(b) **Procedure.**—Solutions to be used as solvents for the hydrazine picrate were made by dilution of stronger stock solutions to give the desired concentration of each reagent. Care was taken to minimize loss of acetone by volatilization. Solubility measurements were made for the most part in sealed tubes. Some of the later ones were made in well stoppered bottles. In a few cases to serve as a check against volatilization losses, small weighed ampules of acetone were broken in the solubility bottle after closing it. All of the methods gave concordant results. Hydrazine was determined by the iodic acid method.[5] Previous tests had shown that picric acid does not interfere with this method.[3]

It was necessary to remove acetone. This was done by acidifying the solution and boiling for several minutes to decompose acetone hydrazone and drive off the acetone. Tests were made to prove the efficacy of this procedure. Additional tests were made to ensure that acetone did not have a solvent effect additional to that caused by reaction with hydrazine. This was done,by determination of the solubility of a similar salt, potassium picrate, in 0.2 M sodium chloride and then in 0.2 M sodium chloride plus 0.1 M acetone. No increase in solubility was found in the acetone solvent.

(c) Calculations.—The values of the solubility were plotted on a large scale and a curve was drawn through the points. Interpolated values were taken from this for the calculations. Since acetone hydrazone is decomposed by boiling before titration, the concentration of hydrazine found by titration represents the sum of the $N_2H_5^+$ (A) and the acetone hydrazone (D) and therefore also the concentration of the picrate ion (Pic.–). The concentration *(A)* at equilibrium is found by dividing the solubility product of hydrazine picrate by (Pic.–). Acetone hydrazone (D) is then obtained by subtracting *(A)* from the total hydrazine *(A* + D) found by titration. The acetone concentration (B) is equal to the original concentration of acetone in the solvent, minus (D).

In solutions which contain added sodium picrate or picric acid (in the solvent) allowance must be made for this in determining $K_{\text{s.p.}}/\text{Pic.}^- = N_2H_5^+ = (A)$. Furthermore, our earlier work has shown that small amounts of picrate ion have a marked specific effect on the solubility of picrates with the result that the solubility product increases considerably due to the additional hydrazine picrate dissolved by the acetone, even in the small range covered in these determinations of solubility. Approximate correction-was made for this increase and the $K_{\text{s.p.}}$ used in calculating is given in each case.[6]

[5] Bray and Cuy, THIS JOURNAL, 46, 858 (1924).

[6] This correction was made as follows:

at 15° $K_{\text{s.p}}$ $N_2H_5\text{Pic.}$ in 0.2 M NaCl + 0.02 M HCl = 2.19×10^{-4} (1)

at 15° $K_{\text{s.p.}}$ $N_2H_5\text{Pic.}$ in 0.2 M NaCl + 0.01 M HCl = 2.08×10^{-4} (2)

at 15° $K_{\text{s.p.}}$ $N_2H_5\text{Pic.}$ in 0.2 M NaCl = 1.99×10^{-4} (3)

by interpolation $N_2H_5\text{Pic.}$ in 0.2 M NaCl + 0.0033 M HCl = 2.01×10^{-4} (4)

$$\text{by expt. } N_2H_5\text{Pic. in } \left\{\begin{matrix} 0.133\ M\ \text{NaCl} \\ 0.067\ M\ \text{NaPic.} \end{matrix}\right\} + 0.0033\ M\ \text{HCl} = 2.98 \times 10^{-4} \qquad (5)$$

From (4) and (5) it may be seen that changing Pic.$^-$ from 0.0709 to 0.0142 M causes

The values of the equilibrium constant calculated from measurements in *0.0033 M* hydrochloric acid were rather high (Table IV), but when the constant for the equilibrium between hydrazine, acetone and dimethylketazine was determined (Part 2) it was seen that this acid concentration is so low that appreciable amounts of ketazine were present, in addition to the acetone hydrazone. When allowance was made for this, much better agreement was obtained, as noted in the "corrected K," Table IV.

1B. Determination of Equilibrium **2a from Distribution Experiments.**—Mainly as a check on the solubility method the equilibrium was determined also by the distribution of acetone between benzene and solutions containing 0.2 M sodium chloride and 0.02 M hydrochloric acid, without and with addition of hydrazine hydrochloride. Knowing the distribution ratio when no hydrazine was present, the amount of free acetone in the equilibrium solution when hydrazine is present readily may be calculated. The difference gives the amount which has combined to form acetone hydrazone. The results are summarized in Table V.

TABLE V

EQUILIBRIUM FROM DISTRIBUTION OF ACETONE BETWEEN BENZENE AND HYDRAZINE HYDROCHLORIDE SOLUTIONS

Solvent: 0.2 M $NaCl$–0.02 M HCl with or without 0.02 M N_2H_5Cl

Concn. acetone in water layer, with no N_2H_5 present	Concn. acetone in water layer with 0.02 M N_2H_5Cl	*A*	*D*	K_{2a}
0.0593	0.0510	0.0117	0.0083	(13.9)
.0297	.0260	.0163	.0037	8.74
.0297	.0262	.0165	.0035	8.10
.0593	.0513	.0120	.0080	(13.0)
.0297	.0258	.0161	.0039	9.4

(a) Procedure.—The strong stock solutions were diluted to give the proper concentration of each reagent and 50 cc. each of benzene and the solution were rotated together for eighteen hours at 15°. Fifteen cc. samples were then taken and the acetone in the benzene layer was determined by Messinger's method.[7]

The validity of the distribution method depends upon the assumption that no hydrazine or acetone hydrazone passes into the benzene layer. Since the solution is acid, both should be present as salts. There is reason to believe that the salts would be little soluble in benzene but several benzene samples were carefully tested for the presence of hydrazine after boiling with *3* M acid. The results were entirely negative, proving the absence of hydrazine, hydrazone and ketazine from the benzene layer. The high solubility of acetone in benzene reduced the available concen-

---

a change of 0.97 X 10^{-4} in the $K_{s.p.}$. It was assumed that this increase would be linear and that smaller changes in Pic.– such as would be met when acetone is added to the solvent (increasing the solubility) would cause a proportional change.

[7] Goodwin, THIS JOURNAL, 42, 39 (1920).

tration in the water layer so much that small errors are magnified in obtaining the equilibrium data, but the results give good confirmation for the solubility measurements.

The mean value of K_{2a} from all the experiments, both solubility and distribution, is 10.3, but in view of the uncertainty regarding salt effects which may exist it is reasonable to round it off to 10.0. This will be used in the subsequent calculations.

Having thus established the relation existing between acetone, hydrazine and acetone hydrazone, it is possible to determine the hydrolysis equilibrium of dimethylketazine.

Part II

Determination of the Equilibrium Constant for the Hydrolysis of **Dimethylketazine.**—The hydrolysis was studied with the use of a device previously described,[8] by which the investigators followed the addition of anions to the ethylene oxides. The essential part consisted of a microburet with a very fine tip from which acid was run into the solution at a rate just sufficient to replace the H^+ used in the hydrolysis of the ketazine. The previous reaction differed from the present in that it was independent of the hydrogen-ion concentration, while in our work the hydrogen ion was one of the reactants. It was necessary therefore to have a much closer regulation of the PH in this case.

(a) Procedure.—The vessel containing the ketazine solution was placed in a narrow, transparent, constant-temperature bath and sky light reflected through it. A suitable amount of indicator (brom cresol green) was placed in the reacting solution, and in similar vessels on each side were placed, with the same amount of indicator, phthalate buffer solutions differing by 0.1 *PH* unit (greater and less) from the *PH* desired for the equilibrium mixture. A mechanical stirrer was provided, operating through a stopper, and acid (0 8089 M) was run in from the buret at a rate to keep the color of the indicator within the limits set by the standards on either side. The readings of the buret were taken from time to time and they furnished a record of the velocity of the reaction for Part **3.** The final reading was taken after a matter of hours in order to ensure attainment of equilibrium. It would appear that the best results one might hope for would be not closer than 0.1 *PH* unit, but by working only when the light was good much better results than this were actually realizable, as the curves show.

(b) Results.—Equilibrium data were obtained at 15° over a range of ketazine concentration from 0.007 to 0.037 M at *PH* 5.35 and 4.95;[9] at *PH* 5.00 and 4.60 with M sodium chloride as solvent instead of water, and, finally, at 20°, at *PH* 5.35, using in all cases brom cresol green as indicator. The reacting solution had a volume of 51 cc. (50 in a few runs) to which were added during the reaction varying amounts of perchloric acid—never more than 1.10 cc. This was corrected for in calculating the

[8] Bronsted, Kilpatrick and Kilpatrick, THIS JOURNAL, 51, 428 (1929).

[9] These *PH* values have been corrected as suggested by Koltlioff. J. Phys. *Chem.*, **32,** 1820 (1928), for differences between reacting salt concentration and the concentration of the standard buffers.

constants. In Fig. 1 there is plotted as ordinate the fraction "α" of dimethylketazine which has been hydrolyzed at equilibrium; as abscissa the total concentration of ketazine, hydrazine and acetone hydrazone. This was determined by boiling a measured sample of the equilibrium mixture with dilute acid to decompose the acetone compounds and volatilize the acetone, and then titrating the hydrazine. This gives C_0, the original concentration of ketazine with allowance made for dilution by the added acid. For the sake of economy of space not all the data for Fig. 1 are included but Table VI gives typical results, together with the percentage deviation of the individual points from the smooth curve. For only one point in Fig. 1 is the deviation greater than 5%. Since by our device

the H^+ is kept constant during any series of runs, the reaction becomes essentially monomolecular to the right (see Equations 1 and 1a), and bi- or trimolecular in the reverse direction. Dilution will thus favor the hydrolysis, and as C_0 approaches zero, α will approach 1.0. This fact was taken into consideration in drawing the best curve for each set of points.

(c) Calculations.—For the calculation of the hydrolysis equilibrium there were in each case four quantities available: (1) C_{H^+}, which was constant and used only in the final calculation (ordinarily it was included with the constant); (2) the sum of the equilibrium concentrations of ketazine, acetone hydrazone and hydrazine (C + D + A) (This is equal to C_0, the total ketazine if no hydrolysis had taken place.) **(3)** the concentration of acid needed to bring the system to equilibrium at the desired PH. (This is equal to the concentration of the hydrazine plus that of acetone hydrazone (D + A) and also equal to αC_0 = amount of ketazine hydrolyzed); (4) the equilibrium constant, K_{2a}, which fixes the relation between acetone, hydrazine and acetone hydrazone.

$$K_{2a} = \frac{D}{A \times B} = 10.0 \text{ or } \frac{A \times B}{D} = 0.1 \tag{4a}$$

With these at hand calculation was made as follows: Equations 1 and 2 show that if neither hydrazine nor acetone is added from without

$$\text{the concentration (B) of acetone at equilibrium} = 2A + D \tag{6}$$

for if A = 0, B = D; if D = 0, B = 2A. Then

$$\frac{A \times (2A + D)}{D} = 0.1 \tag{4a}$$

but

$$A + D = \alpha C_0 \text{ and } D = (\alpha C_0 - A) \tag{7}$$

Substituting this value for D in (4a) and solving

$$N_2H_5^+ = A = \frac{-(\alpha C_0 + 0.1) + \sqrt{(\alpha C_0 + 0.1)^2 + 0.4\alpha C_0}}{2} \tag{8}$$

Using (8), (7) and (6), the quantities needed for the calculation of K_1 or K_{1a} may be obtained from the two experimental figures C_0 and α.[10]

The constant so obtained contains in it the constant factor C_{H^+}. Introducing a numerical value for C_{H^+} gives a value for K_{1a} which may be used for the calculation of the hydrolysis under any desired condition of acidity. Table VII gives the results at different PH and temperatures. They may be summarized as indicated in Table VIII.

---

[10] The concentration of acid added will only be equal to that of the hydrazine and hydrazone formed by hydrolysis if the unhydrolyzed ketazine itself does not act as a base. To test this, acetone was added to dimethylketazine, with a small amount of water. This served to prevent hydrolysis of the ketazine. When no indicators were added to the solution, it was found to be slightly acid to brom thymol blue, slightly basic to brom cresol green, and neutral to brom cresol purple, showing that the ketazine itself does not, under these conditions at least, function as a base.

[a] 0.01 M N_2H_5 added before the run.

(d) Discussion.—The equilibrium may be calculated either on the basis of

$$\frac{C_{N_2H_5^+} \times C_{\text{Acetone}}^2}{C_{\text{Ketazine}}} = K_{1a}\cdot C_{H^+}, \text{ or}$$

$$\frac{C_{\text{Acetone hydrazone}^+} \times C_{\text{Acetone}}}{C_{\text{Ketazine}}} = K_1\cdot C_{H^+}$$

As seen in Table VIII the constant in the second case will be 10 times that in the first, since $K_1 = K_{1a} \cdot K_{2a} = 10K_{1a}$. Since K_{1a} deals with the final simple products of the reaction, it is perhaps preferable to K_1 and the tables have been so prepared. For some purposes K_1 is better. Thus from Table VIII we can find that in water at 15° K_1 has a mean value of 370. If now a value of 0.01 is taken for C_{H^+} and some typical results are chosen from Table II; A = 0.01245, B = 0.03543 and D = 0.00457; then C, the concentration of ketazine present, will be $(0.00457 \times 0.0345)/(C \times 0.01) = 370$; $C = 0.00004$ M. This is less than 1% of the acetone hydrazone present and may therefore be neglected in calculating K_{2a} (as in Part 1) when 0.01 M acid is present.

TABLE VIII

HYDROLYSIS CONSTANTS FOR DIMETHYLKETAZINE AT 15°

PK	Solvent	$K_1 \cdot C_{H^+}$	$K_{1a} \cdot C_{H^+}$	K_{1a}
5.35	Water	1.64×10^{-3}	1.64×10^{-4}	36.5
4.95	Water	$4.5 \times$	4.5×10^{-4}	37.5
5.00	1 *M* NaCl	6.93×10^{-3}	6.93×10^{-4}	73.8
4.60	1 M NaCl	$15.9 \times$	15.9×10^{-4}	69.3
5.35 (20°)	Water	3.8×10^{-3}	3.8×10^{-4}	84.4

On the other hand, if $C_{H^+} = 0.0033$, as in Table IV, C becomes an appreciable quantity. Using typical data

$$C = \frac{0.02264 \times 0.0559}{370 \times 0.0033} = 0.00012$$

The ketazine = $0.00012/0.00264 \times 100 = 4.5\%$ of the hydrazone present. This explains the fact that using uncorrected figures for the concentration of hydrazone in this solvent a very high value for K_{2a} is obtained. Allowance for the ketazine brings K_{2a} into agreement with the values found in the presence of stronger acid where the ketazine concentration is negligible.

A rise in temperature shifts the equilibrium greatly to the right, favoring the hydrolysis.

The use of a concentrated (1 *M*) sodium chloride solution as solvent gives a large positive salt effect on the equilibrium constant, the value being approximately double what it is in the solutions of low ionic strength. Writing the equilibrium

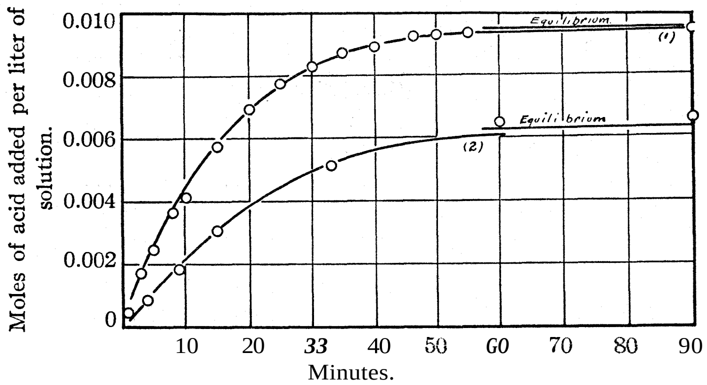
$$K_{18} = \frac{C_{N_2H_5^+} \times C_{Acetone}^2}{C_{Ketazine} \times C_{H^+}} \times \frac{f_1 f_0^2}{f_0 f_1}$$

it is seen that in quite dilute solution there will be approximate equality between f_1 in the numerator and f_1 of H^+ in the denominator; likewise between the activity coefficient of the acetone and ketazine, so the factor reduces to f_0, simply. These assumptions will not hold in such a strong solution as 1 M and the calculation of salt effect would be difficult.

Finally, inspection of the tables shows that at low acidity such as used in this work there is in all cases sufficient of both hydrazine and acetone hydrazone present so that neither may be neglected. All of the equilibria must be taken into account simultaneously. Having thus established the conditions of equilibrium it is possible to study the kinetics of the reaction.

Part III

The Kinetics of the Hydrolysis of Dimethylketazine.—This hydrolysis is representative of a large group of reactions where H^+ or OH– is taken up at a measurable rate. The method as used here is applicable only in cases where the PH may be kept low enough for the proper functioning of indicators, but where applicable gives a valuable method of approach as it effects a considerable simplification of the kinetics.



1, at 20°; 2, at 15°. Note: Run 2 went past the equilibrium point. The curve was drawn below the last two points, but tangent to equilibrium line. This is necessary since the mean K_E is used in the calculation.

Fig. 2.—Velocity of hydrolysis of dimethylketazine at *P*H **5.35.**

(a) Procedure.—The rate of hydrolysis was followed by reading at intervals from the buret (as in Part 2) the amount of acid which had been added. At PH 5.35 the rate was such that it could be readily followed both at 15 and at 20°. The buret was calibrated and a graph constructed by which readings could be translated into cubic centimeters, and thence to moles of acid per liter of solution.

(b) Results.—In Fig. 2 the concentration of acid added, in moles per liter, is plotted as ordinate against time for two representative runs. The data are given in Tables IX and X. Constants were calculated at points read from the curves.

(c) **Calculations.**—C_H^+ is maintained constant during the reaction and the hydrolysis will proceed as a first-order reaction opposed by a bimolecular reaction (Equation 1), or by a trimolecular reaction (Equation 1a). Since the data are interdependent and both reactions are represented in the final state of equilibrium, the kinetics will give no indication and the data will fit both assumptions.

35	.00874	.00740	0.69	.00747	.01621	81.0
					Mean	78.0

$k_1 = K_{1a} \cdot k_2 = 0.000380$ X $78.0 = 0.0294/C_H$.

As pointed out in Part 2, the buret reading at time "t" gives $A + D = \alpha C_0$; acetone concentration $(B) = 2A + D$, and

$$A = \frac{-(\alpha C_0 + 0.1) + \sqrt{(\alpha C_0 + 0.1)^2 + 0.4\alpha C_0}}{2}$$

Final titration of a sample for total hydrazine present gives C_0 and $C = (1 - \alpha)C_0$. Then

$$\frac{d(\alpha C_0)}{dt} = k_1(C_0 - \alpha C_0)C_{H^+} - k_2 \cdot A \cdot B^2 \tag{9}$$

or

$$\frac{d(\alpha C_0)}{dt} = k_1(C_0 - \alpha C_0)C_{H^+} - k_2' \cdot B \cdot D \tag{10}$$

Since the values of A, B and D are all expressed in terms of αC_0, the equation becomes awkward to treat analytically and the purpose is well served by a graphical solution: $K_{1a} = k_1/k_2$ in (9), while in (10) $K_1 = k_1/k_2'$.

For the reason given in Part 2, K_{1a} and Equation 9 have been employed in calculations. The final result is the same in either case.[11] Substituting

[11] It has been suggested by the reviewer that since the expression $K_{1a} = k_1/k_2' = (A)(B^2)/(C)(H^+)$ may also be stated $K_{1a} = k_1'/k_2' = \frac{(A)(B)}{(C)(H^+)/(B)}$ the velocity may be expressed by the equation (using the alphabetical symbols adopted in the paper)

$$-d(C)/dt = k_1'(C)(H^+)/(B) - k_2'(A)(B) \tag{x}$$

as distinct from the one actually used, which was based on Equation 9, *i. e.*

$$-d(C)/dt = k_1(C)(H^+) - k_2(A)(B)^2 \tag{y}$$

Equation (x) involves a reverse reaction of the second order, while (y) is based upon a reverse reaction of the third order. When the experimental values are substituted, constant values are obtained for k_1 and k_2 (Equation y) while a drift of several hundred per cent. is observed in the values of k_1' and k_2' (Equation x).

KINETICS OF HYDROLYSIS AT 15°; PH 5.35

10	.00907	.000195	.00227	.00464	135.0	0.63
15	.00837	.000167	.00291	.00599	131.8	..
20	.00760	.000137	.00358	.00743	130.7	..
25	.00695	.000119	.00412	.00862	142.7	1.2
30	,00645	.000088	.00457	.00957	137.5	..
35	.00605	.000063	.00490	.01030	137.0	1.5

$k_1 = K_{1a} \cdot k_2$ in (9), also the values of A and B in terms of αC_0 and solving for k_2, the velocity constant for the reverse reaction

$$k_2 = \frac{\dfrac{d(\alpha C_0)}{dt}}{C_{H^+} \cdot K_{1a}(C_0 - \alpha C_0) - \left[\dfrac{-(\alpha C_0 + 0.1) + \sqrt{(\alpha C_0 + 0.1)^2 + 0.4\alpha C_0}}{2}\right]} \times \frac{1}{\left[\dfrac{\alpha C_0 - 0.1 + \sqrt{(\alpha C_0 + 0.1)^2 + 0.4\alpha C_0}}{2}\right]^2}$$

Tangents drawn at suitable points on the curves give $d(\alpha C_0)/dt$ with sufficient accuracy.

By this method is obtained a value of $k_2 = 75.0$ at 20° and 135.0 at 15°; $k_1 \cdot C_H$ becomes 0.0294 at 20° and 0.0221 at 15°. This corresponds to a temperature coefficient of 2.65 for a 10° rise for the hydrolysis. On the other hand, the reverse reaction has a lower constant at 20° than at 15°. A rise in temperature will therefore shift the whole equilibrium markedly to the right, favoring the hydrolysis.

Having at hand the values of the equilibrium constant at two temperatures, ΔH may be found from the expression

$$\frac{d \ln K}{dT} = \frac{\Delta H}{RT_2}. \quad \text{From the data, } \Delta H = 9100 \text{ cal.}$$

It is also interesting to calculate the standard free energy change ΔF° for the reactions involved. For Equation 1a the formation of one mole of hydrazine ion and two moles of acetone from one mole of dimethylketazine, one mole of H^+ and two of water

$$\Delta F^\circ_{288} = -RT \ln K_{1a} = -1323 \log 37.0$$
$$\Delta F^\circ_{288} = -2075 \text{ cal.}$$

For Equation 1, the formation of one mole of acetone hydrazone and one mole of acetone from one mole of ketazine, one mole of H^+ and one mole of water

$$\Delta F^\circ_{288} = -RT \ln K_1 = -1323 \log 370$$
$$\Delta F^\circ_{288} = -3400 \text{ cal.}$$

These values are small, as would be expected with a reversible reaction, but taken as they stand would indicate that Reaction 1 is a more probable course for the reaction than 1a, and hydrolysis of dimethylketazine gives first acetone and acetone hydrazone, followed by hydrolysis of the hydrazone to give hydrazine ion and more acetone.

The author wishes to express his gratitude to the John Simon Guggenheim Memorial Foundation and the Regents of the Oregon State College for providing the opportunity for this study. He is especially indebted to Professor Bronsted for the hospitality of his laboratory and for suggestions in the prosecution of the work.

Summary

1. The hydrolysis of dimethylketazine has been studied at 15 and at 20° by a kinetic method.

2. The reaction is reversible and an equilibrium is reached involving H^+, dimethylketazine, acetone hydrazone, acetone and hydrazine.

3. Equilibrium constants have been evaluated under several conditions.

4. The kinetics of the reaction have been studied at the two temperatures and velocity constants for the forward and reverse reactions obtained.

5. Some of the free energy values have been calculated.

THE EFFECT OF STRUCTURE OF ORGANIC HALIDES ON THEIR RATE OF REACTION WITH INORGANIC HALIDES.

III. THE EFFECT OF THE PHENYLTHIO, ALPHA-NAPHTHOXYL AND BETA-NAPHTHOXYL GROUPS

BY W. R. KIRNER AND G. HOLMES RICHTER

RECEIVED MAY 4, 1929 PUBLISHED NOVEMBER 8, 1929

Previous papers published from this Laboratory on the effect of structure of organic chlorides on their rate of reaction with potassium iodide in absolute acetone solution have included the effect of the phenoxyl and methylthio groups,[1] and it seemed of interest to determine how these rates would be affected by substituting an α- and β-naphthoxyl group for a phenoxyl, and a phenylthio group for a methylthio group. The data also give a comparison of the relative effect of an oxygen and sulfur atom in compounds of the structure $C_6H_5O(CH_2)_nCl$ and $C_6H_5S(CH_2)_nCl$. These comparisons are summarized in Table I.

A study of this table brings out the following relationships of structure to reactivity. 1. A chlorine atom in the β-position to a given group has a reactivity which is in every case less than the reactivity of the chlorine atom when in the γ-position to the same group. The ratio of these reactivities at 50° varies between 1:1.53 for the phenyl group, which is the smallest ratio, to 1:6.14 for the α-naphthyl group, which is the greatest.

2. The temperature coefficient ***A*** is in every case higher in the compounds with two carbon atoms between the chlorine and the activating group than in the corresponding compounds with three carbon atoms. The values for A in the first case average approximately 4600 and approximately 4150 in the second case.

3. A phenylthio group in the β- or γ-position to a chlorine atom causes the reactivity of that chlorine atom to be about twice as great as when a

[a] Conant and Kirner, THIS JOURNAL, 46,235 (1924). [b] From the second paper of this series. [c] From the first paper of this series.

phenoxyl group is in the same position. This gives a direct comparison of the effect of the replacement of a sulfur atom by an oxygen atom.

4. The introduction of an oxygen or sulfur atom between the phenyl group and the @-carbonatom (with reference to the chlorine atom) decreases the reactivity of the chlorine atom; but the reactivity of the chlorine is increased if the oxygen or sulfur is introduced between the phenyl group and the γ-carbon atom.

5. 'She phenylthio group in the β-position to a chlorine atom produces a lower degree of reactivity than a methylthio group, but a greater reactivity when in the y-position. This is probably what the various theories of alternate polarity would predict on the basis of the greater negativity of the phenyl group compared to the methyl group.

6. An α- or β-naphthoxyl group in the β- or y-position to a chlorine atom has essentially the same effect as a phenoxyl group in the same position, possibly causing a very slightly greater reactivity. There is no detectable difference in the reactivity caused by an α- or β-naphthoxyl group.

The above conclusions are verified in the data collected in Table II, which compares the reactivities of the compounds RCH_2CH_2Cl and $RCH_2CH_2CH_2Cl$ with ethyl and n-propyl chloride, respectively. This table shows the effect of replacing a @-hydrogenin ethyl chloride and a y-hydrogen in n-propyl chloride by an R group. The additional relationship is brought out from this table that the introduction into the β-position with respect to the chlorine atom, of any of the groups considered, decreases the reactivity of the chlorine atom from $^{1}/_{2}$ to $^{1}/_{8}$ (depending on the particular R group) of its reactivity in the unsubstituted ethyl chloride. If the R group is introduced into the y-position with respect to the chlorine, the reactivity of the chlorine is increased from 1.5 to nearly **3** times its original reactivity in n-propyl chloride. From this viewpoint there appears to be a distinct alternation in reactivity; the substituting group, when in the β-position, depresses the reactivity below that of the unsubstituted chloride but exalts the reactivity above that of the unsubstituted chloride when in the y-position. However, the group which produces the greatest decrease in reactivity in the β-position does not necessarily produce the greatest exaltation when in the y-position.

[a] Conant and Hussey, THIS JOURNAL, 47,477 (1925). [b] From the second paper of this series. [c] From the first paper of this series. [d] Conant and Kirner, *ibid.*, 46, 235 (1924).

While this work was in progress a paper appeared by Bennett and Berry[2] in which they also made the β-chloro-ethyl and y-chloropropyl phenyl sulfides and studied the rate of hydrolysis and also the rate of reaction with potassium iodide, using the method developed by Conant and Kirner. In the synthesis of these compounds they did not isolate the ω-hydroxyalkyl phenyl sulfides and they claim "an attempt to distil phenyl-β-hydroxyethyl sulfide under diminished pressure gave an unsaturated compound, probably due to the splitting out of water from the side chain, giving rise to phenyl vinyl sulfide." No mention is made of a similar attempt at the isolation of the y-hydroxy compound.

We were unable to confirm the statements of Bennett and Berry regarding the instability of the β-hydroxyethyl phenyl sulfide. We isolated this compound as well as the y-hydroxypropyl phenyl sulfide by vacuum fractional distillation at 2 mm. and used the pure hydroxy compounds for the preparation of the chlorides.

In calculating the molecular refraction, the value used for sulfur was n_D 7.97 (the atomic refraction of sulfur in organic sulfides), as given by Price and Twiss.[3] The exaltation in the molecular .refraction of com-

---

[2] Bennett and Berry, J. *Chem. Soc.*, 130,1676 (1927).

[3] Price and Twiss, *ibid.*, 101, 1264 (1912).

pounds which have an unsaturated atom (in this case sulfur) conjugated with a double bond (in this case with a double bond in the phenyl group) as observed by Clarke and Smiles[4] was also found to occur in these phenylthio ethers, the exaltation averaging 0.52 unit. A similar exaltation occurred with the naphthoxyl ethers, in which oxygen is the unsaturated atom, the exaltation averaging 2.512 units.

Bennett and Berry also state that "Andrews' method for estimation of iodide in presence of chloride was found to be unsatisfactory in the present investigation owing to reaction between the iodic acid and the organic sulfide in the chloroform used for indicator. Even after removal of the organic compound the end-point with chloroform as indicator was not well defined." They therefore used the method of Lang,[5] which, as modified, appears to be considerably more tedious and requires both extraction with chloroform and steam distillation of each sample before titration.

In our work on these sulfur compounds we used Andrews' method of titration with the chloroform extraction recommended in previous papers. No difficulty was experienced with ill-defined end-points. The maximum deviation of the velocity constants obtained by us on the β-phenylthio compound was about 11% at both 50 and 60°, whereas Bennett and Berry had a deviation of 16%. Their deviation on the y-compound was but 6%, whereas ours was considerably higher and there was a marked drift in the constants, particularly at 60°, which, however, is not necessarily due to errors involved in the titration. Table III indicates the excellent agreement in the absolute values of Bennett and Berry's velocity constants compared with ours despite the fact that two different methods of titration were used and by different operators. It seems to us that this agreement establishes the Andrews' method as yielding satisfactory results. Our results are calculated to 55° by the use of the temperature coefficient A.

became quite sore to the touch and after five days there was an incipient blistering of the skin. A brownish stain persisted for several months. The y-compound produced no effect whatsoever.

The β-chloro-ethyl phenyl sulfide is thus seen to be considerably less vesicant than the β-chloro-ethyl methyl sulfide. The conclusions reached in the second paper of this series[6] were completely verified.

Experimental

I. The Phenylthio Series

A. Preparation of the **ω-Phenylthio-alkyl** Chlorides.—The first member of this series, phenylthiomethyl chloride, is missing and no attempt was made to synthesize it because of previous unsuccessful attempts to prepare both its oxygen analog and methylthiomethyl chloride.[7]

1. Preparation of **β-Hydroxyethyl** and y-Hydroxypropyl Phenyl Sulfides.—The most recent attempt recorded in the literature to synthesize these substances is that of Bennett and Berry,[2] who treated sodium thiophenoxide with ethylene and trimethylene chlorohydrin, respectively. They did not succeed in isolating these substances in a pure state and therefore did not characterize them; they merely used the crude product from the reaction mixture for another reaction. Steinkopf, Herold and Stohr[8] made the (3-hydroxy compound in a similar manner but made no attempt to isolate it.

The method used in this work was analogous to that suggested by Powell for the preparation of the oxygen analogs.[9] Fifty grams (0.454 mole) of thiophenol was dissolved in 180 cc. of 10% sodium hydroxide solution (0.045 mole), and then treated with slightly more than the theoretical amount of the desired chlorohydrin. The reaction took place rapidly and the mixture was refluxed for half an hour to insure its completion. The oily layer was separated, the aqueous layer extracted twice with ether and the combined oil-ether layer washed with water and dried over anhydrous sodium sulfate. The ether was distilled off, leaving a practically quantitative yield of nearly pure product which was carefully fractionated several times under reduced pressure from a Claisen fractionating flask. Phenyl (3-hydroxyethylsulfide is a water-white liquid with a rather sweet, not unpleasant odor.

Anal. Subs., 0.2160: $BaSO_4$, 0.3241. Calcd. for $C_8H_{10}OS$: S, 20.79. Found: S, 20.61.

There was no difficulty whatsoever experienced during the fractional vacuum distillation and there was no evidence of unsaturated compound formation as reported by Bennett and Berry. They did not state at what pressure their distillation was carried out, but at 1–2 mm. the above hydroxy compound distils smoothly and without decomposition and yields a pure product, as indicated by the analysis.

Phenyl **γ-hydroxypropyl** sulfide is a water-white liquid.

Anal. Subs., 0.1808: $BaSO_4$, 0.2490. Calcd. for $C_9H_{12}OS$: S, 19.06. Found: S, 18.91.

2. Preparation of **β-Chloro-ethyl** and y-Chloropropyl Phenyl Sulfides.—The β-chloro-ethyl compound was first prepared by Steinkopf and co-workers8 by passing hy-

drogen chloride into the crude hydroxy compound. They give the boiling point as 144.5" at 26 mm. and 245° at atmospheric pressure; yield, 76%. Lecher and Stöcklin[10] also obtained it in good yield by the addition of phenyl sulfur chloride to ethylene. They give the boiling point as 122° at 13 mm. and mention the vesicant action of the compound. Bennett and Berry made both the β-chloro-ethyl and y-chloropropyl compounds by the application of Darzens' reaction to the corresponding hydroxy compounds. They give the boiling point of the β-chloro-ethyl compound as 117° at 12 mm. and the boiling point of the γ-chloropropyl compound as 137° at 13 mm.; they state that the ethyl compound has a very slight vesicant action and that the propyl compound is not appreciably vesicant.

In this work the alcohols previously described were converted into the chlorides by Darzens' method,'' using thionyl chloride and pyridine. Twenty grams of the alcohol was treated with the theoretical amount of pyridine and about a 25% excess of thionyl chloride was added dropwise. The characteristic precipitate appeared after about half of the thionyl chloride had been added but redissolved on further addition, forming two layers. The sulfur dioxide was removed by heating on a steam-bath. The yield of crude product was quantitative and the yield after several vacuum fractionations was 80–85%.

β-Chloro-ethyl phenyl sulfide is a colorless liquid.

II. The α-Naphthoxyl Series

A. Preparation of the w-Chloro-alkyl a-Naphthyl Ethers.—The first members of both the *a*- and β-series are unknown and their synthesis was not attempted.

1. Preparation of **β-Hydroxyethyl** and y-Hydroxypropyl **α-Naphthyl** Ethers.—The @-hydroxyethylether was first prepared by Boyd and Marle[12] by treatment of ethylene oxide with sodium a-naphthoxide. They give the melting point as 42". In this work these substances were made analogously to the method used for the preparation of the phenylthio ethers described above. The reactions go rapidly, the emulsion appearing in about ten minutes and the reaction appears to be completed a few minutes later. The mixture is worked up in the usual way; it was found necessary to carry out several extractions of the oily ether layer with 5% sodium hydroxide solution to remove excess or-naphthol.

β-Hydroxyethyl α-naphthyl ether boiled at 167° at 2 mm It had a light yellow color. Numerous attempts were made to crystallize it from various solvents, simple and mixed, but they all failed. On long standing in an ice box the oil started to crystallize but the best melting point obtainable was 22–24°. It is possible that some decomposition occurred during distillation which caused the melting point to be so much lower than that reported by Boyd and Marle.

y-Hydroxypropyl **α-naphthyl** ether is a new compound. It was crystallized from petroleum ether, giving a pure white mass of needle-shaped rosets; m. p. 65.5–66.5°; yield (crude), 79%.

Anal. Subs., 0.2082: CO_2, 0.5894; H_2O, 0.1362. Calcd. for $C_{13}H_{14}O_2$: C, 77.19; H, 6.98. Found: C, 77.27; H, 7.32.

2. Preparation of **β-Chloro-ethyl and γ-Chloropropyl** a-Naphthyl Ethers.—Clemo and Perkin[13] first made the β-chloro-ethyl compound by the direct introduction of the chloro-ethyl group into a-naphthol, using β-chloro-ethyl *p*-toluenesulfonate. They give the melting point as 28° and the boiling point as 202" at 16 mm. We obtained this compound by carrying out a Darzens reaction on the corresponding alcohol, using pyridine and thionyl chloride. The sulfur dioxide was removed by heating on a water-bath for two hours; yield of crude product, 85%. This was carefully fractionated three times in a vacuum, giving a 61% yield of highly purified material. β-Chloro-ethyl or-naphthyl ether is a rather viscous, yellow oil which did not crystallize.

naphthoxide with ethylene chlorohydrin; m. p. 76–77°. We obtained it using precisely the same method that was used for the a-isomer. Crystallization from a mixture of one part of benzene and two parts of petroleum ether gave a product melting at 75–76°; yield of pure product, 57%.

The γ-hydroxypropyl ether was also prepared by Rindfusz and co-workers with a 25% yield; m. p. 99–99.5°. We found the preparation of this compound to go more slowly than the ethyl ether. Crystallization from a mixture of benzene and petroleum ether gave the pure product melting at 98.7–99.4°; yield, 38%

2. Preparation of β-Chloro-ethyl and γ-Chloropropyl β-Naphthyl Ethers.—Clemo and Perkin also made this chloro-ethyl ether. A quantitative yield of crude product was obtained. The pure crystallized compound melted at 83°. We obtained the compound by the Darzens reaction on the alcohol, the crude product also being obtained in quantitative yield. Repeated crystallization from 95% alcohol gave a pure product melting at 80–81°.

Anal. Subs., 0.3217: AgCl, 0.2199. Calcd. for $C_{12}H_{11}OCl$: Cl, 17.16. Found: Cl, 16.91.

γ-Chloropropyl β-naphthyl ether is a new compound and was made by the procedure already described; the yield of crude product was 96%. Crystallization from absolute alcohol gave pure white crystals melting at 47–47.5°.

Anal. Subs., 0.3020: AgCl, 0.1966. Calcd. for $C_{13}H_{13}OCl$: Cl, 16.07. Found: Cl, 16.10.

Summary

1. The effect of the phenylthio and α- and β-naphthoxyl groups upon the reactivity of a chlorine atom in the β- and y-positions has been determined by studying the velocity with which the chlorine is replaced

by iodine using potassium iodide in absolute acetone solution. A comparison was made of the effect of these groups with the methylthio, phenoxyl and phenyl groups when similarly situated.

2. β-Chloro-ethyl phenyl sulfide was found to have only a weak vesicant action and the y-chloropropyl phenyl sulfide was completely non-vesicant.

3. The following substances were isolated and characterized for the first time: β-hydroxyethyl phenyl sulfide, y-hydroxypropyl phenyl sulfide, y-hydroxypropyl a-naphthyl ether, y-chloropropyl a-naphthyl ether, y-chloropropyl β-naphthyl ether.

HOUSTON, TEXAS

[A COMMUNICATION FROM THE LABORATORY OR ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

COMPETITIVE HYDROGENATIONS

BY HOMER ADKINS, F. F. DIWOKY AND A. E. BRODGRICK

RECEIVED MAY 27, 1929 PUBLISHED NOVEMBER 8, 1929

The importance of precise information on the relation of the structure of a compound to its reactivity as manifested in the ease of reduction led Vavon and Husson[1] to devise a unique method for the experimental study of the rate of reduction of certain derivatives of cinnamic acid. Their method consisted in adding one mole of hydrogen to a mixture of one mole of d-a-pinene and one mole of the compound under consideration, and then calculating the distribution of the hydrogen between the two compounds from the change in optical activity of the mixture. They assumed that the distribution of the hydrogen between the pinene and the unsaturated compounds was a measure of the ease of reduction of the unsaturated compounds. If, for example, cinnamic acid took up 57% of the hydrogen (pinene 43%) and a-methylcinnamic acid took up 26% (pinene 74%), they concluded that cinnamic acid was reduced much more easily than the substituted acid. This method of comparison has two very considerable advantages over the usual one of noting the rate of absorption of hydrogen by a single compound. The latter method for an accurate comparison demands that the comparisons be made over catalysts of identical activity. This is a condition which it is difficult if not impossible to meet if an extended list of compounds is to be compared. This method also presupposes that there is no impurity in any of the compounds which would lower the activity of the catalyst. An attempt was made to repeat and extend their work because of our interest in simultaneous reactions and because previous work in this Laboratory made it seem probable that the ratio of the distribution would be a func-

---

[1] Vavon and Husson, *Compt.* rend., 176, 989 (1923).

tion of the particular catalyst and the solvent used as well as of the structure of the organic compounds reduced.

Four hundredths of a mole of d-a-pinene and 0.04 of a mole of cinnamic acid or other unsaturated compound were mixed in a solvent and the volume made up to 100 cc. A quantity of Adams and Voorhees' platinum oxide was added and followed by 0.04 mole of hydrogen under a pressure of 0.2 of an atmosphere. The bottle containing the reaction mixture was agitated. A polarimetric reading of the mixture was taken before and after the addition of hydrogen. A second solution containing only d-a-pinene was fully reduced and the rotation noted. The distribution of the hydrogen between the two compounds may be calculated from the readings on the hydrogenated pinene, the unreduced mixture and the mixture after absorption of one mole of hydrogen. Whenever a new catalyst was prepared, its activity was standardized by a trial run. Allowance was made for the volume of hydrogen absorbed by the platinum oxide on being reduced to platinum black. All of the results given in this paper were checked at least once and most of them several times, using different preparations of catalyst and solvent.

There is no very marked difference in the rate of reduction of a mixture of pinene and cinnamic acid irrespective of whether methyl *(33* m.) or ethyl alcohol *(37* m.) or acetic acid (40 m.) is used. The rate is much lower in ethyl acetate (70 m.) and the higher alcohols propyl (65 m.) and butyl (85 m.). Ferrous sulfate has no effect upon the rate but 0.001 mole of manganese (55 m.) and especially zinc (180 m.) and nickel acetates (180 m.) very greatly reduce the rate of hydrogenation. There was very little difference in the rate of reduction of mixtures in acetic acid of pinene and cinnamic acid (40 m.), a-methylcinnamic acid (35 m.), methyl β-methylcinnamate (33 m.) and ethyl β-methylcinnamate (33 m.).

TABLE I

The data referred to in the last paragraph were obtained at an earlier time and with samples of catalysts which differed somewhat in activity from those referred to in Table I. In Col. 1 of this table is given the time in minutes for the addition of 0.04 mole of hydrogen to 0.04 mole of cinnamic acid or other unsaturated compound. In Col. 2 is given the time required for the similar reduction of pinene and in Col. **3** is given the time required for the addition of 0.04 mole of hydrogen to a mixture of 0.04 mole of pinene and 0.04 mole of the other unsaturated compound under consideration. The percentage of the hydrogen taken up by the pinene is given in Col. 4.

The nature of the solvent and the structure of the cinnamic acid derivatives play a very large role in determining the ratio of distribution of the hydrogen between the compounds of the mixture, as has been pointed out by Vavon and his associates. In an acetic acid solution of cinnamic acid and pinene, 65% of the hydrogen goes to the acid, while in ethyl acetate, acetal or the dimethyl ether of ethylene glycol the acid receives from 81 to 85% of the hydrogen. In an acetic acid solution a-methylcinnamic acid gets only 7% of the hydrogen, while the esters of β-methylcinnamic acid get only 9 to 13% of the hydrogen.

In acetic acid solution Vavon and Husson found that 57% of the hydrogen went to the cinnamic acid, 26% to the a-methylcinnamic acid, 45% to the methyl β-methylcinnamate and 31% to the ethyl β-methylcinnamate. Our results are in only fair agreement with those of Vavon and Husson for cinnamic acid and are markedly different for the derivatives of the acid. It is not believed that this is a reflection on the work of either set of investigators, but shows, rather, that the nature of the pinene used affects the distribution of hydrogen. It should be noted that our platinum catalysts were not prepared by the same method as that used by Vavon and his associates.

The salts which have so great an influence on the rate by hydrogenation had no effect upon the distribution of hydrogen between the two unsaturated compounds present in the mixture. The activity of the catalyst is entirely without effect upon ratio of the distribution of the hydrogen.

The most striking results noted in this study have to do with the rates of reduction of pure compounds as compared to the reduction of mixtures. Pinene is much more rapidly reduced in acetic acid solution than is cinnamic acid, yet in a mixture the acid is reduced more rapidly than is pinene. Pinene and octene are reduced at very similar rates, yet in a mixture the octene gets about 75% of the hydrogen. It requires almost seven times as long to reduce a mole of allyl alcohol as it does one of pinene, yet in a mixture allyl alcohol gets 92% of the hydrogen at a rate very similar to that for pinene. These results show that there may be no relationship between the relative rates of reduction of pure compounds and their rate of reduction in mixtures.

An attempt was made to find a set of conditions under which the distribution of hydrogen between two compounds could be studied over both a platinum and a nickel catalyst. This was unsuccessful, since nickel is not active toward the compounds under consideration at room temperature, nor in the presence of ethyl acetate or acetic acid. Platinum is apparently not active at the higher temperatures at which nickel functions as a catalyst. Mixtures of 0.25 mole of cinnamic acid and 0.25 mole of pinene and of octene and pinene were hydrogenated at 135° in a glass container at a pressure of from one to two atmospheres using 10 g. of Reid and Rather's[2] nickel catalyst reduced for two hours at 450°. The calculated distribution of hydrogen between the competing compounds is given in Table I.

Reduction of Furfural Acetone.—Since the solvent apparently plays so large a role in determining the relative rates of reduction of various pairs of unsaturated compounds, some experiments were carried out on a larger scale upon the reduction of furfural acetone, which contains four points of unsaturation in the molecule.

One-half mole of hydrogen was added to 0.5 mole of furfural acetone in 125 cc. of the solvent at from one to three atmospheres' pressure of hydrogen, using 0.2 g. of catalyst in alcohol and ethyl acetate and 0.5 g. of a less active catalyst in petroleum ether. The hydrogenation was complete in three to four hours. The larger amount of catalyst used in the petroleum ether was necessary in order to complete the reduction in the usual time as the hydrocarbon mixture apparently dissolved rubber from the stopper of the hydrogenation bottle and thus the catalyst became poisoned. Six of these reaction products were combined (total 540 g.) and fractionated six times at 3 mm. through a 50-cm. Vigreux column (see Table II). The second fraction boiled at 201–202° at atmospheric pressure and the third melted at 38–39'. The semicarbazones from the second fractions melted at 143°. These values show that the fractions were almost pure 4-α-furfurylbutanone-2 and furfural acetone, respectively. The lower fractions consisted very largely of the butanone and the third fraction was made up largely of furfural acetone.

TABLE II

HYDROGENATION OF FURFURAL ACETONE IN VARIOUS SOLVENTS

---

[2] Reid and Rather, THIS JOURNAL, 37,2116 (1915).

A comparison of ethanol, ethyl acetate and petroleum ether as solvents for the reduction of furfural acetone shows that much more furfural acetone was left after the addition of the hydrogen when ethyl acetate was used as a solvent. This means that this solvent facilitated the addition of more than one molecule of hydrogen to a molecule of the ketone, thus causing more complete hydrogenation and poorer yields of 4-a-furfurylbutanone-2. Ethyl alcohol facilitated resinification so that although the yield of the 4-a-furfurylbutanone-2 was higher than with ethyl acetate the recovery of furfural acetone was very low. Petroleum ether did not facilitate the complete hydrogenation noted with ethyl acetate, nor was resinification so high, so that excellent yields of the 4-a-furfurylbutanone-2 were obtained.

Reagents

d-α-**Pinene** was obtained through the kindness of Professor Floyd E. Rowland of the Oregon Agricultural College and the Western White Cedar Co., Marshfield, Oregon. It came from a source which yields a pinene having the highest specific rotation that has been reported in the literature.[3] Its constants were those given by Dr. Thurber, i. e., b. p. 156–156.5°, $[\alpha]_{D}^{20}$ +53.01. The authors were very fortunate to obtain this pure d-or-pinene as the pinene separated from ordinary American turpentine has only a small optical activity. Vavon and Husson presumably used pinene from French turpentine, which contains a much larger proportion of the dextro isomer than does ordinary American turpentine.

Platinum oxide was prepared as by Adams, Voorhees and Shriner.[4] The platinum black after use was converted to platinic chloride either by the method described in their papers, using hydrobromic acid or by dissolving in aqua regia. After several such recoveries the platinum was purified as by Wichers.[5]

Allyl alcohol was purified according to the method of "Organic Syntheses."[6] It absorbed the theoretical quantity of hydrogen and distilled at 95.5–96.5". The petroleum ether was an Eastman Kodak Company product purified by permanganate and boiling at 35–60°. Furfural acetone was prepared as indicated in "Organic Syntheses,"[7] and showed a melting point of 38". The octene used was that isomer known as di-*iso*-butylene and was prepared from tertiary butyl alcohol by Walter Arthur, using a method similar to that described by Edgar.[8] It boiled at 101° at 742 mm. and absorbed the theoretical amount of hydrogen. The cyclohexene was fractionated so that the sample used had a boiling-point range from 81.9 to 82.1". It absorbed 96% of the theoretical quantity of hydrogen.

The cinnamic acid was purified from a commercial product by repeated recrystallization from a mixture of 60% alcohol and 40% water. The melting point was 133°. The α-methylcinnamic acid (m. p. 74–76") was made by a standard laboratory method for cinnamic acid by substituting sodium propionate and propionic anhydride for the

corresponding acetates. The methyl (b. p. 152" (26 mm.)) and ethyl (b. p. 162–163° (26 mm.)) esters of β-methylcinnamic acid were made as described by Lindenbaum[9]

Summary and Conclusions

It appears that the factors determining the distribution of hydrogen by platinum between two competing reactants, like the factors determining the proportion of dehydration and dehydrogenation of an alcohol over zinc oxide, for example,[10] bear little relationship to those factors which determine the amount of material reacting in unit time. The addition of zinc and nickel acetates, for example, retarded the rate of reduction but did not modify the distribution of hydrogen. The use of acetic acid, ethyl acetate and various alcohols as solvents modified the rate of reaction of hydrogen and in addition determined in part the ratio of its distribution between the two reactants. It seems that the salts poison the catalyst for the reaction of the two unsaturated compounds to an equal extent,[11] presumably through adsorption in certain areas of the catalyst. It may be suspected that in addition to this the solvent plays a part in the rate of formation and the stability of an intermediate compound of platinum–hydrogen–reactant–solvent.

The relative ease of reduction of two substances in a mixture may not be certainly determined even qualitatively by determining the rates of reduction of the two substances separately.

In the reduction of furfural acetone there are three competing reactions: (1) simple hydrogenation of the alkene linkage in the open chain, (2) the addition of more than one molecule of hydrogen to a molecule of the ketone and *(3)* "resinification." The ratio of these reactions may be markedly changed by varying the solvent.

The esterification of cinnamic acid or the substitution of a methyl group for a hydrogen on the a- or @-carbonatom very greatly reduced the proportion of hydrogen going to the alkene linkage when the compounds in a mixture with d-a-pinene were treated with hydrogen. No considerable difference was observed between the adsorption of hydrogen by the methyl and ethyl esters of β-methylcinnamic acid.

THE REGULARITIES IN THE MELTING POINTS OF SOME CRYSTALLINE DERIVATIVES OF VARIOUS ALIPHATIC ALCOHOLS[1]

BY G. B. MALONE[2] AND E. EMMET REID

RECEIVED JUNE 3, 1929 PUBLISHED NOVEMBER 8, 1929

Introduction

The fact that certain regularities exist in the melting points of various homologous series of aliphatic organic compounds is well known. As early as 1877 Baeyer[3] pointed out a definite alternation in the melting points of the saturated dibasic acids. Tsakalotos[4] and Forcrand[5] investigated the hydrocarbons of the methane series, while Biach[6] and Timmermans[7] made rather exhaustive investigations of many different series, the latter concluding that the alternation in melting points between the odd and even members of homologous series is a general phenomenon and attempting an explanation on the basis of the symmetry and spatial structure of the molecule. Tammann,[8] Cuy,[9] Pauly[10] and Garner and his co-workers[11] have studied the same general phenomenon of the fatty acids somewhat at length. This brief summation is by no means exhaustive, but it illustrates the type of work done. Throughout very little is said of the melting points of the alcohols themselves. Such alternation as may be seen from an examination of the melting points is much smaller than that of the hydrocarbons and fatty acids for example, and it was thought consequently that the alternate high and low melting points might be much more pronounced in a series of derivatives of the alcohols from one to ten carbon atoms. Such regularities have been found in a series of ketones, homologs of acetophenone,[12] in which the alkyl varies from C_{10} to C_{17}. Accordingly, the 3,5-dinitrobenzoates of the normal

alcohols from methyl to decyl were prepared because there have been more of these particular derivatives reported for these alcohols than any of the standard ones. Later this series was supplemented with an iso (homologs of *iso*butyl, *iso*-amyl, etc.) and a secondary (hydroxyl on carbon atom number two) series.

Discussion of Results

The accompanying figure shows the melting points of the three abovementioned series of esters plotted against number of carbon atoms. The iso series extends to octyl and the secondary series to nonyl. In the normal series the alternating effect may be seen all the way through (with the esters of an even number of carbon atoms in the aliphatic portion high and those of odd carbon atoms low). With the lower members the effect is not so pronounced, in view of the low percentage of the molecular weight due to the alkyl part of the ester. The *iso* series shows the same type of curve except for a slightly greater tendency toward convergence and that the general swing of the curve has not reached a minimum

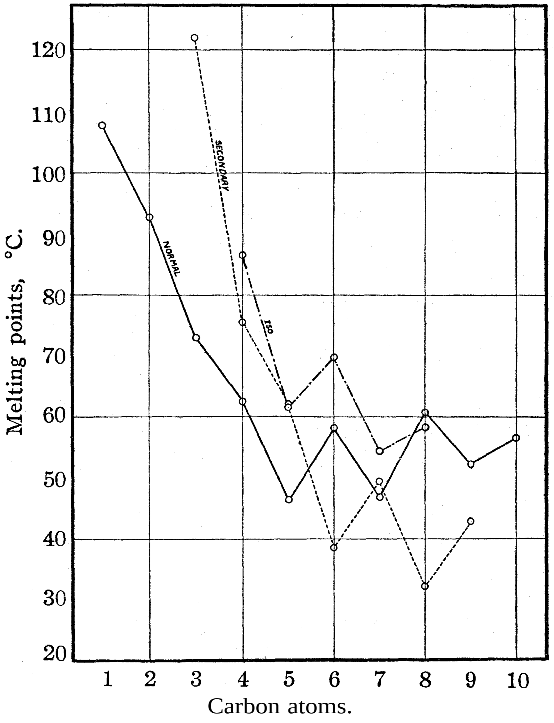

Fig. 1.—Melting points of alkyl esters of 3,5-dinitrobenzoic acid.

and started back up again, which would probably be the case could the curve be extended.

The secondary series offers an interesting variation. Here the esters of odd-numbered carbon atoms melt high and those of even carbon atoms low, just the opposite of the normal and *iso* series. An examination of the structural formulas, representing the aromatic residue by X, would seem to indicate that only the longest carbon chain, namely, that included in R, attached to the "key" carbon atom (designated by a star) affects the melting point. The fact that the isopropyl ester has an extremely high melting point is probably due to the presence of two identical units, the methyl group, on the key carbon atom, resulting in a highly symmetrical arrangement.

one part of ethyl ether, in which free acid and acid chloride are only very slightly soluble. The solvent was allowed to evaporate and the residue recrystallized to a constant melting point from 95% ethyl alcohol. Final melting points were taken with Anschütz thermometers graduated in tenths of a degree, for which certificates of the Reichsanstalt were available. These melting points were determined in the ordinary way with finely drawn out tubes of about one mm. diameter. A large glass tube equipped with a rotary stirrer of the paddle wheel type, driven at high speed by a small motor, was employed as a bath. This in turn was encased in a still larger tube whose corresponding dimensions were 1.0–1.5 cm. larger, the intervening air-bath serving to insure more even heating, this being carried out with a micro flame. To the mean of the final melting point range, in no case over 0.4° and in most cases 0.2° or less, were added the proper stem and tabular corrections, the figure to the nearest 0.1° being taken as the true value of the melting point. For brevity, only final corrected melting points are given. Included with these in the accompanying table are melting points obtained from the literature of such of these esters as have been previously reported.

The sources of the various alcohols were as follows. The methyl, ethyl, n-propyl, *iso*propyl, n-butyl, secondary butyl and isobutyl alcohols were cut sharply from good commercial grades on high precision stills, boiling point ranges being 0.2–0.3° and agreeing with accepted values. Normal and secondary octyl alcohols were supplied by the Eastman Kodak Co. and redistilled. The remaining alcohols were synthesized by the Grignard reaction; boiling points of the higher alcohols are:[21] *n*-amyl 137.8_{760}; *n*-hexyl 156.1_{758}; n-heptyl 176.0_{755}; n-octyl 195.3_{765}; n-nonyl 213.5_{758}; *sec.*-amyl 119.3_{760}; *sec.*-hexyl 139.7_{759}; *sec.*-heptyl 158.5_{754}; *sec.*-octyl 180.3_{765}; *sec.*-nonyl 198.2_{760}; *iso*hexyl 151.7_{758}; isoheptyl 169.5_{735}; *iso*-octyl 188.0_{767}.

Summary

The 3,5-dinitrobenzoates of twenty saturated aliphatic alcohols have been prepared.

Certain regularities have been observed in their melting points.

BALTIMORE, MARYLAND

THE DIRECT INTRODUCTION OF SULFUR INTO AROMATIC HYDROCARBONS[1]

BY H. B. GLASS[2] AND E. EMMET REID

RECEIVED JUNE 3, 1929 PUBLISHED NOVEMBER 8, 1929

Sulfur, in the presence of aluminum chloride, reacts with benzene to give thiophenol, diphenyl sulfide and diphenylene disulfide.[3] The same products are obtained by the dry distillation of the sodium salt of benzenesulfonic acid.[4] Since sulfur may be introduced into benzene by the use of a catalyst at low temperatures it was thought that at elevated temperatures this could be accomplished without the aid of a catalyst. Accordingly, the action of sulfur on benzene and ethylbenzene was investigated.

Results and Discussion.—Benzene and sulfur when heated together at 350° for twenty-four hours gave thiophenol, diphenyl sulfide, diphenyl disulfide, diphenylene disulfide (thianthrene) and hydrogen sulfide. It has been shown that diphenyl disulfide is obtained by heating thiophenol with sulfur,[5] and that this is decomposed on further heating to give diphenyl sulfide and free sulfur.[6] Diphenylene disulfide is formed by heating diphenyl sulfide with sulfur.[7] From the fact that thiophenol is obtained from sulfur and benzene, with the aid of a catalyst, it is probable that this is the first product formed at high temperatures without the aid of a catalyst. The formation of all other products isolated can be accounted for by the action of heat and sulfur on this one product.

The action of sulfur on ethylbenzene is quite different from that on benzene and much more rapid. When oxygen is passed into ethylbenzene, acetophenone is formed.[8] By analogy the action of sulfur should be such as to give thioacetophenone and hydrogen sulfide; no thio-ketone, however, was detected in the reaction mixture. Instead there was isolated a good quantity of 2,4-diphenylthiophene, this being the only sulfur-containing product, other than hydrogen sulfide. Baumann and Fromm[9] have shown that thioacetophenone polymerizes readily to give tri-thioacetophenone and that this is both depolymerized and decomposed on heating, anhydro-trithioacetophenone and 2,4-diphenylthiophene being

formed. Further, they have shown that anhydro-trithioacetophenone decomposed on heating to give styrene and 2,4-diphenylthiophene, and that styrene may react in either of two ways to give ethylbenzene or 2,4-diphenylthiophene. Diphenylthiophene, being a comparatively stable compound, when once formed does not undergo further change, while the other above-mentioned compounds readily decompose on heating. It is for this reason that the only sulfur-containing compound obtained from the reaction was diphenylthiophene, the analogy, however, of sulfuration to oxidation being supported.

Experimental

Benzene and sulfur were heated in a steel bomb, of 100-cc. capacity, at 350° for twenty-four hours.[10] Upon opening the bomb much hydrogen sulfide escaped and within the bomb there was a brown oil having the odor of thiophenol. On distillation of this oil there was obtained a small fraction boiling between 76 and 90" and a smaller fraction boiling between 140 and 175°. These two fractions were redistilled several times, thus obtaining unchanged benzene and thiophenol. The latter was identified by its lead mercaptide (calcd., Pb, 48.7; found, Pb, 48.8). That portion of the reaction product boiling above 175° was distilled at a pressure of 5 mm., a mixture of an oil and a solid coming over between 120 and 210" which gave no clear-cut fractions. The residue was a hard, black, glass-like tar. Most of the distillate went into solution on treatment with cold, absolute alcohol but there remained a white solid, difficultly soluble in hot alcohol, which after several recrystallizations gave a melting point of 156 5°. With hot concentrated sulfuric acid this solid gave an intense purple coloration and was identified as diphenylene disulfide (thianthrene) by a mixed melting point with a known sample.

The alcoholic solution from above was concentrated by boiling and cooled to −10°, a white solid separating out which was filtered while still cold. This solid, after recrystallization several times from alcohol, melted at 60°, and on treatment with dilute hydrochloric acid and zinc dust gave at once the odor of thiophenol; sulfur analysis gave 29.5% of sulfur (calcd. sulfur for diphenyl disulfide, 29.4%). It was thus identified as diphenyl disulfide. Vacuum fractionation of the residue from the above alcoholic solution gave an orange-colored liquid having a boiling-point range of 180–185° at 5 mm. This substance was identified as diphenyl sulfide by oxidation to the sulfone, melting point 127.5–128°.

