \qquad (8)$$

$$R^+\text{—}(X_1AlCl_3)^- \rightleftharpoons RX_1 + AlCl_3, \text{ and } R_1{}^+\text{—}(XAlCl_3)^- \rightleftharpoons R_1X + AlCl_3 \qquad (9)$$

If either of the new alkyl halides, R_1X or RX_1, happened to be volatile in comparison with RX and R_1X_1, the reaction $RX + R_1X_1 \longrightarrow R_1X + RX_1$ should occur. On the other hand, if all of the alkyl halides were of the same order of volatility, the reaction should proceed to an equilibrium point.

There are many cases noted in the literature in which there is an exchange of halogen between metallic halides and aliphatic halogen compounds,[5] but the only example found in which there was actual transfer from one hydrocarbon radical to another under the influence of aluminum chloride was one in which an alkyl iodide was involved. Walker[6] observed that when a small amount of aluminum chloride was added to a mixture of ethyl iodide and chloroform, a vigorous reaction resulted; the products were ethyl chloride and iodoform. Similarly, methyl iodide and carbon tetrachloride yielded methyl chloride and carbon tetra-iodide. He seemed doubtful whether these transformations were general and would take place in the case of mixtures of chlorides and bromides.

In order to make sure that Walker's reactions involving iodides were general and not specific to mixtures containing chloroform or carbon tetrachloride, some experiments have been carried out in which the chlorides were replaced by bromides. Methyl iodide and ethyl bromide were mixed and a small piece of aluminum chloride was added. After gentle warming for a minute, a vigorous reaction commenced; methyl bromide

---

[5] Meyer, J. *prakt. Chem.*, [2] **34**, 104 (1886); Pouret, *Compt. rend.*, **130**, 1191 (1900); Ber., [3] 25, 191, 293 (1901).

[6] Walker, *J. Chem. Soc.*, *85*, 1082 (1904).

was evolved and ethyl iodide was isolated. Twenty g. of ethylene bromide and 30 g. of ethyl iodide were mixed and 1 g, of aluminum chloride was added. Here again there was a vigorous reaction; ethyl bromide was evolved and obtained in about a 70% yield. Undoubtedly the principal reactions which occurred were as follows

$$CH_3I + C_2H_5Br \longrightarrow CH_3Br\uparrow + C_2H_5I$$
$$C_2H_4Br_2 + C_2H_5I \longrightarrow C_2H_5Br\uparrow + C_2H_4I_2$$

The reaction mixtures became highly colored as soon as the aluminum chloride was added, some free iodine was liberated, tars were formed and the reactions were not clean cut.

Since alkyl iodides cannot be used successfully in the Friedel-Crafts syntheses, a reaction between chlorides and bromides in the presence of aluminum chloride would have much more bearing on the point under discussion. Walker observed that if chlorides and bromides react at all, they do so very slowly. It has been found that they do react and, under the proper conditions, without appreciable formation of complex by-products and tars. A solution was made of one mole of ethyl bromide and one of chloroform and a small amount of aluminum chloride added. There was distinct warming and the appearance of a bright red color. When warmed to 45–50°, there was bubbling and a slow evolution of ethyl chloride but no such activity as in the case of the iodides. Some hydrogen halide was formed and raising the temperature increased the amount, so it seemed best not to attempt to distil out all of the ethyl chloride formed in this way but to allow the reaction mixture to stand at room temperature. After thirty-six hours, water and dilute hydrochloric acid were added, the liquid was washed with dilute sodium hydroxide solution and dried over calcium chloride. On fractionating, in addition to a very low boiling portion which represented the remainder of the ethyl chloride formed, an ethyl bromide and a chloroform fraction, there was a small amount of liquid (b. p. 120–122°) and a rather larger fraction (b. p. 88–93'). The latter on redistillation boiled constantly at 91–92' and had a specific gravity of 1.975 at 15°. These are the properties of dichloromonobromomethane. *Anal.* Calcd. for $CHBrCl_2$: Cl and Br, 92.06. Found: 91.80. In this and other experiments the yield of the mixed halogen compound was about 35% of the theoretical based on the equation: $CHCl_3 + C_2H_5Br \longrightarrow CHCl_2Br + C_2H_5Cl$. The small fraction (b. p. 120–132") ran high in halogen, above 93%, and was probably a mixture of dibromomonochloromethane and bromoform. Difficulties in the fractional distillation made it impossible to identify these two compounds with certainty or to make anything like a quantitative separation of all the constituents in the reaction mixture. Both tar formation and the evolution of hydrogen halide seemed to increase with rise of temperature and were kept at a minimum by running the reaction at 20–25°.

In order to make a semi-quantitative study of this type of reaction and to test its reversibility, reactants were chosen which should produce only one new compound and that one not very volatile. Ethylene bromide and ethylene chloride should give ethylene chlorobromide: $C_2H_4Cl_2 + C_2H_4Br_2 \longrightarrow 2C_2H_4ClBr$. The reactants were mixed in equimolar proportions and about 0.04 of a mole of aluminum chloride added. It was found that the reaction was complete after standing for 35 hours at 25°. The reaction mixture was treated as in the case of the chloroform–ethyl bromide experiment and submitted to careful and repeated fractional distillation using an efficient fractionating column. Only three distinct fractions were found: the first and third had the properties of the reactants, while the middle one (b. p. 106–109") had a specific gravity of 1.73 at 19°, agreeing with that of ethylene chlorobromide. A halogen determination gave 80.7%; calculated for C_2H_4ClBr, 80.45%. Careful weighing of the fractions and taking account of losses of manipulation and material left in the fractionating apparatus indicated that the above reaction was complete when the three compounds were present in the ratio of 2 moles of ethylene chlorobromide to one each of ethylene chloride and ethylene bromide. This is what might be expected on the law of chances if it is assumed that the system contains highly polarized or ionized molecules and the energy content of the three compounds is approximately the same.

An attempt was made to test the reversibility of the reaction and to arrive at the equilibrium point from the other direction. Ethylene chlorobromide and aluminum chloride were mixed and allowed to stand under the same conditions as in the previous experiment. On fractionating the same three fractions were obtained and the weights were approximately in the same ratio, which indicates that the reaction is easily reversible and should be represented by the equation: $2C_2H_4ClBr \rightleftharpoons C_2H_4Cl_2 + C_2H_4Br_2$. The reaction mixtures darken in color as the reaction progresses and a small amount of hydrogen halide is evolved. Very little tar is formed, however, and this by-reaction is evidently very superficial in nature when the experiment is conducted at room temperature. To make sure that no exchange of halogen occurred between aluminum chloride and ethylene bromide, an experiment was tried in which ethylene chloride was omitted. The ethylene bromide was unchanged. Plans are being made to study these reactions more accurately; both equilibrium and velocity measurements will be attempted.

I wish to take this opportunity to thank Professor Frank O. Rice of Johns Hopkins University for his helpful advice in carrying out this work, and the Department of Chemistry at Johns Hopkins University for so kindly allowing me the privileges of the laboratory during the spring term of 1927–1928.

Summary

A mechanism for the Friedel-Crafts reaction has been suggested.

The hypothesis predicts that metathetical reactions will occur between certain types of aliphatic halogen compounds in the presence of aluminum chloride. Experimental evidence is given that such reactions do occur, and some of them have been studied.

SYNTHESIS OF EPHEDRINE AND STRUCTURALLY SIMILAR COMPOUNDS. I. A NEW SYNTHESIS OF EPHEDRINE

BY RICHARD H. F. MANSKE[1] AND TREAT B. JOHNSON

RECEIVED OCTOBER 15, 1928 PUBLISHED FEBRUARY 5, 1929

Although the constitution of ephedrine (III) is no longer in doubt, interest in this base has been renewed by the pharmacological work of K. K. Chen.[2] Since it seemed not improbable that other bases analogously constituted might possess more desirable or at least interesting physiological properties,[3] the authors entered this field with a view to the improvement of known methods of synthesis or to the discovery of new ones.

It was observed that a solution of 1-phenyl-1,2-propanedione,[4] C_6H_5-$COCOCH_3$, in petroleum ether reacts exothermally with dried gaseous methylamine to form a colorless crystalline compound with the elimination of water. This substance is unstable and gradually decomposes to an indefinite mixture, Treatment with acids regenerates the two components and titration shows that approximately one molecule of amine is combined with one of the diketone. Aside from purely speculative formulas for this compound only two (I and II) need be mentioned, and of these the former may at once be disposed of on purely theoretical grounds.

$C_6H_5C{=}(NCH_3)COCH_3$	$C_6H_5COC{=}(NCH_3)CH_3$	$C_6H_5CH(OH)CH(NCH_3)CH_3$
I	II	III

The considerable affinity demand of the phenyl group[5] leaves the a-carbon relatively saturated so that any negative ions (CN, HSO_3, etc.) have a tendency to attach themselves to the β-carbon in preference. Furthermore the effect of the carbonyl groups is reciprocal (the ketone group of ethyl pyruvate is more reactive than those of acetone, ethyl acetoacetate, or ethyl levulinate),[6,7] that is, each enhances the additive capacity of the other. Finally, methylbenzyl ketone reacts readily with bisulfites, whereas ethylbenzyl ketone does not, and the former is more reactive than acetone,' so that the phenyl group enhances the additive capacity of the β-carbon, an effect in accord with the Flürscheim's theory of alternate affinity demand.[5]

Sufficient experimental proof of the correctness of Formula (II) is found in the fact that catalytic reduction leads to ephedrine (111), that is, the carbonyl group is reduced to a secondary alcohol and the imino double bond (—C=N—) is reduced at the same time.

It is interesting to note that only a very small proportion of \$-ephedrine accompanies the main product, dl-ephedrine. The method of Eberhardt[S] yields a considerable amount of the ψ-form and that of Spath and Gohring[S] yielded the \$-form almost exclusively. To offer an explanation for this observation the authors assume that there is a repulsion between the N- and the ketonic O-atoms, their mean positions in space being on opposite sides of the carbon chain, so that the reduced product also tends to have the HO- and CH_3NH-groups distant from each other, a postulate already

advanced on other grounds for ephedrine. Conversely, it has been proposed that these groups are specially adjacent in ψ-ephedrine.[10]

Experimental Part

&Ephedrine.—A mixture of 50 cc. of absolute ethyl alcohol, 7.4 g. of methylphenyl diketone ($^1/_{20}$ mole) and an alcoholic solution of methylamine containing 1.6 g. ($^1/_{20}$ mole) was reduced catalytically with hydrogen in the presence of 0.1 g. of platinum oxide.[11] In some experiments there was a long induction period and then the yield was low. This behavior could be obviated by reducing the catalyst first and then adding the reactants. When reduction no longer proceeded, the catalyst was removed by filtration and about half the alcohol removed under reduced pressure. By this means any excess of methylamine was removed. The solution was made just acid with alcoholic hydrogen chloride and evaporated to dryness. The solid hydrochloride was washed with cold acetone and dried. The yield was 2.5–4.0 g. A small amount of ψ-ephedrine hydrochloride could be extracted from this by means of hot chloroform and by working up a number of extractions sufficient was obtained for deiinite identification (m. p. 164°; free base, m. p. 118°).[9,11] The dl-ephedrine hydrochloride was purified by recrystallizing once from alcohol–acetone and melted at 189°.[9]

Anal. Calcd. for $C_{10}H_{15}ON\cdot HCl$: N, 6.95; Cl, 17.60. Found: N, 6.98; Cl, 17.70.

The free base was recrystallized from chloroform–petroleum ether and melted at 75°.[12]

Anal. Calcd. for $C_{10}H_{15}ON$: C, 72.71; H, 9.09; N, 8.49. Pound: C, 72.43; H, 9.01; N, 8.20.

Summary

1. A new reaction has been discovered whereby it is possible to synthesize the alkaloid ephedrine.
2. This reaction consists in taking advantage of the differential additive capacity of the two ketonic groups in alkylaryl o-diketones.
3. 1-Phenyl-1,2-propanedione condenses with one molecule of methylamine and the condensation product on reduction yields dl-ephedrine.
4. Several homologs of ephedrine have been synthesized by this method and their description will form the subject of an early communication.

STUDIES IN THE DIPHENIC ACID SERIES. III

BY H. W. UNDERWOOD, JR., AND L. A. CLOUGH[1]

RECEIVED OCTOBER 17, 1928 PUBLISHED FEBRUARY 5, 1929

When the dichloride, diamide, diethyl ester, dimethyl ester, mono-ethyl ester, monomethyl ester, mono-amide and imide of diphenic acid are heated with concentrated sulfuric acid, each compound is transformed into a member of the diphenyleneketone-4-carboxylic acid series; evidently sulfuric acid causes a rotation of the rings in the biphenyl nucleus.[2] By means of acetic anhydride diphenic acid can be transformed into its anhydride and diphenimide secured from the mono-amide of diphenic acid;[2] these reactions are dehydrations and involve a joining of the side-chains attached to the rings. A part of this paper deals with an investigation of the action of acetic anhydride on the four esters of diphenic acid mentioned above, as well as the diamide; diphenamic acid has also been studied again.

p,p'-Dinitrodiphenic acid is unique in that it does not form an anhydride or a ketone acid; a plausible explanation of the behavior of this compound may be found by postulating that the meta orienting nitro group in each ring loosens the hydroxyl groups in the carboxyl and strengthens the bond which holds the hydrogen atom in the latter as well as the force holding the ring hydrogen which is meta to the nitro group. This idea would lead one to expect that a compound, such as *p,p'*-dibromodiphenic acid, in which the substituents are not meta orienting would form an anhydride. We have secured evidence regarding this point.

In a previous paper[3] it was pointed out that the results obtained by Bischoff and Adkins[4] regarding the condensation of diphenic anhydride and resorcinol were somewhat different from those which one of us described. Later Adkins, Steinbring and Pickering[6] questioned the validity of the criticisms. We are now ready to reaffirm the latter and to describe additional experimental evidence which supports our point of view.

Discussion of Experiments and Interpretation of Results

All of the temperatures given below are uncorrected.

Esters of Diphenic Acid.—The preparation of the monomethyl, mono-ethyl, dimethyl and diethyl esters of diphenic acid has been previously described.[2] Six g. of

---

[1] Some of the experimental results described in this paper are taken from a thesis submitted to the Faculty of the Massachusetts Institute of Technology by L. A. Clough in partial fulfilment of the requirements for the degree of Master of Science.

each of these compounds was heated with 12 g. of glacial acetic acid and 18 g. of acetic anhydride for sixteen hours at 145°. The major part of the liquid was then removed by distillation and the residue kept in an ice chest until crystallization took place. In every case practically all of the ester was recovered unchanged. The results of these experiments indicate that the hydroxyl and alkoxyl groups in these esters are very firmly held.

Diphenamic Acid.—A mixture of 30 g. of diphenamic acid (the mono-amide of diphenic acid), 60 g. of glacial acetic acid and 60 g. of acetic anhydride was heated at 145° for one hour. The solid which formed upon cooling was collected on a filter, thoroughly washed with cold sodium carbonate solution and water and subsequently dried at 110°. This product, m. p. 219°, was identified as diphenimide. Acidification of the sodium carbonate extract yielded a precipitate which melted at 168° after washing with water and drying at 110°. The compound gave a qualitative test for nitrogen; heating with concd. ammonium hydroxide did not produce the diamide of diphenic acid and the melting point was not changed by recrystallization from ethyl alcohol and from water. It was thought that this substance might be 1-cyanobiphenyl-10-carboxylic acid. In order to check our hypothesis, analyses and hydrolyses were carried out. Approximately 0.5 g. of the compound melting at 168° was heated on a water-bath for four hours with a mixture of 2 cc. of 95% sulfuric acid and 3 cc. of water; the solid gradually dissolved. The cold reaction liquid was poured into water and the precipitate collected on a filter, washed with water and finally crystallized from ethyl alcohol. By means of a mixed melting point the product of the hydrolysis was identified as diphenic acid. Upon dilution of the acetic acidanhydride reaction mixture with water, more of the dissolved material was obtained; this was separated into its components by the procedure already described. The total yield of diphenimide was 18.2 g. and that of cyanobiphenylcarboxylic acid was 3.8 g.

Anal. Calcd. for $C_{14}H_9O_2N$: C, 75.31; H, 4.06; N, 6.28. Found: C, 74.70, 74.68; H, 4.35, 4.40; N, 6.60, 6.40.

Diamide of Diphenic Acid.—The solution obtained upon heating 10 g. of the diamide of diphenic acid, 25 g. of glacial acetic acid and 40 g. of acetic anhydride at 145° for eight hours was concentrated by distilling most of the liquid. When water was added to the residue a precipitate was formed. This was collected on a filter and dried at 110°. The solid, which was insoluble in cold sodium carbonate solution, did not melt sharply. By extraction with a large amount of hot methyl alcohol most of the product was dissolved. After about one-half of the solvent had been removed by distillation, the solution on standing deposited long, flat needles which melted at 172° when dry. Further concentration of the solution yielded a crystalline mass which apparently contained an impure acetyl derivative of the diamide; this material did not melt sharply. By careful treatment of the substance with dilute sodium hydroxide solution and subsequent recrystallizations from methyl alcohol, more of the compound melting at 172' was secured.

It was thought that the latter was 2,2'-dicyanobiphenyl produced by the removal of two molecules of water from one molecule of diphenic acid diamide. The compound was insoluble in solutions of sodium carbonate and sodium hydroxide; recrystallization from ether and from acetone did not change the melting point; qualitative tests showed the presence of nitrogen. Approximately 1 g. of the substance was heated on a water-bath for four hours with a mixture of 4 cc. of 95% sulfuric acid and 4 cc. of water; the solid gradually dissolved. The cold reaction liquid was poured into water, the precipitate collected on a filter, washed with water and finally crystallized from ethyl alcohol. By means of a mixed melting point the hydrolysis product was identified as diphenic acid. The use of more concentrated sulfuric acid and a shorter time of heating gave some diphenamic acid. These experiments as well as the neutral character of the substance and the results of analyses indicated that the compound melting at 172° was 2,2′-dicyanobiphenyl. In one run 1.9 g. of the latter was obtained from 10 g. of the diamide; it was difficult to get check yields on account of the necessity for several crystallizations. A small amount of the so-called acetyl derivative of diphenic acid diamide was purified by several crystallizations from large amounts of ether; the material melted sharply at 166–167°. It was not studied further since the isolation of it involved many troublesome steps and the compound did not appear to be important in our work. Treatment of the substance with dilute sodium hydroxide solution gave the diamide of diphenic acid.

Anal. (Crystals, m. p. 172°.) Calcd. for $C_{14}H_8N_2$: C, 82.32; H, 3.95; N, 13.72. Found: C, 81.80, 81.85; H, 4.17, 4.06; N, 14.05, 14.10.

***p,p′*-Dibromodiphenic Acid.**—Schmidt and Junghans[6] made *p,p′*-dibromodiphenic acid by the oxidation of 2,7-dibromophenanthraquinone. The procedure which we used was based upon their work; details are similar to those given by one of us in describing the preparation of *p,p′*-dinitrodiphenic acid,[2] except that glacial acetic acid was employed as a solvent. The oxidation proceeded very slowly and it was frequently necessary to remove the dibromodiphenic acid by treatment of the solid reaction product with sodium carbonate solution. Unchanged dibromophenanthraquinone was then heated with more oxidizing agent. This process was repeated several times. It was not possible to estimate yields accurately. The 2,7-dibromophenanthraquinone used in this experiment was prepared by another investigator; details of the procedure employed in making it are not available.

Approximately 1 g. of *p,p′*-dibromodiphenic acid (m. p. 277–278°), 10 g. of glacial acetic acid (solvent) and 20 g. of acetic anhydride were heated at 145° for eleven hours. After some of the liquid had been distilled, the reaction mixture upon cooling deposited crystals; these were collected on a filter, washed and dried. The white solid melted at 304–305°. It was insoluble in sodium carbonate solution; when heated with 20% aqueous sodium hydroxide it slowly dissolved; acidification of the liquid yielded *p,p′*-dibromodiphenic acid.

Anal. Calcd. for $C_{14}H_6O_3Br_2$: Br, 41.84. Found: Br, 41.50, 41.61.

This experiment shows that *p,p′*-dibromodiphenic acid readily forms an anhydride; the results support the ideas stated in the introductory part of the paper. However, it is necessary to consider the possibilities regarding stereoisomerism as well as the influence of ring substituents upon carboxyl groups in order to get a complete account of the reasons for the unique behavior of *p,p′*-dinitrodiphenic acid.

Condensation of Diphenic Anhydride with Resorcinol. Work of Bischoff and Adkins.—In commenting upon the investigation[3] by one of us, Adkins and his associates[5] declared (without stating detailed experimental evidence) that the use of a temperature (175°) higher than 135–150° for condensing diphenic anhydride and resorcinol caused fundamental changes in structure which were avoided by Bischoff and Adkins. It was also said that Bischoff early in his work learned that when the anhydride was condensed with resorcinol at temperatures in the vicinity of 175°, a non-fluorescent compound was formed, sometimes with the evolution of carbon dioxide. We believe this observation has an important bearing on the results which Bischoff and Adkins reported and that they should have mentioned it.

---

[6] Schmidt and Junghans, Ber., 37,3567 (1904).

In order to answer the question regarding the influence of temperature on this reaction, we carried out the experiment described by Bischoff and Adkins, using the proportions of reagents, temperature, time of heating and extraction procedure which they gave. We readily obtained crystals by dissolving the reaction product in alcohol and gradually diluting the solution with water. The carefully purified crystalline material (resorcinoldiphenein) dissolved in aqueous sodium hydroxide, forming a greenish-yellow liquid, but did not produce marked fluorescence. On the other hand, the amorphous residue (ketone acid derivative) gave a strongly fluorescent liquid when added to sodium hydroxide solution. We repeated the condensation three times; in every case the results were practically the same. By the use of a very small amount of the crystalline substance a melting point of 178–179° was found; these figures were previously given by one[3] of us. A mixture of the crystals obtained by the Bischoff and Adkins method and those prepared some time ago in this Laboratory melted at 247–249°. We also found that the melting point of our resorcinoldiphenein (secured from a condensation product made at 175°) had changed from 178–179° to 247–249° upon standing in a stoppered test-tube. When a large amount of the crystals obtained by the Bischoff and Adkins method was heated in a capillary tube, it was observed that as soon as the temperature reached 175–178° liquefaction began; this was soon followed by solidification; it was necessary to heat the solid to 247–249° before it melted again. The compound now remained liquid or pasty even after cooling. These results indicate that the crystalline substance obtained through the condensation of diphenic anhydride and resorcinol at 135–150° is apparently the same as that which one of us made by the use of a higher temperature, 175°. Also it is obvious that the melting point of resorcinoldiphenein changes when the material is heated or allowed to stand for a long time. This may be due to isomerization, loss of water or other causes. We intend to study this matter further.

Bischoff and Adkins stated that acetylation of their resorcinol-diphenic anhydride condensation product (by heating with acetic anhydride) yielded a substance which was insoluble in alkalies and that the analogous ketone acid derivative was soluble in alkali. Later Adkins and his associates[6] repeated these statements and implied that one of us had overlooked them when criticizing the work. This differentiation procedure might be valid if one were dealing with homogeneous substances, but it is necessary to remember that the material obtained from the diphenic anhydride condensation is a mixture.

We have treated with acetic anhydride the amorphous reaction mass which we obtained by working at 175°, the material secured by the use of Bischoff and Adkins' procedure, and a mixture containing about 70% of crystalline resorcinoldiphenein and 30% of amorphous ketone acid-resorcinol condensation product. In each case 10 cc. of acetic anhydride was used for 1 g. of solid; heating was continued for four hours at 140°; then the mass was cooled, poured on ice and allowed to stand, with occasional stirring, scratching of the walls of the container and additions of cold water, until a pasty solid appeared. The latter was collected, washed with a small amount of sodium carbonate solution and with water; then the solid was pressed on a porous plate. In every case when the material was stirred with *N* sodium hydroxide solution the latter became yellowish-green; some of the solid remained undissolved. Acidification of the filtered liquid gave a considerable amount of precipitate. These experiments show clearly that the material obtained by acetylating Bischoff and Adkins' reaction product is not entirely insoluble in alkali; the results support the criticisms of the work of these investigators.

Summary

When monomethyl diphenate, mono-ethyl diphenate, dimethyl diphenate and diethyl diphenate were heated with acetic anhydride, each ester remained unchanged. Under similar conditions diphenamic acid was dehydrated in two different ways, giving diphenimide and 1-cyanobiphenyl-10-carboxylic acid; the diamide of diphenic acid was transformed into 2,2′-dicyanobiphenyl, through the loss of two molecules of water. *p,p′*-Dibromodiphenic acid formed an anhydride upon treatment with acetic anhydride; the behavior of this acid is different from that of *p,p′*-dinitrodiphenic acid.

Bischoff and Adkins obtained an amorphous substance by condensing diphenic anhydride with resorcinol at 135–150° in the presence of anhydrous zinc chloride and discussed the product as though it were practically homogeneous. This work has been repeated; it was found that the material is apparently identical with that which one of us secured by working at 175°. It contains two substances, resorcinoldiphenein, which can be obtained in crystalline form, and an amorphous condensation product derived from diphenyleneketone-4-carboxylic acid. Incidentally it was learned that the melting point of resorcinoldiphenein apparently changes when the compound is heated or allowed to stand for a long time. Solutions of pure resorcinoldiphenein in aqueous sodium hydroxide do not show marked fluorescence.

THE THERMAL DECOMPOSITION OF SODIUM ETHYL

BY WALLACE H. CAROTHERS AND DONALD D. COFFMAN

RECEIVED OCTOBER 18, 1928 PUBLISHED FEBRUARY 5, 1929

Application of the octet theory to sodium ethyl leads to the completely polar formula  $\mathrm{Na}^{+}\ :\overset{\mathrm{H}}{\underset{\mathrm{H}}{\ddot{\underset{..}{\mathrm{C}}}}}:\overset{\mathrm{H}}{\underset{\mathrm{H}}{\ddot{\underset{..}{\mathrm{C}}}}}:\mathrm{H}^{-}$. A non-polar or partially polar formula is excluded by the fact that each of these ions has a complete octet. Sharing of electrons between them is therefore impossible.

Sodium alkyls have been prepared in a state of approximate purity by Schlenk and Holtz[1] and their physical properties may be compared with those listed by Lewis[2] as typical of polar substances. They are non-volatile solids which do not melt without decomposition. They are insoluble in petroleum ether and benzene. That they are capable of behaving as true electrolytes has been established by the important work of Hein.[3] Hein showed that solutions of sodium ethyl in zinc ethyl conduct (zinc ethyl is a non-conductor); that the conduction follows Faraday's law; that the ethyl group is actually involved as an anion in the transport of the current; and that it is discharged at the anode with the formation of ethylene and ethane.[4]

The theory and the facts thus agree in all particulars and it seems completely justified to assume that sodium ethyl is composed of sodium ion and ethyl anion. This latter represents one of the possible reactive species of ethyl, and indeed the only one which is capable in a certain sense of being isolated. The spontaneous changes which it undergoes are therefore of considerable theoretical interest. Moreover, these spontaneous changes occur smoothly at temperatures well below 100°, a fact which provides some assurance of the absence of deep-seated secondary reactions.

Wanklyn, who in 1858 prepared $\mathrm{Zn(C_2H_5)_2 \cdot NaC_2H_5}$, the earliest known example of a sodium alkyl, observed that it was decomposed by rather gentle heating with the formation of gases and a residue consisting of a mixture of sodium and zinc. Of this behavior he says,[5] "this reduction of a sodium compound by mere heating is, I think, unique, and is to be regarded as a chemical anomaly."

[4] When a lead anode was used the product was lead tetra-ethyl.

[5] Wanklyn, Ann., 108, 67 (1858).

The thermal decomposition of sodium ethyl was studied by Schorigin,[6] who observed that the gaseous products consisted exclusively of ethylene and ethane in equivalent amounts. This is, of course, a result which might be expected if the ethyl anion were to lose one electron to the sodium cation with the formation of the ethyl radical. The peculiarity of Schorigin's results which led to a repetition and extension of his experiments was the fact that the first fractions of the gas contained more ethane than ethylene and the last more ethylene than ethane. Such behavior is inconsistent with the assumption that the first products of the reaction are metallic sodium and the ethyl radical.

Schorigin carried out his experiments by mixing mercury ethyl and sodium wire in an atmosphere of nitrogen and immediately heating the mixture until thermal decomposition set in and was complete, the gas being collected over water containing sodium hydroxide and saturated with sodium chloride. The last portion of the hydrocarbon gases was swept into the receiver by a stream of carbon dioxide. In preliminary experiments made by the writers in this way the gas obtained was found to consist chiefly of ethylene. A similar result was obtained when the compound $Zn(C_2H_5)_2 \cdot NaC_2H_5$ was prepared in the pure state and decomposed *in vacuo*, and when sodium ethyl prepared by the method of Schlenk and Holtz was isolated and decomposed *in* vacuo.

All of these methods involved experimental difficulties capable of introducing large errors, and all of the data here presented were obtained by the following procedure.

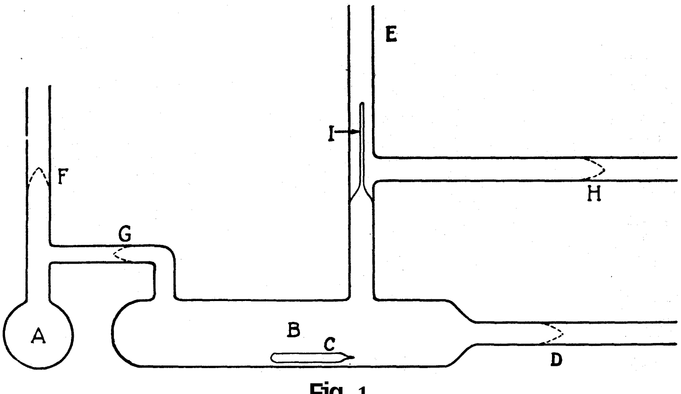

Fig. 1.

Preparation of the Sodium Ethyl.—The tube B containing a known amount of mercury ethyl in the sealed capsule C was sealed at D to a high vacuum line. A large excess of sodium (1–2 g. in all) was placed in the flask A, which was then sealed off at F. The mercury vapor pump was then started and when the pressure had been reduced to less than 0.1 micron, the sodium was distilled into the tube B by heating A with a

---

[6] Schorigin, *Ber.*, 43, 1931 (1910).

free flame, the tube C being cooled by a stream of water falling on B. The sodium condensed as a bright mirror completely covering the walls of B. After the distillation the flask **A** was removed by sealing at G and the tube B was sealed off at D. The tube B was then shaken vigorously to break the capsule C. The thinner portions of the sodium mirror were rapidly blackened by the mercury ethyl: after standing for twelve hours the liquid in the tube had completely disappeared and black granules were present which could readily be broken loose from the surface. After a period of twenty-four to forty-eight hours no trace of mercury ethyl could be found in the tube. These results indicated that mercury ethyl is, under these conditions, quantitatively converted into sodium ethyl.

To obtain the products of the thermal decomposition of the sodium ethyl, the tube B was sealed at E to a Toepler pump and an iron slug was placed in H, which was then sealed. After the system had been completely evacuated, the iron slug was raised by a magnet and allowed to fall on the valve I, thus opening the tube B to the system. The tube B was placed in an oil-bath. The gas was pumped off as it was evolved and collected over mercury.

Analysis of Gases.—The precise analysis of small samples of hydrocarbon gases presents experimental difficulties which have not yet been completely solved. It is thought, however, that none of the analytical results here presented is sufficiently in error to affect any of the conclusions of this study. The apparatus used was that of Bone and Wheeler,[7] which permits the use of 5–20 cc. samples. Hydrogen was determined by direct absorption with Paals' Pd-sol. Ethylene was absorbed by bromine water containing potassium bromide. This reagent slowly attacks ethane also, so that there is some uncertainty in the ethylene : ethane ratios.

Experimental Results

Experiment 7.—Sodium ethyl from 1.312 g. of $Hg(C_2H_5)_2$ and 1.5 g. of sodium was decomposed. Between room temperature and 142°, 213 cc. of gas (S. T. P.) or 94% of the calculated amount was obtained. Of this gas, 6 cc. was present before heating; 7.5 cc. was evolved between 29 and 90° and about 14.5 cc. between 117 and 142°.

Anal. C_2H_4, 84.30; H_2, 0.24; C_2H_6 (by contraction), 14.95; C_2H_6 (by absorption), 14.97; total, 99.51: C/A, 1.248; C_2H_4/C_2H_6, 5.63.

$$C/A = \frac{\text{Contraction in volume due to combustion}}{\text{Contraction in volume due to absorption by KOH}} = \frac{H_2O}{CO_2}$$

Calcd. for ethane, 1.250.

At 142° pumping was continued until no more gas was evolved. The oil-bath was then removed and the tube heated with a free flame. Gas was again copiously evolved. In all 107.5 cc. of gas (S. T. P.) was collected. This gas proved to be nearly pure hydrogen.

Anal. (1) C_2H_4 (by Br absorption) 1.11; H_2 (by Pd absorption) 97.65; C_2H_6 (by difference) 1.24; C_2H_4 (by Br absorption) 1.24. (2) By combustion and absorption, H_2, 97.70; C_2H_6, 1.22.

---

[7] See Grice and Paymen, Fuel *Science* Practice, July, 1924.

Although the C/A ratio indicated the absence of higher hydrocarbons, a special search for butane was made as follows: 150 cc. of the gas of Experiment 7 was placed in communication with an evacuated bulb of 10 cc. capacity which was immersed in a mixture of carbon dioxide snow and acetone. No liquid was observed to condense. The bulb while still in the freezing mixture was sealed off and after warming was opened under mercury so as to transfer the gas directly to the gas analysis apparatus. Some air was admitted during this process. Ethane found by contraction was 11.52 and by absorption 11.80%, the ratio being 1.218. Assuming no experimental error in the analysis, this would indicate the presence of about 0.03% of butane in the original sample.

Experiment 8.—The following experiment is typical of those in which the gas was collected in a series of fractions and each fraction analyzed separately: 0.635 g. of mercury ethyl; 1.0 g. of sodium.

Frac.	Temp. of bath, °C.	Vol. of gas, cc.	C_2H_4	C_2H_6		Total	C/A	$\frac{C_2H_4}{C_2H_6}$
				By contr.	By abs.			
1[a]	20	3	26.87	69.50	67.50	94.37	1.29	0.41
2	90	26.0	74.10	24.98	25.50	49.60	1.225	2.91
3	90	16.2	85.70	13.90	13.71	99.41	1.267	6.25
4	90	18.5	88.20	11.30	11.24	99.64	1.257	7.85
5	91	16.4	89.60	9.78	9.80	99.40	1.247	9.14
6	90	20.0	89.40	10.03	10.05	99.40	1.248	8.90
7	90–150	8.9	86.85	12.17	11.62	99.43	1.312[b]	7.48

Total, 109.0 cc. = 102.6 cc. (S. T. P.) or 94% of calcd. amount.

[a] Large experimental error owing to small volume of gas.

[b] Including 0.96% of H_2.

Discussion of Results

The analytical data indicate the presence of not more than traces of any other substances than ethylene and ethane in the gases evolved below 150°. Repeated qualitative tests for acetylene were negative and the data of Expt. 7 indicate the absence of higher hydrocarbons.

The data of Expt. 7 show that the gas formed between 25 and 142° consists of ethylene and ethane in the ratio 5.6:1 and that after the reaction has completely stopped at 142°, large amounts of hydrogen are evolved on heating to much higher temperatures. The only obvious way of accounting for this is to suppose that the principal reaction is the transformation of sodium ethyl into ethylene and sodium hydride. The sodium hydride then decomposes at higher temperatures with the liberation of hydrogen.

$$NaC_2H_5 \longrightarrow NaH + C_2H_4 \qquad (1)$$
$$2\,NaH \longrightarrow 2\,Na + H_2$$

Using the polar formula given above, this reaction involves simply the elimination of the unshared electron pair of the ethyl anion together with one of the protons-as hydride ion.

In this connection it is interesting to observe that Jolibois[8] found that both $Mg(C_2H_5)_2$ and C_2H_5MgI decompose at 175° with the formation of ethylene, leaving a residue of MgH_2.[9]

To account for the presence of ethane, one may suppose that the following reaction occurs

$$2\ NaC_2H_5 \longrightarrow Na_2C_2H_4 + C_2H_6$$

This reaction involves simply the transfer of a proton from one ethyl anion to another. The first ion thus becomes a doubly charged anion and the second the neutral molecule, ethane. If one regards ethane as a very weak polybasic acid, this reaction finds many analogies. Thus, $NaOHCH_2$-CH_2OH on heating is converted into $NaOCH_2CH_2ONa$ and $HOCH_2$-CH_2OH.

The data of Expt. 8 show that the gas which is slowly formed at ordinary temperature contains more ethane than ethylene,[10] and there appears to be no simple and obvious way to account for this other than by the equation represented above.

Some idea of the fate of the $Na_2C_2H_4$ may be obtained from a study of the data in Expt. 7. These data show

Sodium ethyl used = 0.01015 mole
H_2 found 105 cc. = 0.00469 mole
C_2H_4 found 180 *cc.* = 0.00804 mole
C_2H_6 found *33 cc.* = 0.00147 mole
Deficit = 0.00064 mole

The number of atoms of hydrogen thus considerably exceeds the number of moles of ethylene, and the total ethane and ethylene lacks 6% of accounting for all of the sodium ethyl. These facts may be accounted for by assuming the following changes

$$\begin{array}{ll}
4\ NaC_2H_5 & \longrightarrow 2\ Na_2C_2H_4 + 2\ C_2H_6 \\
2\ Na_2C_2H_4 & \longrightarrow C_2H_6 + Na_2CHCHNa_2 \\
Na_2CHCHNa_2 & \longrightarrow 2\ NaH + NaCCNa \\
\hline
4\ NaC_2H_5 & \longrightarrow 3\ C_2H_6 + H_2 + 2\ Na + NaCCNa
\end{array}$$

In this series of reactions, which resulted in the formation of 0.00147 mole of ethane, there would be formed 0.00049 mole of sodium acetylide while the carbon deficit would require 0.00064 mole. Unfortunately, no test on the residue for sodium acetylide was made. It was, however, observed, after no more gas was produced by strongly heating the residue, that the admission of air to it caused a brilliant flash of fire. Corresponding to the ethane, there would also be formed 0.00049 mole of hydrogen. When this is subtracted from the 0.00469 mole of hydrogen found, one obtains 0.00420 mole, whereas the 0.00804 mole of ethylene found would require, in accordance with Equation 1, 0.00402 mole. The agreement is all that could be expected from data of this type.

---

[8] Jolibois, Compt. rend., 155, **353** (1912).

[9] Jolibois makes no mention of the presence of any ethane in this gas.

[10] This has been repeatedly verified in other experiments not reported here,

The precise verification of these relationships must await more elaborate experiments, which cannot be performed at this time.

The manner in which the ethylene : ethane ratios changed from less than 1 to more than 9 in successive fractions and then fell off again toward the end clearly indicates the presence of a series of successive reactions or of simultaneous reactions with different temperature coefficients.

One simple and quite obvious reaction finds no place in the above scheme

$$NaC_2H_5 \longrightarrow Na^+ + C_2H_5^-$$

In this reaction the ethyl anion loses one of its unshared electrons to the sodium ion and is converted into the ethyl radical which may then undergo disproportionation or polymerization. It seems possible that the ethyl anion may, under certain conditions, behave in this way (cf. the work of Hein referred to above), and, assuming the correctness of Schorigin's results, this reaction might completely describe the thermal decomposition of sodium ethyl. This reaction requires, however, that ethane and ethylene be formed in precisely equivalent amounts. In all experiments made by the writers with sodium ethyl prepared by various methods, the ethane constituted only a relatively small fraction of the gas evolved and the nature of the data indicates that only a small part of it could have been formed by this reaction.

Summary

1. Mercury ethyl reacts completely with an excess of sodium *in vacuo* with the formation of sodium ethyl.

2. The thermal decomposition of sodium ethyl (in the presence of sodium and mercury) begins very slowly at room temperature and is quite rapid at 100°.

3. The gas formed by the thermal decomposition of sodium ethyl at temperatures in the neighborhood of 90–100° consists of ethylene and ethane in the ratio of about 85 to 15. Sodium hydride is found in the residue. The principal reaction is, therefore, $NaC_2H_5 \longrightarrow NaH + C_2H_4$.

4. The gas formed by the spontaneous decomposition of sodium ethyl at ordinary temperature contains more ethane than ethylene. This is supposed to be due to the reaction $2NaC_2H_5 \longrightarrow Na_2C_2H_4 + C_2H_6$. The analytical data furnish some information concerning the fate of the $Na_2C_2H_4$.

THE PREPARATION OF ZINC ALKYLS AND THEIR USE IN THE SYNTHESIS OF HYDROCARBONS

BY C. R. NOLLER

RECEIVED OCTOBER 23, 1928 PUBLISHED FEBRUARY 5, 1929

In attempting to prepare in considerable quantity the lower hydrocarbons of the type R_4C, several possible methods were investigated. Since the most promising method seemed to be by way of the Grignard reagent, this was tried first, but a number of difficulties were encountered. When a primary alkylmagnesium halide is allowed to react with a tertiary alkyl halide, the reaction is slow and incomplete, the yield is low due to the removal of halogen acid, and higher boiling products are formed from which it is difficult to separate the desired product. Furthermore, if the hydrocarbon has a high vapor pressure, it is difficult to separate it from the ether, which is always present even though a portion is distilled before carrying out the reaction with the alkyl halide. The same difficulties arise if a tertiary alkylmagnesium halide is treated with a compound such as diethyl sulfate, and in addition the yield of Grignard reagent is low (40–45% using the tertiary chlorides, 12–15% using tertiary bromides). Attempts to prepare these hydrocarbons by the Wurtz reaction from a mixture of tertiary and primary halides were entirely unsuccessful. These facts led to an investigation of the method by which these compounds were first prepared, namely, through the use of zinc alkyls. During the course of this work, several improvements in the preparation and manipulation of zinc alkyls have been made.

Preparation of Zinc Alkyls

There are four chief objections to the use of zinc alkyls for synthetic purposes. 1. They are spontaneously inflammable. 2. The preparation of the zinc–copper couple by reduction of a mixture of zinc dust and copper oxide cannot be performed on a large scale. 3. The process is expensive because of the necessity of using alkyl iodides rather than the bromides. 4. With the exception of zinc methyl and zinc ethyl, the yields are low. A fifth consideration that has done much to prevent their use is that for most purposes they can be replaced by the alkylmagnesium halides.

The objection to the use of zinc alkyls on the grounds of spontaneous inflammability was overcome by Blaise,[1] who worked with solutions of alkyl zinc iodides in toluene and in petroleum fractions. Here, however, it was necessary to use ethyl acetate to bring about the reaction, thus introducing a low boiling liquid, which is often objectionable. Furthermore, the exact quantities of alkyl zinc halide could be determined only by anal-

---

[1] Blaise, *Bull. soc. chim.*, [4] **9**, 1 (1911).

ysis. In the present investigation it was found that by dissolving the pure zinc alkyls in an equal weight of a solvent of the desired boiling point, for example, toluene, xylene or tetralin, the solutions could be readily handled in the open air and poured from one flask to another without danger of ignition. Moreover, in using the zinc alkyls, the presence of a solvent invariably gave better yields than when the reactions were carried out in the absence of a solvent.

Various methods of preparing the zinc for the reaction have been used. The best yields of zinc alkyls have been obtained with the zinc–copper couple of Gladstone and Tribe[2] as prepared by Lachman.[3] This method consists of mixing zinc dust with about 10% of its weight of powdered copper oxide and heating in a current of hydrogen to incipient fusion. It is rather difficult to heat to just the right temperature and almost impossible to carry the method out on a large scale. The product must be protected from the air to prevent oxidation. The present work shows, however, that equally good results can be obtained by using fine turnings of an alloy of zinc with from 5 to 8% of copper. This can be readily prepared in the laboratory from zinc and brass turnings in runs of a kilo or more and as much as five kilos made in four hours. Moreover, it will keep indefinitely in a dry, stoppered bottle.

It has been reported in the literature that alkyl bromides do not react to give either zinc alkyls according to the method of Lachman[3a] or alkyl zinc halides, according to the method of Blaise.[1] Job and Reich[4] state that ethyl bromide reacts with the zinc–copper couple in the presence of a catalyst prepared by causing aluminum to react with ethylene bromide. When using this catalyst, however, the reaction requires from six to eight hours for completion. Inasmuch as the reaction of alkyl iodides is very vigorous after it has started and requires continual watching and intermittent cooling, attempts were made to replace a portion of the iodide by the bromide. If an equimolecular mixture of alkyl iodide and bromide is used, the reaction starts easily, proceeds smoothly and if the product is distilled in *vacuo* the yields are equal to those obtained with iodide alone. A smaller proportion of iodide is necessary in preparing the higher zinc alkyls, such as zinc dibutyl, where one may use a mixture of one mole of butyl iodide to three moles of butyl bromide. It is entirely possible, even in the case of zinc ethyl, to start the reaction with the iodide and keep it going by the addition of the bromide, but this requires careful regulation and is not always successful.

The yields of zinc alkyls are greatly increased if the distillation from the crude reaction mixture is carried out under a vacuum. This was early

[3] (a) Lachman, *Am. Chem. J.*, 19, 410 (1897); (b) 24, 31 (1900).

[4] Job and Reich, *Bull. soc. chim.*, 33, 1424 (1923).

recognized by Gladstone and Tribe,[2] but for some reason, probably because zinc ethyl and zinc methyl are obtained in excellent yields from the iodide by ordinary distillation, they are the only ones who report such a procedure. The advantage of vacuum distillation is markedly brought out when bromides are used. When zinc ethyl is prepared using a mixture of ethyl iodide and ethyl bromide, ordinary distillation gives a yield of 68%, which is increased to 89% on vacuum distillation. It is even more noticeable in the case of the higher zinc alkyls. Thus ordinary distillation using mixed alkyl halides gives only 39% of zinc dipropyl, whereas on vacuum distillation the yield is 86%.

It is interesting to point out a possible course of the reaction using the mixed halides. In one experiment using a mixture of iso-amyl iodide and iso-amyl bromide, the reaction did not go to completion and since the run was of considerable size, the unused alkyl halides were recovered during the distillation. It was expected that since the iodide reacts most readily with the zinc, the unused halide would be the bromide. Actually the recovered halide was practically pure iodide. This might be explained by assuming that the alkyl iodide reacts with the zinc to give zinc alkyl iodide and this in turn reacts with the alkyl bromide to give more of the alkyl iodide.

$$\mathrm{Zn} + \mathrm{RI} \longrightarrow \mathrm{ZnIR}$$
$$\mathrm{ZnIR} + \mathrm{RBr} \longrightarrow \mathrm{RI} + \mathrm{ZnBrR}$$

This suggests that only a small quantity of iodide would be necessary to bring about the reaction. It was found, however, that a considerable concentration of iodide is necessary to keep the reaction going.

The zinc alkyls which were successfully prepared were zinc diethyl, zinc di-n-propyl, zinc di-n-butyl and zinc di-*iso*-amyl. Secondary halides such as iso-propyl and iso-butyl halides gave chiefly gaseous products, presumably the saturated and unsaturated hydrocarbons,[2] and only minute quantities of the zinc alkyl.[5] Cyclohexyl bromide was found to react with the zinc–copper couple at the boiling point of the bromide to give a mixture of cyclohexene and dicyclohexyl. Diethyl sulfate does not react with the couple,

Preparation of Hydrocarbons

Most textbooks of organic chemistry state that hydrocarbons may be prepared by the action of zinc alkyls on alkyl halides and give as a general reaction

$$\mathrm{ZnR_2} + 2\mathrm{R'X} \longrightarrow 2\mathrm{R{-}R'} + \mathrm{ZnX_2}$$

---

[5] Bohm [J. Russ. *Phys.-Chem. Soc.*, 31, 46 (1899); Chem. *Zentr.*, I, 1067 (1899)] claims a yield of 25% of zinc di-isopropyl, while Gladstone and Tribe (ref. *2)* get only gaseous products. Garzarolli-Thurnlackh and Popper [*Ann.*, 223, 168 (1884)] claim a yield of 3541% of zinc di-isobutyl.

The only alkyl halides which we have found to react with the zinc alkyls are the tertiary alkyl halides. Primary and secondary halides and such compounds as diethyl sulfate and allyl bromide could not be made to react under the conditions of the experiment. Moreover, hydrocarbons reported in the literature as prepared by means of zinc alkyls are all prepared from the tertiary halides. Because of their ease of preparation, the chlorides only have been used in the present work.

It has been found that the yields are improved by carrying out the reaction in the presence of an inert solvent of such a boiling point that the product could be separated easily by distillation. Thus the yield of trimethylethylmethane was 18% without using a solvent and 45% using xylene as a solvent. To obtain a product as free from halogen as possible, the solution of alkyl halide is run into a slight excess of the zinc alkyl in the desired solvent.

The temperature used was the lowest that would permit the reaction to run smoothly. It is *absolutely essential* that only a small amount of the halide be added at first and the mixture warmed until the reaction starts. The mixture is then kept at this temperature throughout the reaction. If a considerable amount of the halide is added without the reaction starting, there is danger that the reaction will take place with explosive violence.[6] This would seem to indicate that the reaction is auto-catalytic and it would be interesting to attempt to find catalysts that would allow the reaction to start easily and possibly to proceed at lower temperatures.

In all cases the yields are low (25–51%) but it is believed that this method gives higher yields and purer products with less trouble than any other now available.

Experimental

General Procedure for Preparing Zinc Alkyls.—In a 1-liter round-bottomed flask fitted with a reflux condenser and a heavy stirrer is placed 130 g. (approx. 2 moles) of fine turnings of a zinc–copper alloy containing from 5 to 8% of copper. To this are added 0.5 mole of alkyl iodide and 0.5 mole of alkyl bromide and the mixture is gently refluxed with slow stirring. From twenty to forty minutes after refluxing begins the reaction starts, as is evidenced by the greatly increased rate of refluxing, and the source of heat should be removed. In case the reaction should become too vigorous, the flask is cooled with ice water but only to the point where the reaction is again under control. At the end of half an hour from the time the heat was removed the reaction is usually

---

[6] In one instance the solution of zinc alkyl was cooled in an ice–salt bath and kept at a low temperature whiie the alkyl halide was added. No reaction seemed to take place at first, but shortly and without warning an explosion of such violence took place that it resembled a detonation. An enameled pan containing the ice–salt mixture was crumpled by the force of the explosion. On repeating the experiment on a smaller scale, the same violent reaction took place, though with less destructive force. If, however, the proper precautions are taken to start the reaction, it proceeds smoothly and without any danger whatsoever.

over. The flask is allowed to cool, transferred to a distilling head and' condenser and distilled directly from the reaction flask under a pressure of less than **30** mm. of mercury. The apparatus need not be swept out with an inert gas before starting the distillation but at the end, when the vacuum is released, dry carbon dioxide is admitted to the apparatus instead of air. On redistillation in *vacuo* through a column, practically the entire product boils over a range of **3** to 5°. After weighing the product, an equal weight of the desired dry solvent is added and the solution is ready for use in subsequent reactions.

solvent. A small amount of the chloride is run into the flask and the mixture is gradually heated until a sharp rise in temperature takes place, indicating that the reaction has started. (Caution: The reaction must get started before a large amount of the chloride has been added or an explosion may result.) More halide is then slowly added, keeping the mixture at the temperature at which the reaction started. At the end of the addition the mixture is decomposed with dilute hydrochloric acid, washed, dried and the hydrocarbon distilled from the solvent through a column. A second distillation gives a product boiling over a range of 1 to 2°. A considerable amount of gas or a low-boiling fraction is always obtained, either during the reaction or the distillation. This was not investigated but is probably a mixture of saturated and unsaturated hydrocarbons.