The bomb leaked to some extent as shown by the fact that a piece of paper soaked in lead acetate solution placed above it during heating turned very black. From 50 g. of sulfur and 39 g of benzene there were obtained: 6.3 g. of hydrogen sulfide (absorbed in lead acetate solution and weighed as the sulfide); 8.6 g. of unchanged benzene; 1.8 g. of thiophenol; 27.8 g. of a mixture of diphenyl sulfide, diphenyl disulfide and diphenylene disulfide; 22.1 g. of tar; a total of 66.6 g. The loss was 22.4 g.

The sulfide and disulfide seem to be formed in about equal quantities (molal) while the amounts of thiophenol and diphenylene disulfide are about equal and are about half as great as those of the sulfide and disulfide.

It was thought possible that the iron of the bomb was acting as a catalyst for the reaction. A mixture of benzene and sulfur, in the same proportions as used in the bomb, was sealed in a glass tube and this placed in the bomb, surrounding it with ben-

---

[10] For a description of the bomb and method of temperature control, see the paper by Herndon and Reid, THIS JOURNAL, 50,3086 (1928).

zene to equalize the pressure. The identical reaction took place in the glass that had taken place in the steel.

Sulfur and **Ethylbenzene.**—For this reaction a much larger bomb, of a capacity of 800 cc., was employed than that used for benzene. Ethylbenzene (4.1 moles) and sulfur (6.2 moles) were placed in the bomb and heated at 340–350" for forty minutes, at which time a small leak in the bomb head developed and heating had to be stopped. When the bomb had cooled down to room temperature there remained a pressure of 1200 lb. per sq. in. in it. The bleeder valve was opened and 78 g. of hydrogen sulfide was removed. The leak was repaired and the bomb again heated at 340–350°, this time for four hours, at the end of which time a serious leak developed in the brass bleeder valve and heating had to be stopped. Hydrogen sulfide at high pressures seems to attack the brass threads of the valve very rapidly. This second leak caused a large loss in material.

There was removed from the bomb 378 g. of liquid containing a small amount of solid. The solid was filtered off and the liquid distilled, about **5** cc. coming over between 30 and 40", at which point the temperature of the distilling vapors jumped rapidly to 130". There was obtained 126 g. of liquid boiling between 130 and 145°, at which point the vapors became slightly yellow and the distillation was stopped. This liquid consisted chiefly of ethylbenzene, but contained a small amount of styrene in as much as it decolorized a small amount of bromine very rapidly. The residue in the distilling flask, along with the solid filtered from the original reaction mixture, was extracted with hot alcohol; this solution on cooling deposited 86.5 g. of a light yellow crystalline substance, which on recrystallization gave a melting point of 119.5–120.5". On analysis it was found to contain 13.4% of sulfur; with concentrated sulfuric acid and isatin it gave an intense green-blue coloration. It was thus identified as 2,4-diphenylthiophene (calcd. sulfur, 13.56%).

Summary

Benzene reacts with sulfur at 350° to give thiophenol, diphenyl sulfide, diphenyl disulfide, diphenylene disulfide and hydrogen sulfide. In the case of ethylbenzene the side chain is the point of attack and 2,4-diphenylthiophene is the final product.

CHARACTERIZATION OF CERTAIN STARCHES AND THEIR AMYLOSES[1]

BY T. C. TAYLOR AND R. P. WALTON

RECEIVED JUNE 3, 1929 PUBLISHED NOVEMBER 8, 1929

In pursuing further the study of starches of various genera, we have followed two main channels of investigation. The one has had for its purpose the characterization of a starch as a function of its constituent amyloses; the other, a search for those chemical properties that would give us more rigid definitions of the amyloses themselves. All the work in this Laboratory is based primarily on the assumption that the organized starches are heterogeneous materials, the two principal components being designated as a- and β-amylose. This nomenclature corresponds approximately to that of Arthur Meyer.[2] From this point of view the amyloses are not to be considered as degradation or scission products and do not correspond to the types of amyloses obtained by Pringsheim through the action of B. *Macerans*, to those obtained by Pictet through the action of heat or to those obtained by Ling and Nanji through the action of enzymic agents.

Part I. Ratio of Amyloses in Wheat and Tapioca Starches

This consideration that starch granules are composed of different chemical substances rather than one homogeneous material was first definitely advanced by Raspail[3] in 1525. In his report a soluble and an insoluble fraction exhibited different colorations with iodine. The conception of differing chemical individuals was immediately challenged by some experimenters and defended by others. Since that time fully a hundred major investigations have been devoted to the problem of separating and characterizing these components. Specific reference need not be made here to the various observations and hypotheses which have been communicated, as a complete review of this literature has been published recently.[4]

The most obvious feature to be noted in a review of these earlier communications is the marked divergence in the reported ratios of the two or more materials. This might naturally be expected in that there are no precise definitions for these components and in all methods of separa-

---

[1] The work covered in this paper is taken from a dissertation presented by R. P. Walton to the Faculty of Pure Science of Columbia University in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] A. Meyer, "Untersuchungen über die Stärkekorner," Jena, **1895.**

tion it is necessary first to get these materials out of the granule, an end not easily accomplished by the ordinary hot water treatment most generally used.[5]

In the last few years, however, the ratios of the amyloses in a given starch reported by various workers have been more generally consistent.

The method of separation used in this Laboratory[6] has been so chosen because it is believed that interference due to unbroken or partially broken granules is eliminated, because fairly concordant results may be obtained easily and because the products have reasonably definite characteristics. The previous separations in this Laboratory gave ratios for the amyloses in corn, rice and potato starches. In this work separation studies have been carried out on wheat and tapioca starches because of certain specially significant characteristics of these common starches.

Experimental

The preliminary treatment with boiling alcoholic hydrochloric acid, as prescribed by Taylor and Iddles, was found to be too drastic for the starches used in this investigation. Treatments with alcoholic hydrochloric acid at 40–50° for one-half to one hour were usually sufficient to furnish starches which gave a relatively fluid paste upon subsequent thiocyanate gelatinization. The original purpose of this treatment was the removal of nitrogenous impurities, although it also serves to lower the viscosity of the resulting gelatinization mixture.[5] The granules remain intact, as shown by microscopic examination, although there are evidences of incipient rupture. When all starches thus far investigated are so treated and later gelatinized with hot water, a relatively thick paste is obtained, except in the case of wheat starch.

Wheat Starch.—Two hundred and fifty grams of air-dried starch was made into a paste with 170 cc. of alcohol, mixed with 150 cc. of alcoholic hydrochloric acid and mechanically stirred for one hour at 50° The concentration of alcoholic hydrochloric acid corresponded to 0.08 g. of hydrochloric acid per cc. of alcohol, as determined by titration. The alcoholic hydrochloric acid was removed by suction filtration and the starch washed free of hydrochloric acid by successive additions of fresh alcohol. The starch thus treated was introduced slowly into a large mortar containing 90 g. of ammonium thiocyanate in a solution of 450 cc. of water and 120 cc. of alcohol. After grinding for one hour at 45–50°, the solution became fluid and translucent. Microscopic examination indicated complete disruption of the granules. The gelatinized starch was thereupon precipitated from solution by alcohol and dehydrated by vigorous and prolonged grinding with absolute alcohol. After washing with ether and drying in air, 178.2 g. (dry weight) was mixed with 300 cc. of alcohol. introduced into 4 liters of water at about 55° with vigorous stirring and the resulting suspension placed in the usual apparatus[6] with a d c potential of 220 volts across the electrodes. Unless the gelatinized starch is introduced as an alcohol paste, bulky lumps will form which are difficult to break

---

[5] Taylor and Beckmann, THIS JOURNAL, 51, 294 (1929).

[6] Taylor and Iddles, *Ind. Eng.* Ckem., 18, 713–717 (1926).

down. In the course of one or two weeks the combined effects of gravity and anodic migration caused a sharp separation of solid at the bottom of the jar, leaving an upper clear layer. The upper layer containing the soluble fraction (β-amylose) was siphoned off, fresh distilled water added and the procedure repeated until the upper layer no longer gave an iodine coloration. Toward the end of the operation the fresh distilled water was first heated to a temperature of $50-60^\circ$ and the suspension stirred vigorously. The β-amylose was obtained from the clear solution by precipitation with alcohol. The insoluble fraction (a-amylose) was collected on a suction filter and dehydrated with a current of air at 100° for about five days.

Tapioca Starch.—The same technique was used as before. The behavior is different from that of wheat starch in that the first downward movement of the boundary layer is somewhat slower. Toward the end of the procedure, however, the effect of the electrical potential is very marked. If the electrodes are reversed a sharp upward movement of the boundary layer may be noted. Also, the physical consistency of the alcohol precipitate differs from that obtained with wheat starch. With the latter the precipitate was mealy and easily ground with alcohol, although with tapioca starch the product was stiff and more difficult to dehydrate with alcohol.

Corn Starch.—Separations of the amyloses from corn starch were made in order to obtain products for the subsequent nitrations. Dehydration was effected by heating on a steam-bath with an excess of benzene and absolute alcohol.[5] The alcohol precipitate from the gelatinization mixture had the same consistency as tapioca starch.

While not of any unique significance, the record of the electrophoretic treatments is given in Table I. It serves to show that with the potential employed the separation is not fast and that repeated washing is necessary in order to accomplish complete separation.

TABLE I

RECORD OF ELECTROPHORETIC SEPARATION

Starch	Tapioca	Tapioca	Tapioca	Wheat	Wheat
Sample no.	1	2	3	1	2
Dry gelat. starch in 4 liters of water, g.	299	138	133.1	178.2	167.4
Electrodialysis, days	48	24	28	46	36
Changes of dialysis water	14	10	11	17	10

In Table II the amount of a-amylose as separated by this method is given for two starches not heretofore investigated.

TABLE II

α-AMYLOSE IN TAPIOCA AND WHEAT STARCHES

Starch	Tapioca	Tapioca	Tapioca	Wheat	Wheat
Sample no.	1	2	3	1	2
α-Amylose, g.	52.4	22.5	21.9	42.5	39.5
α-Amylose, %	17.5	16.3	16.4	23.8	23.5

The specific rotations of the soluble or β-amyloses from these starches are given in Table III.

TABLE III

OPTICAL ROTATIONS OF β-AMYLOSES AT 25°

Sample	Wheat No. 1	Wheat No. 2	Tapioca No. 2
Concn., g./20 cc. water	0.2032	0.4776	0.3728
Angular rotation, 2-dm. tube	4.51"	10.67°	8.14°
Sp. rot. λ = 5461 Å.	221.2"	223.4"	218.3"
Sp. rot. λ = 5892.5 Å.	186.9"	188.7"	184.4"

The factor (0.845) for converting readings with the green mercury line (5461 Å.) to the D sodium line (5892.5 Å.) was obtained by direct comparisons, using a concentrated aqueous solution of β-amylose. The lines were obtained from a continuous spectrum, patches of which having passed the spectroscope were chosen so that the optical center of each path had the desired wave length. The optical centers were determined by means of a quartz test plate calibrated by the Bureau of Standards. The procedure has been described by Levene and Bencowitz.[7] All β-amyloses gave the usual deep blue colorations with iodine–iodide test solutions.

From the results in Table II it is seen that the ratio of a- to β-amylose in the case of tapioca starch is approximately 17:83, the β-amylose being calculated by difference. Taylor and Iddles obtained practically the same ratio for corn and rice starches. The ratio of a- to β-amylose in the case of wheat starch is approximately 24:76 and indicates a higher content of a-amylose than any of the starches previously investigated by this method.

Part II. Characterization by Determination of Associated Non-Carbohydrate Materials

In the foregoing section it was stated that the particular method of separation used was preferred because of certain advantages in manipulative technique and because the separated products exhibited distinctively different characteristics which did not seem to be dependent merely upon the method of separation.

From the standpoint of physical behavior it has been found that P-amylose is fairly soluble and a-amylose relatively insoluble. β-Amylose passes through collodion membranes of a definite degree of permeability, whereas a-amylose is retained by the same membranes. β-Amylose does not migrate under the electrical potential imposed, whereas a-amylose exhibits a definite electro-negative behavior. As found previously for corn, rice and potato starches, these physical characteristics were likewise noted here in the case of wheat and tapioca starches.

The distribution of associated non-carbohydrate material, notably

---

[7] Levene and Bencowitz, J. *Biol. Chem.*, 72, 627–634 (1927).

fatty acid residues and phosphate residues, has also been found previously to constitute a further basis of definition of the amyloses. This distribution accordingly was determined in these cases also and is reported in the following.

Experimental

Fatty acids were determined according to the method of Taylor and Nelson,[8] all analyses being run in duplicate. The results agreed within 2% for "fatty acids by hydrolysis." although determinations of "extraneous fat" were considerably less accurate and the extraneous fat extracted from some samples is negligible.

The acid number for the ether-soluble, fatty material liberated by hydrolysis was determined by titration with 0.05 N alkali, after dissolving the fat in hot alcohol previously neutralized to phenolphthalein. In the case of corn starch, Taylor and Lehrman[9] have shown that these fatty acids consist exclusively of palmitic, oleic and linolic acids, the combination giving an acid number of 186.

The results of the inquiry into the content of non-carbohydrates in these two newly investigated starches is given in Tables IV and V.

TABLE IV

DISTRIBUTION OF ETHER-SOLUBLE MATERIAL IN WHEAT AND TAPIOCA STARCHES

Sample	Wheat starch	Gelat. wheat	Wheat a-amylose		Tapioca starch	Tapioca α-amylose
No.	....		1	2	....	2
Extraction time, hours	3	7	6	6	5	10

The phosphorus may be considered as non-dialyzable phosphate for the case of the a-amylases, in that they have been in contact with several changes of water over a period of about two months. This is not the case, however, for the whole starches or the β-amyloses.

From the fatty acid determinations given in Table IV it is evident that wheat starch is closely similar to those other cereal starches, corn and rice starch, characterized by Taylor and Iddles. A large proportion of the "fatty acids by hydrolysis" is retained by the starch even after complete disruption of the granule. Practically all the fatty acids of the whole starch are accounted for in the insoluble a-amylose fraction, separated by electrodialysis.

Tapioca starch, a tuber or root starch, likewise contains a definite amount of ether-soluble material, although in considerably smaller quantity. The insoluble a-amylose fractions in all cases contain an appreciably greater amount of fatty acid residues than the whole starch.

In the case of wheat starch it is evident that practically all of the combined phosphorus of the whole starch is contained in the a-amylose fraction. With tapioca starch the unusually low content of phosphorus makes such a conclusion somewhat hazardous, although it is reasonably safe to assume that here also practically all the combined phosphorus is contained in the α-amyloses.

The unusually low content of phosphorus and of fatty acids in tapioca starch may possibly be connected with its reported superiority in certain industrial processes. This starch has been considered by some operators as being the most suitable source material for the manufacture of alkali-starch adhesives, nitro starches and certain types of dextrin.

Part III. Characterization by Means of Derivatives

In Part II physical differences of starch components were described and differences in amount of associated non-carbohydrate materials were determined. In this section nitrate derivatives were prepared and characterized in a further attempt to define the amyloses. These nitrate esters were investigated as a continuation of the work of Taylor and Werntz,[12] in which the chemical behavior of the amyloses was studied in methylation and acetylation reactions. Also, the rather recent industrial prominence of starch nitrates as explosive materials lent interest to the study of these derivatives.

Nitration.—A number of investigators consider that starch is not subject to extensive degradation during the usual nitration processes. Brown and Millar[13] treated a starch nitrate with ammonium sulfide and hydrogen sulfide and demonstrated that the regenerated starch had the

[12] J. H. Werntz, "Studies of the Corn Amyloses," Columbia Dissertation, 1926,

[13] Brown and Millar, *J. Chem. Soc.*, **75,** 308–315 (1899).

same rotatory power as soluble starch. Béchamp[14] treated various starch nitrates with ferrous salts and also showed that the rotation of the regenerated starch was identical with that of soluble starch. Okada[15] regenerated with alcoholic ammonium hydrosulfide and demonstrated a low content of reducing material in the recovered product. All regenerated starches exhibited the characteristic deep blue iodine coloration. Commercial nitrations with "mixed acids" leave the starch granules practically unchanged in physical appearance.

On the premise that nitration does not involve profound degradation it was considered that a comparison of the optical rotations of the amylose nitrates might have a bearing on certain of the definitions given for amylose and amylopectin'' by Samec and Mayer.[17] According to their definition the molecular weights of amylose and amylopectin from potato starch are approximately 80,000 and 113,000 as determined by osmotic pressure methods. Also they report the optical rotation of amylopectin or rather its immediately solubilized succedent as being about 7° higher than that of amylose.

Should there be a relation of 2:3 in the molecular complexity of these components in common starches, it might be expected that uniformly prepared nitrate derivatives would also exhibit significant differences in rotatory power. In the following work, however, a fairly close agreement was obtained with the nitrates of the different amyloses from three starch varieties.

With respect to further possible chemical distinctions in the derivatives of the starch fractions, the recent communication of Friese, Smith and Hess[18] is of interest. They report that the solubilities of the triacetates of "amylopectin" and "amylose" from wheat starch differ qualitatively in the solvents chloroform, acetone, benzol and ethyl acetate, the amylopectin derivative being insoluble and the amylose derivative being fairly soluble. These fractions were separated by successive treatments of starch with hot water. The reported insolubility of the acetate, however has not been confirmed by the recent findings of Brigl and Schinle.[19]

In the following the uniform nitrate derivatives of the two fractions obtained from three different starches indicated no qualitative differences in solubility. This was noted with acetone, in which both are readily soluble, and in hot and cold alcohol, in which the solubility is comparatively slight.

Experimental

The method of Will and Lenze[20] was selected as being best adapted to the preparation of stable nitrates of fairly high nitrogen content and of sufficient uniformity. According to this procedure, oven-dried starch is dissolved in 10 parts (by weight) of cold fuming nitric acid (sp. gr. 1.52) and the nitrate precipitated by the addition of 20 parts of cold, concentrated sulfuric acid. The nitrating acids are removed by washing repeatedly with cold water and the lower nitrate derivatives by fractional extraction with hot alcohol. Further impurities are removed by dissolving the resulting nitrate in a mixture of acetone and alcohol and precipitating by evaporation of the acetone. The product is stabilized by boiling an aqueous suspension for at least twenty-four hours.

This latter treatment with boiling water is essential to the stability of the product, although the duration of the procedure may be shortened if a stabilizing treatment such as that recently proposed by Snelling[21] is used. This method involves suspending the nitrate in a boiling aqueous solution of sulfur dioxide and subsequently neutralizing with a small amount of ammonia. Unstable nitrates are supposedly reduced without affecting the more stable nitrates. Fairly good results were obtained by this method. The addition of stabilizing agents such as those used in industrial practice[22] was not resorted to because of the probability that such materials would affect the constants subsequently determined. A typical product prepared in these experiments showed a heat stability of twenty minutes at 135° with methyl violet test paper[23] and an explosion temperature of 182° when a 0.25-g. sample was heated in a test-tube at the rate of 2° per minute.

Starch nitrates are invariably decomposed on drying unless they have been subjected to some stabilizing treatment; even drying *in vacuo* at 50° initiates a steady decomposition involving the loss of nitrogen. This marked instability of starch nitrates has, until the last few years, prevented their successful application as commercial explosives, despite a number of very serious attempts in this direction.

In order to obtain strictly comparable nitration conditions, the temperature of the nitrating acid was maintained at 2–6° and the time of nitration made exactly two hours. This was sufficient to obtain practically complete solution of the materials nitrated. Occasional small lumps of undissolved starch nitrate were removed by filtering through glass wool. The method of Will and Lenze prescribes a twenty-four-hour treatment, which may explain the higher nitrogen content of their products. Introduction of the starch as a fine dust by means of an air jet was found to give good results, although this procedure was not used consistently.

Besides tapioca starch and potato starch, specially purified corn starch has been found suitable for large scale nitrations, Sadtler's preliminary purification treatment[24] being particularly satisfactory. This special treatment consists essentially in successively treating the starch with 2% aqueous sodium hydroxide and saturated bleaching powder solutions. Removal of fatty material is probably one of the principal purposes of this operation. That this material may be an interfering element is evidenced by the difficulty encountered when nitrating corn a-amyloses

in these experiments, a preliminary treatment with dilute alkali being necessary for successful nitration. Wheat α-amylose, however, was nitrated without the necessity of such a treatment, although clear solutions in acetone were obtained only when the material had been first washed with dilute alkali before the nitration.

Nitrogen was determined by decomposing the nitrate with alkali and alcohol, reducing with Devarda's alloy in alkaline solution and distilling the resultant ammonia into standardized acid as described by Kesseler.[25] The alcohol acts as a highly effective catalyst in the alkaline saponification of the nitrate ester. Analyses were run in duplicate, the results agreeing within 2%. The method was found to agree well with the micro-Dumas combustion method. Identical samples, for example, analyzed by this method and the micro-Dumas gave 12.22 and 12.12% of nitrogen, respectively. As noted by Kesseler and several other experimenters, determinations with the Lunge nitrometer were generally unsatisfactory because of the insolubility of starch nitrate in sulfuric acid.

A commercial starch nitrate prepared with "mixed acids" and still retaining the characteristic granular form of starch was included in the

determinations. The sample was subjected to preliminary washings with carbon tetrachloride and water.

Rotations with the green mercury line were converted to those of the yellow sodium line by means of the factor 0.849, determined with a spectroscope and calibrated quartz plate in the way mentioned previously for β-amyloses. Corrections were not made for ash content of the nitrates, which was ordinarily less than 0.20%.

The influence of degree of nitration on the corresponding rotatory power has been investigated by Béchamp, whose work constitutes the only previous report on the optical rotation of starch nitrates. Calculating the approximate relation of the wave length of light used in his experiments to the D sodium light, a rotation of $\alpha_{\mathrm{D}} = 142.0°$ is found to correspond to a mono-nitrate (6.7% of nitrogen), while a rotation of $\alpha_{\mathrm{D}} = 120.0'$ corresponds to a di-nitrate (11.1% of nitrogen). Accordingly for each variation of 1% in the nitrogen content of the whole there is an approximate decrement of 5° rotation. It is apparent that the nitrogen content of the products in the above table was of sufficient uniformity for the purposes of this experiment.

Conclusion.—From the close correspondence of solubilities and optical rotations of the nitrate derivatives of several different amyloses obtained in these experiments, it might be concluded that they are closely similar in molecular complexity. The observations obtained with these nitrate derivatives, however, do not help to delineate the chemical nature of the amyloses.

Acknowledgment.—Mr. Kaufman of the Stein-Hall Company and Mr. W. A. Nivling of the Huron Milling Company supplied the samples of starches used. Dr. L. W. Bass, of the Rockefeller Institute for Medical Research, assisted in the determination of relative rotatory dispersions. Dr. A. Elek, of the same institution, carried out the micro-analytical determinations of nitrogen and phosphorus. These favors have been gratefully appreciated.

Summary

1. The α- and β-amylose ratio, according to the method of Taylor and Iddles, was determined for wheat and tapioca starches.
2. Relative rotatory dispersions of β-amylose and starch nitrate were determined for the green mercury line and the yellow sodium line.
3. The distribution of the non-carbohydrate constituents, fatty acids and phosphate residues was determined for wheat and tapioca starches.
4. Physical characteristics of the nitrate derivatives of starch components and of whole starches were determined.

THE COMPOSITION OF CHOLLA GUM. I. THE ISOLATION OF *l*-ARABINOSE, *d*-GALACTOSE AND *l*-RHAMNOSE

BY LILA SANDS AND ROSALIND KLAAS

RECEIVED JUNE 11, 1929 PUBLISHED NOVEMBER 8, 1929

Until recently not much work has been done upon plant gums since the work of O'Sullivan[1] and Tollens.[2] It is only lately that they have come into a position of importance more in keeping with their significance. Butler and Creteher[3] have classed them as acid polysaccharides and, as the name suggests, they present a phase of carbohydrate chemistry quite distinct from that connected with starch and cellulose.

These substances occur in nature as the salts of a complex acid, the molecule of which seems to be built about a nucleus of uronic acids. The monosaccharides, arabinose, galactose and frequently rhamnose, are attached in such a manner that it is possible to hydrolyze off one kind of monosaccharide more or less completely under suitable conditions without detaching another kind. For example, arabinose may be removed almost quantitatively from cholla gum while a part of the galactose and virtually all of the rhamnose remain in combination with the acid nucleus. The galactose, in turn, can be hydrolyzed off while the rhamnose remains attached to the uronic acid group. In like manner mesquite gum[4] was found to release its arabinose while the galactose-uronic acid complex remained intact.

Whether these various monosaccharides are attached to the acid nucleus in long chains arranged in the order in which they are removed or whether the relative ease of hydrolysis depends on the nature of the linking which holds them to the nucleus, we cannot say as yet. Since the original cholla gum does not reduce Fehling's solution, all of the aldehyde groups must be involved in the linkings that hold the molecule together. All hydrolytic products reduce Fehling's solution but no product reduces it vigorously in the cold until after it is hydrolyzed in the autoclave, a procedure which removes the most difficultly hydrolyzable sugar, rhamnose. Evidently the aldehyde group of the uronic acid in the cholla gum is joined to the rhamnose by a glucosidic linking. The other linkings remain a subject of conjecture.

The occurrence and general properties have been described by Anderson and Sands.[5] The present communication describes work preliminary

to the determination of the structure of the molecule and includes the isolation of *l*-arabinose, d-galactose and *l*-rhamnose and the identification of d-galacturonic acid as the uronic acid present.

Cholla gum as it comes from the plant is not a single compound. When it was ground to pass a forty-mesh sieve, ethanol dissolved 1% of its weight. Although the gum has a light yellow color and a faint, not unpleasant odor, this alcoholic extract upon evaporation of the solvent, was dark brownish-red and highly odoriferous. A part of this extract was ether-soluble and a part could be saponified with alkali, showing that this fraction contained the lipins and the fat-soluble substances and was not carbohydrate. The remainder of the gum is carbohydrate in composition but can be separated into two fractions. After extraction with 140 times its weight of water during a period of forty-eight hours,[6] about one sixth of the total volume contained the greatly swelled, water-insoluble portion amounting to 80% of the gum, while the remainder was a slimy, opalescent solution containing the rest of the gum. This procedure gave an imperfect separation, it is true, but analysis of the two fractions showed them to contain the same components though in somewhat different amounts. The water-soluble fraction was nearly twice as high in uronic acid as the water-insoluble fraction, while the latter fraction contained practically all of the non-hydrolyzable, cellulose-like fraction of the gum.

Analysis of the gum on a water-free basis gave the following results: ash, 8.4%; uronic acid,[7] 11.5%; arabinose,[8] 53.2%; rhamnose,[9] 5.5%; galactose,[10] 8.4%.

[6] The gum was thoroughly mixed with 80 times its weight of water and allowed to stand for twenty-four hours. Three-fourths of the volume was siphoned off and replaced with water. After another twenty-four hours the supernatant liquid was again siphoned off and the very mobile suspension of water-insoluble material was concentrated by centrifuging.

[7] The uronic acid was determined by the method of Lefèvre: (a) Van der Haar, "Anleitung zum Nachweis, zur Trennung and Bestimmung der Monosaccharide und Aldehydesauren," Gebrüder Borntraeger, Berlin, **1920,** p. 71–76; (b) Lefèvre and Tollens, Ber., **40, 4513** (1907); (c) Tollens, *Z. physiol.* Chem., 61, 95 (1909); (d) Lefèvre, "Untersuchungen uber die Glucuronsäure," "Dissertation," Gottingen, **1907.**

[8] Pentoses were determined according to "Methods of Analysis," A. O. A. C., 1925, and calculated as arabinose. Since furfural is liberated from the uronic acid as well as from the arabinose during a pentosan determination, the arabinose in the substance under consideration had to be calculated by correcting the total amount of furfural phloroglucide for that which was derived from the acid. To our knowledge, the relationship between galacturonic acid and its furfural-phloroglucide production has not been determined, so for this purpose the factor given by Lefèvre, expressing the relationship between glucuronic acid and its phloroglucide production, was used [Van der Haar, Ref. 7a, p. 71]. The accuracy of such a method is questionable. Any error from this source together with that resulting irom the inaccuracy of the pentosan determination itself when applied to difficultly hydrolyzable substances must be kept in mind in consideration of data determined by this method.

General Procedure for Separating the Constituents of **Cholla** Gum.—In order to separate the constituents, the cholla gum was subjected to a series of hydrolyses. After the liberation of arabinose by hydrolysis at 80°, the partially degraded gum acid was turned into its calcium salt (calcium salt "A") and separated from the sugar. Calcium salt "A" was further hydrolyzed at 100° and the calcium salt of the still simpler acid (calcium salt "B") was separated from the galactose. Calcium salt "B" was next hydrolyzed in the autoclave and the calcium salt of the resulting acid (salt "C") was separated from the rhamnose. Details of the procedure follow.

Initial Hydrolysis of the Gum.—The gum was ground to pass a 40-mesh sieve and extracted with ethanol to remove the lipoid substances. One kilo was mixed with ten liters of 2% sulfuric acid, placed in three-liter flasks and heated for thirty hours in water-baths kept at 80°.[11] After hydrolysis there remained a residue of a cellulose-like substance amounting to 10% of the weight of the gum, which resisted further decomposition even in the autoclave at 120°. It was filtered off and discarded.

The solution was neutralized with calcium carbonate, decolorized with norit and the resulting almost colorless solution was concentrated in the presence of excess calcium carbonate in large evaporating dishes over the free flame.[12] At low volume it was filtered and concentrated to 45% solids. The sirup was poured into 3 to 4 times its volume of 95% ethanol, slowly and with vigorous stirring. The light yellow, curdy precipitate was filtered off and washed with hot 95% alcohol. To ensure the complete removal of any sirup that was occluded, the precipitate was dissolved in water and after diluting to 26% solids[13] it was poured into 3 to 4 times its volume of ethanol; it came down again as a flaky precipitate. This was washed with hot alcohol and then ether. It gave 286 g of powdery light yellow calcium salt "A."

Isolation of *l*-**Arabinose.**—Since any sugar which hydrolyzed off the gum remained

---

[9] Methyl pentoses were determined by the method of Ellett and Tollens and of Haywood and calculated as rhamnose: (a) Ellett and Tollens, *Z. deut. Zuckerind.*, *42*, 19 (1905); (b) Haywood, Bulletin 105, U. S. Bureau of Chemistry, 1907, p. 112.

[10] Galactose was determined according to van der Haar, Ref. 7a, pp. 123–130. The total amount of mucic acid resulting from a determination represented that produced from the galacturonic acid present as well as that from the galactose. We have found no statement of the exact relationship between galacturonic acid and its mucic acid production, but Ehrlich obtained from tetra-galacturonic acid a yield of 70% or more of pure mucic acid [*Chem.-Ztg.*, 41, 198 (1917)]. Since galactose gives about 75% of its weight of mucic acid, van der Haar determined galacturonic acid by multiplying the weight of mucic acid by the same factor that was used to determine galactose (Ref. 7a, p. 336). In this work the total weight of mucic acid was converted to galactose by use of the table compiled by van der Haar, and this value minus the weight of galacturonic acid as determined by the method of Lefèvre was taken as the weight of galactose in the original sample.

[11] The acid concentration and time of hydrolysis here and in later instances were chosen as optimum after hydrolyzing samples of the gum and the various salts under a variety of conditions.

[12] Evaporation at reduced pressure was not feasible because of the tendency of the solution to foam.

[13] The optimum concentration of the salt solutions for precipitation with alcohol was, in all cases, the most concentrated solution that could be added to the alcohol and give the desired finely divided precipitate in place of droplets of sirup which would coalesce into a gummy mass and thus carry down sugar. The volume of alcohol used was sufficient to prevent coalescence of the flaky precipitate as the watery sirup was added.

dissolved in the alcohol, all filtrates and washings were combined, allowed to stand overnight to permit any calcium salt remaining in colloidal suspension to settle and then concentrated to 84–86% of solids. The sirup was thinned with 200 cc. of methanol,[14] cooled and seeded with arabinose. Crystallization began within an hour, but the sirup was allowed to stand in the refrigerator for a week with occasional stirring in order that as much of the sugar as possible might separate. Enough 95% ethanol was added to make the thick mass into a thin paste and the crystals were filtered off with suction. The sugar was washed by triturating it with a mixture of one part of glacial acetic acid and three parts of 95% ethanol and later with ethanol alone. This gave 250 g. of light-colored, fairly pure product.

When the mother liquor from the arabinose was evaporated approximately to dryness in *vacuo,* there remained 328 g. of a vitreous, dark red, transparent sirup. Analysis showed the presence of 5.3% of uronic acid, 7.7% of galactose, 3.7% of rhamnose and 4.7% of ash. These substances doubtless were present as a calcium salt of a complex acid resembling that in salt "A," which owed its presence to its appreciable solubility in alcohol. In addition the sirup contained arabinose to the extent of 34.4% or 113 g. However, the second crop of arabinose never amounted to more than a few grams. The procedure followed in the case of mesquite gum, namely, the purification of the sirup by the precipitation of a second crop of salts in order to permit the further crystallization of the sugar, failed in this case. Bertrand's method failed to give cadmium xylonate, and the sirup was not fermented by yeast, showing the absence of both xylose and glucose. Why the mixture resisted separation has not been determined.

Identification of **l-Arabinose.**—When the sugar referred to above was purified by the method of Anderson and Sands[4] it melted at 155–157° and in 4% solution gave a specific rotation of $[\alpha]_D$ $+101.9°$. The hydrazone, after recrystallization from 95% alcohol, melted at 150–151° with decomposition.[15] **A** portion of the sugar was oxidized with bromine to arabonic acid. The phenylhydrazide of this acid was a creamy white substance melting at 212–213° and having a specific rotation of $[\alpha]$ $+15.2°$ in 1% solution. Fischer[16] gave 215° as the melting point and Hudson[17] gave the rotation of the hydrazide of d-arabonic acid as $[\alpha]$ $-16.09°$. These facts, together with the fact that seeding with arabinose caused crystallization of the sirup, identified the sugar as arabinose.

Nature of Calcium Salt "A."—Analysis of the salt gave the following results: ash, 9.4%; uronic acid, 33.9%; arabinose, 5.5%; galactose, 5.1%; rhamnose, 27.9%.

The success with which the arabinose was removed by hydrolysis at 80° was evidenced by the reduction of the arabinose content from 53.2% in the original gum to 5.5% in salt "A." **A** rather large portion of the galactose was lost, however. The 5.1% of salt **"A"** corresponds to 14.5 g. of galactose, while the mother liquor left after the removal of the arabinose contained 25.3 g. of galactose. The high rhamnose content of salt, together with the small amount of rhamnose found in the mother sirup mentioned above (3.7%), indicated the success with which this sugar was left undisturbed. Evidently this salt was the calcium salt of fragments of the original gum molecules derived by the loss of the arabinose, a part of the galactose and possibly a little of the rhamnose.

Hydrolysis of Calcium Salt "A."—The 280 g. of calcium salt **"A"** was dissolved in

---

[14] Methanol was more suitable for diluting this sirup than ethanol since the calcium salt which remained dissolved in the sugar fraction was more soluble in the methanol and consequently showed less tendency to precipitate as a gummy mass.

[17] Hudson, THIS JOURNAL, **39,** 462 (1917).

ten times its weight of 1% sulfuric acid plus enough sulfuric acid to precipitate the calcium and heated in the boiling water-bath for six hours. The solution was then neutralized with calcium carbonate, decolorized and evaporated in the presence of excess calcium carbonate. At low volume it was filtered, the concentration adjusted to 55% solids, and when cold the sirup was precipitated with ethanol as in the case of salt "A." The light yellow granular precipitate (calcium salt "B") amounted to 200 *g.*

Isolation and Identification of d-Galactose.—The alcoholic filtrates and washings obtained in the isolation of salt "B" were concentrated as much as possible *in vacuo* and then mixed with an equal volume of glacial acetic acid and seeded with galactose. Crystallization followed within a few minutes. After standing for a few days in the refrigerator, the galactose was filtered off and washed with a mixture of one part of glacial acetic acid and three parts of 95% alcohol. The yield of crude sugar was 18 g.[18] After purification[4] the product melted at 163–165°, gave a specific rotation of $[\alpha]_D$ 79.7° in 4% solution and produced approximately the quantitative yield of mucic acid when oxidized with nitric acid. These data identified the sugar as d-galactose.

Nature of Calcium Salt "B."—Analysis of this salt was as follows: ash, 9.5%; uronic acid, 40.8%; galactose, 0%; arabinose, 2.7%; rhamnose, 28.5%.

The hydrolysis at 100° appeared successful in the complete removal of galactose and, in view of the inaccuracy involved in the arabinose determination, the small percentage of that sugar found in salt "B" might as well be interpreted to indicate its absence as not. The fact that further hydrolysis of the salt in the autoclave left its pentose content unchanged substantiated the assumption that arabinose was completely removed from the gum by this second hydrolysis. The high rhamnose content of this salt, together with the fact that only 4.3% of rhamnose was found in the mother liquor from the galactose, showed that rhamnose was not conspicuously disturbed by hydrolysis at 100". Calcium salt "B" differed from salt "A" mainly in that galactose and the last remnant of arabinose had been removed from the molecule.

Hydrolysis of Calcium Salt "B."—One hundred ninety-five grams of salt "B," dissolved in ten times its weight of 2% sulfuric acid with a sufficient excess to precipitate the calcium, was hydrolyzed in the autoclave at one atmosphere gage pressure or 120° for eight hours. The solution was neutralized, decolorized, concentrated to 50% solids and the salts were precipitated with alcohol exactly as in the two preceding cases. Eighty-six grams of light brown calcium salt "C" resulted.

Isolation and Identification of *l*-Rhamnose Hydrate.—Again the alcoholic filtrates and washings were evaporated in *vacuo* to a very thick sirup and mixed with an equal volume of glacial acetic acid. Without seeding the sirup showed no evidence of crys-

---

[18] The fact that the yield of galactose was larger than the total galactose content of salt "A" as shown by analysis is not surprising in view of the lack of reliability of the method used when applied to galactans in the presence of foreign material. Schorger found that one sample of galactan from the larch gave values of galactan content varying from 44.56 to 93.77%. Dore found that varying the sample of pure galactose from 0.2 to 2 g. caused the yield of mucic acid to range from 54 to 90%. Lippman has shown that foreign organic substances may prevent entirely the separation of mucic acid. In the work on mesquite gum in this Laboratory it was difficult to get the analytical results to shoa a total galactose content which equaled the galactose actually isolated from the gum. The application of the method to duplicate samples of the hydrolytic products of cholla gum gave results that checked within 2–3% and led to conclusions that seemed reasonable in the light of other experimental results. It was with these facts in mind that the results of these determinations were used in this article: (a) Schorger, J. Ind. Eng. *Chem.*, 8, 498 (1916); (b) Dore, *ibid.*, 7, 721 (1915); (c) Lippman, "Chemie der Zuckerarten," 3d ed., Vol. I, p. 274.

tallization at the end of three weeks, but upon seeding with rhamnose, crystals formed rapidly with the liberation of heat. After several days the sugar was filtered off and washed with the acetic acid–alcohol mixture. The yield was 27 g. The sugar was purified by dissolving it in water, decolorizing, concentrating to 86% solids and adding half its volume of glacial acetic acid. The sugar obtained melted at 92–94° and formed a phenylosazone which melted at 178–180°. In 4% solution the specific rotation was $[\alpha]_D$ $-5.1°$ after five minutes and $[\alpha]_D$ 0° after ten minutes, while the final constant value was $[\alpha]_D$ $+7.8°$. The sugar was thus identified as *l*-rhamnose hydrate.

Nature of Calcium Salt "C."—Analysis of the salt gave: ash, 17.0%; uronic acid, 36.1%; galactose, 0%; arabinose, 2.9%; rhamnose, 10.5%.

The rhamnose was incompletely hydrolyzed off but was reduced from 28.5% in salt "B" to 10.5% in salt "C." Therefore salt "C" approached very closely in composition the calcium salt of the nucleus of the gum. Work on the constitution of this salt as well as the salts "A" and "B" is in progress in this Laboratory. The destruction of the uronic acid during the vigorous hydrolysis required to remove the rhamnose was shown by its reduction from 81.6 g. in salt "B" to 31.1 g. in this final salt.

Identification of d-Galacturonic Acid.—The calcium salt "C" reduced Fehling's solution almost immediately in the cold and gave the naphthoresorcinol test, properties peculiar to the uronic acids. Oxidation with nitric acid produced mucic acid in amounts corresponding to the galacturonic acid as determined by the method of Lefèvre. When this salt was treated with bromine water in the cold, a white precipitate of mucic acid formed which was soluble in sodium hydroxide, reprecipitated upon acidification with hydrochloric acid and melted at 215°. When oxidized with bromine water at 100°, the salt yielded 17.7% of mucic acid, an amount corresponding in magnitude to 20.7% obtained by oxidation with nitric acid. Galactose will not give appreciable quantities of mucic acid when oxidized with bromine, whereas Ehrlich[19] found tetra-galacturonic acid to yield 60–70% of its weight of mucic acid. These facts proved that the uronic acid in cholla gum was d-galacturonic acid. The absence of glucuronic acid was established by failure to obtain potassium acid saccharate from the oxidation products of calcium salt "C."

Summary

1. Cholla gum, by a method of successive hydrolyses, was changed into salts of three distinct acids, each differing from its precursor in the loss first of arabinose, then galactose and finally rhamnose.
2. l-Arabinose, d-galactose and *l*-rhamnose hydrate were isolated and identified.
3. d-Galacturonic acid was definitely proved to be the uronic acid in cholla gum.

SOME ALKOXY DERIVATIVES OF DIPHENYL OXIDE

By Carrol A. Doran[1]

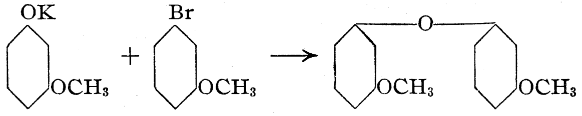
Received June 18, 1929 Published November 8, 1929

Since the stability of diphenyl oxide in the presence of alkalies has rendered compounds of this character valuable in soap perfumery, it seemed of interest to study the effect of substituents and especially of alkoxy groups on the properties of the compounds.

Ullmann and his co-workers[2] prepared diphenyl oxide by condensation of bromobenzene with potassium phenoxide, which required a temperature of 180–210° for a period of twelve hours. They found that by this method the yield was only 9% of the theoretical, but if a small quantity of metallic copper was used as catalyst, they were able to obtain a yield of 87%. o-Methoxy compounds were prepared by the same method.

Sabatier and Mailhe[3] prepared some mixed aryl ethers by the use of thorium oxide as catalyst. Weston and Adkins[4] prepared diphenyl oxide by treating phenol with metallic potassium and adding bromobenzene in the presence of a copper catalyst, heating the mixture to 210° for two hours.

The preparation of *m*-methoxydiphenyl oxides presented difficulties, as some of the intermediate compounds were not easily obtainable and did not condense as readily as the ortho or para compounds. In preparing the m-bromomethoxy and ethoxy compounds, preparatory to their condensation with alkoxy phenols to form the diphenyl oxides, the following steps were involved: nitrobenzene ⟶ *m*-bromonitrobenzene ⟶ *m*-bromoaniline ⟶ m-bromophenyldiazonium sulfate ⟶ m-bromophenol ⟶ *m*-methoxybromophenol. Phenols of the latter type were condensed with m-alkoxyphenols, which were prepared by the partial alkylation of resorcinol. The condensation apparently occurred as follows



A number of catalysts were used in attempts to improve the yield, under varying conditions of temperature and time, and optimum results obtained by the methods described.

Experimental Part

Choice of Catalysts.—Attempts were made to prepare the diphenyl oxide derivatives by the condensation of two phenols having other groups in meta position. While it was possible to prepare diphenyl oxide from phenol using aluminum chloride as catalyst, no condensation took place when the m-alkoxyphenols were used. When metallic potassium was used with *m*-methoxyphenol, and the resulting salt refluxed with m-metlioxybrotnobenzene in the presence of finely divided freshly reduced copper, only a trace of a high-boiling product resulted. Substitution of metallic sodium gave no better results, and in both cases a large amount of charring took place during addition of the metal to the phenol. Trials were also made with zinc chloride, concentrated sulfuric acid and freshly prepared thorium oxide on the mixed phenols, at temperatures ranging from 200 to 350°, but in no case did appreciable condensation take place. The most satisfactory method proved to be the condensation of potassium salts of phenols with the aryl halides at high temperatures, in the presence of finely divided freshly reduced copper as catalyst. This method gave fair results with bromo-alkoxy compounds but the chloro compounds gave much poorer yields.

Preparation of m-Bromo-aniline.—Nitrobenzene was brominated in the presence of powdered iron as catalyst. The product was fractionally distilled and crystallized from ether; m. p. 52.5". The m-bromonitrobenzene was reduced to m-bromo-aniline by the use of concentrated hydrochloric acid and stannous chloride, which gave an 85% yield. The speed of reaction must be controlled by cooling at the beginning, to prevent loss, and after the oil disappeared the mixture was refluxed vigorously for about thirty minutes. The solution was made alkaline, the oil extracted with ether, dried and distilled, giving a light brown product, b. p. 255–259°. Separation by steam distillation was not as satisfactory as extraction with ether.

Preparation of *m*-Bromophenol.—*m*-Bromo-aniline was diazotized and the product hydrolyzed to give m-bromophenol. The phenol could not be separated readily by steam distillation, due to formation of resins. The difficulty was overcome by carrying out the hydrolysis of the diazonium salt in an aqueous acid layer, under a benzene layer kept at its boiling temperature. The phenol derivative formed by hydrolysis was dissolved in the benzene layer as rapidly as it formed, and the final product was obtained by distillation of the benzene layer. No resinous by-products were formed and a yield of 76% of the m-bromophenol was obtained, b. p. 240–244°. The use of the benzene layer is a modification of a method of general application for prevention of resin formation in such reactions.

Preparation of *m*-Methoxybromobenzene.—The m-bromophenol was methylated by the method of Perkin, Ray and Robinson,[5] using dimethyl sulfate on the potassium salt. The mixture was refluxed on the steam-bath for one and a half hours, cooled, extracted with benzene, dried and distilled. The product had a boiling point of 218–221°; yield, 75%.

3,3'-Methoxydiphenyl Oxide.—To 4.1 g. of *m*-methoxyphenol[5] in an evaporating dish was added 1.9 g. of granulated potassium hydroxide, and the mixture heated to 90° until all solid potassium hydroxide had reacted. The temperature was then raised to 200° and the compound stirred for several minutes until the water formed during the reaction was driven off. There was a slight charring during this process. The dried potassium salt was then placed in a small flask with 6.2 g. of m-methoxybromobenzene and 0.1 g. of freshly reduced finely divided copper. This mixture was refluxed for six to seven hours at 300–320°; the temperature slowly rose as the reaction proceeded. The mixture was cooled, extracted several times with ether and the ethereal solution washed until the wash water showed very little color. The ether layer was dried over

anhydrous sodium sulfate and fractionated, yield, 26%, giving a viscous oil of low surface tension, with a light brown color and a pleasant odor resembling that of diphenyl oxide; boiling point 332–334°; very soluble in benzene, ether or carbon tetrachloride; slightly soluble in alcohol or ligroin. It is not affected by aqueous potassium hydroxide solution and does not give a color reaction with ferric chloride in dilute alcohol.

Anal. Calcd. for $C_{14}H_{14}O_3$: C, 73.04; H, 6.09. Found: C, 73.07, 72.91; H, 5.97, 5.98.

3,3′-Ethoxydiphenyl Oxide.—*m*-Bromophenol was treated with ethyl sulfate and the mixture heated for five hours on the steam-bath; the yield of the *m*-ethoxybromobenzene was 85%; boiling point 228–231°. *m*-Ethoxyphenol was prepared by semi-ethylation of resorcinol; yield about 43%; boiling point 254–258°. The two monoethoxy compounds were condensed by treatment of the m-ethoxyphenol with solid potassium hydroxide and refluxing with m-ethoxybromobenzene in the presence of copper catalyst, as in the preparation of the dimethoxyphenyl oxide. The refluxing was continued for ten hours, the temperature slowly climbing to 350°. The ethereal extract when dried and fractionated gave a 36% yield of a pale brown liquid boiling at 341–344°; very soluble in benzene, ether, ligroin or carbon tetrachloride; only slightly soluble in cold alcohol. It is not affected by aqueous potassium hydroxide and does not give a color test with ferric chloride.

Anal. Calcd. for $C_{16}H_{18}O_3$: C, 74.42; H, 6.98. Found: C, 74.22, 74.28; H, 6.93, 7.04.

3-Methoxy-3'-ethoxydiphenyl Oxide.—This compound was prepared by treating m-methoxyphenol with solid potassium hydroxide and refluxing with *m*-methoxybromobenzene for eight hours in presence of the copper catalyst. Upon extraction and purification, a 20% yield was obtained, b. p. 338–341°. The compound has a light brown color and a pleasant odor. It is readily soluble in ligroin, benzene, ether or carbon tetrachloride and moderately soluble in cold alcohol. It does not react with potassium hydroxide solution and gives no color reaction with ferric chloride.

Anal. Calcd. for $C_{15}H_{16}O_3$: C, 73.77; H, 6.56. Found: C, 73.59, 73.66; H, 6.71, 6.52.

3,4′-Methoxydiphenyl Oxide.—*p*-Bromophenol was methylated, giving a 75% yield of the *p*-methoxybromobenzene, which was condensed with the potassium salt of m-methoxyphenol by refluxing for ten hours in the presence of the copper catalyst. The compound was separated by ether extraction and gave a yield of 30%; b. p. 336–338°. It is a light brown oil with a more pronounced odor than that of the 3-3'-alkoxy derivatives described above. It is less viscous but more soluble in alcohol than the 3,3′-methoxydiphenyl oxide. It is not affected by aqueous potassium hydroxide and gives no color reaction with ferric chloride. In order to determine whether the high temperature of the reaction had caused a rearrangement in position of groups the process was repeated as outlined above, except that the temperature of the reaction was never allowed to rise above 200°, as in the procedure of Ullmann.[6] The time of reaction was increased to thirty-five hours. There was no difference in boiling point between this compound and that formed at the higher temperature.

Anal. Calcd. for $C_{14}H_{14}O_3$: C, 73.04; H, 6.09. Found: C, 72.97, 73.17; H, 6.16, 6.05.

2,3′-Methoxydiphenyl Oxide.—o-Bromophenol was methylated by treatment with potassium hydroxide and dimethyl sulfate to form *o*-methoxybromobenzene; a yield of 45% was obtained. The latter compound was condensed with m-methoxyphenol by

---

[6] Ullmann, Ber., 38, 2211 (1905).

treatment with potassium hydroxide and refluxing at 350° for ten hours in the presence of copper as catalyst. A yield of 33% was obtained, distilling at 326–329°. It has a pleasant odor, crystallizes in small cubical crystals which melt at 33–34° and is soluble in most solvents, though only slightly soluble in ligroin. It is not affected by potassium hydroxide in aqueous solution and gives no color reaction with ferric chloride.

Anal. Calcd. for $C_{14}H_{14}O_3$: C, 73.04; H, 6.09. Found: C, 72.82, 73.18; H, 6.14, 6.02.

Summary

1. Five new alkoxy derivatives of diphenyl oxide were prepared. They are compounds of great stability to alkalies or acids and to heat, of pleasant odor and of low surface tension.

2. In the preparation of phenols for condensation, a new method of procedure was discovered, namely, the hydrolysis of diazonium salts in hot acid solution under a layer of inert solvent, which prevents the formation of tarry by-products by removing the phenol from the acid hydrolyzing solution as rapidly as it is formed.

3. Of several catalysts used, finely divided freshly reduced copper gave the best yields.

OMEGA-HYDROXY ALIPHATIC ACIDS. II. CONVERSION OF OMEGA-HYDROXYDECANOIC ACID TO CHAIN POLY-INTERMOLECULAR ESTERS AND TO A DIMERIC CYCLIC ESTER[1]

BY W. H. LYCAN[2] AND ROGER ADAMS

RECEIVED JUNE 20, 1929 PUBLISHED NOVEMBER 8, 1929

In a previous paper a satisfactory method of preparation for many ω-hydroxy aliphatic acids was described. Attention was called to the fact that by the action of heat on such acids compounds were produced which appeared to be of high molecular weight. In this investigation these latter compounds are described in more detail. Several other reactions of w-hydroxy acids have been studied.

A recent paper by W. H. Carothers[3] has given a very clear exposition on polymerization: a proper definition, conditions of ring formation and an introduction to the theory of condensation polymers. The terminology in that publication has been adopted here. As pointed out in a general discussion by Carothers, bi-functional reactions may be either intramolecular or intermolecular. In the first case, the products will be monomeric

---

[2] This paper is an abstract of a thesis submitted by W. H. Lycan in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

[3] Carothers, THIS JOURNAL, 51, 2548 (1929).

rings; in the second case the products will be polymeric rings or long chains. Intramolecular reaction takes place with readiness only when five- or six-membered rings are possible; whenever an intramolecular reaction would lead to rings of greater size, the reaction almost invariably proceeds intermolecularly with the formation of chain polymers.

The sole products of heating w-hydroxydecanoic acid alone or with solvents, with or without a catalyst, were chain poly-esters. A lactone was never detected among the products. The general structure of these high molecular weight compounds may be represented by the formula

$$HO(CH_2)_xCO_2—[(CH_2)_x—CO_2—]_n(CH_2)_x—COOH$$

The poly-esters were obtained as complex mixtures and crystallized from solvents as fine white powders. The crystals were less than microscopic in dimension but were definitely crystalline, inasmuch as sharp x-ray diffraction patterns were readily obtained.[4] The mixtures were, in general, soluble in the hot in acetone, alcohol, chloroform, benzene, toluene and ethyl acetate, but were only sparingly soluble in the cold. They were completely insoluble in water and ether.

The presence of the free carboxyl group in these molecules was demonstrated by the fact that their potassium salts were completely soluble in hot water. Furthermore, the exactly neutral potassium salt was perfectly stable in hot water, This was shown by the fact that a polymer recovered from its potassium salt by acidification with mineral acid had exactly the same properties and the same molecular weight as it had before neutralization. If ring compounds were present in the original polymer, either it would not be completely soluble in alkali or it would be partially hydrolyzed. In the latter event the recovered polymer might be expected to give a different average molecular weight determination, and different properties from the original polymer. There was no evidence that either of these things occurred.

The presence of a free hydroxyl group was also demonstrated beyond reasonable doubt. A polymeric mixture of average molecular weight of about 1100 yielded an acetyl derivative upon heating with acetic anhydride in boiling benzene. The fact that the average molecular weight of the product increased to about 1800 during the course of this reaction was not entirely unexpected. In addition to acting as an acetylating reagent the acetic anhydride might readily have acted as a catalyst for further intermolecular esterification. Intermolecular esters prepared in boiling benzene, using p-toluenesulfonic acid as a catalyst, had average molecular weights of about 2500. Thus the reactions of acetylation and further intermolecular esterification may be regarded as competing re-

---

[4] Dr. G. L. Clark of the Chemistry Department of the University of Illinois has been kind enough to take x-ray photographs of some of these polymers. The detailed results will be published independently in a later communication.

actions. The acetyl polymer was characterized by its lower melting point (68–72° as compared to 74–76° for unacetylated derivative) and increased solubility in solvents. After hydrolysis with aqueous alkali and acidification with phosphoric acid, distillation yielded an acidic distillate. That this acetic acid could not have resulted from combination of the acetic anhydride with the free carboxyl group in the form of mixed anhydride is indicated by the increased molecular weight of the product. If it be assumed that acetic anhydride does not catalyze intermolecular esterification to a greater extent than *p*-toluenesulfonic acid, a decrease in average molecular weight would result from mixed anhydride formation.

The ordinary methods of molecular weight determination have never been extremely satisfactory for compounds of high molecular weight. In most cases the high polymers have not been sufficiently soluble in solvents to produce differences in boiling points, freezing points or vapor pressure large enough to permit of accurate measurement. Furthermore, it has not been possible to show that high molecular weight values thus obtained have not resulted from some kind of abnormal association in solution. Several attempts were made to determine average molecular weight values for a polymeric mixture, both by the boiling-point and freezing-point methods in benzene. The results varied from 1500 to 3000 in successive readings, and the same values could not be duplicated with any degree of accuracy. Average molecular weights were determined on the same material by titration of the free carboxyl group and these values never varied more than 5–8% from a mean of 2800. Inasmuch as free hydroxyl and free carboxyl groups often lead to abnormal molecular weights by the ordinary methods, it need not necessarily be inferred that the varying results obtained above are the limits of accuracy for other polymers.

The average molecular weights of these poly-esters were obtained easily by titration of the free carboxyl group. Large samples were titrated with fiftieth normal alkali solutions and from the values thus obtained average molecular weights were calculated. Inasmuch as the results of these titrations could be duplicated fairly closely with successive samples of the same mixture of polymers, it seems reasonable to assume that these were close approximations of the correct values. Furthermore, the values obtained from successively recrystallized samples increased in the regular manner expected; that is, the recrystallizations resulted in the concentration of the less soluble and more highly polymerized molecules. The filtrates yielded the more soluble fractions, which were constituted of fewer molecules of the parent acid, and the molecular weights determined for these fractions were characterized by a corresponding decrease. As the molecular weight of the polymer increased, the values obtained were subject to increased error. Even with polymers of average molecular weight as high as 9000, however, the error was not over 10%. The error in the values obtained for the lower polymers was ordinarily considerably less than 10%.

It has been previously intimated that the samples of poly-esters used for the molecular weight determinations were mixtures rather than individual compounds. It was impossible to obtain pure definite components from the highly complex mixtures in the reaction products because of the wide number of possible combinations and the similarity in solubility between each of them. The difference in solubility between a polymer constituted of twenty structural units and one constituted of ten is great enough to permit of separation, but when the mixture is made up of molecules containing every possible constituent from five or six to thirty structural units, separation becomes impossible. These mixtures were separated into fractions in which the components of each fraction were constituted of members of the same order of magnitude of structural units. However, the solubilities of the individual compounds of any one of these fractions were so similar that separation into individual components could not be effected. The molecular weight values observed, therefore, represent average values for a mixture constituted of a number of very similar components.

The addition polymers of Staudinger[5] result from equilibrium reactions and higher temperatures usually lead to lower polymers, whereas the poly-esters are formed by the elimination of molecules of water, and higher temperatures always lead to higher polymers. The lower temperature limit for the formation of polymers of ω-hydroxydecanoic acid without the presence of catalyst, was in the neighborhood of 100°. At any rate, heating the fused acid by itself at this temperature resulted in the formation of polymers composed of an average of between five and six structural units. Heating in a solvent required a somewhat higher temperature, perhaps because the alcohol–acid molecules were more widely dispersed. Heating in boiling toluene (b. p. 110°) over a considerable period of time resulted in only the very beginning of esterification. However, heating in cymene (b. p. 175°) resulted in a polymeric mixture of molecules constituted of an average of about six structural units. Other polymeric fractions were obtained by heating the fused acid over long periods of time at 200–210° and at 220–250°, respectively. The latter experiment produced polymers of average molecular weight of about 9000. In other words, these mixtures were composed of molecules constituted of in the neighborhood of fifty structural units.

[5] Staudinger *and* co-workers, *Helv. Chim. Acta.*, 5, 785 (1922); 7, 23, 842 (1924); 8, 41, 65, 67 (1925); **9,** 529 (1926); Ber., **53,** 1073 (1920); **57,** 1203 (1924); **59,** 3019 (1926); **60,** 1782 (1927); 61, 2427 (1928); 62, 241, 263, 442 (1929); **Ann.,** 447, 97, 110 (1926); Z. *physik. Chem.*, *126*, 426 (1927); *Kautschuk*, 237 (1927).

The use of *p*-toluenesulfonic acid permitted the reaction to proceed at a considerably lower temperature and resulted in a higher degree of poly-intermolecular esterification. The reaction proceeded smoothly in boiling benzene (b. p. 80°) with the production of a polymer of average molecular weight of about 2000. About the same results were obtained by its use in boiling toluene (b. p. 110°) but in cymene (b. p. 175°) polymers of much higher molecular weight mere formed.

A few words should be said concerning the nature of one of these reaction mixtures from any of the sources described. The original mixture might have, for example, an average molecular weight of 2000. This product would then be recrystallized repeatedly and samples titrated during the progress of their recrystallizations. The values obtained for the less soluble material continually increased, and after ten recrystallizations the average molecular weight would be in the neighborhood of 4000. The first few filtrates yielded samples whose average molecular weights were in the neighborhood of 1000. In other words, the mixtures all contained compounds constituted of a large number of degrees of esterification, and heating at increased temperature and the presence of a catalyst resulted in an increased predominance of the more highly esterified compounds.

The polymers obtained by these poly-intermolecular esterification reactions are obviously analogous to the natural "etholidcs" obtained by Bougault and Bourdier[6] from the waxes of a variety of conifers. These natural poly-esters were extracted from the desiccated leaves of the conifers with alcohol, and were purified by repeated crystallizations from the same solvent. As has been the case with their synthetic analogs, no pure components were isolated. They were characterized as being white powders and had, in general, the same solubilities that have been observed for the poly-esters of ω-hydroxydecanoic acid. These compounds yielded, upon hydrolysis, the two natural acids, juniperic and sabinic acids, mentioned in the previous paper.[1] It is entirely possible that both acids are combined in the single complex compounds which constitute the polymeric mixture. The following general structure was assigned to the polymer as a result of their experiments.

$$HO(CH_2)_x—CO[O(CH_2)_y—CO—]_nO(CH_2)_zCO_2H$$

Titration values indicated that the average molecular weight of the natural substances was between 1000 and 2000. The only products of complete hydrolysis were the alcohol–acids and the saponification numbers experimentally determined corresponded closely to the values calculated on this assumption. Furthermore, it was possible to prepare an acetyl derivative and the saponification number was modified an amount corresponding to the theoretical amount calculated, assuming the presence of one free hydroxyl group.