Summary

1. Improvements in the preparation and manipulation of zinc alkyls are given.
2. The zinc alkyls have been used to prepare a number of hydrocarbons of the type R_4C.

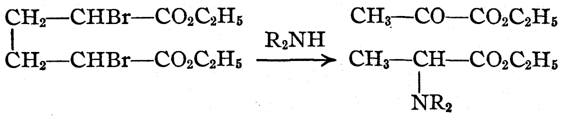
THE CLEAVAGE OF DIETHYL ALPHA,ALPHA'-DIBROMO-ADIPATE BY SECONDARY AMINES[1]

BY REYNOLD C. FUSON AND RAYMOND L. BRADLEY

RECEIVED OCTOBER 31, 1928 PUBLISHED FEBRUARY 5, 1929

It has been shown by von Braun, Leistner and Miinch[2] that diethyl α,α'-dibromo-adipate when treated with certain secondary amines is cleaved in such a way as to give ethyl pyruvate and an amino ester reported by them to be ethyl a-dialkylaminopropionate.



$$\begin{array}{l} CH_2—CHBr—CO_2C_2H_5 \\ | \\ CH_2—CHBr—CO_2C_2H_5 \end{array} \xrightarrow{R_2NH} \begin{array}{l} CH_3—CO—CO_2C_2H_5 \\ \\ CH_3—\underset{\underset{NR_2}{|}}{CH}—CO_2C_2H_5 \end{array}$$

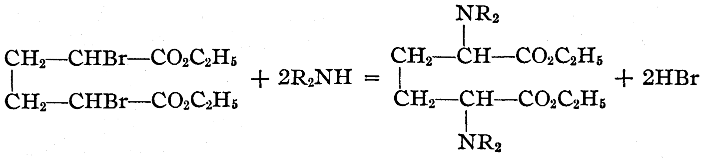
They reported that diethylamine, di-n-propylamine, copellidine and di-iso-amylamine produce the same type of cleavage, yielding in each case ethyl pyruvate and an a-dialkylaminopropionic ester. This list has subsequently been extended by von Braun, Jostes and Wagner[3] to include a number of similar amines of this class. Dimethylamine and piperidine, however, gave no cleavage but were found to react normally to give the corresponding tetra-alkyldiarnino-adipicesters.

---

[1] This work was presented before the Midwest Regional Meeting of the American Chemical Society at Minneapolis, June 9, 1928.

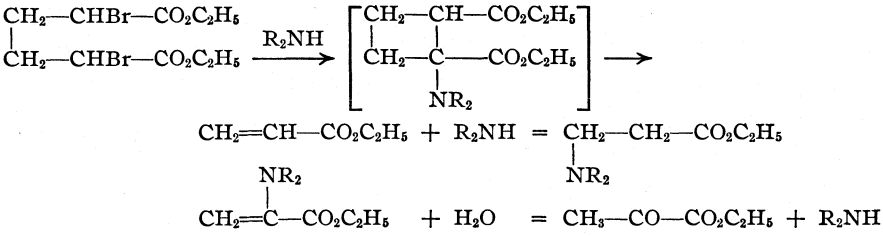
[2] Von Braun, Leistner and Munch, **Ber., 59B, 1950 (1926).**

[3] Von Braun, Jostes and Wagner, *ibid.,* **61B, 1423 (1928).**



$$\begin{array}{l} CH_2-CHBr-CO_2C_2H_5 \\ | \\ CH_2-CHBr-CO_2C_2H_5 \end{array} + 2R_2NH = \begin{array}{l} CH_2-\overset{NR_2}{\overset{|}{C}}H-CO_2C_2H_5 \\ | \\ CH_2-\underset{NR_2}{\underset{|}{C}}H-CO_2C_2H_5 \end{array} + 2HBr$$

In a recent paper Fuson[4] presented a mechanism to explain the apparently novel type of chain rupture, assuming the formation of a cyclobutane derivative as an intermediate compound.



$$\begin{array}{l} CH_2-CHBr-CO_2C_2H_5 \\ | \\ CH_2-CHBr-CO_2C_2H_5 \end{array} \xrightarrow{R_2NH} \left[\begin{array}{l} CH_2-CH-CO_2C_2H_5 \\ |\qquad\quad | \\ CH_2-\underset{NR_2}{\underset{|}{C}}-CO_2C_2H_5 \end{array}\right] \longrightarrow$$

$$CH_2{=}CH-CO_2C_2H_5 + R_2NH = \underset{NR_2}{\underset{|}{C}}H_2-CH_2-CO_2C_2H_5$$

$$CH_2{=}\overset{NR_2}{\overset{|}{C}}-CO_2C_2H_5 + H_2O = CH_3-CO-CO_2C_2H_5 + R_2NH$$

It was pointed out that a dissociation of this hypothetical intermediate into two molecules of ethylenic character, a type of reaction characteristic of cyclobutane derivatives, would yield, respectively, ethyl acrylate and ethyl a-dialkylamino acrylate. The former would be expected to combine with a molecule of the dialkylamine to give ethyl β-dialkylaminopropionate; the acrylic ester would be hydrolyzed to ethyl pyruvate.

The proposed mechanism agreed with the findings of von Braun, Leistner and Münch except in that it postulated the formation of β-dialkylpropionic esters instead of the a-esters reported. This difficulty was cleared away when it was shown that in the reaction between diethyl-α,α-dibromoadipate and diethylamine the amino ester obtained is actually ethyl β-diethylaminopropionate and not the a as reported by von Braun and his co-workers.[3]

The importance of this point in relation to the theory is such that it has been checked also in the case of di-n-propylamine. As was to be expected, ethyl β-di-*n*-propylaminopropionate was obtained and not the corresponding a-ester. The position of the amino group was established as in the previous case by a mixed melting-point determination of the methiodide of the amino ester with that of the authentic specimen. The amount of cleavage in the case of di-n-propylamine was 85%.

Von Braun and his co-workers believe that the tendency of a given amine to produce the cleavage is dependent on the form of the amine. Thus they point out that while piperidine does not produce cleavage the pipecolines and copellidine do so. This, they say, is because piperidine is dish-shaped and may be inserted into the adipic ester molecule without

---

[4] Fuson, THIS JOURNAL, 50, 1444 (1928).

disrupting it. Amines which cause cleavage do so, it is asserted, because of their more three-dimensional form.

On the basis of the proposed cyclobutane mechanism for the cleavage, it is difficult to understand why the slight difference between piperidine and the pipecolines should have such a profound effect on the tendency to cause cleavage. The action of piperidine has, therefore, been re-examined.

It has been shown that, contrary to the findings of von Braun and his students, cleavage takes place, giving in addition to the diethyl α,α'-dipiperidino-adipate reported by them the cleavage products ethyl pyruvate and ethyl-β-piperidinopropionate. The former, owing presumably to the fact that it is readily hydrolyzed by water, was obtained in a relatively small amount. The yield of ethyl-β-piperidinopropionate, however, was 75% of the theoretical. It was proved to be the β- and not the α-amino ester by comparing its methiodide with an authentic specimen.

Experimental

***Meso*-diethyl-α,α'-dibromo-adipate and Di-*n*-propylamine.**—The method of von Braun, Leistner and Munch[2] was used. A mixture of 36 g. (0.1 mole) of *meso*-diethyl-α,α'-dibromo-adipate and 60.6 g. (0.6 mole) of di-n-propylamine was heated gently until reaction had begun. The reaction was allowed to proceed under its own heat until it had moderated somewhat. The mixture was then heated for five hours on the steam-bath, cooled and shaken with ether and excess dilute hydrochloric acid. The ether layer was removed, dried over sodium sulfate and distilled. Only a small amount of ethyl pyruvate was obtained.

The aqueous layer was made alkaline with sodium hydroxide and extracted thoroughly with ether. The ether extract was dried over sodium sulfate and distilled. The ethyl-β-di-*n*-propylaminopropionate distilled at 112–114° (20 mm.). (This base was prepared by von Braun, Leistner and Munch, who identified it as ethyl-α-di-*n*-propylaminopropionate. They reported a boiling point of 102–104° (12 mm.) for the base and a melting point of 76° for its methiodide.) The yield was 15 g. or 85% of the theoretical. The identity of the ethyl-β-di-*n*-propylaminopropionate obtained was confirmed by means of a mixed melting-point determination. When its methiodide was mixed with that of an authentic specimen of the base (preparation described below) there was no depression of the melting point.

Ethyl-β-di-*n*-propylaminopropionate.—Ten g. of di-n-propylamine dissolved in dry benzene was treated with 3 g. of ethyl-β-chloropropionate. The mixture was heated on the steam-bath for an hour, cooled and washed with water to remove the di-n-propylamine hydrochloride. The benzene solution was dried and distilled. The ethyl-β-di-*n*-propylaminopropionate boiled at 112–114° (20 mm.). Its methiodide melted at 76°.

***Meso*-diethyl-α,α'-dibromo-adipate** and Piperidine.—The method of von Braun and Münch[5] was used but inasmuch as the results were considerably different, the exact procedure is indicated. Thirty g. of *meso*-diethyl-α,α'-dibromo-adipate was heated under reflux for one and one-half hours with 50 g. of piperidine. The reaction was very vigorous and the flask had to be cooled somewhat at the beginning. The reaction products were isolated in the manner indicated above in the experiment with di-n-propylamine. Only a small amount of ethyl pyruvate was isolated. It was identified

---

[5] Ref. 2, p. 1947.

by means of a mixed melting-point determination with its phenylhydrazone (m. p. 118°) and that of an authentic specimen of ethyl pyruvate.

Of the basic product twelve g. distilled at 114–116° (22 mm.) and was shown (see below) to be ethyl-β-piperidinopropionate; yield, 75% of the theoretical; d_{20}, 0.927.

Anal. Calcd. for $C_{10}H_{19}O_2N$: C, 64.85; H, 10.35. Found: C, 64.6; H, 10.0.

The methiodide melted at 100–102°. A mixed melting-point determination with the methiodide prepared from a known sample of the piperidino ester, whose preparation is described below, served to identify the compound.

The residue from the distillation proved to be diethyl-α,α'-dipiperidino-adipate. Four g. of this compound was isolated After four recrystallizations from ether and one from petroleum ether the compound melted sharply at 94° (von Braun and Münch give 99° as the melting point).

Anal. Calcd. for $C_{20}H_{36}O_4N_2$: C, 65.2; H, 9.8. Found: C, 65.3; H, 9.8.

Ethyl-β-piperidinopropionate.—Seventeen g. of piperidine dissolved in 50 g. of dry benzene was refluxed with 6 g. of ethyl-β-chloropropionate. The product distilled at 113–116° (22 mm.). The methiodide melted at 100–102°.

Summary

Meso-diethyl-α,α'-dibromo-adipate is cleaved by piperidine to give a 75% yield of ethyl-β-piperidinopropionate.

Di-n-propylamine gives ethyl-P-di-n-propylaminopropionate in a yield of 85%.

The identity of ethyl-β-piperidinopropionate and of ethyl-β-di-*n*-propylaminopropionate has been established by mixed melting-point determinations of the methiodides with authentic specimens.

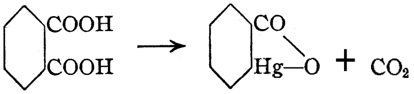
THE REPLACEMENT OF CARBOXYL BY MERCURY IN CERTAIN 3-SUBSTITUTED PHTHALIC ACIDS. PRELIMINARY PAPER

BY FRANK C. WHITMORE AND PAUL J. CULHANE

RECEIVED NOVEMBER 2, 1928 PUBLISHED FEBRUARY 5, 1929

It has long been known that the treatment of phthalic acid with mercuric acetate gives an o-mercurated benzoic acid.[1] The present study was undertaken to determine the mechanism of the mercuration and to find the effect of substituents on the reaction.

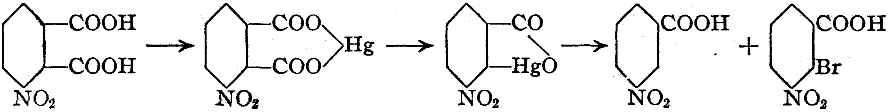


The first step in the reaction is the formation of an insoluble mercuric salt, as is the case in the mercuration of benzoic acid. The mercuric phthalate may then lose carbon dioxide with the replacement of the carboxyl by mercury. Another alternative is that the mercuric salt under

---

[1] Pesci, *Atti accad. Lincei,* [5] *10,* 1, 362 (1901).

the influence of heat may mercurate the benzene ring ortho to one of the carboxyls as happens in the mercuration of benzoic acid. The product would be a 3-mercurated phthalic acid which, on losing carbon dioxide, would give the observed product, o-mercurated benzoic acid. Working with phthalic acid it is impossible to distinguish between these mechanisms. Consequently, 3-substituted phthalic acids were studied. The mercuration of 3-nitrophthalic acid gave a nearly quantitative yield of a mercury compound which reacted with hydrochloric acid to give *m*-nitrobenzoic acid and with bromine to give 2-bromo-3-nitrobenzoic acid. This proves the reaction to be actually a replacement of carboxyl by mercury. In this case the replacement was limited to the 2-carboxyl. If mercuration had preceded the loss of carbon dioxide, the products would have been either m-nitrobenzoic acid and 2-bromo-5-nitrobenzoic acid or *o*-nitrobenzoic acid and 2-nitro-5-bromobenzoic acid. The actual course of the reactions was as follows.



Similar results were obtained with 3-bromophthalic acid and 3-chlorophthalic acid. In each case mercury compounds were obtained which gave 3-halogen benzoic acids on treatment with hydrochloric acid. 3-Iodophthalic acid reacted with mercuric acetate to give mercuric iodide and a complex organic mercury compound from which no substituted benzoic acid was obtained.

Experimental Part

Reaction of Sodium 3-Nitrophthalate with Mercuric Acetate.—A warm filtered solution of 211 g. of 3-nitrophthalic acid in 800 cc. of water and 80 g. of sodium hydroxide was mixed in a 3-liter long-necked flask with a hot solution of 350 g. of mercuric acetate in 700 cc. of water and 50 cc. of glacial acetic acid. The flask was provided with a reflux condenser and placed in an oil-bath which was gradually heated to 170°. Evolution of carbon dioxide commenced when this temperature was reached. After heating for seventy hours at 170°, no more carbon dioxide was evolved and a small test sample of the mixture was completely soluble in sodium hydroxide solution. The solid product was washed with water and with alcohol and dried to constant weight at 110°; yield of anhydro-2-hydroxymercuri-3-nitrobenzoic acid, 330 g. or 90%.

Anal. Subs., 0.1987, 0.2010: Hg, 0.1071, 0.1118. Calcd. for $C_7H_3O_4NHg$: Hg, 54.9. Found: 53.9, 55.6.

The analysis was made by the gold crucible method.[2] As is often the case with nitro compounds considerable difficulty was experienced because of the somewhat explosive decomposition of the mercury compounds.

Action of the Mercury Compound with Hydrochloric Acid.—A suspension of 36.6 g. of the mercury compound from 3-nitrophthalic acid, 100 cc. of concd. hydrochloric

---

[2] Whitmore, "Organic Compounds of Mercury," Chemical Catalog Co., New York, 1921, p. 365.

acid and 50 cc. of water was heated under reflux for twenty minutes. Complete solution resulted. The crystals obtained by cooling the mixture were crystallized three times from hot water; m. p. 141–143'. Addition of a known sample of m-nitrobenzoic acid did not lower the melting point.

Action of **Fuming** Nitric Acid.—Anhydro-2-hydroxymercuri-3-nitrobenzoic acid dissolved completely in a large excess of hot fuming nitric acid. The mercury was not removed from organic combination even after refluxing for five hours. Dilution of the mixture precipitated unchanged material. The filtrate gave no test for inorganic mercury either with sodium hydroxide or hydrogen sulfide.

Action of Halogens on Anhydro-2-hydroxymercuri-3-nitrobenzoic Acid.—A solution of bromine in carbon tetrachloride was without action on the anhydro compound. On being stirred with an aqueous solution of potassium bromide and bromine, reaction took place, as evidenced by the disappearance of color. Since the reaction was slow, the following procedure was adopted. The anhydro compound (3.7 g.) was heated under reflux with 10 cc. of 2 molar potassium perbromide solution. This represented a 100% excess of bromine. The powdered mercury compound went into solution within two minutes. On cooling, bromine separated from the mixture although before adding to the mercury compound all the bromine had been in solution. The bromine was removed by extraction with chloroform. The aqueous solution was diluted to about 100 cc. and acidified with 5 cc. of concd. hydrochloric acid. The resultant crystalline precipitate was filtered and dried. It contained no mercury and melted at 186–188'. A mixed melting-point determination with 2-bromo-3-nitrobenzoic acid obtained by A. F. Holleman[3] by the nitration of o-bromobenzoic acid showed the identity of these materials.

By a similar process 2-iodo-3-nitrobenzoic acid, melting at 204–205.5°, was obtained.

Treatment with chlorine gave 2-chloro-3-nitrobenzoic acid melting at 180–182". Holleman gives the melting point as 185°.[4]

Mercuration of 3-Bromophthalic Acid.—A solution of 10 g. of 3-bromophthalic acid (m. p. 186.5–189") in 100 cc. of water containing 4 g. of anhydrous sodium carbonate was mixed with a solution of 13 g. of mercuric acetate in 100 cc. of water and 5 cc. of glacial acetic acid The resulting precipitate was filtered, washed and dried. The precipitated mercuric salt was suspended in 200 cc. of water and heated under a reflux condenser for fifty-three hours. At that point the mixture was completely soluble in sodium hydroxide. The entire mixture was made alkaline with sodium hydroxide, filtered from a slight residue and acidified with acetic acid. The precipitate formed was always obtained in a gelatinous form which seemed impossible to purify. Boiling this material with concd. hydrochloric acid gave m-bromobenzoic acid melting at 150–154°. Addition of known m-bromobenzoic acid did not lower the melting point.

Mercuration of 3-Chlorophthalic Acid.—3-Chlorophthalic acid (m. p. 185–187°) was mercurated in a similar way. Treatment of the mercury compound with hydrochloric acid gave m-chlorobenzoic acid melting at 150.5–154°. Addition of known m-chlorobenzoic acid failed to lower the melting point.

Summary

1. 3-Nitro-, 3-bromo- and 3-chlorophthalic acids react with mercuric acetate on long refluxing to form carbon dioxide and products containing mercury in place of the 2-carboxyl.

---

[3] Holleman and de Bruyn, *Rec. trav. chim.*, 20,211 (1901).

[4] **Ref.** 3, p. 209.

2. The mercury compound from 3-nitrophthalic acid is obtained in good yield and reacts with bromine and with iodine to give good yields of the otherwise difficultly obtainable 2-bromo-3-nitrobenzoic acid and 2-iodo-3-nitrobenzoic acid.

3. Anhydro-2-hydroxymercuri-3-nitrobenzoic acid can be refluxed with fuming nitric acid without breaking the C-Hg linkage. On the other hand a short heating with concd. hydrochloric acid removes the mercury completely from the organic molecule.

4. The results obtained with the 3-substituted phthalic acids show that the mercuration reaction consists in the replacement of the 2-carboxyl by mercury.

THE PREPARATION OF CERTAIN CHLORO AND BROMO DERIVATIVES OF 2,4-DIHYDROXYDIPHENYLMETHANE AND -ETHANE AND THEIR GERMICIDAL ACTION[1]

BY EMIL KLARMANN AND JOHN VON WOWERN

RECEIVED NOVEMBER 6, 1928 PUBLISHED FEBRUARY 5, 1929

Introduction

The introduction of aryl groups into the nucleus of resorcinol leads to compounds showing a very pronounced germicidal action.[2] It has been shown that of the three aryl groups, *viz.*, benzyl, phenylethyl and phenylpropyl, the introduction of the second produces the most active aryl derivative of resorcinol, the phenol coefficient of which was reported as being 41, against B. *typhosus*.[3]

It is well known that halogen substitution of phenol and its alkyl derivatives leads to compounds, the germicidal potency of which is very considerably greater than that of the unsubstituted compounds. While the germicidal action increases with the number of halogen atoms introduced (one molecule of pentabromophenol has the same effect upon B. *diphtheriae* as *500* molecules of phenol), the toxicity first drops but later rises again. Thus monohalogen phenol is less toxic than phenol, while the general toxicity of trihalogen phenol approximately equals that of phenol itself; tetra- and pentahalogen phenol derivatives are more toxic than phenol.[4]

[1] Presented in part before the Division of Biological Chemistry at the meeting of the American Chemical Society in Swampscott, Massachusetts, September, 1928.

[2] E. Klarmann, THIS JOURNAL, 48,791 (1926).

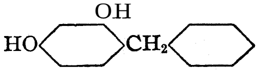
[3] E. Klarmann, *ibid.*, 48,2358 (1926).

[4] *R.* Koch, Mitt. *Kais. Gesundheitsamt, 1,* 234 (1881); H. Bechhold and P. Ehrlich, *Z. physiol. Chem., 47,* 173 (1906); K. Laubenheimer, "Phenol und seine Derivate als Desinfektionsmittel." Berlin-Wien. 1909.

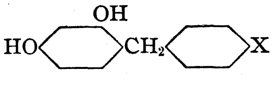
In continuing our work on the relationship between the germicidal action and chemical constitution we have taken another factor into consideration, *k.* ,inactivation of the disinfectant in the presence of organic matter (particularly of protein character), which may be regarded as eminently important from both a practical and theoretical viewpoint. It is well known that many chemicals which are strong germicides in the absence of organic matter may be greatly or even totally inactivated in its presence. Bechhold and Ehrlich found that the very pronounced germicidal efficacy of polyhalogen substituted phenols and phenol derivatives is greatly reduced in the presence of serum; such reduction need not necessarily be accompanied by a precipitation of the protein. On the other hand, there is evidence that the inactivation by organic matter of unsubstituted phenol or cresol takes place to a much less degree.

Discussion

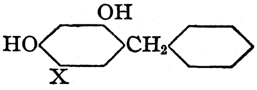
We were interested in determining the influence of monohalogen substitution upon the germicidal action of certain aryl derivatives of resorcinol. Considering the structural formula, e. g., of 2,4-dihydroxydiphenylmethane



the halogen may be introduced either into the benzene nucleus which bears the hydroxyl groups or into the unsubstituted one. In this paper we have considered halogen substitution in the positions 4' and 5, respectively; thus the compounds studied belong to the two types



or



wherein X stands for either Cl or Br. The difference in germicidal action resulting from such substitution is indicated in Table I. The figures under I are phenol coefficients determined according to a modified Rideal-Walker procedure using B. typhosus, under II the same in the presence of standard organic matter, under III phenol coefficients against Staphylococcus pyogenes aureus, under IV the same as under III in the presence of organic matter.

TABLE I

DIFFERENCES IN GERMICIDAL ACTION

	I	II	III	IV
2,4-Dihydroxydiphenylmethane	18.3	14.5	11.3	7.3
5-Chloro-2,4-dihydroxydiphenylmethane	48.2	36.0	36.7	19.6
4'-Chloro-2,4-dihydroxydiphenylmethane	63.1	27.1	40.1	16.7
5-Bromo-2,4-dihydroxydiphenylmethane	37.3	15.7	44.6	18.3
4'-Bromo-2,4-dihydroxydiphenylmethane	54.8	18.9	51.4	13.6

It appears that the presence of halogen very considerably enhances the germicidal effect; the introduction of the halogen into the nucleus which bears the hydroxyl group leads to derivatives with a lower germicidal potency than substitution in p'-position. There is no very distinct difference between B. *typhosus* and Staph. *pyog. aureus;* this fact tends to indicate that the substances dealt with may probably be regarded as general disinfectants rather than specifics.

Organic matter causes a very considerable reduction of germicidal action of the halogen substituted derivatives (in all cases but two, more than 50%); in contrast to this the inactivation of the unsubstituted 2,4-dihydroxydiphenylmethane is much less pronounced.[5]

We attempted to extend our investigation to the corresponding halogen derivatives of 2,4-dihydroxydiphenylethane. The germicidal action of this compound is indicated in Table II.

TABLE II

GERMICIDAL ACTION OF 2,4-DIHYDROXYDIPHENYLETHANE

	I	II	III	IV
2,4-Dihydroxydiphenylethane	40.8	16	22.1	8.5

The figures under I, II, III and IV correspond with those under the respective headings in Table I. It appears that the presence of organic matter impairs the germicidal action of the 2,4-dihydroxydiphenylethane

---

[5] While this work was in progress a paper was published by Bettylee Hampil, *J. Infectious Diseases,* ***43,*** *25* (1928), according to which the disinfectant action of the higher alkylresorcinols is also very considerably impaired by organic matter, *e. g.,* about 70% in the case of hexylresorcinol and more than 80% in that of heptylresorcinol at 37°. Great differences were also found depending upon the kind of peptone used in compounding the "organic matter." The present bacteriological concept of "organic matter" is rather vague from a chemical viewpoint. Both constituents of the so-called "organic matter," required by certain bacteriological methods for standardization of disinfectants, *viz.,* gelatin and peptone, represent products of partial hydrolysis of protein and probably consist of a mixture of amino acids, polypeptides and amino acid anhydrides which will differ qualitatively and quantitatively depending upon the initial material and the method and duration of the protein hydrolysis.

We assume that the impairment of disinfectant action of phenols, polyphenols and their derivatives is due to the fixation of their hydroxyl group or groups by means of secondary valencies by a reactive group in protein (NH_2, possibly COOH, OH, NH, SH). The stability of this, what may be termed additive (molecular) compound under the conditions of the bacteriological experiment, is regarded as one factor which influences the extent to which the impairment of the disinfectant action takes place. It is obvious that this idea of the impairment of disinfecting action by reactive groups in proteins may be used in a hypothetical explanation of the disinfecting action proper, since it is possible that the reactive groups in "organic matter" which hinder the disinfecting action may resemble those which attach the disinfecting chemical to the microorganism; this is probably the first step in disinfection.

We expect to continue our investigations with the view of contributing experimental evidence in support of this theory.

to a much greater extent than that of the corresponding methane derivative. We also succeeded in obtaining the 5-chloro and bromo derivatives of 2,4-dihydroxydiphenylethane but experienced great difficulties in their bacteriological investigation because of the insolubility of these compounds.

The synthesis of the 4'-halogen substituted derivatives of 2,4-dihydroxydiphenylmethane was carried out according to a method applied by one of us for the preparation of 2,4-dihydroxydiphenylmethane proper, *viz.*, condensation of *p*-chloro- or p-bromobenzonitrile with resorcinol in the presence of dry hydrogen chloride, according to Hoesch,[6] transformation of the 4′-halogen-2,4-dihydroxybenzophenone-imide hydrochloride into the 4′-halogen-2,4-dihydroxybenzophenone and reduction of the latter with amalgamated zinc and hydrochloric acid to the 4′-halogen-2,4-dihydroxydiphenylmethane. Direct condensation of the halogen benzyl chloride with resorcinol in nitrobenzene solution in the presence of anhydrous aluminum chloride may also be used for the synthesis of these compounds.

The 5-halogen derivatives of 2,4-dihydroxydiphenylmethane and -ethane were obtained by direct action of sulfuryl chloride or of bromine upon the respective compounds.

Experimental Part

A. Chemical

Preparation of 4′-Chloro-2,4-Dihydroxydiphenylmethane, $C_6H_3(OH)_2CH_2C_6H_4Cl$.—This compound was prepared according to the following two methods.

Method I.—Seventy g. of resorcinol, which was previously dried at 100° for a period of twelve hours, and 50 g. of anhydrous aluminum chloride were dissolved in 300 g. of freshly distilled, dry nitrobenzene. The solution was placed in a flask fitted with a dropping funnel and connected with an air condenser and a calcium chloride tube. A solution of 50 g. of *p*-chlorobenzyl chloride in 100 g. of dry nitrobenzene was added drop by drop under continuous stirring. After addition of the total quantity, the flask was heated on the water-bath and kept at a temperature of 70" for four hours. The resulting dark liquid was poured upon chopped ice and allowed to stand; the watery portion was drawn off and the oil washed with dilute hydrochloric acid and then with water. After addition of an equal volume of ether, the liquid was shaken repeatedly with a 10% solution of sodium hydroxide. The alkaline extract was shaken with ether repeatedly in order to remove the adhering nitrobenzene completely. Then hydrochloric acid was added and the whole boiled for half an hour. The precipitated dark oil was washed with water and distilled in a vacuum at 5 mm. The main part distilled at 200–225° as a heavy oil; by dissolving this in a large quantity of boiling water and cooling, the 4′-chloro-2,4-dihydroxydiphenylmethane crystallized in white needles; yield, 55%. After drying in a micro vacuum desiccator, the melting point is 80.4" (uncorr.). The halogen determination was carried out according to Pregl's micro modification of Carius' method.

Anal. Subs., 4.166 mg.: AgCl, 2.550 mg. Calcd. for $C_{13}H_{11}O_2Cl$: Cl, 15.11. Found: Cl, 15.14.

Method 11.—Sixty g. of dry resorcinol and 50 g. of *p*-chlorobenzonitrile, previously

---

[6] R. Hoesch, *Ber.*, 48, 1122 (1915).

dried in a vacuum desiccator over phosphorus pentoxide, were dissolved in 200 cc. of dry ether and 10 g. of zinc chloride, previously fused and powdered, was added. A current of hydrogen chloride, dried by means of sulfuric acid, was passed through the mixture for a period of about five hours. A heavy oil formed. The vessel was allowed to stand in an ice box for twenty-four hours; then cold hydrochloric acid (15%) was added, whereby the oily keto imide hydrochloride was transformed into a crystalline mass. The crystals were filtered off and washed repeatedly with cold ether in order to remove the unchanged nitrile; yield, 72%.

The 4'-chloro-2,4-dihydroxybenzophenone-imide hydrochloride thus obtained was boiled with approximately 1 liter of water for half an hour, whereby the imide hydrochloride was transformed into the ketone. The latter was recrystallized from water; yield, 65% of the imide hydrochloride. The 4'-chloro-2,4-dihydroxybenzophenone forms pinkish needles which after drying in a micro vacuum desiccator melt at 155° (uncorr.). A solution in dilute alcohol gives a purple coloration with ferric chloride.

This keto compound was reduced by boiling with 150 g. of amalgamated zinc and hydrochloric acid (10%) until a sample of the oil when dissolved in alcohol and diluted with water gave no distinct coloration with ferric chloride. The mixture was shaken with ether, the ether solution washed with dilute hydrochloric acid (2%) and finally with water. The ethereal layer was drawn off, dried with sodium sulfate, the solvent evaporated and the residue distilled in a vacuum at 5 mm. Further purification was carried out as described under Method I; yield, 70% of the keto compound; total yield, 33%.

Preparation of **4'-Bromo-2,4-dihydroxydiphenylmethane, $C_6H_3(OH)_2CH_2C_6H_4Br$.**—This compound was prepared according to the procedure given under Method II. The 4'-bromo-2,4-dihydroxybenzophenone melts at 169° (uncorr.); yield, 89% of the corresponding imide hydrochloride. The 4'-bromo-2,4-dihydroxydiphenylmethane melts at 96° (uncorr.); yield, about 70% of the keto compound; total yield, 45%.

Anal. Subs., 4.227 mg.: AgBr, 2.855 mg. Calcd. for $C_{13}H_{11}O_2Br$: Br, 28.67. Pound: Br, 28.74.

Preparation of **5-Chloro-2,4-dihydroxydiphenylmethane, $C_6H_2(OH)_2ClCH_2C_6H_5$.**—One part of 2,4-dihydroxydiphenylmethane was dissolved in 10 parts of dry ether. The theoretical quantity of sulfuryl chloride was added drop by drop under continuous stirring and cooling. The ether solution was washed with water repeatedly, dried over sodium sulfate, decolorized with Darco and the solvent evaporated. The residue was recrystallized from carbon tetrachloride. The compound crystallizes in white needles which after drying melt at 122° (uncorr.); yield, 51%.

Anal. Subs., 5.785 mg.: AgCl, 3.583 mg. Calcd. for $C_{13}H_{11}O_2Cl$: Cl, 15.11. Found Cl, 15.32.

Preparation of **5-Chloro-2,4-dihydroxydiphenylethane, $C_6H_2(OH)_2ClCH_2CH_2C_6H_5$.**—This compound was prepared by chlorination of 2,4-dihydroxydiphenylethane according to the method used for the corresponding methane derivative. It crystallizes in needles melting at 136.7° (uncorr.); yield, 40%.

Anal. Subs., 5.637 mg.: AgCl, 3.331 mg. Calcd. for $C_{14}H_{13}O_2Cl$: Cl, 14.25. Found: Cl, 14.62.

Preparation of **5-Bromo-2,4-dihydroxydiphenylmethane, $C_6H_2(OH)_2BrCH_2C_6H_5$.**—The bromination was carried out in exactly the same way as the chlorination, using the theoretical quantity of bromine. The same method of purification was used. The compound melts at 122.4' (uncorr.); yield, 71%.

Anal. Subs., 15.329 mg.: AgBr, 10.415 mg. Calcd. for $C_{13}H_{11}O_2Br$: Br. 28.67. Found: Br, 28.92.

Preparation of 5-Bromo-2,4-dihydroxydiphenylethane, $C_6H_2(OH)_2BrCH_2CH_2$-C_6H_5.—This compound was prepared exactly like the foregoing one from 2,4-dihydroxydiphenylethane. It melts at 152.1° (uncorr.).

Anal. Subs.. 14.774 mg.: AgBr, 9.408 mg. Calcd. for $C_{14}H_{13}O_2Br$: Br, 27.27. Found: Br, 27.10.

B. Bacteriological

The determination of the phenol coefficients was carried out according to a modified Rideal-Walker procedure, using 0.5 cc. of broth culture to 5 cc. of diluted disinfectant. The dilutions of disinfectant were prepared in such a way that first the solid substance was dissolved in a small quantity of alcohol and then diluted with water. In no case was the concentration of alcohol more than 5% at the final dilution when the killing of the germ took place. The organic matter used in the investigation of the impairment of germicidal efficacy was a solution of 5% gelatin (French Gold Label) and 10% peptone "Difco." One cc. of this solution was added to 4 cc. of the dilute disinfectant, so that the final solution before introduction of the culture contained 1% of gelatin and 2% of peptone. Subcultures were made after five, ten and fifteen minutes of contact of bacteria and disinfectant, one loop being transplanted into fresh media.

Our thanks are due to Dr. V. A. Shternov and Mr. A. Grawehr for the determination of the phenol coefficients.

Summary

It appears from previous experiments that certain aryl derivatives of resorcinol show a very pronounced germicidal action. Since it is known that halogenation leads to derivatives, the germicidal efficacy of which is more pronounced than that of the unsubstituted compounds, we were interested in determining the influence of the introduction of chlorine and bromine into 2,4-dihydroxydiphenylmethane and -ethane (benzyl- and phenylethylresorcinol). Another point studied was the difference resulting from the introduction of the halogen into the unsubstituted or the dihydroxyl substituted nucleus. It has been found that halogenation greatly increases the germicidal efficacy of these compounds against B. *typhosus* and *Staph. pyog. aureus.* Some interesting observations have been made regarding reduction of the germicidal efficacy of these substances by "organic matter." The methods of preparation of the new compounds 4′-chloro- and 4-bromo-2,4-dihydroxydiphenylmethane and 5-chloro- and 5-bromo-2,4-dihydroxydiphenylmethane and -ethane have been described.

STUDIES ON REACTIONS RELATING TO CARBOHYDRATES AND POLYSACCHARIDES. XXI. COMPARISON OF TENDENCIES OF SATURATED AND UNSATURATED ALDEHYDES TOWARD CYCLIC ACETAL FORMATION

BY HAROLD HIBBERT, EDWARD O. HOUGHTON[1] AND K. AUSTIN TAYLOR[2]

RECEIVED NOVEMBER 8, 1928 PUBLISHED FEBRUARY 5, 1929

Previous work on cyclic acetal formation carried out during the last few years[3] has dealt only with the cyclic acetals from saturated carbonyl derivatives. The tendency of unsaturated aldehydes toward cyclic acetal formation has apparently not been investigated.

The possibility that the lignin complex, as it occurs in wood, may contain an unsaturated aldehyde grouping,[4] and that in this case the latter may be linked up with a carbohydrate complex in the form of a cyclic acetal, or half acetal, pointed to the necessity for obtaining further information regarding the interaction of unsaturated aldehydes with polyhydroxy compounds.

In the present investigation experiments were carried out on the condensation of ethylene glycol with cinnamic aldehyde, α-monochlorocinnamic aldehyde, β-phenyl-α,β-dichloropropionaldehyde, a-methyl-@-ethylacrolein, crotonaldehyde, α-monochlorocrotonaldehyde and dichlorobutyraldehyde, using dilute sulfuric or phosphoric acid as catalyst.[5] The yields of cyclic acetal obtained provide a basis for comparison of the tendencies of saturated and unsaturated acetals toward cyclic acetal formation.

The unsaturated cinnamic and crotonaldehydes and a-methyl @-ethylacrolein, show practically no tendency to form cyclic acetals under the given experimental conditions, the yields obtained being almost negligible. In the case of cinnamic and crotonaldehydes, the yield of the cyclic acetals was not sufficiently high to enable them to be separated and identified as such. With α-methyl-β-ethyl-acrolein a yield of about 10% of an impure product was obtained, the analysis of which corresponded approximately to that of the acetal.

The unsaturated halogenated aldehydes, containing chlorine attached to the a-carbon atom, show a greater tendency toward cyclic acetal for-

[5] Five-tenths to 1 cc. of the 40% acid was employed per mole of aldehyde used.

mation, apparently due to the activating influence exerted by the negative chlorine atom on the carbonyl group. Both α-monochlorocinnamic aldehyde and α-monochlorocrotonaldehyde, when condensed with ethylene glycol, gave a yield of 22% of the cyclic acetal.

The saturated aldehydes, *viz*, phenyldichloropropionaldehyde and dichlorobutyraldehyde, readily formed cyclic acetals with yields of 37 and 50%, respectively.[6]

Experimental Part

Cinnamylidene Ethylene Glycol,  $C_6H_5CH{=}CHCH\left\langle\begin{array}{l}O-CH_2\\ \vert\\ O-CH_2\end{array}\right.$.—Thirty-three grams (one-quarter mole) of cinnamic aldehyde, thirty-one grams (one-half mole) of ethylene glycol and three drops of 40% sulfuric acid as catalyst were heated to 100° on the water-bath for six hours. The reaction mixture was then neutralized with solid potassium carbonate, extracted with ether and the ether extract dried and distilled. A small yield of the acetal was indicated but could not be separated from the large amount of unchanged aldehyde present.

β-Phenyl-α,β-dichloropropylidene Ethylene Glycol,  $C_6H_5CHClCHClCH\left\langle\begin{array}{l}O-CH_2\\ \vert\\ O-CH_2\end{array}\right.$.—β-Phenyldichloropropionaldehyde was prepared according to the method of Naar.[7] Two hundred and three grams (1 mole) of the aldehyde was condensed with 124 g. (2 moles) of ethylene glycol by heating at 70° for four hours. The hydrochloric acid split off from the aldehyde was sufficient to bring about the condensation. The ether extract was shaken with saturated sodium bisulfite solution to remove any unchanged aldehyde, washed, dried and the recovered oil distilled; b. p. 164–166° at 8 mm.; yield, 37%.

Anal. Calcd. for $C_{11}H_{12}O_2Cl_2$: Cl, 28.74. Found: Cl, 28.88, 28.45.

α-Monochlorocinnamylidene Ethylene Glycol,  $C_6H_5CH{=}CClC\begin{array}{l}\diagup O-CH_2\\ {}^{\diagdown}H \quad\ \vert\\ \diagdown O-CH_2\end{array}$.—α-Monochlorocinnamic aldehyde (b. p. 132–134° at 8 mm.) was prepared by a modification of Naar's method by refluxing β-phenyldichloropropionaldehyde with aqueous sodium acetate. One mole of the chloro-aldehyde and two moles of ethylene glycol were heated at 130° for three hours, using three drops of 40% sulfuric acid as catalyst. The mixture was extracted in the usual manner, yielding an opaque, reddish oil which

---

[6] From the recently published work of Adkins, This Journal, 49, 2517 (1927), relating to equilibrium data on simple acetal formation, it is apparent that the tendency of unsaturated aldehydes to form acetals is very much less pronounced than that of the saturated, a fact which seems to point to the much lower stability of the acetals from the former. Possibly by working in a medium of much lower acid concentration it might be possible to isolate the cyclic acetals from unsaturated aldehydes. Experiments are in progress using other condensing agents such as copper sulfate, calcium chloride, zinc chloride, iodine, etc.

[7] Naar, *Ber.*, 24, 244 (1891). A more convenient method of preparing the dichloro-aldehyde is to dissolve the theoretical amount of chlorine in carbon tetrachloride and to add this to the cinnamic aldehyde at −5°; yield, 72%; b. p. 94–97° (2 mm.).

on cooling deposited the acetal in the form of fine, white crystals. These were recrystallized from benzene; m. p. 69–70'; yield, 22%. The crystals were readily soluble in alcohol, ether and benzene.

Anal. Subs.: 0.2110, 0.2017; CO_2, 0.4867, 0.4646; H_2O, 0.1023, 0.0960. Calcd. for $C_{11}H_{11}O_2Cl$: C, 62.70; H, 5.23; Cl, 16.86. Found: C, 62.90, 62.82; H, 5.38, 5.28; Cl, 17.72, 17.60.

α-Methyl-β-ethylacrylidene Ethylene Glycol, $CH_3CH_2CH{=}C(CH_3)C\left<\begin{array}{l}O{-}CH_2\\ \quad\;\,|\\ O{-}CH_2\end{array}\right.$.—

Twenty grams of **α-methyl-β-ethyl-acrolein,** condensed in a similar manner with 25 g. of ethylene glycol, using three drops of 40% sulfuric acid as catalyst, gave a high-boiling fraction, b. p. 170–174° (12 mm.), which was free from aldehyde (semicarbazide reaction). This product is the acetal but is evidently contaminated with other products.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.60; H, 9.86. Found: C, 66.42, 66.74; H, 9.82, 9.55.

Crotylidene Ethylene Glycol, $CH_3CH{=}CHCH\left<\begin{array}{l}O{-}CH_2\\ \quad\;\,|\\ O{-}CH_2\end{array}\right.$.—One hundred and forty grams (two moles) of crotonaldehyde was heated with 186 g. (three moles) of glycol for four hours at 95°, using 2 cc. of 20% phosphoric acid as catalyst. Examination of the mixture showed that only a negligible amount of condensation had occurred.

Dichlorobutylidene Ethylene Glycol, $CH_3CHClCHClCH\left<\begin{array}{l}O{-}CH_2\\ \quad\;\,|\\ O{-}CH_2\end{array}\right.$.—Dichlorobutyraldehyde was prepared by passing the theoretical quantity of chlorine into crotonaldehyde at −5°. One hundred and forty-one grams (one mole) of the crude aldehyde was then condensed directly, without any further purification, with 91 g. (1.5 moles) of glycol by heating on the water-bath for one hour. No catalyst was added. The yield of acetal (b. p. 100–105°, 13–15 mm.) was 50.3%.

Anal. Calcd. for $C_6H_{10}O_2Cl_2$: Cl, 38.37. Found: Cl, 37.74.

a-Monochlorocrotylidene Ethylene Glycol, $CH_3CH{=}CClCH\left<\begin{array}{l}O{-}CH_2\\ \quad\;\,|\\ O{-}CH_2\end{array}\right.$.—α-Monochlorocrotonaldehyde (b. p. 147–150°, 760 mm.) was prepared by mixing dichlorobutyraldehyde with aqueous sodium acetate and steam distilling the product. Seventy grams (two-thirds mole) of the aldehyde was condensed with 62 g. (one mole) of glycol, using 1 cc. of 20% phosphoric acid as catalyst. Considerable polymerization occurred. After extraction, the acetal obtained was refractionated several times under reduced pressure; b. p. 76–80' (14 mm.); yield, 22%.

Anal. Calcd. for $C_6H_9O_2Cl$: Cl, 23.87. Found: Cl, 23.45, 23.58.

Summary

1. A comparison has been made of the tendency of saturated and unsaturated aldehydes to form cyclic acetals. The aldehydes were condensed with ethylene glycol, using dilute sulfuric or phosphoric acid as catalyst, and the yields of the resulting cyclic acetal determined.

2. The unsaturated aldehydes, cinnamic aldehyde, crotonaldehyde and

α-methyl-β-ethyl-acrolein show practically no tendency toward cyclic acetal formation under the experimental conditions used.

3. The unsaturated aldehydes containing chlorine attached to the α-carbon atom, namely, α-monochlorocinnamic aldehyde and α-monochlorocrotonaldehyde, give a yield of about 22% of the corresponding cyclic acetal. The greater tendency of these aldehydes to form cyclic acetals is probably due to the activating influence exerted by the negative chlorine atom on the carbonyl group.

4. The saturated aldehydes, *viz.*, phenyldichloropropionaldehyde and dichlorobutyraldehyde, show the normal tendency of saturated aldehydes to form cyclic acetals, the yields being 37 and 50%, respectively.

SYNTHESIS OF CYCLOBUTANE ACIDS. I. NORPINIC ACID

BY CARL A. KERR

RECEIVED DECEMBER 5, 1928 PUBLISHED FEBRUARY 5, 1929

It is remarkable that while *cis*-cyclobutane-1,3-dicarboxylic acid,[1] methylcyclobutane[2] and 1,2-dimethylcyclobutane-3,4-dicarboxylic acid[3] have been synthesized from open-chain compounds, all attempts to effect cyclobutane ring closure in carbon chains having the gem.-dimethyl group as substituent have failed. This is particularly evident from the repeated failures to synthesize the well-known norpinic acid or 2,2-dimethylcyclobutane-1,3-dicarboxylic acid, which is a key acid formed in the oxidation of α- and β-pinene and some other terpene compounds. In an attempt to synthesize norpinic acid, Ganguly[4] found that ethyl α,α′-dibromo-β,β-dimethylglutarate did not react with methylene iodide in the presence of sodium to give the expected cyclobutane compound, while Vogel[5] showed that the disodium derivative of ethyl-β,β-dimethyl-α-cyanopropane-α,α′,α′-tricarboxylate failed to give a ring compound when treated with methylene iodide. Clemo and Welch[6] failed to get a cyclic compound from an attempted condensation of maleic or fumaric ester and dimethylketene, and further showed that the disodium derivative of β,β-dimethylpropane-α,α,α′,α′-tetracarboxylic ester did not react with methylene iodide to give a cyclobutane compound, as expected. Prior to the publication of Clemo

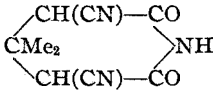
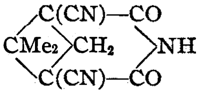
[6] Clemo and Welch, *ibid.*, 130, 2621 (1928).

and Welch's experiments[6] the author had also failed to get ring closure between methylene iodide and the same disodium derivative used by these authors. In spite of the failure of Ganguly's experiment[4] with β,β-dimethyl-α,α-dibromoglutaric ester, it seemed probable that a,@,@-trimethyl-α,α'-dibromoglutaric ester, as a result of the position of its additional methyl group, might react with methylene iodide in the presence of sodium to give the ester of caryophyllenic acid or 2,2,1-trimethylcyclobutane-1,3-dicarboxylic ester, but the products of this reaction were unsaturated esters, with no evidence of ring formation.

In view of these discouraging results with open-chain compounds, it was thought that if an easily ruptured six-membered ring were first formed, the spacial configuration of the atoms might be more prone to the formation of four-membered rings, and this proved to be the case. The six-membered ring chosen was Guareschi's[7] imide, α,α'-dicyano-β,β-dimethylglutarimide (I) and it was found that the sodium derivative of this compound reacted with methylene iodide to give a 70% yield of the dicyclic imide (II). It is interesting to note that in spite of the number of ways in which sodium derivatives of (I) might react with methylene iodide, cyclobutane ring formation took preference. The proof of the constitution of (II) was established by its hydrolysis to glutaric acid, by the formation of a mono-silver salt, and by determination of its molecular weight.

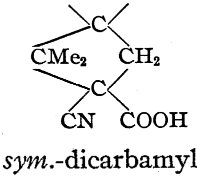


I

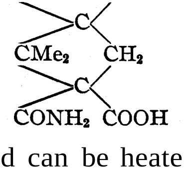


II

Hydrolysis of the dicyclic imide (II) by sulfuric acid at temperatures ranging from 80 to 140° ruptured the cyclobutane ring with the formation of varying quantities of glutaric acid and of phorone, which was undoubtedly formed from acetone produced by the disruption of the ring and the addition of water. Treatment of (II) with 100% phosphoric acid or with nitrous acid failed to produce a nitrogen-free acid. On the other hand, dilute alkali produced about equal quantities of *sym.*-dicyanonorpinic acid (III) and *sym.*-dicarbamylnorpinic acid (IV) when boiled with the imide.



III



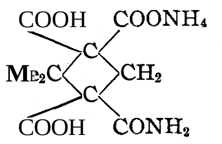
IV

Although *sym.*-dicarbamylnorpinic acid can be heated with four molecular equivalents of sodium hydroxide without hydrolysis taking place, both (III) and (IV) are hydrolyzed to the corresponding 2,2-dimethylcyclobutane-1,1,3,3-tetracarboxylic acid (V) by concentrated alkali. A

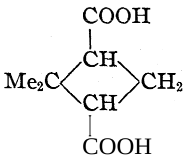
---

[7] Guareschi, *Atti, accad. sci. Torino,* 34,928 (1899).

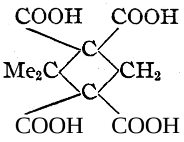
point of particular interest in regard to (IV) is the conversion of one of the carbamyl groupings to the corresponding ammonium salt by the addition of a molecule of water. Pure *sym.*-dicarbamylnorpinic acid, when dissolved in boiling water and the solution evaporated, leaves a white, crystalline water-soluble compound which has the structure represented by (VI).



VI



VII



V

An acidified aqueous solution of (VI) deposits crystals of a water-insoluble acid containing nitrogen, m. p. 236°, which gives 2,2-dimethylcyclobutane-1,1,3,3-tetracarboxylic acid on boiling with concentrated alkali, and is probably 1-carbamyl-2,2-dimethylcyclobutane-1,3,3-tricarboxyic acid. This compound is still being studied with a view to proving its structure definitely.

When 2,2-dimethylcyclobutane-1,1,3,3-tetracarboxylic acid (V) is heated at 200 to 205°, until no further evolution of carbon dioxide takes place, an oil remains which solidifies. This substance proved to be *trans*-norpinic acid (VII), described by Perkin and Simonsen,[8] who prepared it from the cis modification, which is an oxidation product of pinene. *Trans*-norpinic acid softened at 138° and melted at 146°, after repeated recrystallization from water. It is easily soluble in water, ether, alcohol and acetone, and separates in hard nodules from either aqueous solution or hydrochloric acid.

Now that a satisfactory method has been found for the formation of substituted cyclobutane acids in good yield, that is, by the condensation of substituted α,α′-dicyanoglutarimides with methylene iodide and hydrolysis of the resulting dicyclic compounds, the syntheses of other cyclobutane acids are under investigation, especially that of 2,2,1-trimethylcyclobutane-1,3-dicarboxylic acid, known as caryophyllenic acid and which is a key product in the oxidation of caryophyllene. Up to the present neither the structure of caryophyllenic acid nor of caryophyllene has been definitely determined.

Experimental

Ethyl **α,α′-Dibromo-α,β,β-trimethylglutarate.**—This was prepared by the method of Pandya and Thorpe.[9] Attempted condensation of the dibromo ester with methylene iodide in the presence of sodium failed, the product of the reaction being a mixture of unsaturated esters.

β,β-Dimethylpropane-α,α,α′,α′-tetracarboxylic Ester.—On preparing this ester

---

[8] Perkin and Simonsen, J. *Chem. Soc.*, 95, 1176 (1909).