---

[6] Bougault and Bourdier, *J. pharm. chim.* [6] 29, 561 (1909); [6] **30,** 10 (1909).

One anomalous fact presents itself with respect to the melting points observed for both the natural etholides and the synthetic polymers. Bougault and Bourdier recorded that, although they were unable to separate the natural mixture into pure definite compounds, they found that the melting points tended to group themselves around certain definite temperatures, namely, 68, 72, 78 and 82°. They assumed that this fact indicated that they were dealing with a mixture containing but a few components. It was found in these researches, however, that after the mixtures attained an average molecular weight of 2000, further increases in average molecular weight up to one of 9000 had no effect on the melting point. Every sample melted over 2° ranges between 74 and 77°. Several samples whose average molecular weights were of the magnitude of about 1000 melted over a range of only 2 or 3° around 65°.[6a] Bougault and Bourdier had recrystallized their etholides repeatedly before molecular weight determinations were made, so it is impossible to say whether or not the lower melting fractions also had lower average molecular weights.

The mixtures obtained from the conifers were composed of molecules constituted chiefly of a sixteen carbon and a twelve carbon hydroxy acid. The highest melting fraction, which had an average molecular weight of about 2000, melted around 80°. Since the two components, juniperic acid and sabinic acid, melt at 95 and 84°, respectively, it will be seen that the mixture melts considerably lower than either of the two component parent substances. This was true also in the case of the synthetic polymers of ω-hydroxydecanoic acid where the low fractions melted at 10° lower than, and the higher fractions at almost the same temperature as, the parent molecule.

An entirely satisfactory explanation of these facts does not present

---

[6a] After the manuscript of this communication was in the hands of the printer, the article by Chuit and Hausser appeared [*Helv. Chim. Acta,* 12, 463 (1929)] entitled "Sur les acides-alcools polyméthylène-carboniques de 8 a 21 atomes de carbone." These authors have stated that upon heating ω-hydroxydecanoic acid at various temperatures, no definite products were obtained but merely mixtures of etholides of various size. After heating the hydroxy acid at 125° for ten hours they report that a material was isolated from the product which melted at 72.5–73°. The carbon–hydrogen analysis of this material indicated the presence of about six structural units in the molecule. All of the polymers studied and described in this communication which melted at approximately the point mentioned by Chuit were shown by molecular weight to contain ten or more structural units, while molecules of lower molecular weight (5–8 structural units) melted somewhat lower. As a consequence, Chuit's experiment was repeated and led to a product which melted at 74 to 76° and gave by neutral equivalent a molecular weight of about 2000 (12 structural units). Since minor details of experimentation frequently affect the size of the polymer materially, the difference between Chuit's results and those in this investigation may, probably, be accounted for in this way. Chuit found that ω-hydroxynonanoic acid gave entirely different results when subjected to polymerizing conditions. A careful comparison of the polymerization of the various ω-hydroxy acids is now under way in this Laboratory.

itself, Inasmuch as the polymers are mixtures, they might be expected to melt at lower temperatures than individual components of the mixture but, unfortunately, the latter may not be determined. The only plausible idea that suggests itself is based upon a consideration of the fundamental principle of the melting point. The temperature at which any substance melts depends only upon the forces operating between the molecules within the crystal. Whenever the temperature is sufficiently high to overcome these forces, then the substance fuses or melts. It is probable that any individual crystal of the poly-esters of w-hydroxydecanoic acid is composed of molecules constituted of unequal numbers of structural units. In fact the preliminary x-ray examination,[4] mentioned above, indicates this to be a fact. Other examples of the same phenomenon have been observed, particularly in the case of the polyoxymethylenes.[7] Inasmuch as the homologous molecules in each individual crystal are so similar, it may be assumed that the forces operating between two homologous molecules are of the same order of magnitude as those which would operate between two identical molecules. It must also be assumed that beyond certain limits of dimension of molecules, the magnitude of the operating forces is constant. If these two assumptions are correct, the melting points of the various fractions of the poly-esters might be expected to be constant. It is realized that this explanation is not entirely satisfactory, but more data are necessary before indulging in further speculation.

Carothers and Arvin[8] have prepared a large number of poly-esters by heating dibasic acids with glycols. The structure assigned to these compounds,  $—(\overset{O}{\overset{/\!/}{C}}—(CH_2)_x—\overset{O}{\overset{/\!/}{C}}—O—(CH_2)_y—O)—$, is very similar to that of the poly-esters of w-hydroxydecanoic acid. It is not surprising, therefore, that many properties are common to these two series of compounds. The various fractions of both series are crystalline, although this property is not highly developed in either case. The property of crystallinity in general seems to be more highly developed in these compounds where the recurring ester groups are separated by shorter carbon chains. Decamethylene sebacate, which is most similar in structure to the poly-esters of w-hydroxydecanoic acid, is described as a dusty powder which has a great tendency to become electrified. The same general description applies to the various fractions of the present series, and the tendency to become electrified is quite pronounced.

The solubilities of the two series are also somewhat similar. The polyesters produced from ethylene glycol and the lower dibasic acids such as succinic acid are the least soluble of those described by Carothers and Arvin. Decamethylene sebacate is more soluble and in this respect is

---

[7] Hengstenberg, *Ann. phys.*, 84, **245** (1928).

[8] Carothers and Arvin, THIS JOURNAL, 51, 2560 (1929).

again more similar to the poly-esters of w-hydroxydecanoic acid. The previous authors point out that the behavior of their compounds on going into solution is indicative of the fact that the solutions are true molecular dispersions. This conclusion was drawn from the facts that solutions of their compounds in acetone, ethyl acetate, and glacial acetic acid were noticeably viscous only when fairly concentrated, and that the rate of solution was very rapid. The concentrated solutions of the poly-esters of ω-hydroxydecanoic acid were not at all viscous and solution in hot solvents was almost instantaneous. These compounds, therefore, present another group of substances of very high molecular weight which give normal solutions in contrast to the apparently colloidal solutions obtained from the polymers of high molecular weight of cyclopentadiene, isopropene and styrene.

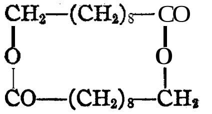
Carothers and Arvin also reported certain anomalies with respect to the melting points of their compounds. They found that the rate of heating had a marked effect on the melting point. Furthermore, they observed that the highest melting point obtained for any sample was within 5° of the lowest and that range was ordinarily within 2°. The effect of rate of heating on the melting points of poly-esters of w-hydroxydecanoic acid is not so pronounced but the short ranges and constancy for various fractions of the same material are similar. These phenomena have already been discussed. It is interesting to observe that the melting point recorded by Carothers and Arvin for decamethylene sebacate is 74°. This checks very closely the mean value of 74–76' obtained for all of the fractions of average molecular weights of between 2000 and 9000 of the poly-esters of w-hydroxydecanoic acid.

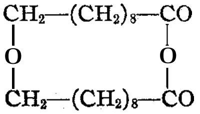
An acetyl derivative of w-hydroxydecanoic acid was obtained by the action of acetic anhydride on the pure acid. The reaction product consisted, in fact, of a mixture of the acetyl derivative of the acid with the diacetyl derivative of its anhydride. The diacetyl anhydride was readily converted to the acetyl derivative of the acid by shaking with water at ordinary temperatures. Although the free w-hydroxydecanoic acid could not be distilled at any pressure and temperature, its acetyl derivative was easily distilled without change under diminished pressures. In other words, the tendency to eliminate acetic acid from this molecule was considerably less than the tendency to eliminate water from its parent substance.

It has been pointed out that the bi-functional condensations present the possibility of proceeding either intramolecularly to form monomeric rings, or intermolecularly to form either chains or large rings. Carothers has pointed out that with dibasic acids and glycols ring formation occurred only when five- or six-membered rings could result. In a similar manner chain intermolecular esterification of w-hydroxydecanoic acid has been found to occur so readily that no cyclic compounds were isolated, It seemed, however, possible that if the chain intermolecular condensation could be inhibited, intramolecular or ring intermolecular condensation might occur. With this in mind, the potassium salt of ω-hydroxydecanoic acid was heated first with acetic anhydride and the product after removal of the acetic anhydride by distillation was dry distilled in a vacuum. If chain intermolecular condensation occurred the products would be non-volatile, not only because of their high molecular weight, but also because the potassium salt would be produced. On the other hand, the monomeric lactone produced by intramolecular condensation and the lower members of the products of ring intermolecular condensation might be expected to be volatile and could thus be isolated from the reaction mixture.

By carrying out the reaction as mentioned, a white crystalline material distilled, accompanied by a few drops of a high-boiling liquid. Traces of acetic anhydride and the few drops of high-boiling material were decanted from the crystals. These proved to be surprisingly pure, as shown by the sharp melting point, 95–95.5°, and by the fact that recrystallization did not alter this value. This substance by analysis and molecular weight determination corresponded to a dimeric lactone of Formula I.

I





II

Furthermore, it was readily saponified with aqueous alkali to yield ω-hydroxydecanoic acid, the original starting material. It also proved to be perfectly stable to water, inasmuch as it was recovered unaltered after shaking with water overnight. These latter two properties exclude the possibility that the compound may have a cyclic ether anhydride formula, II. It is impossible to say whether the dilactone results from the combination of two simple molecules or from the heat decomposition of higher chain polymers.

The dilactone is differentiated from the intermolecular chains by its higher melting point and greater solubility in solvents. It is, apparently, perfectly stable and reacts, in fact, as a normal ester.

The yields obtained in a number of experiments were approximately 5% of the theoretical amount and this value compares favorably with the yields obtained by Ruzicka,[9] in the preparation of large membered cyclic ketones. It should be pointed out that this is the second type of a very large ring which has been capable of direct preparation, and that it conforms to the present idea of the stability of large rings as embodied in the Sachse–Mohr theory.

Such a small amount of the high-boiling liquid accompanying the

---

[9] Ruzicka, *Helv. Chim. Acta*, 9,249 (1926).

crystals has as yet been isolated, that a determination of its composition has not been effected. It appears to be a mixture and a preliminary examination has indicated that it is not a monomeric lactone. A mixture closely resembling this high-boiling material was obtained by the dry distillation of the potassium salt of ω-hydroxydecanoic acid itself. Apparently, no dilactone was formed during the course of this reaction.

Experimental

w-Hydroxydecanoic acid was chosen for the study of intermolecular esterification as it was the most readily available of the homologs previously described. It was found, in fact, that this acid could be obtained in yields of 65–75% of the theoretical amount, calculated from the weight of methyl undecylenate.

Intermolecular Esterification of ω-Hydroxydecanoic Acid.—The general method employed for the intermolecular esterification of w-hydroxydecanoic acid consisted in heating the acid alone at various temperatures and in various inert solvents at their boiling points, with and without a catalyst. Heating was continued from eight to sixty-five hours and chain poly-esters resulted. In the experiments where no catalyst was used, the products were recovered directly by merely cooling the fused mass or by cooling the solvent in ice and salt. When *p*-toluenesulfonic acid was used to catalyze the reaction the product was obtained as follows. The solvent was cooled in ice and salt, whereupon the product and catalyst separated together. The mixture was removed by filtration and sucked and pressed dry on the filter. The lumps were then crushed and powdered and suspended in a large excess of water at room temperature. After shaking vigorously for several minutes, the suspension was filtered and the product washed with many successive portions of water. It was then dried and an average molecular weight determination made. Both the products of the reactions wherein the catalyst was used, and wherein the acid was heated alone, were recrystallized repeatedly from successive portions of ethyl acetate and average molecular weight determinations were made at intervals during this process.

Molecular-Weight Determinations.—The average molecular weights of the various fractions were obtained by titrations. The general procedure employed consisted in dissolving a weighed sample (0.4–1.2 g.) of the poly-ester in 100 cc. of boiling alcohol which had been distilled over lime. Four drops of phenolphthalein indicator solution was added and an excess of fiftieth normal potassium hydroxide in 75% alcohol solution was run rapidly into the hot solution from a standard buret. About 100 cc. of cold water was added at once, and the resulting alkaline solution was back titrated with standard fiftieth normal aqueous potassium acid phthalate solution. It was found possible to obtain duplicate results within a maximum limit of 10%.

Intermolecular Esterification of ω-Hydroxydecanoic Acid in Boiling Benzene.—A 10-g. sample of w-hydroxydecanoic acid was recovered practically unchanged after heating in boiling benzene without a catalyst over a period of eight hours. When 0.2 *g.* of *p*-toluenesulfonic acid was added to a solution of 10 g. of the acid in 75 cc. of anhydrous benzene and refluxing was continued for twelve hours, a different result was obtained. To the resulting solution, 75 cc. of petroleum ether (b. p. 25–40') was added, and a fine white precipitate was obtained by cooling to −10°. After filtering and drying the product was powdered and suspended and shaken vigorously with 250 cc. of water at room temperature. It was filtered, washed in the filter with three additional 100-cc. portions of water and finally dried. The melting range of the dry polymer was 74.5–76.5" and titration gave an average molecular weight value of 2572.

The remainder of the product was recrystallized from 100 cc. of hot ethyl acetate.

This was accomplished by dissolving the material in 100 cc. of boiling ethyl acetate and cooling immediately in a flow of tap water of an average temperature of about 20°. The precipitate was filtered and dried and an average molecular weight determination made. To the filtrate was added 100 cc. of petroleum ether (b. p. 25–40°) and the resulting solution was cooled to −10°. In this manner additional polymer was recovered and another molecular weight determination made.

The main product was recrystallized four more times from ethyl acetate in the manner described and another average molecular weight determination was made. The combined filtrates from these recrystallizations yielded another fraction. The main product was again four times recrystallized from 100-cc. portions of ethyl acetate. An analysis for carbon and hydrogen and an average molecular weight determination were made on the 9-times recrystallized product. Table I will summarize the results of this experiment.

TABLE I

DATA ON RECRYSTALLIZED PRODUCT

Intermolecular Esterification of w-Hydroxydecanoic Acid in Boiling Toluene.—A 5-g. sample of ω-hydroxydecanoic acid was heated in 50 cc. of boiling anhydrous toluene for fifteen hours. The resulting product consisted chiefly of unchanged acid melting at 58–67°. This was shown by the fact that its neutral equivalent was 204 as compared with the theoretical value 180 for the pure acid. In a second experiment, 10 g. of w-hydroxydecanoic acid was heated in a boiling solution of 0.2 g. of *p*-toluenesulfonic acid in 75 cc. of anhydrous toluene through a period of sixty-five hours. The product was recovered and subjected to the same process as that obtained in the previous experiment with benzene as a solvent. In this experiment duplicate titrations were made on two fractions. In addition a sample of neutralized polymer was recovered from the neutral titration mixture by shaking with an excess of very dilute hydrochloric acid. This product was once recrystallized from hot ethyl acetate by cooling to −10° and a second molecular weight determination was made. The results are tabulated below. An analysis was made on a fraction obtained after five crystallizations.

A second experiment was conducted in which 10 g. of w-hydroxydecanoic acid was heated for thirteen hours in a solution of 0.2 g. of *p*-toluenesulfonic acid in 60 cc. of anhydrous toluene. The product was recovered in the same manner as in the previous experiments. The titrations were conducted as follows. The sample was dissolved in 100 cc. of alcohol which had been distilled over lime and the acid was directly titrated to phenolphthalein with twentieth normal alkali. The results of this experiment are summarized in Table III.

Intermolecular Esterification of **ω-Hydroxydecanoic** Acid in Boiling Cymene.—A 5-g. sample of w-hydroxydecanoic acid was heated in boiling cymene for ten hours. The product was recovered by cooling the solution to −10° and the cymene mother liquors were completely recovered by recrystallizing once from a 100-cc. portion of ethyl acetate. The dried material melted at 64–67°. An analysis for carbon and hydrogen and an average molecular weight determination were run.

Upon heating **ω-hydroxydecanoic** acid with p-toluenesulfonic acid in ether, the acid was recovered essentially unchanged.

Intermolecular Esterification of **ω-Hydroxydecanoic** Acid without ***a*** Solvent.—A ***5-g.*** portion of w-hydroxydecanoic acid was heated in a test-tube at 100° for ten hours under a pressure of 100 mm. **After** one recrystallization from ethyl acetate, the product melted at 63–67° and gave the following value for neutral equivalent.

Neutral equivalent. Subs, 0.4240: cc. 0.0158 *N* alk., 27.8; cc. 0.0219 N acid, 1.5. Neut. equiv., 1043.

A second sample of 10 g. of w-hydroxydecanoic acid was heated for ten hours at 200–210° in a test-tube. This product was recrystallized twenty times from 100-cc. portions of ethyl acetate after which it melted at 74–76" and gave a value of 6618 for average molecular weight.

Neutral equivalent. Subs., 0.9651: cc. 0.0158 N alk., 12.1; cc. 0.0219 N acid, 2.1. Neut. equiv., 6618.

A third experiment was conducted in which 10 g. of o-hydroxydecanoic acid was heated at 220–250° in a test-tube for fifteen hours. The material, upon cooling, was an amber-colored wax which could be readily recrystallized from ethyl acetate. The fractions obtained by recrystallizing this product are summarized in Table V. A sample was analyzed after the first crystallization.

TABLE V

ANALYTICAL AND OTHER DATA

	Times recryst.	Av. mol. wt.	Subs., g.	0.0158 *N* alk., cc.	0.0219 *N* acid, cc.	M. p., °C. (corr.)
1	0	5250	0.9241	12.8	1.2	...

3	5	8733	.7772	6.9	.9	74–76

Anal. Subs., 0.1539: CO_2, 0.3968; H_2O, 0.1463. Calcd. for $(C_{10}H_{18}O_2)_{31}\cdot H_2O$ = $C_{310}H_{560}O_{63}$: C, 70.53; H, 10.59. Found: C, 70.32; H, 10.64.

An attempt was made to prepare poly-esters of higher average molecular weight by heating a fused sample of w-hydroxydecanoic acid with *p*-toluenesulfonic acid, but only charring resulted at 240°.

w-Acetoxydecanoic Acid.—Twenty grams of w-hydroxydecanoic acid was added slowly to 150 cc. of ice-cold acetic anhydride. There was no apparent evolution of heat during the addition. The solution was transferred to a 500-cc. round-bottomed flask and was stirred overnight. After heating at 90° for three-quarters of an hour, the resulting solution was distilled under diminished pressure. After the acetic anhydride and the acetic acid were removed, no constant boiling fraction was obtained, but the entire product distilled from 190–220° (1 mm.) and solidified in the receiving flask. It had a pleasant, fruit-like odor and did not lend itself to crystallization from any of the variety of solvents. An analysis indicated the probability that the product consisted of a mixture of the acetyl derivative of the simple acid with the diacetyl derivative of its anhydride.

Anal. Subs., 0.1855: CO_2, 0.4337; H_2O, 0.1592. Calcd. for $C_{12}H_{22}O_4$: C, 62.56; H, 9.63. Found: C, 63.85; H, 9.55.

Fifteen grams of this mixture was shaken with 100 cc. of water overnight. An emulsion was formed but the product was easily removed by extraction with 150 cc. of absolute ether. The ether solution was dried with anhydrous magnesium sulfate, filtered and distilled. The product boiled at 168–170° (1 mm.) and was finally recrystallized several times from 100-cc. portions of petroleum ether (b. p. 60–70°). It was thus obtained in shining white plates which melted at 35–36° (corr.). The neutral equivalent and analysis correspond to the theoretical values calculated for the acetyl derivative of w-hydroxydecanoic acid.

Neutral equivalent. Subs., 0.2395: cc. 0.0733 *N* alk., 14.1. Calcd. for $C_{12}H_{22}O_4$: 230.2. Found: 231.

Anal. Subs., 0.2029: CO_2, 0.4670; H_2O, 0.1751. Calcd. for $C_{12}H_{22}O_4$: C, 62.56; H, 9.63. Found: C, 62.77; H, 9.65.

Action of Acetic Anhydride on Poly-esters of w-Hydroxydecanoic Acid.—A 2-g. sample of poly-esters of average molecular weight of 1100 (obtained by melting pure ω-hydroxydecanoic acid in boiling cymene) was introduced into a solution of 1.0 cc. of acetic anhydride in 50 cc. of anhydrous benzene. The resulting solution was refluxed for one hour and then cooled in ice water. The resulting precipitate was filtered and recrystallized once from ethyl acetate. It was observed that this product was more soluble both in benzene and ethyl acetate than the corresponding simple poly-ester. The dried product melted at 68–72" and gave the following values for analysis and neutral equivalent.

Neutral equivalent. Subs., 0.3780: cc. 0.0158 N alk., 15.0; cc. 0.0219 N acid. 1.3. Neut. equiv., 1812.

Anal. Subs., 0.2067: CO_2, 0.5262; H_2O, 0.1948. Calcd. for $CH_3CO_2(CH_2)_9CO$-$[O(CH_2)_9CO]_8$-$O(CH_2)_9CO_2H$: C, 69.48: H, 10.47. Found: C, 69.43; K, 10.54.

This product was then refluxed for two hours with 10% aqueous potassium hydroxide solution. The alkaline solution was cooled and acidified with an excess of phosphoric acid. Upon distillation the distillate was strongly acidic to litmus.

Preparation of the Dimeric Lactone of ω-Hydroxydecanoic Acid.—In a small Claisen distilling flask, 10 g. of the pure potassium salt of ω-hydroxydecanoic acid was covered with acetic anhydride. This mixture was heated just below the boiling point of acetic anhydride for about one hour. The excess acetic anhydride was then removed from the solution on a water pump and the dry potassium salts distilled under a pressure of about 5 mm. A liquid–air trap between the receiving flask and the vacuum pump protected the latter. During the 'distillation the solid salts fused between 350 and 400° (estimated temperature) and distillation occurred between 400–500°. Two products resulted. One of these was an oil which boiled in the neighborhood of 170–190° and was obtained only in small quantities. It was never identified. The second product was a crystalline solid which readily could be recrystallized from acetone and was obtained thus pure as fine, white needles, melting at 95–95.5°. The yield was from 0.3–0.35 g. and was about the same in each of a number of experiments.

A molecular weight determination in benzene agreed with the theoretical value within 4%. *Mol. wt.* Subs., 0.4714; wt. of benzene, 18.61; lowering of f. p. 0 395". Calcd. for $C_{20}H_{36}O_4$, 340. Found: 328.

The values obtained upon analysis for carbon and hydrogen also checked the calculated values. *Anal.* Subs., 0.1881: CO_2, 0.4854; H_2O, 0.1790. Calcd. for $C_{20}H_{36}O_4$: *C*, 70.58; H, 10.67. Found: C, 70.40; H, 10.59.

A 0.2-g. sample of this material was hydrolyzed in 10 cc. of 5% alcohol in potassium hydroxide solution. Water was added and the alcohol removed by distillation. Upon cooling and acidifying with dilute hydrochloric acid, ω-hydroxydecanoic acid precipitated, which was recovered and identified as follows. The aqueous suspension was extracted with several 5-cc. portions of alcohol-free ether. The combined ethereal solutions were washed with water and dried with anhydrous magnesium sulfate. After filtering, the ether was removed under diminished pressure and the product was recrystallized from ethyl acetate. It melted at 75–76° and a mixed melting point with pure ω-hydroxydecanoic acid (m. p. 75–76°) showed absolutely no depression.

A 0.1-g. sample of this product was shaken with 25 cc. of water overnight at a temperature of 20–30°. The product was filtered and recrystallized once from acetone. The melting point remained unchanged at 95–95.5° and a mixed melting point with some of the original material showed no depression.

The dry distillation of the potassium salt of ω-hydroxydecanoic acid led to the formation of water and a high-boiling oil. After separating from the water, the oil was distilled, but no constant boiling fraction was obtained, although the major portion boiled at 170–190°. Attempts were made to hydrolyze this product and to condense it with phenylhydrazine and semicarbazide, but no pure products were isolated.

Summary

1. The intermolecular esterification of w-hydroxydecanoic acid has been studied and found to proceed easily with the formation of mixtures of chain polymers. These mixtures were separated by crystallization into fractions of average molecular weights ranging from 1000 to 9000.

2. These poly-esters were titrated quantitatively with standard alcoholic potash solutions and average molecular weights thus determined. By boiling with excess alcoholic potassium hydroxide, they were converted back to the original acid.

3. A twenty-two-membered dimeric lactone of w-hydroxydecanoic acid was prepared by dry distillation of the product obtained by the action of acetic anhydride on its potassium salt.

THE APPARENT RACEMIZATION OF PINENE

BY JAMES B. CONANT AND G. H. CARLSON

RECEIVED JUNE 21, 1929 PUBLISHED NOVEMBER 8, 1929

The thermal decomposition of d-pinene was noted by Wallach[1] many years ago in connection with his study of the action of heat on a variety of essential oils. He showed that at 250–270° the final products were dipentene and polymerized material. Very recently Smith[2] has made a quantitative study of the loss of optical activity of pinene at somewhat lower temperatures (185–237°) and concludes that the reaction consists for the most part of a simple racemization. This view he supported by distillation of a sample which had been heated until it had lost about a third of its original optical activity. This evidence did not seem to us conclusive, however, and we decided to determine, if possible, whether the loss of optical activity of pinene was the result of racemization or rearrangement. From a physico-chemical point of view the question is probably of relatively little significance and most of Smith's conclusions are not affected by our final results, which establish that the process he was measuring was in reality a rearrangement and not a racemization. From the standpoint of the organic chemist, however, the point at issue is obviously of importance.

A few experiments convinced us that a definite answer to the problem could not be obtained by fractional distillation. Although there is a 20° difference in the boiling points of pinene (155°) and dipentene (176°), a mixture of equal amounts of the compounds was very incompletely separated by several fractionations through an efficient Widmer column.

---

[1] Wallach, *Ann.*, 227, 282 (1885).

[2] Smith, THIS JOURNAL, 49, **43 (1927).**

The incompleteness of the separation was evidenced both by the unsatisfactory boiling points of the high and low fractions and also by the optical activity of what should have been pure inactive dipentene and the low rotation of what should have been pure pinene. We therefore turned to another method of determining the amount of pinene and dipentene in a mixture.

The catalytic hydrogenation of mixtures of pinene and dipentene proved to be a very satisfactory method of determining the proportion of the two constituents. Pinene absorbs one mole of hydrogen, dipentene two; the two compounds are isomeric; therefore the composition of a mixture may be calculated from the amount of hydrogen absorbed by a given weight of material. The method was tested by using both pure compounds and known mixtures; the accuracy of the method is about ±4% of the total hydrogen absorbed. Since difficulty was experienced in obtaining pure dipentene, d-limonene was substituted for it in making the known mixtures (dl-limonene = dipentene). The hydrogenation was carried out in a special constant volume apparatus using Adams' catalyst and glacial acetic acid as a solvent. The details are given in the experimental part of this paper.

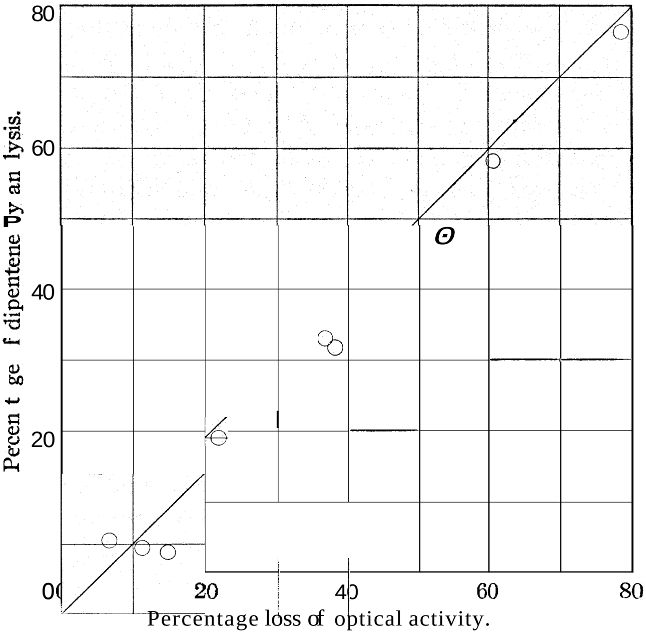

Fig. 1.

Using this method of analysis the amount of dipentene was determined in samples of pinene which had been heated in the gaseous phase at 200 ± 5°

until the optical activity had been diminished. The results are shown graphically in Fig. 1. It is clear that there is a complete parallelism between the amount of dipentene found by the hydrogenation method and the loss of optical activity. There seems no escape from the conclusion that the apparent racemization of pinene is in reality a rearrangement of pinene to dipentene.

Similar results were obtained on heating d-pinene in the liquid phase at 200'. Samples heated until all of the optical activity had been lost (in some cases the rotation became slightly levo) absorbed between 90 and 95% of the amount of hydrogen calculated for pure dipentene. Wallach's original observations were verified by distilling some material which had been heated for 100 hours at 200°. About 30% of polymerized high-boiling material was found and the distillate (b. p. 167–183°) on treatment with bromine yielded crystalline dipentene tetrabromide, though in low yield, which is to be expected in view of the difficulty of obtaining satisfactory amounts of crystalline bromide from pure dipentene.[3]

The Rearrangement of *d*-Pinane.—The saturated dicyclic compound, d-pinane, is much more difficult to rearrange than the corresponding unsaturated compound (d-pinene). For example, heated in the liquid phase for 176 hours at 200°, it lost only 14% of its actvity, whereas the rearrangement of d-pinene at the same temperature was practically complete in fifty hours. It was necessary to heat d-pinane to 285° in order to obtain a rate of rearrangement that was comparable to that of d-pinene at 200°. As in the case of the unsaturated compound, hydrogenation showed that the loss of optical activity is to be attributed to rearrangement and not to racemization. This is clear from Table I, in which the percentage of isomerization was calculated from the amount of hydrogen absorbed, assuming that the product was a monocyclic unsaturated compound, $C_{10}H_{18}$.

As in the case of d-pinene, the rearrangement is accompanied by some polymerization. A sample which had been heated to 285° for fifty hours yielded on distillation a 10% residue of very high-boiling material, The

[3] Wallach, *Ber.*, 40, 603 (1907).

major portion of the distillate boiled at 165–167°, and on catalytic hydrogenation absorbed 65% of the amount of hydrogen calculated for a monocyclic unsaturated compound, $C_{10}H_{18}$. No attempt was made to separate this mixture; undoubtedly a number of isomeric monocyclic compounds are produced and the possibility of some open chain dienes is not excluded.

Experimental

The d-pinene used was purified by fractional distillation over sodium. Two samples were employed in this work which had the following constants: (1) b. p. 156–156.3°, $[\alpha]_D^{23}$ (pure liquid) +43.94°, n_D^{20} 1.4658, d_{20} 0.8600; (2) b. p. 155.3–155.6°, n_D^{20} 1.4560, d_{20} 0.8591, $[\alpha]_{5461}^{23}$ (in acetic acid solution) +65.2°. The d-pinane used was prepared by the catalytic hydrogenation of d-pinene using Adams' catalyst and pressure of 35 lbs. Two samples had the following constants: (I) b p. 167–168.5°, $[\alpha]_{5461}^{23}$ (pure liquid) +26.84°, n_D^{20} 1.4619, d_{20} 0.8579; (2) b. p. 166–166.7°, $[\alpha]_{5461}^{23}$ (pure liquid) +23.71°, n_D^{20} 1.4621, d_{20} 0.8571.

Method of Analysis by Catalytic Hydrogenation.—The catalytic hydrogenation was carried out in a constant volume apparatus so arranged that there was no rubber connection between the reaction vessel and the supply of hydrogen. The reaction vessel, which was a tube about 9 cm. long and had a capacity of about 10 cc., was attached by a ground-glass joint on its upper side and an inverted elbow to a reservoir bulb of about 50-cc. capacity. The bottom of this bulb was constricted and attached by rubber tubing to a leveling bulb. The total volume of the apparatus to a graduation on the constricted bottom of the reservoir was 76.34 cc. About 0.1 g. of material was employed, 2 to 4 mg. of Adams' catalyst and exactly **3** cc. of glacial acetic acid. The apparatus was filled with hydrogen by evacuating and filling three times. The course of the hydrogenation was followed by measuring the pressure difference between the leveling bulb and the constant volume mark. During the hydrogenation a positive pressure of about 3–4 cm. of mercury was maintained. The agitation of the reaction vessel was accomplished by rocking the whole apparatus back and forth about an axis at right angles to the plane of the reaction tube. The pressure was read every half hour until it was constant. The volume of hydrogen absorbed by the catalyst was found to be negligible for one lot of catalyst; for another a correction of ***2*** cc. per ***35*** mg. had to be made.

The following data on the hydrogenation of pure pinene are typical: barometer reading, 757.5; temp., 21.2°; 95.3 mg. of sample; 2.7 mg. of catalyst; pressure difference in mm. of Hg, after 1 hr., 190 mm., after 2 hrs., 189 mm.; cc. of hydrogen found, 17.5; ***cc.*** of hydrogen calculated, 16.95.

In Table II are collected some of the results which demonstrated the applicability of the method for analyzing mixtures of dipentene and *d*-pinene. Since the best samples of dipentene we could obtain absorbed only 80% of the calculated quantity of hydrogen, we substituted *d*-limonene for dipentene.

TABLE II

ESTIMATION OF *d*-PINENE AND *d*-LIMONENE BY CATALYTIC HYDROGENATION

Composition of material taken	Pinene, %	100	0	41	60
	Limonene, %	0	100	59	40
Composition found by catalytic hydrogenation	Pinene, %	103	...	48	53
	Dipentene, %	...	102	**52**	**47**

Isomerization of *d*-Pinene in the Vapor Phase.—The pinene was weighed in a thin-walled bulb which was sealed off and introduced into a bulb of pyrex glass of 300-cc. capacity which was evacuated and sealed. The smaller bulb was then broken and the whole heated in an electric oven at 200 ± 5°. The large bulb, after cooling, was opened and glacial acetic acid added from a weight buret. The rotation of this solution was taken in a decimeter tube using the green mercury line 5461, and the specific rotation calculated and compared with that of the original pinene in glacial acetic acid solution. The analyses of a weighed portion of the solution were then carried out by the catalytic hydrogenation method described above.

In Table III a few typical results are given in full; all of the experiments are summarized in Table IV; the points in Fig. 1 are from Table IV.

TABLE III

TYPICAL DATA OBTAINED IN THE ISOMERIZATION OF PINENE

Temp., 200 ± 5°; time of heating, 1080 min.; $[\alpha]_{5461}$ + 65.2' in acetic acid initially

Expt.	Pinene, mml.	Acetic acid, g.	$[\alpha]_{5461}$	Loss in rotation, %	Sample for analysis, g.	$C_{10}H_{16}$ in sample, mml.	H_2 absorbed. mml.	Dipentene found, %
1	2.978	8.856	$51.0	21.8	3.082	0.9897	1.178	19.1
					3.121	1.005	1.210	21.0
2	3.295	8.743	+40.9	37.7	3.067	1.097	1.515	38.1
					3.111	1.115	1.494	34.0

In calculating $[\alpha]_{5461}$ the density of all of the solutions (which had nearly the same percentage composition) was taken as 1.03.

Since the percentage of dipentene is calculated from the formula

$$\% \text{ dipentene} = \frac{\text{moles } H_2 - \text{moles } C_{10}H_{16}}{\text{moles of } C_{10}H_{16}} \times 100$$

it is evident that the error in determining the amount of hydrogen absorbed is magnified in the calculation of the percentage of dipentene. An error of a few per cent. in the total hydrogen absorbed may make an error of as much as 20% in the percentage of dipentene, if this is small. This effect is evident in Table IV. For this reason duplicate analyses were always carried out.

TABLE IV

SUMMARY OF RESULTS ON THE ISOMERIZATION OF *d*-PINENE IN THE GASEOUS PHASE AT 200 ± 5°

Heating, min.	Loss of rotation, %	Percentage of dipentene by analysis (hyd. method) 1	2	Av.	Heating, min.	Loss of rotation, %	Percentage of dipentene by analysis (hyd. method) 1	2	Av.
720	6.6	11.0	10.0	10.5	2070	36.9	33.9	32.0	33.0
1110	14.9	10.6	7.0	8.8	1080	37.7	38.1	34.0	36.0
1440	11 2	6.74	12.2	9.5	1680	53.7	44.7	50.5	47.6
1080	21.8	19.1	21.0	20.0	2070	60.4	61.7	54.7	58.2
2220	38.2	31.6	31.7	31.7	3030	78.5	77.9	74.7	76.3

Since no attempt was made to hold the temperature constant, the rate of isomerization varied from experiment to experiment. The range of the monomolecular constants was 23.6 X 10^{-5} to 4.2 × 10^{-5} with **a** mean of ten experiments of about 20 X 10^{-5}. Smith gives the value for 198° as 8.6 × 10^{-5} and for 218° as 54 X 10^{-5}. It is thus evident that our process was proceeding at a rate comparable to his and we were studying the same reaction.

Isomerization of *d*-**Pinene** in Liquid Phase.--Samples of d-pinene were sealed in Carius tubes and heated in a gas furnace to 200 * 10°. **A** sample heated for fifty hours showed $[\alpha]_D$ +2.4°, as compared with $[\alpha]_D$ +43.9° initially, percentage loss in rotation, 95; 87.8 mg. of the material with 2 4 mg. of catalyst absorbed 29.3 cc. of hydrogen at 763 mm. and 23°; the calculated amount for pinene is 15.6, the percentage of dipentene was therefore 90. Other samples heated for 100 or 150 hours showed a slight levorotation ($[\alpha]_D$ −0.44 to −0.78'); they absorbed 90 to 95% of the amount of hydrogen corresponding to pure dipentene. 8.8 *g.* of d-pinene which had been heated to 200° for 100 hours yielded 6.7 g. of a distillate, b. p. 167–183.5°; the residue of 1.9 g. was very high boiling. A sample of the distillate absorbed 91% of the amount of hydrogen calculated for dipentene; 2 g. of the same distillate was treated with bromine in ether and alcohol at 0°. On spontaneous evaporation 2.7 g. of crude crystals was left which on recrystallizing from ethyl acetate yielded 1.3 g. of dipentene tetrabromide (m. p. 125°), which was identified by a mixed melting point. Pinene which had been heated for 200 hours at 200° yielded only about 50% of a volatile material (b, p. 172–177°); the residue on distilling in *vacuo* boiled at 180–235° at 2 mm. The fraction which boiled at 172–177° absorbed 92% of the amount of hydrogen calculated for dipentene and yielded the crystalline tetrabromide on brominating.

Isomerization of *d*-**Pinane.**—The pinane was heated in a Carius tube in the same manner as pinene. The material was tested for any unsaturated material before heating, by catalytic hydrogenation in acetic acid in the manner described. No appreciable amount of hydrogen was absorbed. The impurity was therefore less than 1.8%. The results of the isomerization experiments have already been summarized in Table I. The rotation was measured in the pure liquid; the analysis by catalytic hydrogenation was exactly as described for pinene–dipentene mixtures. The amount of unsaturated monocyclic compound, $C_{10}H_{18}$, was taken as equal to the amount of hydrogen absorbed.

A sample of d-pinane (6 g.) which had been heated for fifty hours at 285° yielded 4.8 g. of a distillate, b. p. 165–167°; 0.4 g. of b. p. 170–300°; viscous residue about 0.5 g.; 85.2 mg. of the distillate, b. p. 165–167°, absorbed 9.9 cc. of hydrogen at 767 mm. and 26"; calcd. for $C_{10}H_{18}$ (unsat.), 15.0; 95.6 mg. of the higher fraction absorbed 9.7 cc. of hydrogen at 772 mm. and 26°; calcd. for $C_{10}H_{18}$ (unsat.), 16.7.

Summary

1. The loss of optical activity of d-pinene on heating in the liquid or gaseous phase has been shown to be due to the isomerization to dipentene and not to simple racemization. The presence of dipentene in amounts sufficient to account for the loss of activity has been shown by catalytic hydrogenation.

2. d-Pinane on heating to above 200° in the liquid phase is isomerized with loss of optical activity and the formation of unsaturated hydrocarbons. The process is much slower than in the case of d-pinene.

THE KINETICS OF THE POLYMERIZATION OF ACETYLENE[1]

BY ROBERT N. PEASE

RECEIVED JUNE 26, 1929 PUBLISHED NOVEMBER 8, 1929

In the course of an investigation of the polymerization of ethylene, some data on the analogous reactions of acetylene were obtained which indicated a relatively simple reaction mechanism. It has seemed worth while to amplify these somewhat and present them for publication, especially in view of the fact that no such study has previously been reported.

It has been known since Berthelot's time that acetylene is readily polymerized on heating, giving a complex of products, many of which are aromatic in character. At the same time, resolution into carbon, hydrogen and methane takes place to a degree which is greater the higher the temperature, as has been shown especially by Bone and Coward.[2] The investigation here reported has had as its object the examination of the manner in which acetylene reacts, rather than the determination of the products of reaction, though some attention has necessarily been given to this point.

The flow method has been used. Acetylene from a tank of this gas was washed with water and dried by calcium chloride. It then passed through a flowmeter into a pyrex reaction tube which was heated in an electric tube-furnace. The off-gas passed through a trap to remove liquid products and thence either to the air or to a small gas-holder, where it could be collected over mercury. The gas was analyzed by absorption in concentrated sulfuric acid to remove higher unsaturated hydrocarbons (correction being made for absorption of acetylene), followed by absorption in dilute bromine water to remove acetylene. In some cases the residue was analyzed for hydrogen and saturated hydrocarbons.

Results

Preliminary experiments revealed that reaction was detectable at 400° on seven minutes' exposure, a white mist appearing in the off-gas accompanied by a rather powerful odor reminiscent of carburetted water-gas. The rate increased rapidly as the temperature was raised and the mist gave place to a brown mobile liquid which collected in the trap.

---

[1] This paper contains results of an investigation carried out as part of Project No. 7 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund donated by Mr. John D. Rockefeller. This fund is being administered by the American Petroleum Institute with the cooperation of the Central Petroleum Committee of the National Research Council. Professor Hugh S. Taylor, of Princeton University, is Director of Project No. 7.

[2] Bone and Coward, J. *Chem. Soc.*, **93,** 1197 (1908).

Very little permanent gas was formed until the temperature approached 550°, even though more than half of the acetylene might react. Beyond this point hydrogen and small quantities of methane and ethane appeared. At 600° regular "flashing" began at higher flow rates, though it was possible to carry the reaction to 650° with low flow rates. Experiments were not continued beyond this point. In this high temperature range, finely-divided carbon was carried out of the tube.

Liquid Products,—Some attention was given to the more volatile liquid products, with the special purpose of determining whether benzene formation preponderated. The liquid was placed in a small flask to which was sealed a collecting tube and a stopcock. The system was evacuated after cooling the liquid to −79°. The flask was then held at 25° while the collecting tube was at −79°. Distillation took place rather rapidly, and in different experiments from one-third to three-fourths of the liquid came over. The distillate had in all cases a density close to 0.850 (benzene 0.878, dipropargyl 0.805), which was indicative of aromatic character. It did not freeze sharply but was in general completely solid at −10 to −20°. This material was considerably polymerized (or carbonized) by concentrated sulfuric acid but gave a residue which after distillation was solid at −3°, and which gave nitrobenzene on nitration. The original distillate gave no test with ammoniacal cuprous chloride solution, indicating the absence of compounds with terminal CH groups (such as dipropargyl). The indication is that benzene formation does occur but that it does not predominate under the conditions of these experiments.

About a half of the residue from the above distillation distilled over up to 300°, leaving a pitch. Nothing further was done with this.

Reaction Kinetics.—Preliminary experiments revealed that the reaction rate varied with concentration and time, approximately as would be expected for a bimolecular reaction. Thus, for example, at 550° and 1 atm. total pressure, 32% of the acetylene reacted in twenty-five seconds when the pure gas was admitted, and 18% when the acetylene was diluted with its own volume of nitrogen. If the reaction is bimolecular and the conversion is low (lower than the above figures), dilution with nitrogen should have cut the yield in half. It is obvious that this state of affairs is approached, and that we are dealing with a process which is initiated by a change involving two molecules.

The question arises as to whether the reaction is homogeneous, or takes place on the walls. To answer this, experiments were carried out with a reaction tube packed with broken pyrex glass (4–20 mesh). Under these conditions the yield was materially decreased. Thus, at 550° and 1 atm., only 17% reacted in twenty-five seconds when the gas was pure acetylene, as compared to 32% in the empty tube. The conversion is nearly halved. The indication is thus not of a positive but rather of a negative catalytic action of the walls. This is doubtless bound up with the exothermicity of the reactions which are taking place. The condensation of three molecules of acetylene to benzene would liberate 149,200 cals. per mole of benzene, for example. The wall material may be assumed to act to maintain the temperature, or to deactivate excited product materials.

The results of the rate measurements are conveniently expressed in terms of a bimolecular reaction constant. The calculation of such constants cannot be put on an altogether satisfactory basis, however. These reactions are carried out at constant pressure and involve a volume decrease. Hence the time of heating depends upon the amount of reaction, since the resulting volume contraction progressively decreases the linear flow rate within the reaction tube. Further, the true volume contraction at all points within the reaction tube is unknown because of the complexity of the reactions, and uncertainty as to whether the polymerization is entirely completed within the reaction tube. Under the circumstances a precise analysis of the results is not possible. The best that can be done is to assume some average value for the volume change and calculate on this basis. Considering the results of the distillation analyses, it has seemed most reasonable to set this at 4 to 1, which amounts to assuming that the average composition of the product is $(C_2H_2)_4$.

The rate constants are calculated in the following way. We assume that the primary reaction, which is the slow rate-determining process, is $2C_2H_2 \longrightarrow (C_2H_2)_2$. This is followed by a series of rapid reactions such as $(C_2H_2)_2 + C_2H_2 \longrightarrow (C_2H_2)_3$, etc., which lead to the final product whose composition is on the average $(C_2H_2)_4$. Let v_0 be a volume of acetylene and v_N a volume of nitrogen admitted to the reaction tube at a rate of S_0 cc./second. These and all volumes are for the moment considered as measured at the temperature and pressure of the reaction tube. At some later time a volume, $v_0 - v$, of acetylene has reacted to give $1/4(v_0 - v)$ of product. The total volume of gas at this time is

$$V_g = v + v_N + {}^1/_4(v_0 - v) = {}^1/_4v_0 + v_n + {}^3/_4v$$

The corresponding flow rate is

$$S = S_0 \frac{V_g}{v_0 + v_N}$$

Suppose the gas is passing through a cylindrical reaction tube of length, l, and cross section πr^2. At any point, l', along the tube, the linear flow rate is

$$\frac{dl}{dt} = \frac{S}{\pi r^2} = \frac{S_0}{\pi r^2(v_0 + v_N)} \times V_g$$

Consider a section of the tube at l' equal to ar^{2}dl. Any element of gas volume is in this section for a time dt. During this time some reaction takes place. If the action is bimolecular, we may write for its rate

$$-\frac{1}{v}\frac{\mathrm{d}v}{\mathrm{d}t} = k\frac{v}{V_g} \times \frac{p}{760}$$

where k is the fractional conversion per second when the acetylene is at a pressure of 1 atm. Eliminating dt from these equations, we obtain

$$\frac{\pi r^2(v_0 + v_N)}{s_0 V_g}\,\mathrm{d}l = \frac{V_g \cdot 760}{kv^2 \cdot p}\,\mathrm{d}v$$

Integrating and solving for k, we obtain

$$k = \frac{760\ S_0}{p(v_0 + v_N)V_r}\left[{}^9/_{16}\,(v_0 - v) + {}^6/_4({}^1/_4 v_0 + v_N)\ln\frac{v_0}{v} + ({}^1/_4 v_0 + v_N)^2\frac{v_0 - v}{v - v_0}\right]$$

Here $V_r = \int_0^l \pi r^2 \mathrm{d}l$ = volume of the reaction tube.

The gas volumes are supposed to have been measured at the temperature and pressure of the tube. An examination of the above equation indicates, however, that any other basis of comparison is equally good, provided only that the actual tube volume be corrected to correspond, for we may as well think of the tube shrinking as of the gases expanding. Since the gas volumes were all corrected to 25° and 1 atm., the tube volume has been calculated to these conditions and is so recorded.

Data on experiments between 400 and 650° are given in Table I.

[b] "C_nH_m" refers to the higher volatile hydrocarbons absorbed in concd. sulfuric acid.

Conclusions

The data show clearly that polymerization is the only reaction of importance up to 600°, though secondary or less important primary reactions do begin to yield hydrogen and methane at the higher temperatures. The polymerization produces a complex of products, as has already been pointed out, and there is no evidence from these results that any one product predominates under any particular set of conditions. Especially, there is no evidence of a quantitative yield of the first product of polymerization of two molecules of acetylene. This might be expected to show under "C_nH_m," which represents absorption in concd. sulfuric acid.

Although the kinetic studies are not conclusive, the indication is that the rate-determining process is the primary reaction involving two molecules of acetylene. The reaction is shown to be homogeneous by the fact that the rate is not increased by a glass packing, but is actually decreased. This decrease is undoubtedly bound up with the exothermic nature of the reactions taking place.

Summary

The polymerization of acetylene has been studied by the flow method. Results indicate that the polymerization is a homogeneous, bimolecular reaction which is partially suppressed by use of a glass packing. The polymerization is the only reaction of importance between 400 and 600°. It yields a complex of products of a wide range of volatility. Benzene

is present along with other volatile hydrocarbons subject to attack by concd. sulfuric acid.

SOME REARRANGEMENT REACTIONS OF ALPHA-NAPHTHYLMETHYLMAGNESIUM CHLORIDE

BY HENRY GILMAN AND JAMES E. KIRBY

RECEIVED JUNE 27, 1929 PUBLISHED NOVEMBER 8, 1929

Introduction

In continuation of investigations[1] concerned with so-called rearrangements of some organomagnesium halides, a study has been made of the reactions of a-naphthylmethylmagnesium chloride (α-$C_{10}H_7CH_2MgCl$). It is known that some RMgX compounds (in particular, benzylmagnesium chloride and triphenylmethylmagnesium chloride) react both normally and abnormally with some reagents, especially with aldehydes.[2] We wished to ascertain whether such abnormal reactions were characteristic of organomagnesium halides with the grouping $>C{=}\overset{|}{C}{-}CH_2MgX$. The results of the present study show that a-naphthylmethylmagnesium chloride does behave abnormally with some compounds that give rise to rearrangement products with a type like benzylmagnesium chloride. Accordingly, mechanisms to be offered[2] for such rearrangements must include a-naphthylmethylmagnesium chloride.

The preparation of a-naphthylmethylmagnesium chloride by earlier investigators has been attended with more than ordinary difficulties. Weitzenbock and Lieb[3] had no success in the synthesis of ethyl α-naphthylacetate from a-naphthylmethylmagnesium chloride and ethyl chlorocarbonate. They probably did not have any of the desired Grignard reagent in hand. When they treated a-naphthylmethyl chloride (prepared by the direct chlorination of α-methylnaphthalene)[4] with magnesium they had difficulty in getting the magnesium to react, and after treating their reaction mixture with ethyl chlorocarbonate, the only product they isolated was di-a-naphthylethane formed as a result of a coupling reaction.[5] Then Mayer and Sieglitz[6] found that magnesium was used up to only a

slight extent in its reaction with a-naphthylmethyl bromide, and they also obtained only the coupling product (di-α-naphthylethane) in a reaction with acetaldehyde. More recently, Conant, Small and Sloan[7] had better success with their chloride prepared by the method of v. Braun and Moldaenke.[8] However, their chloride reacted slowly with magnesium and the reaction was about complete at the end of three hours; their yield of crude a-naphthylmethylxanthenol from xanthone was about 15%.

Our chloride, prepared from a-naphthylcarbinol and thionyl chloride, reacted with comparative ease with ordinary magnesium turnings to give quite satisfactory yields[g] of several products. Abnormal reactions were observed with ethyl chlorocarbonate and formaldehyde, the products having the carboxyethyl and carbinol groups, respectively, in the β- and not in the a-position. Normal products were obtained with carbon dioxide, dimethyl sulfate and phenyl isocyanate.

One reaction was carried out between the relatively inaccessible and expensive β-naphthylmethylmagnesium bromide and carbon dioxide, and the expected β-naphthylacetic acid was obtained.

Experimental Part

Preparation of a-Naphthylmethyl Chloride.—First, α-naphthylcarbinol was prepared in 50–53% yield in accordance with the method of Ziegler[10] by the action of gaseous formaldehyde on a-naphthylmagnesium bromide. Then, to 25 g. (0.15 mole) of the carbinol dissolved in 100 cc. of dry toluene was added 25 g. of thionyl chloride in small quantities. A reaction set in at once and after the spontaneous reaction ended the solution was refluxed gently until evolution of gases ceased. This required about three hours. The toluene and thionyl chloride were removed under reduced pressure and fractional distillation of the residue gave 23.2 g. or a 79% yield of the chloride boiling at 135–139° (6 mm.).

Preparation of the Grignard Reagent.—In a first experiment we used a-naphthylmethyl chloride prepared by the direct chlorination of α-methylnaphthalene.[4] Although we obtained the Grignard reagent from this chloride, the reaction was unsatisfactory. In all subsequent experiments we used the chloride prepared from the corresponding carbinol With this chloride reaction set in as readily as with bromobenzene and magnesium when the usual small crystal of iodine was used as a catalyst.

In some preliminary experiments the reagent was prepared in a test-tube in connection with the color test of Gilman and Schulze.[11] It was observed that once the

[9] No study was made of optimal conditions ior the preparation of the a-naphthylmethylmagnesium chloride. It is highly probable, however, that yields of about 90% or more can be obtained by following the directions of Gilman and McGlumphy, Bull. *soc. chim.*, **43**, 1322 (1928), for the preparation of allylmagnesium bromide. Judging by the yields of some of the products obtained from a-naphthylmagnesium chloride it is fair to state that this Grignard reagent was obtained in the present study in yields of at least 80%. See Gilman and St. John, *Rec. trav. chim.*, **48**, 593 (1929).

[10] Ziegler, *Ber.*, **54**, 737 (1921).

[11] Gilman and Schulze, THIS JOURNAL, **47**, 2002 (1925); *Bull. soc. chim.*, **41**, 1479 (1927).

reaction started it continued in the presence of the Michler's ketone to give a pronounced characteristic color test on subsequent hydrolysis. Of course the same test was obtained in another test-tube experiment when the ketone was added after the reaction between the chloride and magnesium was complete.

In the subsequent reactions, 10 g. (0.057 mole) of the a-naphthylmethyl chloride in 50 cc. of ether was added slowly to 1.38 g. (0.057 atom) of magnesium turnings covered with 85 cc. of ether.[12] The RMgCl solution was of a yellowish-green color.

Carbon Dioxide.—a-Naphthylacetic acid was prepared in the customary manner[13] from carbon dioxide. A negative color test[11] was obtained at the end of twenty minutes. The yield of acid from 0,057 mole of chloride was 59.4%.[9] It was characterized both by its melting point and the melting point of α-naphthylacetamide[14] prepared from it.

Dimethyl Sulfate,—The reaction between the Grignard reagent (0.057 mole of chloride) and dimethyl sulfate was carried out in accordance with the general directions of Gilman and co-workers.[15] The yield of a-ethylnaphthalene was 55.1%. It distilled at 247–249° (742 mm.) and was identified as the picrate, which melted at 98–99°. The melting point of the picrate as reported by Carnelutti[16] is 98°.

Phenyl Isocyanate.—A vigorous reaction took place when 10 g. (0.08 mole) of phenyl isocyanate in ether was added slowly to the Grignard reagent prepared from 17.6 g. (0.1 mole) of a-naphthylmethyl chloride. After working up the reaction product in a customary manner,[17] 9.3 g. or a 36% yield of α-naphthyl acetanilide was obtained. The compound melted at 155° when crystallized from alcohol and its identity was confirmed by a mixed melting point determination with the anilide prepared from α-naphthylacetyl chloride[18] and aniline.

In a preliminary experiment it was noticed that phenyl isocyanate stopped a reaction between a-naphthylmethyl chloride and magnesium. This reaction could not be induced to start again either by warming or by the addition of iodine. A similar case of negative catalysis with phenyl isocyanate was noted earlier by Gilman and Kirby[19] with benzohydrylmagnesium chloride $(C_6H_5)_2CHMgCl$. In another experiment a small quantity of an as yet unidentified solid melting at 136–137" was obtained. This may be a rearrangement product.

Ethyl Chlorocarbonate.—The Grignard reagent prepared from 0.095 mole of the chloride was rapidly decanted from unused magnesium into a separatory funnel, and then added slowly to 43 g. (0.4 mole) of ethyl chlorocarbonate in ether. On working up the reaction products in a customary manner, subsequent to hydrolysis by iced dilute hydrochloric acid, a 41% yield of ester distilling at 145–150° (3 mm.) was obtained. The ester was hydrolyzed by heating with alcoholic potash and the acid obtained from the hydrolysis melted at 174°. It may be crystallized from either hot water or benzene.

The neutralization equivalent (184.8, whereas the calculated value for $C_{12}H_{10}O_2$ is 186) showed it to be isomeric with α-naphthylacetic acid. It was definitely shown to be a-methyl-p-naphthoic acid by a mixed melting point determination with an

[18] Prepared from a-naphthylacetic acid and thionyl chloride by heating in a benzene solution. The acid chloride was not isolated.

[19] Gilman and Kirby, THIS JOURNAL, **48,** 1734 (1926).

authentic specimen of the acid kindly provided by Professor v. Auwers.[20] This rearrangement product is remindful of a like rearrangement of benzylmagnesium chloride2 which with ethyl chlorocarbonate gave both ethyl o-toluate and ethyl phenylacetate. The ester described above is undoubtedly chiefly ethyl a-methyl-p-naphthoate.

The anilide of α-methyl-β-naphthoic acid was prepared after the method[1]*used for the preparation of the anilide of a-naphthylacetic acid and melted at 217–218° after crystallization from alcohol.

No definite products were obtained in the attempts to oxidize a-methyl-p-naphthoic acid by alkaline permanganate and by chromic acid in acetic acid. Mayer and Schnecko[21] also had no success in their attempts to oxidize the same acid to α,β-dicarboxynaphthalene.

Formaldehyde.--The reaction between gaseous formaldehyde and the Grignard reagent prepared from **0.1** mole of the chloride gave 6.4% of the coupling product (di-a-naphtbylethane), an as yet unidentified small fraction distilling between 100–130° **(6** mm.) and **2.6** g. of a yellow oil distilling at 167–170° **(6** mm.) and melting at 121° when crystallized from benzene. It showed reactions of an active hydrogen compound and its phenylurethan (prepared from phenyl isocyanate in benzene) melted at 125°. No definite product was obtained in the attempted oxidation of the carbinol by means of alkaline permanganate to the corresponding acid. In this connection it is interesting to note that Ziegler and Tiemann[22] were unsuccessful in their attempted oxidation of the isomeric β-methyl-α-naphthylcarbinol to the corresponding aldehyde. They used chromic acid; a part of their carbinol was completely oxidized and the remainder was unchanged. These difficulties in oxidation may be due to steric influences. Undoubtedly the carbinol is α-methyl-β-naphthylcarbinol formed as **a** result of a rearrangement reaction that has been confirmed by several with benzylmagnesium chloride and formaldehyde. None of the normal and known reaction product, a-naphthylethyl alcohol, has as yet been isolated.

The Reaction between β-Naphthylmethylmagnesium Bromide and Carbon Dioxide.—The reaction between β-naphthylmethyl bromide and magnesium in ether started easily with the aid of a crystal of iodine. The Grignard reagent was carbonated in the customary manner[13] and the β-naphthylacetic acid obtained after crystallization from benzene melted at 138°. Its identity was confirmed by a mixed melting point determination with the acid prepared according to Blank[23] by the hydrolysis of β-naphthylacetonitrile.

Summary

It has been shown that α-naphthylmethylmagnesium chloride can be readily prepared in satisfactory yields and that it reacts normally with carbon dioxide, dimethyl sulfate and phenyl isocyanate, but abnormally with ethyl chlorocarbonate and formaldehyde. The rearrangement reactions of this organornagnesium chloride can be correlated with like reactions shown by compounds with the $—CH{=}CHCH_2MgX$ grouping.

THE ACTION OF AROMATIC GRIGNARD REAGENTS ON ARYLARSINE OXIDES[1]

BY F. F. BLICKE AND F. D. SMITH[2]

RECEIVED JUNE 28, 1929 PUBLISHED NOVEMBER 8, 1929

The preparation of several tetra-arylarsyl oxides from arsenic trioxide and arylmagnesium halides has been described recently and a reaction mechanism to account for their formation has been suggested.[3]

A second method for the preparation of tetra-arylarsyl oxides, by means of which simple as well as mixed oxides of the type RR'As—O—AsR'R can be obtained, is the subject of this paper.

Diphenyl, di-p-tolyl, di-p-anisyl and di-a-naphthyl mercury were prepared by the interaction of arylmagnesium halides and mercuric chloride. $RMgX + HgCl_2 \longrightarrow RHgX + ClMgX$; $RHgX + RMgX \longrightarrow RHgR + MgX_2$. Hitherto only diphenylmercury has been obtained by this method.[4]

The diarylmercury compounds were heated with arsenic trichloride with the formation of aryldichloro-arsines which, upon hydrolysis, yielded arylarsine oxides.

$$RHgR + AsCl_3 \longrightarrow RAsCl_2 + ClHgR$$
$$ClHgR + AsCl_3 \longrightarrow RAsCl_2 + HgCl_2$$
$$RAsCl_2 + 2NaOH \longrightarrow RAsO + 2NaCl + H_2O$$

In those instances in which it is impractical to prepare the mercury diaryls, the oxides can be obtained by reduction of the corresponding diarylarsinic acids.