[9] Pandya and Thorpe, *ibid.*, 123,2852 (1923).

according to the method of Kötz,[10] the high yields claimed by this author could not be attained. Using ether, benzene, toluene and methyl alcohol in turn as solvent, methylene iodide was allowed to react with the discdium derivative of β,β-dimethylpropane-$\alpha,\alpha,\alpha',\alpha'$-tetracarboxylic ester, but the product proved to be a mixture of malonic ester, *iso*propylidene malonic ester and a small undistillable residue.

β,β-Dimethyl-α,α'-dicyanoglutarimide was prepared according to the instructions of Kon and Thorpe,[11] but yields of only 60% of pure imide could be obtained, instead of 75%, as claimed by Kon and Thorpe.[11]

Condensation of **β,β-Dimethyl-α,α'-dicyanoglutarimide** with Methylene **Iodide.**—To a solution of 7.2 g. (6 atoms) of sodium in 100 cc. of methyl alcohol was added 20 g. of the imide and the whole refluxed on the steam-bath for one-half hour. Forty-four g. (3 moles) of methylene iodide was added through the condenser and refluxing continued for one and one-half hours, when all the methylene iodide had gone into solution. After standing overnight the mixture was again heated for one hour, cooled and the reaction mixture poured into 200 cc. of water containing 20 cc. of concd. nitric acid. Dicyanonorpinimide at once separated, was isolated by filtration and washed in the filter funnel several times with ether to remove the considerable quantity of methylene iodide which collects with the precipitate. When dried on a porous plate a yield of 15.5 g. was found and on recrystallization from glacial acetic acid 12 g. of pure dicyanonorpinimide separated in fine rhomboidal plates, m. p. 305–306° (decomp.). An attempt to purify dicyanonorpinimide by neutralizing with alkali and acidification by hydrochloric acid failed, only a small quantity of the imide being reprecipitated. Dicyanonorpinimide is slightly acid to litmus and is insoluble in all the common organic solvents and in water. It dissolves readily in alkali and in ammonium hydroxide.

Anal. Calcd. for $C_{10}H_9O_2N_3$: C, 59.1; H, 4.4; N, 20.7. Found: C, 58.5; H, 4.6; N, 20.4. Mol. *wt.* Calcd.: 203. Found: 203, 209.

Silver Salt of **Dicyanonorpinimide.**—When ammoniacal silver nitrate is added to a solution of the imide in ammonium hydroxide, the mono silver salt separates slowly.

Anal. Calcd. for $C_{10}H_8O_2N_3Ag$: Ag, 34.8. Found: Ag, 34.2.

Action of Sulfuric Acid on **Dicyanonorpinimide.**—3.6 g. of dicyanonorpinimide was added to 5.4 cc. of sulfuric acid and then 1 cc. of water. After heating on a sand-bath at 135° until all evolution of carbon dioxide had ceased, 1.8 cc. of water was added and heating continued at 140° for one hour. The cooled mixture was diluted with water and by extraction with ether six times an oil resulted which soon crystallized. This on recrystallization from hot benzene melted at 98–99° and was proved to be glutaric acid from a mixed melting point and analysis.

Anal. Calcd. for $C_5H_8O_4$: C, 45.5; H, 6.1. Found: C, 45.3; H, 6.3.

In the hope of obtaining norpinic acid, the imide was hydrolyzed as above by sulfuric acid, but the temperature was maintained at 100° throughout. Glutaric acid was again formed. At 80° sulfuric acid produces a very small yield of an acid containing nitrogen which was not identified. From the action of alkaline hydrogen peroxide on the imide no definite products could be isolated.

Preparation of *Sym.*-**dicyanonorpinic** Acid and *Sym.*-**dicarbamylnorpinic** Acid.—Dicyanonorpinimide on treatment with dilute alkali gives both *sym.*-dicyanonorpinic acid and *sym.*-dicarbamylnorpinic acid, the yield of the latter increasing with prolonged heating of the reaction mixture. The yellow solution obtained by dissolving 10 g. (1 mole) of dicyanonorpinimide in 180 cc. of 2.15% sodium hydroxide (slight excess over 2 moles) on heating gives off ammonia. At the end of two hours the solution was con-

---

[10] Kotz, J. *prakt. Chem.*, [2] 75,498 (1907).

[11] Kon and Thorpe, J. *Chem. Soc.*, 119,818 (1919).

centrated to half its bulk, acidified with sulfuric acid and 25 cc. of concentrated sodium sulfate solution was added. A white, crystalline solid separated from solution in flat plates, which when filtered, washed well with ice cold water and dried had a m. p. of 190° (decomp.). This was pure *sym.*-dicarbamylnorpinic acid; yield, 5.0 g.

Anal. Calcd. for $C_{10}H_{14}O_6N_2$: C, 46.5; H, 5.4; N, 10.85. Found: C, 46.8; H, 5.5; N, 10.75. Equivalent (by Ag salt method): 127.5. Calcd. equivalent: 129.

The acid filtrate above was extracted six times with ether and on concentrating the dried ethereal extracts a solid separated. This can be crystallized from glacial acetic acid but separates from this solvent with one molecule of acetic acid attached. It is best recrystallized from a mixture of ether and petroleum ether (40–60°) and separates in small, hard nodules, m. p. 225–226° (decomp.). This was *sym.*-dicyanonorpinic acid; yield, 4.0 g.

Anal. Calcd. for $C_{10}H_{10}O_4N_2$: C, 54.0; H, 4.5; N, 12.6. Found: C, 53.9; H, 4.6; N, 12.5. Calcd. equivalent, 111. Found: equivalent (from silver salt): 111.

The dimethyl ester of *sym.*-dicyanonorpinic acid can be prepared by refluxing the dried silver salt of the acid with excess of methyl iodide in ether solution for twelve hours. The ether solution on filtration and concentration gives the solid dimethyl ester, which may be purified by recrystallization from ether and separates in short prisms, m. p. 139–140°.

Anal. Calcd. for $C_{12}H_{14}O_4N_2$: C, 57.6; H, 5.6. Found: C, 57.8; H, 5.7.

Action of Water on *Sym.*-dicarbamylnorpinic Acid.—Although this substance is quite insoluble in cold water, it was found that it readily dissolves on heating, but the substance recovered by evaporation of the solvent was found to be a totally different compound, being soluble in water and chlorohydrin and giving off ammonia in the cold on grinding with sodium hydroxide, whereas the dicarbamylnorpinic acid has none of these properties. That one of the dicarbamyl groups passed over to the corresponding ammonium salt was shown by analysis of the compound and the existence of two equivalents.

Anal. Calcd. for $C_{10}H_{16}O_7N_2$: N, 10.15. Found: N, 10.21. Calcd. equivalent (by silver salt): 92; by titration with potash: 138. Found equivalent: 92; by titration with potash: 138.

On acidification of an aqueous solution of this mono-ammonium salt with dilute sulfuric acid, a precipitate of a water-insoluble acid comes down slowly. This acid is soluble in ether and, though not definitely identified, is most probably 1-carbamyl-2,2-dimethylcyclobutane-1,3,3-tricarboxylic acid, since it also gives 2,2-dimethylcyclobutane-1,1,3,3-tetracarboxylic acid on further hydrolysis with concentrated alkali.

Preparation of 2,2-Dimethylcyclobutane-1,1,3,3-tetracarboxylic Acid.—When 0.75 g. (1 mole) of *sym.*-dicarbamylnorpinic acid was heated with 0.52 g. (4.5 moles) of sodium hydroxide under reflux for one and a half hours and then acidified, a precipitate at once was formed. This when washed well with water and dried had a melting point of 185–190° and was unchanged dicarbamylnorpinic acid; yield, 0.5 g. However, when 3.7 g. of *sym.*-dicarbamylnorpinic acid was refluxed with 50 cc. of 10% sodium hydroxide solution for nine hours, acidified with sulfuric acid and extracted five times with ether, an oil was found which slowly solidified. The solid was partially purified by filtering its aqueous solution and boiling down the filtrate to dryness. It can be purified by recrystallization from a mixture of acetone and benzene, being very soluble in the former. When pure, 2,2-dimethylcyclobutane-1,1,3,3-tetracarboxylic acid melts at 200° and is very soluble in water, acetone and alcohol, but insoluble in benzene, chloroform and petroleum ether. The equivalent of this acid is difficult to determine, as a very indefinite end-point is experienced on direct titration with alkali and the silver salt tends to be explosive on heating. By mixing the silver salt with a little pure cane sugar before heating, an equivalent was found.

Anal. Calcd. for $C_{10}H_{12}O_8$: C, 46.15; H, 4.6. Found: C, 46.4; H, 4.7. Calcd. equivalent: 65. Found: 66.

Tetramethyl Ester of **2,2-Dimethylcyclobutane-1,1,3,3-tetracarboxylic** Acid.—This ester can be made by refluxing the silver salt of the acid with excess of methyl iodide in ether solution for twelve hours. The filtered ether solution gave an uncrystallizable oil which distilled with slight decomposition at 100° (25 mm.).

Anal. Calcd. for $C_{14}H_{20}O_8$: C, 53.1; H, 6.3. Found: C, 53.4; H, 6.4.

The Action of Alkali on *Sym.*-**dicyanonorpinic** Acid.—When heated for six hours under reflux a solution of 2.0 g. of dicyanonorpinic acid in 25 cc. of 20% caustic soda ceased to evolve ammonia. The mixture was acidified with sulfuric acid and extracted six times with ether; by concentrating the dried ether extracts an oil remained which solidified. This on purification gave a melting point of 200° and was proved to be 2,2-dimethylcyclobutane-1,1,3,3-tetracarboxylic acid by a mixed melting-point determination; yield, 1.2 g.

Preparation of *Trans*-**norpinic** Acid.—When 3.5 g. of 2,2-dimethylcyclobutane-1,1,3,3-tetracarboxylic acid was maintained at 200–205° for half an hour, all evolution of carbon dioxide ceased. On cooling, the dark yellow oil solidified. This was dissolved in water, filtered and concentrated to small bulk on the water-bath. Crystals which softened at 132° and melted at 140° separated, and these after two further recrystallizations from aqueous solution yielded a substance which softened at 138° and melted at 146°. This is without doubt trans-norpinic acid, described by Perkin and Simonsen,[8] who prepared it from cis-norpinic acid by heating with hydrochloric acid, and who record that it softens at 137 and melts at 144°. In agreement with Perkin and Simonsen it was found that trans-norpinic acid separates in hard nodules from concd. hydrochloric acid.

Anal. Calcd. for $C_8H_{12}O_4$: C, 55.8; H, 6.9. Found: C, 56.0; H, 6.9.

This opportunity is taken to express thanks to Professor M. Gomberg, who not only granted every facility for this research, but also gave the benefit of his very wide experience in the experimental problems which arose in this investigation. To the Commonwealth Fund the author is also indebted for a Fellowship during the tenure of which this work was carried out.

Summary

1. The syntheses of trans-norpinic acid, dicyanonorpinic acid, dicarbamylnorpinic acid and 2,2-dimethylcyclobutane-1,1,3,3-tetracarboxylic acid are described.

2. The synthesis of a new type of bicyclic imide, dicyanonorpinimide, is described.

3. A method capable of general application has been found for the synthesis of substituted cyclobutanedicarboxylic acids.

ANN ARBOR, MICHIGAN

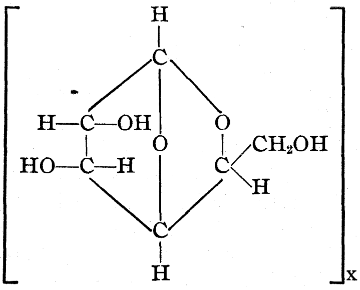
[COMMUNICATION FROM THE DEPARTMENT OF INDUSTRIAL AND CELLULOSE CHEMISTRY, McGILL UNIVERSITY]

STUDIES ON REACTIONS RELATING TO CARBOHYDRATES AND POLYSACCHARIDES. XXII. THE ISOMERIC CINNAMYLIDENE GLYCEROLS

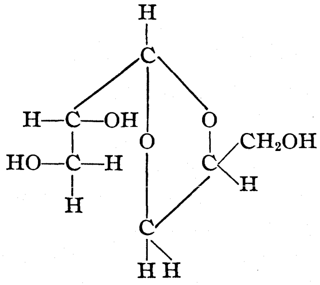
BY HAROLD HIBBERT AND MYRON S. WHELEN[1]

RECEIVED DECEMBER 18, 1928 PUBLISHED FEBRUARY 5, 1929

The properties of cyclic acetals and the nature of cyclic acetal formation in relation to carbohydrates and polysaccharides have been repeatedly emphasized in the course of this series of communications. Of added interest is the close connection for example, between cellulose, considered as an anhydro glucose (I) (a suggestion first put forward by one of us)[2] and 1,2-dihydroxypropylidene glycerol (II).[3]



I



II

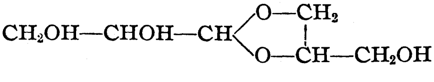
For this reason it becomes highly desirable to synthesize such derivatives as 1,2-dihydroxypropylidene glycerol (II) and glycol, in order to

---

[1] Holder of Studentship, Canadian National Research Council. The authors wish to express their thanks to the Canadian National Research Council and the Canadian Pulp and Paper Association for the generous support accorded to them.

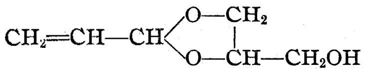
[2] Hibbert, *Chem. Met.* Eng., 22, 838 (1920). The constitution of cellulose was discussed at length in a later communication [Hibbert, *Ind.* Eng. *Chem.*, 13, 256, 334 (1921)] in which the view was taken that no decision could be reached as to whether this substance was to be regarded as a polymerized (or associated) anhydroglucose or as a very large ring compound. The question still remains an open one, as is evident from the recent discussions on this subject [Bergmann, Herzog and Jancke, *Naturwissenschaft.*, 16, 464 (1928); Kurt Hess and Carl Trogus, *Ber.*, 61, 1982 (1928); Meyer and Mark, *Ber.*, 61, 593 (1928)]; Kurt Meyer, Z. *ang. Chem.*, 41, 935 (1928); Sponsler and Dore, "Colloid Symposium Monograph," 4, 174 (1926); THIS JOURNAL, 50, 1940 (1928); Katz, "*Ergebn. exakt. Naturwiss.*" 3, 363, J. Springer, Berlin, (1924); 4, 185 (1928); Haworth, *Helv. Chim. Acta,* 11, 534 (1928). The extensive chemical investigations carried out by Kurt Hess in this field—an excellent summary of which is to be found in his recent valuable textbook on "Cellulose Chemistry"—provide, in the writers' opinion, considerable support for the theory that cellulose may be an associated form of an anhydro-dextrose building unit.

[3] The formula is more customarily written

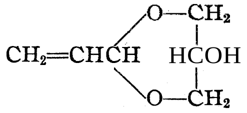


$$CH_2OH—CHOH—CH\begin{matrix}/O—CH_2 \\ \quad | \\ \backslash O—CH—CH_2OH\end{matrix}$$

ascertain how far such structures exhibit a tendency toward polymerization or association.[4] The simplest mode of synthesis of these products appeared to lie in the primary preparation of cyclic acetals from unsaturated aldehydes (acrolein, trotonaldehyde, cinnamic aldehyde) and glycerol. Isolation of the two structurally isomeric acetals, for example (III) and (IV)



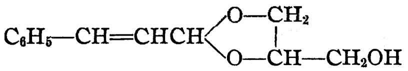
III



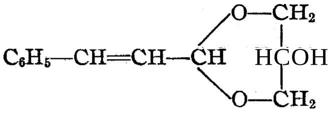
IV

could then be followed by conversion of (III) into the corresponding dihydroxy compound, *viz.*, dihydroxypropylidene glycerol (II).

Both acrolein and cinnamic aldehyde condense readily with glycerol, the former without the use of a catalyst. The present paper deals with the isolation, identification and properties of the two structurally isomeric cinnamylidene glycerols (V) and (VI).



V



VI

The only literature reference to cinnamylidene glycerol is a short communication by Peacock[6] in which he states this product may be "readily obtained as a viscous oil, which slowly solidifies to a mass of crystals, m. p. 110–112°," but gives no directions as to its preparation. He pointed out that the cinnamylidene group and the carbinol group may exhibit *cis-trans* isomerism with respect to the heterocyclic rings and that in addition to this possibility of isomerism there is also that due to the double linking in the cinnamylidene group, which may again cause the formation of *cis* and *trans* isomerides. The number of possible isomerides for each formula is therefore four, neglecting optically active members. Peacock only isolated a single isomer, the structure of which was left unsolved, and gave no indication of a belief in the possibility of *simultaneous* formation of both ring structures such as is demanded by the Michael partition principle.

Previous work carried out in this field[6] shows that in the condensation of a saturated aldehyde with glycerol, a partition between the 1,1′- and 1,2-hydroxyl groups always occurs, resulting in the formation of two structural ring isomers, *viz.*, a five- and a six-membered cyclic acetal, respectively. Peacock in his work apparently only expected to find a one-ring system. The simultaneous formation of both types is now shown to

---

[4] The synthesis of dihydroxypropylidene glycol has now been accomplished and that of dihydroxypropylidene glycerol is in progress.

[5] Peacock, *J. Chem. Soc.*, 107, 816 (1915).

[6] Hibbert and co-workers, THIS JOURNAL, 50, 2235, 2242 (1928).

be true in the cases of cinnamic aldehyde and the isolation and properties of two structural isomeric ethers (five- and six-membered ring isomers) of cinnamylidene glycerol are described in the experimental part. The process outlined serves as a convenient method for the synthesis of these somewhat inaccessible products.

In the condensation of cinnamic aldehyde and glycerol the crude cinnamylidene glycerol is left as a viscous oil which slowly solidifies in about twenty-four hours to a thick pasty mass of crystals, readily separable from the accompanying oil. Purification of the crystals, followed by methylation and hydrolysis, yields glycerol β-methyl ether, thus identifying the ring structure as the six-membered acetal (VI). The oil[7] remaining after the removal of the crystalline isomer and the unchanged cinnamic aldehyde, on similar treatment, yields glycerol a-methyl ether, thus serving to identify it as the five-membered acetal (V). It is of interest that the methyl ethers of both the 1,2- and 1,1′-cinnamylidene glycerols are very sensitive to hydrolysis (involving ring scission), much more so in fact than the free acetals. This is in agreement with observations made by Irvine, Macdonald and Soutar[8] on isopropylidene glycerol.

Only one of the numerous possible isomers of each of the structural five- and six-membered cinnamylidene glycerols was isolated, due possibly to the labile character of the other forms, although no special effort was made to investigate this phase of the problem, the direct object being to prove the simultaneous formation of both types of structural ring isomerism.

Investigations dealing with the action of benzoyl hydroperoxide on the cinnamylidene glycerols and the synthesis of phenyl 1,2-dihydroxypropylidene glycerol are in progress.

Experimental

Preparation **and** Isolation of the Isomeric **Cinnamylidene** Glycerols.--One hundred and thirty-two g. (1 mole) of pure cinnamic aldehyde, 92 **g.** of glycerol and five drops of 40% sulfuric acid were heated together with constant shaking by hand in a round-bottomed pyrex Bask under a pressure of 20 mm. At approximately 50° water began to distil over. At the same low pressure the temperature was gradually raised during the course of approximately twenty-five minutes to 100°, at which it was maintained for thirty minutes, or until there was complete miscibility and water ceased to be given off. The reaction product was a viscous oil which slowly solidified after about twenty-four hours to a **thick,** pasty mass of crystals, the pasty mass containing a considerable quantity of an adhering oil. This product was disintegrated and thoroughly washed with water at 30° to remove unchanged glycerol and sulfuric acid, then filtered and pressed as dry as possible on a suction filter, the solid remaining as a thick, pasty mass. This was dissolved in warm benzene, separated from water in a separatory funnel and the warm benzene solution dried by shaking with anhydrous sodium sulfate. On filtering the hot solution and cooling, yellowish-white crystals separated out which

---

[7] It was not found possible to isolate this product in a sufficiently pure state for analysis.

[8] Irvine, Macdonald and Soutar, J. Chem. *Soc.*, **107, 337 (1915).**

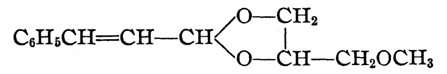
on recrystallization from benzene yielded **38** g. of long, asbestos-like needles, m. p. 121°.

Anal. Subs., 0.1557: CO_2, 0.4004; H_2O, 0.090. Calcd. for $C_{12}H_{14}O_3$: *C*, 69.90; H, 6.79. Found: *C*, 70.08; *H*, 6.54. Molecular weight determinations carried out in ethylene bromide gave values ranging from 238–260; theoretical, 206.

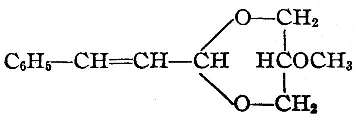
Attempts to crystallize the unpurified oil obtained after the removal of the above solid were futile. Distillation under reduced pressure was unsatisfactory, yielding only a portion of unchanged cinnamic aldehyde and a small amount of oil, b. p. 200–225° (6 mm.), which solidified on cooling. This solid was identified as 1,1′-cinnamylidene glycerol which had not been removed by crystallization. The bulk of the mother liquor remained as a gummy product and, as shown later, consisted of the 1,2-cinnamylidene glycerol.[7]

During the course of this investigation the very labile character of these carbon–oxygen cyclic structures was observed, in that samples of the solid 1,1-cinnamylidene glycerol, m. p. 121°, slowly changed on standing into an oily liquid. From analogy with the corresponding benzylidene glycerols[9] this was presumably due to an interconversion of one isomeric form into the other, but the product was not investigated.

Determination of Structure.—The methylation hydrolysis method of Irvine and co-workers was followed in order to determine the identification of the isomeric cinnamylidene glycerols. Methylation with silver oxide and methyl iodide gave the corresponding cinnamylidene glycerol methyl ethers (VII) and (VIII)

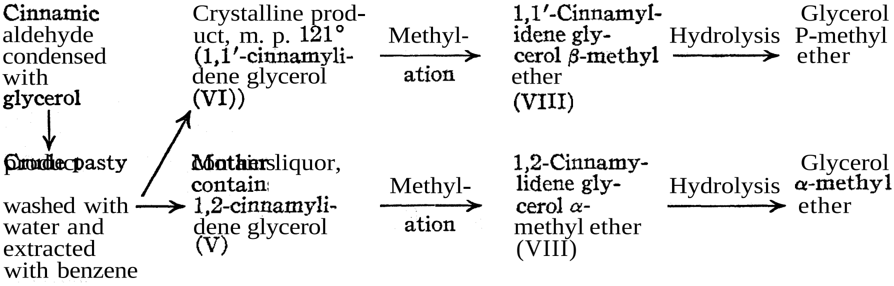


VII



VIII

the crystalline 1,1′-cinnamylidene glycerol (VI) (m. p. 121°) giving exclusively the crystalline 1,1′-cinnamylidene glycerol β-methyl ether (VIII), and the mother liquor from the original condensation reaction, after removal of the acetal (VI) yielding the liquid 1,2-cinnamylidene glycerol a-methyl ether (VII). Hydrolysis of the latter product gave glycerol a-methyl ether, while hydrolysis of the former yielded glycerol β-methyl ether as indicated in the following scheme



---

[9] Hill, Whelen and Hibbert, THIS JOURNAL, 50,2235 (1928).

No trace of the crystalline β-methyl ether (VIII) was found in the methylation product obtained from the liquid acetal (V) although it is admittedly impossible to remove all of the solid acetal (VI) from the liquid acetal (V) by crystallization.

Synthesis of 1,1'-Cinnamylidene Glycerol β-Methyl Ether (VIII).—Thirty-three grams of crystalline 1,1'-cinnamylidene glycerol (VI) was methylated in the usual manner, using 60 g. of silver oxide and 115 g. of methyl iodide. The reaction mixture was thoroughly extracted with warm benzene from which, on partial evaporation and cooling, 1,1'-cinnamylidene glycerol β-methyl ether (VIII) separated, mixed with a small amount of unchanged 1,1'-cinnamylidene glycerol. Fractional recrystallization from benzene, with final recrystallization from ligroin (b. p. 80–90°), yielded 13 g. of white, pearly leaflets, m. p. 79–80°. The only other substance isolated was 4.8 g. of white needles, m. p. 115–118°. A mixed melting point determination with approximately equal quantities of this substance and 1,1'-cinnamylidene glycerol (m. p. 121°) gave a m. p. of 119°, showing these substances to be identical.

Anal. (1,1'-Cinnamylidene Glycerol β-Methyl Ether.) Subs., 0.1596 : CO_2, 0.4180; H_2O, 0.970. Calcd. for $C_{13}H_{16}O_3$: C, 70.86; H, 7.33. Found: C, 71.43; H, 6.80.

Hydrolysis of 1,1-Cinnamylidene Glycerol β-Methyl Ether (VIII).—Sixteen g. of crystalline cinnamylidene glycerol β-methyl ether was hydrolyzed by boiling under a reflux condenser for seventy minutes with 150 cc. of 75% aqueous ethyl alcohol containing 0.5% of hydrochloric acid. Fifty cc. of water was then added and the alcohol removed under reduced pressure.

The considerable quantity of cinnamic aldehyde present was separated in a separatory funnel from the hydrolysis product and the latter extracted with ether. The aqueous solution was then neutralized with lead carbonate, filtered and concentrated under reduced pressure. The residual oil on distillation yielded 3.8 g. of glycerol β-methyl ether, b. p. 123" (13 mm.); $n_D^{17°}$, 1.4497.[8]

Anal. Subs., 0.1345: CO_2, 0.2208; H_2O, 0.1119. Calcd. for $C_4H_{10}O_3$: C, 45.28; H, 9.45. Found: C, 44.78; H, 9.26.

Methylation of 1,2-Cinnamylidene Glycerol.—The benzene solution obtained after removal of the crystalline 1,1'-cinnamylidene glycerol (p. 623) was concentrated in order to remove the solvent and thirty grams of the residual mother liquor containing the 1,2-cinnamylidene glycerol was then methylated in the usual manner with 60 g. of silver oxide and 115 g. of methyl iodide. The reaction mixture was extracted with benzene, the solvent evaporated and the residual oil fractionated. It yielded 9.4 g. of cinnamic aldehyde and 13.2 g. of 1,2-cinnamylidene glycerol a-methyl ether, b. p. 164–166° (6 mm.); $n_D^{20°}$, 1.5455.

Attempts to obtain a satisfactory analysis were unsuccessful due to the ease of hydrolysis and difficulties in combustion of the material. As in cated below, however, its identity was definitely established by its hydrolysis into glycerol a-methyl ether.

Hydrolysis of Cinnamylidene Glycerol a-Methyl Ether.—Twelve g. of cinnamylidene glycerol methyl ether, on hydrolysis by the same method as used for the @-derivative, yielded 3.6 g. of glycerol a-methyl ether, b. p., 110" (13 mm.); $n_D^{17°}$, 1.4435.

Anal. Subs., 0.1588: CO_2, 0.2609; H_2O, 0.1291. Calcd. for $C_4H_{10}O_3$: C, 45.23; H, 9.45. Found: C, 44.80; H, 9.09.

Ease of Hydrolysis of the Cinnamylidene Glycerols and Ethers.—When compared with the methylidene and benzylidene glycerols and their corresponding ethers, the cinnamylidene glycerol derivatives exhibit a very much more pronounced tendency toward hydrolysis.

Summary

1. Cinnamic aldehyde when heated with glycerol and a small amount of 40% sulfuric acid under reduced pressure readily condenses to give a pasty crystalline mixture of isomeric five- and six-membered cinnarnylidene glycerols.

2. From the crude material a crystalline solid and an oil can be readily separated, the former of which is shown to be the six-membered acetal (1,1′-cinnamylidene glycerol) and the latter the five-membered derivative (1,2-cinnamylidene glycerol).

OMEGA-HYDROXY ALIPHATIC ACIDS. SYNTHESIS OF SABINIC ACID

BY W. H. LYCAN[1] AND ROGER ADAMS

RECEIVED DECEMBER 27, 1928 PUBLISHED FEBRUARY 5, 1929

In a previous research[2] it was shown that the ethyl esters of w-aldehydo aliphatic acids could be prepared readily by the ozonization of various unsaturated esters. These substances are convenient intermediates for the preparation of the esters of w-hydroxy aliphatic acids, since the aldehyde esters are quantitatively converted by means of hydrogen and platinum to the corresponding alcohols. By saponification the ω-hydroxy acids result. In this investigation the five compounds, 9-hydroxynonanoic, 10-hydroxydecanoic, 11-hydroxyundecanoic, 12-hydroxydodecanoic and 13-hydroxytridecanoic acids have been synthesized and studied.

$$\left.\begin{array}{l} CH_3(CH_2)_7CH{=}CH(CH_2)_7CO_2CH_3 \\ CH_2{=}CH(CH_2)_8CO_2CH_3 \\ CH_2{=}CH(CH_2)_9CO_2CH_3 \\ CH_2{=}CH(CH_2)_{10}CO_2CH_3 \\ CH_3(CH_2)_7CH{=}CH(CH_2)_{11}CO_2CH_3 \end{array}\right\} \xrightarrow{O_3} CHO(CH_2)_xCO_2CH_3 \xrightarrow{2H} CH_2OH(CH_2)_xCO_2CH_3 \longrightarrow CH_2OH(CH_2)_xCO_2H$$

The o-hydroxy acids are of interest from several standpoints: first, a number of them are naturally occurring compounds; second, they may be valuable intermediates for the synthesis of large-membered lactones and, third, they offer an opportunity to study the compounds formed by intermolecular esterification.

Among such acids isolated from natural sources which have been studied

---

[1] This paper is an abstract of a thesis submitted by W. H. Lycan in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

[2] Noller and Adams, THIS JOURNAL, 48, 1074 (1926); Tomecko and Adams, *ibid.*, 49, 920 (1927); Davies and Adams, *ibid.*, 50, 1749 (1928).

are sabinic and juniperic acids. These were extracted by Bougault[3] and the structures determined as 12-hydroxydodecanoic acid and 16-hydroxyhexadecanoic acid, respectively. The synthetic 12-hydroxydodecanoic acid, which melted at 83–84°, proved to be identical with the natural product, as determined by the melting point and mixed melting point with a sample of sabinic acid kindly furnished by Dr. Bougault. In a recent article by Bhattacharya, Saletore and Simonsen,[4] 12-hydroxydodecanoic acid was prepared as an intermediate in the course of another investigation. It was reported as melting at 78–79°. The method of synthesis might readily lead to the presence of impurities difficult to remove and the low melting point indicates this to be the case. During the preparation of this manuscript, a paper by Ruzicka and Stoll[5] has come to hand which describes ω-hydroxy acids containing 13 to 17 carbon atoms. The method of preparation used by them differed entirely from that used in this research and consisted in the saponification of the corresponding lactones produced in turn by the oxidation of the cyclic ketones. It was found that the 16-hydroxyhexadecanoic acid was identical with juniperic acid. Moreover, the melting point of the 13-hydroxytridecanoic acid proved to be identical with that obtained for the same acid in this investigation.

Large-membered lactone rings have been shown to occur naturally by Kerschbaum[6] who isolated the lactone of ambrettolic acid and of pentadecanolic acid from certain natural oils. Such ring compounds are also of considerable importance from a purely theoretical standpoint as they offer an opportunity to study quantitatively the relative stability of large rings. In the latest paper by Ruzicka,[5] our work along this line has been anticipated. He has prepared analogous large-membered lactones by oxidizing the corresponding cyclic ketones.

The study in this Laboratory is, therefore, being centered on the preparation of intermolecular esters from the hydroxy acids. These compounds, possible structures for which are represented by Formulas I and II, present an interesting field of polymeric-like substances which, on account of their properties, may readily be studied.

Bougault[3] believed that sabinic and juniperic acids probably existed in the plant in the form of such polymers which he designated as etholides.

---

Ruzicka[6] noticed by-products in the oxidation of the cyclic ketones which he assumed to be etholides. One of these he purified and by analysis showed it to be a dimolecular compound. In this investigation the 9-hydroxynonanoic acid was heated and converted into a well-crystallized polymer melting at 64–66°, which analyzed also for a dimolecular compound. It has not yet been determined whether the molecule consists of a simple dimolecular lactone, a polymer of such a lactone or a very long, open-chain compound in which the free hydroxyl and carboxyl groups have practically no effect on the analysis. It is readily saponified by aqueous potassium hydroxide to the simple hydroxy acid. A more quantitative study of these substances and their derivatives will be reported in a subsequent paper.

Experimental Part

Methyl Esters of ω-Aldehydo Aliphatic Acids.—The method of preparation of the methyl esters of the ω-aldehydo acids and the unsaturated esters from which they are made has been described in previous papers.[2] The ozonizations of the methyl esters of 11,12-dodecenoic acid and 12,13-tridecenoic acid have not been as fully described as those of the other unsaturated acids used in these syntheses. In this communication are described the by-products obtained in the two ozonizations mentioned, the monomethyl esters of nonane-1,9-dicarboxylic acid and decane-1,10-dicarboxylic acid, respectively, isolated from the residues remaining after the distillation of the corresponding aldehyde esters.

Monomethyl Ester of Decane-1,10-dicarboxylic Acid.—The residue from the distillation of ω-aldehydo-undecanoate was recrystallized six times from petroleum ether (b. p. 50–60°) and melted at 51.5–52°.

Anal. Subs., 0.1784: CO_2, 0.4692; H_2O, 0.1953. Calcd. for $C_{13}H_{24}O_4$: C, 63.91; H, 9.91. Found: C, 63.73; H, 9.94.

Nonane-1,9-dicarboxylic acid, m. p. 109–110°, and decane-1,10-dicarboxylic acid, m. p. 126.5–127°, were obtained by the hydrolysis of the monomethyl esters with 10% aqueous sodium hydroxide solution and subsequent acidification.

Semicarbazone of Methyl 11-Aldehydo-undecanoate.—The semicarbazone was prepared by shaking equal weights of the aldehyde ester and semicarbazide sulfate with twice the weight of sodium acetate in dilute alcohol solution. The semicarbazone was recrystallized several times from ethyl acetate; m. p. 90–92°.

Anal. Subs., 0.1659: CO_2, 0.4179; H_2O, 0.1953. Calcd. for $C_{14}H_{28}O_3N_3$: C, 58.70; H, 9.84. Found: C, 58.36; H, 9.50.

Methyl Esters of the ω-Hydroxy Aliphatic Acids.—The methyl esters of the ω-aldehydo acids were reduced to the corresponding methyl esters of the ω-hydroxy acids according to the method of Carothers and Adams[7] for the reduction of aldehydes to primary alcohols. A solution of 0.2 mole of the aldehyde ester in 100 cc. of 95% ethyl alcohol, to which had been added 0.2 g. of platinum oxide catalyst and 2 cc. of freshly prepared 0.1 M ferrous sulfate solution, was shaken with hydrogen under about 2.5–3 atm. pressure. Usually about two hours were required for the absorption of the theoretical quantity of hydrogen. The solution was then filtered to remove the platinum black and the alcohol was removed on a steam-bath. The hydroxy ester was dissolved in 350 cc. of ether and the ether solution was washed, first with 150 cc. of 20% sodium

---

[7] Carothers and Adams, THIS JOURNAL, 45, 1071 (1923).

bisulfite solution, then with **150** cc. of **10%** sodium carbonate solution and finally with **500 cc.** of water. The ether solution was then dried with anhydrous magnesium sulfate. The alcohol esters were finally distilled under diminished pressure. The yields were from **80–90%** of the theoretical.

Phenyl Urethans of the Methyl Esters of the **ω-Hydroxy Acids.**—The phenyl urethans of the methyl esters of the w-hydroxy acids were prepared by mixing the ester with one-third its weight of phenyl isocyanate. The reaction was ordinarily spontaneous and was hastened by gentle warming on a hot-plate. The mixture was allowed to stand for one hour, after which the product was purified by repeated. crystallizations from petroleum ether or mixtures of benzene and petroleum ether (b. p. 50–60°).

TABLE II

PHENYL URETHANS OF THE METHYL ESTERS OF ω-HYDROXY ACIDS

	Formula	M. p., °C. (corr.)	Analyses Calcd., % C	Calcd., % H	Found, % C	Found, % H

ω-Hydroxy Aliphatic Acids.—The methyl esters of the w-hydroxy acids were hydrolyzed with a 10% excess of **10%** aqueous potassium hydroxide solution. The hydrolysis of **0.1** mole of the ester required about two and one-half hours. When solution was complete the water was removed by evaporation on the steam-bath and the potassium salts thus obtained were crystallized three times from absolute ethyl alcohol. The potassium salts crystallized as fluffy white crystals which analyzed for the theoretical percentage of potassium. The pure salt was dissolved in a small amount of water and evaporated on a steam-bath to remove traces of alcohol. It was again dissolved in water and the acid was freed by titration to Congo Red paper with **1** N hydrogen chloride solution. The acid which separated as a gelatinous precipitate was extracted with ether, the ether solution washed with water and dried with anhydrous magnesium sulfate. The solvent was removed under diminished pressure at ordinary temperatures and the resulting acids were purified by careful crystallization.

The compounds were dissolved in hot ethyl acetate and immediately cooled in an ice-and salt-bath. Crystallization in the usual way resulted in the formation of a small amount of insoluble polymeric material.

TABLE III

ω-HYDROXY ACIDS

	Formula	M. p., °C. (corr.)	Analyses Calcd., % C	H	Found, % C	H
1	$CH_2OH(CH_2)_7CO_2H$	53–54	62.07	10.43	62.30	10.67
2	$CH_2OH(CH_2)_8CO_2H$	75–76	63.77	10.72	63.56	10.75
3	$CH_2OH(CH_2)_9CO_2H$	65.5–66	65.29	10.96	65.36	10.83
4	$CH_2OH(CH_2)_{10}CO_2H$	83–84	66.59	11.20	65.50	11.20
5	$CH_2OH(CH_2)_{11}CO_2H$	77–78	67.82	11.39	67.88	11.39

Polymer of 9-Hydroxynonanoic Acid.—When 9-hydroxynonanoic acid was heated at a pressure of 3 mm. for half an hour at 220–230°, water was eliminated and a polymer-like product was obtained. This substance was crystallized from a mixture of benzene and petroleum ether (b. p. 50–60°) and was obtained as a fluffy, white, finely-divided powder; m. p. 64–66°.

Anal. Subs., 0.1921, 0.1898; CO_2, 0.4852, 0.4793; H_2O, 0.1774, 0.1765. Calcd. for $(C_9H_{16}O_2)_x$: **C,** 69.18; **H,** 10.33. Found: C, 68.88, 68.86; H, 10.33, 10.40.

This compound was insoluble in the cold in ethyl alcohol, petroleum ether, acetone and ethyl acetate, but was soluble in the hot. It was insoluble in cold aqueous potassium hydroxide solution. Upon warming with 10% aqueous potassium hydroxide solution on a steam-bath for one hour hydrolysis was complete. The potassium salt was crystallized from absolute alcohol and the acid freed as before was identical with the 9-hydroxynonanoic acid.

Molecular weight determinations in benzene both by boiling-point and freezing-point methods gave such variable results that more reliable data are needed before publication.

Summary

1. A general method is given for the preparation of w-hydroxy esters and w-hydroxy acids by reduction of the aldehydo esters obtained upon ozonization of the methyl esters of unsaturated acids.
2. A polymer of one of these w-hydroxy acids is described.

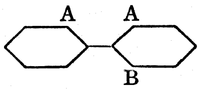
STEREOISOMERISM OF DIPHENYL COMPOUNDS. RESOLUTION OF 3,3'-DIAMINODIMESITYL. II[1]

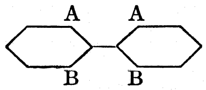
BY WENDELL W. MOYER[2] AND ROGER ADAMS

RECEIVED JANUARY 17, 1929 PUBLISHED FEBRUARY 5, 1929

The diphenyl compounds which have thus far been resolved into pairs of mirror images have, in every case, been 2,6,2'-trisubstituted, or 2,6,-2',6'-tetrasubstituted compounds, represented by the two general formulas I and II.



I



II

Of Type I only compounds in which A = carboxyl, B = nitro[3] have been made; of Type II, several combinations have been prepared in which A = carboxyl, B = nitro;[4] A = carboxyl, B = chlorine;[5] A = carboxyl, B = methoxyl;[6] A = amino, B = methyl;? A = acetamino, B = methyl;? A = acetamino, B = carboxyl;[7] A = carboxyl, B = the —CH= group in a benzene nucleus;[8] A = carboxyl, B = —CO— group in an anthraquinone nucleus.[9] It is thus reasonably certain that there is no specific effect due to any particular group.

Owing chiefly to experimental difficulties, other diphenyl derivatives with three or four substitutions in the 2,6- and 2,'6'-positions of the general tri- and tetrasubstituted type A,B,C, or A,B,C,D, have not been prepared and studied, but it can hardly be questioned that these could also exist in the form of optical isomers.

The only reasonably logical explanation of such isomerism is to assume that the two benzene rings are coaxial and not coplanar. The important problem then resolves itself into determining the mechanism by which various groups located in the 2,6- and 2',6'-positions as outlined above can prevent free rotation of the nuclei.

Turner and Le Fèvre[10] suggested that the electrical nature of the sub-

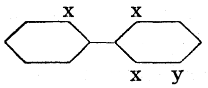
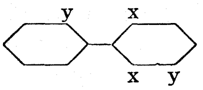
stituted groups, the residual affinity on each ring and the internuclear forces were important influences. They believe the isomerism arises from an inherent property of the parent hydrocarbon. Such a theory would lead to the expectation of easy racemization in optically active diphenyl compounds. Bell and Kenyon[11] preferred to look on the isomerism as due, primarily, to the ortho-substituting groups acting as obstacles to free rotation, though they believed the size and electrical character of the substituting groups might have an influence. On the other hand, Mills[12] considered the isomerism to be entirely mechanical in character. He assumed that the 2,6- and 2′,6′-groups are unable to get by each other due to their size and their proximity in space, and thus the two rings are never in the same plane.

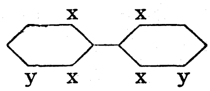
In a previous paper[1] it was pointed out that on the basis of the mechanical theory three other types of diphenyl compounds should be capable of resolution, Formulas III, IV and V.



III

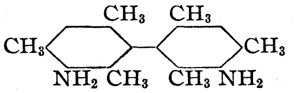


IV

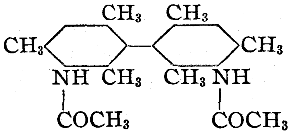


V

Here the substituting groups in the 2,6- and 2′,6′-positions are the same and the individual rings are asymmetric, due to the substitution of some group in the proper position. In this investigation two compounds have been made which fall into the class represented by Formula V. The substances are 3,3′-diaminodimesityl (VI) and 3,3′-diacetaminodimesityl (VII).



VI



VII

The 3,3′-diaminodimesityl was readily resolved into its optical isomers. The d- and l-forms were both isolated pure; d = $[\alpha]_D + 42.3°$, $l = [\alpha]_D$ $-41.5°$, and from them the active diacetaminodimesityls were prepared. The d-diaminodimesityl was boiled for long periods with both alcoholic potassium hydroxide and hydrochloric acid. No racemization took place with the alkali and only an extremely slight change in the rotation was noted with the acid treatment.

The fact that groups in the 2,6- and 2′,6′-positions in resolvable diphenyls may be the same, and that the compounds are not easily racemized, eliminates the possibility of explaining the isomerism as being caused entirely by the electrochemical character of the ortho substituted group. The presence of the two amino or acetamino groups produces

---

[11] Bell and Kenyon, *J. Soc. Chem.* Ind., 45, 864 (1926).

[12] Mills, *ibid.*, 45,884 (1926).

asymmetry in each of the rings, a condition which must be fulfilled if optical isomerism is to be possible, even though the rings are not in the same plane. These results offer strong additional evidence that the present mechanical theory may be correct.

To prepare diaminodimesityl, monobromomesitylene was converted to the Grignard, which by the action of cupric chloride gave, in better than 20% yields, dimesityl. This procedure is far more satisfactory than that described in the literature, the action of copper on mono-iodomesitylene. Considerable difficulty was encountered in the nitration of dimesityl, since all of the common nitrating reagents gave either a pure tetranitro derivative or a mixture of mono, di and tri. Acetyl nitrate proved satisfactory, however, and yielded a pure dinitro compound, even though an excess of reagent was used. Since by the use of this reagent mesitylene can be nitrated only to the mono nitro derivative, it seems certain that the dinitrodimesityl must be the 3,3′-substitution product. The reduction to the corresponding diamino was carried out in the usual way and the resolution of the latter was very readily accomplished through the dicamphorsulfonate. There was an extremely wide variation in the solubility of the diastereoisomeric salts and as a consequence the isolation of both forms in a pure state was a simple matter. The salts, on hydrolysis, gave the pure "d" and "*l*" bases. The active diacetamino derivatives were made by the action of acetic anhydride on the active diamino dimesityls.

It might be stated that attempts to condense nitro-iodomesitylene with copper to get the same dinitrodimesityl mentioned above were unsuccessful. Moreover, several experiments attempting the partial reduction of tetranitrodimesityl to 3,3′-dinitro-5,5′-diaminodimesityl resulted in mixtures. There was no difficulty in preparing 3,3′-dibromodimesityl but attempts to form the corresponding mono Grignard and from it the carboxylic acid gave negative results.

The facts that compounds of this type may be resolved and, moreover, that they may readily be prepared, make possible a much wider study of this general field. Other tetra-ortho-substituted compounds of a similar character are now being prepared. Compounds containing a di-ortho-substituted benzene nucleus attached to another residue, not a benzene, in which the atom combined to the benzene may have a fixed structure, are also being studied.

Experimental Part

Preparation of Dimesityl.—The application of the general method for preparing hydrocarbons discovered by Sakellarios and Kyrimis[13] was found much more satisfactory for preparing dimesityl than the method described by Ullmann.[14]

---

[13] Sakellarios and Kyrimis, *Ber.*, **57**, 322 (1924).

[14] Ullmann, *Ann.*, **332**, 48 (1904).

In a 3-liter, three-necked flask fitted with a vigorous stirrer, reflux condenser and a 500-cc. dropping funnel were placed 48.7 g. of magnesium turnings and 125 g. of bromomesitylene in 150 g. of anhydrous ether, and a few crystals of iodine. By warming, without stirring, the reaction was started and allowed to proceed for a few minutes. Mechanical stirring was begun and a solution of 273 g. of bromomesitylene in 600 g. of dry ether was added at such a rate that the ether refluxed steadily. The addition of the halide required two and one-half to three hours, after which the solution was stirred for half an hour longer. The flask was then surrounded by ice and a suspension of 300 g. of finely powdered anhydrous cupric chloride in 600 cc. of dry ether was added as rapidly as the heating of the reaction mixture permitted. The flask was then warmed on a steam-cone until the ether refluxed gently and the stirring was continued for six hours. At the end of this time the mixture was cooled and poured slowly, with constant stirring, into cracked ice and strong hydrochloric acid. After the decomposition was complete, more hydrochloric acid was added in order to take all the cuprous chloride into solution. The ether layer was washed successively with hydrochloric acid, water, ammonia and water. After removing the ether, about 180 g. of low-boiling material distilled over and then 65 g. of dimesityl from 142–160° at 5 mm. The distillate solidified and upon crystallization from alcohol, 52 g. (22%) of dimesityl that melted at 99.5–100° was obtained.

Tetranitrodimesityl.—In small amounts at a time, 18 g. of dimesityl was added to 130 g. of fuming nitric acid (sp. gr. 1.50) which was stirred mechanically and cooled by a freezing mixture. When the dimesityl came in contact with the nitric acid, a dark coloration appeared for an instant and then quickly faded. Toward the end of the reaction some solid nitro compound separated from solution. The sides of the flask were washed down by 20 g. more of nitric acid and then, after standing for half an hour, the mixture was poured into cracked ice. The tetranitro compound separated as a slightly yellowish, flocculent precipitate which, after washing and drying, weighed 31.6 g. (quantitative yield). After recrystallization from glacial acetic acid, the compound was obtained pure and melted at 270–271°.

Anal. Subs., 0.2184: CO_2, 0.4146; H_2O, 0.0839. Calcd. for $C_{18}H_{18}O_8N_4$: C, 51.65; H, 4.34. Found: C, 51.77; H, 4.30.

Partial Reduction of **Tetranitrodimesityl.**—An attempt was made to reduce tetranitrodimesityl by means of alcoholic ammonium sulfide to 3,3′-diamino-5,5′-dinitrodimesityl in somewhat the same way that dinitromesitylene was reduced to nitro-aminomesitylene.

In the first attempt, 8 g. of tetranitrodimesityl was added to a solution of 18 g. of ammonium hydroxide (sp. gr. 0.90) in 55 g. of absolute alcohol that had been saturated with hydrogen sulfide gas. The mixture was placed in an autoclave and heated at 140–150° for twelve hours. The brownish-red reaction mixture was acidified with dilute hydrochloric acid, the sulfur filtered off and the alcohol distilled from the acid solution. Upon adding ammonia, a reddish-yellow precipitate came down. This product was recrystallized from dilute alcohol and obviously was a mixture. An analysis showed that the tetranitro compound had been reduced on the average just beyond the triamino stage.

A second reduction using 10 g. of tetranitrodimesityl with 10 g. of ammonium hydroxide in 35 g. of absolute alcohol saturated with hydrogen sulfide, at 105–110° for twelve hours, also gave a mixture.

3,3′-Dibromodimesityl.—To a solution of 6.37 g. of dimesityl in 20 g. of carbon tetrachloride was added, with stirring and cooling in ice-water, a solution of 8.6 g. of bromine in 10 g. of carbon tetrachloride. The solution was allowed to stand in the dark overnight, after which the carbon tetrachloride was removed under reduced pressure.

A solution of 2 g. of sodium in 50 cc. of 95% alcohol was then added to the residue and the solution refluxed for half an hour. The mixture was poured into water and the product extracted with ether. The compound (6.6 g. or 63%) obtained was recrystallized from alcohol several times. When pure it melted at 112–113°.

Anal. Subs., 0.3160: CO_2, 0.6369; H_2O, 0.1443. Calcd. for $C_{18}H_{20}Br_2$: C, 54.55; H, 5.09. Found: C, 54.97; H, 5.11.

An attempt to make a mono Grignard in ether solution was not very successful. Only part of the magnesium went into solution. When all evidences of reaction were over, carbon dioxide was introduced just over the surface of the solution. Upon working up in the usual way a gummy product resulted from which no pure substance could be separated.

Tetra-aminodimesityl.—Six grams of the mixture of aminonitrodimesityls, obtained by the partial reduction of the tetranitrodimesityl, was reduced in a similar manner to that used in the preparation of diaminodimesityl. The tetra-amino compound thus obtained was slightly colored, and this color was removed by treating with 150 cc. of boiling alcohol, in which the amine was insoluble, and then adding a slight excess of concentrated hydrochloric acid which took all of the material into solution. Upon cooling the hydrochloride separated in glistening yellowish crystals. The hydrochloride was dissolved in water and the tetra-aminodimesityl precipitated by ammonia as a white, finely-divided material. Upon standing in the light, the compound became colored to a yellow-brown. The crude product (3.5 g.) was recrystallized from dilute pyridine and gave buff-yellow crystals that did not melt at 360°.

3,3′-Dinitrodimesityl.—Acetyl nitrate was found to nitrate mesitylene to give a quantitative yield of pure mononitromesitylene and consequently was used as a reagent for the preparation of 3,3′-dinitrodimesityl. Acetyl nitrate is much more easily prepared than benzoyl nitrate, a reagent which had been shown by Francis[15] to react with mesitylene to give mononitromesitylene.

The acetyl nitrate was prepared according to the original method devised by Pictet and Khotinsky.[16] It was used in acetic anhydride solution (approximately 1 g. of nitrogen pentoxide in 3–4 g. of acetic anhydride). The molar concentration per gram of the solution used was calculated so that it was easy to weigh out definite amounts of the acetyl nitrate. The acetyl nitrate solution was kept at −15°; at room temperature it turns brown and evolves red fumes.

A solution of 0.1 mole (23.8 g.) of dimesityl was made in 70 g. of carbon tetrachloride and cooled to 0° with a freezing mixture. Then with mechanical stirring and continued cooling, an amount of the acetyl nitrate solution that contained 0.3 mole of acetyl nitrate was slowly added. Care must be taken to add only a few cc. until the reaction starts. After a few minutes considerable heat was evolved and the mixture warmed to 35–40°. The remainder of the acetyl nitrate was then added at such a rate that the temperature remained at this upper limit. In trial runs it was demonstrated that it was necessary to have a temperature of 30–40° (as high as 50° without harm) toward the end of the nitration until completion in order to obtain the dinitro derivative pure—if nitration continued throughout at 0–10°, a low-melting product was obtained (m. p. 100–109°) that was probably the mononitro derivative or a mixture of dinitro- and mononitrodimesityl.

After the heat of the reaction had ceased, the stirring was continued at room temperature for another hour. The mixture was decomposed with water and the carbon tetrachloride steam-distilled out. The dinitrodimesityl was filtered off as a granular

---

mass and weighed **32** g. **(98%).** Alternate recrystallizations from acetic acid and alcohol gave a pure product of constant melting point, 162.5–163.5° (corr.).

Anal. **Subs., 0.2149: CO_2, 0.5193; H_2O, 0.1156. Calcd.** for $C_{18}H_{20}O_4N_2$: C, **65.82; H, 6.14.** Found: **C, 65.90; H, 6.02.**

Nitration of dimesityl in hot glacial acetic acid solution or in the cold with carbon tetrachloride as solvent and the theoretical amount of nitric acid gave mixtures of nitro products. Nitration with the theoretical amount (for the dinitro derivative) of potassium nitrate in concentrated sulfuric acid gave a mixture from which the tetranitro derivative was isolated.

3,3′-Diaminodimesityl.—To a solution of **180** g. of glacial acetic acid, 40 *g*. of water and **10 cc.** of concentrated hydrochloric acid, was added **16.4** g. of pure dinitrodimesityl. Then with constant stirring, **100** g. of zinc dust was added in small amounts. The flask was at first cooled in an ice mixture and the zinc added so that the temperature went to 80–90°. This temperature was maintained by the heat of reaction as long as possible; then it was allowed to cool as the reaction ceased. More water was added from time to time. Zinc acetate separated after two hours and the reaction was stopped. The mixture was filtered and the residue washed with water and dilute hydrochloric acid. The filtrate was then made alkaline with an excess of ammonia in order to take all of the zinc salts into solution. The flaky white diaminodimesityl was filtered and again treated with acid and ammonia in order to remove any traces of zinc salts. The dried product weighed **13.2** g. Several recrystallizations from **60%** alcohol raised the melting point to the constant value, 206–207° (corr.). The yield of pure diaminodimesityl was **8.2** g. **(61%).**

Anal. Subs., **0.1989: CO_2, 0.5880; H_2O, 0.1587.** Calcd. for $C_{18}H_{24}N_2$: **C, 80.53; H, 9.02.** Found: **C, 80.62; H, 8.93.**

3,3′-Diacetylaminodimesityl.—A mixture of **10** g. of acetic anhydride and **1** g. of pure diaminodimesityl was shaken for a few seconds. The diamino compound went into solution at once with evolution of heat, and then within two minutes the diacetyl derivative crystallized out from the anhydride solution. After standing for half an hour the compound was filtered and then washed thoroughly with water. The yield was quantitative and the derivative pure, as recrystallization from dilute methyl alcohol did not raise the melting point. **303–304'.**

Anal. Subs., **0.1656: CO_2, 0.4563; H_2O, 0.1212.** Calcd. for $C_{22}H_{28}O_2N_2$: C, **74.95; H, 8.01.** Found: C, **75.15;** H, **8.18.**

Resolution **of 3,3′-Diaminodimesityl.**—To 200 cc. of boiling water containing **9.8** g. (0.042 mole) of d-camphorsulfonic acid was added **5.36** g. (0.02 mole) of diaminodimesityl. When complete solution was effected, Norite decolorizing charcoal was added and the solution filtered. The filtrate was allowed to stand in a cool place for thirty-six hours. At the end of this time a crop of large, light-yellow, transparent crystals had separated, which were essentially a pure salt, as shown by rotation and melting point as compared with recrystallized material. These crystals were filtered from the solution and washed with cold water; weight, 6.5 g. The salt did not have a sharp melting point, 175–187°, and gradually softened with gas evolution. The compound was found to be hydrated and, after drying, melted at 186–188° with previous softening.

Rotation. **0.2020 g.** made up to **20 cc.** with water at **20°** gave $\alpha_D = +0.33°$, $l = 2$; $[\alpha]_D^{20} = +16.3°$.

The salt was recrystallized from **150 cc. of** water. The melting point again was not sharp, but it melted exactly like the original material.

Rotation. *(a)* **0.2170** g. made **up** to **20** cc. with water at 20° gave a, = +0.35°, I = 2; $[\alpha]_D^{20}$ = +16.1°. (b) **0.2265 g.** made up to **20** cc. with 95% alcohol at 20° gave α_D = +0.73°, l = 2; $[\alpha]_D^{20}$ = +32.2°.

The salt was again crystallized from water. The melting point did not change.

Rotation. **0.2255** g. made up to **20** cc. with 95% alcohol at 20° gave a, = +0.73°, l = 2; $[\alpha]_D^{20}$ = +32.4°.

Anal. (Parr Bomb). Subs., **0.5000: $BaSO_4$, 0.3056.** Calcd. for $C_{38}H_{56}O_8N_2S_2 \cdot H_2O$: S, 8.54. Found: **S, 8.40.**

Anal. Subs., **0.2434** g. (air-dried salt): 140–150° for three hours lost **0.0054** g. Calcd. for $C_{38}H_{56}O_8N_2S_2 \cdot H_2O$: **$H_2O$, 2.40.** Found: **$H_2O$, 2.22.**

The mother liquor from the first crystallization, to which none of the subsequent recrystallization filtrates had been added, was then evaporated to 80 cc. and allowed to stand in the cold for a week. At the end of this time 0.4 g. of salt was removed and the liquid was further concentrated to 25 cc. Upon standing for another week a small amount of finely granular material separated. The weight was 0.2 g., m. p. 174–189' with no gas evolution. The rotation in alcohol was +25.9° This was probably an impure sample of the more insoluble salt. The filtrate was shown to be a solution of the other diastereoisomeric salt in essentially pure form. No attempt was made to isolate the solid salt, but the solution was hydrolyzed directly to obtain the pure 1-base.

d-3,3′-**Diaminodimesityl.**—The pure crystalline (less soluble) dicamphorsulfonate salt was dissolved in an excess of hot water and the active diamino compound precipitated in white flakes with ammonia. After washing and drying, the compound was essentially pure, melting point 203.5–204.5 (corr.). Recrystallization from dilute alcohol did not raise the melting point and the product tended to acquire a slightly yellowish color.

Rotation. **(a)** 0 **1907** g. made up to **20** cc. with **0.3** N hydrochloric acid at 20° gave α_D = +0.23°, l = 2; $[\alpha]_D^{20}$ = +12.0°. (b) **0.2456** g. made up to **20** cc. with acetone at 20° gave α_D = +1.04°, l = 2; $[\alpha]_D^{20}$ = +42.3°.

d-**3,3′-Diacetaminodimesityl.**—The diacetyl derivative of the d-base was prepared in the same way as the racemic diacetate. The melting point of the compound, purified by crystallization from dilute alcohol, was 312–313° (corr.), with shrinking at 307°.

Rotation. **0.2370** g. made up to **20** cc. with absolute alcohol at 20° gave α_D = +0.73°, *1* = 2; $[\alpha]_D^{20}$ = +30.8°.

Anal. Subs., **0.1727: CO_2, 0.4738; H_2O, 0.1254.** Calcd. for $C_{22}H_{28}O_2N_2$: C, **74.95;** H, 8.01. Found: C, 74.82; H, 8.12.

1-3,3′-**Diaminodimesityl.**—The final mother liquors from the resolution were diluted to 100 cc. and the diamino precipitated with ammonia. After recrystallization from dilute methyl alcohol, it melted at 203–204° (corr.).

Rotation. **0.2265** g. made up to **20** cc. with acetone at 20° gave α_D = −0.94°, 1 = 2; $[\alpha]_D^{20}$ = −41.5'.

l-3,3′-Diacetaminodimesityl.—This derivative was made by the same method as described for the d-form. It melted at 311–313° (corr.), with previous shrinking at 307°.

Rotation. 0.2300 g. made up to 20 cc. with absolute alcohol gave $\alpha_D = -0.70'$. $l = 2$; $[\alpha]^{20}_{D} = -30.4°$.

Racemization Experiments.—The optical stability of the d-3,3′-diaminodimesityl was studied under two different sets of conditions.

1. A solution of 0.3 g. of the d-base in a mixture of 20 cc. of absolute alcohol and 3 g. of potassium hydroxide in 3 cc. of water was refluxed for five hours. The rotation of the recovered diamine showed that practically no racemization had occurred.

Rotation. 0.2262 g. made up to 20 cc. with acetone at 20° gave $\alpha_D = +0.92°$, $1 = 2$; $[\alpha]^{20}_{D} = +40.7°$.

2. A solution of 0.2 g. of d-diaminodimesityl in 30 cc. of concentrated hydrochloric acid was refluxed for nine hours. Racemization took place to a very slight extent.

Rotation. 0.1645 g. made up to 20 cc. with acetone at 20° gave $\alpha_D = +0.64$, $l = 2$; $[\alpha]^{20}_{D} = +38.9°$.

Nitro-aminomesitylene.—Dinitromesitylene was prepared by the action of cold fuming nitric acid on mesitylene at 0°, according to the method by Fittig.[17]

The partial reduction of dinitromesitylene to nitro-aminomesitylene was most readily accomplished by a modification of the original procedure of Kiister and Stallberg.[18] A solution of 100 g. of aqueous ammonia (sp. gr. 0.90) in 300 g. of absolute alcohol was cooled in an ice-bath and saturated with hydrogen sulfide. The ammonium sulfide solution was then placed in an autoclave with 80 g. of dinitromesitylene and the mixture heated at a temperature of 110–115" for fifteen hours. The yield (89%) was better than that reported previously.

Nitro-iodomesitylene.—To a hot solution of 150 cc. of water, 70 cc. of concentrated hydrochloric acid, and 5 cc. of alcohol, was added 27 g. (0.15 mole) of nitro-aminomesitylene and the solution cooled to 0°. As the solution cooled, the hydrochloride separated. To the cold mixture was then added with constant stirring, 10.5 g. of sodium nitrite in 20 cc. of water. The diazonium salt solution was filtered from insoluble material. Then with stirring a solution of 30 g. of potassium iodide in 50 cc. of water was added. A red solid separated and then as the mixture approached room temperature, nitrogen was evolved and the color changed to yellow. The mixture was warmed to 45° and allowed to stand for several hours. The product was filtered and treated with hot sodium hydroxide solution

---

[17] Fittig, Ann., 141, 133 (1867).

[18] Kiister and Stallberg, *ibid.*, 278, 213 (1894).

and acid successively. After recrystallization from alcohol a yield of 32.5 g. (72%) of buff-colored crystals was obtained, melting at 96–97°.

Anal. Subs., 0.2230: CO_2, 0.3133; H_2O, 0.0715. Calcd. for $C_9H_{10}O_2NI$: C, 37.11; H, 3.46. Found: C, 38.31; H, 3.59.

Several attempts to make 3,3′-dinitrodimesityl by the action of Naturkupfer C on nitro-iodomesitylene between temperatures of 200–300° gave only tars from which no definite compound was obtained. An attempt with nitrobenzene as a solvent yielded no better results.

Summary

1. 3,3′-Diaminodimesityl has been prepared and resolved through the dicamphorsulfonate to yield pure *l*- and d-modifications.
2. The active diamines were converted into the corresponding active diacetamino derivatives.
3. These are the first diphenyl derivatives resolved with the 2,6,2′,6′-positions, all occupied by the same group. This lends support to the mechanical theory for explaining the optical isomerism in certain diphenyl compounds.

URBANA, ILLINOIS

NOTE

The Electrolysis of Metallo-Organic Compounds.[1]—Gaddum and French[2] have recently reported a series of experiments on the electrolysis of ether solutions of the Grignard reagent. In their paper they comment on the chemical reactivity of the metallic magnesium which was deposited at the cathode but do not describe its physical properties. Some time ago the authors made a series of experiments on the electrolysis of magnesium ethyl bromide in ether solutions, using platinum electrodes. The solutions showed a good conductivity and a beautiful crystalline deposit of metallic magnesium quickly formed upon the platinum cathode. This deposit adhered quite firmly to the electrode surface. Products were detected in the solution similar to those reported by Gaddum and French, which are to be attributed to the anode reaction, but it is impossible to say whether these were produced by direct electrolysis or by a secondary reaction of bromine, which had been liberated at the anode, with the Grignard reagent. In order to get away from the effects of the halogen liberated at the anode, zinc diethyl was used in place of the Grignard reagents in some of the electrolysis experiments. Zinc diethyl in the pure state shows no appreciable conductivity but an ether solution showed a specific conductivity of 10^{-4}. With an applied potential of 110 volts

---

[1] The experimental results noted here were originally included in a paper which was submitted to THIS JOURNAL for publication in June, 1926.

[2] Gaddum and French, THIS JOURNAL, 49, 1295 (1927).

appreciable quantities of metallic zinc were deposited upon the cathode. The zinc deposit was smooth, firmly adherent and not of as brilliant a luster as the magnesium deposits obtained in the earlier experiments. The products at the anode dissolved in the solution and were not satisfactorily identified but there can be little doubt that the ethyl radical was liberated at the anode.

NEW BOOKS

The Collected Works of J. Willard Gibbs, Ph.D., LL.D. Formerly Professor of Mathematical Physics in Yale University. Edited by WILLIAM RAYMOND LONGLEY and RALPH GIBBS VAN NAME. Two volumes. Longmans, Green and *Co.*, 55 Fifth Avenue, New York, N. Y., 1928. xxviii + 434 pp. xviii + 284 pp. 15.5 × 23.5 cm. Price, $6.00 per set.

This is the first complete edition of the writings of J. Willard Gibbs. It is a reprint of the 1906 publication, with the addition of "The Elementary Principles of Statistical Mechanics." The first volume contains the various contributions to thermodynamics, while the second comprises Statistical Mechanics, Dynamics, Vector Analysis and Multiple Algebra, Electromagnetic Theory of Light and some shorter papers, including a biographical sketch of Clausius and of H. A. Newton.

When the 1906 edition appeared, a very eulogistic foreign review expressed regret that the price of the volumes was so high; it was felt that the University or the Nation whose privilege it was to claim Gibbs as their own should have offered the world this fundamental contribution to science at a nominal price, "as a duty of honour." This reproach is now removed by the publication of the present collection at a price which "has been made possible by the generosity of Professor Irving Fisher of Yale University, a former pupil of Willard Gibbs, and by the economy resulting from the use of photographic reproduction, which was also desirable as a means of avoiding typographical errors."

It is now fifty years since the last of the articles on the "Equilibrium of Heterogeneous Substances" was published in the Transactions of the Connecticut Academy. The reviewer cannot help wondering how many books on thermodynamics written at the present day will bear republishing fifty years hence, without apology, without adaptation and without a single verbal change. Gibbs' thermodynamics has not been changed by other writers during this period, but the attitude of chemists has been changed profoundly. The durability characteristic of Gibbs' work is due to the complete absence of all matter extraneous to thermodynamics, which is nowadays often slipped in unawares or unannounced. The change in the public has been brought about by the very thing Gibbs so deliberately avoided, for the great number of less durable, but also less difficult, books which have been published since have had the very useful effect of popularizing thermodynamics, and the time is now ripe for a return to the master. The reviewer's advice to any chemists who may have, long ago, given up Gibbs in despair, is: Try him again, he's much easier than he used to be.

FRANK B. KENRICK

Kurzes Lehrbuch der Chemie in Natur und Wirtschaft. (A Short Treatise on Chemistry in Nature and Human Affairs.) Band I. Allgemeine Chemie. (Vol. I. General Chemistry.) By PROF. JOHANN MATULA; Anorganische Chemie. (Inorganic Chemistry.) Band II. Organische Chemie. (Vol. II. Organic Chemistry.) By PROF. CARL OPPENHEIMER. Second revised edition. Georg Thieme, Antonstrasse 15–19, Leipzig C 1, Germany, 1928. xvi + 566 pp. 65 figs. xiv + 471 pp. 7 figs. 17 X 24.5 cm. Price, Vol. I, unbound, M. 23; bound, M. 26; Vol. II, unbound, M. 19; bound, M. 22.

In the introduction to the first edition Professor Oppenheimer stated that this book arose from a desire to prepare a readable treatise of moderate length which should present the leading ideas on which chemistry has been developed into an unusually attractive and well ordered science, and which should also show the innumerable interrelations between chemistry and the work of the biologist and technologist. To this end the treatise was to contain everything that would serve to give a clear and adequate picture of the science, but in the choice of illustrative material preference was always to be given to matters that were important in nature, in the biological sciences or in industry. No substance was to appear in it unless it represented a type, was a natural product, had biological significance or technological interest. In the main, the authors have consistently followed this prescription.

Approximately half of the first volume is devoted to "general chemistry." This part, which was prepared by Professor Matula of Vienna, necessarily deals with many subjects that are usually treated in texts on physical chemistry, but the matter is presented as a necessary introduction to inorganic and organic chemistry—not as an independent discipline. Subjects like catalysis, complex formation, constitutional formulas, isomerism, tautomerism and polymerism, therefore, receive far more attention than they commonly do in books on physical chemistry. Professor Matula has a rare ability to present and apply physico-chemical principles without an elaborate use of mathematics, hence this section is exceptionally interesting and instructive for readers not primarily interested in physical chemistry.

In the remainder of the volume the senior author presents descriptive inorganic chemistry, interspersed with brief historical notes, discussions and practical applications. The descriptive material differs but little from that contained in other texts on the subject except in its very extensive use of structural formulas. These are written without evidence and with a finality that frequently is unwarranted. The historical notes **and** theoretical discussions also present little that is novel in content or treatment. But the author writes with real enthusiasm when he is dealing with topics of biochemical interest—the mechanism of biological oxidations, the fixation of nitrogen, the pharmacology of carbon monoxide, the role of iron compounds in living organisms and similar topics.

As will be seen from the foregoing description this treatise is in no sense a "popular" presentation; it presupposes at least as much knowledge as could be obtained in good fundamental courses in organic and inorganic chemistry. It should appeal especially to the biologist and the medical practitioner but it also contains much that is stimulating and extremely interesting to the chemist.

E. P. KOHLER

Atlas der letzten Linien der wichtigsten Elemente. (Atlas of the Persistent Lines of the Most Important Elements.) By DR. FRITZ LÖWE. Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1928. iii + 44 pp. 13 plates. 15 X 22.5 cm. Price, bound, R. M. 12.

The chief value of this atlas for the spectrum analyst lies in the reproductions of spectra and the tables which it contains.

For 42 of the elements (chiefly metallic) reproductions of spectrograms with a wave-length scale are accompanied by lists of the wave lengths of the most important lines with their relative intensities in spark and arc. The spectra in each case cover the particular region of the ultraviolet where the most important lines occur. Condensed spark spectra with self-induction on lamp graphite are used. For each element the four spectra result from moistening the electrode with solutions of 1.0, 0.1, 0.01 and 0.001 normal concentration.

Following the plates is a wave-length table of persistent lines (656), according to de Gramont, and Pollok and Leonard, for 64 elements, with relative intensities in arc and spark, ionization state and wave length of the strong line of next longer wave length as given by Kayser. The range 1863–6708 Å. is covered.

References to more important literature are given.

G. P. BAXTER

Atomstruktur und Atombindung. (Valence and Atomic Structure.) By DR. J. STARK. Polytechnische Buchhandlung, A. Seydel, Koniggratzerstrasse 31, Berlin, S. W. 11, Germany, 1928. xx + 198 pp. 15 figs. 14.5 X 22.5 cm. Price, R. M. 9.

In this book the author presents at considerable length a theory of atomic and molecular structure which differs widely in many respects from other more generally accepted theories. Starting with the assumptions that atoms, and also the protons ("archions") and electrons in atoms, possess axes and equatorial planes and with known facts regarding magnetic moments, ionizing potentials, valence, etc., he deduces electron distributions for the different kinds of elements. To enable electrons to have fixed equilibrium positions outside the nucleus, "innerkinetic" forces are assumed, these balancing the Coulomb forces at small distances. Although in the main the distributions of electrons in layers conform to previously proposed distributions, there are many differences in detail.

The nucleus is assumed to be composed of "helions"—units consisting of two protons and one electron—equal in number and identical in arrangement with the electrons outside. To account for isotopes and radioactivity, "neutrons," each consisting of one proton and one electron, are supposed to be in random motion in the space between the nucleus and the innermost layer of extra-nuclear electrons.

According to the author, atoms are usually held together in non-polar compounds by means of two coaxially placed valence electrons. Because of the peculiarities of the atomic structures assumed, many of the molecular structures proposed are quite different from all others which have previously been proposed for the same compounds, but the reviewer could not see that they fit the experimental facts better than the more common structures.

To one who is already familiar with the experimental facts and with other current theories on the subject, this book is interesting and suggestive in that it shows how many phenomena can be related or explained in quite unorthodox fashion. To others, however, this book can hardly be recommended, for throughout the work the author presents his theory without giving the reader much basis for comparison with other theories. The reviewer, for one, found many of the arguments which were given quite unconvincing.

MAURICE L. HUGGINS

Über Lösungs- und Verdünnungswärmen einiger starker Elektrolyte. (The Heats of Solution and Dilution of Some Strong Electrolytes.) By DR. ERICH LANGE, Lecturer at the University of Munich. Gebrüder Borntraeger, W 35 Schoneberger Ufer 12a, Berlin, Germany, 1928. ii + 83 pp. 10 figs. 16.5 × 25.5 cm. Price, M. 6.40.

In this monograph the author outlines the thermo-chemistry of dilute solutions in a comprehensive manner. With copious references to a wide range of original articles, he reviews the theories of heats of solution and dilution of electrolytes and the experimental methods by which these theories can be tested.

The first section of the book is devoted to definitions, thermodynamic relationships and theoretical development. Here Dr. Lange shows how the heat of solution of an electrolyte has been calculated, by the methods of mathematical physics, from the lattice energy of the salt and the energy of solvation of the resulting ions. He briefly summarizes the "inter-ionic attraction" theory of Debye and Hückel and gives their equations for heats of dilution, pointing out the difficulties in extending these calculations above the extremely dilute "limiting range."

The second section, devoted to calorimetric methods, starts with a discussion of units of heat (the calorie and joule). Here the author unfortunately confuses with the joule the mayer (= 1 joule/degree) suggested by T. W. Richards to designate *heat* capacity in the c. g. s. system.

Dr. Lange rightly emphasizes the error in the usual method of calculating heats of solution of "insoluble" salts from the heats of precipitation without knowing the corresponding heats of dilution. These are by no means negligible. He shows that in the case of silver chloride this error amounts to a hundred calories and that it would be even greater with higher valent salts.

A good review of calorimetric principles and precautions and thermometry is followed by a brief description of his own adiabatic calorimeter (for measuring large heat changes) and his adiabatic differential calorimeter for very small heat changes. The latter is indeed remarkable as much for its fundamental simplicity and compactness (a two-liter vacuum flask divided in half by a sheet of hard rubber) as for the sensitivity of $^1/_2$ millionth of a degree attained by an iron-constantan thermel of 1000 junctions. To insure corresponding accuracy required meticulous attention to details—complete and rapid mixing, carefully controlled heat of stirring and a consideration of such possible disturbing factors as the adsorption of the solute ions on the walls of the calorimeter.

Curves of the integral and differential heats of dilution of most of the alkali halides are shown in three figures. The basic numerical values of the integral heats of dilution of these electrolytes are given in a table which includes also results for nine other salts of higher valence types. These results are found to agree essentially with those of Nernst, Orthmann and Naudé, in the few instances where comparison is at all possible.

Dr. Lange's results qualitatively check the predictions of the Debye-Hückel theory. Below 0.01 M the heats of dilution of all five uni-univalent salts investigated are positive, although the slopes of the actual curves are not exactly that of the theoretical "limiting law." There is, however, considerable uncertainty in the value of the dielectric constant of water and especially its temperature coefficient, from which the theoretical constant is derived. A conclusive test of the Debye-Hückel theory must await a more exact determination of this constant.

Dr. Lange's book will prove stimulating and useful to the thermochemist interested in the latest developments in extremely sensitive calorimetry. Whatever his specialty, the reader will find it a good summary of the increasingly large amount of theoretical work which has appeared, within the past few years, in the field of electrolytic solutions.

FRANK T. GUCKER, JR.

Soluble Silicates in Industry. By JAMES G. VAIL. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., New York, 1928. 443 pp. 185 figs. 16 X 23.5 cm. Price, $9.50.

In this book Mr. Vail has given a thorough, systematic and authoritative discussion of the history, constitution, properties, preparation and industrial utilization of the soluble silicates and their solutions. The thirteen hundred references attest a detailed study of the literature and a desire to give credit to other chemists for their investigations and ideas and yet the book is not a systematic and complete collation of the literature, good, bad and indifferent, of the Germanic type. The book gives the impression that it is written primarily out of the author's own experience and knowledge. Facts are stated with a clearness and positiveness derived from first-hand acquaintanceship; a corroborative reference is cited if available but it seems to make no real difference if corroboration of the author's views is not available. Here there is no hedging between the conflicting views of other authorities so characteristic of the mere compiler. Moreover, the facts are marshaled in accordance with *a* logical plan which greatly facilitates the use of the book.

The number and variety of uses of water glass which are discussed in detail will astonish most readers. In the discussion of uses, few receipts are given, but the function of each ingredient in the complex mixtures is clearly analyzed in a manner to aid the reader in adapting the composition to his own special requirements. This book is a valuable addition to the Monograph Series of the American Chemical Society.

GRINNELL JONES

Gesammelte Abhandlungen. (Collected Works.) Volume V. By Dr. F. KEHRMANN, Professor at the University of Lausanne. Georg Thieme, Leipzig, Germany, 1928. **321** pp. **53** figs. **17** X 25 cm. Price, unbound, M. 30.

The fifth volume of Kehrmann's collected papers contains reprints on a great variety of subjects. The first section presents, besides some early papers on complex acids which for one reason or another were not included in the first volume, Kehrmann's most recent work on the "basic properties of carbon" and on "oxonium compounds." The second section deals with recent investigations on quinonimide, fluorindine and carbazine dyes. The third, which is entitled "Miscellaneous," contains early and historically interesting papers on such topics as the structure of benzoquinone and the action of ammonium sulfide on halogen nitro compounds, as well as recent work on the blue oxidation product of diphenylamine.

On a concluding page Kehrmann presents the relation of his work to the three fundamental facts which in his opinion have contributed greatly to the present aspect of organic chemistry: the discovery of steric hindrance, oxonium salts and salts in which complexes of carbon and hydrogen can act as positive ions.

E. P. KOHLER

Elementary Organic Chemistry. By HOMER ADKINS, Ph.D., AND S. M. MCELVAIN, Ph.D., Department of Chemistry, University of Wisconsin. First edition. McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York, 1928. xi + 183 pp. 14.5 × 21 cm. Price, $2.25.

In this brief book of twenty chapters, the writers aim to present "organic chemistry in a one semester course," and "have laid emphasis upon the characteristic reactions of the important functional groups." The arrangement of the earlier chapters is essentially that so successfully used by the late Professor Ira Remsen. Sections of the text are designated by numbers and cross references are frequently indicated. The make-up of the book indicates a continuance of the high standard of the International Chemical Series. There are occasional misspellings and some slight errors in English, which it is hoped subsequent printings will rectify. The term "deracemize" has not the opposite meaning of racemize as the term is generally used, and has little to commend it. The type is good and the arrangement makes for particularly easy reading.

In the introductory part, at least by inference, the complete non-exist-
nce of inorganic isomers might be assumed. This is unfortunate. At
twice where hydrogen is indicated in an equation, it is written in
form, which is certainly not to be advocated when the product
the gas as it is in the cases cited. The reviewer is particularly
hat in dealing with the action of phosphorus trichloride on
planation is given for the observed evolution of hydrogen
ndard equation usually given for the preparation of
s not account for the production of this material.
s which elementary students in organic chemistry
insufficient acquaintance with inorganic chem-
ted that the fact that tertiary amines do not
ot specifically stated. Primary and secondary
student is apparently expected to infer that
e nitrogen the reaction does not proceed.
lcohols, the term "active" is used with no
rently the authors do not care to discuss
but the better student, the one who is really
rtainly call for an explanation from his instruc-
n were very briefly given in the text, it would be

helpful to all concerned. On at least two occasions, namely, in the preparation of iodoform and in the preparation of phenylhydrazine, the reduction is indicated simply by "2H." This is a particularly unhappy method of expression, since it tells very little, and the student interested in the subject will raise the question "How is this hydrogen obtained?" and the one not quite so concerned will assume that the reaction proceeds merely by supplying hydrogen gas. In most cases in this text the particular reagent for accomplishing a particular end is indicated. This is as it should be, and if sodium arsenite and stannous chloride were indicated in the cases just mentioned, these two instances would not stand out as they now do. The objection to the rigid Kekulé formula for benzene (*i. e.*, with fixed alternate double and single bonds), namely, that such a substance should be readily oxidizable, is not as pertinent as the fact that such a structure would lead theoretically to a greater number of disubstitution products than have been found in the case of benzene derivatives. It would seem advisable to suggest this at any rate. Under azo dyes a somewhat complicated formula is given and the preparation of this compound is described in detail. There seems to be no good reason why the fact that it is known as Congo Red and that this is an important direct dye for cotton should not be brought to the student's attention.

The criticisms indicated are the more noticeable because, as a whole, the book is accurate and shows careful preparation. The authors are to be commended on the restraint shown by them in keeping the text elementary and concise. This volume should be decidedly useful in the teaching of so-called "short courses" in organic chemistry.

G. ALBERT H

The Journal of the American Chemical Society

VOL. 51 MARCH, 1929 No. 3

THIRTY-FIFTH ANNUAL REPORT OF THE COMMITTEE ON ATOMIC WEIGHTS. DETERMINATIONS PUBLISHED DURING 1928

BY GREGORY PAUL BAXTER

RECEIVED FEBRUARY 12,1929 PUBLISHED MARCH 6, 1929

The German Committee on Atomic Weights has issued its Annual Report.[1] During the past year the following investigations were published.

Addingley and Whytlaw-Gray,[2] by a differential method, have found the ratio of the deviations from Boyle's Law for oxygen and hydrogen to be 1.00148 for the pressure range 0–1 atmosphere.

Potassium.—Hönigschmid and Goubeau[3] have confirmed by analysis of potassium bromide the value recently found by them by analysis of the chloride. Potassium oxalate was recrystallized five times with rejection of mother liquors and small head fractions in each case. Conversion to bromide with an excess of the purest bromine was followed by double crystallization of the bromide. The salt was dried in a current of pure nitrogen at gradually increasing temperatures and finally was fused in this atmosphere. Comparison with silver was followed by the determination of the silver bromide formed. Weights in air are corrected to vacuum.

TABLE I

THE ATOMIC WEIGHT OF POTASSIUM

Wt. of KBr	Wt. of Ag	Ratio KBr:Ag	At. wt. K	Wt. of AgBr	Ratio KBr:AgBr	At. wt. K

Hevesy and Logstrup[4] through ideal distillation have effected a slight concentration of the heavier isotope of potassium. The atomic weight of the residual material has been determined by Honigschmid and Goubeau to be 39.109 instead of the normal value found by them, 39.105.

Titanium.—Baxter and Butler[5] by the analysis of titanium tetrabromide have confirmed the result obtained by them through the analysis of the tetrachloride (see report for 1927). The tetrabromide was prepared by the action of bromine carried by helium on (1) titanium, and (2) a mixture of titanium dioxide and carbon. The product was fractionally distilled eighteen times in an exhausted glass apparatus, without exposure to air after the ninth distillation. In each distillation a head and a tail fraction were removed in sealed glass bulbs. Certain head and tail fractions obtained after the tenth distillation were analyzed by comparison with silver. Weights are corrected to vacuum. The numbers of the fractions increase with decreasing volatility.

		Average	.851788	47.900

Copper.—Ruer[6] finds that copper which has been ignited in hydrogen at 750° to constant weight takes up not more than 0.001% of air (oxygen). The experimental values for the atomic weights of copper found by Ruer and Bode (see report for 1924) are lowered by only 0.002 if corrections for air adsorbed by copper oxide and copper are made.

Cesium.—Richards and Françon[7] extracted cesium salt from pollucite (Maine, U. S. A.) and purified cesium alum by several recrystallizations. Sulfate was removed by means of barium chloride and the cesium precipitated as perchlorate, which was recrystallized several times. Cesium chloride was obtained by thermal decomposition of the perchlorate and twice recrystallized. Drying by fusion in nitrogen containing a small

	Average	1.55977	132.811

[a] Corrected for error in calculation.

Barium and Silver.—Honigschmid and Sachtleben[8] dried barium perchlorate at 260° and converted it to chloride with hydrogen chloride at 550". Both substances were weighed in exhausted vessels to avoid air adsorption. The barium chloride was then compared with silver in the usual way and the silver chloride was weighed in a few experiments.

recrystallized chloride was dehydrated at gradually increasing temperatures, first in a current of nitrogen and hydrogen chloride, then in pure hydrogen chloride, and ultimately was fused. Comparison with silver was followed by the determination of the silver chloride. Weights in air are corrected to vacuum.

TABLE V

THE ATOMIC WEIGHT OF CERIUM

Wt. of $CeCl_3$	Wt. of Ag	Ratio $CeCl_3:3Ag$	At. wt. Ce	Wt. of AgCl	Ratio $CeCl_3:3AgCl$	At. wt. Ce
3.43507	4.51018	0.76163	140.122	5.99272	0.57321	140.114
2.39181	3.14058	.76158	140.107	4.17266	.57321	140.116
3.05998	4.01767	.76163	140.123	5.33803	.57324	140.130
4.17583	5.48247	.76167	140.136	7.28454	.57325	140.131
1.34828	1.77015	.76168	140.138	2.35210	.57322	140.122
2.04994	2.69147	.76164	140.127	3.57628	.57320	140.113
2.38287	3.12846	.76168	140.138	4.15673	.57326	140.135
2.57235	3.37733	.76165	140.130	4.48755	.57322	140.120
2.16635	2.84432	.76164	140.127	3.77918	.57323	140.126
		.76164	140.127		.57323	140.123

This result is lower than that obtained by Brauner, 140.25, which has been in use for some time.

Erbium.—Boss and Hopkins[10] further fractionated material already limited in content to erbium and yttrium by (a) nitrate decomposition and (b) nitrite precipitation. Head fractions were converted to chloride and portions which had been dehydrated by gradual heating to the fusion point were weighed and compared with silver. Weights in air are corrected to vacuum.

TABLE VI

THE ATOMIC WEIGHT OF ERBIUM

Method of purif.	Wt. of $ErCl_3$	Wt. of Ag		Ratio $ErCl_3:3Ag$	At. wt. Er
a	2.25485	2.66270		0.84683	167.69
a	0.30165	0.35630		.84663	167.63
a	1.02242	1.20761		.84665	167.64
b	0.38998	0.46068		.84654	167.60
b	.38219	.45144		.84662	167.63
b	.17445	.20604		.84668	167.65
			Av.	.84666	167.64

The result is very slightly lower than the current one.

Rhenium.—W. and I. Noddack[11] have determined the atomic weight of rhenium by several methods, of which they consider the reduction of the disulfide the most reliable.

	2.9395	188.5
Av.	2.9423	188.7

Lead.—Lotze[12] on the basis of determinations of the uranium and thorium content and of the atomic weight of the lead contained in uranium minerals computes the atomic weight of actinium lead to be 207.

Uranium.—Honigschmid and Schilz[13] have continued the work of Honigschmid (see report for 1914) on uranium by the preparation and analysis of uranous chloride. Two preparations were employed: A, used in the earlier investigation, was obtained from commercial nitrate; B was obtained from Norwegian euxemite and samarskite. Both specimens were subjected to the same elaborate purification and ultimately converted to oxide. To prepare the uranous chloride the oxide was mixed with pure sugar charcoal and heated in a current of chlorine in a quartz sublimation apparatus. The first product was then sublimed into a quartz weighing tube and fused in an atmosphere containing varying proportions of nitrogen and chlorine as follows.

In Series I the chloride was resublimed and fused in pure nitrogen. In Series II resublimation in pure chlorine was followed by fusion in pure nitrogen or very dilute chlorine and the salt was solidified in pure nitrogen. In Series III, after resublimation in a mixture of nitrogen and chlorine, the chloride was twice melted and cooled in pure nitrogen.

To analyze the product, the solution, after acidification with nitric acid and oxidation with hydrogen peroxide, was compared with silver

and the silver chloride was collected and weighed. Weights in air are corrected to vacuum.

The final average, 238.14, is slightly lower than the earlier one.

Ruer and Kuschman[14] have investigated the adsorption of air on inorganic solids. One of the important findings is that fused powdered potassium chloride and precipitated dried lead chloride adsorb less than 0.5 mg. of air per 100 g. of solid.

Hogness and Kvalnes[15] confirm Aston's suspicion of the existence of an isotope of neon of mass 21 and estimate the proportions of the three isotopes as Ne^{20}, 88%, Ne^{21}, 2%, Ne^{22}, 10%.

Aston[16] has discovered additional isotopes of zinc and germanium which are listed below in the order of abundance, together with those already known.

Zn	64,	66,	68,	67,	65,	70,	69	
Ge	74,	72,	70,	73,	75,	76,	71,	77

In the table of atomic weights on p. **653** changes from the 1928 table are made in the cases of hydrogen, phosphorus, sulfur, barium, cerium, erbium, potassium, radium, thorium and uranium. The value for hydrogen depends largely upon the evidence of the mass spectrograph. In the cases of phosphorus and sulfur, the uncertainty of existing data makes the third decimal place of dubious value. The value for potassium is given to two decimal places only, since the cause of the discrepancy between that found by Richards, Staehler and Mueller, 39.095, and the recent one by Hönigschmid and Goubeau, 39.105, is not evident. The atomic weight of

ACTIVE NITROGEN. II. THE INFLUENCE OF SURFACE ON THE AFTERGLOWS IN NITROGEN AND OXYGEN[1,2]

BY BERNARD LEWIS[3]

RECEIVED JULY 21, 1928 PUBLISHED MARCH 6, 1929

It has been contended by some workers[4] that pure nitrogen subjected to the action of an electric discharge shows no afterglow but that its restoration is effected by the addition of a trace of oxygen. Other investigators[6] have shown that pure nitrogen undoubtedly could give rise to an afterglow, which, however, is intensified by the addition of oxygen or certain other impurities. More recently Bonhoeffer and Kaminsky[6] have concluded that pure nitrogen is glowless but the introduction of certain optimum amounts of such impurities as oxygen, hydrogen sulfide and methane into the discharge mixture produces a glow of maximum intensity.

The action of the impurities has been thought to be due to the formation of a layer of gas on the surface of the vessel which inhibits the catalytic combination of nitrogen atoms thereon. The atoms must now combine in the gas phase with consequent emission of the a-bands. It was the purpose early in these experiments to ascertain whether the impurity, oxygen, entered into the mechanism of afterglow production. The possibility could not be entirely excluded that oxygen was necessary in some physical action to induce the afterglow in the gas phase, notwithstanding results by Bonhoeffer and Kaminsky, namely, that different impurities are without effect on the character of the afterglow.

Initial Experiments.[7]—Accordingly, pure nitrogen was introduced into a liter bulb[8] into the center of which pure oxygen could be admitted more or less uniformly in all directions through an inner tube perforated at one end. In impure nitrogen the active species which eventually give rise to the glow remain for some time after the cessation of the discharge. If similar circumstances exist in pure nitrogen (assuming it is glowless) and provided the presence merely of ordinary oxygen is required to create the afterglow, then the glow may be expected to appear if oxygen is introduced immediately after discontinuing the discharge.

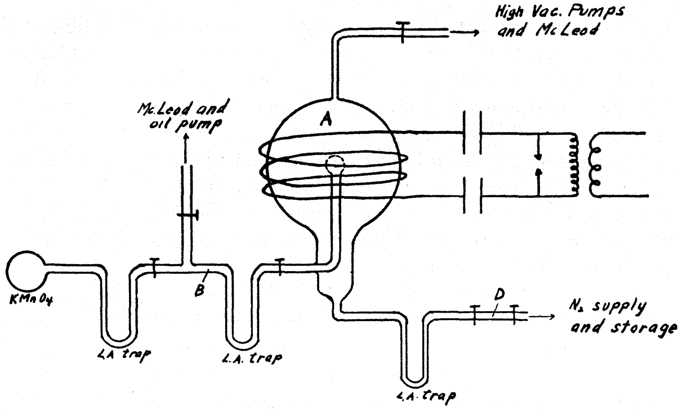

Fig. 1.

The apparatus given in Fig. 1 requires no explanation. Pure oxygen was prepared from potassium permanganate and pure nitrogen by two methods: (1) from bromine water and ammonia,[9] and (2) by heating sodium trinitride (NaN_3). Water vapor was removed from the gases in liquid-air traps. In the first method the nitrogen, prepared in a special generator, was also stored over phosphorus pentoxide to remove ammonia. The electrodeless discharge was employed in all experiments, thus eliminating a possible contaminating influence of metallic electrodes. A static method was used.

For some time it was impossible to produce absolutely glowless nitrogen, even though utmost precaution had been taken to ensure the complete absence of oxygen and other impurities. Only after thoroughly baking out the bulb at high temperature and under high vacuum as well as the occasional passage of the discharge was a glowless pure nitrogen obtained[10] (nitrogen pressure about 0.1 mm. of mercury). Upon the

[8] The bulb and all connecting tubes, made of pyrex, were carefully cleaned with hot chromic acid and subsequently heated almost to melting before assembling the apparatus.

[9] Waran, *Phil. Mag.*, 42, 246 **(1921);** Kenty and Turner, *Nature,* **120, 332** (1927).

[10] With this treatment the glow gradually disappeared. It must be remarked that in using a static system in a glass vessel, it is not easy to remove the glow entirely by heating alone. It was noted on several occasions that whereas no glow was evident after the discharge was discontinued, during the passage of the latter the characteristic nitrogen glow could be observed, though weak, to extend about 1.5 cm. into the wide tubing directly below the bulb.

introduction of pure, dry oxygen (1%, the pressure was adjusted in dosing tube B) in the manner described above, ***no glow was produced.*** This was repeated several times using nitrogen from both sources with similar results. Furthermore, after the oxygen had been admitted and the mixture subjected to the discharge, little or no glow was discernible.[11] This seemed very strange indeed in view of the previous work of Strutt, Bonhoeffer and Kaminsky and others. It is evident that neither ordinary oxygen molecules nor "active" oxygen takes part in the excitation process which produces the luminosity. This conclusion is not at variance with Bonhoeffer and Kaminsky's observation mentioned above regarding the effect of impurities on the afterglow spectrum.

Further Experiments.—The electrical arrangement was modified somewhat in order to increase the energy in the coil wrapped around the bulb, so that the discharge could be passed at higher gas pressures. A spark gap made with heavy zinc electrodes 4 cm. in diameter was connected in series with two condensers (each of 10 double-thickness glass plates 18 X 20 inches, immersed in transformer oil) which in turn were in series with the coil. The latter (4 turns) and leads (which were made as short as possible) consisted of 0.25-inch copper rod. The secondary of a transformer was connected across the spark gap, which was 2.5 to 3 cm. wide. The secondary voltage was about 50,000 volts and the primary current 21.5 amperes. A glass tube 20 cm. long and about 7 cm. in diameter was substituted for the bulb. Two liquid-air traps protected the tube from stopcock grease. Nitrogen could be obtained at will from sodium nitride or from a nitrogen cylinder (containing 0.3% of oxygen by analysis) and the oxygen was obtained from potassium pennanganate. All gases entered the discharge tube by way of the dosing Tube B in which water vapor, etc., was removed with liquid air. In all of the experiments to be described the discharge tube was initially baked out at a temperature of 350–470° from six to eighteen hours under high vacuum. All connecting tubes were heated frequently almost to melting. Unless otherwise stated, (1) the gas admitted was previously deprived of water vapor by long standing (six to twenty-four hours) at liquid-air temperature and (2) both traps in direct communication with the discharge tube were immersed in liquid air.

During the progress of the following work a paper appeared by G. Herzberg[12] on the influence of the walls on the nitrogen and oxygen afterglows. The results recorded here, in so far as the two works overlap, substantiate Herzberg's observations. The method employed to restore the afterglow was unlike that used by him. Some interesting new phenomena in temperature and pressure effects have also been found.

A.—Tank nitrogen was admitted at a pressure of 0.704 mm. The glow was weak and lasted for fourteen seconds.[13] Normally in an unbaked vessel and with water removed from the entering gas, the afterglow lasted for about 130 sec. and with greater intensity. With intermittent discharging the duration and intensity of the glow gradually diminished to < 0.5 sec. The vessel now being evacuated to 0.31 mm., no glow was visible. Upon removing the liquid air from both traps the glow reappeared,

---

[11] It will be shown in a subsequent contribution (Part III) that a mixture containing 1% of oxygen at a pressure of about 0.1 mm. gives rise to an intense afterglow of long duration under ordinary circumstances.

[12] G. Herzberg, *Z. Physik,* 46, 478 (1928).

[13] Observation of the enhanced afterglow at the liquid-air trap with a spectroscope indicated the presence of a-bands.

lasting for eighteen sec. (Under ordinary conditions and at this pressure the glow would last for 190 sec.) By the same procedure (discharging[14] with liquid air on the traps) the glow could again be eliminated, a pressure decrease < 0.01 mm. being recorded on the McLeod gage. Thus it is evident that some gas is being condensed out.

B.—Tank nitrogen was admitted at a pressure of 0.318 mm. The glow lasted for twelve sec. Fresh tank nitrogen was admitted at a pressure of 0.349 mm., the glow lasting for ten seconds. This was increased to twenty sec. when the liquid air was removed from both traps. This is to be expected, since in a system containing a given amount of active gas, the glow is enhanced at liquid-air temperature resulting in a more rapid removal of the glow-producing species. Ordinary tank nitrogen (moist) was now admitted, with the following results:

Pressure (mm.)	0.357	0.290	0.129
Duration (sec.)	90	130	160

The vessel was evacuated and fresh moist tank nitrogen admitted:

Pressure (mm.)	1.3	0.328	0.205
Duration (sec.)	72	115	140–150

Liquid air was replaced on both traps and this gas (0.205 mm.) was subjected to the discharge, the glow becoming weaker and of shorter duration until finally it disappeared entirely. The pressure had decreased to 0.16 mm.[15] In this glowless condition fresh, dry tank nitrogen was admitted at about 3 mm. and the vessel evacuated to a pressure 0.22 mm. *Practically no afterglow was observed.* If any was present it was exceedingly faint and lasted less than a fourth of a second (possibly due to weak phosphorescence of the glass, which is sometimes observed). Repetition of the above on other occasions failed to show any glow whatsoever. When the liquid air was removed the glow reappeared with its usual intensity and endured for 117 sec. These experiments indicate conclusively that even in the presence of sufficient oxygen to produce a very marked glow under ordinary conditions, the afterglow can be eliminated if the vessel is treated as outlined above.

[14] Herzberg also found that in order to eliminate the afterglow in a glass vessel, completely, the discharge had to be passed, for only in this way can the last traces of water vapor or other occluded gas be removed from the walls.

[15] It is not understood why such a decrease in pressure should have occurred unless it be due to the usual "clean-up" effect. In the initial experiments recorded above, this pressure decrease was so marked at times, after long discharging, that the discharge ceased to pass. Thus it was observed that the pressure sometimes decreased from 0.1 to 0.001 mm. The gas could be recovered by removing the liquid air and heating the bulb. Some investigation of this was carried out but the results are not sufficient to warrant mention here. Herzberg also noted this extraordinary "self-evacuation."

C. I.—Experiment B was repeated but the traps were cooled to a temperature of only —85° (carbon dioxide and ether). Dry tank nitrogen showed a weak glow lasting for nine sec. which disappeared as before after some discharging. The condensate therefore cannot be ozone, nitric oxide or nitrous oxide. Other possibilities are water, nitrogen peroxide, nitric acid, and nitrogen pentoxide. We are interested here in the substance which, when removed, causes the glow to disappear. Since (1) the glow can be eliminated even in the presence of oxygen, (2) the same effect takes place in pure nitrogen (see Section D) and (3) the glow, it will be shown, can be restored by addition of small amounts of water vapor to pure or tank nitrogen, it is probable that the effective substance is water vapor. The Last traces of water which adhere tenaciously to the glass walls are liberated by the discharge and condensed. It is quite possible that nitrogen peroxide also is condensed out from tank nitrogen as Majewska and Bernhardt believe.[16]

C. **II.** Reversed Pressure Effect with **Tank** Nitrogen.—Fresh dry tank nitrogen was admitted to the vessel in the condition as left in C I.

Pressure (mm.)	0.390	0.267
Duration (sec.)	1	0.6

The carbon dioxide–ether baths were removed and replaced by liquid air after the trap had warmed up. The glow which appeared (seven sec.) was removed completely by discharging. Fresh, dry tank nitrogen was admitted again.

Pressure (mm.)	>1.0	0.40	0.275
Duration (sec.)	7	1.4	<0.25

The vessel was evacuated and fresh, dry tank nitrogen admitted again. At a pressure of 0.148 mm. there was no glow. This procedure was repeated; at a pressure of 0.445 mm. the glow lasted for one sec., while at 0.210 mm. there was no glow.

These results are in agreement with those in Section B as long as the pressure of nitrogen is low (about 0.20 mm). However, when the pressure is increased, an afterglow undoubtedly appears even though of short duration. This may be explained as follows. At higher pressures some of the clean surface is poisoned by adsorption of the gases (both oxygen and nitrogen). The combination of nitrogen atoms on the walls being somewhat hindered, more combinations can occur in the gas phase and give rise to the afterglow. At lower pressures the decreased adsorption exposes more free surface for atomic combination. The same effect is observed when pure nitrogen is used (see Section D).

The interesting fact established is, that *with a "clean" surface a pressure effect is observed which is reversed from that observed with an "unclean"*

---

[16] Majewska and Bernhardt, Z. *Physik,* 48, 140 (1928).

surface. That is to say, with the latter the afterglow increases in duration and intensity with reduction in pressure (see Section B and also Part III), whereas with the former the duration and intensity decrease with pressure.

D. Reversed Pressure Effect with Pure Nitrogen—Pure dry nitrogen (from sodium nitride) was admitted.

Pressure (mm.)	1.7	0.260	0.158
Duration (sec.)	12	5	3.5

Thus the reversed pressure effect is also evident with pure nitrogen. In this case also the glow disappeared completely by passing the discharge. As mentioned in Section C this is probably due to the removal of the last traces of adsorbed water. However, even under these circumstances, the admittance of a fresh supply of pure nitrogen at higher pressures causes a short glow to appear.