The arylarsine oxides, when allowed to react with an aromatic Grignard reagent, were converted into tetra-arylarsyl oxides, as follows

$$2RAs{=}O + 2\,RMgX \longrightarrow 2RRAs(OMgX)$$
$$2RRAs(OMgX) + 2H_2O \longrightarrow RRAs{-}O{-}AsRR$$
$$2RAs{=}O + 2R'MgX \longrightarrow 2RR'As(OMgX)$$
$$2RR'As(OMgX) + 2H_2O \longrightarrow RR'As{-}O{-}AsR'R$$

The simple tetra-arylarsyl oxides were obtained directly from the reaction mixture in crystalline form. The mixed oxides, however, could be isolated only in the form of oils which would not crystallize. These products were treated with chlorine,[5] the crystalline tetrachlorides hydrolyzed to the arsinic acids, the latter reduced and the reduction products

isolated in the form of the diarylarsyl halides. The latter when hydrolyzed yielded the pure tetra-arylarsyl oxides

$$\mathrm{RR'As{-}O{-}AsRR'} \longrightarrow \mathrm{RR'As(Cl_2){-}O{-}As(Cl_2)R'R} \longrightarrow \mathrm{2RR'As(O)OH}$$
$$\mathrm{2RR'AsCl} \longrightarrow \mathrm{RR'As{-}O{-}AsR'R}$$

Experimental Part

Preparation of Mercury Diaryls

General Procedure.—The Grignard reagent was prepared in a liter, three-necked flask from **0.4** mole of the aryl halide, **0.4** of an atomic equivalent of magnesium and **200** cc. of ether. A mechanical stirrer was introduced and the arylmagnesium halide diluted with **100** cc. of dry benzene. Forty-eight g. **(0.18** mole) of dry mercuric chloride was added, cautiously, in four portions during the course of an hour with rapid stirring; the stirring was continued for eight hours. The reaction mixture, which consisted of the mercury diaryl and the arylmercuric halide, was treated with ice and a small amount of hydrochloric acid. In the case of mercury diphenyl, the ether-benzene layer was decanted, filtered and dried with fused sodium sulfate. The solvent was removed and the residue washed with petroleum ether (40–60°). In the preparation of mercury ditolyl only a small amount of the substance is present in the ether-benzene layer and in the case of mercury dianisyl and mercury dinaphthyl practically all of the material is found in the reaction mixture as a precipitate. In the latter instance the dry mixture of the mercury diaryl and the arylmercuric halide was placed in a Soxhlet apparatus and the diaryl mercury extracted with benzene.

Yield, %	**75**	**70**	**62**	**90**

[a] Pfeiffer and Truskier, ref. 4, obtained a **42%** yield; m. p. 120°. [b] Whitmore, "Organic Compounds of Mercury," The Chemical Catalog Co., Inc., New York, 1921. [c] Matsumiya, Mem. *Coll. Sci. Kyoto Imp. Univ.*, *8*, **394** (1925), obtained this compound from α-naphthylmagnesium bromide and α-naphthyl mercuric chloride in **69%** yield.

Preparation of Arylarsine Oxides

General Procedures (a).—The mercury diaryl was heated with one and one-half times the theoretical amount of freshly distilled arsenic trichloride for three hours at 130–140°. The reaction mixture was extracted with benzene and filtered. After removal of most of the benzene on a steam-bath, the mixture was distilled under diminished pressure in an atmosphere of nitrogen until the excess arsenic trichloride had been removed. The crude aryldichloro-arsine was added to a warm **10%** solution of sodium hydroxide with rapid stirring; sufficient alkali should be used to dissolve all of the arylarsine oxide formed. The solution was filtered from mercury compounds through a Jena filter. The alkaline filtrate was neutralized, the precipitate washed by decantation and then filtered.

The oxides, with the exception of the naphthyl compound, were dissolved in hot benzene and an equal volume of absolute ether added to the cold benzene solution. The oxides precipitated slowly. The naphthylarsine oxide was obtained in a pure state in the following manner: the crude oxide was suspended in benzene, treated with dry hydrogen chloride and the solution of naphthyldichloro-arsine heated until the solvent was removed. A small amount of petroleum ether **(40–60°)** was added to the oily residue. The latter became crystalline and the material was then recrystallized from petroleum ether; m. p. 70–72°.[6] Upon hydrolysis of the dichloride there was obtained pure naphthylarsine oxide.

(b) Sulfur dioxide was passed into a mixture prepared from one part of the arylarsinic acid,[7] five parts of methyl alcohol, two parts of concd. hydrochloric acid and about 0.1 g. of potassium iodide dissolved in a small amount of water. The greater part of the aryldichloro-arsine formed precipitated as an oil. Water was added to precipitate the chloride completely and after decantation of the aqueous layer the oil was washed thoroughly with water. The oily chloride was treated with warm 10% sodium hydroxide until a clear solution was obtained. The latter was neutralized, whereupon the arylarsine oxide precipitated.

TABLE X

ARYLARSINE OXIDES

	Phenyl	*p*-Tolyl	*p*-Anisyl	α-Naphthyl
M. p., °C.	144–146[a]	188–190[b]	114–116[c]	245[d]
Yield (method a),[e] %	60	.....	.....	60
Yield (method b),[f] %	80	87	90	..

[a] Michaelis, Ber., 10, 623 (1877), recorded the melting point as 119–120°. Gryszkiewicz-Trochimowski, Mateyak and Zablotscki, Bull. soc. chim., [4] 41, 1327 (1927), state that the substance melts at 129–130° when prepared by hydrolysis of phenyldicyano-arsine. [b] La Coste and Michaelis, Ann., 201, 257 (1880), found the melting point to be 156°. Tolyldichloro-arsine, from which this oxide was prepared by hydrolysis, was analyzed. Calcd. for $C_7H_7AsCl_2$: Cl, 29.95. Found: 29.87, 29.65. [c] Michaelis and Weitz, Ber., 20, 51 (1887), described this substance as a crystalline crust but recorded no melting point. When this compound is recrystallized from a mixture of benzene and ether, it melts at 93–95° and seems to lose solvent of crystallization. After it has been heated it melts at 114–116°. The latter melting point was obtained when the compound was recrystallized from a mixture of chloroform and ether. [d] If the oxide is dissolved in alkali, precipitated with an acid and then air dried it melts at 245°. After recrystallization from tetralin the melting point was 206–210°. When the compound obtained from tetralin was heated with benzene the melting point was 185–190°. Solvent of crystallization can be seen to escape from the melting-point tube when the latter is heated. [e] The yield is based on the diaryl mercury compound. [f] The yield is based on the arylarsinic acid which had been recrystallized from water.

Interaction of Arylmagnesium Halides and Arylarsine Oxides

General Procedure.—Three hundredths of a mole of the arylarsine oxide was dissolved in 100 cc. of dry benzene, the solution cooled with ice and stirred rapidly. Forty-five hundredths of a mole of the Grignard reagent was then added. After one-half hour the ice-bath was removed and the mixture was stirred for four hours longer. After twelve hours the reaction mixture was decomposed with ice and a small amount of acetic acid, the ether–benzene layer separated, washed with 10% sodium hydroxide and then dried over fused sodium sulfate. The solvents were removed and the oily residue, which could not be obtained in crystalline form in the case of the mixed tetra-arylarsyl oxides, RR′As—O—AsR′R, was dissolved in absolute ether and the solution saturated with chlorine. The tetrachloro derivative of the tetra-arylarsyl oxide precipitated to some extent in the form of an oil which soon became crystalline. The solvent was removed from the mixture and the residue treated with 5% sodium hydroxide

---

[6] Gryszkiewicz-Trochimowski, Mateyak and Zablotscki, Bull. *soc. chim.*, *[4]* 41, 1328 (1927), record the melting point as 69.5–70°.

[7] The arylarsinic acids were all prepared according to the method of Schmidt, Ann., 421, 169 (1920).

solution to convert the tetrachloride into the arsinic acid. The alkaline solution of the latter substance was extracted with ether to remove by-products, the solution heated on a steam-bath to remove dissolved ether and then neutralized, whereupon the arsinic acid precipitated in the form of a gum; after some time the latter became solid. The crude arsinic acid was boiled with acetone, the solution cooled and then filtered. This process was repeated several times. The arsinic acid dissolves in the acetone only to a slight extent but the by-products in the crude acid are much more soluble. Phenylbiphenylarsinic acid can be recrystallized from alcohol.

The diarylarsinic acid was then converted into the diarylarsyl chloride by the action of sulfur dioxide and hydrochloric acid in the same manner as described above under general procedure (b). The diarylarsyl chloride precipitated immediately in some cases as an oil, in other instances as a solid. The chloride was then heated with alcoholic sodium hydroxide, whereby it was converted into the tetra-arylarsyl oxide.

TABLE III

DIARYLARSINIC ACIDS[a]

	M. p., °C.	Formula	Arsenic analyses[c] Calcd.	Found
Phenyl-*p*-tolyl	148–150[b]	$C_{13}H_{13}AsO_2$	27.17	27.65
Phenyl-*p*-anisyl	167–169	$C_{13}H_{13}AsO_3$	25.68	26.08
Phenyl-a-naphthyl	175–176	$C_{16}H_{13}AsO_2$	24.03	24.87
Phenylbiphenyl	218–220	$C_{18}H_{15}AsO_2$	2220	22.10
p-Anisylbiphenyl	228–231	$C_{19}H_{17}AsO_3$	20.38	20.59

[a] All of the diarylarsinic acids are practically insoluble in hot acetone, soluble in a mixture of alcohol and hydrochloric acid, soluble in hot benzene and only slightly soluble in hot water. [b] Michaelis, **Ann.**, 321, **157** (1902), recorded the melting point as 158–160". [c] Ewin, *J. Chem. Soc.*, **109**, **1356** (**1916**).

TABLE IV

DIARYLARSYL CHLORIDES

	M. p., °C.	Formula	Chlorine analyses (Volhard) Calcd.	Found
Phenyl-*p*-tolyl[a]	Oil	$C_{13}H_{12}AsCl$	12.73	12.67
Phenyl-*p*-anisyl	Oil	$C_{13}H_{12}OAsCl$	12.04	12.26
Phenyl-a-naphthyl	Oil	$C_{16}H_{12}AsCl$	11.27	11.12
Phenylbiphenyl	83–85°	$C_{18}H_{14}AsCl$	10.41	10.31
p-Anisylbiphenyl	Oil	$C_{19}H_{16}OAsCl$	9.57	10.01

[a] Michaelis, Table III, footnote b, states that this substance is an oil.

TABLE V

TETRA-ARYLARSYL OXIDES

	Reagents for the preparation Oxide	Mg compound	M. p., °C.
Diphenyl-di-*p*-tolyl[a]	Phenylarsine	Phenyl-Mg-bromide	7.577
Diphenyl-di-*p*-anisyl	Phenylarsine	Anisyl-Mg-iodide	Oil
Diphenyl-di-a-naphthyl	Phenylarsine	Naphthyl-Mg-bromide	Oil

Tetra-p-anisyl	Anisylarsine	Anisyl-Mg-iodide	128–129
Tetra-a-naphthyl	Naphthylarsine	Naphthyl-Mg-bromide	250–251

[a] Michaelis, footnote a, Table II, prepared the substance by the hydrolysis of the chloride, which had been obtained by heating phenyldichloro-arsine with an excess of ditolyl-mercury. He described it as being an oil.

Summary

1. The preparation of diphenyl, di-*p*-tolyl, di-*p*-anisyl and di-α-naphthyl mercury from the interaction of an arylmagnesium halide and mercuric chloride has been described.

2. Phenyl-, *p*-tolyl-, *p*-anisyl- and a-naphthylarsine oxide have been prepared. Two methods of preparation were used: (a) the diaryl mercury compound was heated with arsenic trichloride and the aryldichloroarsine formed was hydrolyzed; (b) the arylarsonic acid was reduced with sulfur dioxide in the presence of hydrochloric acid and the aryldichloroarsine was hydrolyzed.

3. A number of tetra-arylarsyl oxides of the type RR'As—O—AsR'R were prepared from the interaction of an arylarsine oxide and an arylmagnesium halide. In addition several mixed diarylarsinic acids and mixed diarylarsyl chlorides have been described.

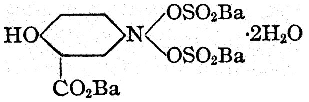
CLEAVAGE OF AZO DYES BY MEANS OF SULFITES. THE CLEAVAGE OF 4-HYDROXY-AZOBENZENE-5-CARBOXYLIC ACID AND OF 3-METHYL-4-HYDROXY-AZOBENZENE-5-CARBOXYLIC ACID

BY KARL H. ENGEL

RECEIVED JUNE 28,1929 PUBLISHED NOVEMBER 8, 1929

It has been reported in THIS JOURNAL[1] that azo dyes suffer a distinctive cleavage when heated with aqueous sulfite solutions. In a further study of this reaction, the behavior of the above-mentioned dyes has been investigated. The cleavage of these dyes followed closely the reaction course of 4-hydroxy-azobenzene: the primary dye component yielded aniline and an N-sulfonic acid of aniline, the secondary components N-mono- and N-disulfonic acid derivatives of salicylic and of o-cresotinic acids, respectively.

4-Hydroxy-azobenzene-5-carboxylic acid yielded an interesting N-disulfonic acid which could be isolated in pure form, as its tribarium salt, represented, presumably, by the formula

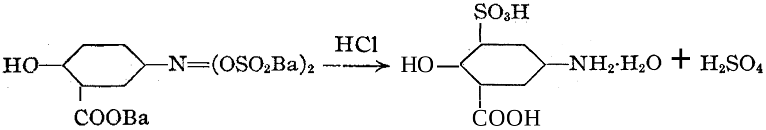


This compound was rather difficultly soluble and perfectly stable in neutral or alkaline solution. It rearranged, in the presence of mineral acids, in a

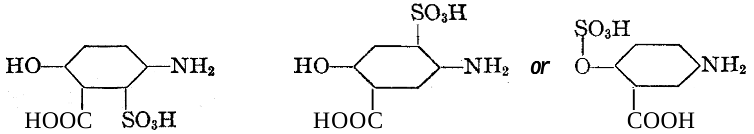
---

[1] Engel, THIS JOURNAL, 51,2986 (1929).

definite and clear cut way, yielding, quantitatively, the difficultly soluble aminosulfosalicylic acid, which may also be obtained by direct sulfonation of aminosalicylic acid.



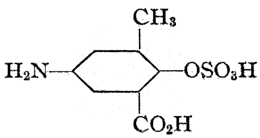
The N-monosulfonic acid, which was obtained in a smaller yield, differed strikingly from the N-disulfonic acid. It was extraordinarily soluble, sensitive to light and to air oxidation. Its free acid rearranged into an extremely soluble sulfonic acid derivative of aminosalicylic acid which could be diazotized and coupled with secondary azo components. It could possess one of the following structures

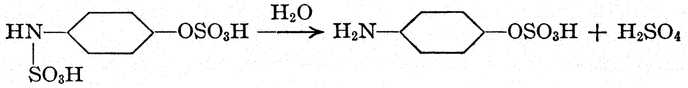


The first two formulas appeared highly improbable (especially the first), in view of the generally observed resistance of *p*-aminophenols to sulfonation in the *m*-position to the hydroxyl group. Since the reduction products of 4-hydroxy-azobenzene yielded the extremely soluble sulfonic ester of 1-amino-\$-phenol and no trace of the isomeric 1-amino-4-phenol-6-sulfonic acid, it might be concluded that the dye under investigation yielded a similar product, represented by the third formula.

The decided difference between the N-sulfonic acids, their strikingly reversed solubility relations, may be cited in support of a previously developed view that the N-disulfonic acids encountered in cleavage experiments should be looked upon as sulfurous esters of a substituted o-nitrous acid, N-monosulfonic acids as derivatives of amines, or true "sulfaminic" acids.

The cleavage of 3-methyl-4-hydroxy-azobenzene-5-carboxylic acid was investigated for a theoretical and a practical end. It was hoped that this dye, like its simpler homolog, would yield an N-disulfonic acid amenable to isolation in the form of its barium or lead salt, a hope which was not fulfilled. It was furthermore reasoned that such a product, of which a fair yield could be expected, might hydrolyze instead of yielding a nuclear sulfonic acid, the usual rearrangement, sulfonation in o-position to the hydroxyl group being prevented by the presence of substituents. The expected product, aminocresotinic acid, economically made, would be a useful dye intermediate. These premises proved correct to some extent; 18% of the theoretically possible yield of the desired substance was actually obtained. Unfortunately, for the economic aspects, the larger part of the N-disulfonic acid reacted in a third, and not completely unexpected, way, yielding the stable and extremely soluble sulfonic ester of aminocresotinic acid: a dye intermediate of much smaller value. The N-disulfonic acid derived through cleavage of 4-hydroxy-azobenzene[1] furnished a parallel to this behavior. It yielded 1-amino-4-phenol-5-sulfonic acid and, to a smaller extent, a compound which retained both sulfonic acid groups at a lower temperature, but lost one of these on further heating (or on diazotization in the cold), yielding aminophenol sulfonic ester, the reaction presumably proceeding in the following way





Sulfate Formation During Cleavage.—The cleavage of 3-methyl-4-hydroxy-azobenzene-5-carboxylic acid resulted in the formation of a considerable amount of mineral sulfate, corresponding to 12.1% of the sulfite consumed, as compared with 3.4% in the case of the salicylic acid derivative, and with 1.2% in the cleavage of 4-hydroxy-azobenzene. It was observed, as a general rule, applying to hydroxy as well as to amino azo dyes, that compounds which contained highly reactive secondary components (capable of coupling in the presence of a considerable hydrogen-ion concentration) yielded negligible amounts of sulfate, about 1%. On the other hand, dyes with weak secondary components, which coupled only in alkaline solutions, invariably yielded higher percentages. Reaction temperatures above 100° caused a considerable increase in sulfate formation, particularly in the latter class of dyes.

Increased sulfate formation did not lead to a gain in totally unsulfonated products, but to a decrease of N-disulfonic acids of the secondary components, reflected in a decrease in yield of their typical acid rearrangement products. Since the N-disulfonic acids, once formed, appeared resistant to prolonged heating at the reaction temperatures employed, it could be concluded that sulfate formation was due to hydrolysis of the first-formed sulfonic acid of the hydrazo bodies.

Experimental

Preparation of the Pure Dyes.—The sodium salts of the crude dyes were prepared by the usual coupling reactions, and the free dye acids by addition of acetic acid to solutions of the recrystallized sodium salts. The dried products were insoluble in alcohol, acetone or benzene, but became readily soluble in these solvents after a single recrystallization from 90% acetic acid. They also possessed sharp melting points then, whereas they charred without softening before recrystallization. The dyes were repeatedly recrystallized from ethyl alcohol. **4-Hydroxy-azobenzene-5-carboxylic** acid was found to melt at 220.5°, corr.

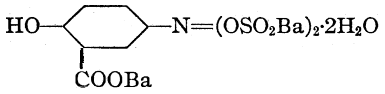
Anal. Calcd. for $C_{13}H_{10}O_3N_2$: N, 11.59. Found: N, 11.50.

3-Methyl-4-hydroxy-azobenzene-5-carboxylic acid melted at 202.0" corr.

Anal. Calcd. for $C_{14}H_{12}O_3N_2$: N, 10.96. Found: N, 10.92.

Cleavage of 4-Hydroxy-azobenzene-5-carboxylic Acid.—Twenty-four and twenty hundredths g. of the pure dye (0.1 mole) dissolved in water, the requisite amount of ammonia to form the ammonium salt, and ammonium sulfite equivalent to 420.2 cc. of 1 N solution (a total volume of 320 cc.) were heated in a nitrogen-filled pressure bottle at 90 to 93°. Decolorization was complete after six hours. This experiment, for quantitative determinations, was carried out in duplicate; the bottle contents were diluted accurately to 500 cc. Larger quantities of reagents (0.5 mole of the dye) were heated under identical conditions in a closed iron container. A qualitative separation of cleavage products from the resulting solution was attempted.

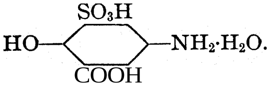
Isolation of Cleavage Products.—Aniline, which had formed as a result of the cleavage, was removed by benzene extractions. One equivalent of barium hydroxide, in solution, was then added for every sulfite equivalent originally present; precipitated barium sulfate and sulfite were removed by filtration of the hot suspension. The filtrate was evaporated to about 1200 cc. under a current of carbon dioxide, and additional precipitate again removed. On standing the clear filtrate yielded a heavy white precipitate of uniform composition. It was isolated and recrystallized from hot water. It was found to be the tribarium salt of an N-disulfonic acid derived from the secondary dye component, and may be assigned the formula



$$HO{-}C_6H_3(COOBa){-}N{=}(OSO_2Ba)_2\cdot 2H_2O$$

Anal. Calcd. for $C_7H_4O_9NS_2Ba_3\cdot 2H_2O$: N, 2.55: S, 11.62; Ba, 37.25. Found: N, 2.43; S, 11.49; Ba, 37.05. Calcd. for $2H_2O$, 6.52; loss on drying, 6.76. (The material was dried under a current of nitrogen at 120". It regained its original weight when exposed to the atmosphere.)

It tended to form clusters of microscopic crystals, short rods, apparently belonging *to* the rhombic system. The substance was capable of reducing ammoniacal silver solution but was quite resistant to air oxidation, even in solution. It produced, at great dilutions, a deep violet blue or prune coloration with ferric chloride and acetic acid. Addition of mineral acid caused rearrangement into **aminosulfosalicylic** acid,



$HO{-}C_6H_2(SO_3H)(COOH){-}NH_2\cdot H_2O$. This compound was practically insoluble in cold but readily soluble in hot water. It was identical in composition and crystal habit and in **its** ferric chloride and diazo reactions, with the product obtained by direct sulfonation of **1-amino**-4-hydroxybenzene-5-carboxylic acid.

Anal. Calcd. for $C_7H_7O_6NS\cdot H_2O$: N, 5.58; S, 12.77; H_2O, 7.17. Found: N, 5.53; S, 12.78; loss on drying (over P_2O_5), 7.37.

The yield of this product from 3.000-g. portions of the tribarium salt was quantitative, 1.347 g. (theoretically possible, 1.365 g.).

Phenylsulfaminic Acid, Barium Salt.—The mother liquor of the tribarium salt, described above, contained additional amounts of that product, which was precipitated by an equal volume of acetone. The filtered acetone solution was then evaporated to 200 cc.; to the remaining aqueous solution was added 500 cc. of methanol which precipitated the barium salt of phenylsulfaminic acid, $C_6H_5NHSO_3Ba$. This was isolated by filtration, washed with methanol and directly analyzed. It yielded aniline and sulfuric acid in the presence of hydrochloric acid. In solution, it was sensitive to air oxidation.

Anal. Calcd. for $C_6H_6O_3NSBa$: N, 5.83; S, 13.32; Ba, 28.47. Found: N, 5.62; S, 13.04; Ba, 28.61.

The alcoholic mother liquor, after concentration to a small volume, deposited mixtures of barium salts, which, on addition of acids, yielded both aniline and an extremely soluble salicylic acid derivative. Presumably the mixture contained the barium salt of the N-monosulfonic acid derived from the secondary dye component,  It was quite sensitive to air oxidation. Ferric chloride caused a claret-red coloration.

Quantitative examinations of the 500-cc. solutions, containing a tenth mole of dye, were made in the manner described for 4-hydroxy-azobenzene.' Aniline, recovered by benzene extractions, required 65.0 and 65.4 cc. of normal nitrite solution, a yield of 65.2% of the theoretical. An excess of 26.6 cc. of 1 *N* sulfite solution was found present after cleavage; 393.6 cc. of a normal, or 196.8 cc. of a molar solution of sulfite was therefore consumed, or 1.968 mole to one mole of dye. Sulfate formed during cleavage corresponded to 1.596 g. of barium sulfate, equivalent to 13.7 cc. of 1 N sulfite solution or to 3.4% of the consumed sulfite. No totally unsulfonated derivative of the secondary dye component could be detected.

Upon the preceding determinations the following tabulation of products and yields could be based.

CLEAVAGE OF THE DYE 
From primary component **From secondary component**

Ia  65.2% IIa  58.4%

Ib  34.8% IIb  41.6%

Two hundred and fifty-cc. portions (0.05 mole of dye) were heated to 95° and acidified with 60 cc. of concd. hydrochloric acid, thus causing decomposition of phenylsulfaminic acid (Ib) into aniline and sulfuric acid, rearrangement of the N-disulfonic acid (IIa) into nuclear aminosulfosalicylic acid with incidental hydrolysis of one of its sulfonic acid groups, and rearrangement of the N-monosulfonic acid (IIb) into the extremely soluble sulfonic ester of aminosalicylic acid. The aniline liberated and isolated required 16.3 cc. of 1 N nitrite solution; 7.253 g. of aminosulfosalicylic acid ($1H_2O$) was isolated. Diazotization of the remaining soluble aminosalicylic acid derivative consumed 20.2 cc. of 1 N nitrite solution. The product itself could not be induced to crystallize from its solution. It was quite resistant toward hydrolytic action of strong acids. Prolonged heating at 100° in the presence of about 5 M hydrochloric acid solution caused some decomposition but no appreciable sulfuric acid formation. The diazonium derivative was coupled with 1-naphthylamine in the presence of acetate and acetic acid. The resulting brown dye was insoluble, in the form of its free acid, and permitted quantitative isolation. Nitrogen and sulfur determinations showed the presence of one sulfonic acid group in the dye molecule.

Anal. Calcd. for $C_{17}H_{13}O_6N_3S$: N, 10.87; S, 8.28. Found: N, 10.67; S, 8.03; sulfated ash, none.

Azo dyes differed very little in dyeing shades from corresponding azo derivatives of the nuclear aminosulfosalicylic acid. They did possess greater solubility.

ACTUAL YIELDS OF FINAL USEFUL PRODUCTS FROM REARRANGEMENT OF PRODUCTS TABULATED ABOVE

Ia  $C_6H_5-NH_2$..... 65.2%

IIa →  $HO-C_6H_2(SO_3H)(COOH)-NH_2$.....57.8%

Ib →  $C_6H_5-NH_2$..32.6%

IIb →  $HO_3SO-C_6H_3(COOH)-NH_2$. 40.4%

Cleavage of 3-Methyl-4-hydroxy-azobenzene-5-carboxylic Acid.—Portions of one tenth mole of dye, 25.622 g., an equivalent amount of ammonia for its solution and ammonium sulfite corresponding to 419.6 cc. of 1 N solution, contained in about 320 cc. of water, were heated in closed nitrogen-filled bottles at 90 to 93°. The dye was reduced with exceptional ease, three hours of heating being sufficient. The solutions were diluted to 500 cc., accurately, and analytical determinations made as described before.

Aniline, extracted with benzene, consumed 66.0 cc. of 1 N nitrite solution for diazotization. N-sulfonic acids remaining in solution could not be induced to crystallize from solution either as calcium, barium or lead salts. Their solution was quite sensitive to air oxidation. Dilute ferric chloride caused a transient reddish-blue coloration.

Determination of unconsumed sulfite showed the presence of 27.9 cc. of 1 N solution; 391.4 cc. of 1 N or 195.7 cc. of a molar solution was therefore used, or slightly less than two moles of sulfite to one of dye. Sulfate generated during cleavage was determined in 25-cc. portions of the ammoniacal solution. 0.2810 g. of barium sulfate was found, or 5.620 g. in 500 cc. of the original solution, corresponding to 48.2 cc. of 1 *N* solution, or to 12.1% of the sulfite consumed. Dilute acetic acid added to the cold solution of cleavage products did not cause a precipitate. Totally unsulfonated aminocresotinic acid, which is difficultly soluble, therefore, could not have been present. On these various determinations may be based the following tabulation of primary cleavage products and their approximate yields.

CLEAVAGE OF THE DYE  $C_6H_5-N{=}N-C_6H_2(CH_3)(COONH_4)-OH$

From primary component **From secondary component**

Ia  $C_6H_5NH_2$..........66.0%

IIa  $HO-C_6H_2(CH_3)(COONH_4)-N{=}(OSO_2NH_4)_2$..41.8%

Ib  $C_6H_5-NHSO_3NH_4$..34.0%

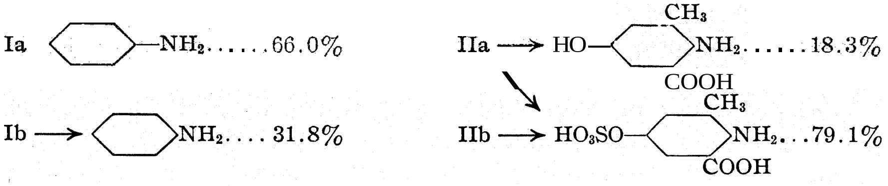
IIb  $HO-C_6H_2(CH_3)(COONH_4)-NHSO_3NH_4$ 48.2%

Decomposition and Rearrangement of N-sulfonic Acids.—Addition of an excess of mineral acid to the hot solution of cleavage products caused decomposition of the primarily formed phenylsulfaminic acid, aniline corresponding to 31.8 cc. of 1 *N* nitrite solution and sulfuric acid being formed. The secondary component yielded two products: aminocresotinic acid and an extremely soluble monosulfonic acid derivative of the same compound. One-tenth mole of dye yielded 3.052 g. of aminocresotinic acid, or 18.3% of the theoretically possible amount.

Anal. Calcd. for $C_8H_9O_3N$: N, 8.40; acidity, 1.0000 g. = 5.983 cc. of 1 *N* NaOH solution. Found: N, 8.26; acidity (electrometric titration with 0.1 N NaOH), 1.0000 g. = 5.830 cc. of 1 N NaOH.

The sulfonated aminocresotinic acid differed distinctly in solubility and crystal habit from the product obtained through direct sulfonation of aminocresotinic acid. It appeared highly probable, therefore, that the rearrangement product was not a nuclear sulfonic acid but a phenol ester . Diazotized and coupled with azo components, this compound yielded dyes which differed from corresponding azo derivatives of aminocresotinic acid and of its nuclear sulfonic acid by a visible shift toward absorption in regions of longer wave lengths. Diazotization of the sulfonic ester of aminocresotinic acid, originating from one-tenth mole of dye, required 79.1 cc. of 1 N nitrite solution.

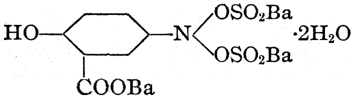
REARRANGEMENT OF N-SULFONIC ACIDS TABULATED ABOVE (ACTUAL YIELDS)



Summary

1. The sulfite cleavage of 4-hydroxy-azobenzene-5-carboxylic acid and of its 3-methyl homolog has been investigated.

2. A difficultly soluble barium salt of an N-disulfonic acid derived from 1-amino-4-hydroxybenzene-5-carboxylic acid could be isolated in pure form. Its distinctive reactions substantiated a newly proposed formulation for N-disulfonic acids as, for example



3. Hydrolysis and rearrangement of N-sulfonic acids resulted in complete re-formation of the primary dye component, aniline. The secondary component of the first dye yielded aminosulfosalicylic acid, , and the sulfonic ester, . The secondary component of the other dye yielded aminocresotinic acid, , and its sulfonic ester, .

STRUCTURE OF METHYLATED SUGARS. I. PRELIMINARY PAPER

BY CARRELL H. WHITNAH

RECEIVED JULY 1, 1929 PUBLISHED NOVEMBER 8, 1929

The recognized conflict of the results obtained by C. S. Hudson,[1] by comparing differences of optical rotations of sugars, with the results of W. N. Haworth and co-workers[2] from the properties of methylated sugars, suggests the possibility that the ring structure of glucose may be changed by the processes used to establish it.

The possibility of variation of the ring structure of methylated sugars with the temperature and alkalinity of methylation is suggested by the convincing evidence that "normal" or "abnormal" glucoside rings are formed on condensation of sugars with alcohol containing small amounts of hydrogen chloride at high[3] and low[4] temperatures, respectively.

The production of "normal" glucoside at low temperature in alcohol containing more acid[5] indicates the importance of the alkalinity factor.

The care deemed necessary by Hibbert[6] in drawing conclusions as to carbohydrate structure from methylation experiments, carried out in "slight hydrogen-ion concentrations," and the indications[7] that more than one ring structure is formed on methylation of galactose and arabinose with methyl sulfate and sodium hydroxide, justify the attempt to find conditions under which glucose will yield a methylated product of unusual structure.

Experimental Part

Twenty grams of glucose was dissolved in 25 cc. of water and placed in a bath at thirty degrees. The solution was made alkaline with sodium hydroxide and then fifteen to twenty cc. of methyl sulfate added Thirty per cent. sodium hydroxide was then added a drop at a time so as to maintain the solution alkaline to brom thymol blue but acid to phenolphthalein One cc. of 30% sodium hydroxide eventually neutralized about an equal volume of methyl sulfate. The alkalinity was determined by dropping a drop of the reaction mixture into a drop of indicator on a spot-plate. A much more sensitive and convenient indicator of alkalinity was a simple potentiometer attached to a cell made by suspending in the reaction mixture electrodes of platinum and antimony. The potentiometer determinations required occasional checking against the determina-

tions with color indicators, as the potential corresponding to a given alkalinity changed slowly with the composition of the solution.

More methyl sulfate was added from time to time so that there was an excess of at least 10 cc. over the sodium hydroxide added.

From 30 to 35 cc. of sodium hydroxide was added during from eight to ten hours before the mixture ceased to reduce Fehling's solution. The alkalinity and temperature were then somewhat increased and thereby the rate of methylation. The reaction was stopped when 100 cc. of methyl sulfate had been used up and the bath finally was heated to about 70° to insure destruction of all of the methyl sulfate. Tests for active sugar have not been obtained from any experiment in which the final destruction of methyl sulfate was carried out in a boiling water-bath.

After cooling, the sugar solution was extracted with chloroform, the extract dried over calcium chloride, the chloroform evaporated and the residue distilled at about 2-mm. pressure and at temperatures always over 100°. The distillate when dissolved in water, acidified with hydrochloric acid and treated with barium chloride, showed no trace of sulfate even after standing for several days.

The first test used to demonstrate the presence of active glucoside was to decolorize a few drops of dilute permanganate with a few drops of the product dissolved in water. One-tenth gram of methylated sugar would completely decolorize three drops of permanganate within one minute, while a similar solution of ordinary methylated glucose retained the color of one drop of permanganate for several minutes. **A** more definite comparison of rates of oxidation is indicated by Table I and the curves of Fig. 1.

The substances examined include **(A)** a stable methylated glucoside obtained by methylating at 60° in a solution of about 0.025 N sodium hydroxide; (B) glucose; (C) the methylated glucoside prepared above; and (D) a solution made by hydrolyzing this glucoside in 0.10 N hydrochloric acid and then neutralizing with sodium hydroxide.

The weight of the substance indicated was dissolved in 50 cc. of water and made neutral to litmus. The permanganate solution was then added as required. Except for the last observation on substance (A), each addition of permanganate was one drop as soon as the solution failed to depolarize a cell made by inserting electrodes of silver and platinum in the solution.[8]

Other tests to prove the existence of active sugar depend on the possibility of hydrolysis with dilute hydrochloricacid. Ready hydrolysis in a boiling water-bath was indicated by the increase of specific rotation of 1.2 g. of substance in 15.00 cc. of 0.10 *N* hydrochloricacid, from 32.7" to 65° in three hours.

On standing overnight at room temperature after two hours in a boiling water-bath, the specific rotation rose from 61.7" to 90.8°. The final value at room temperature, after the rotation in a boiling water-bath became constant at 67.8°, was 112.5".

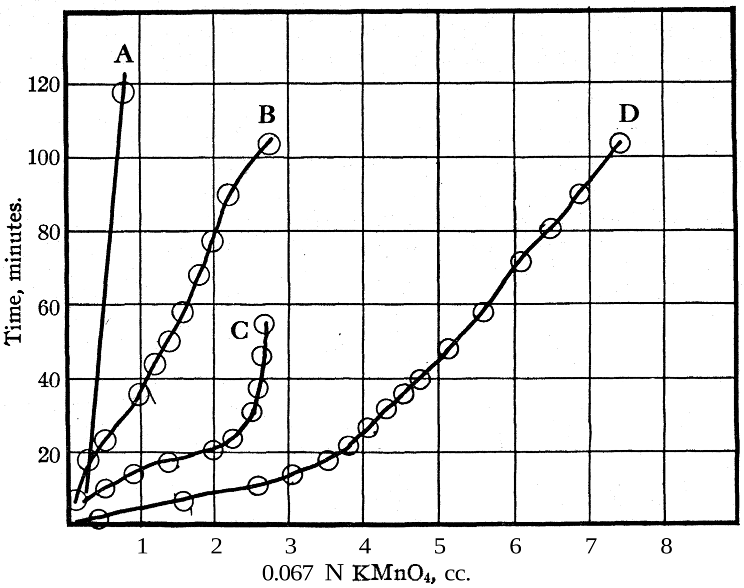

Fig. 1.

Hydrolysis at 60° was indicated by the fact that 1 g. of substance in 10 cc. 0.10 *N* hydrochloric acid increased its capacity for oxidation by iodine[9] from an initial value of 0.24 g. of iodine to 1.10 g. after three and one-half hours and to 1.37 g. after twenty-one hours. Corresponding values for α-methylglucoside were from an initial value of 0.187 g. of iodine to 0.382 g., after three and one-half hours, and 0.536 g. after twenty-one hours.

For both glucosides, hydrolysis with 8% or 2.14 N hydrochloric acid finally produced a decreasing iodine capacity. The values for the active glucoside were 0.64 g. of iodine after one and seven-tenth hours, 0.312 g. after three and one-half hours and 0.147 g. after twenty-one hours.

The relative rates of hydrolysis at 60° were also indicated by the fact that the above solution of active methylated glucoside after hydrolysis with 0.10 N hydrochloric acid had to be diluted about nine times as much as the similar solution of α-methylglucoside

in order that equal volumes of the two solutions would completely reduce equal volumes of Fehling's solution.

Summary

Methylation of glucose with methyl sulfate and sodium hydroxide at a temperature of 30° in a solution kept alkaline to brom thymol blue and acid to phenolpthalein resulted in a product which definitely gave a positive response to several common tests for an active or gamma sugar.

THE PREPARATION OF TRIPHENYLMETHYLMAGNESIUM CHLORIDE

BY HENRY GILMAN AND E. A. ZOELLNER

RECEIVED JULY 2, 1929 PUBLISHED NOVEMBER 8, 1929

Introduction

In connection with studies[1] involving triphenylmethylmagnesium chloride, it was necessary to develop a procedure for the preparation of this Grignard reagent in consistently high yields. We have had indifferent success, for some time, in preparing this reagent by methods commonly employed for the preparation of typical RMgX compounds.

The method described at this time gives excellent yields (96% and higher). These yields have been checked by different workers in this Laboratory so that the preparation is not as erratic as formerly. Our acid method of titration was used in determining the optimal factors reported at this time. The method of titration is very probably sound, and the high yields are unquestionably real because carbonation of the triphenylmethylmagnesium chloride has given yields of triphenylacetic acid as high as 91%.[2]

Experimental Part

The general procedure followed was that described recently by Gilman, Zoellner and Dickey[3] for the determination of yields of a variety of Grig-

---

[1] (a) Gilman and Jones, THIS JOURNAL, 51, 2840 (1929); (b) Gilman and Fothergill, *ibid.*, 51, 3149 (1929).

[2] Unlike some other directions on optimal conditions for the preparation of unusual Grignard reagents reported from this Laboratory [such as allylmagnesium bromide by Gilman and McGlumphy, *Bull. soc. chim.*, 43, 1322 (1928), and *tert.*-butylmagnesium chloride and *tert.*-amylmagnesium chloride by Gilman and Zoellner, *Rec. trav. chim.*, 47, 1058 (1928)], considerable work has been done by others on triphenylmethylmagnesium chloride, particularly in connection with free radicals. Among such earlier work are the following important references: Schmidlin, Ber., 39, 628, 4183 (1906), and Chichibabin, *ibid.*, 40, 3965 (1907); *ibid.*, 42, 3469 (1909). These authors have reported unusually high yields of products from triphenylmethylmagnesium chloride.

[3] Gilman, Zoellner and Dickey, THIS JOURNAL, 51, 1576, 1584 (1929).

nard reagents. Before describing a typical experiment for the preparation of triphenylmethylmagnesium chloride, a short discussion will be given of the effect of some factors on the yield of this Grignard reagent.

The quantities of materials used in our present optimal conditions (in the titration studies) were as follows: 2.79 g. (0.01 mole) of triphenylchloromethane, 0.5 g. (0.021 atom) of magnesium of 80–200 mesh; 0.32 g. (0.025 atom) of iodine, and 40 *cc.* (0.39 mole) of anhydrous ether. The equivalent molecular (or atomic) ratios of these reactants are 1.0 of triphenylchloromethane, 2.1 of magnesium, 0.25 of iodine and 39.0 of ether.

Halide.—The triphenylchloromethane as finally used was the pure compound obtainable from the Eastman Kodak Company. Despite the fact that some of the samples have a distinct odor of hydrochloric acid, the chloride evidently is of high purity for the present purpose. Samples of the chloride frequently contain two distinct kinds of crystals, white and yellow, each variety melting at **110–112".** Experiments were carried out with samples of each and no essential difference in yield was noted.

Magnesium.—The magnesium was of **80–200** mesh. Ordinary magnesium turnings may be used, but optimal yields (under our conditions) with such magnesium require that **1.5** g. or **6.3** atom equivalents (instead of **2.1** with the **80–200** mesh magnesium) be taken. The yield varies with the quantity of magnesium **(80–200** mesh), decreasing with small quantities of magnesium. It should be understood that the reacting ratio of magnesium is greater than one, inasmuch as a part of the **2.1** atom equivalents is used up not only by the triphenylchloromethane but also by the **0.25** equivalent of iodine. Several experiments with **30–80** mesh magnesium showed no essential difference in yield.

Iodine.—The iodine was dried in a desiccator over sulfuric acid and need not, of course, be powdered. The quantity of iodine has a marked effect on the yield. A progressive decrease in yield, under our conditions, was noted when less than **0.25** atom equivalent of iodine was used. Apparently, the yield is not improved by using more than **0.25–0.30** atom equivalent of iodine. The function of the excess magnesium and excess iodine in this preparation is made clear in the preliminary paper by Gilman and Fothergill[1b] on the dissociation of triphenylmethylmagnesium chloride. Actually, when the triphenylmethylmagnesium chloride is prepared by means of this relatively large quantity of iodine, there may be present, at the end of the reaction, some triphenylmethylmagnesium iodide.'

Ether.—The ether must be dry. Ether dried over sodium and kept over sodium was found to produce a turbidity in the mere transferal on a *humid* day. On such days the ether was distilled from sodium directly into the special reaction flask[3] for our quantitative studies. This extra refinement is unnecessary for ordinary purposes. The **39** molecular equivalents used in our determinations is unquestionably greater than that required. Ordinarily no more than 6–8 equivalents of ether are needed for the preparation of Grignard reagents.[2,3] This large quantity was used to prevent the triphenylchloromethane from splashing on the sides of the flask and so being removed, in part, from reaction with the magnesium. The large quantity of ether is desirable in effecting reactions of this Grignard reagent because of its sparing solubility in ether.

The benzene used to dissolve the RMgX compound so that aliquots could be removed for titration was dried over sodium. Such solution is unnecessary in the carbonation leading to the preparation of triphenylacetic acid, and the high yields of acid were obtained from the suspension of the RMgX compound in ether. However, the

---

[4] Gilman and St. John, *Rec. trav. chim., 48 (1929).*

benzene-ether solution of triphenylmethylmagnesium chloride may be desirable, if not necessary, for the preparation of other compounds from this Grignard reagent. Also, solution in an ether–benzene mixture may be necessary in separating the Grignard reagent from the excess of magnesium, for special reactions wherein the magnesium is harmful.

Atmosphere.—All experiments were carried out in an atmosphere of pure dry nitrogen. In both of the larger-sized runs in which triphenylacetic acid was prepared and in the smaller analyses the trap of Gilman and Hewlett[6] was found eminently satisfactory and made it possible to dispense with a continuous stream of inert gas

Preparation of Triphenylmethylmagnesium Chloride.—The 0.01 mole runs were carried out in special flasks of the kind described recently.[3] The 0.02 mole run was carried out in a 200-cc, and the 0.04 mole preparations in a 500-cc. three-necked flask provided with a mercury-sealed stirrer and a spiral water condenser the top of which was attached directly to the trap[6] after the flask was swept out by a stream of dry and oxygen-free nitrogen or hydrogen.

The magnesium, ether and iodine are added to the carefully dried flask, and when all of the iodine has reacted with the magnesium (as indicated by the disappearance of the iodine color)[6] the triphenyichloromethane is added as a solid and at one time. Partial solution is effected, during stirring, by directly heating the flask with a small flame for a few moments. With such heating a spontaneous reaction sets in, and as the halide reacts an insoluble complex forms. The reaction mixture is then refluxed moderately (in our experiments by heating with an electric hot-plate) for three hours.[7]

The following series of color changes occurs under anhydrous conditions during the course of heating. First, the greenish-yellow solution resulting on dissolution of the chloride turns brown about ten or fifteen minutes after the initial heating. Then, after thirty to forty minutes the solution becomes reddish-brown and the mixture contains little if any precipitate. During the next five or ten minutes the quantity of buff or fawn-colored precipitate increases markedly, and in some cases with distinct suddenness. The quantity of precipitate increases up to one and one-half hours of refluxing and then completely fills the solvent.[8] With refluxing beyond one and one-half hours the volume of precipitate frequently decreases somewhat. At the end of the three-hour (total) period of refluxing, the reaction is done,[9] and can be used directly for the prepa-

---

[5] Gilman and Hewlett, *Rec. trav. chim.*, 48 (1929). By regulation of the trap it is an easy matter to distil off ether and replace it by benzene (or another solvent) without a continuous flow of inert gas.

[6] Stirring is started at once and the iodine disappears in a few minutes. At this stage, if the reagents and apparatus were dried carefully, the solution has only a very slight turbidity and with special care it is entirely clear. When anhydrous conditions are not present the yield is decreased at least 4–5%.

[7] In the smaller 0.01 runs the time of heating was one and one-half hours plus the twenty to thirty minutes of heating during the removal of ether prior to the addition of benzene to get soluble aliquots for analysis. In either the 0.01, 0.02 or 0.04 mole runs a two-hour period of heating is sufficient to give an excellent yield by titration; however, our best yields of acid (from carbonation of the Grignard reagent) were obtained after a three-hour period of heating. The yield of acid drops about 7% with a one and one-half to two hour period of heating.

[8] It is partly for this reason that the large volume of ether is desirable in order to facilitate completion of reaction. If stirring is interrupted at this stage, the precipitate settles somewhat, revealing a thin upper ethereal layer of a reddish color.

[9] Should it be desirable to remove aliquots for titration or to dissolve the Grignard reagent for a special subsequent reaction, the ether is removed by heating with a hot

ration of triphenylacetic acid and other derivatives, particularly those which form ether-soluble magnesium complexes.[10]

Summary

Conditions have been determined for the preparation of triphenylmethylmagnesium chloride in excellent yields.

THE REACTION BETWEEN ALKALI METAL ALKYLS AND QUATERNARY PHOSPHONIUM HALIDES

BY D. D. COFFMAN AND C. S. MARVEL

RECEIVED JULY 6, 1929 PUBLISHED NOVEMBER 8, 1929

The question of whether or not phosphorus ever has a valence of five is still open. It is generally accepted that in the phosphonium salts its valence is four and that the negative ion is held by a polar valence to the phosphonium ion. Lewis[1] believes that phosphorus shares five pairs of electrons with five chlorine atoms in phosphorus pentachloride and has therefore a valence of five. Langmuir[2] has said that the valence of phosphorus in this compound is four and that one chlorine atom is held by a polar valence. Prideaux[3] has presented the idea that three of the chlorine atoms are attached to the phosphorus atom by means of true covalences whereas the remaining two are joined by singlet linkages. Sugden[4] has advanced experimental evidence favoring this view.

Staudinger and Meyer[5] attempted to prepare penta-alkyl phosphorus compounds by the action of zinc ethyl on tetra-ethylphosphonium iodide. However, at low temperatures no reaction was noted and at higher temperatures they obtained triethylphosphine, butane and zinc iodide. The same investigators[6] have prepared the compound $(C_6H_5)_3P{=}C(C_6H_5)_2$, called by them triphenylphosphinediphenylmethylene, in which all of the valences of phosphorus are satisfied by carbon atoms. This compound

water-bath (60–80°). Then the addition of a volume of benzene in slight excess of that of the ether removed dissolves the reagent. For titration purposes it is merely necessary to make several marks on the reaction flask in order to measure subsequently the total volume of Grignard solution.

[10] Details will appear shortly on some general preparations involving triphenylmethylmagnesium chloride.

was prepared by combining triphenylphosphine with diazodiphenylmethane to give a phosphazine which lost nitrogen when heated.

$$(C_6H_5)_3P + (C_6H_5)_2CN_2 \longrightarrow (C_6H_5)_3{-}P{=}N{-}N{=}C(C_6H_5)_2 \longrightarrow (C_6H_5)_3P{=}C(C_6H_5)_2 + N_2$$

The phosphinemethylene resembled in many respects the tetramethyltriphenylmethylammonium, which was prepared previously by Schlenk and Holtz.[7] It is a brilliant red compound which is sensitive to air and moisture. With water it gives triphenylphosphine oxide and diphenylmethane, and with acids the corresponding phosphonium salt. Two of Staudinger's students, Lüscher[8] and Isler[9] have obtained some phosphinemethylenes by the action of molten potassium on quaternary phosphonium salts.

$$2R_3PBr{-}CHR_2 + 2K \longrightarrow 2R_3P{=}CR_2 + 2KBr + H_2$$

Only the compound containing five phenyl groups was stable enough for isolation in the pure form although certain others were formed in solution.

In the hope of gaining further knowledge concerning the valence of phosphorus, the reactions of alkali metal alkyls with phosphonium salts have been investigated. Two alkali metal alkyls, lithium n-butyl and sodium triphenylmethyl, have been used. The first phosphonium salt studied was tetra-ethylphosphonium iodide. The reaction of this compound with sodium triphenylmethyl ran smoothly at ordinary temperatures. The color of the sodium triphenylmethyl faded and on working up the reaction mixture triphenylmethane, triethylphosphine and sodium iodide were obtained. This reaction is exactly analogous to the reaction between tetra-ethylphosphonium iodide and zinc ethyl reported by Staudinger and Meyer.[5] It is also analogous to the reactions of quaternary ammonium salts with alkali metal alkyls which have been studied by Hager with Marvel.[10]

Preliminary experiments with triphenylalkylphosphonium halides and alkali metal alkyls seemed to give colored solutions or colored insoluble compounds which resembled the phosphine methylenes. Accordingly, triphenyldiphenylmethylphosphonium bromide was prepared and treated with lithium n-butyl and with sodium triphenylmethyl. Both reagents produced triphenylphosphinediphenylmethylene in good yields. The reaction proceeds at room temperature and goes especially smoothly with lithium n-butyl.

The other phosphonium salts which were used were methyltriphenylphosphonium iodide, ethyltriphenylphosphonium iodide and *iso*propyltriphenylphosphonium bromide. These compounds reacted with an

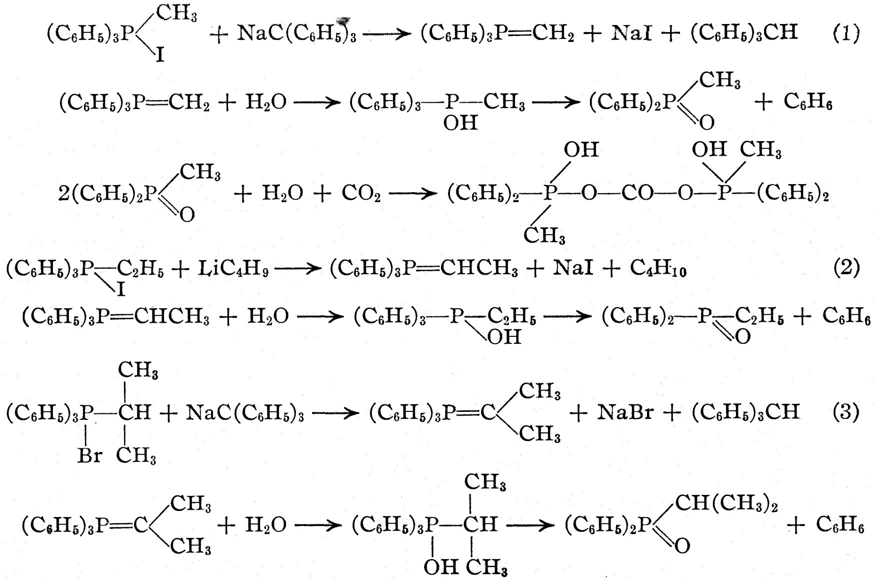
ether solution of sodium triphenylmethyl or lithium *n*-butyl to give colored solutions which decolorized on exposure to moist air. The products isolated after decomposition were, respectively, a derivative of methyldiphenylphosphine oxide, ethyldiphenylphosphine oxide and *iso*propyldiphenylphosphine oxide. The formation of these compounds can best be explained by assuming that a phosphinemethylene is the first product of the reaction between the alkali metal alkyl and the phosphonium salt. When moist air is admitted to the reaction mixture the phosphinemethylene is converted to the quaternary phosphonium hydroxide, which then decomposes to the diphenylalkylphosphine oxide and benzene.[11]

The following equations illustrate the steps in these reactions



$$(C_6H_5)_3P\begin{matrix}CH_3\\ I\end{matrix} + NaC(C_6H_5)_3 \longrightarrow (C_6H_5)_3P{=}CH_2 + NaI + (C_6H_5)_3CH \qquad (1)$$

$$(C_6H_5)_3P{=}CH_2 + H_2O \longrightarrow (C_6H_5)_3{-}\underset{OH}{P}{-}CH_3 \longrightarrow (C_6H_5)_2P\begin{matrix}CH_3\\ O\end{matrix} + C_6H_6$$

$$2(C_6H_5)_2P\begin{matrix}CH_3\\ O\end{matrix} + H_2O + CO_2 \longrightarrow (C_6H_5)_2{-}\underset{CH_3}{\overset{OH}{P}}{-}O{-}CO{-}O{-}\overset{OH\ CH_3}{P}{-}(C_6H_5)_2$$

$$(C_6H_5)_3P\begin{matrix}C_2H_5\\ I\end{matrix} + LiC_4H_9 \longrightarrow (C_6H_5)_3P{=}CHCH_3 + NaI + C_4H_{10} \qquad (2)$$

$$(C_6H_5)_3P{=}CHCH_3 + H_2O \longrightarrow (C_6H_5)_3{-}P\begin{matrix}C_2H_5\\ OH\end{matrix} \longrightarrow (C_6H_5)_2{-}P\begin{matrix}C_2H_5\\ O\end{matrix} + C_6H_6$$

$$(C_6H_5)_3\underset{Br}{P}{-}\underset{CH_3}{\overset{CH_3}{CH}} + NaC(C_6H_5)_3 \longrightarrow (C_6H_5)_3P{=}C\begin{matrix}CH_3\\ CH_3\end{matrix} + NaBr + (C_6H_5)_3CH \qquad (3)$$

$$(C_6H_5)_3P{=}C\begin{matrix}CH_3\\ CH_3\end{matrix} + H_2O \longrightarrow (C_6H_5)_3\underset{OH}{P}{-}\underset{CH_3}{\overset{CH_3}{CH}} \longrightarrow (C_6H_5)_2P\begin{matrix}CH(CH_3)_2\\ O\end{matrix} + C_6H_6$$

There was no indication in any of the reactions studied that a penta-alkyl phosphorus compound analogous to the penta-alkyl nitrogen derivative of Schlenk and Holtz[7] had been obtained. Neither was there any evidence of penta-alkyl phosphorus compounds in which five equivalent valences were combined with the organic radicals. The phosphinemethylenes which are represented as intermediates in all of the above reactions are probably not compounds in which phosphorus has a valence of five but rather resemble the amine oxides and phosphine oxides in their structure.

In all the phosphonium salts thus far studied there has been one group which carried a hydrogen atom on the carbon attached to the phosphorus atom. Some compounds are now being studied where this is not true,

---

[11] Michaelis and Soden, *Ann.*, 229, 315 (1885).

and preliminary results indicate that penta-alkyl phosphorus compounds may thus be obtained.

Experimental Part

Sodium triphenylmethyl solution in dry ether was prepared according to the general method of Schlenk and Holtz.[7] The modified reaction flask shown in Fig. 1 allows easy separation of the solution of the metallic alkyl from the excess amalgam and sodium chloride. Lithium n-butyl was prepared by the method of Hager and Marvel.[10] The triphenylphosphine was obtained by the method of Dodanow and Medox[12] and the phosphonium salts were prepared as described by Lüscher[8] and by Michaelis and Soden.[13] The apparatus used in the reactions was similar to that described by Hager and Marvel.[10]

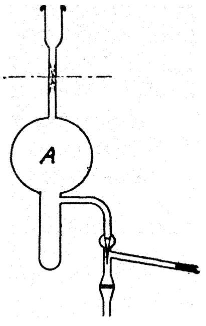


Fig. 1.

Lithium n-Butyl and Triphenyldiphenylmethylphosphonium Bromide.—The lithium n-butyl solution obtained by the action of 1.6 g of di-n-butyl mercury and 0.5 g. of lithium in petroleum ether was run onto 5 g. of triphenyldiphenylmethylphosphonium bromide. The colorless salt immediately turned bright red. After two days the reaction flask was opened, the reaction mixture was filtered and the red reaction product was separated from the unreacted phosphonium salt and sodium bromide by dissolving it in dry benzene. After several crystallizations the product was dried in an atmosphere of nitrogen over phosphorus pentoxide. The yield was 0.8 g. The product melted at 172–174° and all of its properties agreed with those ascribed to triphenylphosphine-diphenylmethylene by Staudinger and Meyer.[6] A mixture of this material and some made by the published method melted at 172–174°.

Anal. Subs. 0.2087: CO_2, 0.6645; H_2O, 0.1158. Calcd. for $C_{31}H_{25}P$: C, 86.91; H, 5.85. Found: C, 86.83; H, 6.16.

Sodium Triphenylmethyl and Triphenyldiphenylmethylphosphonium Bromide.—An ether solution of 0.0027 mole of sodium triphenylmethyl was added to 1.2 g. (0.002 mole) of the phosphonium salt. After shaking for a few minutes the solution lost its color and a red precipitate of the phosphinemethylene appeared. After one day the reaction flask was opened and the reaction mixture was filtered. From the precipitate triphenylphosphinediphenylmethylene melting at 171–173° was obtained. From the ether solution triphenylmethane (m. p. 91–92°) was isolated. Its identity was established by a mixed melting-point determination with known triphenylmethane.

Sodium Triphenylmethyl and Triphenyl-isopropylphosphonium Bromide.—An ether solution of 0.003 mole of sodium triphenylmethyl was added to 1.2 g. of triphenyl-*iso*-propylphosphonium iodide. The reaction mixture was allowed to stand for about forty-eight hours. During this time the color of the solution changed slightly and no longer was that of the original solution. When the reaction mixture was opened to the air the color was almost instantly discharged. The insoluble salts were removed by filtration. The filtrate was evaporated, the residue was dissolved in benzene and to the concentrated solution was added some petroleum ether (b. p. 40–60°). This gave a precipitate which after recrystallization from benzene and petroleum ether melted at 142–143°. Analysis of the product showed it to be diphenyl-isopropylphosphine oxide.

---

[12] Dodanow and Medox, *Ber.*, **61B**, 907 (1928).

[13] Michaelis and Soden, Ann., 229, 295 (1885).

Anal. Subs., 0.1144: CO_2, 0.3092; H_2O, 0.0734. Calcd. for $C_{21}H_{22}PO$: C, 73.77; H, 6.97. Found: C, 73.71; H, 7.12.

From the benzene–petroleum ether mother liquors, triphenylmethane (m. p. 91–92°) was isolated.

Sodium Triphenylmethyl and Triphenylmethylphosphonium Iodide.—An ether solution containing 0 01 mole of sodium triphenylmethyl was added to 4 g. (0.01 mole) of triphenylmethylphosphonium iodide. The deep red color of the solution was discharged and at the end of three weeks a light orange colored solution remained. On exposure to the air, this color disappeared almost entirely. Moist carbon dioxide was passed into the solution and a white precipitate separated. The precipitate was removed by filtration. From the filtrate triphenylmethane (m. p. 91.5–92°) was obtained.

The precipitate produced by the carbon dioxide was purified by solution in chloroform, followed by precipitation with dry ether. In this way a compound melting at 109–111° with evolution of gas was obtained. This compound was very soluble in alcohol. When treated with acids it liberated carbon dioxide.

Anal. Subs., 0.2442: CO_2, 0.5886; H_2O, 0.1291. Calcd. for $C_{27}H_{28}P_2O_5$: C, 65.59; H, 5.67. Found: C, 65.74; H, 5.86.

The properties and analysis of this compound indicated that it was the basic carbonate of diphenylmethylphosphine oxide,  $(C_6H_5)_2\overset{CH_3}{\underset{OH}{P}}—OCO—O—\overset{CH_3}{\underset{OH}{P}}(C_6H_5)_2$.

Lithium *n*-Butyl and Triphenylethylphosphonium Iodide.—A petroleum ether solution containing 0.025 mole of lithium n-butyl was added to 10 g. (0.024 mole) of triphenylethylphosphonium iodide. In a short time the solution took on an orange color. After the reaction flask had stood for four days it was opened and water vapor was admitted. The color disappeared at once. Most of the petroleum ether was evaporated and the residue was extracted with benzene. Some unreacted phosphonium salt and the lithium iodide were undissolved. Addition of petroleum ether to the benzene solution precipitated an oil which slowly crystallized. This product was recrystallized from alcohol and water and again from benzene and petroleum ether. It then melted at 118–119.5°. It was shown to be ethyldiphenylphosphine oxide since the melting point (119–120°) was unchanged when mixed with an authentic specimen of this compound.

When sodium triphenylmethyl was used with triphenylethylphosphonium iodide, there was some difficulty in isolating a pure phosphine oxide.

Sodium Triphenylmethyl and Tetra-ethylphosphonium Iodide.—Preliminary experiments demonstrated that sodium triphenylmethyl solutions in ether reacted with tetraethylphosphonium iodide to give colorless products. Dry carbon dioxide had no effect on the reaction mixture. Water in contact with the ether solutions was neutral, showing that no basic oxide was present.

An ether solution of 0.01 mole of sodium triphenylmethyl was added to 2.7 g. (0.01 mole) of tetra-ethylphosphonium iodide. On opening the reaction flask a strong odor of triethylphosphine was noted. To a portion of the filtered ether solution was added an aqueous solution of zinc iodide in an attempt to isolate the double salt which Hofmann[14] reports as having a melting point of 99°. A small quantity of a solid melting at 82–88° was obtained. A second portion of the ether solution was treated with ethyl iodide and the quaternary phosphonium salt separated. This melted at 270–278°. Triphenylmethane (m. p. 91–92") was isolated from another portion of the ether solution. Attempts to identify the ethylene which must also have been produced were not successful.

---

[14] Hofmann, Ann. *Supl.*, 1, 1 (1861).

Summary

1. Alkali metal alkyls react with quaternary phosphonium halides at room temperature.

2. Tetra-ethylphosphonium iodide and sodium triphenylmethyl give at once colorless products and the reaction is apparently analogous to that between alkali metal alkyls and quaternary ammonium salts.

3. Triphenylalkylphosphonium halides react with alkali metal alkyls to give colored products, apparently identical with the phosphinemethylenes of Staudinger, as the primary products of the reaction. The products isolated from several different reactions of this type are easily explained as decomposition products of the intermediate phosphinemethylenes.

THE REACTION BETWEEN SULFOCHLORIDES AND ORGANOMAGNESIUM HALIDES

BY HENRY GILMAN AND ROBERT E. FOTHERGILL

RECEIVED JULY 8, 1929 PUBLISHED NOVEMBER 8, 1929

Introduction

In connection with studies on the electronic interpretation of the ethylenic linkage, Gilman and Peterson[1] reported a complete reaction between ethylmagnesium bromide and di-*p*-tolyldisulfonethylene. In order to throw some light on the nature of that reaction it was advisable to study a simpler conjugated system of the same type, namely, styryl-*p*-tolylsulfone (p-$CH_3C_6H_4\underset{O\quad O}{\underset{\diagup\diagdown}{S}}—CH=CHC_6H_5$). With this in view, we set out to prepare the sulfone from p-toluenesulfochlorideand styrylmagnesium bromide. The indifferent success attending this synthesis prompted a more general investigation of the reaction between sulfochlorides and RMgX compounds.

Earlier studies of this reaction were made by Hepworth and Clapham[2] and by Wedekind and Schenk.[3] Hepworth and Clapham[2] proposed the following reactions to account for the sulfones ($R—\underset{O\quad O}{\underset{\diagup\diagdown}{S}}—R$), sulfoxides ($R—\overset{O}{\overset{\diagup\!\!\diagup}{S}}—R$) and sulfides (R—S—R) isolated by them from the reaction between benzenesulfochloride and some RMgX compounds.

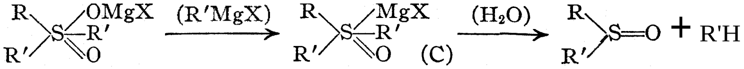
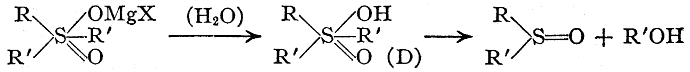
Compound B may then react further with R'MgX, as follows



(II)

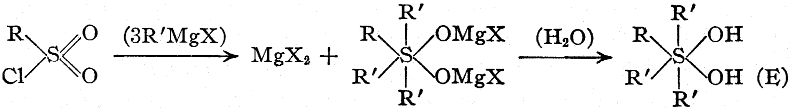


(III)

They explained the formation of sulfides by the further action of organomagnesium halide on Compounds B and C.

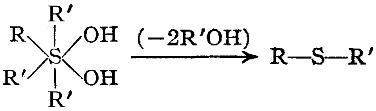
There are several objections to these reactions. First, an R'Cl compound is formed, the R' coming from the R'MgX and the Cl from the sulfochloride. Apparently they did not observe the formation of the chloride. Second, it is very doubtful if the intermediate compounds B, C and D are formed. Were such compounds formed, then it is reasonable to suppose that from Compound C, for example, one should get a mixture of sulfoxides, $R-\underset{\underset{O}{\|}}{S}-R'$ and $R'-\underset{\underset{O}{\|}}{S}-R'$. Actually, such mixtures of sulfoxides have not been reported. Third, the removal of oxygen when Compound B is converted to Compound C by means of an excess of R'MgX compound involves the oxidation of the R'MgX to an alcohol or a phenol; but, as stated by them in connection with their Reaction III, alcohols and phenols were not observed. It is, of course, possible that the atom of oxygen might be removed by two additional molecules of RMgX to give R·R and $(MgX)_2O$. This, however, has the objection of requiring a larger quantity of R·R than that actually found.

Wedekind and Schenk[3] proposed the following reactions to account for the same compounds isolated by Hepworth and Clapham,[2] in addition to the thiosulfonic ester, $R-\underset{O\;\;O}{S}-S-R$, they obtained.



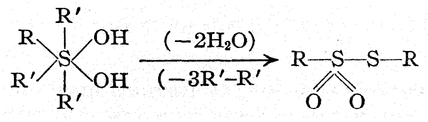
(IV)

The formation of sulfide was explained by the removal of two molecules of R'OH, as follows



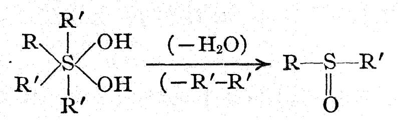
(V)

They explained the formation of the thiosulfonic ester by the removal of two molecules of water and three molecules of an R'–R' compound from two molecules of Compound E, as follows:



$$2\,\mathrm{RR'_3S(OH)_2} \xrightarrow[(-3\mathrm{R'}\text{-}\mathrm{R'})]{(-2\mathrm{H_2O})} \mathrm{R{-}\underset{O\ \ O}{S}{-}S{-}R}$$ (VI)

Finally, they proposed the following reaction for the formation of sulfoxide



$$\mathrm{RR'_3S(OH)_2} \xrightarrow[(-\mathrm{R'}\text{-}\mathrm{R'})]{(-\mathrm{H_2O})} \mathrm{R{-}\underset{\overset{\|}{O}}{S}{-}R'}$$ (VII)

There are also several objections to these reactions proposed by Wedekind and Schenk.[3] First, they make no mention of the formation of R'Cl compound. Second, the thiosulfonic esters are only what might be termed accidental reaction products; that is, the thiosulfonic esters only come into the picture of things after one of the true reaction products—the sulfinic acids, RSO_2H—are formed. It has long been known that sulfinic acids are readily converted to thiosulfonic esters.[4] Actually, we have shown that only sulfinic acid is obtained when the reaction products are worked up promptly, and that thiosulfonic esters and not sulfinic acids are obtained when the solutions containing sulfinic acids are allowed to stand for an appreciable time. Third, it seems reasonable to expect that Reaction V should give rise to a mixture of sulfides, namely, R—S—R' and R'—S—R'. Fourth, it seems equally reasonable to expect that Reaction VI should lead to a mixture of thiosulfonic esters, and Reaction VII to a mixture of sulfoxides, $\mathrm{R{-}\underset{\overset{\|}{O}}{S}{-}R'}$ and $\mathrm{R'{-}\underset{\overset{\|}{O}}{S}{-}R'}$. A fifth objection can be raised against Reactions VI and VII. Each of these reactions postulates the formation of R·R compounds. In our studies the quantities of diphenyl and of di-p-tolyl are only slightly greater than one would expect of these R·R compounds incidental to the preparation of phenylmagnesium bromide and p-tolylmagnesium bromide, respectively. Wedekind and Schenk[3] believed that Reactions VI and VII were reasonable because of the quantity of diphenyl they obtained. Actually, however, the yields of diphenyl reported by them are no greater than those generally obtained in a careful preparation of phenylmagnesium bromide.

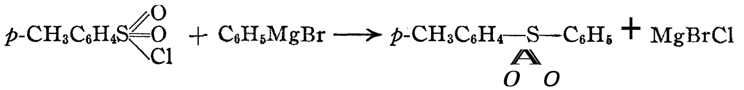
As usual, it is generally an easier thing to criticize a series of reactions than to propose a series that can withstand criticism. The chief products isolated by us, and under our experimental conditions, were sulfones, sulfinic acids and RX compounds (the R coming from the Grignard reagent and the X from the sulfohalide). In the later more exact experiments, after we were aware of the formation of sulfinic acids and RX com-

---

[4] **Gilman, Smith and Parker, This Journal, 47,** 851 (1925). **This paper, on the constitution of thiosulfonic esters, contains many of the important and leading references to the reactions of sulfinic acids, etc.**

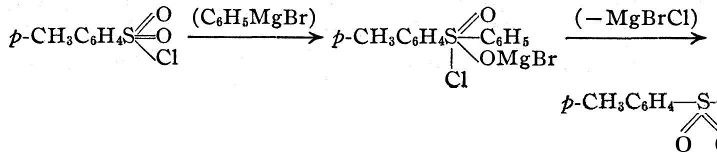
pounds, we observed that these two products were formed in about equivalent quantities.

The most reasonable reaction for the formation of sulfones is a so-called direct substitution, as follows



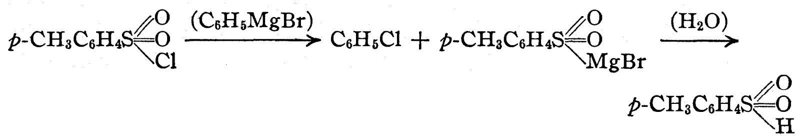
$$p\text{-}CH_3C_6H_4S\begin{smallmatrix}\diagup\!\!\diagup O\\ = O\\ \diagdown Cl\end{smallmatrix} + C_6H_5MgBr \longrightarrow p\text{-}CH_3C_6H_4\text{—}\underset{O\quad O}{\underset{\diagup\!\!\diagup\,\diagdown\!\!\diagdown}{S}}\text{—}C_6H_5 + MgBrCl \qquad (VIII)$$

Of course, there is the possibility that these products might have resulted subsequent to addition of the Grignard reagent to the sulfonyl group (S=O), as follows



$$p\text{-}CH_3C_6H_4S\begin{smallmatrix}\diagup\!\!\diagup O\\ = O\\ \diagdown Cl\end{smallmatrix} \xrightarrow{(C_6H_5MgBr)} p\text{-}CH_3C_6H_4\underset{Cl}{\underset{|}{S}}\begin{smallmatrix}\diagup\!\!\diagup O\\ \text{—}C_6H_5\\ \diagdown OMgBr\end{smallmatrix} \xrightarrow{(-MgBrCl)} p\text{-}CH_3C_6H_4\text{—}\underset{O\quad O}{\underset{\diagup\!\!\diagup\,\diagdown\!\!\diagdown}{S}}\text{—}C_6H_5 \qquad (IX)$$

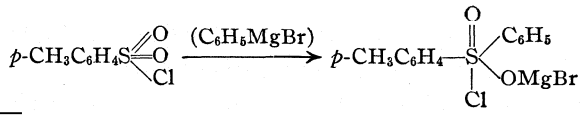
Probably the most acceptable reaction for the formation of sulfinic acid and halide is again a direct substitution (like that of Reaction VIII) but this time the halogen of the sulfohalide is replaced by the —MgX group and not by the R-group of the RMgX compound, as follows



$$p\text{-}CH_3C_6H_4S\begin{smallmatrix}\diagup\!\!\diagup O\\ = O\\ \diagdown Cl\end{smallmatrix} \xrightarrow{(C_6H_5MgBr)} C_6H_5Cl + p\text{-}CH_3C_6H_4S\begin{smallmatrix}\diagup\!\!\diagup O\\ = O\\ \diagdown MgBr\end{smallmatrix} \xrightarrow{(H_2O)} p\text{-}CH_3C_6H_4S\begin{smallmatrix}\diagup\!\!\diagup O\\ = O\\ \diagdown H\end{smallmatrix} \qquad (X)$$

A direct substitution of the kind pictured in Reaction X finds support in reactions between the Grignard reagent and compounds having halogen attached directly to sulfur.[5]

There is an attractiveness to postulating addition of the RMgX compound to a sulfonyl group after the proposals of Hepworth and Clapham,[2] Wedekind and Schenk[3] and Reaction IX. However reasonable such a mode of reaction may appear for the explanation of reactions of sulfochlorides, sulfones and sulfoxides, it is of dubious value in interpreting the formation of sulfinic acid and RX compound. If a reaction of this type occurred



$$p\text{-}CH_3C_6H_4S\begin{smallmatrix}\diagup\!\!\diagup O\\ = O\\ \diagdown Cl\end{smallmatrix} \xrightarrow{(C_6H_5MgBr)} p\text{-}CH_3C_6H_4\text{—}\overset{O}{\underset{Cl}{\underset{|}{\overset{\|}{S}}}}\begin{smallmatrix}\diagup C_6H_5\\ \\ \diagdown OMgBr\end{smallmatrix} \qquad (XI)$$

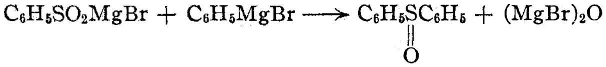
(F)

---

[5] Ferrario, Bull. *soc. chim.*, *7*, 518 (1910), obtained increasing quantities of chlorobenzene from the reaction between sulfur monochloride, dichloride and tetrachloride, respectively, with phenylmagnesium bromide. However, because we have not obtained chlorobenzene from sulfur monochloride, nor from aryl sulfur chlorides (RSCl), and because chlorobenzene is obtained from organic hypochlorites (ROCl) [see Durand and Naves, ibid., 37, 717 (1925); Gilman and Heckert, *Rec. trav. chim.*, *49*, *(1930)*] there is a possibility, even though somewhat remote, that sulfochlorides might have a hypochlorite structure, RS(=O)(OCl), in equilibrium with the RSO_2Cl form.

then it appears eminently reasonable that the splitting products should be mixtures of chlorobenzene and *p*-chlorotoluene, and benzenesulfinic acid and p-toluenesulfinic acid. Such mixtures were not observed, and the products isolated were cldorobenzene and p-toluenesulfinic acid. Furthermore, from benzenesulfochloride and *p*-tolylmagnesium bromide the products were benzenesulfinic acid and *p*-chlorotoluene. This pair of reactions, with the R groups interchanged in the sulfochloride and Grignard reagent, militates against a preliminary addition and indicates a direct substitution.[6]

Our experimental conditions were not those of earlier workers.[2,3] We used equivalent molecular proportions of sulfochloride and Grignard reagent and did not heat the reaction mixtures. However, when we did follow their general directions, we obtained some diphenyl sulfide, a large yield of diphenyl sulfoxide, an equally large yield of chlorobenzene but no sulfinic acid. The absence of sulfinic acid and the high yield of sulfoxide is very probably due to the following reaction[4]



$$C_6H_5SO_2MgBr + C_6H_5MgBr \longrightarrow C_6H_5\underset{\underset{O}{\|}}{S}C_6H_5 + (MgBr)_2O \qquad \text{(XII)}$$

Closely related to the present studies is earlier work by Oddo[7] on sulfuryl chloride (SO_2Cl_2) and by Oddo,[8] Grignard and Zorn,[9] and Strecker[10] on thionyl chloride ($SOCl_2$).

Experimental Part

The reactions were carried out in a three-necked flask provided with a mercury-sealed stirrer, separatory funnel and condenser. The flask containing generally 0.3 mole of sulfochloride in one liter of ether was cooled by an ice-salt mixture. To this was slowly added (three to four hours) the Grignard reagent, and when one molecular equivalent of RMgX compound was added the reaction mixture generally gave the color test described by Gilman, Schulze and Heck.[11] The cold reaction mixture was hydrolyzed with 10% hydrochloric acid, the ether layer separated and then combined with the ether washings of the acid-aqueous layer.

---

[6] Of course, we would not be understood to mean that there is no preliminary addition here of a loose type not involving primary or chief valences of the sulfur or oxygen or chlorine or, for that matter, of the magnesium or ether in the Grignard reagent. What we do mean is that a hypothetical compound like Compound F is unreasonable if the phenyl and the *p*-tolyl groups are attached to the sulfur by primary valences. Also, admittedly, the sulfur–carbon linkages holding the phenyl and *p*-tolyl groups would not be, in all probability, of equal strength even though both such linkages were primary. Linkages of slightly different strengths should result, generally, in mixtures having slightly different percentages of components.

[a] Unless otherwise stated, the quantity of RMgX compound used was equivalent to the sulfohalide. That is, with 0.3 mole of sulfohalide, 0.3 mole of RMgX compound was used.

[b] The sulfinic acid obtained was that corresponding with the sulfohalide. For example, with benzenesulfochloride there was obtained benzenesulfinic acid. A search was not always made for the sulfinic acid.

[c] The reactions between benzenesulfochloride and phenylmagnesium bromide were the first studied, and the very small yields of sulfinic acid and chlorobenzene given in Table I were due to an initial unfamiliarity with the course of the reaction. Several experiments were made on the reaction between benzenesulfochloride and phenylmagnesium bromide, and although the yield of diphenylsulfone was consistently around 35%, the yield of chlorobenzene varied between 12.2 and 43.7%. A reaction between these reagents at a temperature below −63° (by solid carbon dioxide and acetone cooling) gave 12.2% of sulfone, 43.7% of chlorobenzene and 6.5% diphenyl, but the sulfinic acid was lost by an attempted vacuum distillation. We had little success in a low temperature reaction so carried out that a mixture of benzenesulfochloride and bromobenzene was added to magnesium and ether.

[d] In addition to the products listed there was obtained 5.2% of di-p-tolyl. No p-cresol was obtained.

[e] A few crystals melting at 97–100° were obtained. These, however, were not the expected α-naphthylphenylsulfone, because of the depression to 70–80° in a mixed melting point determination with an authentic specimen of the sulfone. Unfortunately the alkaline extract that might have contained the sulfinic acid was lost by a mishap.

[f] The yield of diphenylbutadiene from this experiment was **34.2%**. We believe that this high yield of R·R compound is due to the extensive coupling reaction incidental to the preparation of β-styrylmagnesium bromide. No sulfone was obtained and inasmuch as the sulfone that might have been expected here was the cause of this study a further investigation is in progress on this reaction. The recovery of a 33.6% yield of styrene (which very probably resulted from hydrolyzed Grignard reagent) is indicative of a lesser reactivity of this RMgX compound toward benzenesulfochloride.

[g] The recovery of phenylacetylene in a 51.2% yield is indicative of a very slow or poor reaction of phenylacetenylmagnesium bromide. This supports other studies now in progress on the relative reactivities of Grignard reagents. However, only 4.5% of the benzenesulfochloride was recovered.

[h] The yield of dibenzyl was **7.7%**. In a careful preparation of benzylmagnesium chloride the yield of dibenzyl is 4–5%.

[i] A residue, non-volatile with steam, was obtained. This melted at 68" when recrystallized twice from **95%** alcohol. The yield was 13.2 g, and analyses for sulfur by the Carius method gave **17.07** and 17.40% of sulfur. Gilman and Beaber, THIS JOURNAL, 47, **1449** (1925), reported *n*-butyl-*p*-tolylsulfone as a liquid boiling at **173–175" (3.5** mm.).

[j] A very small quantity **(0.2** g.) of a solid melting at 86° was obtained from the residue of the steam distillation.

[k] The yield of diphenyl was 4.5% of that normally obtained incidental to the preparation of phenylmagnesium bromide.

[l] The *p*-toluenesulfobromide and *p*-toluenesulfo-iodide were prepared according to the directions of Whitmore, THIS JOURNAL, 45, **1069 (1923).** The sulfobroinide was partially dissolved in **700** cc. of ether and **0.4** mole of phenylmagnesium bromide was required for a positive color test. The reaction flask was cooled by an ice-salt bath, and **20%** hydrochloric acid was used in the hydrolysis. The 30.2% yield of *p*-toluenesulfinic acid is based on the yield of *p*-tolyl-*p*-toluenethiosulfonate isolated in this experiment.

[m] The quantity of phenylmagnesium bromide required for a positive color test was **0.7** mole. The initially violent reaction may have been due to some free halogen. No *p*-toluenesulfinic acid was actually isolated and the yield of this compound was based on the *p*-tolyl-*p*-toluenethiosulfonate (see Footnote *l*.)

[n] As in other experiments with phenylmagnesium bromide, the yield of diphenyl was that to be expected from the preparation of phenylmagnesium bromide.

The ether layer, after washing with 5% sodium hydroxide and then with a little water, was steam distilled. The steam distillate was extracted with ether and from the vacuum distillation of this dried ether extract there was obtained the RX and R–R compounds. The residue from steam distillation gave the sulfone.

The alkaline extract was immediately acidified with hydrochloric acid and extracted with ether. This ether solution was then dried by sodium sulfate, and on the rapid removal of the ether by dry air the sulfinic acid was obtained as faintly colored crystals.

The identity of all of the solid reaction products was confirmed by mixed melting point determinations with authentic specimens. The liquid RX compounds were identified by conversion to solid nitro-halogen derivatives, and mixed melting point determinations were then made of these solids with authentic compounds. The results are given in Table I and the footnotes which accompany it.

Benzenesulfochloride and **Phenylmagnesium** Bromide.—This experiment was carried out under conditions unlike those followed in the runs described in Table **I**, but like those described by Hepworth and Clapham[2] During the addition of **53** 0 g. **(0.3** mole) of benzenesulfochloride in **200** cc. of ether to **0.9** mole of phenylmagnesium bromide solution (450 cc.), the reaction flask was cooled by an ice–salt mixture When addition was ended, the mixture was allowed to stand at room temperature for seventeen hours and then warmed by a hot plate for one hour. After hydrolysis by dilute hydrochloric acid, the mixture was worked up in the customary manner The following products were obtained: 52.5% of chlorobenzene, 60.2% of diphenyl sulfoxide, 4.1% of diphenyl sulfide, 6.4% of diphenyl, but no benzenesulfinic acid.

Summary

The chief products obtained from the reaction between arylsulfohalides and organomagnesium halides are sulfones, sulfinic acids and RX compounds having the R-group of the RMgX compound and the halogen of the sulfohalide. Previous explanations of this reaction have been corrected and a new interpretation of the reaction has been proposed.

TETRAMETHYLETHYLENE SULFIDE

BY MERRILL A. YOUTZ AND PHILIP P. PERKINS

RECEIVED JULY 11, 1929 PUBLISHED NOVEMBER 8, 1929

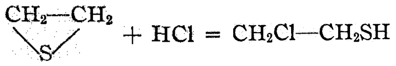
It is only in comparatively recent years that substances of the type of ethylene sulfide $\overline{\mathrm{CH_2SC}}\mathrm{H_2}$ have been synthesized. Previous attempts to do so by treating alkylene dibromides with potassium sulfide, etc., have given either a dimer, such as diethylene disulfide or amorphous substances of even higher molecular weights. This is not especially surprising and probably in some cases long chains could be produced by the reaction of each mole of potassium sulfide with two different molecules of $C_2H_4Br_2$. However, the matter is even more involved than this as the recent successful preparation of several of these compounds by Delépine[1] has shown that, even if pure, they polymerize readily. The tendency to polymerize diminishes with increasing molecular weight. His method was to treat a 1,2-dibromide with potassium or ammonium thiocyanate, purify the dithiocyanate and to treat this with dilute sodium sulfide. Especially with the lowest member it was necessary to have the sodium hydrogen sulfide present with the sodium sulfide in order to avoid polymerization during the reaction.

The compounds are readily polymerized by bases or acetic or sulfuric acids. Nitric acid oxidizes them to sulfuric or sulfonic acids. Hydrochloric acid appears to combine forming a chloromercaptan which can be removed with sodium plumbite, etc. Probably the oxidation by nitric

---

[1] Delépine, *Compt. rend.*, **171**, **36** (1920); **172**, 158 (1921); Bull. *soc. chim.*, [4] **27**, 740 (1920); **29**, 136 (1921).

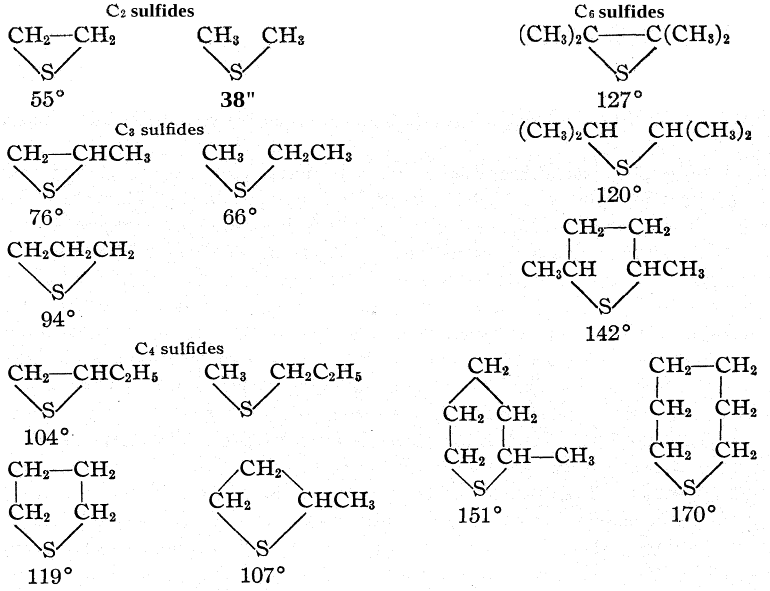
acid, which takes the same course as with a mercaptan, is preceded by this mercaptan formation



They form addition compounds with heavy metal salts and methyl iodide. The boiling points are a little higher than those of the corresponding alkyl sulfides but lower than those of the isomers having a larger ring.

TABLE I

SULFIDES AND THEIR BOILING POINTS



The tetramethylethylene sulfide here described resembles the simpler members in its chemical properties though it is more stable. It was prepared by the reactions

$$\text{Acetone} \xrightarrow{\text{H}} \text{Pinacone hydrate} \xrightarrow{70\%\ \text{HBr}} \text{Teramethylethylene dibromide} \xrightarrow{\text{KSCN}} \text{Dithiocyanate} \xrightarrow{Na_2S} \text{Sulfide}$$

As might be expected from its symmetry, it is a solid, m. p. 76°, b. p. 127°, and has great powers of crystallization. The crystals are usually needle-like if sublimed, but if allowed to sublime at room temperature by standing in a container, it forms perfect cubic crystals of diamond-like brilliancy. On one occasion the whole of a preparation crystallized overnight from a petroleum ether solution in a single crystal over two inches long and weighing about ten grams. It has an extremely powerful odor, not exceedingly unpleasant and resembling that of camphor. It is very soluble in all the usual organic solvents though not in water. It cannot be recrystallized satisfactorily at elevated temperatures because of its volatility. It can be recrystallized from low-boiling (25–40°) petroleum ether by evaporating off part of the solvent with an air stream at a low temperature and then chilling to −15 or −20° and filtering on a cold filter. It can also be purified by sublimation.

It is easily polymerized to amorphous insoluble particles by concentrated sulfuric acid even in dilute naphtha solution, from which it is very completely removed. It forms addition compounds with mercuric chloride and with silver nitrate in absolute or 95% alcohol solution. It reacts only slightly with methyl iodide.

Experimental Part

Pinacone Hydrate.—This was made from acetone by reduction with magnesium amalgam.[2]

Tetramethylethylene **Dibromide.**—This was made according to the procedure of Thiele[3] by treating pinacone hydrate with 70% hydrobromic acid; yields, 50–85%. The use of spent acid resaturated with hydrogen bromide gave progressively lower yields. Apparently a liquid substance accumulates in solution in the acid. It is a severe lachrymator and is probably the bromohydrin, which is the chief product if insufficient or too weak acid is used. The crude product was dried and recrystallized from glacial acetic acid and used soon after.

Tetramethylethylene **Dithiocyanate.**—Fifty cc. of methyl alcohol and 19.4 g. of potassium thiocyanate (or 15.2 g. of ammonium thiocyanate, 4 moles) were refluxed for a few minutes; 12.2 g. of dibromide was added and the mixture first warmed and shaken, and then refluxed for ten to fifteen minutes; 250 cc. of water was added and the mixture extracted four times with 100-cc. portions of light petroleum ether while still slightly warm. The dithiocyanate is very insoluble in cold naphtha and only slightly soluble in warm naphtha. The naphtha was nearly all evaporated by air blowing on the steam-bath; the remainder was cooled in ice and the hard grainy precipitate filtered with suction. The yield was 4.5–5.5 g. (45–55%). Less potassium thiocyanate reduces the yield, while more increases it only slightly. The dibromide should be freshly recrystallized, dry and free from acetic acid. The dithiocyanate, recrystallized from alcohol, melts at 61°.

Anal. Calcd.: N, 14.0; S, 32.0. Found: N, 14.4, 14.5; S, 31.4, 31.7.

Tetramethylethylene Sulfide.—Twenty grams of dithiocyanate and 50 cc. of methyl alcohol were mixed in a flask provided with a reflux condenser. A solution of 25 g. of $Na_2S{\cdot}9H_2O$ (calcd., 24 g.) in 50 cc. of water was added. A slight warming occurred and the mixture was heated gently (not boiled) with shaking for thirty minutes and then cooled; 50 cc. of very light petroleum ether (b. p. 20–35° or 25–35°) was poured through the condenser to dissolve out sublimed sulfide, then the mixture was placed in a separatory funnel, water added, the mixture shaken and the layers separated. The lower layer was washed again with 50 cc. of the petroleum ether. These extracts were evaporated by an air stream while keeping very cold, until nearly all the solvent was gone (6–8 cc.). The evaporation must not be prolonged as the sulfide is very volatile.

---

[2] Marvel, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1925, Vol. V, pp. 87–89.

[3] Thiele, Ber., 27, 455 (1894).

The solution was chilled in a freezing mixture, the crystals filtered with slight suction on a cold Biichner funnel with paper and the filtrate added to the next preparation; yield, 90–95%. It may contain dithiocyanate, from which it can be freed by sublimation; m. p. 76.1–76.6°; b. p. 127" (corr.) (by the Siwolliboff capillary tube method); sulfur, 27.5%; calcd., 27.6%. The molecular weight of the crude sulfide was determined by the freezing-point method in benzene: (1) 16.00 g. of solvent; 0.1423 *g*. of sample, depression 0.385°, molecular weight 115.5; (2) 0.2672 g. of sample, depression 0.719°, molecular weight 116.1, calcd. 116.19. Hence it contained no polymers.

Summary

Tetramethylethylene sulfide was prepared by the series of reactions acetone → pinacone hydrate → tetramethylethylene dibromide → dithiocyanate → sulfide, and some of its properties have been recorded.

TRIMETHYL- AND TRIMETHYLETHYLTHIOPHENE

BY MERRILL A. YOUTZ AND PHILIP P. PERKINS

RECEIVED JULY 11, 1929 PUBLISHED NOVEMBER 8, 1929

Perhaps the most obvious method of preparing polyalkylthiophenes of known structure is by means of the reaction of phosphorus pentasulfide or phosphorus trisulfide on 1,4-dicarbonyl compounds. If the a-positions of the thiophene are to be substituted with alkyl groups, the carbonyl compound must be a diketone. The preparation of such compounds has proved to be extremely difficult. The only member thus far reported is 3,4-dimethylacetonylacetone prepared by Ciamician and Silber[1] by the action of light on methyl ethyl ketone and by Vladesco[2] by the action of sodium on methyl chloro-ethyl ketone. Willstatter and Clark[3] reported a large amount of work on attempts to produce such a diketone. While the action of iodine on sodium acetoacetic ester readily yields diacetylsuccinic ester, which is hydrolyzable to acetonylacetone with good yields, the attempt to carry out an analogous reaction with ethyl sodium acetoacetic ester has uniformly failed. Also the attempt to introduce alkyl groups into sodium diacetylsuccinic ester leads chiefly to ethers, and such of the desired compound as is produced readily loses one or more acetyl groups by hydrolysis or alcoholysis.[3] We have found that another variation of this synthesis gives negative results: the action of sodium on a-bromo-a-ethyl acetoacetic ester. An attempt to repeat the work of Vladesco where sodium is allowed to react with methyl chloro-ethyl ketone yielded no detectable amount of the desired diketone. Also the ethyl

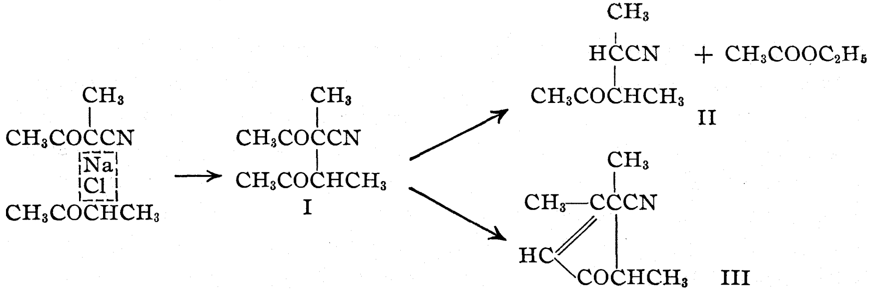
[3] Willstätter and Clark, ***Ber.***, 47, 291–310 (1914).

acetal of this ketone appeared to react with sodium but did not give the diketone acetal or the diketone.

The nitrile $CH_3COCHCNCH_3$,[4,5] prepared from methyl chloroethyl ketone and potassium cyanide, was converted into its sodium compound and this allowed to react with the chloroketone. The reaction yielded, besides unchanged nitrile, a substance b. p. 171° (760 mm.); b. p. 75° (25 mm.); d_4^{20} 0.957 (the first nitrile boils at 145°). It was colorless and had a strong odor. From its low boiling point it could hardly have been the expected diacetonitrile (I) but was perhaps the nitrile of α,β-dimethyl-levulinic acid (II) formed by the alcoholysis of one acetyl group from I, or perhaps a cyclic ketone-nitrile (III) formed from I by internal condensation. The ethyl ester of the acid corresponding to the nitrile (I) was shown to behave in this manner; but III would probably have had a higher boiling point than we observed since the corresponding ethyl ester according to Willstatter had a boiling point of 125–135° at 11 mm., and in general a nitrile of an acid has a boiling point very near that of the ethyl ester of that acid.

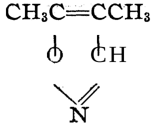


The attempt to prepare a ketone from which a tetra-alkyl thiophene could be prepared directly was then abandoned. α,β-Diacetyl butyric ester (IV) was then prepared from sodium acetoacetic ester and methyl chloro-ethyl ketone by means of a slight modification of the method of

---

[4] Von Reymenant, *Bull. acad. roy. Belg.*, 724–742 (1900); *Chem. Centr.*, I, 95–96 (1901).

[5] There is doubt in the minds of the authors that the substance produced in the manner described is really a nitrile. If it is, it would be the nitrile of methylacetoacetic acid and should have a boiling point of 180–190° instead of 145° as it has. Its elementary composition is that represented by the formula. From its anomalous boiling point, its basic properties, the formation of addition compounds with mercuric chloride and with methyl iodide and its very slow reaction with sodium, it seems much more probable that it is the isomeric 4,5-dimethyl isoxazole, as shown. If so, a whole series of isoxazoles can readily be prepared in a similar manner with high yields. However, such an isoxazole would probably behave toward sodium or sodium ethylate as if it were the nitrile, forming the expected sodium derivative of methyl acetoacetonitrile and hence be suitable for the work here described. The authors wish to reserve this field for further work.



Willstatter and Clark. This ester was hydrolyzed by boiling for several hours with an excess of 20% potassium carbonate solution to the new diketone, 3-methylacetonylacetone (V).

This ketone reacted readily with phosphorus pentasulfide in the cold, giving after purification 2,3,5-trimethylthiophene.

2,3,4-Trimethylthiophene, the only position isomer possible, has been prepared by Victor Meyer.[6] Our thiophene with isatin and sulfuric acid gives a brilliant brownish-red color but not blue or green. 2,5-Dimethylthiophene, where both a-positions also are substituted, does likewise[7] but the 2,3,4-compound gives a green color.

Our thiophene reacted readily with acetyl chloride and aluminum chloride giving 2,3,5-trimethyl-4-acetothienone. This ketone has an unpleasant penetrating odor similar to but much stronger than that of the thiophene itself. The ketone was reduced by the method of Clemmensen, giving 2,3,5-trimethyl-4-ethylthiophene.

This thiophene does not give the indophenine reaction. Both thiophenes dissolve in concentrated sulfuric acid with slight discoloration and a slight heat evolution. Both are reprecipitated on dilution though probably the trimethylthiophene is converted to a sulfonic acid to some extent. This inertness is in great contrast to the ready reaction of thiophene itself with sulfuric acid. Both thiophenes show the characteristic depression of the molecular refraction, while the trimethylacetothienone has *a* normal value.

The trimethylthiophene reacts readily with iodine in the presence of yellow mercuric oxide to give an iodo compound. This was only distillable in steam and was probably impure.

Experimental Part

Diethyldiacetosuccinic Ester.—α-Bromo-α-ethylacetoacetic ester was prepared according to the method of Macbeth.[8] The boiling point, however, is 100–102° at 11 mm. and not 106°. Four and two-tenths grams of sodium (calcd. 3.8 g.) was placed in 150 cc. of dry ether and 26.3 g. of ethylacetoacetic ester added and allowed to reflux for two hours with shaking. The solution was poured off the remaining sodium and mixed with 39.5 g. of a-bromo-a-ethylacetoacetic ester. The solution became warm, and sodium bromide precipitated in one to two minutes, after which the solution was refluxed for ten minutes. It stood for sixteen hours and although still slightly alkaline was treated with water, washed and dried with sodium sulfate. After evaporation of

ether, there remained 36 g. of a brown oil which did not crystallize. It gave no diketone (3,4-diethylacetonylacetone) when boiled with potassium carbonate solution.

3,4-Dimethylacetone.—Methyl α-chloro-ethyl ketone was prepared by passing chlorine into a stirred mixture of two parts of methyl ethyl ketone, two parts of water and one part of powdered calcium carbonate under a reflux and at 60–70° until the calcium carbonate was gone. Sodium was put in 200 cc. of dry ether and 128 g. (3 moles) of chloro ketone added. The mixture boiled spontaneously at first and was then heated until the reaction was complete (about one hour). The solution was filtered, washed, dried and fractionated. No diketone whatever was obtained, the product being unchanged chloro ketone and very high boiling products. Another trial, in which the sodium (as wire) was added during the course of the reaction, gave no better results. Heating of the chloro ketone with Kahlbaum's copper powder in a sealed tube at 150–160° gave no reaction. At 170–180° some decomposition occurred but no diketone was obtained.

Methyl chloro-ethyl ketone diethyl acetal was prepared by the method of Claisen[9] from 75 g. (3 moles) of absolute ethyl alcohol, 66.8 g. of chloro ketone and 102 g. of ethyl ortho-formate; yield, 70% in ten days' standing. The acetal showed b. p. 80–84° (36 mm.); d_4^{20} 0.9773; Cl, 19.3%; calcd. 19.6%. Without ammonium chloride as a catalyzer the yield was 39%. A shorter time of standing (four days) gave a 45% yield. Probably a longer period would increase the yield. Thirteen and seven-tenths grams of sodium wire (calcd. 11.7 g.) was placed in 300 cc. of dry ether with 93 g. of chloro acetal under a reflux condenser bearing a calcium chloride tube. The mixture was refluxed daily for five days, when the sodium was much disintegrated. The liquid was filtered, the residue washed once with dry ether and the combined filtrates were distilled, finally at reduced pressure; 32 g. of very pure acetal was recovered but no other products except ether.

3-Methylacetonylacetone.—α,β-Diacetylbutyric ester was prepared as described by Willstatter and Clark[8] except that a 100% excess of acetoacetic ester was used. This doubled the yield. We obtained 45–60% yields with 60–80% recovery of the excess acetoacetic ester.

Two hundred and six grams of ester was refluxed for six hours with a solution of 200 g. of potassium carbonate in 800 cc. of water. The mixture was diluted with ether, the upper layer separated and the water layer extracted with ether. The combined extracts were dried with potassium carbonate and after removal of ether in a bead column, fractionated at reduced pressure; yield 109 g. **(83%);** b. p. 68–74°; properties: b. p. 71° (10 mm.); d_4^{20} 0.9527; n_D^{20} 1.4260; b. p. (740 mm.) 195–196° (corr.) with some decomposition. It is soluble in all the usual organic solvents and miscible with water in all proportions. As prepared above it had a rather strong odor but after purification with sodium bisulfite (by shaking with saturated sodium bisulfite solution, extracting with ether, and heating the sodium bisulfite solution with sodium carbonate) it had a sweet and pleasant odor. In other respects the purified and unpurified ketones had practically identical properties.

The semicarbazone (di-semicarbazone), when crystallized from hot water, melted at 219–220° corr.

Anal. Subs., 0.0848: 23.5 cc. of N at 0° and 760 mm. Calcd.: N, 34.7. Found: N, 34.7.

The *p*-nitrophenylhydrazone (or possibly the 2,3,5-trimethyl-N-*p*-nitrophenyliminopyrrole) was recrystallized from toluene; m. p. 112–113° corr.

2,3,5-Trimethylthiophene.—Sixty-five to 70 g. of powdered phosphorus pentasul-

---

fide in a flask with a reflux condenser was treated with 96 g. of 3-methylacetonylacetone, the mixture kept cool and not shaken for a few minutes (to avoid a too violent reaction), and then allowed to come to room temperature. Finally, it was heated to boiling for three to four hours with the addition of 10 g. of phosphorus pentasulfide after the first hour. The liquid was poured off the tarry residue, distilled, the distillate dried, refluxed over several portions of sodium and then sodium hydroxide, and fractionated. The yield was 35–40% of a colorless liquid with a durene-like odor; b. p. 163–165° corr. at 746 mm.; d_4^{20} 0.9753; n_D^{20} 1.5131; M_D^{20} 38.88, calcd. 39.50; sulfur calcd. 26.4, found 26.4. The sulfur was determined by analysis of a solution in naphtha by the Burton lamp method.

2,3,5-Trimethyl-4-acetothienone.—To 12 g. of powdered aluminum chloride in 50 g. of cold carbon disulfide in a flask with a reflux condenser was added a mixture of 10 g. of trimethylthiophene, 8 g. of acetyl chloride and 50 g. of carbon disulfide drop by drop during fifteen minutes. The mixture was allowed to stand for three to four hours in ice and water, then overnight at room temperature. The mixture was warmed for a few minutes, then cooled, decomposed with dilute sulfuric acid, diluted with ether, separated and the ether solution washed with dilute sulfuric acid, water, sodium carbonate and water; it then was dried and fractionated. The yield was 12.5 g. (93%); b. p. 245–250° corr. Other preparations gave 85–94% yields. The pure ketone boiled at 248–249" corr. (748 mm.); d_4^{20} 1.0891; n_D^{20} 1.5454; M_D^{20} 48.86, calcd. 48.75. *Anal.* (Parr oxygen bomb). Calcd.: S, 19.05. Found: S, 18.9. It formed no bisulfite compound.

The semicarbazone, when recrystallized from acetone, melted at 157° corr.

The p-nitrophenylhydrazone was recrystallized from xylene; m. p. 162.5–163° corr. *Anal.* Subs., 0.2102: 24.0 cc. of nitrogen at 0° and 760 mm. Calcd.: N, 13.9. Found: N, 14.2.

The phenylhydrazone was an oil which did not crystallize.

2,3,5-Trimethyl-4-ethylthiophene.—The acetothienone was reduced by the method of Clemmensen,[10] using 80 g. of zinc to 400 cc. of 5% mercuric chloride solution, pouring off this solution after one hour, adding the ketone (21.7 g.) and then 40 cc. of 6 N hydrochloric acid and refluxing, with further additions of 40 cc. of hydrochloric acid every one to two hours for fourteen hours. The yield was 70–80% after deducting unchanged ketone (15–25% of the original ketone). This thiophene boiled at 204–206° corr. at 748 mm.; d_4^{20} 0.9609; n_D^{20} 1.5132; M_D^{20} 48.25, calcd. 48.75. *Anal.* Calcd.: S, 20.78. Found: S, 20.8. These thiophenes gave the characteristic depression of the molecular refraction: trimethylthiophene, M_D^{20} 38.88, calcd. 39.50; trimethylethylthiophene, M_D^{20} 48.25, calcd. 48.75; trimethylacetothienone M_D^{20} 48.86, calcd. 48.75. This latter is probably to be interpreted as a depression, since an acetyl group on an aromatic nucleus usually produces an exaltation of 0.5 to 1.0 unit.[11]

Some attempts were made to prepare the compound by preparing iodotrimethylthiophene and treating it with sodium and ethyl bromide, but these were unsuccessful. Trimethylthiophene reacts readily with iodine and yellow mercuric oxide to give an iodo compound (which could not be distilled except with steam) but this gave no considerable amount of the desired product when treated with sodium and ethyl bromide. However, tetramethylthiophene has been made in this way.[12] Perhaps the success of the latter preparation depended on the fact that the group entered the α-position instead of the β-position as in our case. The α-positions are much more reactive.

Summary

Attempts to synthesize a 3,4-dialkylacetonylacetone have yielded negative results, but 3-methylacetonylacetone was prepared and from it 2,3,5-trimethylthiophene by the action of phosphorus pentasulfide. From this thiophene was prepared 2,3,5-trimethyl-4-acetothienone, which was reduced to 2,3,5-trimethyl-4-ethylthiophene.

NEW BOOK

Dispersoidanalyse. Die Methoden der Teilchengrössenbestimmung und ihre theoretischen Griindlagen. (The Methods for the Determination of the Size of Colloidal Particles and the Theoretical Considerations Involved.) BY FRIEDRICH-VINCENZ v. HAHN, Hamburg. Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1928. xxiv + 553 pp. 165 figs. 15.5 × 23.5 cm. Price, unbound, M. 39; bound, M. 42.

This monograph is Volume III of a handbook describing single aspects of colloid science. It deals with a problem which practical men in many fields, as, for example, those interested in the study of soil or clay, or filter-passing bacteria, have to solve. The book provides an admirable summary of our present resources in this direction. It describes the various experimental methods hitherto developed: optical, mechanical (filtration and ultrafiltration), methods depending upon diffusion, or upon Stokes' Law, estimations of the surface of particles and other special methods. It incidentally brings together a large number of interesting observations. There are 165 figures, mainly of apparatus, and the monograph is provided with indexes of authors, of subjects and of substances occupying altogether 55 pages. This is a volume which will provide indispensable information or save any amount of time for all those who happen to be concerned with any of the aspects of this general problem. It is interesting to note that this thorough yet concise treatment of this special subject is almost twice as lengthy as Svedberg's general monograph recently reviewed.

THE TRANSITION TEMPERATURE OF CARBON TETRACHLORIDE AS A FIXED POINT IN THERMOMETRY

BY EVALD L. SKAU AND HARRY F. MEIER

RECEIVED FEBRUARY 4, 1929 PUBLISHED DECEMBER 11, 1929

In a recent paper[1] McCullough and Phipps have suggested the use of the transition point of carbon tetrachloride[2] as a fixed point in thermometry and have given this transition temperature as —48.54 ± 0.02'. For reasons which will appear below it seemed advisable to redetermine this transition temperature and the value found by us is —47.55 ± 0.12'.

Method,—Our observations were made by means of a special cooling curve and heating curve apparatus which will be described in detail in a paper now being prepared for publication by one of us (E. L. S.). The apparatus involves a cryostat whose temperature can be very accurately regulated and in which a 0.7–1.0 g. sample is suspended in an hermetically sealed "freezing point tube." The latter is made of extremely thin-walled glass tubing (0.05 mm. wall thickness) in order that its heat capacity may be negligibly small with respect to that of the sample, and is so constructed that the temperature of the sample may be followed by means of a single-junction thermocouple one element of which fits snugly into a thin-walled capillary tube extending down into the center of the sample. The cold junction is kept at 0°. The readings are made to the nearest microvolt (0.03') by means of a Leeds and Northrup Type K potentiometer.

Calibration and Materials.—The thermocouple, which is made of No. 30 constantan and No. 36 copper wire (B. and S. gage) was calibrated at the ice point, at the freezing point of pure mercury (−38.87°),[3] at the sublimation point of carbon dioxide (−78.51°)[3] and at the boiling point of oxygen (−183.00°).[3] The last two points were established by measuring the vapor pressure of the carefully purified substances in a

---

[1] McCullough and Phipps, THIS JOURNAL, 50, 2213 (1928).

[2] The existence of this transition point was recognized previously by Goldschmidt [*Z. Krist.*, 51, 21 (1912); THIS JOURNAL, 50, 3390 (1928)] and by Latimer [*ibid.*, 44, 90 (1922)]. Neither of these investigators, however, was interested in the exact measurement of the transition temperature.

[3] "International Critical Tables," Vol. I, p. 53.

constant temperature cryostat in which the thermoelement was immersed.[4] In each case the purity of the sample was tested by evaporating to one-half volume and then redetermining the vapor pressure. The calibration at the mercury point was carried out in the same apparatus as the freezing points and under identical conditions.

In order to further corroborate the accuracy of our calibration in the range to be considered, we are recording below the freezing point data obtained by our method on samples of carbon tetrachloride and chlorobenzene kindly supplied to us "for thermocouple calibration" by Professor Jean Timmermans. This same sample of carbon tetrachloride was used for our determination of the transition point in question.

Results.—A number of cooling curves and heating curves were obtained on chlorobenzene at its freezing point, and on carbon tetrachloride at its freezing point and at its transition point. The data given in Cols. 2 and **3** of Table I are the values obtained from these curves using our own thermocouple calibration; those in Col. 4 are the values as determined independently by Timmermans on the same samples for the purpose of thermometric standardization.

TABLE I

FREEZING POINT AND TRANSITION POINT DATA

Substance	Phenomenon	Temperatures, °C. Heating curve	Cooling curve	Timmermans
Carbon tetrachloride	F. p.	−22.84	−22.87	−22.9
Chlorobenzene	F. p.	−45.20	−45.23	−45.2
Carbon tetrachloride	Tr. p.	−47.43	−47.67	......

It will be noted that whereas the freezing point values as obtained by the heating and cooling curves show very good agreement, the corresponding values for the transition point differ by 0.24°. It was found that the heating curve value was fairly reproducible but that the value obtained by cooling curves varied from −47.67 to −47.99°, depending on the conditions, that is, on the degree of supercooling and on the rate of cooling. In cases such as this, where one cannot establish equilibrium by stirring due to the fact that the change takes place in the solid state, it is, of course, to be expected that the proper degree of supercooling before the transition takes place is very important.[5] Our best curves for this point were obtained with a supercooling of 3 to 4°, the rate of cooling being about 0.3° per minute.

---

[4] The details of this method have been fully described by Keyes, Townshend and Young, *J. Math. Phys. Mass. Inst. Tech.*, *1*, 3[illegible]2 (1922); see also Loomis and Walters, THIS JOURNAL, 48,3101 (1926), and Henning, *Ann. Physik,* 43,282 (1914).

[5] Nernst [Z. *physik. Chem.*, *15*, *681* (1894)] discusses the dangers of supercooling too little or too much in cryoscopic determinations in dilute solutions; see also Findlay's "Practical Physical Chemistry," 4th ed., Longmans, Green and Co., London, 1926, pp. 114–115.

Discussion

Our results show that the transition point of carbon tetrachloride is $-47.55 \pm 0.12°$; that is, it must lie between the temperature, $-47.43°$, the value obtained from heating curves, and $-47.67°$, the highest value from cooling curves.

The large discrepancy between our value for this point and that reported by McCullough and Phipps is probably not due to a difference in the purity of the sample used, judging from their freezing point data. It may be caused in part by the fact that their thermometer calibration at the sublimation point of carbon dioxide was not done by the accepted method. It is very likely chiefly due, however, to the inadequacy of their method of obtaining cooling curves, This seems probable at least from the fact that their diagram of the cooling curve for their best sample shows that there was no supercooling.

From the results of our investigation it seems improbable that the transition point of carbon tetrachloride will be entirely satisfactory for general use as a fixed point in thermometry. Except in the case of hydrates, transition points do not lend themselves to this purpose due to the difficulty of attaining a definite equilibrium in the solid state.[6]

We are indebted to the American Academy of Arts and Sciences for a grant from the Cyrus M. Warren Fund to carry out this work.

Summary

The transition point of carbon tetrachloride has been redetermined on a very pure sample in a special apparatus using a thermocouple whose calibration has been very carefully checked. The transition takes place at $-47.55 \pm 0.12°$, about one degree higher than reported by McCullough and Phipps.[1] This transition phenomenon is apparently not suitable as a fixed point for thermometry.

HARTFORD, CONNECTICUT

---

[6] Wyatt [*Trans. Faraday Soc.*, *24*, 429 (1928); 25, 43, 48 (1929)] suggests the suspension of the carbon tetrachloride in a liquid for reproduction of a definite temperature at the transition point. On the basis of values so obtained he places the transition point of carbon tetrachloride at "about −48°C." He used a thermometer in his temperature measurements whose stem-emersion calibration was based upon McCullough and Phipps' value for the transition temperature. Timmermans [*Bull. soc. chim. Belg.*, 37,409 (1928)] has also worked on such binary systems and reports that the transition point of carbon tetrachloride in cyclohexane, chloroform and acetone is −46"; in carbon disulfide, −46.5'.

STUDIES ON COMPLEX COMPOUNDS. I. REMOVAL OF AMMONIA FROM THE COORDINATION SPHERE[1]

BY H. I. SCHLESINGER AND RUBY K. WORNER

RECEIVED APRIL 29, 1929 PUBLISHED DECEMBER 11, 1929

Werner's theory accounts for and predicts clearly the changes which occur when three molecules of ammonia are successively removed from one molecule of a stable hexammine of a trivalent metal; what would happen if more ammonia were removed cannot be definitely foretold. Numerous possibilities present themselves—for example, the coordination number may change or various types of polynuclear compounds may be formed. We are reporting in this paper two such reactions; in one of them a polynuclear compound seems to be the product and in the other a hexacido compound is obtained. In later papers illustrations of change in coordination number will be described.

Cobaltic ammines do not lend themselves to investigations of this sort because they undergo complete decomposition when attempts are made to remove ammonia directly. Hexammine chromic salts are known to be readily convertible into pentammines, but what happens on further removal of ammonia has not been thoroughly studied. For this reason chloro pentammine chromic chloride was chosen by us as the starting material. When this substance is heated in air, in hydrogen, in carbon dioxide, or in ammonia, it decomposes into trichloro triammine chromium. This product, however, immediately reacts further to give a black compound unless the temperature is very carefully controlled.[2] If the pentammine is heated in a stream of dry hydrogen chloride, a very rapid reaction occurs at about 270° with considerable evolution of heat and is accompanied by a marked color change of the material from pink to green. If heating is discontinued at this point, the product washed with cold water to which a little hydrochloric acid has been added and then dried with alcohol and ether, a very insoluble green substance, *trichloro triammine chromium* is obtained.[3,4]

---

[1] The material for this article is taken from a thesis presented in 1925 to the Faculty of the Ogden Graduate School of Sciences of the University of Chicago by Ruby K. Worner in part fulfilment of the requirements for the degree of Doctor of Philosophy. Since the completion of this research considerable further work has been done along these lines, and the report is therefore made very brief. For details not reported herein and aspects of the investigation omitted, reference is made to the thesis.

[2] Ufer, *Ann.* Chem., 112, 281 (1859), and Schrotter, Ann., 37, 148 (1841), report the formation of the black substance, which they describe as a nitride of chromium, and mention the intermediate formation of a green compound, the nature of which they failed to recognize.

[3] It is interesting to note that under no conditions does the pentammine lose but one molecule of ammonia to form tetrammine. Furthermore, the triammine, when

This triammine is markedly different from a substance of the same composition described by Werner.[5] His compound is blue green, dissolves fairly readily in warm water and especially easily in warm dilute hydrochloric acid to give a deep blue solution of trichloro aquo triammine chloride; ours is insoluble in hydrochloric acid or in water, but with the latter it slowly reacts to give a pink solution which has since been shown to contain diaquo tetrammine chromic chloride. Here evidently is a case of isomerism of a type not frequently encountered, but whether it is stereoisomerism, possible according to Werner's theory, or is what is often called "polymerization isomerism" cannot be decided because of the insolubility of the compounds in question.[6]

Attempts to remove some of the three remaining molecules of ammonia from the coordination sphere show the firmness with which chromium retains the coordination number 6. When the triammine is heated to 175° in a stream of hydrogen chloride, ammonia is not withdrawn from the compound, but hydrogen chloride is quantitatively absorbed to give a reddish-purple, very hygroscopic crystalline material which may be considered to be *ammonium chromic hexachloride.*[7] The substance is insoluble in all solvents except water, with which it reacts almost instantly to produce a deep green solution presumably of hydrated chromic chloride.[8]

Those who make a distinction between double and complex salts may prefer to class the substance just described with the former rather than to call it a salt of the complex $[CrCl_6]^{---}$ ion.[9] There are, however, several objections to this point of view. Anhydrous chromic chloride, alone or when mixed with ammonium chloride, reacts with liquid ammonia to give a mixture of hexammine and chloro pentammine chromic chlorides without the intermediate formation of a solution. What we have called ammonium chromic hexachloride dissolves readily in liquid ammonia to give

treated with liquid ammonia, gives pentammine directly, a reaction which requires weeks for completion. These reactions will be discussed further in later papers.

[4] *Anal.* Found for chromium, 24.81; Cl, 50.39; NH_3, 24.29. Calcd. for $[Cl_3(NH_3)_3Cr]$: Cr, 24.83, Cl, 50.79; NH_3, 24.39. All analyses reported in this paper represent averages of the results with from 3 to 5 samples.

[5] Werner, *Ber.*, 43,2286 (1910).

[6] The formation of tetrammines from the triammine here described when they are treated with water or even with acids is a very unusual type of reaction which will be described in more detail in a later paper. It suggests the possibility that these triammines are polynuclear. We are at present attempting to obtain a more soluble example of the type, but have not so far succeeded.

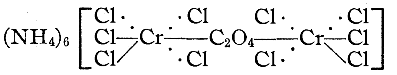
[7] *Anal.* Found: Cr, 16.33; Cl, 66.55; NH_3, 15.90. Calcd. for $(NH_4)_3[CrCl_6]$: Cr, 16.31; Cl, 66.73; NH_3, 16.00.

[8] Two stages in the reaction with water may be observed. At first a reddish solution is formed but this changes to green in a fraction of a second.

[9] No success attended attempts to prepare less soluble salts of this ion by double decompositions.

a green solution which is transformed to the pentammine only after complete evaporation of the liquid. Anhydrous chromic chloride reacts exceedingly slowly with dry gaseous ammonia; the new compound reacts rapidly at ordinary temperatures to give the pentammine. Double salts should possess a color which is the summation of the colors of the constituent salts; the compound here prepared is decidedly different in color from any known form of chromic chloride, the only colored constituent.[10]

In this instance, then, chromium, rather than changing its coordination number as the result of removal of ammonia, takes up hydrogen chloride, and the ammonia, although removed from the coordination sphere, remains in the molecule. A slightly different course is taken by the reaction when the compound *chloro oxalato triammine chromium* is treated as was the simple triammine. The oxalato compound is prepared quite simply by warming our trichloro triammine chromium with solutions of oxalic acid or of oxalates. It is a brick red, microcrystalline powder very insoluble in water or in acids, but when warmed with concentrated hydrochloric acid is reconverted into the triammine from which it was prepared.[11] At 190° it reacts slowly with gaseous hydrogen chloride. When the material attains constant weight, its composition always corresponds to the empirical formula $2CrCl_3 \cdot (NH_4)_2C_2O_4 \cdot 4NH_4Cl$.[12] According to Werner's theory this might be formulated as



in other words, a compound of polynuclear type. Its properties are similar to those of ammonium chromic chloride except that it reacts somewhat

---

[10] If trichloro triammine chromium is heated at 270°, instead of 175°, in a stream of hydrogen chloride, a rapid reaction occurs and continues until the composition of the material corresponds to the formula $2CrCl_3 \cdot 3NH_4Cl$. (*Anal.* Found: Cr, 21.76; Cl, 66.54; NH_3, 10.85. Calcd.: Cr, 21.79; Cl, 66.87; NH_3, 10.70.) Thereafter reaction is very slow and leads to anhydrous chromic chloride. On account of the difference in the rate of reaction before and after the attainment of the composition mentioned, the material can be isolated in fairly pure condition. It is purple in color, but also reacts with water to give hydrated chromic chloride. The fact that this substance has a markedly different color from that of the ammonium chromic chloride shows that we are not dealing with double salts of an unknown form of chromic chloride, for, if that were the case, both double salts should possess the same color. It might be mentioned that in the preparation of trichloro triammine chromium by the method described, some of the purple compound is always obtained. It is removed completely by washing the mixture with cold water.

[11] Further details of this reaction, which leads to rather unusual results when slightly varied, will be described in a later paper. Analytical data are as follows: calcd. for $ClC_2O_4(NH_3)_3Cr$: Cr, 22.96; Cl, 15.65; NH_3, 22.54; C_2O_4, 38.83. Found: Cr, 22.89; Cl, 16.02; NH_3, 22.24; C_2O_4, 38.74.

[12] *Anal.* Calcd.: Cr, 15.89; Cl, 54.16; NH_3, 15.60; C_2O_4, 13.44. Found: Cr, 16.37; Cl, 54.40; NH_3, 15.45; C_2O_4, 13.38.

more slowly with water, although the reaction is still too rapid to permit studies of constitution.[13]

Summary

1. The new substances $[Cl_3(NH_3)_3Cr]$, $[ClC_2O_4(NH_3)_3Cr]$, $(NH_4)_3[CrCl_6]$, and $(NH_4)_6[Cr_2C_2O_4Cl_{10}]$ are prepared and described. The first is an isomer of the trichloro triammine chromium prepared by Worner.