Pressure (mm.)	1.43	0.152
Duration (sec.)	4	<0.25

E. Restoration of the Afterglow by Water Vapor.—These experiments were designed to ascertain whether the introduction of water vapor sufficient to cover the surface could restore the afterglow in pure nitrogen. A small glass tube containing distilled water whose dissolved oxygen was removed by boiling, was connected through a stopcock to the discharge vessel. The water could be maintained at any desired temperature and the vapor pressure above ice calculated from the equation of Nernst[17]

$$\log_{,,} p_{\mathrm{mm.}} = -\frac{2611}{T} + 1.75 \log T - 0.00210\, T + 6.5343$$

which has been substantiated experimentally down to 100°K. by Weber.[18] Nitrogen at a pressure of 0.26 mm. gave only a faint glow lasting for three sec. in the thoroughly baked vessel (liquid air removed from traps). The vessel and water tube were now thoroughly evacuated, the latter being maintained at liquid–air temperature. The liquid air was replaced by a carbon dioxide–alcohol mixture at −39° and water vapor at a pressure 0.11 mm. was admitted to the discharge vessel. The excess water vapor in the gas phase was condensed out in a liquid-air trap and then pure dry nitrogen admitted. A bright afterglow lasting for 75–80 sec. was observed at 0.190 mm. pressure.[19] The whole procedure was repeated, this time admitting water vapor at a pressure $1.2 \mathrm{X} 10^{-3}$ mm. (ice at −73") with the following results:

Pressure (mm.)	1.2	0.54	0.158
Duration (sec.)	37	70	93–100

---

[17] Nernst, *Verh. deut. Phys. Ges., 11,* 313 (1907).

[18] Weber, *Comm. Phys. Lab. Univ. Leyden, 14,* 150A (1915).

[19] Herzberg was able to restore the glow by the addition of small amounts of hydrogen.

It should be noted in the last table that the normal pressure effect is again in evidence with a covered surface.

By discharging with liquid air on one trap the glow was reduced from one hundred sec. to nineteen sec. This was not carried on long enough to diminish the glow further. There was no measurable pressure decrease. Removal of the liquid air caused the restoration of the glow to 140 sec. Thus the afterglow is present or not depending upon the presence of water vapor on the walls. It was found that too much water vapor in the gas phase was prejudicial to the afterglow, a fact also observed by E. P. Lewis.[20]

F.—These experiments will show that the effects in Section E are reproducible with tank nitrogen and that the presence of **0.3%** of oxygen has no effect in prolonging the glow over that observed in pure nitrogen. After the same treatment as in Section E, water vapor at 2.2×10^{-3} mm. (ice at $-69°$) was admitted.

1. Dry pure nitrogen	Pressure (mm.)	1.23	0.27
	Duration (sec.)	36	90

Vessel evacuated.

2. Dry tank nitrogen	Pressure (mm.)	0.88	0.24
	Duration (sec.)	63	100

The increase of ninety to one hundred sec. is to be anticipated on reducing the pressure from 0.27 to 0.24 mm. Note the normal pressure effect in both cases.

G. Reversed Temperature Effect.—It is well known that when an untreated vessel containing nitrogen which gives rise to a long afterglow at room temperatures is heated, the afterglow is considerably reduced both in intensity and duration. For example, in one experiment it was found that the afterglow was diminished from 160 to two sec. at a pressure of nitrogen of 0.155 mm. when the vessel was heated from room temperature to approximately 250° (Bunsen burner used). However, in the course of this work it was found that in vessels which were treated as outlined in this paper, a different phenomenon prevails, namely, that not only is the afterglow not diminished by heating but the duration is increased and the intensity slightly enhanced. Many and varied experiments were carried out both with pure and tank nitrogen; but one example will be given. Pure nitrogen at 0.152 mm. pressure in a baked-out vessel gave rise to a glow lasting for one-half sec. When the vessel was heated with a free flame, it lasted for two and one-half sec. Tank nitrogen at 0.20 mm. pressure showed a glow which lasted for three sec. at room temperature and five and one-fifth sec. when heated. After the vessel had cooled, the glow lasted for two and four-fifth sec. and on heating again for three

[20] E. P. Lewis, *Ann. Physik*, 2, 459 (1900).

and four-fifth sec. The effect is very noticeable if the glow be eliminated completely by discharging with the liquid-air traps in operation. Were the glow can be restored to last almost one second on heating the vessel.

This reverse temperature effect can easily be explained by assuming that when the discharge is passed in a vessel whose walls are "clean," a layer of nitrogen atoms is adsorbed on the surface. Other atoms colliding with the wall will nearly always meet an adsorbed atom and combine to form a molecule. However, when heat is applied much more of the surface is free and atoms will not always "find" an adsorbed atom on colliding with the wall. This leads to many more favorable collisions in the gas phase and thus we observe an enhanced afterglow.

Finally, two sets of data will be given to show simultaneously both the reversed and normal effects of pressure and temperature.

1. Tank nitrogen. Baked vessel.

Pressure (mm.)	**1.5**	**0.20**
Duration (sec.)	**17**	**3**
After heating, duration (sec.)		**5.2**

2. Tank nitrogen after admittance of 2×10^{-3} mm. of water vapor.

After heating, duration (sec.)			**2 3**

H. The Effect of a Paraffied Surface.—A bulb of 250-cc. capacity and about the same diameter as the discharge tube (a new tube was used which had never been baked out) was coated on the inside with paraffin and sealed to the latter tube. The afterglow was observed through a small opening made by warming the paraffin locally. It was found that with a pressure of tank nitrogen of 0.29 mm. the afterglow in the discharge vessel and the paraffined bulb was of the same intensity and duration (275 sec.). Apparently, therefore, not only does the paraffin effectively poison the surface but it does not itself act as a catalyzer for atomic combination.

Experiments with Oxygen

It was shown above that the nitrogen afterglow is made observable only after the surface of the vessel has been effectively poisoned by the adsorption of a layer of gas.

The results of the following experiments show that the afterglow in oxygen likewise is dependent on the surface condition. This may be expected if the view expressed by Thompson[21] is correct that the after-

---

[21] J. J. Thompson, *Phil.* **Mag., 32, 321 (1891); E. P. Lewis, Ann.** *Physik,* 2, **549 (1900);** **R.** J. **Strutt (Lord Rayleigh),** *Proc. Phys. Soc.,* 23, 66 **(1910). It is not certain that the afterglow observed in pure oxygen is the same as the continuous spectrum in air observed by Lord Rayleigh, which he attributed to the oxidation of NO by O_3 (formed in the discharge) to NO_2.** *G.* **Herzberg,** *Z. Physik,* **46,878 (1928);** J. **Kaplan,** *Proc. Nat.* **Acad.** *Sci.,* 14, **258 (1928);** B. **Lewis,** *Nature,* 121, **938 (1928).**

glow observed in pure oxygen is due to the emission accompanying atomic recombination, which is strengthened by the fact that the observed spectrum is continuous.[21] The presence of atoms has been demonstrated by Crew and Hulbert[22] and Copeland.[23] The duration of the afterglow in oxygen is considerably shorter than in nitrogen. This may be attributed to the possibly greater facility with which oxygen atoms combine.[24]

The experimental procedure was the same as outlined above. Pressures were read on a McLeod gage connected to the dosing tube. Observations were made in a completely darkened room, a small spectroscope being used to observe the character of the afterglow. Pure oxygen was prepared from potassium permanganate.

Results

In a discharge tube which had been thoroughly cleaned (hot chromic acid followed by distilled water and heating the glass almost to melting), pure oxygen showed an afterglow whose spectrum was continuous in character and whose duration changed with the pressure as follows:

Pressure (mm.)	0.925	0.475	0.285	0.19	0.15	0.115[25]
Duration (sec.)	8	17.2	25.2	32	36	30.4

Upon discontinuing the discharge, the intensity of the afterglow decreased gradually but after a time it suddenly came to an abrupt end. This is quite unlike the prolonged gradual decay of the nitrogen afterglow. Herzberg[12] recorded a similar observation.

The discharge tube was baked out in a furnace at a temperature of 400–440" for eight hours under high vacuum. Both traps were then immersed in liquid air and pure, thoroughly dried oxygen was admitted. At various pressures between 1 mm. and 0.216 mm. not the slightest indication of an afterglow was visible. A glow was still absent after the removal of the liquid air. This was the first experiment with oxygen. In later work this extreme success merely by baking the vessel was never completely realized.

In another representative experiment in a baked-out vessel a faint afterglow was observed lasting about half a second at a pressure of oxygen of about 1.8 mm. (The first two short discharges showed no glow.) At a pressure of 0.24 mm. the duration was two and one-half seconds. When the liquid-air traps were removed the duration was three and one-half seconds.[26]

[23] Copeland, *ibid.,* **31,** 1113A (1928); Bichowsky and Copeland, *Nature,* 120, 729 (1927).

[24] Bernard Lewis, THIS JOURNAL, **51,** 665 (1929).

[25] This pressure is below the duration maximum of the oxygen afterglow at about 0.16 mm. (ref. 24).

[26] This may have been due in part to the adsorption of ozone condensed by liquid air.

With the liquid air replaced, only a little discharging was required to cause the glow to disappear entirely. Ordinarily in an untreated vessel the oxygen afterglow is destroyed by heat but when heat is applied to a treated vessel containing glowless oxygen, the glow appears. In the present instance it lasted about a quarter of a second. After cooling, it disappeared only to reappear again on heating. This ***reversed temperature effect*** in a vessel with "clean" walls was also observed in the nitrogen afterglow. The explanation advanced for the latter also applies here.

A fresh supply of pure dry oxygen was admitted to the discharge tube which previously contained oxygen whose glow had been removed by discharging. At a pressure of 0.66 mm. there was practically no glow (less than a tenth of a second) and at 0.26 mm. no glow at all. It is quite evident that an afterglow cannot be obtained with pure oxygen in a vessel whose walls are "clean." A "reversed pressure effect" cannot definitely be said to exist due to the exceedingly faint and short afterglow.

An attempt was made to see whether the glow could be restored by the introduction of water vapor sufficient to cover the surface. The general procedure was the same as given above. It was shown first that pure dry oxygen produced only a very faint glow in the baked-out vessel. Water vapor at a pressure 8×10^{-3} mm. (ice at −60°) followed by pure oxygen was then admitted. A bright afterglow was produced[19] whose duration is given in the following table.

Pressure (mm.)	0.66	0.314	0.226	0.111[25]
Duration (sec.)	3	11.4	15	13

Too much water in the gas phase is prejudicial to the afterglow. Thus at a pressure of oxygen of 0.25 mm. and of water vapor of 0.135 mm. (ice at −37°) the glow lasted less than one second; after condensing most of the water vapor in liquid air the duration was 7 seconds.

The results with air in *a* baked-out vessel indicated also that the afterglow is considerably weakened in intensity and duration. It will be shown elsewhere[21,24,27] that the afterglow in air undergoes several changes as the pressure is decreased. In a vessel which was baked out but which was not subjected to the discharge treatment, these changes were still observed but the glows were exceedingly weak. At the minimum separating the oxygen afterglow from the nitrogen afterglow, the glow disappeared entirely.

Finally the effect of a paraffin surface was studied. It was found that the afterglow behaved similarly in the paraffined vessel as in the discharge vessel. The durations and intensities were identical and the same abrupt termination of the afterglow was observed in each.

---

[27] Constantinides, *Phys. Rev.*, 30, 95 (1927), and Bernard Lewis, *Nature*, 121, 938 (1928).

When liquid air was placed on one of the traps the afterglow intensity was not enhanced near the surface of the liquid air, as is the case with the nitrogen afterglow. Instead, it seemed as if it was reduced in intensity or even extinguished. One could not be certain about this last point since the tube was always slightly frosted over. However, it may be noted that Herzberg (ref. 21 p. 892) reports that when the discharge tube is cooled with liquid air no glow is observed.

Summary and Conclusions

The experiments described above show that:

1. Ordinary oxygen or "active" oxygen takes no part in the excitation process which gives rise to the nitrogen afterglow.

2. Pure nitrogen prepared from sodium nitride and nitrogen containing *0.3%* of oxygen show intense afterglows of long duration in an ordinary glass vessel. Pure oxygen shows a characteristic green afterglow (continuous spectrum) in a similar vessel.

3. Pure nitrogen or nitrogen containing *0.3%* of oxygen at about *0.2* mm. pressure can be made to show no glow if the vessel is thoroughly baked out and subjected to the action of the electric discharge. Above this pressure a short glow appears. The afterglow in oxygen disappears in a similarly treated vessel.

4. Admittance of water vapor (*ca.* 10^{-3} mm.) enough to cover the surface of the vessel causes a restoration of the glow to its usual intensity and duration both in pure nitrogen and nitrogen containing 0.3% of oxygen. The afterglow in oxygen may similarly be restored by water vapor. Too much water vapor is prejudicial to the nitrogen and oxygen afterglows.

5. *The condition of the surface of the containing vessel is a determining factor which governs the visibility of the afterglow in nitrogen or oxygen.*

6. Two new phenomena are described, namely, *reversed pressure effect* and *reversed temperature effect.* Whereas in an untreated vessel the duration and intensity of the nitrogen afterglow increase (within the pressure limits employed, *ca.* 1.8 mm. to 0.1 mm.) as the pressure is reduced, in a treated vessel a decrease takes place. Similarly, heat markedly decreases the intensity and duration of the afterglow in an untreated vessel, whereas in a treated vessel the duration increases and the intensity is slightly enhanced with heating. These phenomena are explained. A reversed temperature effect is observed in the oxygen afterglow in a treated vessel, the restored glow being weak and of short duration.

7. Paraffin effectively poisons the surface and does not itself catalyze the removal of the active constituents. The intensity, duration and type of decay of the nitrogen and oxygen afterglows are the same in an ordinary as in a paraffin-coated vessel.

8. The decay of the oxygen afterglow is unlike that of the nitrogen afterglow, the former coming to an abrupt termination.

9. Unlike the nitrogen afterglow the oxygen afterglow is not enhanced at the temperature of liquid air. As far as can be observed the oxygen glow is quenched.

ACTIVE NITROGEN. III. THE MUTUAL EFFECT OF NITROGEN AND OXYGEN ON THEIR RESPECTIVE AFTERGLOWS[1,2]

BY BERNARD LEWIS[3]

RECEIVED JULY 21, 1928 PUBLISHED MARCH 6, 1929

Introduction

In the course of an investigation[2b] dealing with the influence of surface on the nitrogen afterglow and the influence of the impurity oxygen in this phenomenon, it was observed that as the pressure of *a* certain mixture of nitrogen and oxygen was decreased, changes occurred not only in the duration and intensity but also in the character of the afterglow. Studies were therefore made with different mixtures of nitrogen and oxygen at various pressures. Among other things the results to be presented will enable one to establish readily any experimental condition desired (within the limits of pressure employed) involving the production of the nitrogen or oxygen afterglow.

It is well known that when oxygen is subjected to the action of an electric discharge, a yellowish-green glow is observed whose spectrum is continuous in character from the reds to the blues.[2c,4] Nitrogen, on the other hand, gives rise to the characteristic orange-yellow afterglow (α-bands).[5] While the nitrogen afterglow lasted longer than four minutes under suitable conditions in these experiments, the maximum duration of afterglow observed in pure oxygen was about thirty-six seconds.

When a mixture of the gases is subjected to the discharge, the type of afterglow one observes is dependent upon the total pressure and the per-

centage of the components. For example, consider a gas mixture containing 40% of oxygen and 60% of nitrogen between the limits of pressure employed (ca. 1.8 mm. to 0.01 mm.). As the pressure is decreased the color of the afterglow undergoes the following metamorphoses: yellowish-green, greenish-yellow, blue (several shades), lilac-blue, gradual disappearance of the blue and appearance of the orange-yellow nitrogen afterglow.[6] Indeed, all other conditions being equal, at the same certain total pressure a gas containing 20% of oxygen will exhibit the nitrogen afterglow, whereas a mixture containing 35% of oxygen will show only the oxygen afterglow. It is therefore quite comprehensible that Hagenbach and Frey[7] should have observed the N_2 afterglow in air while Strutt observed only the oxygen afterglow. The apparent contradiction is accounted for by the fact that the observations were made at different pressures; above 0.75 mm. the greenish-yellow glow is in evidence while below 0.3 mm. the orange-yellow glow is prominent. The curves which follow will make this clear.

Apparatus, Material and Method

The electrodeless discharge was employed in order to avoid the contaminating influence of metallic electrodes. The electrical arrangement was the same as described in Part II of this series.2 Conditions as to current, temperature, etc., were maintained as constant as possible. The discharge tube, which was about 20 cm. long and 7 cm. in diameter, was connected in the usual way to a mercury-vapor, high-vacuum pump system and also to a Hyvac oil pump through a small dosing tube. The latter was connected to a bulb and a mercury manometer in which the desired mixture of gases was prepared. Pure oxygen prepared from potassium permanganate and tank nitrogen (containing 0.3% of oxygen by analysis) were used. Each gas was maintained at liquid-air temperature for an hour before making up the mixture. A small amount of the mixed gases was maintained at liquid-air temperature in a trap in the dosing tube before its admittance to the discharge chamber. The lower part of the trap was kept in liquid air throughout a run in order to avoid any possible diffusion of mercury vapor. At each pressure a discharge lasting half a second was passed and several readings of the duration of the afterglow were taken after the cessation of the discharge. Pressures were read on a McLeod gage. Simultaneously, observations were made on the character of the afterglow with a small spectroscope. Readings were made in a completely darkened room. No attempt was made to estimate intensities except in a qualitative manner. The intensity curve follows only approximately the duration curve.

Results

Within the pressure limits employed, a maximum may be observed in the oxygen afterglow down to about 12% of oxygen. With decreasing percentages of oxygen (beginning with pure oxygen) the maximum flattens out and finally diappears and with it also the oxygen afterglow. From 100 to 60% of oxygen only the oxygen afterglow is observed even down

---

[6] In general the same sequence of colors was observed by Constantinides, Phys. *Rev.*, **30**, **95** (1927), as the partial pressure of oxygen was changed. Herzberg (ref. 4) records similar changes.

[7] Hagenbach and Frey, *Physik.* Z., 18, 544 (1917); see also Herzberg, ref. 4.

to very low pressures (*ca.* 0.05 mm.). However, in a mixture containing less than 60% of oxygen, in addition to the above maximum, a sharp minimum is observed (blue afterglow) at a somewhat lower pressure, at which point the intensity and duration become quite small. In the region of this minimum, usually just preceding it, the lilac color begins to appear, which is an indication that the nitrogen a-bands have just become visible. Here the spectroscope shows also the blue continuous background.[8] As the pressure is reduced further, the α-bands become more prominent, the blue portion disappearing, until finally only the former are visible. The nitrogen afterglow rises to a duration maximum at very low pressures (0.035–0.04 mm.).

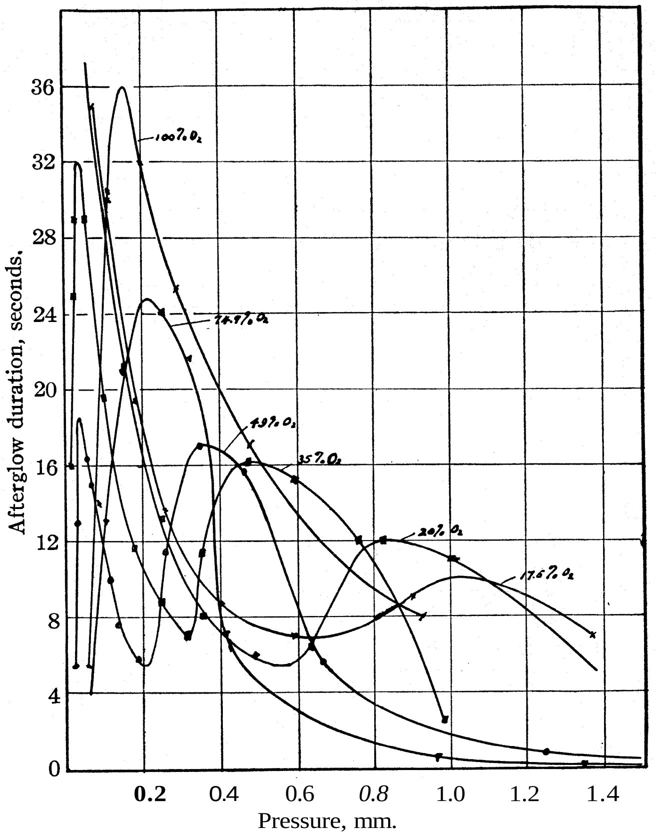

Fig. 1a.

The maximum in the oxygen afterglow, the minimum following it

---

[8] A curious phenomenon was observed in the region of this minimum [*Nature*, 122, 241 (1928)], namely, that entirely different afterglows can be obtained in the same mixture and at the same pressure merely by varying the length of time of discharging.

and the point at which the a-bands are just visible are displaced toward lower total pressures as the percentage of oxygen in the mixture is increased.

The maximum in the nitrogen afterglow duration occurs (within experimental error)[9] at about the same pressure. A few characteristic curves are given in Figs. 1a and 1b to illustrate these points.

If one multiplies the percentage of oxygen by the total gas pressure at the maxima, the minima and the points at which the α-bands appear, constants are obtained. This means that these points always occur at the same partial pressure of oxygen. These oxygen pressures are: maxima, 0.161 mm.; minima, 0.111 mm.; a-bands, 0.123 mm. The following equations, which represent rectangular hyperbolas, are satisfied: $xy = a = 0.161$; $xy = b = 0.111$; $xy = c = 0.123$, in which x is the total gas pressure and y the percentage of oxygen. In Fig. 2 a rectangular hyperbola is

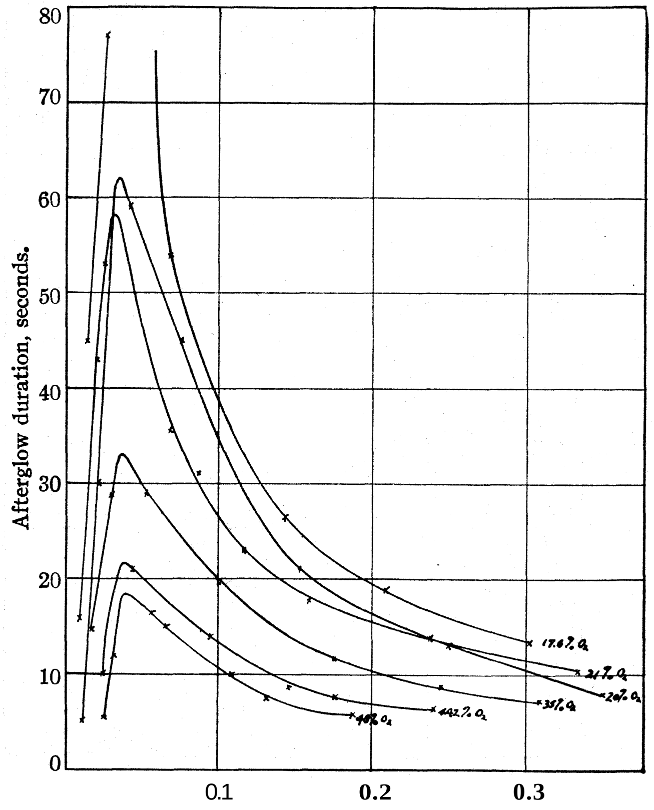

Fig. 1b.

---

[9] Phosphorescence of the glass at lower pressure sometimes prevents an accurate determination of the duration.

plotted for each of these three equations and the experimental points for the maxima, minima and a-bands are laid out on them. The coincidence is **very** good. Another way of emphasizing this is to plot $1/p$ against percentage of oxygen, from which good straight lines are obtained. It is unnecessary, however, to show this. It will be observed (Fig. 2) that for small percentages of oxygen there is a greater divergence between the pressures at which the maxima and minima occur. This means that the maxima should flatten out and become less prominent with decreasing percentage of oxygen. Fig. 1a shows this well. Actually the maxima become so flat as to disappear entirely. Since the oxygen concentration for any set of points is constant, the observed shifts must be due to active nitrogen.

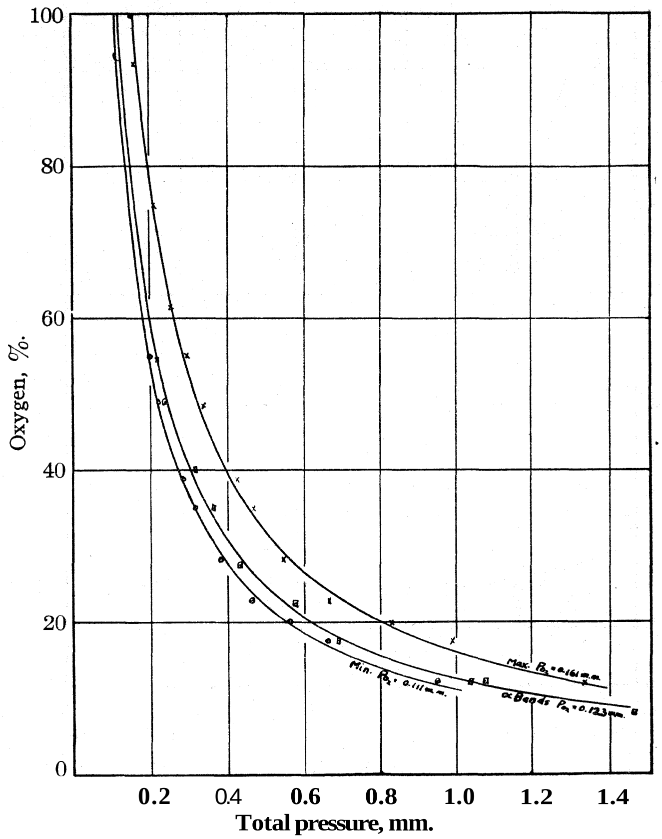

Fig. 2.

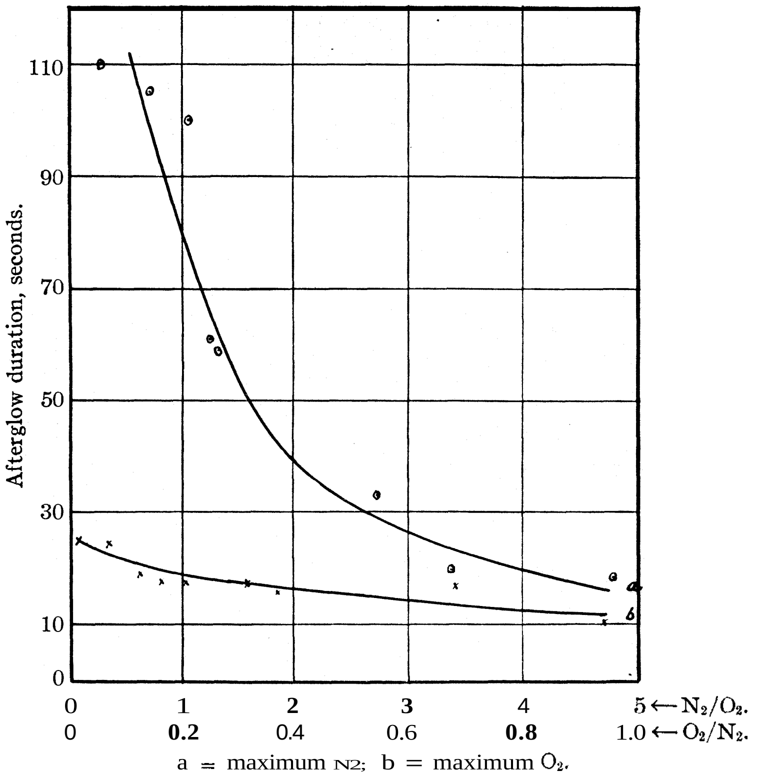
In Fig. 3a the duration of the nitrogen afterglow at the maxima is plotted against the ratio of the oxygen concentration to the nitrogen concentration and in 3b the duration of the oxygen afterglow at the maxima is plotted against the ratio of the nitrogen concentration to the oxygen concentration. These curves are only approximately correct since the surface of the discharge chamber was changed after each run by heating and evacuating. It is seen that whereas the influence of oxygen on the nitrogen afterglow is very marked,[10] that of nitrogen on the oxygen afterglow is certainly very slight (the ratio in the latter varied 70-fold). In agreement with this Herzberg* finds that nitrogen led into a stream of glowing oxygen is without



a = maximum N_2; b = maximum O_2.

Fig. 3 (a and b).

effect. It may be concluded that whereas normal oxygen molecules have a marked quenching action on the nitrogen afterglow, normal nitrogen molecules do not affect the oxygen afterglow. Since in these experiments both gases were activated together, the slight quenching action of the oxygen afterglow is probably due to the action of the nitrogen afterglow carriers or active nitrogen molecules or both. It is evident, therefore, that the effect of active nitrogen in quenching the oxygen afterglow is far

---

[10] Compare Constantinides' (ref. 6) and Strutt's (ref. 9) experiments in which a very rapid quenching is observed on passing oxygen into a stream of glowing nitrogen. The amount of quenching is practically proportional to the oxygen concentration.

less than the effect of active oxygen in quenching the nitrogen afterglow. Thus even when the concentration of nitrogen is five times that of oxygen (Pig. 3b), the nitrogen afterglow is effectively quenched, the oxygen afterglow being the only one visible.

Discussion

In presenting the following discussion, the author realizes that no exact formulation of the processes occurring can be attempted at this stage due to the complexity of the system when exposed to the electric discharge. The manifold possibilities are not by any means exhausted in the following list of reactions.

Normal oxygen molecules must be mainly responsible for the quenching of the nitrogen afterglow or, in other words, the removal of nitrogen atoms."" There are several ways in which this could take place

$$N + N + O_2 = N_2 + O_2 + 263{,}000 \text{ cal.}^{11b} \qquad (1)$$
$$N + O_2 + \text{third body} = NO_2 + 124{,}000 \text{ cal.}$$
$$N + O_2 = NO + O + 29{,}000 \text{ cal.} \qquad (2a_2)$$
$$N + NO_2 = N_2 + O_2 + 140{,}000 \text{ cal.} \qquad (2b_1)$$
$$N + NO_2 = 2NO + 97{,}000 \text{ cal.} \qquad (2b_2)$$
$$N + NO = N_2 + O + 72{,}000 \text{ cal.} \qquad (2c)$$
$$N + O + \text{third body} = NO + 191{,}000 \text{ cal.} \qquad (3)$$

No indication is made of excited states of the products.

It is seen that all these reactions are possible from an energy standpoint and it is probable that all of them contribute to the extinction of the nitrogen afterglow. If the product condensed out in liquid air is nitrogen peroxide,[12] it is probable that $2a_1$ contributes to the quenching in a large measure.[13]

[11a] Kaplan and Cario, ***Nature,*** 121, 906 (1928), believe that the excited nitrogen molecule (11th vibrational state in level B) from which the a-bands proceed is brought about by a collision between a metastable nitrogen molecule in level **A** [8 volts] and a metastable N atom (3.56 volts) in which the energy of the latter is transferred to the former. For a discussion of this see H. O. Kneser, *Ann. Physik,* 21, 707 (1928).

[11b] From recent work by H. O. Kneser, [*Ann. Physik,* 21, 707 (1928)] it appears very probable that the mechanism of a-band emission involves a triple collision between two atoms of nitrogen and a third body. The results of his experiments are not in accord with similar results of Bonhoeffer and Kaminsky [Z. ***physik.*** Chem., 127, 385 (1927)], which earlier led them to doubt the triple collision hypothesis. The most recent value for the heat of dissociation of nitrogen is 9.5 volts (or about 218,000 calories) [Gaviola, ***Nature,*** 122, 313 (1928); Birge and Mulliken, 122, Dec. (1928)]. This new value in no way invalidates the theory of Sponer regarding the origin of the a-bands. The process may still be thought of as occurring between a normal nitrogen atom and a metastable nitrogen atom (2.4 volts) in triple collision with a third body.

[12] Majewska and Bernhardt, *Z. Physik,* **48,** 137 (1928). If a discharge is passed through a mixture of the gases, a gas is condensed out at −85° (see Part II). This gas cannot, therefore, be O_3, NO nor N_2O.

[13] There is also, of course, the possibility of formation of NO_2 by the action of O_3 an NO.

It has been mentioned that normal nitrogen-molecules do not affect the oxygen afterglow. Nitrogen atoms could remove oxygen atoms by collision with a third body and thus quench the glow but the concentration of nitrogen atoms is probably too small for this to be marked. It will be assumed for want of evidence as to the intensity distribution in the continuous spectrum in pure oxygen as compared with that in the continuous spectrum in air or in that produced by the oxidation of nitric oxide by ozone, that the oxygen afterglow is due to the emission of radiation (see Thompson, ref. 4) when two oxygen atoms, possessing any velocity, combine. This may occur in a two body collision,[14] so that competition for the reactions N + O + third body and O + O is in favor of the latter. The small quenching effect of the oxygen afterglow by active nitrogen may easily be due to the active nitrogen molecular species.

It would be valuable from the standpoint of atomic kinetics to make calculations at the minima, where the a-bands appear, of the collisions between the various species present in the glowing gas, to determine if possible at what concentration of atomic nitrogen the a-bands become visible. In view of the complicated system of reactions which may be occurring, the uncertainties involved in the fractions of oxygen and nitrogen which are dissociated by the discharge and the fruitfulness of such collisions as between two nitrogen atoms, it is doubtful whether the calculation would have much meaning. One may simplify the problem by considering only the reactions $2a_1$ and $N + N = N_2' \longrightarrow$ a-bands. In a mixture containing 20% of oxygen, the minimum occurs at 0.56 mm. Assuming 1% dissociation of nitrogen, which may be high,[15] and disregarding dissociation of oxygen, we find the number of collisions between N and O_2 ($\sigma_N = 1.77$ Å. and $\sigma_{O_2} = 1.44$ Å.) equal to 2.77×10^{20} per cc. per sec. Since this requires the intervention of a third body and the ratio of triple to double collisions is[16] about $^1/_{1000}$, this becomes roughly 3×10^{17} collisions per cc. per sec. The number of collisions between N and N is 1.7×10^{19} per cc. per sec. This calculation shows at least that such an encounter as between two nitrogen atoms results in a molecule very infrequently, for otherwise it would be possible to see the a-bands at a much higher pressure than corresponds to the minimum. One arrives at the same result from classical theory. It is believed that only atoms possessing certain velocities can combine.[17] In fact the temperature coefficient of the

---

[14] Oxygen has a continuous absorption spectrum beginning at λ1751 and can emit continuously by electron transition.

[15] Crew and Hulbert, *Phys. Rev.*, 30, 124 (1927).

[16] At atmospheric pressure, Herzfeld, *Z. Physik*, 8, 132 (1921).

[17] Indeed, the persistence of the oxygen afterglow even in the presence of "active" nitrogen at pressures of nitrogen many times that of oxygen, is probably due to the ease with which two oxygen atoms combine as compared with the combination of two nitrogen atoms.

nitrogen afterglow (between room temperature and liquid air temperature) can be accounted for if one assumes that only atoms combine which possess velocities below some small critical value. Since the a-bands just become visible in the region of the minimum it is evident that a sufficient number of these fruitful collisions are taking place. These must increase in number as the pressure is reduced, for the intensity of the a-bands increases. In a general way this can be understood, for the fraction of nitrogen molecules dissociated by the discharge increases as the pressure is reduced[15,18] and the number of suitable collisions between N and N must therefore increase faster than deactivating collisions.

I am indebted and thankful to Professor S. C. Lind for his constant interest and advice during the tenure of this Fellowship and for placing at my disposal the facilities of his laboratories.

Summary and Conclusions

A study is made with the electrodeless discharge of the nitrogen and oxygen afterglows in mixtures of nitrogen and oxygen at various pressures. A sequence of changes in the character of the afterglow is recorded as the pressure is reduced in the same mixture This may' be divided roughly between the oxygen afterglow at higher pressures and the nitrogen afterglow at lower pressures with a maximum in each and a minimum between the two. Within the limits of pressure employed (*ca.* **1.8** mm. to **0.01** mm.) and from **100** to **60%** of oxygen, only the oxygen afterglow with its maximum is observed. At lower percentages of oxygen the minimum appears and also the nitrogen afterglow. Below about 12% of oxygen, the oxygen afterglow maximum disappears and with it also the oxygen afterglow. The α-bands just become visible at a total pressure slightly higher than that at the minimum.

The oxygen maxima, the minima and the points at which the a-bands just appear are displaced toward lower total pressures as the percentage of oxygen increases. It is found that these points always occur at a constant partial pressure of oxygen: oxygen maxima, **0.161** mm.; minima, **0.111** mm.; a-bands, **0.123** mm. The experimental points fit the corresponding hyperbolas very well. The nitrogen afterglow rises to a duration maximum at a pressure of about 0.035–0.04 mm. *The curves and data presented enable one to determine any experimental condition desired (within the pressure limits employed) involving the production of the nitrogen or oxygen afterglows.*

It is concluded that normal oxygen molecules have a marked quenching action on the nitrogen afterglow but that normal nitrogen molecules have no effect on the oxygen afterglow. The slight quenching action in the oxygen afterglow is probably due to active nitrogen molecules.

[18] This is also evident from the fact that with decreasing pressure in either pure nitrogen or oxygen the glow becomes more intense and of longer duration.

Calculations show that the fruitfulness of collisions between two nitrogen atoms to form a molecule is small. The temperature coefficient of the afterglow in nitrogen can be explained on the basis that only atoms possessing velocities below some critical value can combine on colliding.

THE PROPERTIES OF PURE HYDROGEN PEROXIDE. VI

BY G. L. MATHESON AND O. MAASS

RECEIVED AUGUST 6, 1928 PUBLISHED MARCH 6, 1929

The following paper is one of a series[1] that deals with the properties of pure hydrogen peroxide. In it several new freezing-point curves are described and the existence of compounds between hydrogen peroxide and a number of organic bases is investigated. The measurements of the heat of decomposition, the molecular weight in the vapor phase and the explosion temperature of pure hydrogen peroxide are described.

Pure hydrogen peroxide was prepared in much the same manner as was set forth in the first paper of this series with a few slight modifications. The concentration, by evaporation in *vacuo*, was carried out until the strength was about 98% by weight. The distillate produced in the final stages of evaporation was saved. The final purification was carried out as before by means of fractional crystallization.

Freezing-Point Curves.—This section of the experimental work deals with the solubility and freezing-point curves of various substances in pure hydrogen peroxide. These experiments are of interest in comparison with corresponding water systems. The apparatus employed consisted of a long test-tube set in a bath of ether in a transparent Dewar flask. A stirrer was provided in the tube and the bath was stirred by bubbling air through it. Its temperature could be controlled by adding carbon dioxide snow or by changing the rate of flow of air. The temperature was measured by a thermometer placed in the bath. The materials were added in the most convenient manner for each substance. The chemicals used were all carefully purified to remove foreign substances which might decompose the peroxide. The temperatures are those recorded just as the last crystals disappeared when the bath was slowly warmed.

In Table I the results are recorded for potassium chloride, sodium fluoride, potassium sulfate and methyl alcohol, and these systems are plotted in Figs. 1 and 2, with the corresponding water systems.

The data for the water curves are taken from the literature with the exception of the one for sodium fluoride, for which the following points

were determined by the authors: 0.6%, −1.1° and 1.03%, −1.9° with ice as the solid phase. The eutectic was found to be at −2.9° for a per-

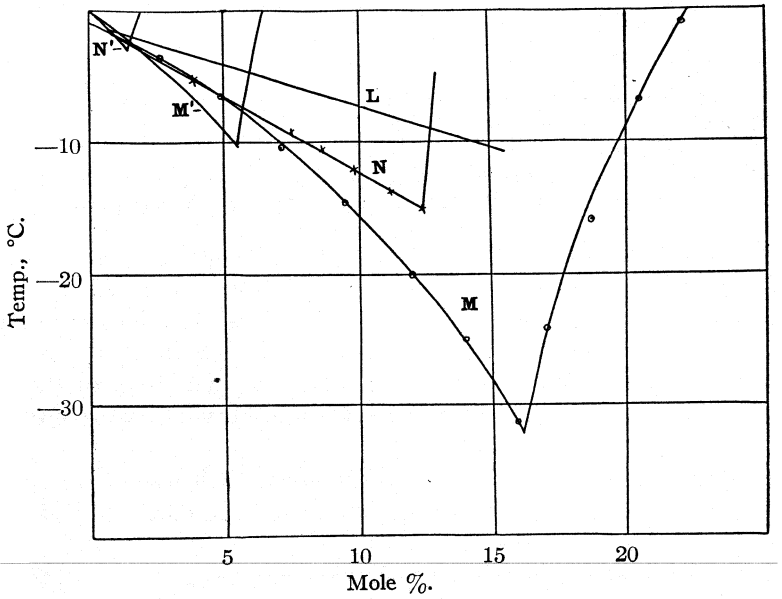

Fig. 1.—Freezing-point curves. L, Theoretical lowering in H_2O_2; M, H_2O_2–KCl; M', H_2O–KCl; N, H_2O_2–NaF; N', H_2O–NaF.

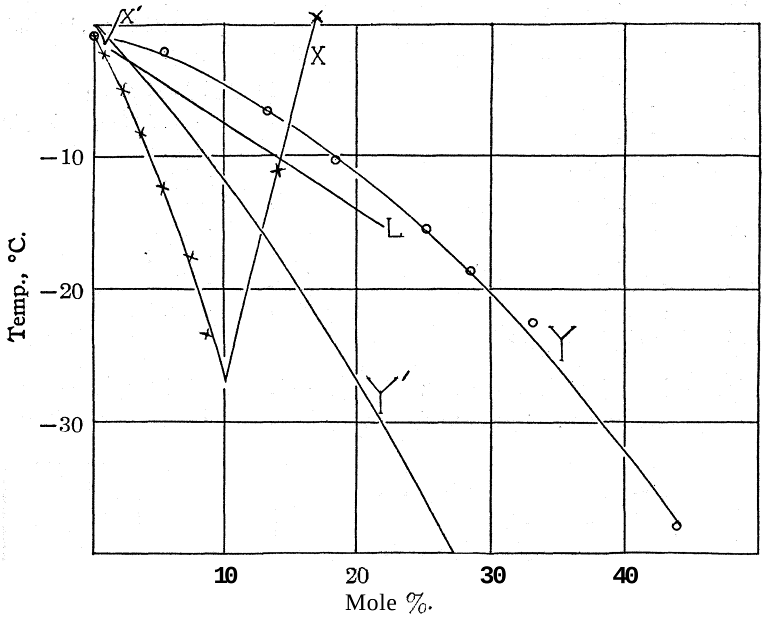
centage of 1.4. —5.6" was obtained by Guthrie as the eutectic,[2] but the authors found that the solution froze to a solid if cooled below −2.9°. The straight line L, plotted in each figure, represents the theoretical lowering of the freezing point in hydrogen peroxide caused by a substance which does not ionize or associate when dissolved.

In the potassium sulfate system no points could be recorded between the concentrations of 8.4 and 14.1% because the liquid froze to a glass. The same difficulty was encountered with methyl alcohol beyond 51.5%.



Pig. 2.—Freezing-point curves. L, theoretical lowering in H_2O_2; X, H_2O_2–K_2SO_4; X', H_2O–K_2SO_4; Y, H_2O_2–CH_3OH; Y', H_2O–CH_3OH.

From the figures it is apparent that the salts are dissociated in pure hydrogen peroxide whereas methyl alcohol is associated, all of which is indicated by the relative angles of the L curves and the freezing-point curves at infinite dilution. In every case, the eutectic in the hydrogen peroxide system occurs at a far higher concentration than in the corresponding water system, indicating a greater solubility in hydrogen peroxide than in water.

Potassium bromide was found to decompose hydrogen peroxide fairly rapidly, no matter how many times the salt had been purified by recrystallization.

When ether is added to hydrogen peroxide only a slight amount dissolves before a separate layer is formed. The peroxide is fairly soluble in this

second layer, a considerable amount of heat being evolved during its solution. Freezing points which were obtained for the ether–hydrogen peroxide system are contained in Table II.

TABLE II

FREEZING POINTS IN HYDROGEN PEROXIDE

Ethyl Ether

Weight, %	M. p., °C.	Weight, %	M. p., °C.
3.5	−1.2 (Two distinct layers)	47.8	− 6.0
41.6	. . . H_2O_2 layer nearly gone	59.2	−16.5
44.3	−4.8	66.5	−33.1
45.2	−5.1	71.5	−47.6

As long as there were two layers present, the freezing point of the lower layer was −1.2°. The freezing point of pure hydrogen peroxide is −0.9°,[3] that is, within 0.3° of the freezing point of the peroxide layer. Since the latter determination may be 0.2" too low on the absolute scale, the lower layer must have consisted of well-nigh pure peroxide. This shows that only a very slight amount of ether is soluble in pure hydrogen peroxide. When the peroxide layer had just disappeared the freezing point was still very high and the solid which crystallized out was filtered off at a low temperature and analyzed. The composition of the solid varied from 51.7% by weight of hydrogen peroxide to 45%, depending on the concentration of the solution. The composition of the ether layer varied with change of temperature when there were two layers in equilibrium, being 60.8% by weight of hydrogen peroxide at 0° and 64% at 20°, with complete miscibility somewhere in the neighborhood of 80°. The solid which is formed on cooling an ether solution may be a solid solution. The complete phase rule diagram is probably similar to that of succinic nitrile and water.

The system sulfuric acid–hydrogen peroxide was examined and where possible the freezing points were determined. The most convenient way of introducing definite quantities of anhydrous sulfuric acid was to add gaseous sulfur dioxide, which united with the peroxide, even when very cold, to form sulfuric acid. Table III contains the data thus obtained.

TABLE III

FREEZING POINTS IN HYDROGEN PEROXIDE

SO_2, mole %	5.8	11.7	13.9	19.5	47.2	48.4	49.7	50.5
M. p., °C.	−5.3	−11.5	−18.0	−31.0	−10.0	−3.3	+2.4	+4.1

The solution was very viscous between 19.5 and 47.2% of sulfur dioxide and no crystals were obtainable. Between these percentages the solution solidified to a glass when the temperature was lowered below 25". Toward the end of the addition a slight decomposition was noticed with the formation of ozone. This accounts for the lowering of the freezing point

---

[3] Cuthbertson, Matheson and Maass, THIS JOURNAL, 50, 1120 (1928).

of the sulfuric acid formed, since at 50% sulfur dioxide the freezing point should have been 10°, that of pure sulfuric acid. The two portions of the curve obtained indicate that more than one eutectic is formed. This would show that some compound between sulfuric acid and hydrogen peroxide is formed. The great tendency to supercool prevented the isolation of crystals.

An apparatus has been described in a previous paper[4] for the examination of the ammonia–hydrogen peroxide system. An attempt was made to use this apparatus for the similar system phosphine–hydrogen peroxide. Great care was taken in the purification of the phosphine. It was found, however, that even in supercooled peroxide phosphine was soluble to an exceedingly slight extent.

The fact that ammonia formed a stable compound with the peroxide, whereas phosphine did not, seemed to indicate that the more basic the substance, the more readily would it combine with peroxide to form a stable compound. With this in view, the effect of a large number of organic bases was tried. It was found that the peroxide remained stable and the amine unoxidized when in contact at low temperatures, that is, below 0°. If the solutions were allowed to warm up to room temperature

[4] Maass and Hatcher, THIS JOURNAL, 44, 2473 (1922).

some of the amines caused decomposition of the peroxide, with oxidation of the amine to the nitro compound. Piperidine was the most active in producing decomposition, and when warmed to room temperature the heat of the reaction was sufficient to accelerate it progressively until the peroxide decomposed with explosive violence. The monobutylamine with the tertiary carbon atom attached to the nitrogen was the most stable of the amines tried, no decomposition taking place. The *iso*-normal-butylamine was next in the order of stability. In a test with the latter, less than 1% of peroxide decomposed after being in contact with various concentrations of this amine for eight hours, at temperatures below 0°.

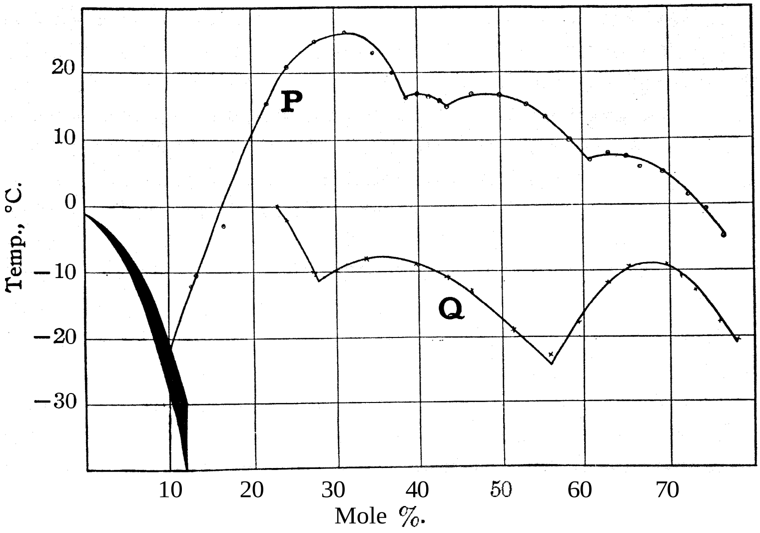

Fig. 3.—Freezing-point curves. Q, Mono *N*-butylamine–hydrogen peroxide. P, Mono butylamine–hydrogen peroxide.

In Table IV are given the freezing-point determinations made with the organic bases and hydrogen peroxide. Only in the case of the isomeric monobutylamines, the normal and tertiary, could a large part of the freezing-point curve be determined. In the case of all the others, no crystals could be formed at the higher concentrations of the organic base, since the mixture froze to a glass once the first eutectic had been passed.

Figure 3 represents all the points given in the above table. The depression of the freezing point of the peroxide was the same for all the bases, within experimental error, with the exception of the dimethylaniline. To prevent confusion the line is broadened to include all these points. In the case of the monobutylamine stable compounds were isolated. The compound having the composition $2H_2O_2 \cdot C_4H_9NH_2$ was obviously the most stable. In the case of the n-butylamine a compound of the same molecular proportions was also isolated, with the indication, also, of a compound containing a greater proportion of hydrogen peroxide. As is well known this amine is oxidized to hydroxylamine at higher temperatures in aqueous solutions. This again illustrates the hypothesis that a molecular compound is generally formed between two substances before reacting and subsequent splitting up. Dimethylaniline, the only benzenoid amine investigated, behaved quite differently compared with the aliphatic amines. It was not as soluble in the peroxide and the small lowering of the freezing point of the peroxide indicated that it was associated in solution.

As it was not improbable that the other amines formed compounds which could not be crystallized out, due to supercooling, an entirely different method was resorted to in an attempt to isolate such compounds. This depended on the precipitation of an oil, from a mixture of anhydrous ether solutions of the amine and the hydrogen peroxide, with subsequent analysis of the resulting oil. This method had been found successful in the isolation of the ammonia compound.[4] The following will illustrate the procedure. When small portions of an ether solution of, for instance, diethylamine, were added to an ether solution of peroxide, successively, with vigorous stirring, at first an oil kept separating out. With further addition of amine this oil went back into solution. It was found that ether was not soluble in this oil, any more than in pure peroxide (see above). Hydrogen peroxide was soluble in the oil and could only be washed out by ether with great difficulty. Amine was also soluble in the oil but its far greater solubility in ether made it relatively easy to wash out the excess amine from the oil by means of anhydrous ether. The amine solution was therefore added until the maximum amount of oil had been precipitated and a slight amount more of amine was added, as indicated by the partial redissolving of the oil. The remaining oil was separated and could then be washed with ether. It was found that the composition of the oil was invariable, independent of the number of washings it had received. Furthermore, the analysis of the oil, in the case of all the amines tried, gave an exact molecular proportion of amine to peroxide.

Permanganate could not be used for titrating the peroxide in the presence of the organic bases. Hence the method used to analyze the oil was to dissolve a weighed portion of it in water and then add powdered manganese dioxide. The peroxide decomposed completely within a minute and the oxygen evolved was then measured.

Dimethylaniline, aniline, pyridine, phenylhydrazine, tripropylamine and di-isobutylamine did not give insoluble oils in ether. It cannot be taken for granted that because an oil does not separate on mixing ether solutions of organic bases and peroxide that no molecular compounds are formed. It was found that the more carbon atoms there were, to the amine, the greater was the solubility of the resulting oil in the ether; in the case of certain amines great care had to be taken to use concentrated ether solutions in order to get any oil at all. It seems probable, however, that some of the above bases do not form compounds with the peroxide. For example, dimethylaniline indicated this by its relative insolubility in the peroxide.