2. The removal of ammonia from the coordination sphere of chromium is briefly discussed.

STUDIES ON COMPLEX IONS. II. THE PREFERENTIAL REMOVAL OF BROMIDE ION FROM THE COORDINATION SPHERE[1]

BY H. I. SCHLESINGER AND D. N. RICKLES

RECEIVED APRIL 29, 1929 PUBLISHED DECEMBER 11, 1929

In order to study the relative tendency of various simple negative ions to become a part of complex positive ions, attempts have been made in this Laboratory to prepare compounds of the type $[CrR_3X_1X_2X_3]$ in which R represents a non-ionic constituent and X_1, X_2 and X_3 are univalent negative ion constituents. The determination of which one of the ionic constituents is driven out in preference to the others by the addition of one or two moles of R per mole of the compound would give evidence of the relative ability of each simple negative ion to form complex positive ions with chromium. A number of compounds having empirical formulas of the character mentioned have been prepared, but some additional data recently obtained have raised the question whether these substances, all of which are insoluble in all solvents, are not perhaps compounds of more complex type. For these reasons, the experimental results only are described in this paper and their interpretation is deferred to a later time.

Following the procedure of Schlesinger and Worner[2] the three "triammines" $[Br_3(NH_3)_3Cr]_x$, $[ClBr_2(NH_3)_3Cr]_x$, and $[Cl_2Br(NH_3)_3Cr]_x$ were prepared by thermal decomposition of the appropriate pentammine at 175°. The green products thus obtained were thoroughly washed with

---

[13] The formation of this compound again suggests that the triammines here described may really have a more complex structure than the name employed implies.

[1] This article is a résumé of a thesis presented by D. N. Rickles to the Graduate Faculty of the University of Chicago in part fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Schlesinger and Worner, THIS JOURNAL, 51,3520 (1929).

water until the washings were colorless. The residues were then dried with alcohol and ether. The properties of the compounds are similar to those of trichloro triammine chromium described by Schlesinger and Worner.[2]

Anal. Calcd. for $[Br_3(NH_3)_3Cr]_x$: Cr, **15.17;** NH_3, **14.91;** Br, **69.93.** Found: Cr, **14.83;** NH_3, **15.54;** Br, **70.86.** Calcd. for $[ClBr_2(NH_3)_3Cr]_x$: Cr, **17.43;** NH_3, **17.12;** Cl, **11.88;** Br, **53.57.** Found: Cr, **17.43;** NH_3, **17.64;** Cl, **12.00;** Br, **53.74.** Calcd. for $[Cl_2Br(NH_3)_3Cr]_x$: Cr, **20.48;** NH_3, **20.12;** Cl, **27.93;** Br, **31.47.** Found: Cr, **19.72;** NH_3, 19.36; Cl, 27.81; Br, **31.43.**

Compounds of this series containing iodo, nitrato or nitrito groups could not be prepared in this manner nor by removing water from aquo triammines.[3]

Dihalido Tetrammine Chromic Salts, ***(Cis*** (?)-Type).—Ten cc. of hydrobromic acid (sp. gr. 1.20) was added to 1 g. of chloro oxalato triammine chromium,[2] $[Cl\cdot C_2O_4\cdot(NH_3)_3Cr]$, and the mixture was boiled until the lavender oxalato triammine was completely converted to a dark green material. The green compound was collected on a filter, while the reaction mixture was still warm, washed with dilute hydrobromic acid and dried with alcohol and ether. The compound was purified by reprecipitating it with hydrobromic acid (sp. gr. 1.70) from its saturated aqueous solution; yield, 0.72 g. That the bromine is not coordinated with chromium is shown by the method of recrystallization and by the fact that the bromine can readily be replaced by double decomposition.

Anal. Calcd.: Cr, **19.19;** NH_3, **25.15;** Cl, **26.17;** Br. **29.94.** Found: Cr, **19.01;** NH_3, 24.85; Cl, 25.66; Br, **28.80.**

When carefully heated the tetrammine decomposes into "dichloro bromo triammine chromium" and a purple substance not further investigated; it reacts with ammonium oxalate to give "chloro oxalato triammine chromium"—a reverse of the reaction by which it is prepared—and by double decomposition to give dichloro tetrammine *chloride, iodide* and other similar salts. The iodide may also be prepared by treating "chloro oxalato triammine" chromium with boiling hydriodic acid (sp. gr. 1.50) free from iodine.[4] Further reactions need not be described as they have no bearing on this paper.

The corresponding dibromo tetrammine chromic bromide, $[Br_2(NH_3)_4Cr]Br$, the preparation of which is important for reasons which will be-

---

[3] In this connection it was noted that when dichloro aquo triammine chromic nitrate was heated in ordinary air at 100°, it took on water, instead of losing it. This extraordinary stability of aquo compounds is unexpected.

[4] If the hydriodic acid contains free iodine, the reaction yields, instead of the green tetrammine, a well crystallized brown substance from which iodine is freely evolved when heat is applied. It dissolves in water to give a brown solution which slowly turns green and contains free iodine. Organic solvents such as chloroform and ether extract no iodine from it. It also is a tetrammine but has not yet been further characterized.

come obvious later, was obtained by treatment of bromo oxalato triammine chromium with hydrobromic add, Details of purification and the properties correspond exactly to those for the analogous chlorine derivatives except in one respect.[5] Unlike the chlorotetrammines, the green bromo tetrammines give a red solution in water, but this change is not a transformation into the isomer to be described below. From the red solution the green tetrammine may be reprecipitated either by the addition of alcohol-ether **mixtures** or of hydrobromic acid, provided the solution is freshly prepared. After the solution has stood for several days both of these reagents precipitate from it red diaquo tetrammine chromic bromide. Obviously the hydration begins as soon as the solution is prepared, but is a slow reaction. Further evidence that the green bromo tetrammine is of the same type as the chloro tetramrnine is found in the fact that both react with oxalic acid to give halido oxalato chromium compounds.

Trans (?) Dibromo Tetrammine Chromic Bromide.—When "tribromo triammine chromium" is heated with hydrobromic acid (sp. gr. 1.20), a reddish-brown mixture of a tetrammine and a pentammine is obtained.[6] The two components may be separated by treating the mixture with a small amount of ice water, and filtering the solution rapidly. The pink pentammine remains undissolved, and the tetrammine may be reprecipitated by the addition of hydrobromic acid (sp. gr. 1.70) to the solution. Re-solution and reprecipitation effect purification. Analysis leads to the formula $[Br_2(NH_3)_4Cr]Br$.

And. Calcd.: Cr, 14.45; NH_3, 18.93; Br, 66.62. Found: Cr, 14.46; NH_3, 19.21; Br, 67.22.

This tetrammine, in contrast to the others described, is dark red instead of green. It dissolves in water to give a red solution, as does the green dibromo tetrammine chromic bromide, but from the solution of the red tetrammine the original substance, not an aquo compound, is precipitated by addition of hydrobromic acid or by alcohol-ether mixtures. The red tetrammine is neither formed from nor does it give "bromo oxalato triammine chromium." It may be noted that the transformation of one type of the tetrammine into the other, a very common reaction in other cis and *trans* series, does not seem to occur with the compounds here described under any conditions we have observed. We have provisionally assigned the cis structure to the green tetrammines because they are formed from and can readily be converted to oxalato compounds. Inasmuch

---

[5] Bromo oxalato triarnmine was prepared by heating tribromo triammine chromium with ammonium oxalate. Analyses of the various compounds mentioned in this paragraph as well as other details are described in the thesis of Dr. Rickles (University of Chicago, 1928).

[6] The pentammine is formed directly from the triammine, for the pure tetrammine does not yield pentammine under analogous conditions. Obviously the reaction of triammines with acids is very complex,

as the reaction involves a transformation of a triammine to a tetrammine or vice versa, in other words a very deep-seated change in the complex ion, the basis for this conclusion is not as secure as might be desired. In fact, there is some evidence which might be considered to favor the opposite interpretation. Oxalato tetrammine chromium[7] compounds are orange-red. Oxalato compounds are always assumed to be the cis type; hence, the red bromo tetrammine might also be considered to be of this structure; but we have preferred to lay more weight on the evidence obtained from its reactions than on that based on color similarities, because it is well known that substitution of different groups in complex ions is very often responsible for color changes.

Possible Structure of the "Triammines."—The reactions of the "triammines" with acids to give tetrammines, as described above, suggests the possibility that they are polymerization complexes which contain a tetrammine ion. Thus what we have called trichloro triammine chromium $[Cl_3(NH_3)_3Cr]$, may be a compound such as $[Cl_2(NH_3)_4Cr]$ $[Cr(NH_3)_2Cl_4]$. There are, on the other hand, rather serious objections to formulas of this type. In the first place, it would be difficult to explain on this basis why in a single reaction the compound, $[Br_3(NH_3)_3Cr]$, should yield both a triammine and a pentammine. In the second place, the formulation suggested would not explain why the tetrammines yield triammines on heating, for a reaction such as

$$2[Cl_2(NH_3)_4Cr]Cl \longrightarrow [Cl_2(NH_3)_4Cr][Cr(NH_3)_2Cl_4] + 2NH_3$$

seems highly improbable. The question is being further investigated.[8]

Reaction of Oxalates with Mixed Halide Complexes.—One gram of $[Cl_2Br(NH_3)_3Cr]_x$ was heated with 5 cc. of a saturated aqueous solution of ammonium oxalate and a solid was obtained which was apparently $[ClC_2O_4(NH_3)_3Cr]_x$.

Anal. Calcd. for $[ClC_2O_4(NH_3)_3Cr]$: Cr, 22.92; NH_3, 22.45; Br, 0.00; Cl, 15.64. Composition of solid: Cr, 22.04; NH_3, 21.90; Br, 0.06; Cl, 16.09.

The low results for chromium and ammonia, the high value for chlorine and the presence of a slight trace of bromine in the reaction product, all point to a slight amount of unchanged starting product rather than to admixture with $[BrC_2O_4(NH_3)_3Cr]_x$. This result suggests that bromo groups are more readily removed from the coördination sphere than chloro groups, but until the exact character of the hypothetical triammines has been established, this conclusion cannot be considered as definitely proved.

The treatment of the compound $[ClBr_2(NH_3)_3Cr]_x$ with ammonium oxalate in the same manner leads to the formation of mixtures.

---

[7] P. Peiffer, Ber., 38, 3598 (1905).

[8] Recently we have discovered a new type of "triammine" which is pink instead of green and which yields hexammines on treatment with acids.

Anal. Calcd. for $[ClC_2O_4(NH_3)_3Cr]$: Cr, 22.92; NH_3, 22.45; Cl, 15.64; Br, 0.00. Calcd. for $[BrC_2O_4(NH_3)_3]Cr$: Cr, 19.17; NH_3, 18.80; Cl, 0.00; Br, 29.42. Analysis of reaction product: Cr, 21.10; NH_3, 21.20; Cl, 10.96; Br, 10.42.

The indications are that a larger percentage of the chloro compound was obtained, but exact calculations are impossible because of the presence of unknown amounts of the starting product. In general the results corroborate the tentative conclusion reached above.

Reaction of Mixed Triammines with Ammonia.—Dry ammonia at atmospheric pressure and 200° passed over the triammines $[ClBr_2(NH_3)_3Cr]$, and $[Cl_2Br(NH_3)_3Cr]_x$ produces mixtures of pentammines. The analytical results need not be given here since they do not permit calculation of the relative amounts of the various pentammines, but when air was mixed with the ammonia in such proportion as to reduce the partial pressure of ammonia to 182 millimeters (as determined by measuring the proportion of the two components by two flowmeters) only $[Br_2Cl(NH_3)_3Cr]_x$ reacted to give appreciable quantities of pentammine in from fifty to seventy hours. The reaction product was washed with water and the aqueous filtrate was treated with ammonium oxalate to precipitate the oxalate of the pentammine. In this way ionized halogen is removed from the compound, thus making the identification of the halogen group in the coordination sphere more exact. Only chloride was present; the quantitative analysis yielded 13.73% of chlorine, in good agreement with 13.62% required for the chloro pentammine chromic oxalate. Again these results suggest that the bromo group is more readily displaced from the complex, but in this case this conclusion is warranted only if the starting products are simple triammines. The interpretation of the results will be given in a later paper.

Summary

1. Several new "triacido triammine chromic" salts, $[Br_3(NH_3)_3Cr]_x$, $[Br_2Cl(NH_3)_3Cr]_x$, $[BrCl_2(NH_3)_3Cr]_x$ and $[Br\cdot C_2O_4\cdot(NH_3)_3Cr]_x$ have been prepared.

2. A method of obtaining chloro and bromo tetrammine chromic salts, hitherto unknown, has been devised. Both cis and *trans* salts have been obtained.

3. The action of mixed "triammines" such as $[ClBr_2(NH_3)_3Cr]$ with ammonia and with oxalates has been studied. In all cases the bearing of the results on the question of the factors which determine the stability of complex ions will be taken up in later papers.

AN ISOTOPE OF OXYGEN, MASS 17, IN THE EARTH'S ATMOSPHERE

BY W. F. GIAUQUE AND H. L. JOHNSTON

RECEIVED JUNE 27, 1929 PUBLISHED DECEMBER 11, 1929

Recently[1,2] the presence of an oxygen isotope, mass 18, in the earth's atmosphere, was reported. In this paper it will be shown that an additional isotope of oxygen with mass 17 is also present. As in the previous case, the conclusion is based on a study of atmospheric absorption spectra obtained by H. D. Babcock of Mount Wilson Observatory. Since our interpretation of the weak A' band in the atmospheric absorption of sunlight as originating from the 18–16 oxygen molecule, Babcock has carried out further measurements which have supplied additional support by extending the various branches of the bands. He has also found a new series of very weak lines. Babcock has kindly permitted us to make use of his manuscript in advance of publication.[3] He suggests that this new series is due to the forbidden alternate rotation levels of the 16–16 oxygen molecule, although, as he states, they do not occupy the correct positions by many times the experimental error.

We have found that these lines originate from an oxygen molecule consisting of an atom of mass 17 in combination with one of mass 16. In agreement with the predictions of the theory of wave mechanics the normal state of this molecule has one-half unit of vibration and both odd and even rotation levels exist.

The method of calculation of the isotopic separation of the lines makes use of the equations given for this purpose by Loomis.[4] In calculating the vibrational isotope effect we have previously made use of the equation given by Birge[6] for the normal oxygen molecule, namely

$$\nu^n = 1565.37\% - 11.37n^2$$

and that given by Dieke and Babcock[6] for the 1.6 volt level as

$$\nu^n = 1415.017\, n - 11.91\, n^2 - 0.3525\, n^3$$

Birge[7] has recently found that the latter equation is incorrect due to an error in computation and should be

$$\nu^n = 1418.69\, n - 13.925\, n^2 - 0\ 02\, n^3$$

where $n = 0, 1, 2, \ldots.$

[1] Giauque and Johnston, *Nature*, 123,318 (1929).

[2] Giauque and Johnston, THIS JOURNAL, 51,1436 (1929).

[3] Babcock, *Proc. Nat. Acad. Sci.*, 15, 471 (1929).

[4] Loomis, *Bull. Natl. Research Council*, 11, Chap. V (1926).

[5] Birge, *ibid.*, 11, Chap. V (1926).

[6] Dieke and Babcock, *Proc. Nat. Acad. Sci.*, 13,670 (1927).

[7] Birge, *Nature*, in press.

As a result of this observation Birge shows that the systematic difference of observed and calculated isotopic effects which occurred in our calculations on the 18–16 molecule is practically eliminated, and demonstrates the remarkable accuracy of the measurements of Dieke and Babcock.[6]

On the basis of the two vibration equations given by Birge, the data for the 18–16 molecule have been recalculated.

The above vibrational formulas should be transposed so that the state given as zero corresponds to $n = {}^1/_2$ as required by the theory of wave mechanics.

The formulas for the separation of the P and R branches of the 18–16 and 16–16 molecules are as follows

$$\Delta\nu_P = 2.07 + 0.0556\,[B''m^2 - \beta''m^4 - B(m-1)^2 + \beta'(m-1)^4]$$
$$\Delta\nu_R = 2.07 + 0.0556\,[B''m^2 - \beta''m^4 - B'(m+1)^2 + \beta'(m+1)^4]$$
$$m = 1/2, 3/2, 5/2, \ldots$$

For the separations of the lines due to the 17–16 and 16–16 molecules

$$\Delta\nu_P = 1.09 + 0.0294\,[B''m^6 - \beta''m^4 - B'(m-1)^2 + \beta'(m-1)^4]$$
$$\Delta\nu_R = 1.09 + 0.0294\,[B''m^2 - \beta''m^4 - B(m+1)^2 + \beta'(m+1)^4]$$

The constants as given by Dieke and Babcock[6] are

$$B'' = 1.438 \qquad \beta'' = 6.31 \times 10^{-6}$$
$$B' = 1.390 \qquad \beta' = 5.75 \times 10^{-2}$$

The lines calculated for the 16–18 and 16–17 molecules are given beside the observed data in Table I. In order to clear up any doubt concerning

the possibility that the new very weak lines might be due to the forbidden alternate rotation levels of the 16–16 molecule, the positions of the forbidden lines are calculated and given in italics along with the assignments of Babcock, also in italics, in Table I.

$$j(P) = m - 1/2 \qquad j'(R) = m + 1/2$$

where j' refers to the rotation levels of the upper electronic state. In addition to the change made in the 16–18 calculated values introduced by the use of the corrected vibrational wave number referred to above, several of the values at the bottom of the R branches have been changed slightly to conform with smooth values of the 16–16 molecule.

Excluding all lines that have been used in more than one place, the algebraic sum of the residuals has been calculated and divided by the number of lines to show the smallness of any systematic deviation. For the 16–18 band we obtain from 54 lines the value -0.012 cm.$^{-1}$ with a maximum deviation of -0.11 cm.$^{-1}$. For the 16–17 band, which is fainter and therefore harder to measure, a consideration of 20 lines leads to -0.018 cm.$^{-1}$ with maximum deviations of -0.15 cm.$^{-1}$ and $+0.15$ cm.$^{-1}$.

As was shown by Mulliken,[8] to whom the interpretation of the 16–16 band is due, the line corresponding to $j' = 0$ of the P_2 branch is excluded. This line is also experimentally absent for the 16–16 and 16–17 molecules. Professor Mulliken has called our attention to a paper by Kramers[9] in which it is shown that for the oxygen molecule the wave mechanics leads to *a* single level for the state where j''_K (rotational quantum number) $= 0$, although the higher levels are triplet in character. As Mulliken points out, this excludes the line corresponding to $j' = 1$ for the R_2 branches of the 16–18 and 16–17 molecules. In the previous treatment[2] of the 16–18 band we placed the line 13,127.42 in one of these positions with the notation that the poor agreement was possibly due to a beginning state anomaly. However, it now appears probable that the above exclusion is correct. The corresponding line for the 16–17 molecule is absent. The line 13,127.42 is in fair agreement with the $j' = 2$ line of the R_1 branch for the 16–17 molecule but there is doubt as to whether this entirely explains its presence since the intensity is much greater than that of the other 16–17 lines. There is, of course, always the possibility that, like a number of other lines intermixed with the oxygen bands, it has some origin other than the oxygen molecule.

Babcock[3,10] has carried out some very accurate intensity measurements to make an estimation of the relative amount of Isotope 18. We are somewhat doubtful regarding the assumption that relative absorption can be used as an exact measure of amount, for, as previously pointed out,[2] the isotopic molecules may be slightly polar due to zero point vibration of the unsymmetrical masses. Such polarity may increase the absorption coefficients of the 18–16 and 17–16 molecules. The values obtained from intensity measurements should be maximum amounts.

It should be possible to obtain information on the question of the effect of unsymmetrical masses on the absorption coefficient in the following

manner. Since electrical dissymmetry results from the vibration of the molecule, a greater effect would be expected for greater amounts of vibration. If intensity measurements on bands resulting from a higher state of vibration were carried out, it is possible that the absence of the above effect might be demonstrated or, if it proved to be real, the data might permit a correction.

Babcock estimates that the 18–16 molecules are present to the extent of one part in 1250 and therefore that oxygen contains one part of Isotope 18 in 2500. However, as previously mentioned,[2] a factor of 2 enters into this calculation, due to the fact that the 18–16 molecules have twice as many states in which to exist as have the 16–16 molecules, thus leading to a corresponding reduction in line intensity. When this factor is considered Babcock's results lead to one part in 625 for the 18–16 molecules and the Oxygen 18 atoms are present to the extent of one part in 1250, as a maximum.

From Babcock's estimate of the relative intensity of the lines due to the 17–16 molecules, we estimate the abundance of Oxygen 17 as about one part in 10,000 as a maximum.

Oxygen of mass 17 has been reported by Kirsch and Pettersson,[11] by Blackett,[12] and by Harkins and Shadduck[13] from data obtained on collisions between alpha particles and nitrogen nuclei. One or two collisions per hundred thousand result in combination of the alpha particle with the nitrogen, forming an unstable isotope of fluorine which immediately ejects a proton and becomes Oxygen 17. Blackett assigned a life of less than 10^{-10} sec. to Fluorine 18. Blackett also showed from the time factor in his fog track experiments that Oxygen 17 had a life of at least one-thousandth of a second.

We wish to thank Professor R. T. Birge for his friendly interest in the work and for calling attention to the collision experiments leading to Oxygen 17.

Summary

A new weak band recently discovered in the atmospheric absorption of oxygen by Mr. H. D. Babcock of Mount Wilson Observatory has been explained and shows that an isotope of oxygen of mass 17, as well as the previously discovered Oxygen 18, is present in the earth's atmosphere. On the basis of accurate intensity measurements by Babcock, 18–16 molecules are present to the extent of one part in 625 and 17–16 molecules to the extent of about one part in 5000. Thus Oxygen 18 has an abun-

FURTHER EXPERIMENTAL TESTS OF THE GIBBS ADSORPTION THEOREM. THE STRUCTURE OF THE SURFACE OF ORDINARY SOLUTIONS

BY JAMES W. MCBAIN AND ROBERT DUBOIS

RECEIVED JULY 10, 1929 PUBLISHED DECEMBER 11, 1929

The present investigation was undertaken to determine by direct measurement the absolute amounts of various solutes adsorbed, or concentrated, at the air–solution interface. The experimental results throw further light on the structure of surface layers of solutions and in addition furnish data for the test of the validity of the Gibbs adsorption equations both in their strict form and in the approximate form commonly used. They fully substantiate the experimental findings of McBain and Davies[1] for the large amounts of solute transported on a moving bubble. It is now undeniable that a bubble moving through a solution actually transports far more solute than can be close packed into a monomolecular layer on its surface, and several fold greater than the amounts predicted from the classical theorem of Gibbs.

The Gibbs adsorption theorem may be expressed in the equivalent form

$$\Gamma = -\frac{\mathrm{d}\sigma}{RT\,\mathrm{d}\ln a} = -\frac{a}{RT} \times \frac{\mathrm{d}\sigma}{\mathrm{d}a}$$

or, approximately

$$\Gamma = -\frac{\mathrm{d}\sigma}{RT\,\mathrm{d}\ln c} = -\frac{c}{RT} \times \frac{\mathrm{d}\sigma}{\mathrm{d}c}$$

where a is the activity of the solute and c its concentration, R is the gas constant, and T is the absolute temperature (Γ, R and a or c being expressed, of course, in consistent units); $\mathrm{d}\sigma/\mathrm{d}c$ is the slope of the surface tension/-concentration curve at the concentration c.

These equations, particularly the last, have been used by numerous writers to calculate the surface concentrations of many substances. The results so obtained have generally been accepted with singular confidence in lieu of actual measurement and are still used as the basis of extensive deductions as to the structure of interfacial adsorption layers and of solution surfaces. It was and is of importance, therefore, that the validity of the equations should be tested experimentally. So far the evidence has been decidedly adverse. Agreement in one case cannot obscure disagreement in all others.

Previous Experimental Tests of the Gibbs Theorem.—Experimental determinations of adsorption at fluid–fluid interfaces have been made by a number of workers, and these are collected in Table I. However, as McBain and Davies have proved, none of the results obtained by earlier workers has recorded the actually much larger amounts of solute transported by moving bubbles. This is due to the fact that all the solution, even that resulting from the collapse and escape of the bubbles, was con-

tained in connected apartments. Whenever a bubble entered the apparatus, it displaced its own volume of liquid into the next compartment and simultaneously from that to the next, and so on. Then as the bubble passed on to each successive compartment, that volume of solution necessarily returned to replace it. Since the liquid within each compartment was kept well stirred by the movement of the bubbles, each of the tens of thousands of bubbles passed in any one experiment acted as an efficient pump for mixing the initial impoverished solution with that from the middle compartments and the final enriched solution. The observed change was, therefore, necessarily far less than that which actually occurred. Even so it is remarkable that in nearly every case the results were far larger than those predicted. The simple expedient of allowing the bubbles to pass into a separate vessel before they collapse removes the possibility of loss by mixing.

It is seen from Table I that results for simple non-electrolytes, p-toluidine, camphor and amyl alcohol (confirmed by Harkins and by the present work), are far in excess of those possible according to the Gibbs equation. This discrepancy is not due to use of concentration in place of chemical potential in the Gibbs formula, for in the case of p-toluidine it makes no difference whether concentration or activity is used as the basis of the calculation.[13] Many further examples are adduced in the present paper.

The picture of the surface of an ordinary solution arrived at by McBain and Davies is that of a monomolecular surface layer of oriented molecules which serve as points of support for the growth of chains of oriented molecules relatively far into the solution, such chains being evanescent, being constantly broken up by thermal vibrations and as constantly replaced. It is very interesting that Sir William Hardy should have arrived independently at the same conclusion from quite other evidence.[14]

Measurements of the Adsorption at the Air–Solution Interface.—In the present work the method of McBain and Davies[1] was used to determine the adsorption at the air–solution interface of the following substances: phenol, p-toluidine, iso-amyl alcohol, resorcinol, thymol, acetic acid, butyric acid, caproic acid, nonylic acid and sodium chloride. The surface excess (or deficiency) of each of these substances was determined over a considerable concentration range and compared (a) with the amount predicted by application of the Gibbs equation both in the approximate and in the strict form and (b) with the amount required to complete a monomolecular surface layer both for vertical and for horizontal orientation of the adsorbed molecules. The surface tension and activity data were taken from the literature.

Experimental Method

Gas bubbles were passed through an aqueous solution of the solute contained in a long, nearly horizontal glass tube of large diameter. The bubbles were caused to drain in a short vertical tube of smaller diameter and to pass over into and collapse in a descending portion of this tube. The liquid thus collected in a separate receiver contained not only the amount of solute to be found in an equal volume of the original solution but also the excess solute adsorbed on the surfaces of the bubbles. The absolute amount of this excess was determined by comparing the concentrations of collected liquid and original solution in a Zeiss interferometer. A number of values of Γ were determined successively in the course of a single experiment without interrupting the course of the bubbling. Nitrogen gas was used because of its inertness. The surface tension is considered to be the same as that at an air–solution interface.

The apparatus, shown diagrammatically in Fig. 1, consists essentially of a system S_1, S_2, S_3 for saturating the nitrogen, an "adsorption tube" CD ending in the short vertical draining tube EP and a receiver B_2.

Nitrogen from a cylinder equipped with a pressure regulator is freed from carbon dioxide present by passage through strong potassium hydroxide solution in the gas washing bottles A, A. From these it passes in a steady stream of bubbles through the saturators, S_1, S_2, S_3, where it comes into equilibrium with a solution of exactly the same concentration as that in the adsorption tube. Many blank tests of the effectiveness of this saturating system were made by bubbling gas through the apparatus in the ordinary way but keeping the liquid supply shut off so that all bubbles collapsed in the horizontal tube. In most cases no change in concentration was produced.

The mercury manometer M is connected as shown. The capillary tube K serves to regulate and steady the flow of gas through the rest of the apparatus.

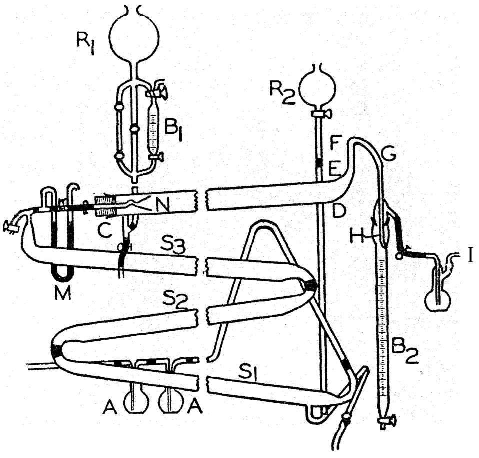

Fig. 1.—The adsorption apparatus.

A constant stream of bubbles of the same size is formed at the specially shaped bubbling nozzle N and passes slowly along the tube CD filled with a solution of the solute whose adsorption is to be determined. Here adsorption, if any, takes place at the surface of the bubbles. Each bubble finally rises through the tube EF, where it joins a column of nearly cylindrical, rapidly draining films, which are continually passing over the bend at F and being replaced from behind. The appearance of this column of films is shown in Fig. *2*. The time required for passage along the tube CD is about twelve seconds, for the tube EF about one and one-half seconds.

The films with their adsorbed surface layers collapse in the descending tube FGH, and the liquid from these collects in the receiver B_2, which is a 100-cc. buret attached to

GH by a ground-glass connection and equipped with a large-bore glass stopcock for rapid emptying. The nitrogen released by collapse of the bubbles leaves the apparatus at I and passes through a gas meter (Boys bell meter). The end of the tube GH was beveled and bent so as to touch the side of the buret. The effect of this detail was to cause the complete collapse of any films which had reached this orifice still unbroken. The end of the buret outlet was cut off close to the stopcock to reduce the amount of liquid remaining in this part.

The reservoirs, R_1 and R_2, are for supplying liquid to the adsorption and the saturating tubes, respectively. The means of emptying the apparatus are shown in the drawing.

DIMENSIONS OF THE APPARATUS

Tube	CD	EF	S_1, S_2, S_3
Inside diameter, cm.	2.5	0.86	1.8
Length, cm.	156	8	120
Slope, %	4–8	Vertical	8

Procedure

At the beginning of each new study the entire apparatus and all glassware to be used were cleaned thoroughly with hot H_2SO_4–$K_2Cr_2O_7$ mixture and rinsed repeatedly with distilled water. The aqueous solutions were made up in most cases with boiled out distilled water and a fresh solution was used for each experiment except in the first and the last few runs, in which cases the solution was carefully protected after use and remixed for the next experiments.

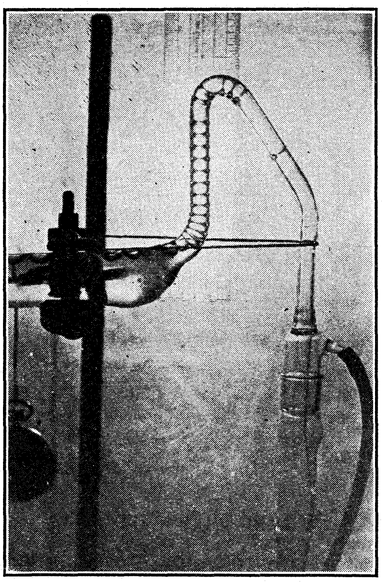

Fig. 2.—Detail of adsorption apparatus.

The adsorption apparatus and the collecting bottles were rinsed with the solution and the entire apparatus was filled. Bubbling was then started and the time noted. The bubble rate and the supply of liquid from reservoir R_1 were adjusted until a stable column of cylindrical films was formed in the draining tube EF and passed over unbroken into the descending tube FGH. During this time collapsed film liquid was allowed to run out of the buret and was not collected.

The adsorption experiment proper was started by closing the stopcock of the receiver-buret, and time and meter reading were noted. After any desired amount of liquid had collected in the receiver, the time was noted, the meter read and the collected liquid run out into a weighed, stoppered bottle. The collection of samples of collapsed film liquid was repeated as many times as desired in exactly the same way, and independent values of Γ were calculated from the separate sets of data. At the close of the run the liquid remaining in the adsorption tube was withdrawn and its concentration compared with that of the original solution. The total change in concentration (usually a loss) was distributed over the whole period of the run, and the observed concentration changes in the samples of collected film liquid were recalculated with reference to the mean concentration of the solution with which the bubbles were in contact at the time of collection.

Analysis of Solutions.—The analysis was made with a Zeiss interferometer for liquids. The following table shows the calibration equivalents for 1° determined in grams per cubic centimeter.

TABLE II

INTERBEROMETER CALIBRATION EQUIVALENTS[a]

	Value of 1 division in g./cc. X 10^6		
Substance	2-cm cell	4-cm. cell	8-cm. cell
Phenol	4.2	(2.0)	
p-Toluidine	3.18	1.54	(0.73)
Iso-amyl alcohol		3.93	1.91
Resorcinol		1.9	(0.91)
Thymol			1.14
Acetic acid		5.74	
Butyric acid		1.63	
Caproic acid		4.00	
Nonylic acid		2.18	
Sodium chloride		2.35	
Menthol			3.3

[a] Numbers in parentheses were calculated in each case by multiplying the actually determined calibration value for another cell (in terms of the same substance) by the ratio of the calibration values of these two cells for a different substance. For example, 1 division (4-cm. cell) = 2.0×10^{-6} g./cc. of phenol = $4.2 \times 10^{-6} \times 1.54/3.18$ (ratio from *p*-toluidine calibrations).

In the analysis great care was taken to ensure freedom from external contamination, to prevent evaporation changes and to secure uniformity of temperature—precautions especially necessary because the interference bands by which the comparisons are made are very easily distorted and shifted by small temperature inequalities in the solutions being measured and because the concentration changes observed were, at the most, very small relative to the total concentration of the solutions used.

Calculation of Results

The adsorption Γ is the absolute excess of solute transported on the bubble surfaces divided by the total adsorbing surface and is expressed in this paper in grams per square centimeter $\times 10^{-8}$.

$$\Gamma = \frac{1^\circ \times r \times V_c \times S_c^m}{2V_g + 2\pi r^3 B}$$

where V_c is the volume of solution collected, determined by weight, assuming unit density; S_c^m is the change in interferometer readings corrected with reference to the mean concentration of the solution during its collection; V_g is the volume of gas and B the number of bubbles passed during the collection of one complete sample. It is assumed that each bubble is a cylinder of radius 0.43 cm. At least 100 sq. cm. of bubble surface should pass over for each cubic centimeter of collapsed liquid collected; that is, the effective depth of the surface studied should not exceed 0.1 mm.

On account of the great difficulty of counting visually the number of bubbles when the rate was high (usually over 200 and frequently 300 to 400 a minute) an automatic, electrical apparatus was devised for the purpose (Fig. 3). By this means the total number of bubbles passing could be determined directly and with accuracy, and observations of duration and bubble rate were no longer necessary for the final calculation.

In Fig. 3 CB is a detail of the adsorption tube showing the bubbling nozzle equipped with a circuit breaking device which consisted of two platinum wires sealed into glass tubes on opposite sides of the nozzle and arranged so that the protruding tips of the wires extended vertically up into the path of the bubbles leaving the nozzle. As each bubble passed, the platinum points pierced it (without affecting its stability) and thus became separated by a non-conducting gaseous gap.

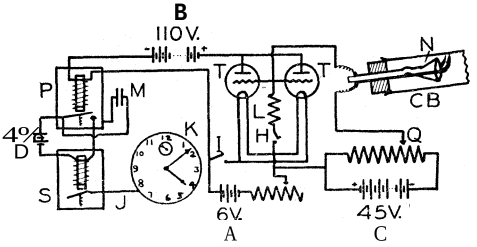

Fig. 3.—The electrical bubble counter.

The circuit breaker was inserted in the grid circuit of a three-electrode vacuum tube. Power amplifier tubes T,T were used of such characteristics that a normal plate current of about 30 milliamperes flowed when the plate voltage B was 110 volts, the filament voltage **A 6** volts and the grid voltage zero. By means of a voltage divider circuit Q connected to a 45-volt dry battery C the optimum (negative) voltage could be applied to the grid. The negative terminal of the C battery was connected through the circuit breaker to the grid (positive terminal to filament). The negative voltage thus applied reduced the plate current to zero, and because of the rectifying action of the tube no current flowed through the grid circuit and so *no electrolysis took place in the solution.*

When a bubble passed over the platinum points and broke the circuit, the grid charge was immediately dissipated through the grid leak I, (2 megohms), and the full current passed through the plate circuit of the tube. In order to double the amplification effect the two power tubes T,T were connected in parallel and their plate currents were fed through a single circuit.

A 150-ohm telegraph relay P was inserted in the plate circuit with suitable capacity across the points (2 mfd. condenser M). The secondary terminals of this relay were connected in series with a circuit composed of a 4-volt source of direct current D and a 20-ohm telegraph relay S.

A clock K was used as a mechanical counting device. After removal of hair spring and balance wheel the escapement lever was connected through J to the armature of relay S, whose movements therefore actuated the escape wheel movement. Two readings of the "apparent time," translated into seconds and multiplied by 2 (gear ratio of escape wheel to seconds wheel), gave the total number of bubbles which had passed during the interval.

The counter works best with solutions of low conductivity. When the conductivity becomes large, a conducting film of liquid is left on the surface of the platinum wires and the glass tubes during the passage of the bubble, and the grid circuit is thus continued down the outside of the wires and across the solution at the surface of the bubble.

Thymol C. P. from Coleman and Bell and Eastman caproic acid were used, Kahlbaum caproic acid being apparently less pure and giving a lower value. The other chemicals were the best obtainable from Kahlbaum. *p*-Toluidine was further purified by sublimation and this doubled the amount of sorption, making it the same as that found by McBain and Davies.

To save space the results are given only as points on the graph but each of these points is the mean of at least five and in many cases more experiments. The value of Γ for 3.0 g. of iso-amyl alcohol per liter is the mean of 129 measurements and is 11.0×10^{-8} as compared with the predicted Gibbs value 3.0×10^{-8}.

Negative adsorption was demonstrated in the experiments with aqueous sodium chloride, for which Harkins and McLaughlin[15] and Goard and Rideal[16] had simultaneously predicted from activity data a negative sorption approximately equivalent to the complete absence of sodium chloride from the first layer of water molecules on the surface. At first sight these experiments would seem to be impossible since stable bubbles or films will not rise from strong solutions of sodium chloride. However, it was discovered in experiments with caproic acid that with our apparatus it made very little difference to the results if the films were broken before

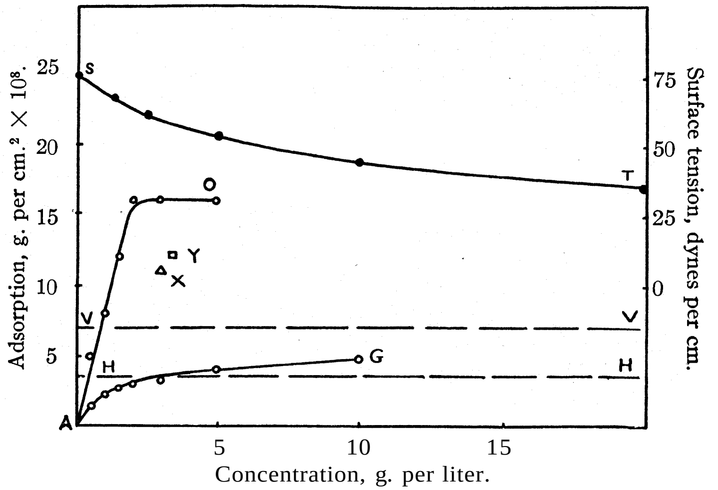

Fig. 4.—Adsorption of amyl alcohol. ST, Surface tension (15°) according to Edwards;[17] AO, adsorption observed by McBain and Davies;[1] X, adsorption observed by writers (mean of 129 measurements); Y, adsorption observed by Harkins and Gans;[12] AG, adsorption calculated (25°) by Gibbs concentration formula; VV, monomolecular adsorption (vertical orientation); HH, monomolecular adsorption (horizontal orientation).

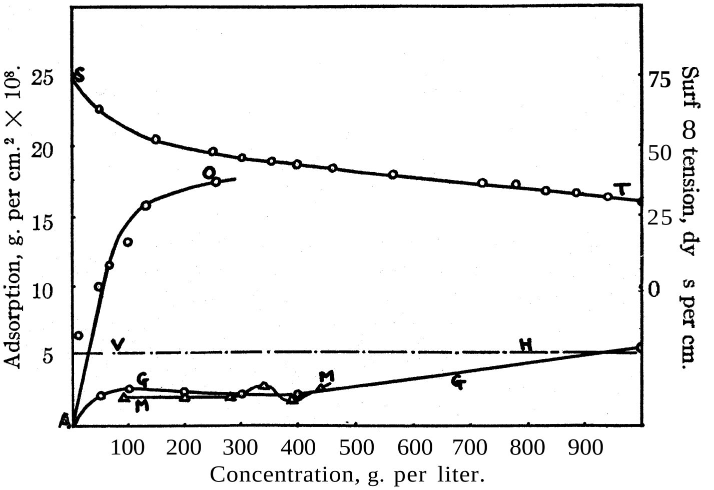

Fig. 5.—Adsorption of acetic acid. ST, surface tension according to Whatmough;[18] AO, adsorption observed; AGG, adsorption calculated by the Gibbs concentration formula (25°); MM, adsorption calculated by Milner[2] from same data and formula; VH, monomolecular adsorption (vertical or horizontal orientation).

---

[17] P. R. Edwards, J. *Chem. Soc.*, 127, 744 (1925).

[18] W. H. Whatmough, *Z. physik.* Chem., 39, 129 (1902).

passing over the bend, provided that a steady flow of liquid slightly larger than usual was allowed to pass over continuously. Using this device the actual deficiency of salt in the liquid flowing over was four to eight times larger than that predicted by the Gibbs equation.

Comparison of **Observed,** "Gibbs" and Monomolecular Adsorption.—Inspection of the curves, Figs. 4 to 13, shows that the adsorption calculated from the approximate (concentration) Gibbs equation increases rapidly with concentration, attains a maximum while the solution is yet fairly dilute and the surface tension is still decreasing, and then drops in a way for which it would be difficult to account on a physical basis. The effect of using the exact equation involving activity, as is shown in the graphs, makes but little difference for the lower concentrations of the simple substances we have selected for study, but it frees the curves from the anomalous decrease in concentrated solutions.

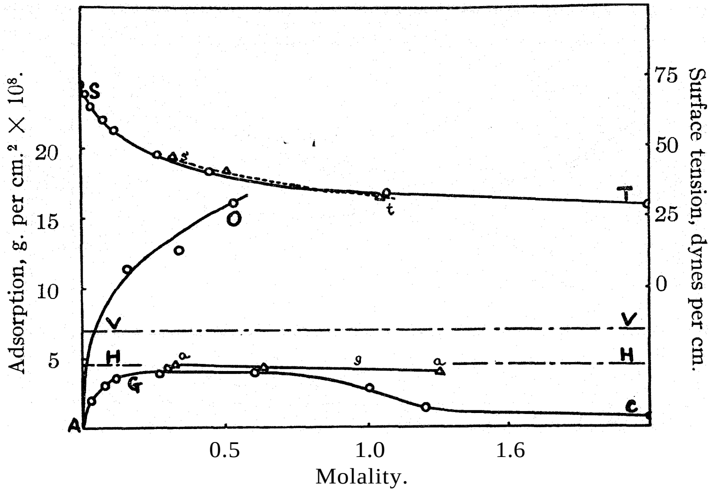

Fig 6.—Adsorption of butyric acid. ST, surface tension (25°), according to Drucker,[19] plotted against molality; ST, surface tension plotted against activity on same scale as molality; AO, adsorption observed; AGC, adsorption calculated *(25")* by Gibbs concentration formula; aga, adsorption calculated (25") by Gibbs activity formula (activity data from Rury);[20] VV, monomolecular adsorption (vertical orientation); HH, monomolecular adsorption (horizontal orientation).

It should be pointed out that "Gibbs" adsorption is not, as commonly supposed, necessarily identical with monomolecular adsorption, although the number of times the maximum "Gibbs" value approximates either one or the other of the monomolecular values is indeed suggestive of a physical reality for the calculated quantity which may be more than fortuitous.

[19] K. Drucker, Z. *physik. Chem.,* 52, 641 (1905).

[20] C. R. Bury, *Phil.* Mag., [7] 4, 980 (1927).

However, the large number of experimental results obtained by McBain and Davies and in the present work indicate very strongly that the Gibbs equation does not supply real values. Of the ten substances investigated in this Laboratory, eight have been found to be adsorbed in amounts which are from two to eight times that predicted by the Gibbs theorem. The plotted curves show this very strikingly. A possible explanation of the relatively lower results obtained with thymol and nonylic acid is given below.

The amounts found to be adsorbed are from two to four times the quantities which could be accommodated in a monomolecular surface layer of vertically oriented molecules with even the closest packing ever observed in condensed films of related compounds. The adsorption effect must, therefore, extend beyond one molecular dimension and the results support McBain's suggestion[1] as to the structure of adsorbed layers at solution surfaces.

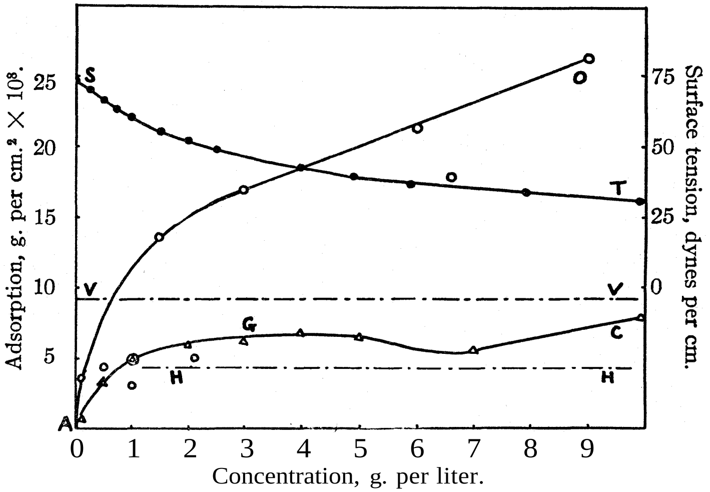

Fig. 7.—Adsorption of caproic acid. ST, surface tension (19°) according to Szyszkowski;[21] AO, adsorption observed; AGC, adsorption calculated (25°) by Gibbs concentration formula; W, monomolecular adsorption (vertical orientation); HH, monomolecular adsorption (horizontal orientation).

Discussion

These moving surfaces carry several times more solute than is compatible with the equation of Gibbs, and yet nearly all the experimental errors would seem to be operating so as to prevent the full real adsorption from being shown. Satisfactory blank tests have shown that the obvious experimental errors, such as incomplete saturation of the gas, have been

---

[21] B. von Szyszkowski, *Z. physik. Chem.*, 64,385 (1908).

eliminated. The following effects would tend to counterbalance part of the true adsorption: (a) traces of contamination or impurity, such as a trace of grease from the stopcocks; (b) the frictional resistance to the movement of the cylindrical walls of the drained bubbles, as discussed by McBain and Davies (in the present work the ratio between radius and length was always between 0.6 and 1.0); (c) if the bubbles were spheres instead of true cylinders, all recorded results should be increased by 10%; (d) the shortness of time (about sixteen seconds) allowed for adsorption to occur; (e) the rubbing of the bubble against the liquid would tend to strip off the more loosely held molecules and chains so that the dynamic surface would sorb less than a motionless static one.

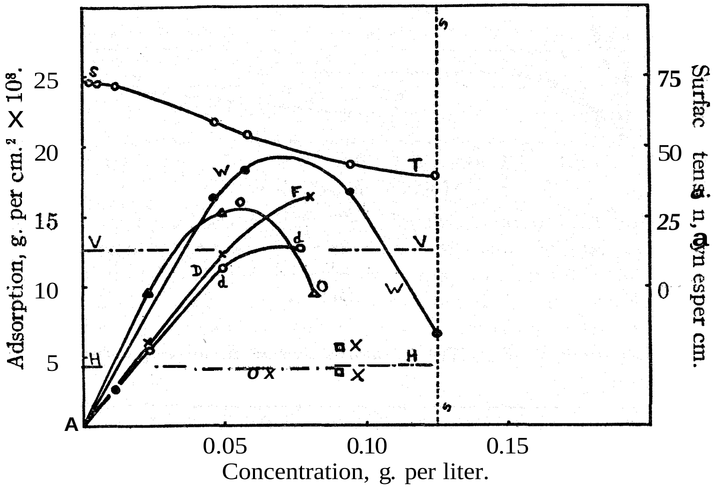

Fig. 8.—Adsorption of nonylic acid. ST, surface tension (18°) according to Forch;[22] AOO, adsorption observed by Donnan and Barker;[4] X, adsorption observed by the writers; ADF, adsorption calculated by Donnan and Barker by Gibbs concentration formula from Forch's S. T. data; Add, adsorption calculated by Donnan and Barker from own S. T. data; AWF, adsorption calculated by writers from Forch's S. T. data; VV, monomolecular adsorption (vertical orientation); HH, monomolecular adsorption (horizontal orientation); ss, saturated solution.

The ad *hoc* assumption has been made in several quarters that adsorption of the substances we have used is quick and desorption abnormally slow, although there is no evidence whatever for this assumption. The idea is that the moving bubble could thus accumulate an undue excess of material in its rear. However, closer examination of the processes of diffusion involved in adsorption renders this assumption less attractive. The extent of the Gibbs adsorption is entirely conditioned by the rate at which

[23] E. R. Jones and C. R. Bury, *Phil.* Mag., [7] 4,841 (1927).

the solute molecules diffuse into the depleted portions of the solution in more immediate contact with the bubble. An instantaneous adsorption would be zero adsorption according to the Gibbs definition. This

[24] W. D. Harkins and E. H. Grafton, This Journal, 47,1330 (1925).

diffusion rate is proportional to the difference in concentration between the solution in this region and that in the bulk phase. In very dilute solutions, in addition to smaller diffusion rate, the molecules have to diffuse from a far greater distance to supply the absolute amount of material adsorbed at the surface, and one would therefore expect low results with such solutions as those of thymol and nonylic acid. However, the practical effect of setting up the ad *hoc* assumption referred to is to discard all measurements made by the dynamic method, and there are no others that have been satisfactorily substantiated. The present custom of using the Gibbs theorem instead of experiment seems decidedly artificial.

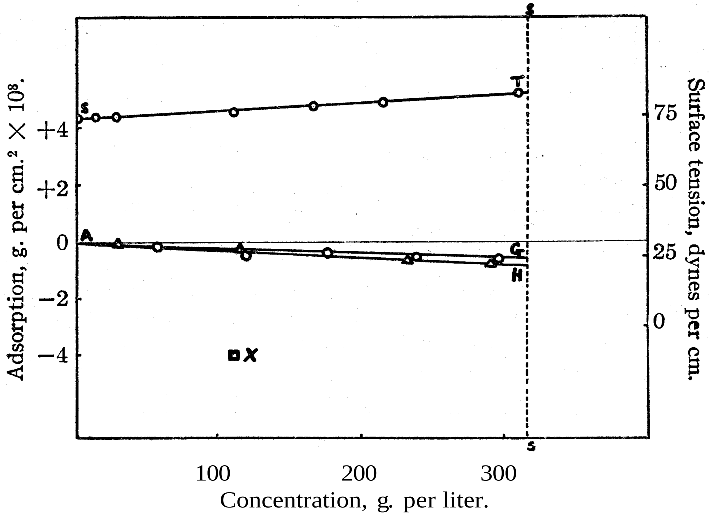

Fig. 13.—Negative adsorption of sodium chloride. ST, surface tension according to "International Critical Tables," Vol. IV, p. 465; AG, adsorption calculated by Goard[25] from the activity formula; AH, adsorption calculated from data of Harkins and McLaughlin[15] based on activities; X, adsorption observed; ss, saturated solution.

We are seeking a decision by the use of static surfaces, and the preliminary measurements with several substances indicate an even greater adsorption and therefore a greater discrepancy between experiment and either the treatment of Gibbs or the limited adsorption corresponding to a monomolecular film.

Further communications will deal with such experiments and with a discussion of the electrical terms ignored in the Gibbs equation.

Summary and Conclusions

1. The method of McBain and Davies has been used to measure the adsorption at the surface of solutions of *iso*-amyl alcohol, acetic, butyric,

[25] A. K. Goard, J. *Chem. Soc.*, 127, 2451 (1925).

caproic and nonylic acids, phenol, *p*-toluidine, resorcinol, thymol, camphor and sodium chloride.

2. When a bubble passes through a solution of a simple substance, it carries with it from 2 to 8 times as much of the solute as is predicted by the Gibbs adsorption theorem either in its exact or in its approximate form. The amounts carried are from 2 to 4 times that which can be accommodated in a monomolecular film of closely packed, vertically oriented molecules.

These findings fully substantiate those of McBain and Davies and support the views of McBain and of Hardy as to the constitution of surfaces of ordinary solutions.

THE PHOTOCHEMICAL DECOMPOSITION OF BENZOQUINONE IN WATER AND IN ALCOHOL

BY PHILIP ALBERT LEIGHTON AND GEORGE SHANNON FORBES

RECEIVED JULY 24, 1929 PUBLISHED DECEMBER 11, 1929

Parabenzoquinone, stable in the solid phase, can be photolyzed in alcohol or water solutions. In alcohol the products are acetaldehyde, hydroquinone and a third more complex product.[1] In water hydroquinone and a larger amount of the complex product are formed. Hartley and Leonard[2] found for the complex product approximately the formula of a dimer.

A similar photochemical decomposition of quinone in ether, glycerin, benzaldehyde, acetaldehyde, toluene, carbon tetrachloride and other solvents has been reported.[3]

Hartley and Little[4] made a qualitative study of the quinone photolysis, and a number of measurements of the absorption spectra of quinone solutions have been made[5,2] chiefly with reference to theories of the structure of the quinone "chromophore."

The absorption spectrum of quinone between 2000 and 6000 Å. consists of three bands or regions, which Light, from an analysis of the vapor spectrum, holds to be due to different electronic states of excitation.

Lifschitz, from a study of the effect of substitution on the absorption spectrum, attributes the visible band to electrons belonging to the central carbon atoms in the conjugated quinone ring, and the first ultraviolet band to electrons belonging to the oxygen atoms.

We have carried out a critical quantitative study of this photolysis, varying wave length and the several concentrations. A second paper will deal with the effect of temperature and of various substituents.

The light source was a quartz mercury vapor arc designed to combine as fully as possible the long life of large diameter arcs with the high intensity of the constricted arc.[6] The legs of an inverted U, 6 mm. in internal diameter, dipped into mercury reservoirs left open to the atmosphere. A 5-cm. capillary, nearly filled with an iron wire, attached to each arm of the U rendered oscillation negligible. The electrodes were water cooled, and by adjusting the relative heights of water and electrode surface, mercury transfer was neutralized. Running on 3 amperes at 12 volts per cm. the radiation flux could be kept constant within 1% by taking readings once an hour.

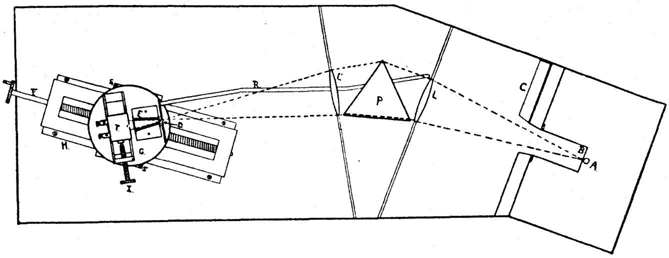

Fig. 1.—The monochromator.

The monochromator, illustrated by Fig. 1, included a fused quartz prism, P, 9.5 cm. along the base and 6.4 cm. high, and two fused quartz lenses, 6.4 cm. in diameter and 25 cm. in focus for λ3030 Å. The lamp A and collimating slit (1.2 by 30 mm.) were fixed with relation to the prism and lenses. The exit slit D (1 by 21.5 mm.) together with trapezoidal cell E and thermopile T were mounted on the table G which could be moved along the focal plane by the screw F and was kept perpendicular to the light beam by the pivoted rod R.

The energy fluxes normally obtained at the exit slit as it was moved along the focal plane were of the following order

Wavelength, mm.	1014	577	435	406	366	313	302	280	270	254
Intensity in ergs./sec. mm.^{2}	325	910	490	360	900	610	420	100	150	99

The thermopile, constructed by one of us, was of bismuth–silver, with 20 couples. The galvanometer, of sensitivity 14.6 mm. per microvolt, was mounted on a heavy Julius suspension. An energy flux of 1.00 erg./sec. mm.^{2} produced a deflection of 1.5 cm. on a scale 5 meters distant. Shunt and series combinations were necessary for many readings. The thermopile was calibrated with two standard carbon lamps

---

[6] Forbes and Harrison, J. Opt. *Soc. Am.*, 11, 99 (1925); THIS JOURNAL, 47, 2449 (1925).

C39 and C40 certified by the Bureau of Standards. Experiments showed that the deflection obtained was not linearly proportional to the energy flux, and that it varied with the position of the mirror (that is, the portion of the scale covered). Accordingly, the galvanometer was adjusted so that the low or zero point of the swing always fell at or near the same point on the scale, and the calibration was extended to cover all possible deflections.[7] Three to five readings, using the ballistic method, were taken and averaged for each measurement.

The height of the focal plane slit, D, and the volume of liquid in the cell were so adjusted that the emergent beam as it fell on the thermopile was exactly the height of the sensitive column. Then by moving the thermopile across the beam by means of the screw I, taking readings at **2** mm. intervals, the entire beam was covered and the energy integrated as twice the sum of these readings ($2\Sigma B$) after the method of Villars devised in this Laboratory.[8] These values agreed to within 0.5% with those obtained by taking readings every mm. This method assumes that the thermopile itself integrates correctly the energy falling on it from top to bottom. The thermopile could be substituted for the cell when desired, in order to measure the relative incident intensity. By repeating this process at suitable intervals during an experiment, the integrals of the energy, incident and absorbed, could be built up.

Several absorption cells, differing in depth and volume, were used. They were covered to prevent evaporation, and so that oxygen could be excluded when desired.

In this reaction the photosensitive substance, quinone, is used up in known amount, with the formation of absorbing products. In addition, the solvent itself may absorb. The method devised takes account of these features.

The decomposition of quinone was followed by iodimetry, The calculation of the light absorbed by the undecomposed quinone was complicated through absorption by the solvent and also by the increase in strongly absorbing reaction products.

Ethyl alcohol was purified by the following steps: (1) allowed to stand over calcium oxide, then distilled; (2) 25 cc. of 12 N sulfuric acid added per liter of alcohol, the mixture refluxed several hours, then distilled; **(3)** 20 g. of potassium hydroxide and 10 g. of silver nitrate added per liter of alcohol, the mixture refluxed and distilled; (4) dried a second time over calcium oxide, this time being filtered before distillation. A one-centimeter layer of this alcohol transmitted 88% of λ2700.

Alcohol purified by addition of iodine[9] was found to fluoresce visibly in the shorter ultraviolet, so this method was not used.

The quinone used was purified by three successive sublimations, using the lowest possible temperature. Quinone was determined by the method of Valeur,[10] that is, adding an excess of hydriodic acid at 0° and titrating the liberated iodine with thiosulfate, using starch indicator, and excluding oxygen by bubbling carbon dioxide or nitrogen through the flask.

The quinone solution to be studied was made up fresh at the start of each experiment, and equal portions were pipetted into two similar cells, one of which was kept in the dark and the other exposed. At first the solution was stirred occasionally with a fine quartz rod during exposure. Later **a** mechanically driven stirrer was inrroduced, and all solutions were kept in an atmosphere of nitrogen at all times.

Integrations of emergent energy, $2\Sigma B$, and the corresponding relative incident intensity, ΣF, were made during each experiment on (a) cell plus water, (b) cell plus solvent, (c) cell plus solution before exposure and (d) cell plus solution after exposure.

[7] G. S. Forbes, J. Phys. *Chem.*, 32,481 (1928).

[8] Villars, THIS JOURNAL, 49, 330 (1927).

[9] Henri and Castille, Bull. *soc. chim. biol.*, *6*, 299 (1924).

[10] Valeur, *Ann. Chem.*, 21,470 (1900).

Also, F readings were made at intervals during the exposure. The time which the solution was exposed in obtaining the energy readings was added to the time of the main exposure. The variation in intensity across the beam as well as from front to back of the cell makes necessary the unreserved assumption of the reciprocity law.

The corrections for reflection by the quartz faces were applied as in the work of Villars,[8] taking account both of the change in n with wave length and of the small deviation from normal incidence of the edges of the beam.

If we let $\Sigma F_{H_2O}/\Sigma B_{H_2O} = K$, it can be shown readily that the reflection correction cancels out and for any absorbing solution the fraction of the light transmitted, compared with the transmission of pure water as 1.00, is

$$L = \frac{\Sigma B_{\text{soln.}}}{\Sigma F_{\text{soln.}}} \times K \tag{1}$$

From the laws of Lambert and Beer it can be shown[11] that

$$Q = (1 - L)\frac{\log L - \log I}{\log L} \tag{2}$$

and

$$Q' = (1 - L')\frac{y(\log L - \log I)}{\log L'} \tag{3}$$

where Q and Q' are the calculated fraction of light absorbed by the quinone only, before and after the reaction, respectively; L and L' are as defined above for the solution before and after the reaction, respectively. As several different cells were used, these values cannot be compared without additional data not included here. I is the light transmitted by pure solvent compared with that transmitted by water as 1; y is the fraction of the original quinone remaining after the exposure.

Lacking a mathematical integration which would give the fraction, Q_m of the total incident energy of the exposure which was absorbed by the quinone alone, we found by experiment that

$$Q_m = \sqrt{QQ'} \tag{4}$$

very nearly. The total incident energy in ergs incident on the solution during the entire exposure is given by

$$E_{\text{total}} = \frac{2(\Sigma F_{\text{av}}S)}{(1 - r)K} \tag{5}$$

where ΣF_{av} is the average between each two successive F readings taken during exposure; S is the exposure in seconds between those same two readings; r is the fraction of the incident light reflected by a quartz wall (both faces).