In Table V are given the results of the analyses of the oils that were formed, the percentages found and calculated being given in weight percentage of hydrogen peroxide. The exact agreement between the percentages found and calculated leaves little doubt as to the existence of these molecular compounds.

TABLE V

COMPOSITION OF OIL SEPARATING FROM ETHER

Base	Weight of H_2O_2 Found	Weight of H_2O_2 Calcd.	Compound
Ammonia	66.7	66.7	$NH_3 \cdot H_2O_2$
Ethylamine	59.5	60.2	$2H_2O_2 \cdot C_2H_5NH_2$
n-Propylamine	53.2	53.7	$2H_2O_2 \cdot C_3H_7NH_2$
Isobutylamine	48.7	48.3	$2H_2O_2 \cdot C_4H_9NH_2$
n-Butylamine	48.5	48.3	$2H_2O_2 \cdot C_4H_9NH_2$
Tert.-monobutylamine	48.3	48.3	$2H_2O_2 \cdot C_4H_9NH_2$
Diethylamine	58.0	58.3	$3H_2O_2 \cdot (C_2H_5)_2NH$
Triethylamine	58.3	57.5	$4H_2O_2 \cdot (C_2H_5)_3N$
Piperidine	44.2	44.4	$2H_2O_2 \cdot C_5H_{10}NH$

Monobutylamine gave an oil which could be solidified at will, and having the same composition and freezing point as the stable compound indicated by the freezing-point curve. The same could be done in the ease of the ammonia. All this indicates that the above method gives a reliable means of isolating those compounds which cannot be separated in the crystal form.

A feature of interest in the above table is the increase in the number of peroxide molecules taken up by the ethylamines with increase in substitution of the nitrogen hydrogens by ethyl groups. As a general conclusion, the possibility of forming a stable compound depends on the basicity of the base.

Heat of Decomposition of Hydrogen Peroxide

The heat of decomposition of hydrogen peroxide into water and oxygen was measured in an adiabatic calorimeter. The decomposition apparatus is shown in Fig. 4. It consisted essentially of two bulbs, A and B, which were joined by means of a ground-glass joint. This apparatus was submerged in the calorimeter water, leaving the two thin-walled glass tubes C and D protruding from the surface. Bulb A was filled with lumps of manganese dioxide which served to decompose any hydrogen peroxide carried over by entrainment. A quantity of peroxide was allowed to flow through a capillary funnel passing through Tube D into Bulb B. The amount which entered in this way was determined by weighing B before and after filling. A rubber tube was attached to C and led to a U-tube filled with pumice stone and sulfuric acid, outside of the calorimeter proper. The object of this was to catch any water vaporized during the decomposition and carried away with the oxygen, and thus to be able to correct for the heat of vaporization of this water. Actually it was found that this correction was very small, since, apparently, most of the water vapor with which the oxygen was saturated was reabsorbed in Bulb A.

After the apparatus had been put together, the calorimeter was brought to thermal equilibrium. The decomposition of the peroxide was started by dropping a small grain of manganese dioxide down Tube D, which was then immediately closed to force the oxygen along the other tubing. Most of the heat given off was transmitted through the walls of Bulb B, directly, from the liquid peroxide. The rate of reaction was controlled by the proper choice of the size of the initial grain of manganese dioxide. Toward the end, when the reaction slowed up, more manganese dioxide was added to increase the rate of decomposition. It was found that the reaction came to an abrupt end, as indicated by the sudden cessation of temperature change in the calorimeter. Throughout the whole process great care was taken to have complete adiabatic control. A sample calculation below gives an idea of the accuracy with which the determinations were made.

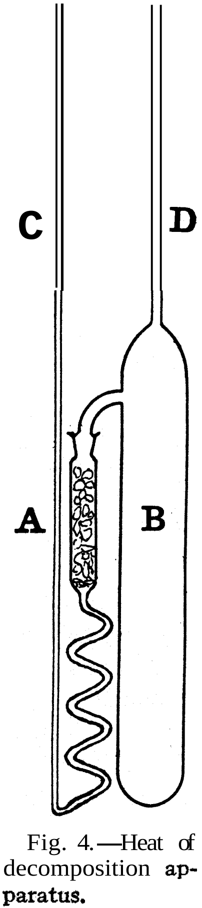

Fig. 4.—Heat of decomposition apparatus.

Sample Calculation

Concentration of peroxide = 38.05%
Weight of calorimeter + water = 1272.8 g.
Weight of calorimeter = 269.6 g.

Weight of water = 1003.2 g.

Water vapor carried out by oxygen
Weight of U-tube + water = 46.7191 g.
Weight of U-tube = 46.7176 g.

Weight of water vapor = 0.0015 g.

Weight of peroxide
Weight of Bulb B + H_2O_2 = 27.236 g.
Weight of Bulb B = 17.275 g.

Weight of H_2O_2 = 9.961 g.

Temperature change of calorimeter
Final reading = 3.784°
Initial reading = 1.345°

Change = 2.439'

The water equivalent of the calorimeter was made up as follows.

21.26 g. of glass: sp. ht. taken as 0.17 cal. Water equivalent = 3.62 cal.
9.38 g. of MnO_2: sp. ht. calculated from the atomic heats. Water equivalent = 1.16 cal.
298.2 g. of copper calorimeter and stirrer. Water equivalent = 24.70 cal.
Total water equivalent = 29.5 cal.

Heat change in water = 2444.4 cal.
Heat change in apparatus = 72.0 cal.
Heat carried off by water vapor = 0 9 cal.
Heat of residual water left in Bulb B = 19.8 cal
Total calories = 2537.1

Molecular heat of decomposition at 20° and concentration of 38.05% is

$$\frac{2537.1 \times 34.01 \times 100}{9.961 \times 38.05} = 22{,}714 \text{ cal.}$$

The heat of the reaction at 20° as represented by

$$H_2O_2(\text{liq.}) = H_2O(\text{liq.}) + \frac{1}{2}O_2(\text{ gas at atmos. press.}) + \text{Heat}$$

was found to be as follows. Two determinations of 97.15% peroxide gave 23,400 and 23,440 cal., respectively. Two determinations of 38.05% peroxide gave 22,746 and 22,714 cal., respectively. The heat of dilution between the above percentages is 690 cal. per mole, and the heat of decomposition of pure hydrogen peroxide averages 23,450 cal., which is considerably higher than values found in the literature.

The Molecular Weight of Hydrogen Peroxide in the Vapor State

The molecular weight of hydrogen peroxide in the vapor phase is difficult to determine because of its rapid decomposition at temperatures which would give measurable vapor pressures. A recent determination of the vapor pressure curve for pure hydrogen peroxide[5] indicated that such an experiment might, however, be carried out with success if the temperature was about 90°. At this temperature the vapor pressure of peroxide is about seven centimeters.

The apparatus used to carry out the experiment was of the Victor Meyer type. It is shown in Fig. 5. It consisted essentially of a large flask C with a long neck. It had a capacity of about 2400 cc. and the neck was 60 cm. long. The flask was sunk in the water-bath I, which was stirred by the paddles N. The connecting tubing E was heated by means of nichrome wire embedded in asbestos. The current was regulated so that the temperature was about 5° above the bath temperature. A small tube F, filled with a few lumps of manganese dioxide, was inserted next to the manometer M. This served to protect it from the peroxide. A and B

---

[5] Maass and Hubert, THIS JOURNAL, 46,2693 (1924).

were outlets to a hydrogen reservoir and a vacuum pump, respectively. The magnetic device K for dropping the capsules of peroxide was fitted to the apparatus by means of a ground-glass joint.

The apparatus was made of pyrex glass but even so peroxide decomposed rapidly in it. It was found that if the glass surface was coated with a thin film of beeswax the decomposition was greatly reduced.

The procedure employed in using the apparatus was as follows. The bath was heated to 92° and at the same time the apparatus was thoroughly evacuated. Then it was filled to atmospheric pressure with dry hydrogen. The capsule with a weighed amount of pure hydrogen peroxide was inserted in the magnetic dropping device. This part of the apparatus was kept cool by blowing a current of air across it when the peroxide capsule was in it. The capsule was made of beeswax. A few drops of peroxide were poured into it and by difference in weight the amount of peroxide was known. The mouth of the capsule was closed after weighing until only a very fine opening was left. This was necessary to allow the air to escape when the pressure was reduced in order not to burst the capsule. When the capsule was in place the pressure was quickly lowered to one centimeter. At this pressure and room temperature the pure peroxide in the capsule was still far from its boiling point and not much could be lost by evaporation through the fine hole in the capsule. When the pressure had been reduced, two or three successive readings were taken on the manometer and then the capsule was dropped to the bottom of the flask C where the wax of the capsule melted and the peroxide was free to vaporize. Pressure readings were then taken at known intervals of time. At the same time the barometric pressure was observed in order to make corrections for its change. The object of the presence of the hydrogen gas was, of course, to prevent peroxide vapor from reaching the manometer. The dimensions of the flask and the narrow tube connections were chosen in order to reduce diffusion through the hydrogen as much as possible.

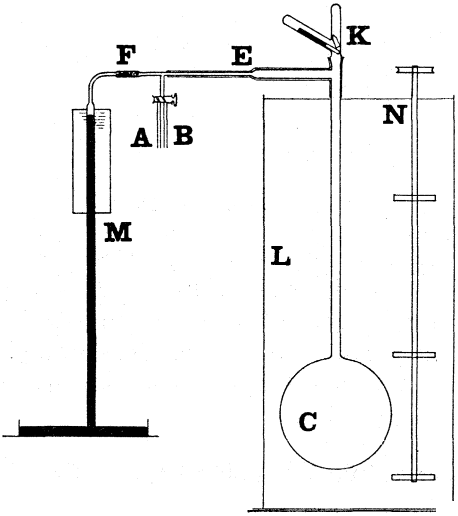

Fig. 5.—Vapor density apparatus.

The results obtained are given in the next table, VI, and plotted in Fig. 6. Experiment E was made with 56.6% peroxide instead of 100%, as in the case of the others.

14	2.35	..	..	.60	..
16	2.38	1.90	..	..	..
18	2.42	..	3.28	..	..
19	..	..	..	.62	..
21	..	1.95	..	..	..
23	..	..	3.35	..	..
24	..	..	..	.64	..
28	..	..	3.40	..	..
29	..	..	..	.66	..
33	..	..	3.45	..	..
34	..	..	..	.68	..

A question that at once arose from the above curves was what portion was to be taken as the final pressure due to hydrogen peroxide vapor only. The answer for curves D and E, where only a small quantity of peroxide was used, was obviously the constant pressure portion. It seemed apparent from curve D that the action consisted, first, of a boiling of the peroxide to form a vapor and then a diffusion upward to the unwaxed portion of the system, the magnetic dropping device, where the peroxide decomposed. When a much larger quantity of peroxide was used the decomposition started before the boiling had finished and no constant pressure was reached. It did not appear correct, therefore, to extrapolate back to zero time and take that pressure as the correct one because the decomposition did not set in at the start. If six minutes from the start was taken as the point where evaporation ceased and decomposition just started, then the molecular weight determinations were as follows: A = **34.0; B** = **34.3;** *C* = **33.9;** D = **34.0;** mean = **34.0.** Thus the molecular weight of hydrogen peroxide in the vapor phase is **34.**

If, on the other hand, the molecular weight is determined by extrapolation of the decomposition curve back to zero time, then the values are: A = 34.9; B = 34.5; C = 34.4; D = 35.2. From what has been said above these values are too high.

In Experiment E, in which 56.6% peroxide was used, the pressure was calculated which would be obtained if 34 were taken as the molecular weight of the peroxide and this pressure was compared with that observed. The observed pressure was $1^1/_3\%$ less than the theoretical. Experiments were carried out with water, under identical conditions of pressure and temperature, to check the apparatus. These gave molecular weights of slightly under 18.1.

The above experiments with peroxide have been repeated many times with the same conclusion that, like water vapor, it is unassociated in the vapor state.

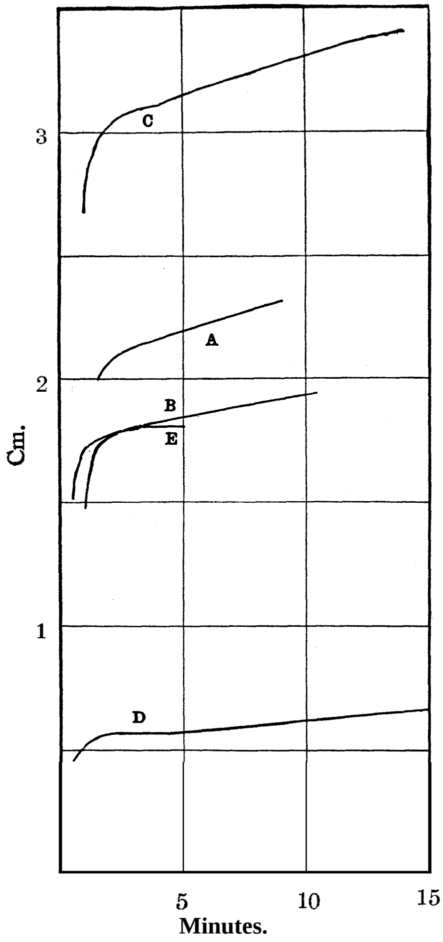

Fig. 6.—Increase of pressure with time.

The Explosion Temperature of Pure Hydrogen Peroxide

The minimum temperature of decomposition of hydrogen peroxide where the rate would be classed as explosive was investigated for a certain set of conditions. In these experiments the decomposition was called explosive when it made an audible report or "bang." The method of procedure was to drop about 0.05 to 0.3 g. of pure peroxide contained in a paraffin capsule into a tube about three centimeters in diameter. This tube was placed vertically in a deep oil-bath. The temperature of the oil-bath was taken with a mercury thermometer totally immersed in it. The results, which could be repeated every time quite independently of the quantity of peroxide used, were as follows: 146°, no explosion; 150°, dull explosion, barely audible; 151°, fairly sharp explosion; 153°, violent explosion; 159°, violent explosion of about the same intensity as at 153°.

The experiments were repeated with a saturated solution of potassium chloride in pure peroxide: 151°, no explosion; 160°, rapid decomposition to give a flame but no audible explosion.

At 160" a 95% solution of peroxide and water gave the same result as the potassium chloride solution at the same temperature.

From the results with the pure peroxide the nature of the explosion was seen to change rapidly between 150 and 153°. This indicates that the pure hydrogen peroxide explodes when it is heated to its boiling point. Dissolved potassium chloride or water, if anything, raise the explosion temperature.

Acknowledgment is made to the Research Council of Canada for a Studentship awarded to one of us during the period in which the work was carried out.

Summary

Melting-point curves were determined in pure hydrogen peroxide and a comparison was made with the analogous curves in water for potassium chloride, potassium sulfate, sodium fluoride and methyl alcohol. Curves were also obtained for ethyl ether and sulfuric acid in hydrogen peroxide.

Melting-point curves of *n*-butylamine and the monobutylamine (tertiary carbon) indicated the formation of compounds with hydrogen peroxide. These compounds are probably the first molecular complexes formed in the oxidation of amines to nitro compounds.

The oils which separate on mixing anhydrous ether solutions of amines and hydrogen peroxide were analyzed and shown to be molecular compounds of peroxide and the base.

An accurate determination of the heat of decomposition of hydrogen peroxide was carried out at 20° which gave the value 23,450 cal. for the molecular heat of decomposition into water and oxygen gas at atmospheric pressure.

A determination of the vapor density of hydrogen peroxide gave the molecular weight to be 34.

The decomposition of pure hydrogen peroxide was found to change rapidly in character about its boiling point, 151°, from that of a quiet reaction to a violent explosion. The addition of a little water or potassium chloride deadened the effect.

THE THERMAL DECOMPOSITION OF AMMONIA ON IRON CATALYSTS. II

BY C. H. KUNSMAN

RECEIVED AUGUST 24, 1928 PUBLISHED MARCH 6, 1929

The development of the following method of investigating catalysts and the results herein reported are the outgrowth of studies on the thermionic properties of the materials and mixtures used as catalysts in the synthesis of ammonia.[1] In order to determine the relative importance of the physical properties of the catalysts and to compare these properties with their catalytic properties, it was necessary to have some measure of the chemical activity of the surface at the same temperature and under as nearly the same surface conditions as when the thermionic measurements were made. The decomposition of ammonia was chosen rather than the synthesis as no appreciable or easily measured amount of ammonia is synthesized at one atmosphere pressure or lower and the present system and methods would not permit of working at higher pressures. The decomposition tests proved satisfactory in every way. The same developments which gave a very uniformly coated catalyst strip as a positive ion source, gave an equally uniform and constant temperature chemically active surface. The temperature of the surface was easily determined within a few degrees and kept constant at the given temperature throughout an entire test. The kinetics of the reaction of such a system are relatively simple in comparison to conditions in a catalyst bed as used in synthesis.

Since the publication of a preliminary account of this work[2] many more tests have been made on these catalyst mixtures, a detailed account of which will follow.

Apparatus.—The main scheme of the arrangement of the apparatus is similar to that used in the previous work[3] and is shown in Fig. 1. Instead of drawn filaments of tungsten, molybdenum or nickel, catalyst-coated platinum strips furnished the hot surface upon which the reaction took place. Very even and uniformly coated surfaces can easily be obtained when the catalyst mixture is first reduced, then finely ground and finally coated onto the strip. In this case the 300-mesh or finer catalyst, which has been ground under benzene, is mixed with paraffin and coated on to the hot strip by means of a glass rod at a temperature just high enough to melt the paraffin. When a thin but uniform layer is obtained on the twisted platinum strip, the temperature is raised by increasing the current through the strip. At a dull red temperature a bright red spot develops at some place on the strip and passes over the entire filament length.

This bright spot is due to the heat produced by the rapid oxidation of the finely divided iron granules, and attains a temperature sufficiently high to sinter or fuse the coating to the twisted platinum strip. A coating of any desired thickness can be had by repeating the process as often as desired. This type of coating, even after reduction in hydrogen or nitrogen–hydrogen mixture, is very firmly attached and uniform in temperature. The only disadvantage is that the surface coated with the reduced material is relatively inactive in comparison to surfaces prepared by coating the platinum strip with the unreduced material. In the latter case the coating of the unreduced mixture and paraffin are applied to the filament and raised *to* a temperature just below visible and allowed to bake for about a half hour, after which another coating is applied and this continued until the desired thickness is obtained. This surface must be handled carefully as portions may break off and destroy the uniformity of the surface. The surface on reduction is very much more active catalytically than the previous one, as will be shown. As the ammonia catalyst is the reduced mixture and not the oxide, care was taken to see that the coated materials were thoroughly reduced either in a nitrogen–hydrogen mixture or hydrogen before the decomposition tests were made.

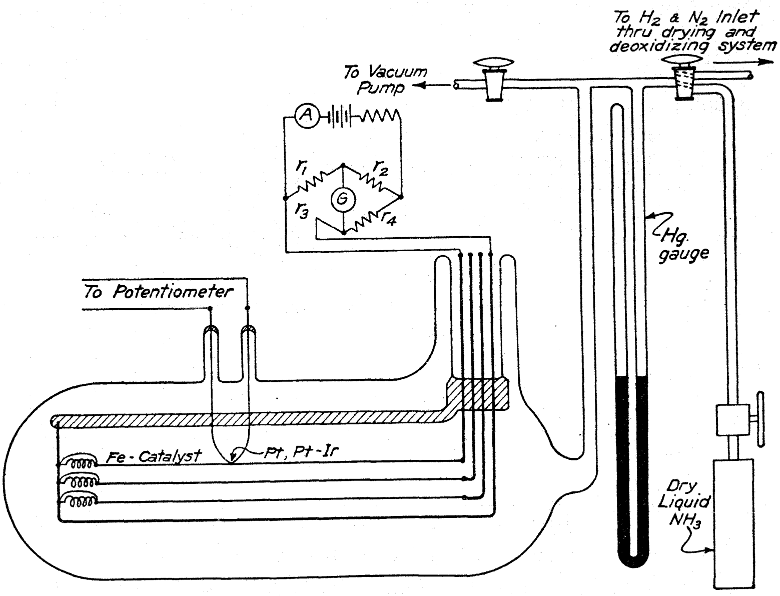

Fig. 1.—Apparatus for the study of the decomposition of ammonia on catalyst coated strips.

The temperature of the coated surface was determined in two ways: first, by means of an optical pyrometer, correcting for the emissivity of the surface and the absorption of the glass, and, second, by means of a thermocouple welded to the platinum strip. In this case the 0.005-cm. diameter Pt–Pt–Ir wire forming the juncture was close to the surface of the catalyst coating. The thermocouple is the more convenient method of determining the temperature and can be used through a wider range of temperatures than the optical pyrometer. Some difficulty was at first encountered in getting these fine wires through a pyrex glass. Any very slow leaks which may result at times at these seals can be closed with de Khotinsky wax.

The temperature as read from the calibrated thermocouple gave an added check on the Wheatstone bridge method of keeping the resistance of the filament and temperature of the hot surface constant throughout the run or until almost the whole of the ammonia was decomposed.

The coated strips were attached at one end through heavy tungsten leads and the other through *a* molybdenum spring and platinum strip. The function of the spring was to keep the filament taut and of the platinum strip to carry most of the current, so that no parts of the assembly would become appreciably hot except the coated surface. From four to eight amperes was used to heat the coated strip. The decomposition chamber w~ immersed in running tap water throughout all tests. A mercury trap, not shown in the sketch, separated the decomposition chamber and McLeod gage from the rest of the apparatus after the proper ammonia pressure, usually one-third of an atmosphere, was obtained.

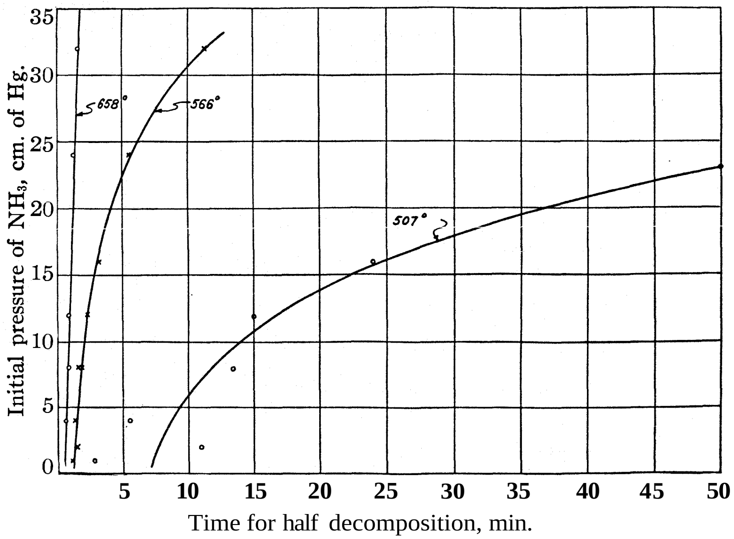

Fig. 2.—The decomposition of ammonia on a Fe–Al–K catalyst at 507, 566 and 658°.

Order of Reaction.—As the results from all the catalyst-coated strips were similar, a detailed account of one catalyst only will be given. In general the system is not as simple as the tungsten or molybdenum. The results obtained in an attempt to determine the order of the reaction are given in Fig. 2. One notices that there was no simple relation between the "half time" and the ammonia pressure, that is, the "half time" had neither a linear variation with the ammonia pressure (test for apparent zero order reaction) nor was it independent of the initial ammonia pressure (test for apparent first order reaction). One cause of this variation is quite evident when we consider the effects of the products of the reaction, nitrogen and hydrogen, on the reaction velocity. This effect can best be shown by referring to Fig. 3. Nitrogen has very little or no effect, while a very marked effect of hydrogen in slowing up of the reaction is apparent at 630°. The data of Fig. 3 were taken four months after those of Fig. 4. The two surfaces, therefore, are not comparable. In the previous results reported for tungsten and molybdenum a small but definite retarding effect was observed for hydrogen and but very little or no effect for nitrogen. In Fig. 2, at the highest temperature, 658°, where there is relatively little hydrogen adsorbed on the catalyst, there is little or no deviation from a straight line (zero order test), but at the lower temperatures, 566 and 507°, the deviation is very marked; since the effect of hydrogen in slowing up the reaction increases with a decrease in temperature, it may constitute the entire difficulty in determining the order of the reaction. Further tests are under way to clear up this point.

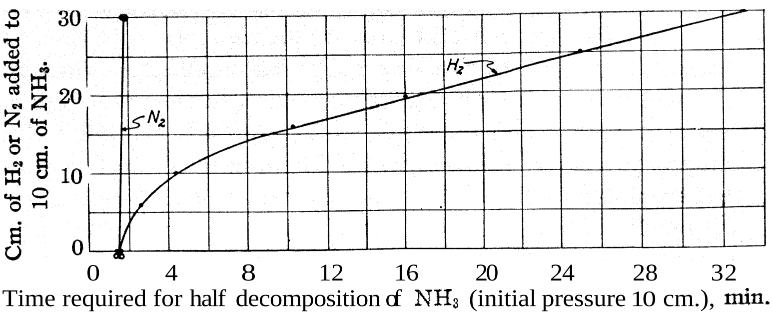

Fig. 3.—The effect of nitrogen and hydrogen on the rate of decomposition of ammonia on a catalyst surface at 630° (Fe–Al–K catalyst).

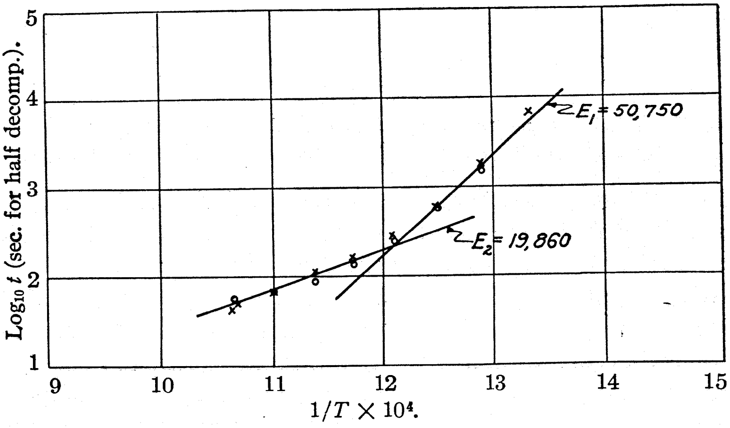

Fig. 4.—The temperature coefficient of the decomposition of ammonia on a catalyst surface (Fe–Al–K catalyst).

Determination of E.—The decomposition results will again be expressed in terms of Arrhenius' equation, rate of decomposition = $Ae^{-E/RT}$, where E will be determined from the temperature coefficient of the surface reaction as a function of the temperature. It is more obvious from Fig. 4 than in the previous work that a smooth curve drawn through all of the points will best represent the observed results, but again we will approximate the data by straight lines representing the range for values of E. Fig. 4 represents the data obtained from the surface when the activity of the surface had become constant after reduction. In this case an unreduced catalyst was coated and then reduced at a relatively low temperature. The test was taken by going from the high to the low temperature; the crosses represent these data, while circles represent the point obtained as the temperature was then increased, The failure of the two curves to be identical represents the effect of some change in surface. Fig. 5 (a) shows the results of a curve taken from one-fourth decomposition for the

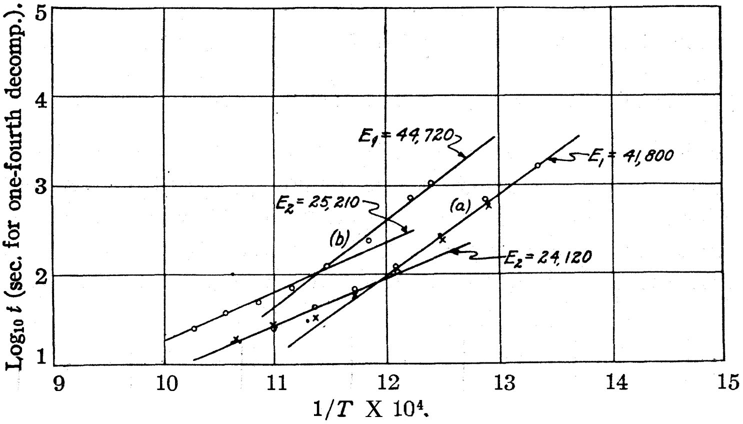

Fig. 5.—The temperature coefficient of **the** decomposition of ammonia on a catalyst, for (a) "1/4 time" and (b) "1/2 time" (Fe–Al–K catalyst).

same test as Fig. 4, in comparison to the other curve, Fig. 5 (b), taken after four months of experiments on the same filament. The values of E and general form of the curve are the same but a considerable shift to a higher temperature range or lower catalytic activity was observed.

The limit for the temperature range of the tests is determined by the length of the decomposition run. It was inconvenient to keep conditions constant over more than about five hours, time for half decomposition at the lowest rates, or to measure rates accurately at high temperatures where the time for half decomposition was less than a few minutes.

Promoters, Poisons and Heat Treatment Studies.—The results shown in Fig. 6 were taken considerably earlier and in a system somewhat different from that giving the other results. The four coated strips, about 10 cm. long and 1 mm. diameter, were mounted horizontally in a two-liter bulb. An effort was made to duplicate the method of coating, keeping the area of all the surfaces as nearly as possible the same. (a), (b) and (c) were mixtures that were first reduced and mixed with paraffin and flashed or coated at about 1000°. (a)[4] was a mixture containing the oxides of Fe–Al–Sn. (b) was a good grade of iron prepared in the form of a catalyst. (c) was one of the best catalysts developed for the synthesis of ammonia, being doubly promoted and containing Fe–Al–K. (d) was the same catalyst mixture as *(c)*, Fe–Al–K, but was powdered, mixed with paraffin and coated in the unreduced form at about 350°. This Fe–Al–K oxide mixture was first thoroughly reduced in an atmosphere of $N_2 + 3H_2$ mixture before being used. The results are in general agreement with their relative activity in the synthesis of ammonia,[5] but, due to the very different conditions as to pressure and method in the synthesis and decomposition, nothing more than a relative comparison can be made. Tin is a very bad poison for a catalyst in the synthesis of ammonia and shows up as having the lowest activity in the decomposition. In comparison to (b), which is a straight iron catalyst, we may say that the tin has the effect of decreasing the rate of decomposition. On the other hand, the Al–K oxide promoter gives a more active catalyst than (b). The relative activity of (d) to (c) is due, undoubtedly, largely to the freedom of sintering in (d) caused by the difference in the method of coating. In this case a 10-fold increase in activity is observed at 527° of (d) over (c).

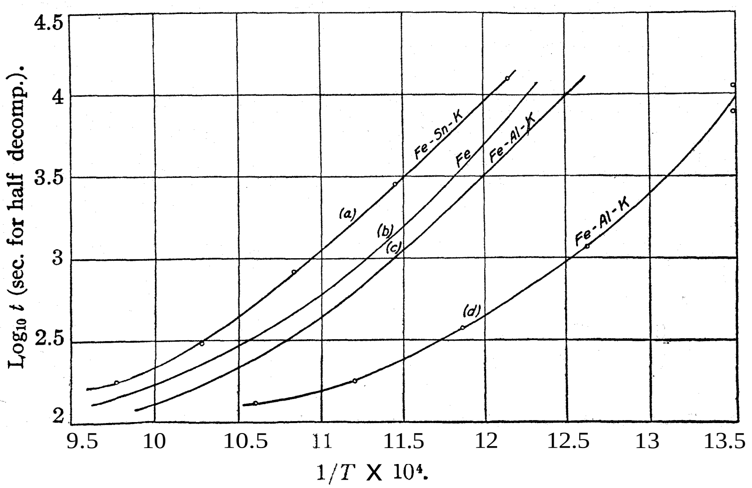

Fig. 6.—The effect of a promoter, poison and heat treatment on the rate of decomposition of ammonia on a catalyst surface.

All curves are of the same general nature, being displaced according to temperature alone. The effect of a promotor and low temperature coating

[5] Almquist and Crittenden, *ibid.*, 18, 1307 (1926); Larson and Brooks, *ibid.*, 18, 1305 (1926).

is to displace the activity curve toward a lower temperature, while the effect of a poison is to displace the curve toward a higher temperature. These curves, including a difference of 16-fold activity at a given temperature, lead one to conclude that again the A or surface constant is of prime importance in determining the relative catalytic activity of these surfaces; that is, the effect of a promoter or poison is to increase or decrease, respectively, the amount of active surface or parts of the surface upon which the decomposition may take place, and is in accord with previous operations on these catalysts.[6]

Figure 7 gives for comparison the relative activity per sq. cm. for the various surfaces tested to date. The catalyst surfaces were determined from careful measurements of the diameter and length of the coated strips.

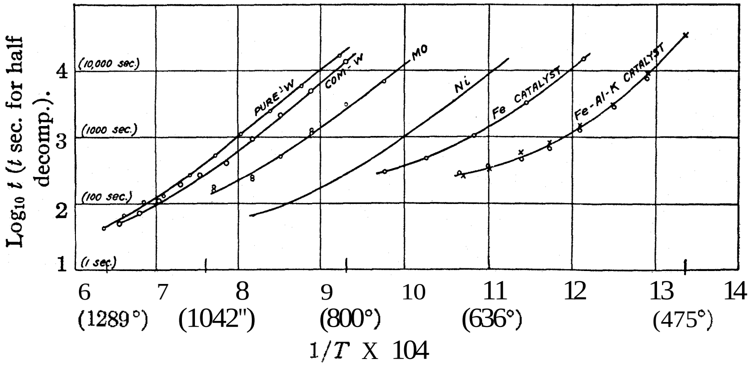

Fig. 7.—The relative activity of metal catalysts per square centimeter of surface for the decomposition of ammonia.

This method was used in the absence of a better method of comparison. These coated strips have more irregular surfaces than the drawn filaments previously tested. It appears from a careful inspection that all coated catalyst surfaces have about the same degree of roughness or irregularity and can therefore be dealt with as having about the same surface exposed to the ammonia gas. An effort was made to determine the activity of a drawn iron filament similar to nickel but without success. Due to bright spots resulting in an uneven temperature and the like, no complete run was obtained. From some individual tests we conclude that the iron curve would come close to the nickel curve.

We notice these marked similarities in all curves; first, that no single straight line will represent the data for an entire temperature range; second, that the more active the catalyst, the more marked deviation from a straight line, or the larger the variation in E with temperature. Drs. W. E. Deming and P. H. Emmett of this Laboratory have recently shown that

---

[6] Almquist, THIS JOURNAL, 48,2820 (1926).

with an increasing adsorption of the products accompanying a decrease in temperature, less surface will be available for decomposition and that the relation between E and T will be a curve similar to the observed graph, Fig. 6, and not a straight line relation. These results will be published later.

The author wishes to express his appreciation to Dr. F. G. Cottrell, Director of the Laboratory, for suggestions and encouragement in this work; to Dr. E. D. Crittenden for valuable assistance in the early stages of the work; to Dr. P. H. Emmett for criticisms of this paper; to Mr. E. S. Lamar for assistance in the experimental work, and especially to Mr. R. A. Nelson for construction of apparatus and assistance throughout these studies.

Summary

The decomposition of ammonia on catalyst surfaces coated on platinum has been investigated and the results have been expressed and interpreted in terms of Arrhenius' equation. The data show that both the A and the E constants vary with temperature for a given catalyst.

The order of the reaction is not a simple one, on account of the retarding effect of hydrogen. The effect of hydrogen varies with the temperature of the catalyst, being small at the higher temperatures but large at the lower temperatures. Nitrogen has no appreciable effect on the rate.

The value of E as determined from the temperature coefficient varies from about 50,000 at the lower temperatures to 20,000 at the higher temperatures.

The effect of a promoter, poison or heat treatment of the surface is to displace the activity curve toward a lower or higher temperature, respectively, without any appreciable change in the form of the curve.

A summary of all of the surfaces tested shows that not only is the metal or mixture important, but of equal or more importance is the method of preparation of the catalyst surface and the heat treatment of the surface.

The results obtained indicate that no simple or easily interpretable meaning can be given to A or E, whereby the exact role played by the catalyst can be determined.

Tests are now in progress, the results of which promise to permit of a rigorous kinetic treatment.

THE THERMODYNAMIC ACTIVITIES OF THE PROTEINS

BY G. S. ADAIR[1]

RECEIVED SEPTEMBER 4, 1928 PUBLISHED MARCH 6, 1929

I. Introduction

In solutions of finite concentrations the osmotic pressures of protein salts may be very different from the values predicted by the ideal solution laws.[2] This paper is concerned with the derivation of formulas correlating the thermodynamic activities of protein salts with the measurements of osmotic pressure and the practical application of these formulas to a salt of hemoglobin.

The empirical formula for a salt like the sodium hemoglobinate, $HbNa_n$, includes a number, n, which is not an integer, because it represents the average number of sodium atoms combined with a protein molecule, in a system in which the number of atoms combined with individual protein molecules may have a wide range of variation. The average value of n is a variable ranging from 0 to 80 in accordance with variations in the activities of sodium and hydroxyl ions.

In certain respects there is a close resemblance between protein salts and typical strong electrolytes, but the theoretical and experimental treatment of the activities of protein salts is modified by the condition that n is neither an integer nor a constant independent of the concentrations of diffusible electrolytes.

II. Thermodynamical Relationship between the Osmotic Pressures and the Average Values of the Potentials and Activities of Protein Salts

The activity or effective concentration of a protein salt is here defined by Formula 1.

$$\mu_{ps} = RT \ln a_{ps} + K_1 \tag{1}$$

K_1 = a constant, defined by the convention that the activity equals the concentration in very dilute solutions. μ_{ps} = the "average value" of potential of the protein salt per gram mole, at the temperature T and the pressure P. a_{ps} = the "activity" of the protein salt, defined by this formula, and is the antilogarithm of the "average value" of $\ln a_{ps}$ in the assemblage of salts represented by an empirical formula of the type $HbNa_n$.

It is well known that the potential or activity of a single substance can be determined by the application of Gibbs' equations[3] (Lewis and Randall[4])

---

and under certain conditions, discussed below, it is possible to determine the average value of the potential, μ_{ps}, by the application of Equation 2, a restatement of Gibbs' equation numbered 97.

$$VdP = \eta dT + m_{ps}d\mu_{ps} + m_1 d\mu_1 + m_2 d\mu_2 \ldots + m_n d\mu_n \qquad (2)$$

V = the volume of the solution; P = the hydrostatic pressure. η = the entropy of the system; T = the absolute temperature; m_{ps} = mass of the protein salt in gram moles in the volume V; m_1 = the mass of water in gram moles; m_2, m_n, denote the masses of other crystalloids; μ_1 = the potential of water; and μ_2, μ_n = the potentials of other crystalloids.

The conditions that the protein system must be stable and that the protein itself must be equivalent to one component can be realized in solutions of hemoglobin at 0°.[2] The protein system, however, differs from an aqueous solution of a typical strong electrolyte in that the presence of a third component such as sodium hydroxide is a condition for the existence of a salt like sodium hemoglobinate. In this work the number of diffusible components has been increased to four by the addition of phosphate mixtures, in order to maintain the protein salt at well-defined hydrogen-ion concentrations.

The practical application of Gibbs' formula is simplified if some of the variables are kept constant, so that their differentials can be omitted, as stated in Formulas 3 and 4 below.

$$m_{ps}d\mu_{ps} = -m_1 d\mu_1 - m_2 d\mu_2 \ldots\ldots - m_n d\mu_n \qquad (3)$$

μ_{ps} symbolizes the potential of the protein in systems where T, P and m_1, m_2, m_n are constants and m_{ps} is varied.

In the protein systems considered in this work the degree of accuracy obtained in measurements of osmotic pressure is much greater than the accuracy attainable in the measurements of the potentials of the diffusible substances, and therefore the calculations of μ_{ps} have been made by Formula 5 (derived from Formula 4 below) rather than the well-known and theoretically more accurate Formula **3.**

The function $(\mu_{ps})_\mu$ defined by Formula 4 differs from μ_{ps} because it refers to conditions where T, μ_1, μ_2, μ_n are constant and the hydrostatic pressure **P** is a variable.

$$m_{ps}d(\mu_{ps})_\mu = VdP = Vdp \qquad (4)$$

In the experiments described below the potentials of the crystalloids have been kept constant by the equilibration of the protein solutions in collodion membranes with a standard solution of crystalloids in which the temperature, the hydrostatic pressure P'' and the composition have been kept constant. Gibbs' equation for membrane equilibrium (No. 77) shows that μ_1, μ_2, μ_n are then constant in the protein solutions, as they are constant in the standard solution or "outer fluid."

p = the observed osmotic pressure is here defined as the pressure difference $P - P''$, measured with a membrane permeable by all the crystalloids but impermeable by protein, under conditions where the protein concentration is varied, T and μ_1, μ_2, μ_n are constants and P'' is equal to 1 atmosphere.[5]

Since the function $(\mu_{ps})_\mu$ refers to a special set of conditions, the results calculated by Formula 4 require correction before they can be compared with the observations on solutions of crystalloids published by previous workers.

In general this correction is complicated by the fact that the "solvent" is not a pure substance but a mixture with three or more components. In the protein systems considered below m_{ps} is relatively small and it appears that a correction which is accurate enough for the purpose of this work can be obtained by assuming that $d(\mu_{ps})_\mu$ is equal to $(\partial\mu_{ps}/\partial P)dp + d\mu_{ps}$.

It is known that the effect of hydrostatic pressure on the potential of a component is represented by an equation of the form $(\partial\mu_{ps}/\partial P) = \bar{v}_{ps}$, where $\bar{v}_{ps}$ is the partial specific volume of the protein salt per gram mole, and it follows that μ_{ps} at a constant hydrostatic pressure is determined by Formula 5.

$$m_{ps}d\mu_{ps} = Vdp - m_{ps}\bar{v}_{ps}dp \tag{5}$$

The determination of the conditions under which the simple Formula 5 is equivalent to Formula 3 is facilitated by the consideration of the "corrected osmotic pressure $(P - P'')$ P where the protein solution is at a constant pressure, P, and the "outer fluid" is at a pressure P'' less than one atmosphere.

It will be assumed that under these conditions the protein solution can be composed of two mixtures, each of which is of constant composition. The composition of the first mixture, designated the "solvent," is the same as the composition of the fluid outside the membrane. The second mixture, designated the "protein salt," includes the pure protein and a certain proportion of the crystalloids that are present in excess inside the membrane.

If these two mixtures of constant composition are treated as the components of the system, a formula for μ_{ps} in terms of μ_x', the potential of the "solvent," can be obtained by the application of Equation 3 as stated in Formula 6. The theory of membrane equilibrium shows that $\mu_x' = \mu_x''$, the potential of the "solvent" in the outer fluid, and by Formula 2 $\mu_x'' = v_x''dP''$, where v_x'' is equal to the volume of one mole of the mixture in the outer fluid at the pressure P''. The corrected osmotic pressure can then be correlated with $d\mu_x'$ and $d\mu_{ps}$ by Formula 6.

$$m_{ps}d\mu_{ps} = - m_x'd\mu_x' = + m_x'[v_x''d(P - P'')_P] \tag{6}$$

---

[5] p is very much smaller than the osmotic pressure measured by a membrane permeable by water only (sympolized π in Formula 11). The relationship between π and the activity of a colloid in an aqueous solution has been worked out by Linderström-Lang, *Compt. rend. Lab. Carlsberg*, **16** (1926).

m'_x = gram moles of "solvent" in the solution containing m_{ps} gram moles of protein.

Experimental evidence given below indicates that the observed and the corrected osmotic pressures are in close agreement, and it follows that Formulas 5 and 6 are equivalent to the simplified Formula 7.

$$v_s dp = (V' - \bar{v}_{ps})dp = d\mu_{ps} = RT\,d \ln a, \tag{7}$$

v_s = liters of solvent per mole of protein. $V' = V/m_{ps}$ = liters of solution per mole of protein.

A formula for the potentials and activities of protein ions (No. 8) can be obtained by the application of Formula **2** to a system in which the individual ions are treated as components. In the case of the sodium proteinate, $HbNa_n$, it is simpler to replace d ln *a*„ in Formula *7* by the equivalent expression d ln *a*, + n d ln a_{Na}, derived from Formula **12.** Since $n = -n_p$, where n_p is the average valence of the protein ions, Formula **13** shows that $n \, d \ln a_{Na} = (n_p F/RT)dE$, where E = the membrane potential.

In the derivation of Formula 8 below, a small correction for the effects of pressure on the activities of the diffusible ions has been omitted

$$v_s dp = d\mu_{ps} = d\mu_p + n_p F dE = RT\,d \ln a, + n_p F dE \tag{8}$$

μ_p = average value of the potential of the protein ions; *a*, = (logarithmic) mean value of the activity of the protein ions; *n*, = mean valence of protein ions, defined as the equivalent cencentration divided by the molar concentration.

III. Definitions of the Standard State of a Protein Salt and the Functions *a*„ and *a*,

Relative values of the potentials and activities can be calculated by integrating Equations 7 and 8, as stated in Formulas **9** and **10,** on the assumption that the composition of the protein salt is constant over the range of osmotic pressure from p° to p'. Experimental evidence concerning the degree of accuracy of this assumption is referred to below.

$$\int_{p^\circ}^{p'} v_s dp = \mu'_{ps} - \mu^\circ_{ps} = RT \ln a'_{ps} - RT \ln a^\circ_{ps} \tag{9}$$

$$\int_{p^\circ}^{p'} v_s dp = \mu'_p - n_p FE' - \mu^\circ_p - n_p FE^\circ \tag{10}$$

There are two conventional definitions of the "standard state" of the protein salt that must be considered in fixing the absolute values of the activities by Formulas **9** and **10.**

The "Hypothetical Standard State" is a very dilute solution of the protein salt in the absence of diffusible crystalloids. The theoretical osmotic pressure of such a salt is given by Formula 11.

$$\pi = (1 + n)C_p RT \tag{11}$$

C_p is the molar concentration and n the number of sodium atoms in the salt $HbNa_n$. With this definition of the standard state, the activity of the protein salt is comparable with the activity of typical strong electrolytes and the following formula may be applied.

$$(a_{ps})_w = (a_p)_w \, a^n_{Na} \qquad (12)$$

(a,,), and *(a,),* denote the activities of the protein salt and the protein ion referred to the hypothetical standard state. These activities cannot be determined by direct methods because the protein salt cannot exist in the theoretical standard state. Indirect methods of estimating these activities and a function f_0 referred to below will be discussed in a later paper. a_{Na}, the activity of sodium ions, can be calculated from measurements of the membrane potential by Formula[6] **13** below, as described in a previous paper.[2]

$$\ln a'_i = \ln a''_i - n_i FE/RT \qquad (13)$$

a'_i = the activity of any diffusible ion (of valence n_i) in the protein solution. a''_i = the activity of this ion in the solution of crystalloids in diffusion equilibrium with the protein solution.

In this case a''_i = a constant and it follows that $d \ln a_{Na} = -(n_i F/RT)dE$.

The "Experimental Standard State" is a very dilute solution of the protein in diiusion equilibrium with the standard solution of crystalloids. The osmotic pressure, p, approaches the value C_pRT rather than $(1 + n)C_pRT$ under these conditions, as shown by the observations in Table I. The symbols a„ and *a,* denote activities calculated on assumption that a„ is equal to the protein concentration in the experimental standard state. The application of Formula 10 shows that a„ and a, are related by Formula 14

$$a_{ps} = a_p e^{n_p u} \qquad (14)$$

$u = EF/RT$, where E is the membrane potential; e = *2.718; a,* = the logarithmic mean value of the activity of the protein ions referred to the experimental standard state. In calculations of *a,* at 0°, from the data given below, Formula 14 can be replaced by 14a.

$$\log a„ = \log a, + n_pFE/2.303RT = \log a, + n_pE/0.0542 \qquad (14a)$$

The relationships between *a,* and a„ and the activities referred to the hypothetical standard state are given below. *(1)* d ln *a,* is equal to d In *(a,)„* and therefore *(a,),* is equal to f_0 a„ here f_0 is an undetermined integration constant. (2) The application of Formula **13** shows that $a_{Na} = a''_{Na}e^{-u}$, and it follows that *(a,,),* $= f_0(a''_{Na})^n a_{ps}$.

The experimental investigations recorded below refer to the functions a„ and a,. The determination of f_0 and *(a,,),* with the assistance of solubility measurements may be considered, but the thermodynamic treatment of solubility measurements must be postponed, because the

---

[6] F. G. Donnan and J. H. Allmand, J. Chem. *Soc.,* **105, 1941 (1914).**

composition of the crystalline phase is not a constant but a function of the concentrations of diffusible electrolytes.[7]

IV. Experimental Investigations

Five groups of measurements are required for the application of the thermodynamic formulas for the activities of protein salts and protein ions.

1. A series of measurements of osmotic pressures and volumes under conditions where the potentials of the crystalloids are nearly constant, supplemented by measurements of the temperature, the pressure and the composition of the solution of crystalloids in diffusion equilibrium with the protein solution.

2. A series of measurements of the effects of the temperature, pressure and the concentrations of the crystalloids on the osmotic pressure at a constant protein concentration. These observations are required to reduce the observed pressures under slightly different conditions to those corresponding to the theoretical standard state in which the potentials of the crystalloids are absolutely constant.

3. Measurements of the magnitude of the error introduced by the assumption that the average composition of the protein salt is independent of the protein concentration under conditions where the potentials of the crystalloids are constant. In the system considered in this work the error due to this assumption appears to be relatively small.

4. Measurements of the partial specific volumes of "solvent" and solute are required in calculations of activities at a constant hydrostatic pressure.

5. Measurements of membrane potentials and the valences of protein ions are required in calculations of the activity of the protein ion.

The subsidiary investigations 2–5 are not quite complete and the numerical values of the activities given in this paper are provisional.

1. Measurements of Osmotic Pressure.—A critical study of the direct method of measuring the osmotic pressure of hemoglobin with collodion membranes permeable by water and salts but impermeable by the protein has been given in a previous paper.[8]

This method has been applied for the purpose of determining the relationship between osmotic pressure and protein concentration under conditions where the potentials of the crystalloids are practically constant.

Collodion sacs containing about 15 cc. of hemoglobin solution have been equilibrated with relatively large volumes of the "Standard Solution" of phosphates, specified in Table I. The results of 32 measurements of the osmotic pressure of hemoglobin in equilibrium with this standard solution have been published in the tables and curves given in a previous

[8] G. S. Adair, *Proc. Roy. Soc. London,* **108A,** 627 (1925).

paper.[2] Calculations of the "osmotic coefficients" for six of these observations are recorded in Table I. In dilute solutions the observed osmotic pressures approach the theoretical values given by van't Hoff's law stated in the form

$$p = C_pRT \tag{15}$$

$C_p = C_{Pr}$, in grams of dry protein, divided by 68,000, where 68,000 ± 2,000 is the molecular weight of sheep's hemoglobin expressed in grams of protein dried at 103°.[9]

TABLE I

OSMOTIC PRESSURES OF A SALT OF HEMOGLOBIN DESIGNATED[a] $Hb(Na + K)_{8.5}$

Conditions: the potentials of the crystalloids have been kept constant by the equilibration of the protein solutions with a standard phosphate mixture containing 0.1 mole of KCl, 0.0613 mole of Na_2HPO_4 and 0.00533 mole of KH_2PO_4 per liter of solution. The temperature of the standard solution is 0° and the hydrostatic pressure is 760 mm. p = observed osmotic pressure in mm. of mercury at 0°. $RT = 22.41 \times 760 = 17{,}033$ at 0°.

Hb per liter of soln., g. C_{Pr}	Hb per liter of soln., mole C_p	Osmotic press., obs., p	Osmotic press., theoretical RTC_p	Osmotic coeff., p/RTC_p
22	0.00032	6.15	5.5	1.11
80	.00118	28.2	20.0	1.42
200	.00294	110.9	50.1	2.21
240	.00353	155.0	60.1	2.58
290	.00426	264.6	72.6	3.64
344	.00506	382.8	86.1	4.44

[a] The formula $Hb(Na + K)_{8.5}$ is provisional. A discussion of the complete formula for the protein salt as it exists in the solution will be given at a later date. The number of Na + K atoms combined with hemoglobin in blood is approximately the same as the number in the salt considered in this paper.