In calculating ergs absorbed by the quinone from this, a small correction is made for the light reflected back into the solution from the rear face. The mean fraction so reflected is given nearly enough by $0.056 \times (L + L')/2$.

---

[11] Luther and Weigert, *Z. physik. Chem.*, **53**, 408 (1905).

Assuming that the same fraction, Q_m, is absorbed as was absorbed in its first passage through the solution, we obtain

$$\text{Total ergs absorbed by quinone alone} = E_{\text{total}}\, Q_m\, [1 + 0.028(L + L')] \tag{6}$$

From this the photochemical efficiency

$$\Phi = \frac{\text{Molecules reduced}}{\text{Quanta absorbed}} = \frac{Nh\nu\ Vx}{1000Q_m\,[1 + 0.028\,(L + L')]E_{\text{total}}} \tag{7}$$

where V is volume of reaction mixture in cc., and x is molal concentration of quinone disappearing during exposure. Now setting A equal to the original molal concentration of quinone, i = absorption coefficient of solvent, q = absorption coefficient of quinone, \$ = absorption coefficient of products (all absorption coefficients given are exponents of the base ten), d = length of path of light beam in cell, in cm., and $E_{\text{total}} = E_0S$, where E_0 is incident intensity in ergs/sec. Equations 1–7 give the following general equation for @.

$$\Phi = \frac{Nh\nu\ Vx}{1000E_0Sq\sqrt{\dfrac{(1 - 10^{-(ic + qA)d})\,(1 - 10^{-(ic + q(A-x) + px)d})\,(A - x)A}{[ic + qA]\,[ic + q(A - x) + px]}}}$$

In the shorter wave lengths water itself becomes an appreciable absorbent.[12] This affects both absorption coefficients and absolute energy measurements. The absorption coefficients of quinone for those wave lengths were so much greater than those of water that the correction was inappreciable, but the absolute energy measurements, being taken as the light *transmitted* by pure water, were in error by the amount which the water absorbed. Accordingly, E_{total} was multiplied by the following factors, calculated from Kreusler's data

λ	1.06-cm. cell	8.27-cm. cell
2537	1.029	1.093
2700	1.025	1.078

Any hydroquinone formed by the reaction combines with more quinone to form quinhydrone. The method of calculating classes absorption by quinhydrone with that of the products and disregards the possible removal of quinone as quinhydrone. Assuming that quinone so removed is rendered completely inactive, that all the quinone reduced goes to form hydroquinone, and using the dissociation constant of Luther and Leubner[13] for quinhydrone, it is found that the calculated values for quantum efficiency would be from 1 to 5% too low, depending on the amount of quinone reduced.

We constructed a quartz spectrograph of 60 cm. focal length, and obtained upon each plate used spectrograms of the light transmitted by our absorption cells with and without solute. The characteristic curve of

---

[12] Kreusler, *Ann. Physik*, 6,421 (1901).

[13] Luther and Leubner, J. *prakt.* Chem., 85,314 (1922).

each of these plates was derived from additional spectrograms made upon it with calibrated blackened wire screens in constant irregular motion. The plates were measured up by using a photometer similar to one described by Harriscn but constructed by us. We are grateful for valuable suggestions offered by Professor Harrison during the measurements. Absorption coefficients were in good agreement. The absorption coefficients of potassium nitrate solutions measured on our monochromator agreed within experimental errors with those obtained by von Halban and Ebert,[14] thus checking our procedure.

Experimental Results

1. Preliminary.—The velocity of the dark reaction is indicated by Table I. In alcohol solution, A3680 is much more strongly absorbed by the products than any other wave length. Addition of 5% hydroquinone actually decreased the absorption of λ3660 by about 2%, so the increase cannot be due to quinhydrone formation.

TABLE I

DARK REACTION

Time,	Relative oxidizing power			Time,	Light absorbed, %		
	In alcohol		In water		In alcohol		In water

TABLE II

TEMPERATURE COEFFICIENT OF DARK REACTION

	Period 20–30°
Calcd. from slope of dx/dt curve	2.8
Calcd. from k ior 1st order reaction	3.0
Calcd. from k for 2nd order reaction	2.9

Measurements of the dark reaction velocity were also made at 20 and 30°, and the temperature coefficient of the velocity calculated (Table II). Assuming $\Delta k_{10°} = 2.9$ for the interval 20–30°, the corresponding activation energy (using Arrhenius' equation) is 18,750 cal. This does not correspond to any of the vibrational periods in the band spectrum as analyzed by Light.[5]

The effects of dissolved substances on the reaction velocity are summarized in Table III. Oxygen retards the light reaction rate slightly in water, more in alcohol. Acids greatly retard the light reaction in water, but accelerate it slightly in alcohol. The dark reaction is much accelerated in alkaline solutions, but the light reaction is retarded.

---

[14] Von Halban and Ebert, *Z. physik* Chem , 112,331 (1924).

TABLE III

EFFECT OF DISSOLVED SUBSTANCES

Dissolved substance	Percentage decomposed, time constant			
	Water in light	Alcohol In light	Alcohol In dark	Alcohol Difference
None (N_2)	27.0	29	0 8	28
Satd. O_2	24 5	17	6	16
0.012 *M* H_2SO_4	13 0	31	0	31
.012 M H_3PO_4		32	.5	32
012 M HCl	2 0	38	4 0	34
.012 M NaCl	8 0		..	
.012 M Na_2SO_4	21 0		..	..
012 M $NaC_2H_3O_2$		38	11 0	27
.012 M NaOH	..	81	70	11

As the products of the dark reaction absorb much of the light, it may be that the actual light reaction is not affected by alkali.

The data in Table IV indicate that quinone is the absorbent sensitive to light, and that the alcohol and the reaction products are "dark" absorbents; also that the reaction proceeds at a constant rate with respect to time.

2. Quantitative Measurements in Pure Water.—See Table V and Graph 1. The presence of an induction period is indicated by Graph 1. The slope of the curves at any point represents the quantum efficiency, Φ, at that point. Removal of oxygen increases the reaction rate evenly over the entire range. One run only at 17° and one at 19°, compared with analogous runs at 25°, show a temperature coefficient of $\Delta k_{10^\circ} = 1.03 \pm 0.08$. This point is being further investigated.

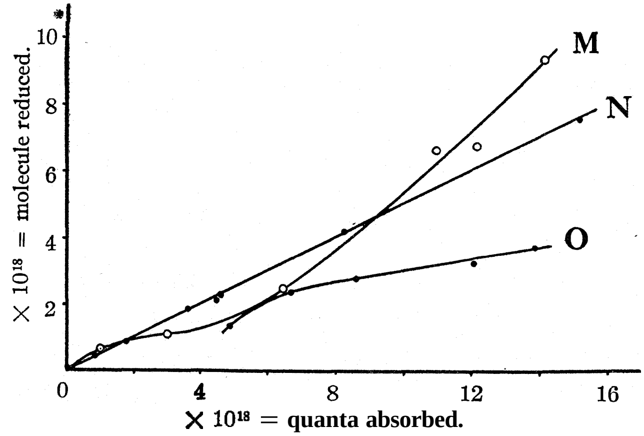
In one experiment the exposure was allowed to proceed long enough to have received the full effect of the inhibition, then interrupted for fifteen



M, water, λ2537; N, alcohol; O, water, λ4350.

Graph 1.—Comparison of reaction rate in water and alcohol.

hours and continued. The result was exactly the same as obtained with an uninterrupted exposure, showing that the cause of the inhibition is something inherent in the solution.

3. Quantitative Measurements in 50% Ethyl Alcohol.—Shown in Table VI. As indicated by Graph 1, the induction period found with water has disappeared. For all runs made in air the quantum efficiency decreases as the percentage of quinone reduced increases, and it becomes necessary to extrapolate back to zero reduction to get a true value of Φ. When oxygen was excluded, Φ was within limits of error independent of the amount reduced. The efficiency is also independent, within the range measured, of the original quinone concentration, and for wave lengths from 4350 to 2537 Å., independent of the wave length. Over this region Φ (extrapolated back to zero reaction for those experiments in air) averages, within limits of error, very close to 0.50. A definite threshold region is indicated by the decrease in efficiency above 4350 Å.

4. Quantitative Measurements in Absolute Ethyl Alcohol.— Shown in Table VII. All were made in an atmosphere of nitrogen. As with 50% alcohol, the quantum efficiency is independent of wave length below λ4350 Å. The average for this region is 0.49. It drops off in λ5460, exactly as in 50% alcohol. The probable error of a single determination is ±0.05.

Discussion

The reaction in water differs from the reaction in alcohol. In water, at the start, when the inhibitive effect is a maximum, light produces little reduction of the quinone, yet the absorption coefficient of the solution increases sharply, showing that some change, not detectable by our method of analysis, is occurring.[2] The increase in absorption during the induction may be due to formation of the dimer postulated by Hartley and Leonard.[2]

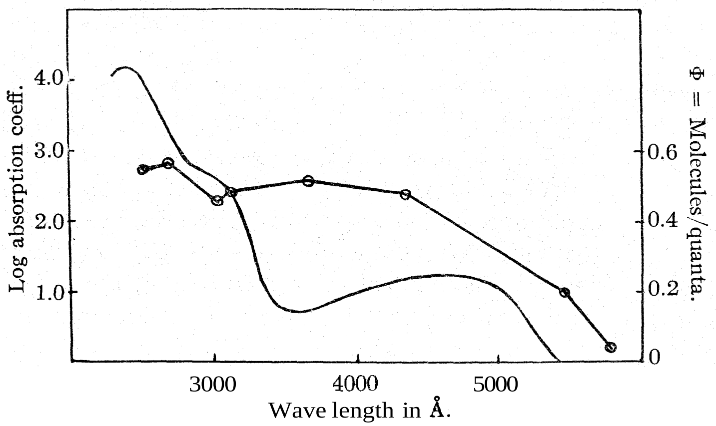
Beyond the induction period, the efficiency, as indicated by the slopes in Graph 1, becomes constant at about 0.16 for λ4350 and 0.9 for λ3660 and 2537. This indicates either a change in efficiency with wave length or else a threshold between λ3660 and 4350. In alcohol solutions the threshold is definitely between λ4350 and 5460, that is, it is displaced toward longer wave lengths by addition of alcohol.

In this regard, Light,[5] in the vapor spectrum, observed a disappearance of fine structure at about λ3100, which is in the second absorption band (attributed to oxygen electrons). According to the ideas developed by Henri this indicates a predissociation or activation which in the presence of a suitable acceptor can produce photochemical reaction. In both water and alcohol solutions, the point at which the molecule becomes sufficiently activated to react is displaced toward longer wave lengths, in fact, into the first absorption band. Light's measurements indicate an incipient disappearance of fine structure at about λ4500 in the first absorption band, which apparently corresponds with the photochemical threshold in alcohol solutions.

It becomes of interest to compare the photochemical efficiency at different wave lengths with the absorption spectrum in absolute alcohol,[5] (Graph 2). The threshold is clearly inside the first absorption band. The efficiency reaches its constant value (within limits of error) at λ4350 *and* remains *at this value into and clear through the second absorption band.*

These two bands probably represent absorption in two parts of the molecule, certainly two different electronic excited states, yet the quantum efficiency of the reaction produced is the same throughout.

The value of 0.5 for the efficiency recalls Weigert's[15] explanation of the same yield for nitrobenzaldehyde as due to the necessity for a groper orientation of the molecule with respect to the incident light before an effective absorption is produced. This explanation can be applied to quinone if one assumes the superoxide formula.



Graph 2.

However, the results can be explained equally well by assuming that every absorbed quantum is effective in producing activation, and that a 50% efficient secondary reaction is responsible for the observed yields. The quantum efficiencies in water solution, and the effect of dissolved substances on reaction rate, favor this latter explanation.

Summary

The photochemical decomposition of benzoquinone in water and alcohol solutions has been quantitatively investigated.

The reaction in water, as measured by amount of quinone reduced, shows an induction period, which disappears in alcohol solutions.

Evidence is shown of a threshold in the first absorption band, lying toward longer wave lengths in alcohol, toward shorter in water. Inside the threshold the photochemical efficiency is independent of wave length throughout the remainder of the first and the whole of the second absorption bands.

In alcohol the efficiency is independent of quinone concentration, and averages 0.5 at 25°. The temperature coefficient, $\Delta k_{10°}$, is near unity for the reaction in water.

NOTE

Apparatus for Determination of Moisture Content of Solids and the Sorption of Gases and Vapors by Solids at Elevated Temperatures.—In the course of an investigation conducted by the writer it was desirable to determine not only the water content but the quantity of water vapor sorbed by a solid, granular substance from various steam–air mixtures at temperatures from 100 to 450°. The apparatus developed for this purpose was unique in several respects and, although requiring the services of a skilled glass blower, may find application in work of a similar nature by others.

The apparatus, shown in the accompanying sketch, consists essentially of a constant-temperature vapor-bath B with liquid boiling under automatically controlled reduced pressure,[1] an air-bath M and a detachable weighing tube D. The construction of the apparatus will be apparent from a description of the procedure in determining, for example, the sorption of water vapor. The method consists in passing a steam–air mixture[2] over a weighed amount of the solid material at constant temperature until equilibrium is established, as evidenced by no further increase in weight. The steam–air mixture enters the air-bath tube M, which is covered by the ground glass cap F, through the preheating coil J. The glass stopper G hanging from the hook on the glass rod H, allows the gases to escape through the tube D containing the granular material and thence out through the ground-glass joint E which also serves as a support for the tube D. The tube M is sealed at I, to the inner tube N of the vapor-bath so that the entire cap F is about two inches below the top of the vapor-bath. The vapor from the boiling liquid[3] in B then fills the annular space between the outer wall of B and the inner tube N, thus maintaining the cap at the bath temperature. The temperature of the system may be read from the mercury thermometer suspended in the vapor-bath from the ground-glass stopper as shown. The outlet tube above the cap is wound with nichrome wire and heated electrically to prevent condensation of steam. A loose plug of glass or cotton wool in the open end of N excludes air currents cooling the cap F.

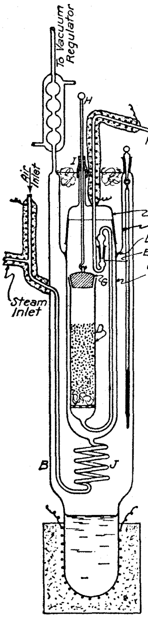

Fig. 1.

The experiment may be interrupted at any time for the purpose of weigh-

ing by sliding the rod H through the rubber connector I, thus closing the stopper G. The tube K is then closed by a short rubber tube and glass bead and the entire sorption tube and cap ensemble removed and placed in a desiccator to cool. A vacuum type desiccator carrying a bottle neck in its cover enables one to insert the weighing tube into the desiccator in a vertical position. A thin rubber sleeve attached to the bottle neck, into which the cap F fits, then seals the desiccator. When cool, the small tube D is detached at the ground joint E for weighing. A correction must, of course, be made for the steam that condenses in the free space of the tube upon cooling.

When the apparatus is used for determining the moisture content of solid materials, the steam generator is cut off and a stream of completely dried air or nitrogen passed over the material in D. The effluent gases are then passed through a series of weighed drying tubes attached at K to collect the moisture. The loss in weight of the material in D serves as a check. The dissociation of moist materials which decompose upon heating with evolution of gases not absorbable by the drying agents used may thus readily be obtained by determining the total loss in weight of the material itself as well as the amount of water vapor evolved. The ability to interrupt the experiment easily and to determine the change in weight also enables one to follow the *rate* of sorption, drying or dissociation quite readily.

THE PYROLYSIS OF HYDROCARBONS: ISOBUTYLENE[1]

BY CHARLES D. HURD[2] AND L. U. SPENCE[3]

RECEIVED MAY 20, 1929 PUBLISHED DECEMBER 11, 1929

In the first paper[4] of this series, data were recorded for the pyrolysis of n-butane and isobutane. The present paper concerns itself with *iso*-butylene, a hydrocarbon which possesses a branched chain of four carbons,

---

[1] This paper contains results obtained in an investigation on "The Non-Catalytic Thermal Decomposition of Pure Hydrocarbons and Related Compounds," listed as Project No. 18 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund of the American Petroleum Institute donated by the Universal Oil Products Company. This fund is being administered by the Institute with the cooperation of the Central Petroleum Committee of the National Research Council.

[4] Hurd and Spence, THIS JOURNAL, 51,3353 (1929).

as does isobutane. It will be shown that isobutylene is much more stable than isobutane under similar conditions. Undoubtedly this observation is connected in some way with the greater or lesser "electron attraction" of the various radicals concerned. It leads to the inference that the carbon-to-carbon single bond in isobutane undergoes scission more readily than the similar single bond in isobutylene.

The literature furnishes no record of a quantitative study of the pyrolysis of isobutylene. Previous workers, however, have identified some of the products formed when this hydrocarbon is decomposed. A. A. Noyes[5] passed isobutylene through a glass tube heated to "low redness," and identified ethylene, propylene, butadiene, methane, hydrogen, benzene, toluene and naphthalene. Nef[6] found propylene, methane, hydrogen and a "small yield" of yellow oil as the decomposition products of *tert.*-butyl alcohol. Presumably isobutylene was an intermediate product. Ipatiev[7] reported that when isobutylene was passed over alumina at 500°, or over zinc chloride at 600°, there was no change into the isomeric butenes, but that some propylene, hydrogen and methane were formed.

Experimental

Isobutylene was prepared by refluxing 400 cc. (4.3 moles) of *tert.*-butyl alcohol with 150 g. (1.2 moles) of oxalic acid dihydrate. The gas evolved was collected and stored over water in a gasholder of 56-liter capacity. The yields of several runs averaged 80–90%. The only impurities in the gas were small quantities of air and the vapors of *tert.*-butyl alcohol. Before passing into the reaction tube, the gas was conducted through a wet test meter and then freed from water and alcohol vapors by a calcium chloride tower. A flowmeter was used for adjusting the flow of gas through the apparatus to a constant rate.

The reaction chamber was of pyrex tubing (2.5 × 90 cm.). It was heated in an electric tube furnace over 76 cm. of its length. The temperature was recorded and controlled accurately by a Leeds–Northrup potentiometer controller, as has been described in the first paper of this series. The volume of the heated portion was approximately 360 cc. and the inside surface was 600 sq. cm. To facilitate the removal of liquid products, the tube was placed vertically. Such liquids were condensed and removed from the escaping gases by passage through two U-tubes filled with glass wool and cooled to 0–5°. The effluent gases were measured by a second wet test meter. A sample of the gaseous products was removed for analysis toward the end of each run. For each experiment, 20–30 liters of *iso*-butylene was employed. A sketch of the apparatus is given in Fig. 1.

[5] Noyes, *Mass. Inst. Tech. Quarterly*, *1*, 278–281 (1888).

[6] Nef, *Ann.*, **318**, 24, 25, 210 (1901).

[7] Ipatiev, *Ber.*, ***36***, 2008 (1903).

The gaseous products were analyzed by the absorption methods which were developed for the work on the butanes. The same sequence and the same precautions were observed. Mercury was used as the confining liquid in the Orsat buret. This work showed that the chief unsaturated hydrocarbons in the effluent gas were isobutylene and propylene (or allene), with a small amount of ethylene and acetylene.

A check on the values for the unsaturated hydrocarbons was obtained in a separate run by converting them into the bromides and then separating these bromides. The proportion of isobutylene and propylene as estimated in this manner agreed closely with the amounts found by gas analysis. The allene content was shown to be very small. Since the fuming sulfuric acid pipet should remove not only ethylene but also benzene and toluene vapors, it was to be expected that the ethylene bromide value for ethylene should be somewhat lower than the absorption value. Such was the case.

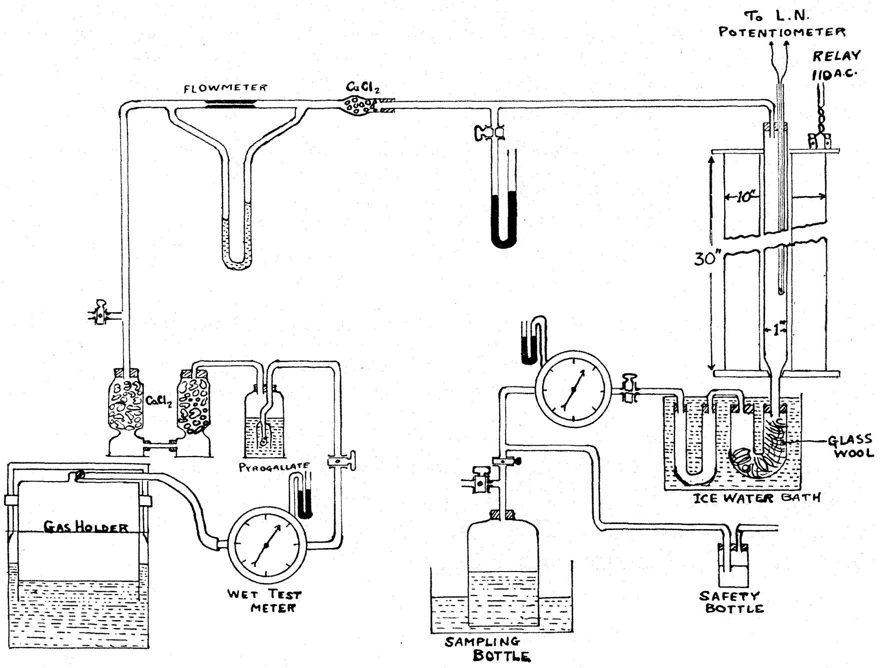

Fig. 1.

The decomposition was quite slow at 600°, but the rate increased rapidly with the temperature. In Table I is shown the amount of decomposition of isobutylene (97–99% purity) at the different temperatures used.

The rate of disappearance of the isobutylene was unchanged by dilution of the entering gas with nitrogen or with hydrogen (Table II). The rate of decomposition is therefore independent of the concentration.

TABLE I

DECOMPOSITION RESULTS

Temp., °C.	Contact time, sec.	Decompn., %	Temp., °C.	Contact time, sec.	Decompn., %
599	18	1.2	700	12	30.2
599	200	20.0	700	18	47.7
			700	23	54.0
652	18	11.1	700	25	51.4
652	27	22.7	700	32	64.3

TABLE II

DILUTION WITH NITROGEN

Temp., °C.	Contact time, sec.	Composition of entering gases Percentage by volume C_4H_8	N_2	O_2	Percentage decomposition
702	23	98.0	1.6	0.4	54.0
704	21	54.8	44.9	0.3	54.4

DILUTION WITH HYDROGEN[a]

Temp., °C.	Contact time, sec.	C_4H_4	Air	H_2	Percentage decomposition
702	23	98.0	2.0	...	54.0
704	22	51.8	3.7	44.5	56.8

[a] Although the extent of decomposition of isobutylene was not appreciably altered by the presence of hydrogen, still this gas was not an "inert" diluent. It was found that 62 cc. of hydrogen disappeared per liter of isobutylene decomposed, while the decomposition without the previous addition of hydrogen produced 265 cc. of hydrogen per liter of isobutylene decomposed. The disappearance of this hydrogen was accompanied by an increase in the methane content to the extent of 205 cc. per liter of *iso*butylene decomposed.

When the surface of the reaction tube was increased to twice its original value by packing the tube with small pyrex tubing, the rate of decomposition was also unchanged. This is revealed in Table III. The decomposition is, therefore, homogeneous or largely so.

TABLE III

EFFECT OF INCREASED SURFACE

Temp., °C.	Contact time, sec.	Vol. of tube, cc.	Surface, sq. cm.	Decomp., %
702	23	360	600	54.0
704	21	345	1200	51.8

Since the decomposition of isobutylene is independent of the concentration of the gas and is unaffected by an increase of surface, the reaction is unimolecular. The rate of decomposition should be given by the equation

$$\frac{dx}{dt} = k(a - x)$$

which, on integration, becomes

$$k = \frac{1}{t}\log_e \frac{a}{(a - x)}$$

In this equation a represents the original concentration of *iso*butylene, $(a - x)$ the concentration remaining after t seconds, and k the specific reaction rate. In the calculation of the values of k, given in Table IV, the concentrations of isobutylene have been expressed in moles per 22.4 liters at 0° and 760 mm.

TABLE IV

RESULTS OF EXPERIMENTS

Temp., °C.	Time, sec.	Concn. in moles per 22.4 liters Start	Finish*	k	Mean *k*
600	200	0.940	0.690	0.0016	0.0016
650	13	.990	.900	.0073	
650	27	.970	.762	.0089	.0081
700	12	.980	.634	.0362	
700	18	.975	.433	.0451	
700	22	.978	.294	.0547	
700	23	.980	.387	.0405	
700	25	.978	.380	.0378	
700	32	.983	.266	.0409	
N_2 700	21	.548	.212	.0451	
H_2 700	22	.518	.206	.0420	
700[b]	21	.978	.399	.0428	.043

[a] The final concentrations are somewhat in error, since the liquid products were removed before measuring the volume of the exit gases. Therefore, the concentration of the isobutylene at the end of the reaction was actually less than the figures in Table IV.

[b] Experiment with increased surface.

The heat of activation was calculated from the change in the specific reaction rate with the temperature, by means of the equation of Arrhenius

$$\frac{d(\log_e k)}{dT} = \frac{A}{RT^2}$$

wherein k is the specific reaction rate; T, the absolute temperature; R, the gas constant in calories; and A, the heat of activation. The mean values of k for the temperature of 600, 650 and 700° were used in these calculations.

Mean temperature, °C.	625	650	675
Heat of activ., *A*, cal./mole	52,700	55,700	59,100

A summary of the data of several experiments on the pyrolysis of *iso*-butylene at 600–700" under varying conditions are arranged in Tables V and VA. In Expt. 12 the olefin was diluted with nitrogen; in No. 13, it was diluted with hydrogen. Experiment No. 15 was an increased surface experiment such as has been mentioned above. In the other 700" experiments it will be seen that for each mole of isobutylene decomposed, 1.3–1.5 moles of other gases was formed with an exposure of from twelve to thirty-two seconds. Methane comprised about half of the gaseous portion, but since liquid products were found to be formed to the extent of 41–63% of the weight of *iso*butylene decomposed, it is apparent that methane formation is not the exclusive major reaction. In the various 700" experiments, methane represented 46–55% of the gases exclusive of the unchanged *iso*-

butylene. Five of the six results showed the hydrogen content to be 19–20%, and the sixth dropped to 14%. In general, therefore, hydrogen comprised about one-fifth of the gases. Propylene represented one-seventh or less (14–17%), and other gases were present in lesser amounts. Expressed somewhat differently, each 100 moles of isobutylene undergoing decomposition under these conditions gave rise to 59–83 moles of methane, 20–30 moles of hydrogen, 20–25 moles of propylene, lesser amounts of isobutane and ethylene and almost negligible quantities of acetylene.

The Nature of the Unsaturated Hydrocarbons Formed at 700°.—In a separate experiment isobutylene was decomposed at 700° at a contact time of nineteen seconds. The unsaturated hydrocarbons in the off-gas were analyzed by the bromide method to serve as a check on the absorption method of analysis. The gaseous products were dried with calcium chloride, and were then absorbed in bromine in dry carbon tetrachloride solu-

OIL FORMATION

Yield of oil, based on the weight of *iso*butylene decomposed, %	42 7	46 8	41 5	45	28.0	22 9	39.4

tion. A volume of **21.3** liters **(53.4** g.) of isobutylene (0°, 760 mm.) was passed through the reaction tube. The volume increase was 20.9%.

After removing the excess bromine from the solution of the bromides, the carbon tetrachloride was distilled off. Of the residue, the lower-boiling portion (b. p. **(30** mm.) 51–68"), which contained the ethylene, propylene and isobutylene dibromides, was found to weigh **94.3** g. The higher-boiling material weighed **43.2** g. After four fractionations with a fractionating column of the type described by Cooper and Fasce,[8] the dibromides were separated into the following fractions

---

[8] Cooper and Fasce, *Ind. Eng. Chem.*, 20,420 (1928).

B. p., °C.	130–139	138–144	145–148
Grams	4.4	21.1	55.2
n_D^{20}	1.5178	1.5158	1.5111

and the residue was added to the first high-boiling residue. The amounts of ethylene bromide, propylene and *iso*butylene bromide were estimated from the distillation curve and also from the refractive index[4] of the three fractions.

Dibromides	Ethylene	Propylene	*Iso*butylene
From refr. index, g.	..	18	63
From distn. curves, g.	1	18	62

The higher-boiling material from the bromides was fractionated at reduced pressure and was also shown to represent isobutylene for the most part. The largest fraction was tribromo-isobutane, which is formed along with higher brominated products when isobutylene reacts with bromine? Considerable tetrabromo-isobutane was found, and also a small residue containing presumably penta- and hexa-substituted *iso*butane. There was also a very small fraction containing acetylene tetrabromide and possibly allene tetrabromide. No butadiene tetrabromide was found, contrary to the work of A. A. Noyes.[5]

Most of the tribromo-isobutane was collected at 75.2–76° (4 mm.); its index of refraction was n_D^{20} **1.5670.** Between **81** and 88°, **4.5** g. of similar material was also collected. Only half a gram distilled in the next fraction at **108–110"** (9 mm.), n_D^{20} **1.5728.** This fraction should represent the acetylene or allene tetrabromides. The next fraction of tetrabromo-*iso*butane weighed **5.8** g. It was collected at **134–150" (15** mm.), and its index of refraction at 20° was **1.6070.** The residue weighed **1.8** g.

On the basis of **123** g. of isolated bromides, 1 g. was from ethylene, **18** g. from propylene, 95 g. from isobutylene (as di-, tri-, or polybromides) and 9 g. of other bromides. The mole percentage of olefins by such an analysis is ethylene **1.0%;** propylene 17.2%, isobutylene 76.0%, others **5.8%.** These results agree closely with the results by absorption methods in the modified Orsat apparatus.

	By absorption. %	Calcd. from bromides, %
Isobutylene	40.6	40.7 (53.6 X 0.760)
Propylene	8.4	9.2 (53.6 X 0.172)
Ethylene	2.4	0.5 (53.6 X 0.010)
Acetylene	2.2	3.2 (remainder)
	53.6	53.6

Reaction of Bromine and Isobutylene.—The proportion of the different bromination products given when *iso*butylene reacts with bromine has been calculated from the results of this fractionation. It is interesting to com-

Tetrabromo-*iso*butanes	6.0		7	
Penta- and hexa-analogs	3.0		1	

The Liquid Products.—The pyrolysis of isobutylene is complicated by the formation of large amounts of liquid products in addition to the gaseous products which have been discussed. When the isobutylene was diluted with nitrogen before passing into the hot tube, the yield of liquid products was appreciably decreased (see Table VA, Expt. 12). Dilution with hydrogen had a similar effect on the yield of liquid products and in addition it served to increase the yield of methane and of propylene appreciably. Also it seemed to increase the yield of gaseous saturated hydrocarbons other than methane (see Table VA, Expt. 13). The accuracy of the combustion method for the determination of such saturated hydrocarbons is open to some question since all of the benzene and toluene vapors may not have been removed by the fuming sulfuric acid (8% free SO_3) before the combustion. The use of stronger acid, on the other hand, would result in the solution of appreciable quantities of such hydrocarbons as *iso*butane and propane.[10] The experiment with hydrogen is rather good evidence that the following reactions of scission and addition normally occur to some extent with the hydrogen which is liberated in the reaction.

$$(CH_3)_2C{=}CH_2 + H_2 \longrightarrow CH_4 + CH_3CH{=}CH_2$$
$$(CH_3)_2C{=}CH_2 + 2H_2 \longrightarrow 2CH_4 + CH_2{=}CH_2$$
$$(CH_3)_2C{=}CH_2 + H_2 \longrightarrow (CH_3)_3CH$$

The important part played in the reaction by the formation of the liquid products is shown in Table VI, in which the yield of liquid products is given in percentage by weight of the isobutylene decomposed.

[10] Worstall, Am. Chem. J., 20, 664 (1898); THIS JOURNAL, 21, 246 (1899); Orndorff and Young, Am. Chem. J., 15, 261 (1893).

Examination of the Oils Formed at 700°.—The density of the oil formed from isobutylene at 700° was found to increase with the contact time. This would be expected, since, as the contact time increases, the reaction of the aromatic hydrocarbons with each other and with the unsaturated hydrocarbons present forms the higher molecular weight aromatic hydrocarbons. The density, for a contact time of twelve seconds, was d_4^{20} 0.8511; for twenty-four seconds, d_4^{20} 0.8899; and for thirty-two seconds, d_4^{20} 0.9053.

Two samples of the liquids were fractionated, with the following results.

B. p., °C.	Weight, g.	% by weight of the oils	B. p., °C.	Weight, g.	% by weight of the oils
65–96	6.2	20.0	65–103	6.8	20.5
97–122	8.5	28.0	103–105	7.0	21.0
137–146	3.5	11.5	125–155	3.0	9.0
146–180	3.8	12.5	170–205	2.2	6.7
180–275	1.5	5.0	205–218	2.2	6.7
275–310	1.0	3.5	230–330	2.2	6.7
310–330	1.0	3.5	360–395	0.3	0.9
Pitch	2.5	8.0	Residue	3.5	10.5
Loss	2.4	8.0	Loss	5.9	18.0
	30.4	100.0		33.1	100.0

The fractions of similar boiling point were then combined and fractionated more closely to separate the individual hydrocarbons. Much of the distillation loss in these fractionations was due to the dissolved *iso*butylene,[11] the last traces of which are removed with difficulty by distillation processes. Table VII shows the results of the final fractionation.

TABLE VII

FINAL FRACTIONATION OF OILS FROM *ISO*BUTYLENE

Fraction	Boiling range. °C.	Weight, g.	n_D^{20}	Probable composition

[11] Brooks, "The Non-Benzenoid Hydrocarbons," The Chemical Catalog Co., Inc., New York, 1923, p. 583: "Kerosene and machine oil dissolve about 220 volumes of isobutylene at room temperature and the gas is only completely expelled on heating to 260°." Benzene–toluene mixtures would probably act similarly, since their solvent action is usually greater.

From the results in Table VII, only Fraction A gave evidence of the presence of appreciable amounts of unsaturated hydrocarbons by the usual tests. The high refractive indices of the fractions are also indicative of the aromatic nature of the hydrocarbons. The following derivatives were prepared.

Fraction	Derivative	Obs. m. p., °C.	Recorded lit. m. p., °C.	Mixed m. p., °C.
B	*m*-Dinitrobenzene	89.5–90	90	90–90.5
D	Trinitrotoluene	80–81	82	81–82
F	Nitro derivative	127–129	178, trinitro-o-xylene 182, trinitro-*m*-xylene 139, trinitro-p-xylene	
H	Picrate	128–131		
		125–134	150, naphthalene picrate	
J	Picrate	142–145	143, phenanthrene picrate	
		157–164	161, anthracene picrate	

Benzene and toluene were thus definitely characterized by their derivatives. The other fractions undoubtedly contained several compounds, since the derivatives were impure after two recrystallizations.

Isobutylene and Isobutane Compared.—Under comparable conditions isobutylene differs quite materially from isobutane in its behavior toward heat, in spite of the fact that both of these substances are branched hydrocarbons which contain four carbon atoms. For example, at 600° the unsaturated hydrocarbon decomposed only 1.2% in eighteen seconds, whereas the saturated hydrocarbon decomposed 13–19.5% in seventeen to twenty-one seconds.[4] For a 20% decomposition of isobutylene at 600°, a hot contact period of 200 seconds was required. With 700° temperatures, the rate of decomposition for both hydrocarbons is markedly increased although the contrast is still apparent. For a hot contact time of twelve to twenty-one seconds, isobutane was broken down to the extent of 70%, whereas with isobutylene decomposition varied between 30 and 50%.

Still more striking a difference in the two cases is to be found in the course of the two reactions. Isobutane was found to decompose almost exclusively into gaseous hydrocarbons which were molecularly smaller than the original substance. Isobutylene, on the contrary, changed quite materially into hydrocarbons of greater molecular complexity. Nearly half of the decomposed isobutylene gave rise to liquid hydrocarbons whereas the remainder appeared in the form of gases. The gaseous products from both isobutane and isobutylene were similar to the extent that methane, hydrogen and propylene were important products of the decomposition, with methane always predominating.

The Mechanism of the Pyrolysis.—Any mechanism for the pyrolysis of isobutylene must provide an explanation not only for the simpler gaseous hydrocarbons of the reaction but also for the generous formation of aromatic hydrocarbons. As major effects, it is suggested that heat may rupture the single C—C or C—H bonds, and that it may activate the C=C double bond. The univalent radicals which are thought to be formed by rupture of the single bonds, namely, $-CH_2-C(CH_3)=CH_2$ or $-C(CH_3)=CH_2$, evidently do not give rise as such to aromatics, since the quantity of liquids formed during pyrolysis of the butanes was very small and since, for the butanes, transient radical formation was also postulated. Such univalent radicals appear to give rise to gaseous products. In the case of the double bond, it is considered that the tie is sufficiently strong to resist complete rupture, thereby creating a radical with two bonds. In the case of *iso*butylene, this is $(CH_3)_2\underset{|}{C}-\underset{|}{C}H_2$. As a working hypothesis it is considered that radicals of the latter type are the precursors of building-up processes. Three such "activated olefin molecules," by combination, would produce a cyclohexane derivative which, at the elevated temperature of formation, would be stripped into benzene derivatives,

Summary

Isobutylene was found to be a more stable hydrocarbon than *iso*butane or n-butane. It was only slowly decomposed at 600°. The pyrolytic reactions were studied at 600, 650 and 700°, especially at 700° where the rate of decomposition was rather high. It was demonstrated that the reaction was unimolecular and largely homogeneous. The velocity constant and the heat of activation for the unimolecular reaction were calculated from the data. The various products of the reaction were identified. The mechanism of the reaction is much more complicated than that of the saturated hydrocarbons studied, but a mechanism is suggested which recognizes not only the decomposition into smaller substances but also the building-up processes into aromatic hydrocarbons.

THE MOLECULAR WEIGHTS OF PHYCOCYAN AND OF PHYCOERYTHRIN FROM PORPHYRA TENERA AND OF PHYCOCYAN FROM APHANIZOMENON FLOS AQUAE

BY THE SVEDBERG AND TOMINOSUKE KATSURAI

RECEIVED JUNE 10, 1929 PUBLISHED DECEMBER 11, 1929

In a previous paper a report has been given of the determination of the molecular weights of phycocyan and phycoerythrin from *Ceramium rubrum* by means of the centrifugal methods developed in this Laboratory.[1] For phycocyan the value 106,000 ± 5000 was found within the PH region 6.8–7.9 and for phycoerythrin the value 208,000 ± 8000 within the PH region 5.0–6.8. It was pointed out that within the limits of experimental error these values are equal to the molecular weight of egg albumin, 34,500, multiplied by the integers *three* and *six*, respectively. It seemed desirable to extend this study to proteins from other algae and to make determinations within *a* wider *PH* range in order to state the stability regions of these proteins. The alga *Porphyra tenera* was chosen as a representative of the *Rhodophyceae* group not too closely related to *Ceramium*. As a representative of the *Cyanophyceae*, the blue-green algae, *Aphanizomenon flos aquae* was chosen.

Experimental

Preparation of Material

Preparation of Phycocyan and Phycoerythrin from Porphyra tenera.—The Japanese product, "Nori," which consists of dried *Porphyra tenera* was extracted with water as described by Kitasato;[2] 2800 g. was used for this work. Four hundred cc. of water was added for each 10 g. of the material, which was kept in the dark. After some days 1% of toluene was added as a preservative and the extraction was carried on for three weeks. In this way a reddish-violet colored solution was obtained. This solution was treated with about 20% of its weight of ammonium sulfate. The proteins thus precipitated were separated by centrifuging in a bucket centrifuge and brought into solution by washing with distilled water. This solution was then treated with increasing amounts of ammonium sulfate up to 25% of its weight. After each addition it was allowed to stand for a day. The precipitate formed was separated by centrifuging. In this way several mixtures containing different relative amounts of the two substances were formed.

The mixed precipitate was washed with cold water, under which conditions the phycocyan dissolved much quicker than phycoerythrin. By repeating the precipitation with ammonium sulfate and washing the precipitate with cold water, the separation of these substances was carried out completely.

Preparation of Phycocyan from Aphanizomenon flos aquae.[3]—The weed was collected from the surface of a lake near Upsala. The fresh material (30 kg.) was freed

[1] Svedberg and Lewis, THIS JOURNAL, **50**, 525 (1928).

[2] Kitasato, "Acta Phytochimica," 2, 75 (1925).

[3] The preparation of this protein was carried out by Mr. Arne Tiselius.

from excess of water on a cloth filter and the residue was left to stand for three days, allowing autolysis to set in. Some gas was evolved and the phycocyan began to penetrate the cell membranes.

At this time the putrefaction was stopped by the addition of toluene. After five days the material was centrifuged and the residue was discarded. The supernatant liquid has a blue-green color and is fluorescent. To this a saturated ammonium sulfate solution was added in the proportion of 700 cc. of the ammonium sulfate to 1000 cc. of the liquid. The precipitate thus formed was separated by centrifuging and dissolved in distilled water. Recrystallization was repeated three times with the addition of one volume of saturated ammonium sulfate to five volumes of the solution. The first mother liquor formed by the addition of ammonium sulfate was green. As the process of recrystallization proceeded it became deep blue and strongly fluorescent. Well-defined crystals were formed when the precipitate was kept in an ice box for some days. A photomicrograph of the crystals is shown in Fig. 1. The crystals were dissolved in water and dialyzed against phosphate buffer (PH 6.8) and against acetate buffer (PH 4.6). The mother liquor was also dialyzed in the same way.

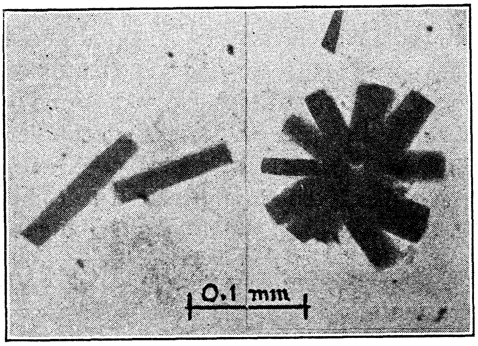

Fig. 1.

Specific Volume.—The partial specific volume was determined pycnometrically at 19.8". The amount of protein in solution was determined by drying a certain amount of the solution at 105" and subtracting the amount of salt in the sample as known from the composition of the buffer.

The value 0.759 was obtained for phycocyan from *Porphyra tenera* at PH 6.8 (solvent 0.0167 M in KH_2PO_4 and in Na_2HPO_4). The determination by A. Tiselius in this Laboratory gave 0.755 for phycocyan from *Ceramium rubrum*. The average value 0.746 was obtained for phycocyan from *Aphanizomenon flos aquae* at various hydrogen-ion concentrations between PH 4.6 and 12.0 (solvent: for PH 4.6, 0.01 M in acetic acid and in sodium acetate; for *PH* 12.0, 0.01 M in Na_2HPO_4 and 0.00864 M in NaOH). No appreciable change with PH was observed. The average value was further found to be almost identical with the values obtained by previous determinations for egg albumin,' hemoglobin: serum albumin and serum globulin: phycocyan and phycoerythrin (from *Ceramium rubrum*).[1]

Light Absorption.—The absorption in the visible spectrum was measured with a Konig–Martens spectrophotometer, and in the ultraviolet with a Judd–Lewis spectrophotometer. Phycocyan and phycoerythrin from *Porphyra tenera* and *Ceramium rubrum* were studied at PH 6.8. The ultraviolet absorption of the phycocyan from *Aphanizomenon flos aquae* was measured at different hydrogen-ion concentrations. No change was observed between PH 4.6 to 6.8, but an appreciable change took place

at *P*H 12.0, where the protein begins to decompose. The chief results are given in Figs. 2, 3 and 4. The specific extinction coefficient, $\epsilon/c = 1/cd \log (I_0/I)$ (where c is the concentration in per cent., d the thickness of the solution, I_0 the intensity of the light after passing through the solvent and I the intensity after passing through the same thickness of solution) is plotted against the wave length. Figure 2, which contains the curves for phycoerythrin from *Ceramium* (solid line) and from *Porphyra* (dotted

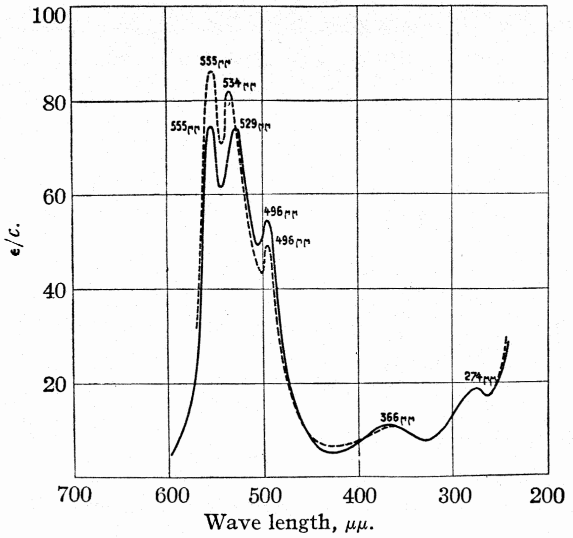

Fig. 2.

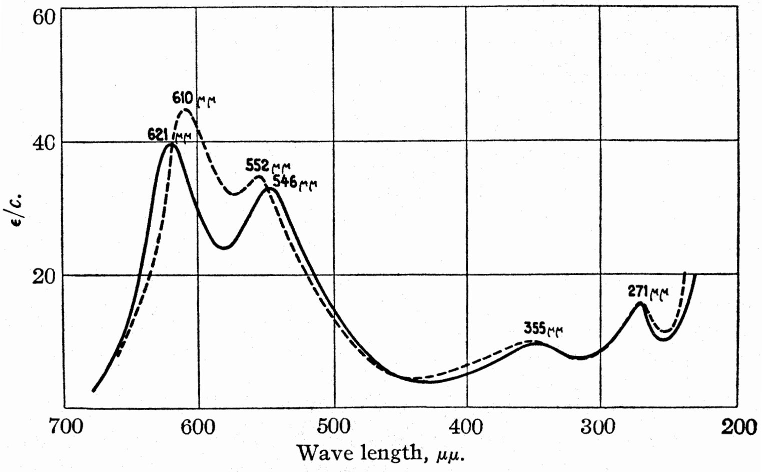

Fig. 3.

line), shows clearly the resemblance of the light absorption of these proteins, as does Fig. **3** in the case of phycocyan from the same two algae. Figure 4 shows that the visible absorption of phycocyan from *Aphanizomenon* is quite different from the absorption of phycocyan from *Ceramium* and *Porphyra*. In the ultraviolet, however, the absorption of phycocyan from *Aphanizomenon* is almost identical with that of phycocyan from *Ceramium* and *Porphyra*. For the purpose of comparing the results obtained with the values obtained previously by different authors, the positions of the maxima are shown in Table I.

The values of the extinction coefficients obtained by Lewis in the ultraviolet region were found to be in error, probably owing to some toluene present. To secure freedom from toluene a current of wet nitrogen gas was blown through the protein solution just before the measurements were made.

Determination of the Molecular Weight

The molecular weights were determined by the sedimentation velocity and the sedimentation equilibrium methods. The apparatus and procedure have already been described.[10,4,5] The photographs were taken by using the mercury line $\lambda = 366\mu\mu$. In order to cut off the other lines, Wratten nickel-glass was used as a light filter. In the case of the sedimentation velocity method the molecular weight is given by the relation

$$M = \frac{RTs}{(1 - V\rho)\,D}$$

where R is the gas constant, T the absolute temperature, s the sedimentation constant[11] or $1/\omega^2 x \cdot dx/dt$, D the diffusion constant, V the partial specific volume of the protein, ρ the density of the solvent, x the distance from the axis of rotation, ω the angular velocity and t the time. The values of the specific sedimentation velocity and of the diffusion constant were all reduced to 20° by means of the relations $s_1/s_2 = \eta_2/\eta_1$ and $D_1/D_2 = T_1/T_2 \cdot \eta_2/\eta_1$, where η is the viscosity of the solution.

---

[8] The light absorption of phycoerythrin seventeen years old was measured; ref. 1, p. 532.

[10] Svedberg, *Z. physik. Chem.*, 121, 65 (1926); 127, 51 (1927).

[11] The term "Sedimentation Constant" has been adopted as a simplified means of expressing the old term "Specific Sedimentation Velocity."

In the case of the sedimentation equilibrium method, the molecular weight is given by

$$M = \frac{2RT \ln (c_2/c_1)}{(1 - V\rho)\omega^2(x_2^2 - x_1^2)}$$

where R, T, V, ρ and ω have their usual meaning and c_1 and c_2 are the concentrations at the distances x_1 and x_2 from the center of rotation. In all, 51 runs were carried out. The results of all of the determinations are given.

Phycocyan from Porphyra tenera.—The values obtained for the sedimentation constant were independent of the time of centrifuging, but the diffusion constant showed a drift with the time, thus indicating slight heterogeneity of the material. The presence of a non-centrifugible substance was also observed. The value of the diffusion constant used for calculating the molecular weight was computed by an extrapolation procedure, as in the case of edestin.[12] The results of each of the runs are given in Table IV. For PH 4.6 and 6.8 the same buffers were used as previously mentioned; for *PH* 11.0 the buffer was 0.0172 M in Na_2HPO_4 and 0.00282 M in NaOH.

TABLE IV

SEDIMENTATION VELOCITY MEASUREMENTS ON PHYCOCYAN FROM *Porphyra tenera*

Concn., %	PH	R.p.m., mean	s, cm./sec. × 10^{13}	D × 10^7, cm.^{2}/sec.	*M*	Concn. of non-centrifugible matter, %
0.17	4.6	24,000	11.11	4.80	206.000	0
.37	6.8	43,000	5.69	5.30	109.000	10
.12	6.8	24,000	6.27	6.10	105.000	35
.10	11.0	41,000	2.06			10

As may be seen from the above table, the protein consists chiefly of molecules of the molecular weight of about 107,000 at *PH* 6.8. It is extremely interesting that the molecular weight is about doubled at *PH* 4.6 near the isoelectric point. At a *PH* of 9.7 the molecules seem to be breaking up, as the *s* is slightly lower than at *PH* 6.8. At higher *PH* (11.0) the protein breaks up into small molecules of various sizes.

Determinations of the molecular weight by the sedimentation equilibrium method were carried out at *PH* 6.8.

Values from 32,000 to 104,000 were obtained in one of the runs, and values ranging from 42,000 to 124,000 in the other. These results show that the molecules are not uniform. This protein contains to some extent molecules of a molecular weight smaller than 107,000.

In the case of Lewis's measurement of the molecular weight of phycocyan from *Ceramium rubrum*, the protein was prepared from the wet algae which was not dried by the sunlight, and the results of the determination of molecular weight have shown that the molecules are quite uniform. In

---

[12] Svedberg and Stamm, THIS JOURNAL, 51,2170 (1929).

the present work the protein was prepared from the sun-dried material, and the results of the determination show that the molecules are not uniform and that the material contains some smaller molecule.

In order to see the effect of sun drying, the protein was prepared from sun-dried *Ceramium rubrum* and the molecular weight was determined at the same PH. As the yield of the protein was very small, only one run could be made but the result showed that part of the molecules were decomposed into smaller ones. The chief part of the phycocyan apparently had been completely destroyed in the drying process. This seems to explain the fact that the phycocyan used in the above experiments which had been prepared from sun-dried material did contain to some extent molecules of various sizes.

Phycoerythrin from Porphyra tenera.—In this case both the sedimentation and the diffusion constants were independent of time of centrifuging, thus indicating that the molecules had a uniform mass. Details of a typical run are given in Table V, and the results of all the runs are summarized in Table VI.

TABLE VI

SEDIMENTATION VELOCITY MEASUREMENTS ON PHYCOERYTHRIN FROM *Porphyra tenera*

Concn., %	PH	Mean speed, r.p.m.	s, cm /sec. $\times 10^{13}$	D, cm.^{2}/sec. $\times 10^7$
0.17	4.6	24,000	11.90	5.00
.65	6.8	43,000	10 90	5.00
.32	6.8	43,000	11 82	5.48
.16	6.8	43,000	11.11	4.55
.16	6.8	22,000	11.71	5 94
.12	6.8	22,630	12.25	5.95
.08	6.8	23,000	11 86	4.77
		Mean	11.65×10^{-13}	5.27×10^{-7}

Mean molecular weight, 214,000.

The values of the sedimentation constant and of the diffusion constant found by Lewis for phycoerythrin from *Ceramium* were 11.30 × 10^{-13} and 5.22 X 10^{-7}, respectively.

The results of the determination of the molecular weight by the sedimentation equilibrium method (using a wave length of 366$\mu\mu$ for illumination) showed that the molecules are of uniform size with a molecular weight of 213,000. The run made with a shorter wave length ($\lambda = 270\mu\mu$) showed that the molecules are not uniform, indicating that the protein has decomposed and that the decomposition products contain no chromophore group.

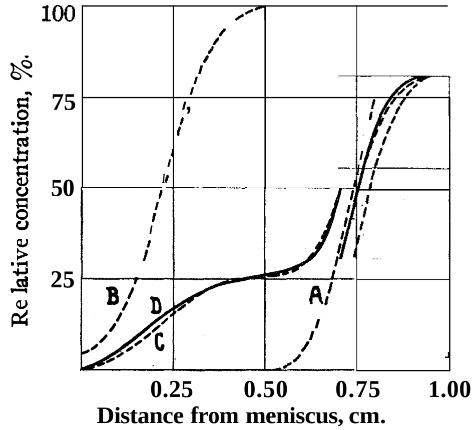

Fig. 5.

A run was made at **PH** 11.0 (phosphate buffer 0.0172 M in Na_2HPO_4 and 0.0028 *M* in NaOH). The speed was 42,000 r.p.m. and the temperature in the cell was 21.4°. In this case there was a large drift in the diffusion constant with time. From the diffusion curve it was calculated that the protein consisted of 75% of molecular weight 208,000 and 25% of molecular weight 34,600 ($^1/_6$ X 208,000). Figure 5 shows the calculated (C) and the experimental (D) relation between concentration and distance from meniscus after two hours of centrifuging, as well as the curves calculated for the cases in which the solutions were composed only of molecules of mass 208,000 (A) or only of molecules of mass $^1/_6$ × 208,000 (B).

Phycocyan from Aphanizomenon flos aquae.—Throughout the low-speed runs (mean r.p.m. 24,000) the values obtained for the sedimentation constant were independent of the time of centrifuging, but a drift of the diffusion constant was observed, showing the heterogeneity of the molecules. Formation of a non-centrifugible substance was observed. From the diffusion curves of the runs made at high speed (r.p.m. 44,000) the proportion of the molecules of the different molecular weight was calculated. The results of the determination of the sedimentation constant in a low-speed run are summarized in Table VII.

The high-speed run (r.p.m. 44,000) at the same **PH** showed that the protein molecules consist of 65% of molecular weight 208,000 and 35% of 104,000. For the purpose of seeing whether any separation can be effected by recrystallization, 10% of ammonium sulfate was added to the solution and the supernatant liquid was dialyzed against the same phos-

TABLE VII

SEDIMENTATION VELOCITY MEASUREMENTS ON PHYCOCYAN FROM *Aphanizomenon flos aquae* AT *PH* 6.8

Concn., %	Mean speed, r.p.m.	s, cm./sec. $\times 10^{13}$	Non-centrifugible subs., %
0.11	24,000	11.66	6
.11	24,000	11.41	0
.11	23,000	10.87	3
.12	24,000	11.75	1
.24	23,000	10.82	0
.40	24,000	11.98	0
	Mean	11.41×10^{-13}	

phate buffer solution. The solution thus obtained was studied with a high-speed run. As the result of experiment, 63% of 208,000 and 37% of 104,000 was obtained, showing that practically no separation takes place by fractional crystallization. It is quite interesting to notice that a run carried out at *PH* 4.6 showed that the protein molecules in this region are uniform, and have a molecular weight of 223,000. Figure 6 gives the calculated (C) and the experimental (D) relations between the concentration and distance from meniscus after 105 minutes for a solution of PH 6.8, at 44,000 r.p.m. and 20°. The curves A and B represent the distribution of concentration in solutions containing only molecules of mass 208,000 and $^1/_2 \times 208{,}000$, respectively. From the experimental curve the sedimentation constant of the heavier component was found to be 11.15×10^{-13} and for the other component 5.77×10^{-13}. These values check very well with those found by Lewis for phycoerythrin and phycocyan from *Ceramium* at *PH* of 6.8 (reduced to 20°), which are 11.30×10^{-13} and 5.59×10^{-13}, respectively. From a run carried out at very low hydrogen-ion concentration (PH 12.0) the value 3.24×10^{-13} cm./sec. was obtained for the sedimentation constant, which is about the same as that of egg albumin, *viz.*, 3.32×10^{-13}, found by Nichols.

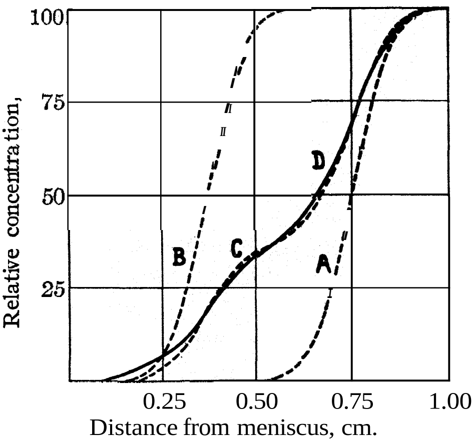

Fig. 6.

For the purpose of seeing whether the change of molecular weight by *PH* is reversible, a solution of *PH* 6.8 was dialyzed against acetate buffer of *PH* 4.6 and the solution thus obtained was studied. As the result of experiment the uniformity of molecules was observed and the value

252,000 was obtained for the molecular weight, showing that the change of molecular weight is reversible.

Determinations of the molecular weight by the sedimentation equilibrium method were also carried out. The protein solution used for the experiment was that obtained by dialyzing the dissolved protein crystals. Two runs made at P_H 6.8 showed that the molecules are of different molecular weight. In one run it was observed that the molecules have a molecular weight from 106,400 to 184,000 and from 117,000 to 200,000 in the other. The run carried out at P_H 4.6 showed the existence of molecules of molecular weight from 115,000 to 207,000.

Discussion of Results

From the results obtained in these experiments, it seems probable that the phycoerythrin from *Porphyra tenera* and from *Ceramium* are identical, and the same is true regarding phycocyan from those algae. The molecular weights and stability regions are probably identical, but further determination is necessary to decide this point completely. Tiselius' determination of the isoelectric points of phycoerythrin and phycocyan from *Ceramium rubrum* showed that these proteins have different isoelectric points, *viz.*, P_H 4.5 for phycocyan and P_H 4.3 for phycoerythrin.

The phycocyan from *Aphanizomenon flos aquae* is different from the above-mentioned proteins. It has a different light absorption and a different isoelectric point (P_H 4.7 as measured by Tiselius) and it seems that the stability region of the molecules is also different. If we consider 34,500 as the unit of the protein molecule and call it A, these proteins consist of molecules of molecular weight A, 3A and 6A, and mixtures of these molecules. It is worth noticing that the existence of the intermediate molecular weights 2A, 4A and 5A was not observed. More determinations are necessary to make up the complete chart of the molecular weights of these proteins as a function of P_H. For the sake of convenience, the names R-Phycoerythrin and R-Phycocyan are proposed for the proteins from *Porphyra tenera* and *Ceramium rubrum* from the name of the family *Rhodophyceae* to which they belong and C-Phycocyan for that from *Aphanizomenon flos aquae* from *Cyanophyceae*.

The expenses connected with these experiments have been defrayed by grants from the Nobel Fund of Chemistry and from the foundation "Therese och Johan Anderssons Minne."

Summary

1. The specific volume, light absorption and molecular weights of phycoerythrin and phycocyan from *Porphyra tenera* and of phycocyan from *Aphanizomenon flos aquae* have been determined at different hydrogen-ion concentrations.

2. The specific volumes of these proteins are identical and independent of PH and, within the limits of error, also identical with the specific volumes of all other proteins studied in this Laboratory, except the hemocyanins. This fact is in line with the result of the molecular weight determinations, according to which all the proteins in question are loosely built up of units of approximately the same mass, *viz.*, 34,500. It is also probable that they have the same general constitution.

3. The light absorption of the phycoerythrins from *Porphyra* and *Ceramium* are identical and the same is the case for the corresponding phycocyans. The light absorption of phycocyan from *Aphanizomenon* is different from that of the *Rhodophyceae* proteins.

4. Near the isoelectric points the molecular weights of these three proteins are identical and approximately 208,000 ± 5000. With increasing PH decomposition of the molecules takes place. The phycoerythrin is the most stable one. At PH 6.8 it is still undecomposed but at PH 11.0 it consists of a mixture of 75% 208,000 and 25% $^1/_6$ X 208,000. Phycocyan from *Porphyra* shows indications of decomposition at PH 6.8 but the bulk of it consists of $^1/_2$ X 208,000 at that PH; at PH 11.0 it is decomposed into small units of varying size. Phycocyan from *Aphanizomenon* is decomposed into a mixture of 65% of 208,000 and 35% of 100,000 at PH 6.8 and is completely decomposed into the protein unit $^1/_6$ X 208,000 at PH 12.0.