2. Corrections for Deviations from the Standard State.—The actual conditions in different experiments recorded in Table I did not correspond exactly with the theoretical standard state, namely, a solution of reduced hemoglobin in equilibrium with a solution containing 0.1 mole of KCl, 0.0613 mole of Na_2HPO_4 and 0.00533 mole of KH_2PO_4 at 0° and 760 mm.

The effects of different variables at a protein concentration (about 190 g. per liter) which gives a pressure of 100 mm. in the standard state have been summarized below.

(i) An increase in temperature from 0 to 1.0° raises the osmotic pressure from 100 mm. to 100.36 mm.

(ii) An increase in the barometric pressure from 760 to 775 increases the osmotic pressure from 100.0 to about 100.02 mm.

(iii) An increase of 10% in the total concentration of crystalloids diminishes the osmotic pressure from 100.0 mm. to 99.6 mm.

(iv) An increase in the hydrogen-ion concentration due to carbon dioxide which

---

[9] G. S. Adair, *Proc. Camb. Phil. Soc. Biol.*, *1*, 75 (1924); *Proc. Roy. Soc. London*, **109A**, 292 (1925); T. Svedberg and R. Fåhraeus, THIS JOURNAL, 48, 430 (1926); T. Svedberg and J. B. Nichols, *ibid.*, 49, 2920 (1927).

corresponds with a change in PH from 7.80 to 7.60 diminishes the pressure from 100.0 mm. to 99 mm.

(v) The oxygenation of the hemoglobin and the formation of met-hemoglobin cause relatively little change in the observed osmotic pressure.

The variations considered above are greater than any that have been observed in the experiments included in Table I.[2] It seems probable that the observed pressures are within about 2% of the corrected pressures for the theoretical standard state.

3. The Effects of Variations in **the** Average Composition of the Protein Salts.—In practice it is impossible to alter the total concentration of a protein without altering some of the conditions which determine the proportions of individual protein salts and the average compositions of the mixture.

If the concentration of a protein salt is increased at a constant hydrogen-ion concentration, there is an alteration in the interionic attractions which tends to increase n, the average number of atoms of sodium in a salt like sodium hemoglobinate.[10]

If the concentration of the sodium hemoglobinate is increased under conditions where the potentials of the crystalloids are constant, there is an increase in a_{H}, the activity of hydrogen ions, (Table II) or a diminution in PH (= $-\log a_{\mathrm{H}}$) which tends to diminish the value of n by approximately 10 units for a diminution of 1 unit in the PH. This estimate is based on the observations of Van Slyke and other workers, referred to in a previous paper.?

The range of variation in PH from 7.80 to 7.77 (shown in Table II) diminishes n from about 8.5 to 8.2, and it seems unlikely that this change is exactly balanced by the effects of interionic forces.

It has been stated that Formulas 9 and 10 are not valid if n is not a constant, and therefore it is necessary to consider the error due to a variation in n. In the previous section it has been pointed out that a variation in the hydrogen-ion concentration from PH 7.8–7.6 alters the osmotic pressure p by about 1%, and therefore it appears that the variation in n caused by a much smaller change in hydrogen-ion concentration cannot have any great effect on the pressure p or the function a,,, which is defined in terms of osmotic pressures. The absolute value of n does not enter into the formula for a,,. In the case of the function (a,,),, which is equal to $(a_{\mathrm{p}})_w a_{\mathrm{Na}}^n$, the absolute value of n and the effects of slight variations in n are of much greater significance.

4. The Partial Specific Volumes of the Solvent and the Protein.—v_x'' = the volume of 1 mole of the standard solution (Table I). $\bar{v}_x$ = the "partial specific volume" of 1 mole of this mixture in the protein solution. $\bar{v}_{\mathrm{ps}}$ = the partial specific volume of 1 mole of the hemoglobin.

Preliminary investigations show that the ratio $\bar{v}_x/v_x''$ varies from 0.9998

---

[10] S. P. L. Sörensen, K. Linderström-Lang and E. Lund, J. *Gen. Physiol.*, **8**, 543 (1927).

at low protein concentrations to 0.999 at higher concentrations. The application of the formula[11] $(\partial p/\partial P) = (1 - \bar{v}_x/\bar{v}''_x)$ shows that the observed osmotic pressure, p, is not appreciably different from the theoretical pressure $(P - P'')_P$ in Formula 6.

The measurement of $\bar{v}_{ps}$ is more difficult because the protein cannot be dried without irreversible changes. As a first approximation it appears that $\bar{v}_{ps}$ is about 65 liters.[2]

5. The Membrane Potentials of the Protein Solutions.—A table of measurements of membrane potentials with saturated calomel electrodes has been given in a previous paper.[2] Calculations based on six of these observations recorded in Table II show that the simple empirical formula No. 16, agrees with the observed results within the limits of experimental error

$$E = -0.24\, m_p \tag{16}$$

m_p = moles of protein per liter of solvent $= C_p/(1 - 65\, C_p)$.

TABLE II

.00353	.0046	−1.05	−1.10	7.781
.00426	.0059	−1.45	−1.42	7.773
.00506	.0075	−1.98	−1.80	7.764

6. The Mean Valence of Protein Ions.—The mean valence of the protein ions is equal to the "equivalent concentration" of the protein divided by its molar concentration. This equivalent concentration must be equal to the difference between the equivalent concentrations of diffusible anions and cations that exist in the free state, uncombined with protein.

The concentrations of the free ions in the solution of strong electrolytes outside the membrane can be determined (Table I) and a provisional estimate of their concentrations in the protein solution can be obtained by applying Donnan's formula (13) to the membrane potentials recorded in Table II. It appears that $n_p = -5.9/f_e$, where f_e is a constant which is equal to unity if the concentrations of the ions are equal to their activities. If $f_e = 0.7$, then $n_p = -8.5$. The figure −8.5 has been adopted in the provisional calculations recorded in Table III. A revision of these calculations will be published when n_p has been determined by more accurate methods.

V. The Activity Coefficients of a Salt of Hemoglobin and its Ions

The activities of protein salts referred to the experimental standard state are different from the activities referred to a hypothetical solution of the protein salt in water, and therefore Formulas 17 and 18, which define the coefficients f_{ps} and f_p, are different from the conventional definitions of the activity coefficients of strong electrolytes.

$$RT \ln f_{ps}m_p = RT \ln a,. = \int v_s \mathrm{d}p + \text{constant} \quad (17)$$

m_p = gram moles of protein salt per liter of solvent and $f_{ps} = a_{ps}/m_p$ is a coefficient which approached unity at low protein concentrations, as shown in Table III. The integration constant is determined by this condition and by the condition that p approaches RTm_p when m_p is very small.

The chief diierence between f_{ps} and the activity of a typical strong electrolyte is due to the application of this formula rather than Formula No. 11, $a = (1 + n)C_pRT$. The function f_{ps} is not useful in comparisons of the properties of protein salts and crystalloids, but it is of importance as a step in the calculations off,, the activity coefficient of the protein ion, and in the treatment of the equilibrium of protein salts in gravitational fields of force, a subject which will be discussed in a subsequent communication.

The activity coefficient f_p defined by the formula $f_p = a_p/m_p$ can be calculated by Formula 14a, or Formula 18 given below.

$$m_pf_{ps} = m_pf_pe^{n_pw} \quad (18)$$

Since $(a,)$, is equal to f_0a_p, where f_0 is an indetermined constant, the product f_0f_p is comparable with the activity coefficient of an ion defined by the formulas of Lewis and Randall, although the resemblance is not quite exact, because f_0f_p is an "average value" and n_p is an average valence.

The results recorded in Table III show that the function f_p increases as the protein concentration increases. An increase in the partial osmotic pressure of the protein ions under these conditions has been referred to in a previous paper.'

A discussion of the kinetic significance of the rise in the activity coefficient is not permissible in a purely thermodynamical treatment of osmotic pressures and activities but there are one or two points which are of interest in connection with the application of the interionic attraction theory of Debye and Hückel to protein ions.

The absolute values of f_p increase as the protein concentration increases, a variation in the opposite direction to that predicted by the theory. **If,** however, the increase in f_p is compared with the increase in f_{pi}, the activity coefficient **of** the isoelectric protein, it appears that the "relative activity coefficient" (f_p/f_{pi})[12] diminishes from 1.0 to 0.8 as the protein concentra-

---

[12] **The ratio (f_p/f_{pi}) has been referred to in a preliminary note on the activity of protein ions,** Adair, *Trans. Faraday Soc.*, *23,* **536** (1927).

tion increases from 0.0 to 0.004, and in this respect the protein salt resembles a typical strong electrolyte.

TABLE III

THE ACTIVITY COEFFICIENTS OF A SALT OF HEMOGLOBIN AND ITS IONS

Conditions: temperature, 0°; pressure, 760 mm.; composition of "solvent," 0.10 mole of KCl, 0.0613 mole of Na_2HPO_4, 0.00533 mole of KH_2PO_4 per liter. Composition of protein salt, Hb $(Na + K)_{8.5}$. Valence of protein ion, $n_p = -8.5$. The membrane potential factor (Formula 14) is calculated from data given in Table II. The activity coefficients of the sodium and potassium ions are approximately equal to 0.7.

Hb per liter of solvent, mole, m_p	Act. of protein salt,[a] a_{ps}	Membrane potential factor, $e^{n_p w}$	Act. coeff. of salt, f_{ps}	Act. coeff. of ion, f_p
0.0002	0.0002	1.02	1.05	1.03
.0010	.0014	1.09	1.40	1.3
.0020	.0040	1.20	2.0	1.7
.0030	.0090	1.30	3.0	2.3
.0040	,0200	1.40	5.0	3.6

[a] The determination of a,, by the evaluation of the integral in Formula 17 may be facilitated by application of the empirical formulas discussed in a previous paper.[2] In dilute solutions the formula $p(v_s - b) = RT$ can be applied and by integration RT ln a,, $= \int v_s dp = RT$ In $p + bp$. Over the range of pressures from 12 to 120 mm., a formula with two empirical constants can be applied, $p(v_s - 107.5) = 1.09$ RT.

Conclusions

Under certain conditions the salt of a protein such as a sodium hemoglobinate is equivalent to one component, although the variations in the average composition of the salt caused by alterations in the activities of diffusible acids and bases prove that the sodium hemoglobinate is a mixture of a great number of individual protein salts.

The conditions for the application of Gibbs' equations to determine the "average values" of the potentials and activities of protein salts have been considered and the following formula has been obtained.

$$RT \text{ In } a, = RT \text{ In } a_p e^{n_p w} = \int_{p^\circ}^{p} v_s dp + \text{constant}$$

ln a,, and ln a_p denote the logarithmic mean values of the activities of the protein salt and protein ion; n_p = the average valence of the protein ion; u $= EF/RT$, where E = the membrane potential; v_s = the volume of "solvent"—(a mixture) per gram mole of protein; p = the osmotic pressure measured with a collodion membrane under conditions where the potentials of the diffusible salts are kept constant by the equilibration of the protein with a standard solution of crystalloids at a constant pressure and temperature.

The integration constant is determined by the convention that a,, is equal to the protein concentration in a very dilute solution in equilibrium with the standard solution of crystalloids. The relationship between a,, and the activities of typical strong electrolytes has been formulated.

The activity of a salt of hemoglobin has been investigated by experiment in order to determine the degree of accuracy in the assumptions that have been made in the thermodynamical treatment of a salt of variable composition in a system of many components.

SPECIFIC HEATS OF SODIUM AND POTASSIUM HYDROXIDE SOLUTIONS[1]

BY THEODORE W. RICHARDS AND LAWRENCE P. HALL

RECEIVED SEPTEMBER 18, 1928 PUBLISHED MARCH 6, 1929

In a previous publication[2] from this Laboratory it was pointed out that a serious discrepancy existed between the value then found for the specific heat of $NaOH\cdot 25H_2O$ and earlier values. Since this datum was to be made the basis for the specific heats of other solutions, heats of dilution, heats of neutralization, etc., the new and higher value demanded confirmation.[3] Hence part of the work was repeated with even greater care, especially studying possible sources of error and inaugurating a few slight modifications and improvements in procedure. The outcome was in general essentially in accord with the work of Richards and Gucker, as will be shown.[4]

Procedure with Modifications

The twin calorimeter system used previously was rebuilt in essentially the same form as described on pp. 1878–1881 of ref. 2. Standardization of new thermocouples showed a sensitivity of 0.000340" per mm. of scale reading for the larger thermocouple and 0.000527° per mm. for the smaller ones. Slight changes in the apparatus made it necessary to redetermine the water equivalent. Later it was found advisable to use a smaller amount of liquid in each can to avoid errors from splashing or spilling in assembling and handling the apparatus.

The chief causes of minor variations were found in maintenance of adiabatic conditions at all times and in trouble from unequal evaporation from the calorimeter cans, one containing water and the other solutions. The former difficulty was in part eliminated by trying out and adjusting

---

[1] On account of the death of Professor Richards on April 2, 1928, the work here described was completed and the manuscript prepared by the junior author.

[2] Richards and Gucker, THIS JOURNAL, 47,1876 (1925).

[3] Earlier records present a bewildering variety of specific heat values for sodium hydroxide solutions, particularly for the more concentrated ones. Richards and Rowe, [THIS JOURNAL, 43, 770 (1921)] took 0.855 for $NaOH\cdot 10H_2O$—choosing from among old values ranging all the way from 0.84 to 0.89. It will be shown that this choice, although perhaps the best possible at the time, was much too low in value.

[4] **Ref.** *2* and the following paper in this series.

the heaters before the experiment, and for this purpose the solutions were put in at a temperature below that at which the experiment proper was to begin. The calorimetric system was then warmed to nearly 16° and during this period of heating the controls were so adjusted that conditions could be kept continuously adiabatic during the measured rise in temperature from 16 to 20". The fore and after drifts were measured as before.

Some variation in adiabatic conditions arose because the small thermels in the outer bath were sensitive to the radiations from the heating lamps. The use of the two 40-watt lamps was discontinued. Also, the thermocouples were placed so that they were shielded from direct radiation of the carbon lamps.

The errors from evaporation have been discussed[5] and likewise methods for their prevention and control. Paper collars were again used. However, from careful observation it appeared that closed calorimeter cans, with the minimum of air space above the solution and water, would be necessary to prevent this source of error.[6]

With conditions exactly adiabatic, unequal evaporation occurred in the two calorimeter cans, due in part to an adsorption effect on the inner surface of the submarine covers. Also it was found on exploration with sensitive thermometers that the surface of the outer bath, on account of evaporation into the room, could become slightly cooler than the bulk of the bath, thereby cooling the submarine lids and encouraging condensation. Since it was not practicable to cover this bath, as has often been done in this Laboratory, the amount of water was increased and the stirrer adjusted so that it drew water more rapidly from below.

Evaporation difficulties were further diminished by keeping the temperature of the outer bath slightly higher than formerly. At 16° with a thermal head of $+0.005$ to $+0.007°$ very little change in the temperature of the calorimetric system itself occurred in the fore period, during which the drift was found to be smaller and more regular. Similar benefits resulted from gradually increasing the thermal head during the course of the heating to a final value of $+0.007°$. Such a positive head would not appreciably influence the temperature of either calorimeter. It was found that when the temperature of either or both of the calorimeters was above that of the bath, peculiar and erratic drifts were obtained. For this reason another slight change in procedure was made when it so happened that a difference in temperature between the water and solution resulted during the heating period. Instead of holding the outside bath at the average temperature of the two cans, it was kept at least as warm as the warmer can. In this way the drifts were made more uniform without introducing any serious error from thermal leakage.

Purification of Sodium Hydroxide

Except for these minor modifications, the experiments were performed in much the same way as described by Richards and Gucker.[2] The sodium hydroxide solutions were prepared as before, except that after crystallization of the hydroxide in platinum and separation of the insoluble sodium carbonate, a small amount of barium hydroxide solution, freshly prepared from recrystallized material, was carefully added to remove the last trace of carbonate. Any excess of barium was not desired. However, on some occasions when a slight trace was found, it was removed with a trace of sulfuric acid.[7]

The solutions thus prepared were apparently free from sulfate, barium, carbonate and chloride. It was later found that a slight amount of potassium was present, amounting (in the case of the solution used in the present work for the specific heat of $NaOH \cdot 25H_2O$) to between 0.1 and 0.2% of potassium (compared with the sodium present). This result was attained by difference through analysis as sulfate and hydroxide, and by direct comparison with similar amounts of precipitate produced with sodium cobalti-nitrite with known standards of similar composition.

In commercially "pure" samples of sodium hydroxide similar to that used for crystallization, sometimes as much as 0.3% of potassium was found; this impurity was reduced to about 0.1% by one crystallization. After a second recrystallization (as in the case of the solution $NaOH \cdot 101H_2O$) no test for potassium could be obtained.[8]

In the first experiments the $NaOH \cdot 25H_2O$ solution was analyzed for caustic alkali, exactly as had been done before, by determining the weight of dried sodium chloride made from it. However, it was found that this method, as it had been carried out in the earlier work,[9] did not give the exact concentration of the solution, in spite of the agreement of the analyses. For this reason the first values obtained in confirmation of the new specific heat were discarded. The solution finally used for $NaOH \cdot 25H_2O$ was standardized not only by sodium chloride and sodium sulfate residues but also by titration with weight burets against hydrochloric acid standardized by silver chloride determinations.[10]

---

[7] *Cf.* Richards and Rowe, ***Proc. Am. Acad.,*** 49,183 (1913).

[8] The manufacturers reported that the potassium content varies from lot to lot and falls between 0.3 and 0.5% for the "c. P." material.

[9] *Cf.* ref. 2, p. 1883.

[10] The method of determining sodium as a chloride residue was investigated to find the error introduced by the retention of water. Some time ago attention was called to the difficulty of obtaining dry salts, especially anhydrous crystals [T. W. Richards, ***Proc. Am. Phil. Soc., 42, 28*** (1903)]. Sodium chloride crystals are notorious for their decrepitation on drying, a phenomenon depending on the bursting forth of included mother liquor.

In order to follow its behavior, a really anhydrous salt was prepared as the starting point. Pure sodium chloride, previously pulverized and dried in an oven, was fused in a covered platinum dish. The material thus obtained was neutral to phenolphthalein, methyl orange and methyl red. Weighed samples of this fused salt were dissolved and the solution evaporated in flasks in an oven at 100°, exactly as in the earlier analysis of sodium hydroxide by sodium chloride residue. Crystals about one cubic millimeter were formed. These gave an apparently constant weight after a few hours' heating at 150°. However, the salt thus dried without fusion was found to weigh 0.66 to 0.80% more than the really anhydrous substance (average 0.73%). The following modification

Analysis of $NaOH\cdot 25H_2O$ by evaporation as chloride showed the water content per mole to be 25.03 H_2O (the average of two analyses); by evaporation and fusion as sulfate, 25.06, 25.08, 25.07, average 25.07 H_2O; by titration with standard acid 25.08, 25.08, 25.09, average 25.08 H_2O.

The calorimetric experiment consisted in finding the weight of solution which showed exactly the same temperature rise as a given weight of water, when precisely the same quantity of heat was added.[11] A new "water equivalent" or weight of water fitting the conditions was determined as 556.42 g. of water at 18.00°, which corrected to vacuum was 557.01 g. in vacuo, as the average of six experiments. The "balancing weight," or thermally equivalent weight of $NaOH\cdot 25.08H_2O$ was 610.21 g. in vacuo, the average of five experiments (609.61, 609.61, 609.49, 609.72 and 609.67 g. in air) at the average temperature of 18.02". By use of the temperature coefficient determined by Richards and Gucker, the specific heat at 18.00' is calculated as 0.91280 for $NaOH\cdot 25.08H_2O$. This value may be accurately corrected to $NaOH\cdot 25.00H_2O$ by determining the value for the temperature coefficient for a dilution by a single molecule of water and by using the proper fraction of this value in Kirchhoff's Law.[12]

The specific heat of $NaOH\cdot 25.00H_2O$ then appears as 0.91262, to which should be added 0.00002 as the correction for cooling due to difference in evaporation of $NaOH\cdot 25H_2O$ solution and water, yielding 0.91264. One further small correction, that for the difference in heat capacity due to the trace of potassium, may be approximated by taking 0.15% (the approximate potassium content) of the difference in specific heats of sodium and potassium hydroxide solutions at this dilution (0 00007). The value 0.91271 is, therefore, the final value for $NaOH\cdot 25.00H_2O$ at 18.00°.

Besides this determination, a direct determination of the specific heat of $NaOH\cdot 101H_2O$ was made. This determination provided a corroboration of the specific heat values determined indirectly from heats of dilution. Analysis as sodium chloride residue, using the method of evaporation in an oven at 150–160°, showed the concentration of this solution to be $NaOH\cdot 101.08H_2O$.[13]

---

of the sodium chloride method was found to reduce to 0.05% or less the error of the result; it is not to be commended except for its rapidity. Indeed, the good result may be partly due to a compensation of errors. Nothing short of fusion will yield perfectly dry salt. If the sample solution of sodium chloride in a 125-cc. Erlenmeyer flask with anti-spattering bulb (such as is used in evaporating filtrates in flasks) is evaporated in an oven maintained at 150–160°, the salt is left as a powder which can be dried almost completely at 300–310°. As there is danger from spattering, the flask and bulb must be weighed together.

[11] Ref. 2, p. 1888.

[12] *Cf.* later paper for details of this correction.

[13] After this specific heat had been determined, it was found, as discussed in a previous footnote, that this method might produce an error of +0 05% in analysis which would correspond to +0.005% error in specific heat.

In this case the "water equivalent" of 596.01 g. *in vacuo* (average of four experiments) was found to be thermally equivalent to 614.84 g. *in vacuo* of solution (average of four determinations), the specific heat of which was, therefore, 0.96939 at 18.00° Correcting this to $NaOH \cdot 100H_2O$, we obtain 0.96904.

A rough measurement of the specific heat of a solution $NaOH \cdot 50.0H_2O$ also was made. This solution was adequately analyzed both by titration with acid and by evaporating the resulting salt in an oven at 160°, which process gave essentially identical results. The value obtained for the specific heat was 0.946 (507.7 g. of water being equivalent to 536.7 g. of solution). Minor temporary defects in the apparatus, chiefly tending to make the result too low, were experienced but the outcome could hardly be far from the truth.

These values are all essentially consistent with one another and with the heats of dilution found by Richards and Rowe. They are, however, all consistently higher than the final values calculated by these latter experimenters, who unfortunately had based their whole series on an erroneous value for $NaOH \cdot 10H_2O$, taken from older work[14] of others. The recent values are unquestionably far more trustworthy.

Since earlier values for the specific heat of sodium hydroxide solutions had been found to be in error, the question arose as to the correctness of specific heats of other hydroxide solutions. Accordingly, a solution of potassium hydroxide was prepared in a way similar to that used for the sodium hydroxide solutions.

This solution by titration against standardized hydrochloric acid was found to be $KOH \cdot 100H_2O$; by residue as KCl, $KOH \cdot 99.96H_2O$. The unimportant difference between these two results was doubtless chiefly due to water retained by the potassium chloride after rapid evaporation at 160°. Two more standardizations for the "water equivalent" (performed immediately after the $KOH \cdot 100H_2O$ solution had been examined) confirmed the value (found in the similar preceding experiments with $NaOH \cdot 101H_2O$) of 596.01 g. *in vacuo.* As the average of four experiments, 622.97 g. *in vacuo* of $KOH \cdot 100H_2O$ was found to be thermally equivalent. The specific heat of this solution, then, is 0.9567—a value which confirms exactly the early value for this dilute solution found by Richards and Rowe,[15] as well as their value found from heats of dilution.[16] Hence, evidently, the older results for potassium hydroxide were very nearly correct.

The authors take pleasure in acknowledging their indebtedness to the Carnegie Institution of Washington and to an anonymous benefactor of this Laboratory for essential financial assistance in carrying out this research.

Summary

1. Several modifications and improvements made in the differential method for the determination of specific heats are presented.

2. The following values were found for specific heats at 18.00°. $NaOH\cdot 25H_2O$, 0.9127, thus confirming the recent high value found by Richards and Gucker; $NaOH\cdot 50H_2O$, 0.946; $NaOH\cdot 100H_2O$, 0.9690 and $KOH\cdot 100H_2O$, 0.9567.

THE HEATS OF DILUTION OF SODIUM HYDROXIDE, ACETIC ACID AND SODIUM ACETATE, AND THEIR BEARING ON HEAT CAPACITIES AND HEAT OF NEUTRALIZATION[1]

By Theodore W. Richards and Frank T. Gucker, Jr.

Received September 18, 1928 Published March 6, 1929

Introduction

The most convenient and accurate way of studying heats of neutralization at successive concentrations is to determine the heat of neutralization at one concentration and the successive heats of dilution of the factors and products. In previous researches this method has been applied to several strong acids and bases, of which the heat of neutralization was found to *decrease* as the concentration decreased.[2] The present publication presents the first detailed study of an opposite case (acetic acid), in which the heat of neutralization was found to *increase* as the concentration decreased.

Method and Apparatus for Determining Heats of Dilution.—The principles involved in this research are essentially those of the previous dilution experiments.[3] Some differences in experimental detail, however, were applied and the calorimeter was greatly improved. The changes are fully described in the present paper.

The Calorimeter Proper

Figure 1 gives a general idea of the calorimetric apparatus. Two concentric platinum cans were used, the inner, C_2, having half the volume of the outer, C_1. (This assembly was designated Aa by Richards and Rowe.) The inner can always contained the solution and the outer can pure water. The liquids were agitated by two reciprocating stirrers, one, S_2, for the inner can and the other, S_1, for the annular space between the two. A somewhat elaborate mechanism was devised to keep the stirrers rigid (thus

---

[1] On account of the death of Professor Richards on April 2, 1928, the work here described was completed and the manuscript was prepared by the junior author under the general direction of Dr. Lawrence P. Hall.

[3] Richards and Rowe, *ibid.*, 42, 1621 (1920); 43, 770 (1921).

avoiding irregular scraping against the sides of the cans). The stroke could be regulated so as to avoid splashing at the surface and still give the maximum permissible stirring.

The calorimeter proper was enclosed in a "submarine" jacket B, which was in turn submerged in a controllable outer water-bath **A,** described in detail later.

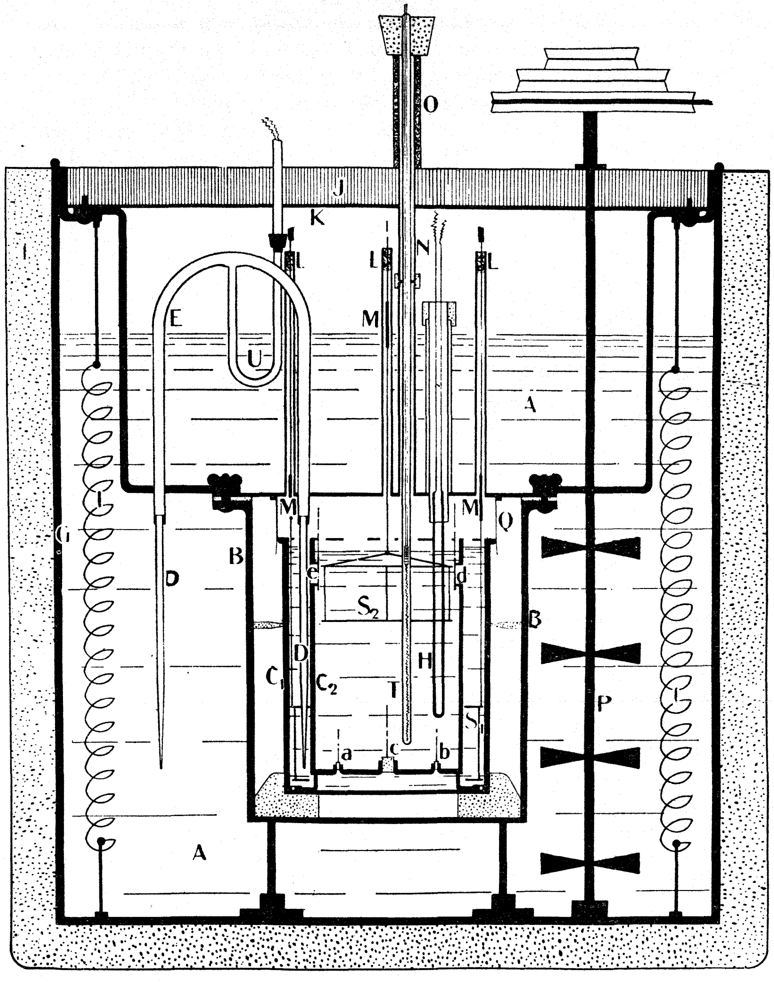

Fig. 1.—Calorimetric apparatus.

Valves between the Concentric Cans.—By opening five valves of different sizes in the inner can, C_2, its liquid could be mixed with that in C_1. The lower valves, a, b, were small platinum plugs, while the upper ones, d, e, were round pieces of thin sheet platinum. Each was sealed with a small quantity of paraffin wax melted into place. The large lower valve, c, was a rubber plug. All the valves were opened by wires passing out of the submarine through fine tubes. Small beads prevented them from being pulled above the level of the solution. The stirrers, moving at the same rate **but** in opposite directions, helped circulate the liquids and facilitated their mixing.

Thermometric Improvements.—The most important improvements in the present apparatus were (1) the substitution of a platinum resistance thermometer, T, for the mercury thermometer formerly employed to read the calorimeter temperature and (2) the use of a specially constructed thermel, DD, to compare the temperature of the outer water-bath (A) with that of the calorimeter itself. The first of these increased the thermometric sensitivity tenfold, while the second eliminated the necessity of reading two thermometers simultaneously in maintaining adiabatic conditions.

Platinum Resistance Thermometer.—The platinum resistance thermometer was of the Callendar four-lead type, made especially for the purpose by Leeds and Northrup. The pure platinum coil, 10 cm. long, mounted on mica and enclosed in a glass tube, was always completely beneath the level of the liquid in the calorimeter. Its constants were found by the Bureau of Standards (September, 1924) to be: $R_{0^\circ} = 25.301$ international ohms; $R_{100^\circ} = 35.151\omega$; $\delta = 1.51$.

A current of 2.5 m.a. was put through the thermometer coil in these standardizations. During the dilution experiments greater sensitivity was secured by using a current of 5 m.a. A half-dozen careful experiments showed that this increased current raised R_0 by 0.0015~. This change, though considerable, was constant and a corresponding correction was easily applied.

Resistance Bridge and its Thermostat.—In measuring the resistance of the thermometer coil, a high sensitivity bridge (of the same manufacture) also standardized by the Bureau (August, 1923) was used with many necessary precautions. At the completion of our experiments (April, 1928), a series of ice-points was taken with the thermometer and this bridge and a value $R_0 = 25.304\omega$ was obtained. This showed the magnitude of the change in the thermometer bridge system during the time it was in use. The average value $R_0 = 25.3025$~ was taken to compute the isothermal dilution temperatures, which are therefore fixed within ±0.015°. A change of 0.01° in this temperature causes a change as large as 1 joule only in the heat of dilution of sodium hydroxide (which has the largest temperature coefficient). It does not affect at all the ***temperature differences*** measured or the values of the temperature coefficients and heat capacities.

In order to make thermometer readings significant to 0.0001°, the bridge was enclosed in an efficient air-thermostat, kept constant within 0.01". The temperature of the resistance coils was undoubtedly yet more constant, since they were enclosed in the wooden and hard rubber box of the bridge.

The thermostat consisted of a large wooden box insulated outside by felt and provided inside with an adequate source of heat, a sensitive thermo-regulator and a fan. The dials and keys of the bridge were operated by extension rods running through the cover of the box.

The bridge was graduated to 0.0001 ohm and the deflections of a high sensitivity galvanometer gave the next decimal place by interpolation. A change of 0.00001 ohm in the resistance of the thermometer (corresponding to a temperature change of 0.0001°) caused a galvanometer deflection of 0.4 mm. External stray currents were kept out of the thermometer and galvanometer circuits by an equipotential shield and parasitic currents in the galvanometer circuit were canceled by a reversing switch.

The **Thermel.**—One of the chief requisites of precise calorimetry is the maintenance of a really adiabatic condition during an experiment. To compare the temperature of calorimeter and surrounding bath, a thermel connected directly to a galvanometer is more sensitive and convenient than two mercury thermometers. The ordinary glass-encased thermel, however, lags appreciably in registering the temperature difference. Accordingly, for this investigation the thermel was encased in platinum tubes, extending 10 mm. above the surface of the liquid. These were fastened with deKhotinsky cement into the glass tube E, forming the rest of the case. This thermel was compared by Dr. B. J. Mair and Dr. L. P. Hall with a glass-enclosed one similar to that used in the specific heat work[4] and found to respond about three times as rapidly to a change in temperature.

The element itself was of copper-constantan, made in two opposable sections of three couples each. The junctions were made in the usual manner[5] and staggered around the outside of a conical bunch, over a distance of 9 cm., in order to secure a "representative sample" of the temperature of the calorimeter over its whole height. This is one advantage of the thermel over the mercury thermometer, with its small bulb, especially when it is used as a zero instrument with changing temperatures. The cone of insulated wires fitted quite snugly into the metal case but to increase thermal conductivity, the interstices were filled with naphthalene.

The leads were carried inside a small water-proof rubber tube, over which was wound a double spiral strip of copper foil, which formed part of the equipotential shield (including the container of the outer bath, a copper plate under the reversing switch and another beneath the galvanometer). A double-pole double-throw switch, the only one in the circuit, served to reverse the galvanometer and so obtain the true deflection. The sensitivity of the thermel circuit was ample—0.0004° per mm. of scale.

Heating Coil.—A small heating coil H was used to adjust the initial temperature of the calorimeter. It was made from 28 cm. of number 30 B. and S. gage asbestos-insulated constantan wire, threaded through small brass tubing which was bent into a long U and heavily gold plated. The upper ends were cemented into a glass tube which fitted into one of the metal tubes in the "submarine" lid.

Outer Water-Bath.—This bath, of ample size, was thermally insulated by felt (F) and stirred by means of a three-stage propeller P, run at a high speed to insure thorough mixing. It was heated by means of two sets of coils of bare manganin wire, I, I, connected in parallel (each with a resistance of about 22 ohms) and supported on glass frames. To reduce the loss of heat by evaporation, a wooden cover (J) (lined with metal) was fitted over the bath.

Thermal Leakage.—To measure a temperature change with the accuracy of 0 0001°, heat leakage between the calorimeter and its surroundings must be made very small. The three main avenues of thermal leakage are (1) the air gap between calorimeter and jacket, (2) the solid connections bridging this space, and (3) evaporation from the surface of the calorimeter or condensation upon it.

(1) Calculation from Barry's[6] data for a nearly identical calorimeter system showed that an average thermal head of not more than ±0.003°, must be maintained during an experiment to avoid appreciable errors from leakage across the air gap. This condition was amply fulfilled during the experiments.

(2) The following precautions were taken to reduce conduction along the necessary solid connections between the calorimeter and the water-bath. The calorimeter was supported on small cork wedges and centered in the submarine jacket by small conical pieces of hard rubber. The platinum wires used to manipulate the valves were terminated just above the surface of the liquid and attached to insulating sections of waxed silk thread (dental floss). The wires supporting the stirrers were fastened into 2-cm. sections of glass tubing MMM to prevent metallic conduction along this avenue. In the small heating coil H the resistance wire was carried across the air gap, since its thermal conductivity was much less than that of the copper leads.

[6] Barry, ibid., 44, 902 (1922).

Heat leakage from the room to the calorimeter over the leads to the temperature indicators was prevented by bringing them to the temperature of the water-bath. The thermel leads passed through a fine copper U-tube (U), which was immersed to the depth of 7 cm. in the water of the outer bath.[7] The protruding portion of the platinum thermometer stem was enclosed in a copper tube N, thermally insulated from the air of the room by a layer of cotton (O). Thus the whole stem was kept very near the temperature of the water-bath. Calculation showed that with the arrangements described the heat leakage by conduction was entirely negligible.

(3) Evaporation affords one of the most important minor possibilities of error in calorimetric work, often insufficiently regarded. One of its effects was pointed out long ago.[8] If the submarine jacket is cooler than the calorimeter, heat is lost from the latter much more rapidly than it is gained if the jacket is the same amount warmer, because in the first case water continuously distils from the calorimeter and condenses upon the jacket.

Barry[9] by careful experiments has also emphasized the importance of this effect. In the present apparatus the paraffined paper collar Q was designed to confine evaporation to the air space immediately above the calorimeter. Supposing this volume of air to be saturated at the beginning of an experiment, the error from additional evaporation, due to the slight change of temperature concerned, could hardly amount to over 0.00001°. Even this small error is at least partly eliminated by noting the temperature drift after the experiment proper. However, if the rise of temperature amounts to 4° (as in many thermochemical determinations) the error involved would be appreciable (0.0006°). If the usual open calorimeter were employed the error might be 0.003" or more.

The thin driving rods of the stirrers were of such cross sections that no significant volume of air was either drawn in or pumped out of the "submarine" during their alternating operation already mentioned. In addition they were packed with cotton (L) at the top of the tubes leading out of the submarine.

Heat Capacity of Apparatus.—The fixed heat capacity of the calorimetric apparatus was calculated as usual (from the weights and heat capacities of all the constituent parts) to be 18.46 (±0.3) cal. per degree, or 77.2 joules per degree (mayers).

The maximum uncertainty (0.03%) of the total heat capacity of the calorimetric system (including the liquids) was unimportant for the present purpose but should be considered in cases where a percentage accuracy of this order is sought.

Materials and Solutions.—The materials were purified and standardized in much the same manner as for the previous research.[4] The most difficult problem was the sodium hydroxide. It was obtained by crystallization from very concentrated solutions with many precautions. The method of standardization of this alkali used in the specific heat experiments and in the first series of dilution experiments has since been shown to be insufficiently exact for the present purpose. Indeed, this would have been suspected at the time, except for the fact that the comparison with "constant boiling" hydrochloric acid and the weighing of sodium chloride had given an identical outcome. The former method, however, is not always trustworthy; the latter is almost certain to yield too high results. It now appears[10] that sodium chloride ob-

---

[7] A similar procedure was adopted by Williams and Daniels, THIS JOURNAL, 46, 905 (1924).

[8] Richards and Burgess, *ibid.*, 32,449 (1910).

[9] Barry, *ibid.*, 44, 899 (1922). W. P. White, likewise, has entirely appreciated the necessity of preventing evaporation.

[10] Richards and Hall, *ibid.*, **51,** 707 (1929). Nearly all the present work was done in 1924–1925 and has been awaiting publication until the subsequent confirmatory work of Richards and Hall could be finished.

tained by evaporation in the particular manner described in our above-mentioned research regularly retains 0.7% of water. The first analysis of the $NaOH\cdot 25H_2O$ solution was, therefore, in error by $0.20H_2O$. All the concentrations in the previous paper are here corrected for this source of error. The final corrected estimate of the concentration of sodium hydroxide employed in the first series of the present work was $NaOH\cdot 25.31H_2O$. That used for the second series was titrated against hydrochloric acid solution, standardized by silver chloride and hence requires no correction.[11]

The acetic acid was a very pure specimen of the glacial acid, which was further purified by three recrystallizations. The composition of the standard acetic acid solution, analyzed by titration against $NaOH\cdot 25.31H_2O$, was found to be $HC_2H_3O_2\cdot 25.17H_2O$.

We wish to thank Dr. L. P. Hall for the laborious recalculation of the first series of sodium hydroxide dilution experiments and the acetic acid dilution experiments to the true concentrations.

The sodium acetate was a "chemically pure" sample from a responsible firm; it was recrystallized twice from a clear solution as trihydrate and duly centrifuged, etc. The standard solution was made at first somewhat too concentrated; after careful analysis it was diluted quantitatively to the concentration $NaC_2H_3O_2\cdot 24.99H_2O$. The analysis was conducted by evaporation at 100° and heating to constant weight at 200°. Later experiments (converting the acetate into the anhydrous sulfate in the usual way) showed that the porous powder thus prepared retained only 0.1% of water. This error would affect the heat of dilution by less than 1 joule at the greatest concentration involved and no corrections were made to the observed values.

In calculating the concentrations of these solutions the following atomic weights were used: $H = 1.008$; $O = 16.000$; $Na = 22.997$; $C = 12.000$ and $S = 32.064$.

The initial solutions (about $25H_2O$) were kept in stock bottles in the manner already described.[4] For each quantitative dilution the required amounts of solution and of water were weighed out (within 0.01%). Since in the thermochemical determinations the dilutions were made in successive steps, the product of one experiment served as a factor in the next. The products were carefully preserved and protected from evaporation, so that it was unnecessary to analyze the successive more dilute solutions.

Experimental Procedure

The technique of experimentation was planned so as to conserve time and avoid evaporation of the weighed solutions. Description of the individual steps would be helpful to any one repeating the work, but would require too much space for the present record. When all was in place the temperature of the calorimeter system was slowly raised to the desired initial temperature by passing a current through the inner heating coil. The temperature of the outer bath was then made the same (± 0.003"). Finally, the inner heating coil was disconnected and the apparatus kept for at least five minutes under careful adiabatic control before the first accurate reading of the resistance thermometer.

---

[11] Richards and Hall (ref. 10), verified these conclusions by making an entirely new solution of sodium hydroxide, analyzing it by titration against a hydrochloric acid solution standardized by precipitation of silver chloride and determining its specific heat with great accuracy. This value exactly agreed with that found by us previously, when allowance was made for the 0.7% of water held by sodium chloride obtained by evaporation. There can thus be no reasonable doubt of the true concentration of sodium hydroxide solution formerly used by us, and of our present solution.

The time of completing the first reading was recorded to the nearest quarter of a minute. Pour minutes later a second reading was made, followed by a third, after an equal interval of time. If the temperature trend during these two periods was sufficiently constant, the experiment was started by pulling out the two platinum valves, a,b, (Fig. 1).[12] This was done at the beginning of an upstroke of the inner stirrer so that the first mixing would occur in the center of the apparatus where it was least likely to cause an uneven temperature on the surface of the calorimeters. The temperature change in the latter (as indicated by the thermel) was carefully paralleled in the outside bath by appropriate heating, or cooling by a small stream of ice water dropping directly over the stirrer. The thermal head for the first two minutes was usually about *0.015°, but for the rest of the experiment it was less than ±0.003°. The average temperature of the bath always was kept slightly higher than that of the calorimeter. When about three minutes had passed and the mixing was practically complete, the other valves were opened. Three minutes later the resistance thermometer was again read to determine the temperature change during the experiment. After eight minutes more a final reading was made to determine the temperature trend after the experiment. The temperature of the bridge thermostat was noted after every thermometer reading in order to be sure that it functioned properly.

A Typical Dilution Experiment.—The full data of a typical experiment will show the method of calculating the true rise of temperature and the amount of heat evolved or absorbed in the reaction.

The temperature drift in eight minutes was equivalent to -0.00009 ohm before the experiment; afterward, -0.00005 ohm. The mean drift was, therefore, -0.00007 ohm during eight minutes (the time of the experiment). Hence the change in resistance during the experiment, corrected for this trend, was $+0.00725 - (-0.00007) = +0.00732$ ohm.

The change of resistance was translated into temperature change by means of a difference formula derived from the familiar Callendar equation by Mueller of the Bureau of Standards.[13] It may be written AT = $\Delta\phi R$. The factor ϕ depends upon the mean temperature of the experiment, increasing 0.03% for every degree of temperature rise; in this case it was 10.0613, so that the change in temperature AT = 0.0737'. The final temperature of the experiment was 20.09".

The quantity of heat absorbed in any single experiment (Ah) was calculated from the temperature change and the heat capacity of the system by the equation $Ah = -\Delta T c_p$. c_p is the sum of the heat capacities (under constant pressure) of the factors and that of the apparatus. The heat

---

[12] When the temperature change was very small (in the experiments at great dilution) the mixing was effected more rapidly by opening the large valves, d, e, first.

		27.3028 (2)	−0.10	27.30280	

[a] The bridge thermostat read exactly 25.00" before and after the experiment. At no time was the thermal head greater than ±0.008°.

[b] The calibration corrections for the 0.000 R coils (in parentheses) were necessary to interpolate the fifth place correctly, since the change was not exactly 0.0001 ohm in each case.

[c] The interpolated values are corrected by adding the calibration corrections to all coils changed during an experiment (here, 0. R to 0.000 R inclusive).

[d] The upper platinum valves, d, e, were opened at 10:24.0 to start the experiment and the lower rubber valve, c, at 10:27 to ensure complete mixing.

capacity of the factors was determined by multiplying the weight of each by its heat capacity per gram, at the mean temperature of the experiment. The values for the heat capacities of the concentrated solutions were taken from the work of Richards and Gucker,[4] as duly corrected by Richards and Hall.[10]

In this particular experiment (using c_2 to signify the heat capacity of the dilute acetic acid and c_1 that of the water used for further dilution)

$$c_2 = 622.09 \times 3.9915 = 2483.1 \text{ mayers (joules per degree)}$$
$$c_1 = 550.00 \times 4.1836 = 2301.0 \text{ mayers (joules per degree)}$$
$$c_a = 77.2 \text{ mayers (joules per degree)}$$
$$c_p = (c_2 + c_1 + c_a) = 4861.3 \text{ mayers (joules per degree)}$$

Hence

$$Ah = - A Tc, = -(0.737) \times (4861.3) = -358.3 \text{ joules.}$$

The heat absorbed (AH) by the dilution of a mole of solute was obtained by dividing the heat absorbed in any experiment *(Ah)* by the number (N) of moles of solute used.[14]

In this case N = 1.2114 and

$$AH = \Delta h/N = -(358.3)/(1.2114) = -295.8 \text{ j}.$$

This value corresponds to isothermal dilution at the final temperature, 20.09°, since the heat capacity of the factors was used in the calculation.[15]

Prom the experimental values of AH at approximately 16 and 20° its temperature coefficient was obtained and used to correct the results to exactly 16 and 20°.

Since the data necessary for these calculations are too bulky for publication in complete form, only the results will be presented.

The difference between parallel experiments often was less than 0.5 joule, which corresponded to an error in temperature reading (AT) of about 0.0001". Occasionally (especially in the case of sodium acetate) the difference amounted to four times as much; in such cases more determinations were made. The sodium acetate experiments were chronologically the first; the better agreement in the other cases is to be ascribed to increased experimental efficiency.

Three blank experiments were carried out to determine any temperature change which resulted from pulling out the plugs and mixing the contents of the two calorimeters. The actual experimental conditions were duplicated as closely as possible. In the first case each calorimeter contained water; in the others a $NaOH\cdot 800H_2O$ solution. The results were: $AT = -0.0000_8°$, $\pm 0.0000_0°$, $-0.0000_5°$, making an average of $-0.0000_4°$. This quantity is beyond the limit of experimental accuracy and the experiments show that no appreciable error can have been introduced in mixing the solution.

With sodium acetate the dilutions were carried to $51H_2O$, $101H_2O$, $201H_2O$, etc., in order to measure directly values required to calculate heats of neutralization. The calculation of the heat capacities per gram is discussed later.

The calculations were carried to two doubtful places and only the final results rounded off in order to prevent cumulative errors.

[14] Attention should be called to a difference between the symbols used in this paper and in previous publications from this Laboratory. Formerly (in conformity with usual practice) U was used to denote diminution of total energy during a reaction (or, where there is no significant change in volume, the heat *evolved).* Unfortunately U recently has been taken to mean the (unknown) total internal energy of a system. — AU in this new notation is identical in meaning to the old U, and AH means heat ***absorbed*** per mole under constant pressure. The new notation, which is now most frequently employed in America, is used herewith; but the whole subject seems to need revision. At present the notation of chemical thermodynamics is in dire confusion, especially because of changes of sign.

[15] Richards, **THIS JOURNAL,** 25,209 (1903).

Note on Sodium Hydroxide.—Two series of determinations were made on the sodium hydroxide solutions. The first series was brought to an abrupt close by a very hot spell in June, 1925. Because of the sudden change of the heat of dilution at the last stage, extrapolation to zero concentration seemed of doubtful value without additional knowledge. Accordingly, in January and February, 1928, the second series was carried out and showed that the heat of dilution actually changed sign at this point. The curve was followed to $NaOH \cdot 3200H_2O$ because, although the percentage accuracy of these figures is not great, they reduce the uncertainty in the final extrapolation to zero concentration.

The diluting water was distilled, then boiled for five to ten minutes to drive out most of the dissolved air and carbon dioxide. Nevertheless, the presence of a minute trace of carbon dioxide would cause the evolution of a relatively large heat of neutralization during the experiment. Tests with barium hydroxide solution gave no precipitate, showing (by comparison with a standard sodium carbonate solution) that the water contained less than 0.00004% carbon dioxide (by weight). The $NaOH \cdot 3200H_2O$ solution, however, showed about 0.00008% of sodium carbonate, which had accumulated during the five dilutions. Estimating that one-eighth of this came from the diluting water and the rest from the air of the room, during the weighing and handling of the solution, a correction, amounting to 0.0002° in each dilution, was applied to the observed heats of dilution in computing the final values and extrapolating to zero concentration. Had this difficulty been fully appreciated at the beginning of the experiments, it might have been avoided by adding to the diluting water enough sodium hydroxide or barium hydroxide to react with the $CO_3^=$. The very dilute carbonate solution resulting would probably, as a diluent, be indistinguishable within the limit of accuracy of the present apparatus, from absolutely pure water. To use pure water (containing an amount of carbon dioxide negligible in diluting hydroxide solutions) in such a calorimetric apparatus would be almost impossible.

Heat Capacities.—Knowing the heat capacities of the initial solutions[16] and the heats of dilution at 16 and 20°, the heat capacities of the products of each dilution were calculated by the principle commonly known as Kirchhoff's Law.[17]

---

[16] Richards and Cucker, **THIS** JOURNAL, *47*, 1883 (*1925*).

[17] $(AH' - \Delta H)/(T' - T) = \Delta C_p$, where $\Delta C_p = C'_p - C_p$. Here C'_p = total heat capacity of products and C_p = total heat capacity of factors. ΔC_p refers to the change in heat capacity at the mean temperature $(T' + T)/2$, in this case *18.00°*. Since, however, the change of ΔC_p with temperature may probably be considered negligible over a 4° interval, the same value of AC_p was used in calculating specific heats at 16, *18* and *20°*.

It is interesting to note that Person in *1851* [*Ann. chim. phys.*, [3] *27, 250 (1849)*; **[3]** *33, 437* (1851)], from an inductive study of his data on heats of solution and specific

These calculations, like the dilution experiments, were carried out in steps, the heat capacities calculated from one dilution becoming those of the factors of the next. The method is illustrated by the following example involving sodium hydroxide at 16.00°.

Factors	Mol. wt.	c_p (per gram), m.	C_p (per mole), m.	ΔC_p, m.
$NaOH \cdot 25H_2O$	490.41 g.	3.8132	1870.03	
$+ 25H_2O$	450.40 g.	4.1837	1884.34	
			3754.4	−31.4

Product	C_p (per mole), m.	Mol. wt.	c_p (per gram), m.
$NaOH \cdot 50H_2O$	3725.0	940.81 g.	3.9572

From these values in the absolute system those in the 20° calorie system are easily computed by dividing by 4.1805 (the absolute heat capacity of a gram of water at 20°). For the more convenient use of others these heat capacities were reduced to exactly even molal concentrations—for example, those of $25.31H_2O$ to exactly $25H_2O$. In the following tables, II, III and IV, all these data are brought together. They (as well as the other final data in this paper) are, of course, corrected for all known errors.

From the data obtained tables were prepared giving the heats of dilution and the change of heat capacities during dilution of the different solutions of the substances studied (see Tables V, VI and VII).

heats, discovered this same relationship and expressed it in a mathematical equation which can be shown to be identical with the Kirchhoff equation. Since his work predated that of Kirchhoff [Ostwald's "Klassiker der Exakten Wissenschaften," No. 101, reprinted from Kirchhoff, *Pogg. Ann.*, 103, 77, 206 (1858); 106, 322 (1859)] by seven years, his priority should be recognized and the principle renamed the "Person-Kirchhoff Law." This would also obviate any confusion between the law just mentioned and the other laws of Kirchhoff in the domain of pure physics.

Other referencesto the use of this equation follow: Winkelmann, *Ann. Phys. Chem.*, 149, 1 (1873); Dupre, *Proc.* Roy. *Soc.*, 20, 336 (1873); Berthelot, *Ann. chim. [a] Heat capacity (at constant pressure) per gram of substance.

The values for infinite dilution were obtained by graphical extrapolation with a Berkeley flexible ruler. The curve for acetic acid was nearly a straight line, which made extrapolation easy. The sodium acetate curve was regular but difficult to extrapolate because it was inclined so obliquely to the axis. The dilute portion of the sodium hydroxide curve was similar to that of sodium acetate.

Considering all the results obtained, including those for the dilution of sodium hydroxide carried out after an interval of two years, it seems probable that the average values for A T are not more than 0.0002° from the true value. In considering the accuracy of the tabulated results and the extrapolations, however, it must be remembered that the error in the molal heat of dilution is doubled with each step, because the molal heat capacity is doubled. This cumulation of errors is inevitable and should be clearly borne in mind.

The possible error in the molal heat of dilution is increased from about 1.6 j. (in the dilution from $MX\cdot 50$ to $MX\cdot 100H_2O$) to almost 24 j. (in the dilution from $MX\cdot 800$ to $MX\cdot 1600H_2O$). The possible accumulated error in the value for the dilution $MX\cdot 50$ to $MX\cdot 1600$ is therefore about 48 j., and that in any extrapolation to zero concentration might amount to as much as 75 or 100 j.

In the sodium hydroxide solutions the uncertainty of the carbon dioxide correction increases the possible error to 0.0003°, or a possible uncertainty of 150 j. in the extrapolation. The fact that, plotting on a large scale, smooth curves are obtained, makes it probable that the *actual* errors are not as large as the *possible* errors just discussed.

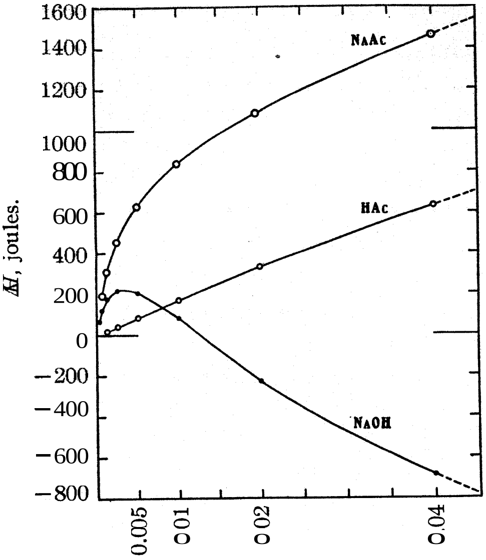
The heats of dilution in Tables V, VI and VII are plotted in Fig. 2 in such a way as to be most directly comparable.

Since at zero concentration all heats of dilution must approach zero, the curves are drawn from a common origin. The concentration is plotted in moles of solute per mole of water as abscissa, while as ordinate is plotted the heat absorbed in going *from* zero concentration to that represented by the abscissa of the point.

It is interesting to see that in every case at the lowest concentration heat is given out by further dilution. Lange and Messner[18] in their recent study of extremely dilute solutions have found this to be a general rule.



Concentration, moles of substance per mole of water.

Fig. 2.—Heats of dilution.

The temperature coefficients of the heats of dilution, which represent the change of heat capacity with change of concentration, were plotted in Fig. 3. Here also the curves are drawn from a common origin, to be more directly comparable. The abscissas again represent concentration and the ordinates the *gain* in heat capacity, per mole of solute, in going from zero concentration to that repre-

---

[18] Lange and Messner, *Naturwissenschaften*, 15, 521 (1927).

sented by the abscissa. The curves for sodium hydroxide and sodium acetate are regular and similar. That of acetic acid is more interesting. In the more concentrated range its slope is opposite to that of the others, but at a concentration of about $HC_2H_3O_2 \cdot 600H_2O$ it changes sign and then behaves normally.

All the solutions of acids, bases and salts studied by Richards and Rowel[g] (including sodium hydroxide) showed a diminution in heat capacity on dilution. This is seen to be true also of sodium acetate and dilute acetic acid solutions. Concentrated acetic acid solutions, however, when diluted show an increase in heat capacity.

The heats of dilution given in Tables V–VII can be used to calculate the change with concentration of the heat of neutralization of sodium hydroxide and acetic acid, by the familiar addition of thermochemical equations.[20]

Knowing the heat of neutralization at any single concentration, the whole course of the curve is fixed. The best value available in the literature is $NaOH \cdot 200H_2O + HC_2H_3O_2 \cdot 200H_2O = NaC_2H_3O_2 \cdot 401H_2O + 13.48$ Cal.[21] Our dilution data show that the heat of neutralization at infinite dilution is 0.04 cal. greater than this, or 13.52 cal. This result is not far below the extrapolated value of 13.62 found for the neutralization of strong acids. It seems safe to conclude that the hea' evolved by the reaction $H^+ + OH^- = H_2O$ is not very far from 13.6 cal. The weakest link in this chain is the heat of neutralization of acetic acid at ordinary concentrations, which will be taken up in a paper by Dr. B. J. Mair and one of us.

The authors take pleasure in acknowledging their indebtedness to the Carnegie Institution of Washington and to an anonymous benefactor of this Laboratory for essential financial assistance in carrying out this research.

Summary

This paper presents new data on the specific heats and heats of dilution at 16 and 20° of sodium acetate, sodium hydroxide and acetic acid. These data are necessary in order to compute the heats of neutralization involved

---

[19] Richards and Rowe, THIS JOURNAL, 43,788 ff. (1921).

[20] Cf. Richards and Rowe, *ibid.*, 44, 700 (1922).

[21] Thomsen found the heat of neutralization of hydrochloric acid at about 18° to be 13.74 Cal. and that of acetic acid to be 0.34 Cal. less, a differenceof 2.5%. The factors in both of these reactions contain $200H_2O$. Richards and Rowe found 57.75 kilojoules for the heat of neutralization of hydrochloric acid at 20° (making a small correction for the error in analysis of the sodium hydroxide used by them). Subtracting 2.5% from this gives 56.3 kilojoules or 13.47 Cal. as the heat of neutralization of acetic acid reduced to the same standard. Mathews and Germann [*J. Phys. Chem.*, 15, 75 (1911)] find that the heat of neutralization at 18° of 0.25 *N* $HC_2H_3O_2$ and NaOH is 2.3% less than that of HCl at the same concentration. This would give a value of 56.4 kj., or 13.49 Cal., at 20°, on our standard. The average of these is 13.48 Cal.

at various concentrations. The apparatus has been improved and all temperature measurements made by a platinum resistance thermometer. A careful study of the possible errors has been made and suitable corrections applied for them.

It has been found that although all the other heats of neutralization studied in this way *decrease* as the concentration of the reagents is diminished, that for acetic acid (which is distinctly less than those of stronger acids) *increases* as the solutions become more dilute. Apparently, however, they tend toward the same value at infinite dilution, about 13.6 Cal. (or 56.8 kilojoules), which would appear to be the most probable value for the heat of the reaction $H^+ + OH^- = H_2O$. A more exact evaluation will be found in a later paper of this series.

HEATS OF DILUTION AND HEAT CAPACITIES OF HYDROCHLORIC ACID SOLUTIONS[1]

BY T. W. RICHARDS, B. J. MAIR AND L. P. HALL

RECEIVED SEPTEMBER 18, 1928 PUBLISHED MARCH 6, 1929

Introduction

Since the publication of preliminary data of the specific heats and heats of dilution of hydrochloric acid solutions by Richards and Rowe,[2] more accurate methods for the determination of these data have been developed in this Laboratory.[3] With the aid of these new methods and apparatus the specific heats of hydrochloric acid solutions at various concentrations have been obtained directly and also indirectly from the heats of dilution at 16 and 20°.[4]

Specific Heats of Hydrochloric Acid Solutions

The specific heats of hydrochloric acid solutions at three concentrations were determined in a manner identical with that previously described.[6] A variable but small error may have been caused by the action of the hydrochloric acid on the gold-plated heating coil, particularly at the soldered connections. At first a celluloid cement was used to coat these sections. In spite of this precaution the acid solution was able to attack the solder

---

[1] On account of the death of Professor Richards on April 2, 1928, the work here described was completed and the manuscript was prepared by the junior authors.

[2] Richards and Rowe, THIS JOURNAL, 42,1621 (1920).

[3] (a) Richards and Gucker, *ibid.*, 47, 1876 (1925); (b) 51, 712 (1929).

[4] The relationship between the temperature coefficient of the heat of dilution and the heat capacity of the factors and products $(AH' - \Delta H)/(T' - T) = \Delta C_p$ generally known as Kirchhoff's Law was used for this purpose (ref. 2).

[5] Richards and Hall, THIS JOURNAL, 51,707 (1929).

very slowly. A thin coating of paraffin was found to be more effective than the cement. Heat evolved by corrosion must have been slight even in the case of the most concentrated solution and would tend to lower the results to a very small extent.

The water equivalent in all of the determinations with hydrochloric acid was 556.71 g. in *vacuo*. A solution of redistilled hydrochloric acid was titrated against $NaOH\cdot 25.08H_2O$ with weight burets and found to be $HCl\cdot 24.96H_2O$ and the same value was found by analysis as silver chloride.

WEIGHTS OF $HCl\cdot 24.96H_2O$ EQUIVALENT TO 556.71 G. OF H_2O

	16.00° *g. in vacuo*		18.00° *g. in vacuo*		20.00° *g. in vacuo*
	636.42		**635.15**		**634.87**
	635.99		**635.36**		**634.62**
			635.25		
	636.29		**635.24**		**634.75**
Av.	**636.23**	Av.	**635.25**	Av.	**634.74**
Sp. ht.	**0.87501**	Sp. ht.	**0.87636**	Sp. ht.	**0.87707**

When these values for specific heats are corrected to $HCl\cdot 25.00H_2O$ by means of the Person-Kirchhoff Law, the following result: at 16°, 0.87518; at 18°, 0.87653; at 20°, 0.87724. These values are subject to a correction of 0.00002 to 0.00004 resulting from differences in evaporation of solution and water.

A solution of redistilled hydrochloric acid was adjusted to about $HCl\cdot 50H_2O$ and analyzed by the silver chloride method as $HCl\cdot 49.99H_2O$. Its specific heat at 18° was found to be 0.9337 as the mean of two experiments requiring 596.24 and 596.18 g. in *vacuo* of the acid.

937.01 g. of this acid was diluted with 901.10 g. of water to make a solution of $HCl\cdot 100H_2O$. From three experiments (576.90 g., 576.90 g. and 576.75 g., all in *vacuo)* the specific heat at 18.03' was found to be 0.9651.

Determination of Heats of Dilution

The apparatus and experimental procedure used in these experiments was essentially that described in a recent paper.[3b] A few minor modifications in apparatus were made. Owing to the solvent action of hydrochloric acid on the gold-plated brass heating coil formerly used to adjust the initial temperature, a simple though adequate heating coil was made from constantan wire (No. **30** B. and S.) enclosed in a thin-walled glass capillary.

One of the most troublesome experimental difficulties encountered was the erratic heating effect arising from the occasional contact of the stirrers with the sides of the calorimeter cans. This difficulty was considerably decreased by bracing the supporting rods of the stirrers and by reducing their width slightly. Further reduction of this heating effect was accomplished by binding the edges of the stirrer in a few places with waxed silk thread.

A new "all copper circuit" galvanometer of high sensitivity was used in conjunction with the platinum resistance thermometer to eliminate thermo-electric currents frequently found in galvanometers of the silver suspension type.

The heat capacity of the apparatus was calculated from the heat capacity of its constituent parts as 76.4 (±3) mayers. Since the total heat capacity of the system with solution was about 5000 mayers, an error of 3 mayers corresponds to an error in total heat capacity of only 0.06%, which is within the accuracy of the rest of the method.

Hydrochloric acid, doubly distilled, using a quartz condenser, was diluted to approximately $HCl{\cdot}25H_2O$. Two solutions were used: the first by analysis as silver chloride was of the concentration $HCl{\cdot}24.95H_2O$; the second, $HCl{\cdot}24.98H_2O$. The first solution was used for experiments at 20° only, while the second was used one year later at both 16 and 20°, after considerable experience had been gained with the apparatus.

No attempt will be made to present the necessary data for all of the calculations. The same general methods of calculation were used here as described in the previous article in this series[6] Two series of dilution experiments were performed with the hydrochloric acid solutions.

The summaries of results are given in Tables I and II.

TABLE I

HEAT CAPACITY PER GRAM OF SOLUTION

The values for heats of dilution here presented are similar to those found by the earlier method of Richards and Rowe,[2] although not identical. The differences resulting from the newer method are due primarily to its greater accuracy and also to the use of more dilute solutions, for it is difficult to handle concentrated solutions such as were used in the earlier work. There are few other values in the literature which can be compared, since Thomsen[7] covered the range from $HCl{\cdot}2H_2O$ to $HCl{\cdot}300H_2O$ and Wrewsky and Sawaritzky[8] almost the same range. If the heat evolved

---

[6] The final temperature in these experiments was known within ±0.015°, as discussed in ref. 3 b, p. 712.

is plotted against concentration, a smooth curve is obtained, which cannot be easily extrapolated to zero concentration since the curve approaches the axis very obliquely. This shows that thermo-neutrality is reached only with exceedingly dilute solutions.

On the other hand, extrapolation of the curve for specific heats plotted against concentration is more certain and yields the value of 1.000 at zero concentration. Table III compares the values for specific heats determined by different methods.

Summary

1. Specific heats of solutions of hydrochloric acid with 25, 50 and 100 moles of water per mole of acid were measured directly by the twin calorimeter method at 18°.

2. Heats of dilution of hydrochloric acid solutions were measured over the range $HCl \cdot 25H_2O$ to $HCl \cdot 800H_2O$ at 16 and 20°.

3. By the use of the Person-Kirchhoff relation the specific heats of the dilute solutions were calculated.

FURTHER STUDIES ON THE THERMOCHEMICAL BEHAVIOR OF SODIUM HYDROXIDE SOLUTIONS[1]

BY THEODORE W. RICHARDS AND LAWRENCE P. HALL

RECEIVED SEPTEMBER 18, 1928 PUBLISHED MARCH 6, 1929

Scope of Work

This paper contains an account of the investigation of the thermal behavior of sodium hydroxide solutions with a study of the heats of dilution of solutions more concentrated than $NaOH \cdot 25H_2O$. From these results the specific heats of the more concentrated solutions have been calculated. Further data were obtained to confirm the short extrapolation necessary to correct the heat of dilution of $NaOH \cdot 25.31H_2O$ and $NaOH \cdot 50.38H_2O$ to integral values.[2] Also the maximum of the curve for heats of dilution with decreasing concentration was determined at 20°.

In the latter part of this paper are collected the thermal data, dealing with sodium hydroxide solutions, which have been found in this Laboratory during the past twenty years. These data have been recalculated, whenever necessary, using the more accurate values for specific heats which have been published recently.[3]

Apparatus and Methods of Procedure

Since approximate results were desired as quickly as possible, an attempt was made to use a simple calorimeter consisting of a 500-cc. Dewar flask with glass stirrer, Beckmann thermometer, glass pipet (for delivering water) and cover. The pipet, bent into a compact U-shape (after the idea of Sugden),[4] was immersed in the hydroxide solution in the vacuum flask in order to keep all parts of the system at the same temperature. After measurement of the fore drift, the water in the pipet was blown by an aspirator bulb into the solution and the temperature change noted.

By this method it was evident that at about a dilution of $NaOH \cdot 17.5H_2O$ there was no measurable heat change upon the addition of small amounts of water. However. too much irregularity existed in this method to yield trustworthy results. Unless the solution inside the Dewar flask was at the same temperature as that of the room, there was always an important temperature drift. The large amount of glass permitted a large and uncertain heat interchange between the room and the solution. Thermal equilibrium within the Dewar was established very slowly. Added to these difficulties was the large and almost indeterminable heat capacity of the Dewar flask.

Accordingly, the Dewar flask calorimeter was abandoned and a simple adiabatic one, very similar to that used by Richards and Rowe,[5] was found to be more satisfactory in every respect.

---

[1] On account of the death of Professor Richards on April 2, 1928, the work here described was completed and the manuscript was prepared by the junior author.

[5] Richards and Rowe, THIS JOURNAL, 42,1621 (1920).

The mercury thermometers (made especially for thermochemical work at 16 to 20°) were carefully standardized by comparison with a calibrated platinum resistance thermometer. Since the apparatus was not perfect, it was necessary to apply a small temperature correction for the drift which was measured both before and after each dilution experiment.

The solutions used in all these dilutions were made from recrystallized "c. p." sodium hydroxide. They contained a few tenths of 1% of carbonate, which would decrease the heat evolved on dilution, but the effect was beyond the accuracy of the method as performed with mercury thermometers. It was found, as would be expected, that a trace of carbonate although present in small varying amounts did not change the value of the temperature coefficients.

The following table summarizes the heats of dilution (corrected to exactly 16 and 20") and their temperature coefficients, expressed in calories, for the range of concentrations studied.

TABLE I

HEATS OF DILUTION (IN CALORIES)

Original soln.	Product of dilution	AH at 20°	AH at 16°	ΔC_p
$NaOH\cdot 10.0H_2O$	$NaOH\cdot 17.5H_2O$	**−93**	−60	− 8.2
$NaOH\cdot 10.0H_2O$	$NaOH\cdot 17.87H_2O$	−92	−59	− 8.2
$NaOH\cdot 17.87H_2O$	$NaOH\cdot 25.00H_2O$	+39	+60	− 5.3
$NaOH\cdot 10.0H_2O$	$NaOH\cdot 25.00H_2O$	−51	+ 4	−13.8
$NaOH\cdot 25.00H_2O$	$NaOH\cdot 26.00H_2O$	+ 5.4	+ 7	....

The value found for the change from $NaOH\cdot 25H_2O$ to $NaOH\cdot 26H_2O$ agrees with the value found by interpolation of the curve for heats of dilution which was used in the publication of this series by Richards and Gucker.[2] This corroboration is important because at a greater concentration than $NaOH\cdot 25H_2O$ the curve suddenly changes its course. Thomsen stated[6] that the change from heat evolved to heat absorbed occurred at about $NaOH\cdot 20H_2O$.

This change in the curve was studied by diluting a solution corresponding to the composition of $NaOH\cdot 10H_2O$ to many stages of dilution ($NaOH\cdot$-$11H_2O$ to $25H_2O$). The values thus obtained for 20" are presented in the small inset of Fig. 1.

This graph depicts the result of the different influences involved in dilution. It is also clear that if a solution of $NaOH\cdot 10H_2O$ were diluted to about $NaOH\cdot 35H_2O$ there would be no heat change. The ordinates thus form a series of "isothermal lines" up to $NaOH\cdot 200H_2O$.

Specific Heat of Concentrated Solutions.—From the temperature coefficients for the above heats of dilution the specific heats of the concentrated solutions can be calculated by the Person–Kirchhoff Law, using the specific heat of $NaOH\cdot 25H_2O$ as the basis.

In a similar way the specific heat of $NaOH\cdot 17.87H_2O$ can be calculated from the temperature coefficient of the dilution $NaOH\cdot 17.87H_2O$ to $NaOH\cdot$-

---

Table II

Heat Capacities and Specific Heats of $NaOH \cdot 10H_2O$

Temperature, °C.	16	18	20
Heat capacity, mayers	3.630	3.619	3.641
Specific heat	0.865	0.868	0.871

$25.00H_2O$ as 0.8962 at 18°. If the value found for the specific heat of $NaOH \cdot 10H_2O$ is used as a basis in the dilution of $NaOH \cdot 10.00H_2O$ to $NaOH \cdot 17.87H_2O$, the specific heat value 0.8966 is obtained. These values agree well with that interpolated from the graph for specific heats at 18° plotted against dilution, 0.8965.

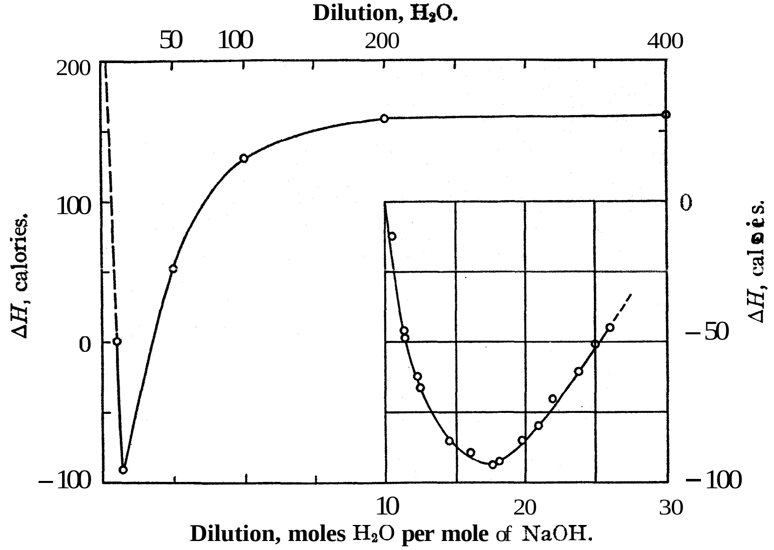

Fig. 1.

Recalculation of Earlier Data.—As was pointed out in a note in the article by Richards and Hall,[3b] the value for the specific heat of $NaOH \cdot 10H_2O$, 0.855, which was used by Richards and Rowe[7] as the basis of calculation, was too low. The recent accurate determination for the specific heat of sodium hydroxide solutions permits the recalculation of the heats of dilution and specific heats published in 1921. These recalculations are summarized in Tables III and IV.

For comparison with the results of Richards and Gucker[2] these values are calculated for the dilution of an initial solution of $NaOH \cdot 25H_2O$ in Table IV.

The good agreement between the recalculated values of Richards and Rowe and those recently published by Richards and Gucker is of particular importance as the stages of dilution in the two researches were quite dif-

[a] Calculated by the Person-Kirchhoff law from heat of dilution.

[b] By interpolation.

[c] Richards and Rowe, *Proc.* Am. *Acad.*, 49, 178 (1913). The error for the value 0.9664 is unexpectedly and inexplicably large. Its cause is not apparent.

It is interesting to note in connection with these comparisons that in the cases of solutions of other substances other experimenters have more recently obtained values consistent with those found by Richards and Rowe. Maass and others[8] have found by an entirely different method essentially identical values for the heat of dilution of sodium chloride.

---

[8] Lipsett, Johnson and Maass, THIS JOURNAL, 49, 925, 1940 (1927).

Lange,[9] working with others, has found confirming values for a number of salts by yet another method. The objection made by Lange[10] to the method of calculation used by Richards and Rowe, has since been courteously withdrawn.[11]

Recalculation of Heats of Neutralization.—The newer values for heats of dilution and specific heat make possible a still more accurate calculation of the heat of neutralization when sodium hydroxide solutions react with strong acids.[12] These new values improve considerably the extrapolation to infinite dilution for the curves plotted for heat of neutralization against dilution.[13]

TABLE VI

HEAT OR NEUTRALIZATION OF $NaOH \cdot 100H_2O$[a]

	18° Cal.	20° Cal.	Kj.
$HCl \cdot 100H_2O$	13,919	13,924	58.21
$HBr \cdot 100H_2O$	13,851	13,856	57.93
$HI \cdot 100H_2O$	13,792	13,797	57.68
$HNO_3 \cdot 100H_2O$	13,846	13,851	57.90

[a] This table replaces part of Table IV, THIS JOURNAL, 44, 699 (1922).

TABLE VII

HEATS OR NEUTRALIZATION AT VARIOUS CONCENTRATIONS IN 20° CALORIES (TEMP., 20°)[a]

Moles H_2O	In factors	25+25	50+50	100+100	200+200	400+400	∞
	In products	51	101	201	401	801	∞
Reaction	NaOH+HCl	14,260	14,026	13,924	13,854	13,794	13,640
	$NaOH+HNO_3$	14,034	13,902	13,851	13,804	13,769	13,640

[a] This table replaces part of the table on p. 702, THIS JOURNAL, 44, (1922).

The values in Table VII for the heat of neutralization at infinite dilution were obtained by graphical extrapolation of the neutralization curves. Another method of finding this value is extrapolation of the heats of dilution of the factors and products to zero concentration and algebraic summation of these values. This may be done with least uncertainty in the case of the neutralization of hydrochloric acid. The dilution of sodium hydroxide has recently been discussed.[2] New values for the heat of dilution of hydrochloric acid recently determined in this Laboratory[14] indicate the evolution of 266 calories on dilution from $HCl \cdot 100H_2O$ to $HCl \cdot \infty H_2O$ at 20°. In order to obtain an extrapolated value for sodium chloride the heat of dilution measured by Richards and Rowe has[15] been combined

[10] Ref. 9 b, p. 189.

[11] Lange, Z. *physik. Chem.*, 117, 336 (1925).

[12] Richards and Rowe, THIS JOURNAL, 44, 684 (1922).

[13] *Cf.* ref. 12, p. 703.

[14] Richards, Mair and Hall, THIS JOURNAL, 51, 727 (1929).

[15] Richards and Rowe, *ibid.*, 43, 779 (1921).

with values found by Lipsett, Johnson and Maass[8] and also with those of Lange and Messner[16] at still smaller concentrations. The resulting curve is a regular one with an inflection at about $NaCl\cdot500H_2O$; at lower concentrations than this a small amount of heat is evolved. Using these values for the factors and products, the following thermochemical equations are obtained.

$NaOH\cdot100H_2O + HCl\cdot100H_2O$	=	$NaCl\cdot201H_2O$	13,924 Cal.
$NaCl\cdot201H_2O + (\infty - 201)H_2O$	=	$NaCl\cdot\infty H_2O$	15 Cal.
$HCl\cdot\infty H_2O$	=	$HCl\cdot100H_2O + (w - 100)H_2O$	−266 Cal.
$NaOH\cdot\infty H_2O$	=	$NaOH\cdot100H_2O + (\infty - 100)H_2O$	−20 Cal.
			13,653 Cal.

The agreement with graphical extrapolation is as good as could be hoped, with due consideration for the difficulties and uncertainties of extrapolations.

The authors take pleasure in acknowledging their indebtedness to the Carnegie Institution of Washington and to an anonymous benefactor of this Laboratory for essential financial assistance in carrying out this research.

Summary

1. The heat of dilution of $NaOH\cdot10H_2O$ has been measured at 16 and 20°. The change from heat evolved to heat absorbed was found to be at $NaOH\cdot17.5H_2O$ at 20°.
2. The specific heats of more concentrated solutions were calculated by the Person–Kirchhoff Law to be 0.868 at 18° for a solution of $NaOH\cdot10H_2O$, and 0.896 at 18° for $NaOH\cdot17.87H_2O$.
3. Earlier work with sodium hydroxide solutions on heats of dilution, specific heats and heats of neutralization has been recalculated and compared with recent researches.
4. The heat of neutralization at 20° of hydrochloric acid and sodium hydroxide is calculated to be 13.65 Cal. at infinite dilution.

THE HEAT OF NEUTRALIZATION OF ACETIC ACID[1]

BY THEODORE W. RICHARDS AND BEVERIDGE J. MAIR

RECEIVED SEPTEMBER 18, 1928 PUBLISHED MARCH 6, 1929

Introduction

The importance of an accurate determination of the heat of neutralization of acetic acid and its significance in calculating the heat of formation of water from its ions has been emphasized in a recent paper by Richards and Gucker.[2] In that investigation data were obtained from which the heat of neutralization at various concentrations could be calculated provided the heat of neutralization at any one concentration was known. The data hitherto available for the heat of neutralization of acetic acid were inadequate[3] to accomplish this with *a* degree of accuracy comparable to that of strong acids and bases previously investigated by Richards and Rowe,[4] for which recalculated values have been presented in a paper of this series.[5] In this paper are presented accurate data for the heat of neutralization of acetic acid and its change with concentration. From these data, together with those of strong acids and bases, a more probable value for the heat of formation of water from its ions is obtained.

Method and Apparatus

The apparatus was that used by Richards and Gucker for the determination of heats of dilution, modified slightly to make it suitable for the larger temperature changes involved.

The small bottom valve holes (designated a,b, by Richards and Gucker) were enlarged to a diameter of 2.5 mm., while the diameter of the large central valve (designated as c) was reduced to 6 mm. Platinum baffles were soldered over the small valve holes, a,b, in order to deflect the solution from the bottom of the calorimeter into the paths of the stirrers in the annular space.

---

[1] On account of the death of Professor Richards on April 2, 1928, the work here described was completed and the manuscript was prepared by the junior author under the general direction of Dr. Lawrence P. Hall.

[2] Richards and Gucker, THIS JOURNAL, 51, 712 (1929).

[3] Thomsen, "Thermochemische Untersuchungen," Leipzig, 1882, Vol. I, p. 271, gives the value 13.40 Cal. for the heat of neutralization of $HC_2H_3O_2{\cdot}200H_2O$ at 20°, and Mathews and Germann, J. Phys. Chem., 15, 75 (1911), give the value 13.23 Cal. for *N*/4 acetic acid. These values are probably low. Thomsen's results for strong acids are about 2.5% lower than those of Richards and Rowe, while Mathews and Germann used unstandardized thermometers and a Dewar flask as a calorimeter. They disclaimed high accuracy.

[4] Richards and Rowe, THIS JOURNAL, 44, 684 (1922).

[5] Richards and Hall, *ibid.*, 51, 731 (1929).

The experiment was performed by opening the two small bottom valves (a,b), the central valve *c* about thirty minutes later when mixing was about three-quarters complete and finally five minutes later the side valves. By this procedure the presence of a hot layer on top, with the deleterious effect produced by distillation of water from the solution to the submarine lid was avoided. The temperature difference between the outer bath and calorimeter was well within 0.01° during most of the experiment but rose to 0.04° for about thirty seconds after the central valve was opened. This approach to true adiabacity with the air gap in question was adequate to obtain an accuracy of 0.001° in the measurement of temperature change. Corrections for the temperature drift were applied and the temperature rise was calculated from the resistance change as described by Richards and Gucker.

The heat capacity of the apparatus (76.4 mayers) was calculated from the sum of the heat capacities of its constituent parts in the manner described in the previous publication.[2]

Preparation and Analyses of Solutions

The sodium hydroxide solution was purified and protected from carbon dioxide in essentially the same manner as that previously employed in this Laboratory.[4,6] Titration with pure standard hydrochloric acid, using weight burets, showed its concentration to be $NaOH\cdot 100.99H_2O$. The acetic acid solution was prepared from crystallized glacial acetic acid and by comparison with standard sodium hydroxide proved to be of the concentration $HC_2H_3O_2\cdot 100.36H_2O$.

TABLE I

HEAT OF NEUTRALIZATION OF ACETIC ACID WITH SODIUM HYDROXIDE[a]

$HC_2H_3O_2\cdot 100.36H_2O + NaOH\cdot 100.99H_2O$

Weight, g.	Heat cap./g. mayers	Total heat cap. incl. cal. (mayers)	AT	Final T	Δh, Joules	ΔH, Joules
610.63A	4.1338	.....	3.627	19.98	−18413	−56331
610.78B	4.0537	5076.54	3.627	20.02	−18413	−56331
.....	....	.....	3.625	20.06	−18403	−56300
.....	....	.....	3.627	20.06	−18413	−56331

Average (AH) corrected to 20.00° = −56324

[a] A slight excess of sodium hydroxide was used throughout to avoid as far as possible errors which result from the presence of sodium carbonate.

Ah refers to the heat absorbed by the quantity used in the actual experiment, while ΔH refers to molal quantities. A and B stand for weights of solutions of acid and base, respectively; the rest of the table is self-explanatory.

The specific heats of the solutions were computed from the values at 18° given by Richards and Gucker[2] for solutions containing exactly 100

---

[6] Richards and Gucker, THIS JOURNAL, 47, 1882 (1925).

moles of water per mole of acid or base by correction for the additional water they contained, with the aid of the Person-Kirchhoff equation.

The heats of neutralization of acetic acid with changing concentration are shown in Table II. The results were calculated from the heats of dilution of factors and products[4] with the aid of the well-known thermochemical equations.

TABLE II

HEAT OF NEUTRALIZATION AT VARIOUS CONCENTRATIONS IN JOULES (20°)

	Moles of H_2O				
In factors	50+50	100+100	200+200	400+400	800+800
In products	101	201	401	801	1601
$HC_2H_3O_2$ + NaOH	55975	56324	56539	56659	56714

The values given in Table II are depicted graphically in Fig. 1, together with the corresponding values[5] for hydrochloric and nitric acids. Independent extrapolations of these curves to infinite dilution yield values ranging from 56.78 to 57.40 kj. Since the reaction at infinite dilution becomes merely $H^+ + OH^- = H_2O$, these curves should approach a common value. Consequently, extrapolation to a point of convergence probably gives a more trustworthy value than the average of the independent extrapolations. Since the curves approach the zero concentration axis from different angles, extrapolation to a point of convergence is less uncertain than was the case with strong acids alone, in which all approached the zero concentration axis from the same direction. A graphical extrapolation to the most probable point of convergence yields the value 57.07 kj. or 13.65 Cal. for the heat of neutralization at infinite dilution.

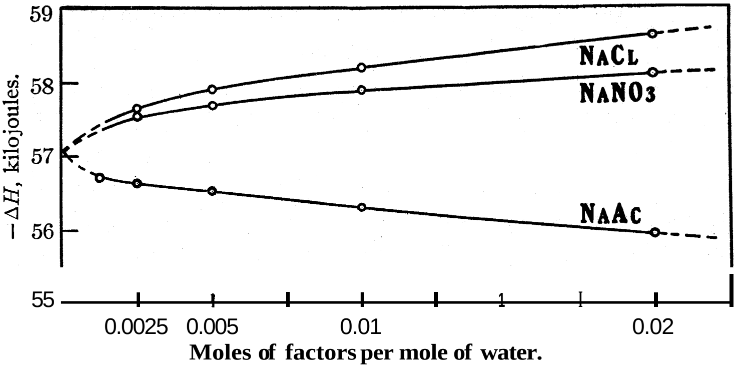

Fig. 1

The authors take pleasure in acknowledging their indebtedness to the Carnegie Institution of Washington and to an anonymous benefactor of this Laboratory for essential financial assistance in carrying out this research.

Summary

The heat of neutralization of acetic acid and sodium hydroxide was found to be 54,324 joules at 20° at concentrations of $HC_2H_3O_2 \cdot 100H_2O$ and $NaOH \cdot 100H_2O$. The heat of neutralization at other concentrations is calculated with the aid of thermochemical data presented in previous publications. By extrapolation, upward for acetic acid and downward for strong acids, the heat of reaction $H^+ + OH^- = H_2O$ was found to be 57.07 kj. or 13.65 Cal. at 20°.

A STUDY OF THE THERMOCHEMICAL BEHAVIOR OF WEAK ELECTROLYTES[1]

BY THEODORE W. RICHARDS AND BEVERIDGE J. MAIR

RECEIVED SEPTEMBER 18, 1928 PUBLISHED MARCH 6, 1929

Introduction

Within the past few years the thermochemical behavior of aqueous solutions of many strong electrolytes has been investigated in this Laboratory.[2] The present investigation is a continuation of that work, particularly with weak electrolytes. Heats of dilution at 16 and 20° of aqueous solutions of citric acid, sodium citrate and the acid citrates were measured and from these values the heat capacities of the resulting solutions calculated by means of the Person–Kirchhoff equation.[2d] The heats of neutralization of citric acid and its acid salts were also measured and from the heats of dilution of factors and products the heat of neutralization at various concentrations was calculated. The significance of such measurements in connection with solution theories needs no explanation. The heats of dilution and resulting heat capacities will be considered first.

Apparatus and Method

The apparatus and experimental procedure have been adequately described elsewhere.[2d,e] The large absorption of heat on dilution of the citrates, however, necessitated one minor modification. A reservoir for ice and water, supported four feet above the apparatus, was connected to a circular rose in the outer bath. The rose, made out of glass tubing with small apertures three inches apart, encircled the "submarine" and

[1] On account of the death of Professor Richards on April 2, 1928, the work here described was completed and the manuscript was prepared by the junior author under the general direction of Dr. Lawrence P. Hall.

[2] (a) Richards and Rowe, THIS JOURNAL, 42, 1622 (1920); (b) 43, 771 (1921); (c) 44, 684 (1922); (d) Richards and Gucker, *ibid.*, 51, 712 (1929); (e) Richards, Mair and Hall, ibid., 51, 727 (1929).

permitted the addition of ice water to take place throughout the bath rather than at any one spot. This, together with the efficient stirrer already in the bath, made it possible to add water rapidly without appreciable thermal inhomogeneity. Since the calorimeter system was identical with that used by Richards, Mair and Hall[2e] its heat capacity was taken as 76.4 mayers, the value previously obtained by them from the heat capacity of its constituent parts.

Purification and Analyses of Solutions Used in the Dilution Experiments

Sodium Citrate Solution.—Sodium citrate, the best obtainable, was further purified by a single crystallization with centrifuging, dried in the oven at 100° and dissolved to make a solution approximately $Na_3C_6H_5O_7\cdot 50H_2O$. The solution was then analyzed by digesting a weighed quantity with sulfuric acid in a long-necked quartz flask of about 100 cc. capacity. The digestion mixture, when clear, was transferred to a weighed platinum crucible and evaporated to dryness on a ring burner. It was fused to constant weight and weighed as Na_2SO_4. The residues were examined for SiO_2, tested for excess SO_3 with methyl orange, and showed no signs of either. Four analyses showed the solution to be of the concentration $Na_3C_6H_5O_7\cdot 49.35 \pm 0.01H_2O$.

Citric Acid Solution.—The best obtainable citric acid was further purified by a single crystallization with centrifuging and dissolved to make a solution of approximately the desired concentration. Two analyses with carbonate-free sodium hydroxide, using phenolphthalein as an indicator, showed the solution to be of the concentration $H_3C_6H_5O_7\cdot 25.07H_2O$. 0.07 g. of thymol was added to three liters of solution. This quantity, insufficient to alter the heat capacity of the solution, adequately prevented the formation of mold.

Monosodium Dihydrogen Citrate and Disodium Monohydrogen Citrate Solutions.—These solutions were made up determinate to the concentrations $NaH_2C_6H_5O_7\cdot 50H_2O$ and $Na_2HC_6H_5O_7\cdot 50H_2O$, using the citric acid and sodium citrate solutions which had been previously analyzed.

Reference to the papers previously mentioned will show how the results were calculated. The rise in temperature, *At*, was the average of two or more experiments agreeing within 0.0003". In a few cases, where there was a larger discrepancy caused by some temporary minor difficulty, a greater number of experiments were performed so that the average deviation from the mean was in no case greater than ±0.0004°. The heat capacities of the most concentrated solutions used in the calculation of the first stage of the heat of dilution were the instantaneous values at 16 and 20°, directly determined by Richards and Gucker,[3] while for the subsequent dilutions the heat capacity at 18° (calculated by means of the Person–Kirchhoff equation) was used to compute the heat of dilution at both 16 and 20°. This approximation was adequate for the accuracy desired.

The experimental data, corrected to integral stages where necessary, are summarized in the following tables.

The values given in Table II for the heats of dilution are depicted graphically in Fig. 1, in which ordinates represent heats of dilution and abscissas

fractions of a mole of salt per mole of water. It is worthy of note that there is no regularity between the heats of dilution of these substances due to the replacement of hydrogen by sodium.

In Table III the heats of dilution, AH, of acetic and citric acids are compared with their degrees of ionization.[4] The first two rows represent the concentration and corresponding degree of dissociation, while the third and fourth rows give the change in ionization and corresponding heat of dilution between the concentrations given in the first row.

---

[4] The only one of the substances investigated in this research on which data necessary for the calculation of the degree of ionization are available is citric acid. Acetic acid, for which accurate data for the heats of dilution have been published in a recent paper of this series (Richards and Gucker, THIS JOURNAL, 51,712 (1929), is the classical example given for the Ostwald dilution law and is consequently particularly suitable for this comparison. The degree of ionization was calculated by the approximate formula $\alpha^2 = K/c$, where α = fraction ionized, c = concentration in moles per liter and K is the equilibrium constant. The dissociation constants used for acetic and citric acids were 1.8 X 10^{-5} and 0.082 $\times$ 10^{-5}, respectively (Creighton and Fink, "Electrochemistry," 1924, Vol. I, p. 309). Accuracy adequate for the present purpose was obtained by neglecting the dissociation of the secondary and tertiary hydrogens of citric acid.

Table III

Comparison of Heat of Dilution and Ionization

Acetic acid	$25H_2O$		$50H_2O$		$100H_2O$		$200H_2O$		$400H_2O$		$800H_2O$
$a \times 10^{-3}$	3.04		4.16		5.78		8.13		11.46		16.14

ΔH, joules		464		353		254		210		193	

An examination of the third and fourth rows shows immediately that the heat change evolved does not parallel the increase in ionization, the heats of dilution decreasing while the change in degree of ionization increases. These results indicate that some other factor or factors must be largely responsible for the heat of dilution (in the range studied), although they do not preclude the possibility that there is a heat effect **due** to ionization masked by some larger effect. Other factors besides ioniza-

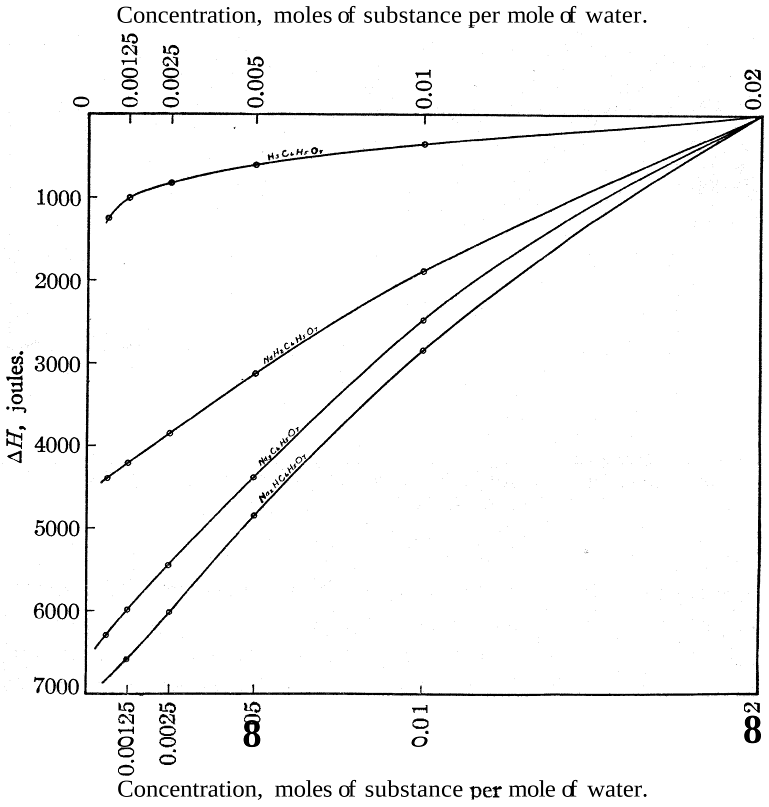

Fig. 1.—Heats of dilution.

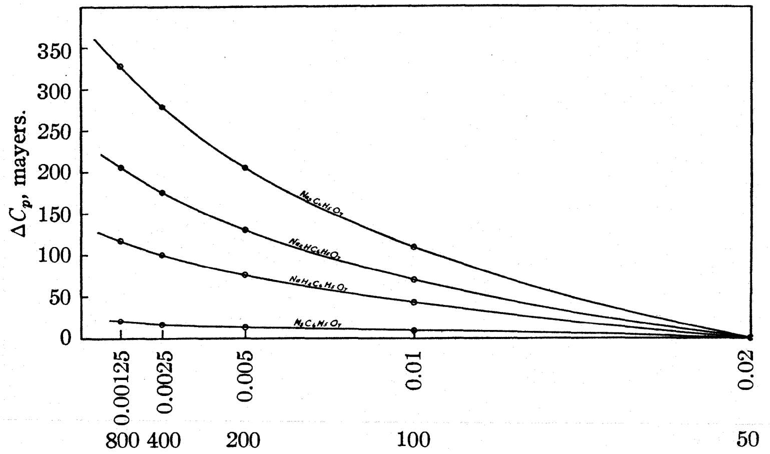
tion responsible for the heat effect might be polymerization or depolymerization of solvent and solute molecules and solvation of molecules or ions of solute.

Another series of quantities worthy of consideration is loss of heat capacity on dilution. These values are depicted graphically in Fig. 2 in a manner identical with that employed for the heats of dilution. An examination of the curves shows that each hydrogen replaced by sodium in the citrates produces an increase in the loss of heat capacity which is almost regular. As was pointed out, no such regularity existed with the heat of dilution. This may be taken to indicate that loss of heat capacity is a function of fewer variables than heat of dilution. Richards and Rowe[2b] have pointed out that ionization should be accompanied by a decrease in heat capacity since the neutralization of strong acids and bases in which H^+ and OH^- are de-ionized is accompanied by an increase in heat capacity. It is interesting to see whether differences in degree of ionization can explain the regularity observed in the loss of heat capacity of the citrate solution. The strength of these substances as electrolytes increases from citric acid to sodium citrate and the percentage increase in ionization over the range investigated probably increases in the same order. Since this is the order in which the loss of heat capacity increases, it is apparent that the loss of heat capacity in these solutions depends to a large extent on the number of ions formed.



Concentration, (a) moles of substance per mole of water. (b) Moles of water per mole of substance.

Fig. 2.—Loss of heat capacity.

The total molal heat capacities are tabulated in Table IV.

These values (in the dilute solutions, at least) exhibit some regularity, heat capacity decreasing as hydrogen is replaced by sodium. This is

TABLE IV

MOLAL HEAT CAPACITIES AT 18° IN MAYERS

	$50H_2O$	$100H_2O$	$200H_2O$	$400H_2O$	$800H_2O$
$H_3C_6H_5O_7$	4079.5	7837.7	15366	30433	60566
$NaH_2C_6H_5O_7$	4091.5	7816.3	15316	30361	60479
$Na_2HC_6H_5O_7$	4083.6	7781.1	15255	30278	60385
$Na_3C_6H_5O_7$	4054.4	7711.9	15152	30147	60234

exactly contrary to the behavior of strong inorganic acids, in which Richards and Rowe found the replacement of hydrogen by sodium to be accompanied by an increase in heat capacity. At infinite dilution it might be expected that the replacement of each hydrogen by sodium would produce the same change in heat capacity, since in such a condition the solution would be completely ionized and the difference in heat capacities would be simply the difference between the heat capacities of the hydrated sodium and hydrogen ions. The above solutions do not show a constant difference nor could it be expected that they would, since citric acid even in $800H_2O$ solutions is but slightly ionized. Some tendency toward a constant difference is noticeable as the solutions become dilute.

Heats **of Neutralization.**—The heat of neutralization of citric acid and its acid salts was determined with the same apparatus and in a manner identical to that previously employed to determine the heat of neutralization of acetic acid.[5]

The purification and analysis of the sodium hydroxide were performed with all the precautions previously described in publications from this Laboratory.[2c,6]

The citric acid was purified and analyzed in the same manner as in the dilution experiments. The acid salt solutions were made up determinate from standard sodium citrate (analyzed as described in the dilution experiments) and citric acid solutions.

By titration with standard sodium hydroxide a direct comparison of the solutions thus prepared was obtained. The results of the direct analyses and the determinate values agreed satisfactorily in all cases.

With disodium monohydrogen citrate a slight excess of base was used to eliminate as far as possible any uncertainty caused by traces of carbonate in the sodium hydroxide. Since this procedure was not possible with citric acid and monosodium dihydrogen citrate, exactly equivalent quantities were used.

The essential experimental data are recorded in Table V. *AT* is the average of at least five experiments which agreed within 0.003° in the cases of citric acid and disodium monohydrogen citrate. The results were not as concordant with monosodium dihydrogen citrate, in which case

[6] Ref. 3, p. 1882.

the average deviation from the mean was 0.004". *Ah* refers to the heat absorbed by the quantities used in the actual experiment, while AH refers to molal quantities. A and B refer to acid and base, respectively.

TABLE V

HEATS OF NEUTRALIZATION OF CITRIC ACID AND ITS ACID SALTS

Weight, g.	Ht. cap. per g., mayers	Total heat cap. incl. Cal. (mayers)	AT, av.	Final T	*Ah* Joules	AH Joules
Citric Acid (Series I). $NaOH\cdot 100.99H_2O + H_3C_6H_5O_7\cdot 100.79H_2O$

587.53B	4.0537	Average at 20.00° = –53291				
Monosodium Dihydrogen Citrate. $NaOH\cdot 99.75H_2O + NaH_2C_6H_5O_7\cdot 100H_2O$						
640.60A	38778	4925.7	3.428	19.88	–16884	–53136
583.73B	4.0523	Average at 20° = –53130				
Disodium Monohydrogen Citrate. $NaOH\cdot 99.75H_2O + Na_2HC_6H_5O_7\cdot 100H_2O$						
640.62A	3.8187	4875.2	3.524	20.05	–17180	–54664
580.60B	4.0523	Average at 20.00° = –54663				

The temperature coefficients of the heats of neutralization were calculated from the heat capacities of the factors and products with the aid of the Person–Kirchhoff equation and are given in the following table.

TABLE VI

TEMPERATURE COEFFICIENT OF HEAT OF NEUTRALIZATION

	Molal heat cap. of fac. at 18°, mayers	Total mayers, *K*	Molal heat cap. of prod. at 18°, mayers, *K*	Average $\frac{\Delta(\Delta H)}{\Delta T}$ or ΔC_p
$H_3C_6H_5O_7\cdot 100H_2O$	7837.7	15301.0	15391.0	+90.0
$NaOH\cdot 100H_2O$	7463.3			
$NaH_2C_6H_5O_7\cdot 100H_2O$	7816.3	15279.6	15329.9	+50.3
$NaOH\cdot 100H_2O$	7463.3			
$Na_2HC_6H_5O_7\cdot 100H_2O$	7781.1	15244.4	15226.7	–17.7
$NaOH\cdot 100H_2O$	7463.3			

The molal heat capacity of the product was obtained by adding to the molal heat capacity of the $200H_2O$ solution the heat capacity of one mole of H_2O and correcting this value for loss of heat capacity on dilution with the aid of curves for ΔC_p given in Fig. 2.

It is interesting to note that two of these acids show a much smaller increase in heat capacity on neutralization than the strong inorganic acids investigated by Richards and Rowe, while one of them actually shows a decrease in heat capacity. This is fully in accord with what has been noted previously with regard to loss of heat capacity and ionization. The degree of ionization of weak acids being less, the total decrease of ions in the solution on neutralization is less also, so that a smaller increase in heat capacity is to be expected. Even the behavior of $Na_2HC_6H_5O_7$ is not so very abnormal. The concentration of hydrogen ions from $Na_2HC_6H_5O_7\cdot 100H_2O$ is probably quite small, so that it is quite conceivable that there actually are more ions present in $Na_3C_6H_5O_7\cdot 200H_2O$ than in equivalent quantities of $NaOH\cdot 100H_2O$ and $Na_2HC_6H_5O_7\cdot 100H_2O$. Whether this is true is not of great significance since examples of a decrease in heat capacity may be expected in such border cases in which changes of solvation of molecules and polymerization of solvent mask the effect produced by increase in the number of ions formed.