THE PYROCHEMICAL DECOMPOSITION OF AZIBENZIL

BY JOHN J. RITTER AND GEORGE M. WIEDEMAN

RECEIVED JUNE 20, 1929 PUBLISHED DECEMBER 11, 1929

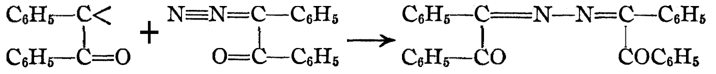
Introduction

Schroeter's[1] method for the preparation of diphenylketene has been recommended by Staudinger[2] in a slightly modified form as the most convenient source of that substance. The operations involved are (1) the preparation of benzil monohydrazone, (2) oxidation of this in benzene with mercuric oxide to azibenzil and (3) decomposition of azibenzil at 110–120° to nitrogen and diphenylketene in an atmosphere of carbon dioxide. During the preparation of diphenylketene in this Laboratory by this procedure certain hitherto unreported observations were made. The purpose of the present communication is to report on these, and also to describe a convenient and somewhat modified procedure used successfully by us in the synthesis of diphenylketene.

[1] Schroeter, *Ber.*, 42, 2336 (1909).

[2] Staudinger, *ibid.*, 44, 1619 (1911).

The decomposition of azibenzil into nitrogen and diphenylketene according to the procedure described by Staudinger yields, in addition, a viscous difficultly volatile nitrogen-containing residue. Staudinger[3] isolated from this residue a yellow crystalline solid melting at 201°, and assumed it to be a product of the addition of diphenylketene to azibenzil. We have noted that the residue yields, on distillation at ordinary pressure, benzonitrile and benzoic acid. The clue as to the source of these latter products was furnished by our further observation that *bis*-benzilketazine is also one of the products of the decomposition of azibenzil by heat. Its formation is apparently due to the addition of the desylene residue, formed by the loss of nitrogen from azibenzil, to a molecule of unchanged azibenzil



$$\begin{array}{l} C_6H_5-C< \\ \quad\;\; | \\ C_6H_5-C=O \end{array} + \begin{array}{l} N\equiv N=C-C_6H_5 \\ \qquad\quad\;\; | \\ \quad\;\; O=C-C_6H_5 \end{array} \longrightarrow \begin{array}{l} C_6H_5-C=\!=\!=N-N=C-C_6H_5 \\ \qquad\quad\;\, | \qquad\qquad\quad\;\; | \\ C_6H_5-CO \qquad\quad\;\; COC_6H_5 \end{array}$$

The formation of azines from aliphatic diazo compounds has been reported by Staudinger and Kupfer[4] and by Hellerman, Cohn and Hoen,[5] and has been explained by these investigators in an analogous manner. It seemed probable, furthermore, that the production of benzonitrile on distillation of the viscous residue from the heat decomposition of azibenzil was due to the presence of bis-benzilketazine. Meisenheimer and Heim[6] obtained, among other products, benzonitrile and stilbene on the distillation of benzaldazine; bis-benzilketazine would be expected to yield benzonitrile and dibenzoylstilbene, if it were to behave in a similar fashion. Curtius and Blumer,[7] who first prepared bis-benzilketazine, reported that it may be distilled without decomposition; Staudinger and Kupfer[4] state that it may be heated for two hours at 180–200° without alteration. We have observed that it yields, on distillation at ordinary pressure, benzonitrile and benzoic acid. It is therefore quite evident that the yellow solid isolated by Staudinger (m. p. 201°) is bis-benzilketazine (m. p. 202°, corr.).

Further study of the decomposition of azibenzil by heat showed that it may be converted to diphenylketene with a yield of 45% by suspending crystalline azibenzil in ligroin and refluxing the mixture for several hours.

Experimental Part

Benzil Monohydrazone.—The best method for the preparation of this compound was found to be the following modification of the procedure of Curtius and Thun:[8] 88 g. of benzil was dissolved in 220 cc. of boiling 95% alcohol in a 500-cc. three-necked flask fitted with a reflux condenser, mechanical stirrer and dropping funnel. The solution was stirred and refluxed while 50 g. of 42% hydrazine hydrate solution was

---

[3] Staudinger, *Ber.*, **44**, 16 (1911).

[4] Staudinger and Kupfer, *ibid.*, 44, 2201 (1911).

[5] Hellerman, Cohn and Hoen, THIS JOURNAL, 50, 1716 (1928).

[6] Meisenheimer and Heim, *Ann.*, 355, 274 (1907).

[7] Curtius and Blumer, *J. prakt. Chem.*, [2] 52, 117, 137 (1895).

[8] Curtius and Thun, *ibid.*, [2] 44, 168 (1891).

slowly added during half an hour. After the hydrazine hydrate had been all added the mixture was refluxed for an additional two hours. During the heating a part of the sparingly soluble monohydrazone separated in crystalline form. After cooling of the mixture, **83** g. of crude monohydrazone was filtered off. The melting point of the crude product was 148–154°, corr. It was crystallized once from boiling 95% alcohol (0.06 g. per cc.), and the recrystallized product was found to melt at 151–152° (corr.). Curtius and Thun[8] report the melting point as 151°.

Oxidation of Benzil Monohydrazone.—Twenty-five grams of recrystallized finely divided benzil-monohydrazone was suspended in 200 cc. of ether in a 500-cc. flask and 25.5 g. of yellow mercuric oxide added. The mixture was stirred mechanically for four hours. The time required for complete oxidation was found to vary considerably with the character of the mercuric oxide used. Uniformly good results were obtained with mercuric oxide prepared in the following manner: 500 cc. of cold 0.3 *M* mercuric acetate solution was added to 200 cc. of cold 2.5 *M* sodium hydroxide solution. The mercuric oxide which was precipitated was washed repeatedly by decantation with cold water until free from alkali. It was then filtered with suction and air-dried. The most rapid oxidation of the hydrazone occurred when freshly prepared mercuric oxide was used; on standing for a short time in diffused daylight the latter decomposed partly with liberation of mercury, and in this condition was not suitable for use.

After completion of the oxidation the ethereal solution of azibenzil was filtered and dried over calcium chloride. It was then placed in a vacuum desiccator and the latter evacuated. After removal of the ether in this way, 17.7 g. of azibenzil, m. p. 79° corr., was obtained in good crystalline form. This method is substantially the same as that of Forster and Cardwell.[9]

Decomposition of Azibenzil by Heat. A.—Twenty-five grams of benzil monohydrazone was oxidized with mercuric oxide in dry benzene and the resulting solution of azibenzil dried over calcium chloride. This solution was then allowed to drop into a small distilling flask at 110–120° while nitrogen was passed continuously through the flask. These operations were carried out according to Staudinger's directions[2]

Diphenyl ketene was formed and removed from the reaction products by vacuum distillation in an atmosphere of nitrogen. A difficultly volatile viscous residue remained in the distilling flask. On distillation at ordinary pressure it yielded an oily distillate with the odor of benzonitrile, boiling from 167 to 189°. On cooling the distillate a portion of it solidified to a colorless crystalline mass.

B.—Seventeen and seven-tenths grams of crystalline azibenzil was suspended in 107 cc. of 60–90° ligroin which had been previously refluxed with potassium permanganate solution, washed and dried. The mixture was refluxed for eight hours on the water-bath, during which time the azibenzil slowly decomposed, the greater part of the decomposition products dissolving in the ligroin. After the azibenzil had disappeared, the solution was allowed to cool and was decanted from a small amount of bis-benzalketazine which was deposited on the walls of the flask during the reaction. The diphenyl ketene content of the ligroin solution was determined by precipitation with aniline and weighing of the diphenylacetanilide formed. Forty cc. of the solution gave 3.5 g. of diphenylacetanilide corresponding to a yield of 45% based on the azibenzil. The bis-benzilketazine melted at 202° (corr.) and its identity was established further by comparison with an authentic sample of the pure material, prepared as described in the following section.

Preparation of *Bis*-benzilketazine.—*Bis*-benzilketazine has been obtained by Curtius and Blumer[10] together with other products, by heating benzoin hydrazone alone

---

[9] Forster and Cardwell, *J. Chem. Soc.*, 103,868 (1913).

[10] Curtius and Blumer, *J. prakt. Chem.*, [2] *52*, 132 (1895).

in alcoholic solution, or by passing hydrogen chloride into a suspension of benzoin hydrazone in ether. Curtius and Kastner[11] obtained it by dissolving benzil monohydrazone in sulfuric acid and pouring the solution into water at zero, or by heating benzil monohydrazone with benzil at 200'. Staudinger and Kupfer[4] heated benzil monohydrazone for two hours at 240° and also got bis-benzilketazine. We were unable to find any mention in the literature of the following simple method used in this work for its preparation.

Fifty grams of benzil was dissolved in 135 cc. of 95% alcohol, 14 g. of hydrazine hydrochloride dissolved in 30 cc. of boiling water was added and the solution boiled on the steam-bath for five minutes. The ketazine separates rapidly from the boiling solution as a voluminous yellow mass. It was filtered from the hot solution, washed with hot alcohol and recrystallized from boiling glacial acetic acid (0.25 g. per cc.). The yield is quantitative. The recrystallized product melted at 202° (corr.). Staudinger and Kupfer report 195–196°; Curtius and Blumer. 202". Our product, like that of Curtius and Blumer, yielded benzil on hydrolysis with aqueous sulfuric acid.

Distillation of *Bis*-benzilketazine.—Twelve grams of recrystallized material was placed in a distilling flask with a low side-arm, and distilled from a metal-bath through an air condenser. When the temperature of the bath reached 250°, a yellow oil began to distil over. Distillation was continued until the temperature of the bath reached 360". A thermometer placed in the vapor during the distillation read 167° at the beginning and 169° at the end of the distillation. A portion of the oily distillate solidified on cooling and was removed mechanically from the air condenser. The oil was found to boil at 189". This fraction was identified as benzonitrile by converting a portion of it to benzoic acid by hydrolysis. The solid which separated from the oil on cooling was identified as benzoic acid.

Summary

1. A modified procedure for the synthesis of diphenyl ketene by Schroeter's reaction has been described.
2. The decomposition of azibenzil by heat has been shown to yield *bis*-benzilketazine.
3. Distillation of bis-benzilketazine yields benzonitrile and benzoic acid.

SALTS OF TRIPHENYLSELENONIUM HYDROXIDE[1]

BY HENRY M. LEICESTER AND F. W. BERGSTROM

RECEIVED JULY 2, 1929 PUBLISHED DECEMBER 11, 1929

In salts of the type of tetramethylammonium chloride, $(CH_3)_4NCl$, and trimethylsulfonium chloride, $(CH_3)_2SCl$, the radicals $(CH_3)_4N$ and $(CH_3)_3S$ play the part of metals, and like the metals can be arranged in an electropotential series or series of relative electro-affinities.[2] Tetramethylammonium and trimethylsulfonium thus occupy positions near the head of this series, comparable with the positions occupied by the alkali metals, which they resemble in character. Now it has customarily been assumed that replacement of one or more indifferent methyl groups by groups of a distinct negative character, such as phenyl, diminishes the electropositiveness of the radical as a whole. While this appears to be true in a qualitative sense[3] there are several apparent exceptions, notably the recently synthesized tri-, tetra- and pentaphenylchromium hydroxides,[4] which are bases of moderate strength in spite of the large number of negative phenyl groups in their molecules.

A determination of the effect of different alkyl or aryl groups upon the position of these substituted -onium radicals in the electropotential series would thus appear to be a problem worthy of further study. The present investigation was undertaken for the purpose of supplying such information for the little known trialkyl and triaryl selenonium groups. As a prelude to this work it was found necessary to devise an adequate method for the preparation of the selenonium salts. In this paper is reported the synthesis of some salts of triphenylselenonium hydroxide.

Jackson[5] prepared the first selenonium compound, trimethylselenonium iodide, $(CH_3)_3SeI$, as well as the corresponding dimethylbenzyl and the tribenzyl salts, the last named not being recognized until Fromm and Martin[6] proved its structure. Pieverling[7] made an extensive study of the triethylselenonium salts, and Pieroni and Coli[8] isolated the selenohydrate, $(C_2H_5)_3SeSeH$. Scott[9] prepared trimethyl- and triethylselenonium per-

iodides. This completes the work on the aliphatic salts. Hilditch and Smiles[10] prepared certain aromatic selenonium salts by the action of aluminum chloride upon anisole or phenetole and selenium dioxide. The yields were very low and the products impure. The structure of these compounds has recently been proved by Morgan and Burstall,[11] who have also prepared several hydroxyarylselenonium salts from phenols and selenium oxychloride. In addition, Carrara,[12] Pope and Neville,[13] and Edwards, Gaythwaite, Kenyon and Philips[14] have prepared compounds in which one of the three organic groups attached to the selenium atom is —CH_2COOH.

The selenium halides of the type $SeCl_4$ seem to offer an excellent starting point for the synthesis of compounds of the desired kind, due to the reactivity of the halogen atoms. However, it was found that too many side reactions occurred, and the Grignard, the Wurtz–Fittig, and the Friedel–Crafts reactions all yielded complex mixtures. It therefore seemed best to simplify the preparation by the use of a compound in which some of the halogen atoms of the selenium tetrahalide were already replaced by organic groups. Such a compound, diphenylselenium dichloride, $(C_6H_5)_2SeCl_2$, was successfully employed in a Friedel–Crafts reaction. The following equations represent the essential steps in the complete synthesis of triphenylselenonium chloride

$$\begin{aligned}
&2C_6H_5N_2Cl + K_2Se = (C_6H_5)_2Se + N_2 + 2KCl\\
&(C_6H_5)_2Se + O \overset{HNO_3}{=} (C_6H_5)_2SeO\\
&(C_6H_5)_2SeO + 2HCl = (C_6H_5)_2SeCl_2 + H_2O\\
&(C_6H_5)_2SeCl_2 + C_6H_6 \overset{AlCl_3}{=} (C_6H_5)_3SeCl + HCl
\end{aligned}$$

The chloride thus prepared forms a white, crystalline hydrate, $(C_6H_5)_3$-$SeCl\cdot 2H_2O$, with great ease on exposure to moist air. From the chloride it is easy to prepare other salts by double decomposition. Thus the water solution of the chloride yields a precipitate of the iodide or dichromate on treatment with a soluble salt of hydriodic or dichromic acid, an alcoholic solution of the chloride gives the picrate with picric acid, and the nitrate may be prepared by mixing aqueous solutions of the chloride with silver nitrate. In crystallizing the chloride from ethylene bromide, it was found that a quantitative conversion into triphenylselenonium bromide took place. This rather unusual reaction forms the best method for the preparation of the water-soluble bromide.

Another observation of some interest is that the melting points of the

---

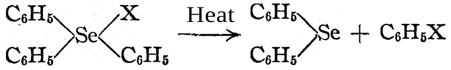
chloride, bromide and iodide are very close to one another, 230, **236** and 237.5°, respectively. In a similar way the tri-(4-hydroxyphenyl)-selenonium chloride of Morgan and Burstall[11] melts at 232° and the bromide at 237°, while their tri-(3-methyl-4-hydroxyphenyl)-selenonium chloride melts at 231°. Since all these melting points are accompanied by decomposition, it appears that the breakdown at this temperature is rather a property of the selenonium type of molecule and is little affected by the substituent parts, as long as these are aryl in character.

In the case of the triphenylselenonium halides the decomposition occurs as follows



$$(C_6H_5)_2Se(X)(C_6H_5) \xrightarrow{\text{Heat}} (C_6H_5)_2Se + C_6H_5X$$

where X is a halogen atom. Presumably the other compounds mentioned decompose in an analogous fashion. This reaction is exactly similar to that of the trialkylselenonium halides, save that the latter is reversible. It was, in fact, this method which Pieverling[7] used in his synthesis, the reaction being

$$(C_2H_5)_2Se + C_2H_5I \longrightarrow (C_2H_5)_2SeI$$

At 80° the reverse reaction occurs and the two liquids on the left-hand side of the equation distil over, to reunite in the cold. The reaction in the aromatic series appears to be irreversible, however, and even ethyl iodide does not react with diphenyl selenide over a period of several months.

Experimental Part

Diphenyl Selenide.—This compound was at first prepared from diphenyl sulfone and selenium, according to the method of Krafft and Lyons.[15] However, an extension of the method of Schoeller[16] was found to be more rapid and economical. Three hundred and sixty grams of powdered potassium hydroxide and 240 g. of black, powdered selenium were thoroughly mixed and heated on an oil-bath to 140°, at which temperature they fused together. To a solution of the fused mass in 400 cc. of ice water was added slowly and in small portions at a time an ice cold solution of diazotized aniline hydrochloride from 138 g. aniline. To complete the reaction, the solution was separated from the viscous selenium-containing black mass in the bottom of the reaction vessel and heated to boiling. While still hot this was poured back upon the viscous black mass, which was then stirred up with the liquid.[17] The precipitate of selenium was filtered off and the lower liquid layer of the filtrate, consisting of diphenyl selenide, separated. The selenium was washed with ether or chloroform and the washings combined with the selenide. The combined liquids were distilled and the fraction boiling at 300–315° was the desired diphenyl selenide; yield, 125 g., or 72%, based upon the aniline used.

Diphenyl Selenium Dichloride.[18]—The diphenyl selenide (125 g.) was dissolved in an excess of commercial concentrated nitric acid and commercial concentrated hydrochloric acid was added. The dense yellow precipitate resulting was filtered, washed with

water and crystallized once from benzene. The compound thus treated is still yellow, but is sufficiently pure to be used in the preparation of triphenylselenonium chloride; yield, 141 g., or 87%, calculated on the basis of the diphenyl selenide.

Triphenylselenonium Chloride, $(C_6H_5)_3SeCl$.—Eighty grams of anhydrous aluminum chloride was suspended in 100 cc. of dry benzene. The reaction flask was cooled with ice and 40 g. of diphenylseleniumdichloride was added in portions over a period of twenty minutes. The flask was cooled and shaken throughout the addition. If these precautions were not observed, the mixture became warm and the product was largely a tar. During the reaction the liquid became dark red-brown, the aluminum chloride dissolved and hydrochloric acid was given off. After all of the dichloride had been added the mixture was allowed to stand for three hours at room temperature; 200 cc. of water was then cautiously added. The benzene layer was separated and discarded and the water solution extracted with chloroform. The extract was evaporated to small bulk and treated with three times its volume of ether. A yellow oil at once separated and quickly solidified to a pale yellow powder. This was filtered and crystallized from methyl ethyl ketone.[19] In this manner 30 g. of white crystals was obtained, a yield of 66%. They were very soluble in water, alcohol and chloroform, slightly soluble in acetone, but insoluble in ether. If the compound was allowed to stand in moist air or was recrystallized from wet solvents, it took up water to form a dihydrate. A sample crystallized from a little water gave the same compound. This became completely anhydrous after heating for half an hour at 100° in air.

[a] All temperatures are corrected. [b] Determined by the method of Shaw and Reid, THIS JOURNAL, 49, 2330 (1927). [c] Begins to lose water at about 82° in air. [d] Percentage loss of two molecules of water at 100°: calcd., 9.43; found, 9.32. [e] Prepared by dissolving the chloride in boiling ethylene bromide. On cooling, the bromide separates out. [f] On exposure to light, the white iodide slowly turns yellow. [g] M. p., 141–142°. [h] Separates from concd. water solution on addition of concd. nitric acid. [i] M. p. 107–108°.

Thermal Decomposition of the Triphenylselenonium Halides.—On heating the iodide to its melting point, a rather violent boiling took place and on cooling the substance remained liquid. This liquid was separated by fractionation into a substance boiling at 180–190° and another boiling at 295–302°. The first fraction was proved to be iodobenzene (b. p. 185°) by conversion into phenyl iodoso chloride. This was further checked by a mixed melting point with a known sample of phenyl iodoso chloride. The second fraction was identified as diphenyl selenide (b. p. 302°) by conversion into

---

[19] The ketone was dried over anhydrous copper sulfate, as suggested by Locke, *Ind. Eng. Chem.*, 16, 956 (1924).

diphenylselenium dibromide, the identity of which was confirmed by a mixed melting point with some known diphenylselenium dibromide.[20]

In an entirely similar manner, triphenylselenonium bromide yielded two liquids boiling at 153–156 and 300–304°. The last was obviously diphenyl selenide, the first, bromobenzene (b. p. 156°). The chloride gave the selenide and a liquid boiling at 130–140°, which appeared to be chlorobenzene (b. p. 132°).

Summary

1. A method has been described for the synthesis of triphenylselenonium chloride, $(C_6H_5)_3SeCl$, by the action of benzene upon diphenylselenium dichloride in the presence of aluminum chloride.

2. From triphenylselenonium chloride the following salts have been prepared by metathesis: the bromide, iodide, dichromate, picrate and nitrate. Triphenylselenonium hydroxide appears to be a base of moderate strength.

3. The chloride, bromide and iodide have been shown to decompose with heat to give diphenyl selenide and chloro-, bromo- or iodobenzene, respectively.

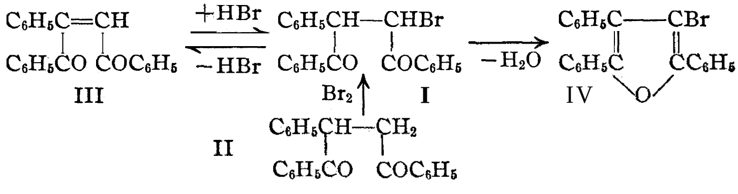
THE BROMINATION OF DESYLACETOPHENONE

BY CHARLES F. H. ALLEN AND ERNEST F. HERRMANN

RECEIVED JULY 10, 1929 PUBLISHED DECEMBER 11, 1929

In an earlier paper[1] in which it was shown that bromofurans are produced when diacylstyrenes are treated with hydrogen bromide, the assumption was made that an open-chain addition product containing bromine was an intermediate product. Such a substance could form the ring compound by a loss of water from its enolic modification. Although the reaction undoubtedly took this course, unfortunately we were unable to isolate this bromo ketone (I)



In an attempt to prepare the latter substance, desylacetophenone (II), the saturated diketone corresponding to phenyldibenzoylethylene (III), was treated with bromine. In both chloroform and acetic acid solutions a quantitative yield of the bromofuran (IV) was obtained. Since the pri-

---

[1] Allen and Rosener, THIS JOURNAL, 49, 2110 (1927).

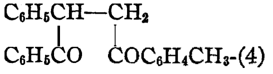
mary reaction was one of substitution, as evidenced by the copious evolution of hydrogen bromide, it was indicated that such a bromo ketone was undoubtedly formed. The closing of the ring doubtless was brought about by the dehydrating action of the hydrogen bromide. Acting upon this assumption, the bromination was carried out in acetic acid solution in the presence of a large amount of potassium acetate, a reagent which has previously been shown to be efficacious in removing hydrogen bromide as rapidly as formed.[2] Under these conditions and using small amounts it was found possible to isolate an open-chain bromo ketone (I) from the mixture. It was found that if large quantities were used, most of the product was the bromofuran, even when a considerable excess of potassium acetate was present. Evidently the acetic acid, acting as a dehydrating agent on a part of the bromo ketone first formed, brought about ring closure during the slow bromination.

We hoped that by selecting a solvent such as ethyl acetate, which was not a dehydrating agent, and using a limited amount of hydrogen bromide, it might be possible to isolate the open-chain bromo compound, starting with phenyldibenzoylethylene. This procedure was unsuccessful, a nearly quantitative yield of bromofuran being obtained.

On treatment with dehydrating agents the open-chain bromo compound loses the elements of water and forms the bromofuran (IV). Alcoholic potash, however, removes hydrogen bromide with consequent production of phenyldibenzoylethylene (III). The relation between these various compounds is shown in the outline above.

Experimental

The desylacetophenone was made by Smith's method.[3] Two homologs, using P-methylacetophenone and methyl *α*-thienyl ketone, were also prepared in the same way.



$$\begin{array}{ll} C_6H_5CH & -CH_2 \\ | & | \\ C_6H_5CO & COC_6H_4CH_3\text{-}(4) \end{array}$$

V

VI	$C_{20}H_{16}O_2S$	126	75.0	5.0	74.8	5.2

Bromination.—Five grams of desylacetophenone was dissolved in 25 cc. of warm glacial acetic acid, a little of the solution transferred to a test-tube and 3.1 g. of pulverized dry potassium acetate added to the remainder, the whole being in a flask fitted with a stirrer, condenser and dropping funnel, the end of which was drawn out into a fine capillary. A little bromine was added to the sample in the test-tube, and once hydrogen bromide was evolved the whole was introduced into the flask. A solution of 2.5 g. of bromine in 6 cc. of acetic acid was admitted, drop by drop, while stirring vigor-

---

[3] Smith, J. *Chem. Soc.*, **57**, **649** (1890).

ously and refluxing in bright sunlight. The red bromine color was still present after boiling for two and a half hours. The mixture was poured into 200 cc. of water containing 5 g. of sodium bisulfite and the oily gum formed removed. The accumulated product from several runs was combined and after a tedious process of fractional crystallization, an open-chain bromo compound (I) and unchanged desylacetophenone (II) were separated in crystal form, The average yield of solid from several runs was 50%, only half of which was the desired bromine compound.

1,2,4-Triphenyl-3-bromobutandione-1,4 (I) crystallizes in long white needles that melt at 119° and decompose at 130°. It is readily soluble in all the usual organic solvents exsept petroleum ether.

Anal. Calcd. for $C_{22}H_{17}O_2Br$: Br, 20.4. Found: Br, 20.2.

When 30 g. of ketone was brominated in a similar way, the only solid containing halogen that could be isolated was 2,3,5-triphenyl-4-bromofuran (IV). This was doubtless owing to the dehydrating action of the acetic acid on the open-chain bromoketone, since it took several hours to add all the bromine.

Bromination in both chloroform and acetic acid in the absence of potassium acetate gave practically quantitative yields of the bromofuran. Thus 5 g. of desylacetophenone in 25 cc. of hot chloroform reacted instantly with the calculated amount of bromine in the same solvent, with copious evolution of hydrogen bromide. After evaporating about one-half and washing with sodium bisulfite, addition of two volumes of methyl alcohol caused the bromofuran to crystallize. This was filtered and a further amount obtained by partial evaporation of the filtrate. The total amount was 5 g. or 85%; it was identified as triphenylbromofuran by comparison with an authentic specimen.

The difference in the results of the two methods indicates that the hydrogen bromide formed must be involved in some way. Since it is known to accelerate the rate of enolization of ketones and because bromine combines rapidly with enolic forms in the absence of potassium acetate, the apparent substitution reaction is much faster; part of the hydrogen bromide may act as a dehydrating agent on the bromo ketone, which by loss of water forms the bromofuran. In the absence of hydrogen bromide, bromination is so slow that other reactions take place, accounting for the large amount of oily product and small amount of bromo ketone. If the treatment with bromine was prolonged until all of the desylacetophenone had disappeared, then the bromofuran appeared, formed by dehydration of the open-chain compound.

Hydrogen Bromide on Phenyldibenzoylethylene in Ethyl Acetate.—To 2 g. of phenyldibenzoylethylene in 25 cc. of hot ethyl acetate was added 2 g. of hydrogen bromide gas and the yellowish solution allowed to evaporate in a current of air. The only product was the bromofuran.

Alcoholic Potash on the Open-Chain Bromo Ketone.—Two-tenths gram of bromo ketone was added to 10 cc. of hot alcoholic potash; it rapidly dissolved. After five minutes the solution was cooled and acidified with acetic acid; 0.14 g. of yellow crystals of phenyldibenzoylethylene (III) slowly separated and was identified by comparison with an authentic specimen. The bromofuran is unaffected by prolonged boiling with alkalies.[1]

Dehydrating Agents on the Bromo Ketone.—A solution of 0.2 g. of bromo ketone in 10 cc. of glacial acetic acid was refluxed for two hours, poured into water and the precipitated gum taken up in a small amount of chloroform. On adding two volumes of alcohol, white, fluffy needles of the bromofuran crystallized in a quantitative yield. Acetic anhydride acted in a similar manner.

This work has been assisted by a grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences,

Summary

1. Desylacetophenone reacts with bromine to form a monosubstitution product, which can be isolated only if the reaction is carried out in the presence of potassium acetate. In the absence of the latter reagent, ring closure takes place with formation of triphenylbromofuran.
2. The structure of the bromo ketone has been determined.

[Contribution from the Laboratory of Physical Chemistry of the University of Upsala]

THE MOLECULAR WEIGHT OF BENCE-JONES PROTEIN

By The Svedberg and Bertil Sjögren

Received July 15, 1929 Published December 11, 1929

Certain diseases, especially myelomas, are characterized by the appearance in the urine of a peculiar protein called after its discoverer Bence-Jones protein.[1] The question of the origin of this abnormal product of cell life has caused much discussion. The comparative rareness of cases which are accompanied by the appearance of this protein has hampered the study of its properties. Recently such a case was reported from the Academic Hospital in Upsala and by courtesy of Professor G. Bergmark we received a sufficient quantity of urine for an ultracentrifugal investigation. In view of the fact that one of the theories about the origin of Bence-Jones protein considers it to be a product of protein cleavage, the determination of its molecular weight seemed to us to be of great interest. From analytical data Cohn has calculated a minimal molecular weight of 24,500,[2] but judging from the results of similar. computations compared with the results of ultracentrifugal determinations no certain conclusion as to *the actual molecular weight in aqueous solution* can be drawn from his calculation.

Preparation of Material.—To 2400 cc. of urine were added 4800 cc. of saturated ammonium sulfate solution and some toluene as a preservative. After standing for twenty-four hours at 0° the precipitate was centrifuged off and washed repeatedly with a mixture of two parts of saturated ammonium sulfate and one part of water. The precipitate was then dissolved in the smallest possible volume of water and reprecipitated with ammonium sulfate solution to a saturation degree of 60%. After standing for twenty-four hours at 0°, the precipitate was filtered off and washed with ammonium sulfate solution of 60% saturation. This material was divided in two parts. One portion was dissolved in phosphate buffer of P_H 5.5 (0.095 *M* in KH_2PO_4 and 0.005 *M* in Na_2HPO_4) and dialyzed at 0° against the same buffer for six days, after which time the SO_4-reaction was negative; volume of solution, 50 cc., concentration 1.19% (Ma-

---

[1] See Wells, "Chemical Pathology," Saunders Co., Philadelphia and London, 5th ed., 1925, p. 596.

[2] Cohn, Hendry and Prentiss, *J. Biol. Chem.*, 63, 764 (1925).

terial I). A second portion was dialyzed against pure water and then electrodialyzed. No precipitate was formed during the electrodialysis. The concentration of this solution was 1.28% and the volume 200 cc. (Material II).

The isoelectric point of Material II was measured by A. Tiselius in this Laboratory and found to be 5.18. In electrochemical respects, therefore, Bence-Jones protein is distinctly different from egg albumin and serum albumin, which have isoelectric points at PH 4.6 and 4.9, respectively (according to recent determinations by Tiselius).

Specific Volume.—The partial specific volume was determined pycnometrically at 19.8°, as described in previous communications.[3] The data are shown in Table I.

TABLE I

PARTIAL SPECIFIC VOLUME OF BENCE-JONES PROTEIN AT 19.8°

Protein concn., %	Solvent	PH of soln	Partial spec vol.
0 80	0 006 M in HAc, 0.014 M in NaAc	5.0	0 747
1.19	0 006 M in HAc, 0 014 M in NaAc	5 0	749
1.32	Pure water	5.1	.751

These specific volumes are identical within the limits of error. The mean value 0.749 is also identical with the specific volumes of egg albumin, hemoglobin, serum albumin, serum globulin, phycocyan, phycoerythrin and edestin. As previously pointed out, this indicates a close relationship between all these proteins.[4]

Light Absorption.—The light absorption of solutions of Bence-Jones protein at various hydrogen-ion concentrations was measured with the Judd–Lewis spectrophotometer. Material II (electrodialyzed) was used and the measurements were carried out directly after making up the solutions. At the isoelectric point determinations were made in concentrations 0.06 and 0.12%, using a tube length of 2.0 cm. and in the concentration of 0.95% with 0.1-cm. tube length. All other determinations were performed on solutions of 0.05 and 0.10% using a tube length of 2.0 cm.

In Table II the positions of the maximum and the minimum of absorption and the extinction coefficients for the maximum are recorded. Figure 1 shows the absorption curves for three different hydrogen-ion concentrations.

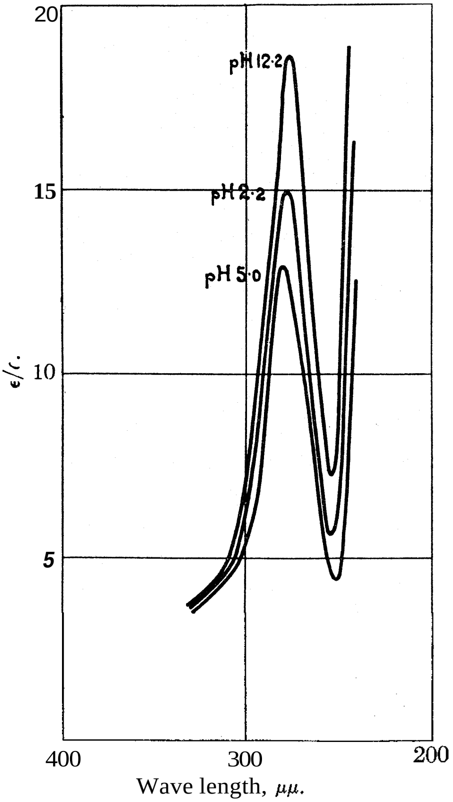

Fig. 1.

The position of the maximum and the minimum of the absorption curve is independent of *P*H. The value of the extinction is independent of *P*H within the region 3.94 to 7.74. In more acid and more alkaline solution, the extinction increases, indicating changes in the protein molecule. As will be seen from the molecular weight determinations, the molecule begins to break up into smaller units in the same *P*H regions where the light absorption begins to rise. There is a distinct difference however between the acid and the alkaline hydrolysis. The rise in light absorption on the acid side is caused by the formation of strongly absorbing noncentrifugible decomposition products, the mass of the centrifugible substance remaining unchanged, while the rise in light absorption on the alkaline side is due to the formation of centrifugible decomposition products.

Determination of Molecular Weight

Sedimentation Equilibrium Method.—A number of runs were made at different hydrogen-ion concentrations in order to determine not merely the molecular weight but also the stability region of the protein. As shown in previous communications[5,6] the molecular weight is given by the relation

$$M = \frac{2RT \ln (c_2/c_1)}{(1 - V\rho)\omega^2 (x_2^2 - x_1^2)}$$

where R is the gas constant, T the absolute temperature, V the partial specific volume of the solute, ρ the density of the solvent, ω the angular

[5] Svedberg and Fåhraeus, THIS JOURNAL, **48, 430** (1926).

[6] Svedberg and Nichols, *ibid.*, **48**, 3081 (1926).

velocity and c_2 and c_1 the concentrations at the distances x_2 and x_1 from the center of rotation.

An improved type of ultracentrifuge for medium speed was used for these determinations. The cells employed were made as follows: an ebonite plate **25** mm. in diameter and with a sectorial aperture of **5°** cut from the periphery down to **7.5** mm. from the center of the plate was coated with a solution of rubber in benzene and after drying for a few minutes covered with two quartz plates of the same diameter and 5-mm. thick and slid into an ebonite collar. The latter was in its turn introduced into a steel collar threaded at the ends. By means of two steel guard rings and thin intermediate ebonite rings the quartz plates were firmly pressed together. Both the ebonite and the steel collar had openings coincident with the opening of the sectorial cell. The opening could be closed by an ebonite lid. Four different thicknesses were used for the ebonite middle plates, *viz.*, *2*, 4, ***8*** and 16 mm., giving the corresponding four thicknesses of solution and thus permitting a wide range of different concentrations to be studied. This new type of cell has proved to be more reliable than the cemented one previously described.[7] The ebonite sector plates do not crack as the glass or quartz sector plates often do when exposed to the centrifugal force, the cell is easier to clean and the rubber is more resistant to salt solutions than the de Khotinsky cement. The ebonite collar around the quartz plates protects them from uneven strain.

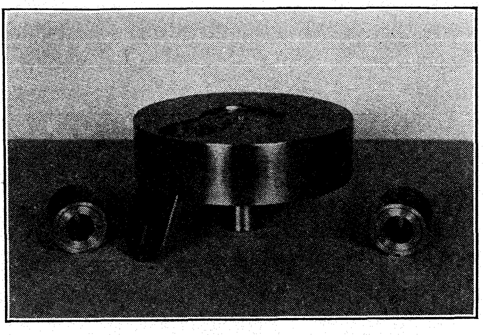

Fig. *2*.

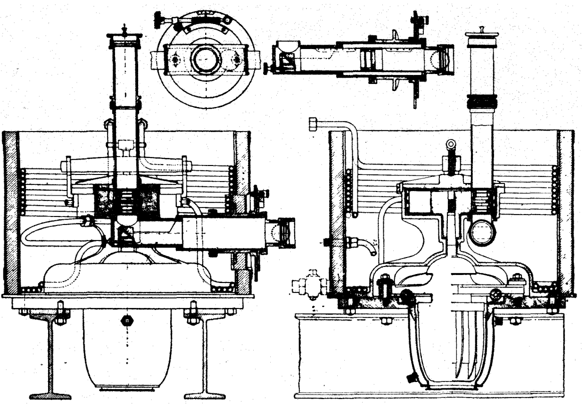

Fig. 3.

By choosing the inner diameter of the cell smaller, a thicker steel collar could be used which was less easily deformed by the centrifugal force. Optically the cell was defined by two steel diaphragms with sectorial apertures of **3°**, one on each side of the cell. The rotor was a chromium–nickel steel cylinder **15** cm. in diameter and 4 cm. thick and was arranged to receive two cells. One of them was used for the solution to be studied; the other was

---

[7] Svedberg and Heyroth, THIS JOURNAL, 51, **552 (1929).**

filled with a non-centrifugible solution for standardizing the intensity of the illuminating lamp. Figure 2 shows the rotor with the two cells and one of the sector diaphragms removed. The rotor was supported upon a vertical steel shaft directly connected to the rotor of a special electric three-phase motor. The speed could be varied from 12,000 r.p m. down to about 2000 r.p.m. by varying the frequency of the current feeding the motor. The centrifuge rotor as well as the rotor of the electric motor was surrounded by hydrogen of atmospheric pressure confined within a casing about the moving parts of the centrifuge. To further ensure constant temperature, the stator of the motor was water-cooled and the casing within which the centrifuge rotor moved was immersed in a water thermostat. Freedom from vibration was ensured by a special circular rubber support for the stator. Suitable arrangements for passing of the light beam through the centrifuge and for taking exposures were made. Figure **3** gives a diagram of the centrifuge and Fig. 4 a photographic view of the whole apparatus except the camera. The latter (Fig. **5)** was placed in a room above the one where the centrifuge was mounted. The optical system used was about the same as previously employed? In Fig. 4 the water-cooled house for the mercury lamp can be seen to the right, then the light filter and the centrifuge follow from right to left. The horizontal illuminating beam is reflected vertically through the centrifuge by a quartz prism. Above the centrifuge is the photographic lens and part of the **camera.** On the wall are mounted the controlling instruments.3

[9] The motor and the generator for the variable three-phase current were delivered by Siemens, Berlin; most of the other parts of the equipment were manufactured in the workshops of the laboratory.

For the runs described below a wave length range 290–240$\mu\mu$ was isolated from the mercury arc by means of bromine and chlorine light filters.

In Table III the results of a typical run are given and in Table IV are collected the main data of all the runs.

Within the PH region 3.94 to 7.74, the molecular weight is independent of the hydrogen-ion concentration, with a mean value of 35,000 ± 1000. The constancy of the molecular weight as a function of distance from center of rotation shows that the Bence-Jones protein is homogeneous with regard to molecular weight within the same PH region. At a PH of 10.85 considerable decomposition has taken place, the values of the molecular weight ranging from 36,100 (the normal weight) to 16,400. An attempt was made to determine the molecular weight at PH 12.66 (0.05 *M* in NaOH, 1% in NaCl) but during the long time required for reaching equilibrium, the light absorption increased enormously, indicating very strong hydrolysis. A sedimentation velocity run performed at the same PH, which required only six hours of centrifuging, indicated a molecular weight of about one-half that of the normal protein.

Sedimentation Velocity Method.—For the sedimentation velocity runs the high-speed oil turbine ultracentrifuge previously described[10] was used. New cells of a somewhat different type resembling those described above for the new medium-speed ultracentrifuge were employed.

For most of the runs light of the wave length region 290–240$\mu\mu$ was isolated from the mercury arc by means of bromine and chlorine filters. Using a 12-mm. cell the lowest concentration of protein that could still be studied with this illumination was 0.10%. In order to render possible the study of still lower concentrations, a cadmium spark lamp was constructed. It was fed by a 1-kilowatt transformer giving 25,000 volts with a condenser parallel to the spark. An image of the spark in natural size was thrown on a small diaphragm by means of a quartz condenser and a slightly converging beam of light was then sent through the centrifuge by means of a second quartz lens possessing a focal length double that of the quartz condenser. By using a chlorine filter of 100 cm. a wave length region 231–214$\mu\mu$ could be isolated from the light given off by the spark. As demonstrated by the curves in Fig. 1, the light absorption of the protein is much higher in this wave length region. As a matter of fact, concentrations down to 0.025% could be studied by means of the cadmium spark lamp in combination with the 100-cm. chlorine filter.[11]

In the steady state of sedimentation the centrifugal force per mole of protein, $M(1 - V\rho)\omega^2 x$, and the frictional force per mole, $f dx/dt$, where f is the molar frictional constant and the other symbols have the same significance as previously, are equal. If we define $s = dx/dt\ 1/\omega^2 x$ as the specific sedimentation velocity or sedimentation constant, we have

$$M = \frac{fs}{1 - V\rho}$$

---

[10] Svedberg and Nichols, THIS JOURNAL, 49, 2920 (1927); Svedberg, "Colloid Chemistry," 2d ed., Chemical Catalog Co., New York, 1928, p. 153.

[11] No bromine filter was used in this case because the light absorption of bromine is too high in the very short waved ultraviolet region. One of the functions of the long chlorine filter is that of absorbing the violet light.

If we assume that the molar frictional constant effective in sedimentation is the same as the one effective in free diffusion we are justified in using the relation $f = RT/D$, where D is the diffusion constant, and thus get for the molecular weight[10]

$$M = \frac{RTs}{D\,(1 - V\rho)}$$

The fact that in most cases hitherto studied the values of the molecular weights obtained by the sedimentation equilibrium and the sedimentation velocity method check within the limits of experimental error (hemoglobin, serum albumin, serum globulin, phycocyan, phycoerythrin, edestin) demonstrates that the above assumption is as a rule justified. Certain exceptions have been observed however. For hemocyanin the diffusion as measured from the sedimentation pictures was abnormally low at higher concentrations but became normal at high dilutions from about $^1/_3\%$ downward.[12] The sedimentation constant was only slightly affected by the forces which at higher concentrations depressed the diffusion. A similar effect has been observed for cellulose.[13] Recently several instances of abnormal diffusion persisting down to very low concentrations have been observed. In such cases the sedimentation velocity has always been perfectly in line with the molecular weight obtained from sedimentation equilibrium measurements. From these facts we must draw the conclusion that the value of the molar frictional constant derived from the diffusion formula where a perfectly free movement of the molecules is assumed is not necessarily the same as the molar frictional constant which is effective in the sedimentation of molecules in a field of force. In the latter case the molecules need not move independently of each other.

The determinations of sedimentation constant and diffusion constant for Bence-Jones protein have shown that the values of the diffusion constant are irregular and abnormally low even down to a few hundredths of a per cent. On the other hand, the values of the sedimentation constant were quite regular. In the following, therefore, only these latter determinations will be mentioned.

In order to explore the PH stability region more in detail than was done by the equilibrium measurements, a series of determinations of the sedimentation constant was performed at different hydrogen-ion concentrations. The solutions were brought to the desired concentration and PH immediately before starting the runs. In Table V the results are summarized. Figure 6 shows the relation between sedimentation constant and PH graphically. In the same diagram are plotted the values of the extinction coefficient at the maximum of absorption as function of PH. In the *PH* region 3.5–7.5, both sedimentation and light absorption are practi-

[13] Stamm, unpublished investigations.

cally constant and no non-centrifugible substance is formed. The protein is very stable in this *P*H region. At lower PH values the light absorption increases, while the sedimentation constant remains unchanged. The photograms of the solution during centrifuging indicate that at PH values of 1.2–1.4, 40–35% of the protein is broken up into a non-centrifugible substance. This accounts for the rise in light absorption. At the acid

[a] Cadmium light was used. [b] 1% in NaCl.

side, therefore, the molecule is directly hydrolyzed into small molecules and what still remains of bigger molecules shows the normal sedimentation of the protein. At PH values higher than 7.5 the light absorption increases while the sedimentation constant decreases. Both curves have a small horizontal **part** in the *PH* region 12.2–12.7 indicating that the centrifugible part of the protein has reached a second stability range. An increasing amount of non-centrifugible substance is being formed, amounting to about 18% at PH 12.7. As an average value of 13 determinations of the sedimentation constant within the stability region including the isoelectric point we get 3.55×10^{-13}. Some of the determinations at high PH values show a marked Donnan effect. While the two runs at *PH* 11.61 and 11.69 gave practically the same sedimentation constant, 2.13 and 2.17, with and without 1% NaCl present, the runs from PH 12.15 show a marked salt effect. Without salt the values of the sedimentation constant are 1.49, 1.40 and 1.44, at the *PH* of 12.15, 12.60 and 12.61, while the values found in the presence of 1% NaCl are 1.69 and 1.69 at the PH of 12.23 and 12.66. The value 1.69 is probably free from any influence of the Donnan effect.

Discussion of Results

The ultracentrifugal study of Bence-Jones protein has shown this substance to be uncommonly stable. Within the *PH* range 3.5–7.5 there is no decomposition of the molecule The sedimentation equilibrium method has given a mean value of 35,000 for the molecular weight, determinations being made in the PH range 3.94–10.85. From *PH* 3.94 to 7.74 the protein was found to contain only molecules of weight 35,000. A run at PH 10.85 showed a drift in the values of the molecular weight from 36,100 at the bottom of the cell to 16,400 at the top of the cell. At this PH, therefore, the protein is a mixture. The sedimentation velocity runs have shown that in the PH region 1.2–3.5 there is hydrolysis of the molecule into a non-centrifugible substance. The remaining protein has the same sedimentation constant as in the PH region, where it is perfectly stable. In the PH region 7.5–12.2 the sedimentation decreases steadily. In the PH range 12.2–12.7 the sedimentation is constant. Now it is of considerable interest to notice that the molecular weight of 35,000 found for the Bence-Jones protein by means of the sedimentation equilibrium method is practically identical with the molecular weight found by the same method for egg albumin,[6] *viz.*, 34,500, and that the sedimentation constant found for the Bence-Jones protein within the stability region which includes the isoelectric point is 3.55×10^{-13}, while the same constant found by Nichols for egg albumin is 3.32×10^{-13}.

The molar frictional constant $f = [M(1 - V\rho)]/s$ for Bence-Jones protein at 20° is 2.48×10^{16} and for egg albumin 2.63×10^{16}. The molar frictional constant f_s for a substance of molecular weight 35,000 and possessing spherical molecules of the same specific volume as Bence-Jones protein can easily be calculated from the relation $f_s = 6\pi\eta N(3MV/4\pi N)^{1/3}$, where η is the viscosity of the solvent, N the Avogadro constant and the other symbols have their usual significance. The value is 2.49×10^{16}. The corresponding value for egg albumin is 2.47×10^{16}. The ratio f/f_s may be taken as measure of the dissymmetry of the molecule. For a spherical molecule this ratio should be unity. From our experimental data we find for Bence-Jones protein $f/f_s = 1.00$ and for egg albumin 1.06. The data at our disposal also permit of the calculation of the radius of these spherical molecules. By means of the formula $r = (3MV/4\pi N)^{1/3}$ we get for Bence-Jones protein $r = 2.18\mu\mu$ and for egg albumin $2.17\mu\mu$.

The normal Bence-Jones protein, therefore, seems to have molecules of the same weight as egg albumin. Both proteins have spherical molecules of a radius of about $2.2\mu\mu$. The molecular weight value for the lightest component in the equilibrium run at P_H 10.85 was 16.400, which is not far from one-half the weight of the undecomposed protein. The sedimentation constant value found at high P_H values in the presence of salt was 1.69, while the value to be expected for a molecule of one-half the weight of the normal Bence-Jones protein and having about the same degree of dissymmetry as the other dissymmetrical protein molecules so far studied in this Laboratory is 1.70. It therefore seems probable that at high P_H values the molecule of the Bence-Jones protein is split up into halves. At the same time an ordinary hydrolysis producing non-centrifugible substance begins.

From the pliysiological point of view it is of interest to observe that native egg albumin also to some extent passes normal kidneys, just as the Bence-Jones protein does, while the appearance of serum albumin in the urine is accompanied by some change in the function of the kidneys. Now serum albumin has the double molecular weight of egg albumin and Bence-Jones protein. It may be, therefore, that the appearance of one or the other of these proteins in urine is more or less a question of permeability.

The expenses connected with these experiments have been defrayed by grants from the foundation "Therese and Johan Anderssons Minne" and from the Nobel Fund of Chemistry.

Summary

1. The ultracentrifugal methods have been applied to the study of the molecular weight and P_H stability range of Bence-Jones protein.

2. In the P_H range 3.5–7.5 the protein is stable and has a molecular weight of 35,000 ± 1000, a sedimentation constant of 3.55×10^{-13} and

a molar frictional constant of 2.48 X 10^{16} (both at 20°); a comparison with the molar frictional constant calculated for a spherical molecule of the same molecular mass and volume shows that the molecule of Bence-Jones protein is spherical and has a radius of 2.18$\mu\mu$.

3. At PH values lower than 3.5 the molecule breaks up into some non-centrifugible substance, the remaining protein having the normal molecular weight. The acid hydrolysis of the protein is accompanied by a rise in light absorption.

4. At PH values higher than 7.5 a slight alkaline hydrolysis sets in, producing a non-centrifugible substance, but the main change brought about by the high ***PH*** is a splitting up of the molecule into a centrifugible substance which probably has a molecular weight equal to half that of the normal molecule. In the PH range 12.2–12.7 the sedimentation constant has a value of 1.69 X 10^{-13}. The light absorption increases in the ***PH*** range 7.5–12.2 and then becomes constant again.

5. A comparison between Bence-Jones protein and egg albumin with regard to molecular weight, sedimentation constant and molar frictional constant shows that the values are identical within the limits of experimental error. Although these two proteins are entirely different as to chemical composition and isoelectric point, their molecular mass and size are almost identical.

STUDIES RELATING TO ALKYL TIN COMPOUNDS. III. SOME PROPERTIES OF TRIMETHYL TIN HYDROXIDE

BY CHARLES A. KRAUS AND RALPH H. BULLARD

RECEIVED JULY 17, 1929 PUBLISHED DECEMBER 11, 1929

Recently Kraus and Harada[1] have described compounds formed between trimethyl tin hydroxide and trimethyl tin halides corresponding to the formula $[(CH_3)_3SnOH]_2(CH_3)_3SnX$. In attempting to establish the constitution of these compounds, it was found necessary to study the properties of trimethyl tin hydroxide, and, particularly, its thermal decomposition. The present paper records the results of the latter investigation.

Preparation of $(CH_3)_3SnOH$.—According to Cahours,[2] trimethyl tin hydroxide is formed on treating trimethyl tin halides with a strong solution of an alkali. The hydroxide is readily soluble in water and sublimes at temperatures above 80°. Considerable difficulty was experienced in the preparation of the pure hydroxide, which was invariably accompanied by a large loss of material. As will be shown later, this loss was probably due

[1] Kraus and Harada, THIS JOURNAL, 47, 2416 (1925).

[2] Cahours, Ann., 114, 377 (1860).

to decomposition of the hydroxide at the higher temperatures. The following method of preparation was found to yield fairly satisfactory results.

Trimethyl tin bromide is introduced into a flask containing a 55% solution of sodium hydroxide (m. p. 40°) at a temperature just above its melting point. The flask is placed in a horizontal position in a sheet metal steam-bath with the neck projecting through an opening in one side. A closely fitting glass tube slipped over the neck of the flask outside the box serves as condenser. Sublimation is continued until droplets of moisture begin to appear on the walls of the condenser. The sublimate consists of practically pure trimethyl tin hydroxide containing a trace of moisture which is removed by means of ordinary drying agents in a desiccator. The yield is in the neighborhood of 75%.

Anal. Subs., 0.4297: SnO_2, 0.3065. Calcd. for $(CH_3)_3SnOH$: Sn, 65.69. Found: Sn, 66.08.

Thermal Decomposition of $(CH_3)_3SnOH$.—According to Cahours,[2] trimethyl tin hydroxide undergoes decomposition at higher temperatures according to the equation

$$2(CH_3)SnOH = [(CH_3)Sn]_2O + H_2O \qquad (1)$$

Our own experiments, to be described below, indicate that decomposition takes place according to the equation

$$2(CH_3)_3SnOH = (CH_3)_2SnO + (CH_3)_4Sn + H_2O \qquad (2)$$

This reaction, in all likelihood, takes place in two stages, as follows

$$2(CH_3)_3SnOH = [(CH_3)_3Sn]_2O + H_2O \qquad (3)$$

$$[(CH_3)_3Sn]_2O = (CH_3)_2SnO + (CH_3)_4Sn \qquad (4)$$

On attempting to sublime a quantity of the hydroxide at 200° in a tube placed in an electric furnace, practically no sublimate appeared, while a white residue was left behind in the tube. On analysis,[3] this residue was found to consist largely of dimethyl tin oxide.

Anal. Subs., 0.3161, 0.3328: SnO_2, 0.2922, 0.3072. Calcd. for $[(CH_3)_3Sn]_2O$: Sn, 69.13; for $(CH_3)_2SnO$: Sn, 72.05. Found: Sn, 72.81, 72.71.

A quantity of trimethyl tin hydroxide was placed in one leg of an inverted U-tube which was then evacuated and sealed. The limb containing the hydroxide was kept in boiling water for three days. The major portion of the hydroxide underwent decomposition. A distillate, consisting of two liquids, collected in the second leg. The less volatile of these proved to be water, while the more volatile was identified as tetramethyl tin, b. p. 77.5°. The residue in the first leg of the U-tube was washed with absolute alcohol to remove traces of undecomposed hydroxide and the resulting product was analyzed for tin.

---

[3] The analyses were carried out according to a modification of the method of Krause, ***Ber.***, 55, 896 (1922). Krause oxidized the compounds by means of a mixture of sulfuric and nitric acids in a crucible. We have found it more advantageous to carry out the oxidation in pyrex tubes having a diameter of approximately 15 mm. and a length of from 15 to 20 cm. Under these conditions the chances of loss are very greatly reduced over the crucible method. In the case of certain compounds which are oxidized with extreme difficulty, fuming sulfuric and nitric acids are employed. In general, fuming acids are not required in the case of tin compounds, but they often are necessary in the case of germanium and silicon. With the use of a counterpoise, reproducible results were obtained with pyrex tubes. If extreme accuracy is required, silica tubes are preferable.

Anal. Subs., 0.1530, 0.1533: SnO_2, 0.1417, 0.1419. Calcd. for $(CH_3)_2SnO$: Sn, 72.05. Found: Sn, 72.95, 72.91.

The residue was dissolved in dilute hydrochloric acid and on evaporating there were recovered crystals melting at 107°; this identifies them as dimethyl tin dichloride, m. p. 108°. As is apparent from the above analysis, the tin content of the residual product was in all cases slightly higher than is required for dimethyl tin oxide. This discrepancy was probably due to partial decomposition of dimethyl tin oxide, as will be shown below. Trimethyl tin hydroxide evidently decomposes according to Equation 2. It is remarkable that, volatile as the hydroxide is, it is so largely decomposed at a moderate temperature. It is of interest to note that according to Chambers and Scherer,[4] triphenyl tin hydroxide decomposes at higher temperatures with the formation of diphenyl tin oxide and tetraphenyl tin.

Thermal Decomposition of Trimethyl Tin Oxide.—A quantity of trimethyl tin oxide, prepared by the oxidation of trimethyl tin,[5] was placed in one limb of an evacuated, inverted U-tube and heated to 120° in a paraffin-bath. A small quantity of liquid collected in the second limb of the tube which failed to freeze at liquid ammonia temperatures. The temperature of the paraffin-bath was then raised to 190° and maintained for some time. On opening the tube, the presence of a permanent gas was noted. The liquid formed in this reaction was identified as tetramethyl tin, b. p. 77.7°. The white residue in the first limb of the tube was analyzed for tin.

Anal. Subs., 0.2272, 0.2839: SnO_2, 0.2068, 0.2587. Calcd. for $(CH_3)_2SnO$: Sn, 72.05. Found: Sn, 71.69, 71.77.

The low value found for tin may have been due to a side reaction, as was indicated by the presence of a permanent gas. For the most part reaction proceeds according to Equation 4. When trimethyl tin hydroxide is heated, therefore, reaction, in all likelihood, first proceeds according to Equation 3, in which trimethyl tin oxide is formed; the latter compound, in turn, decomposes according to Equation 4.

Thermal Decomposition of Dimethyl Tin Oxide.—The high values obtained for tin in the residue left on decomposing trimethyl tin hydroxide suggested that dimethyl tin oxide is not completely stable under the conditions of these experiments. Accordingly, a quantity of dimethyl tin oxide was sealed in one leg of an evacuated U-tube, which was then heated with a free flame, while the other leg was cooled in ice water. A small quantity of liquid appeared in the second leg of the tube and was identified as tetramethyl tin. The residue in the first leg turned black while at the same time a gaseous pressure was built up in the tube. A quantity of this gas was collected and its density determined. The density corresponded to a mean molecular weight of 43.7. It was thought that this high value was due to the presence of tetramethyl tin. Therefore, in a second preparation, the gas was passed through a condenser cooled in liquid ammonia. The density of the resulting gas was found to correspond to a mean molecular weight of 26.5. This seemed to indicate that, while the methyl groups, in part, combined to form ethane, some of them interacted to form methane and ethylene. On passing the gas through a solution of potassium permanganate, the solution was immediately decolorized, indicating the presence of unsaturated hydrocarbons.

The tube used in the first preparation was evacuated and the material heated for some time to a temperature of about 400°. The black residue left behind was analyzed for tin.

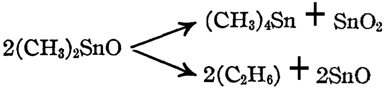
---

[4] Chambers and Scherer, THIS JOURNAL, 48, 1054 (1926).

[5] Kraus and Sessions, *ibid.*, 47, 2363 (1925).

Anal. Subs., 0.3714, 0.1291: SnO_2, 0.4022, 0.1396. Calcd. for SnO_2: Sn, 78.76; for SnO, Sn, 88.12. Found: Sn, 85.29, 85.23.

The analyses indicate that the mixture consisted of 30.5% of stannic oxide and 69.5% of stannous oxide. On heating dimethyl tin oxide, reaction for the most part takes place according to the equations



$$2(CH_3)_2SnO \rightarrow (CH_3)_4Sn + SnO_2$$
$$2(CH_3)_2SnO \rightarrow 2(C_2H_6) + 2SnO$$

The above experiments show that if trimethyl tin oxide is formed in the thermal decomposition from trimethyl tin hydroxide, it is immediately decomposed to dimethyl tin oxide and tetramethyl tin. At still higher temperatures dimethyl tin oxide is decomposed, a mixture of stannous and stannic oxides being left behind, while tetramethyl tin and hydrocarbons are evolved.

Molecular Weight of Trimethyl Tin Hydroxide in Benzene.—The molecular weight of the hydroxide was determined in benzene solution by the cryoscopic method. The results are given in Table I.

TABLE I

MOLECULAR WEIGHT OF $(CH_3)_3SnOH$ IN BENZENE

Benzene, g.	$(CH_3)_3SnOH$, g.	Δt	Mol. wt.
46.23	0.1460	0.072"	219
41.39	.1343	.073°	222

The formula weight of trimethyl tin hydroxide is 180.8. Apparently, the hydroxide is appreciably associated in benzene solution. This result is in agreement with observations of Smith and Kipping.[6] They determined the molecular weight of tribenzyl tin hydroxide in benzene at its freezing point and in chloroform at its boiling point. For the molecular weight they obtained the values 660 and 727–821 in these two solvents, respectively. The formula weight of tribenzyl tin hydroxide is 409. It seems, then, that the tertiary alkyl tin hydroxides have a marked tendency to polymerize when dissolved in solvents of this type.

Summary

A method is described for the preparation of trimethyl tin hydroxide. The apparent molecular weight of the hydroxide in benzene indicates that it is slightly polymerized.

At slightly elevated temperatures trimethyl tin hydroxide decomposes, dimethyl tin oxide, tetramethyl tin and water being formed.

Trimethyl tin oxide undergoes thermal decomposition with the formation of dimethyl tin oxide and tetramethyl tin. At elevated temperatures dimethyl tin oxide decomposes, in part, with the formation of ethane and stannous oxide and, in part, with the formation of stannic oxide and tetra-

THE COUPLING OF GLUCOSE AND GAMMA-FRUCTOSE. CONVERSION OF SUCROSE INTO ISO-SUCROSE

BY JAMES COLQUHOUN IRVINE AND JOHN WALTER HYDE OLDHAM

RECEIVED JULY 19, 1929 PUBLISHED DECEMBER 11, 1929

From the theoretical standpoint the primary condition necessary for the synthesis of sucrose is to have in hand an equimolecular mixture of tetra-acetylglucose and tetra-acetyl-γ-fructose which can be subjected to the action of a dehydrating agent. In a previous paper[1] we have described the results obtained when the required y-form of tetra-acetylfructose was prepared both from fructose and from inulin but when the compound was condensed with tetra-acetylglucose the only crystalline product isolated by us was not the octa-acetate of sucrose but the corresponding derivative of a new disaccharide which we termed "iso-sucrose." This failure to synthesize sucrose octa-acetate cannot be attributed to faulty manipulation in the sense that traces of acids had decomposed any sucrose derivatives which had been formed. Nor can it be ascribed to the use of a fructose acetate containing an oxygen ring in a different position from that present in the fructose component of sucrose. In our former work we established, and have since confirmed, the fact that iso-sucrose is much more readily hydrolyzed by acids than sucrose itself, and the ready isolation of the less stable disaccharide is a guarantee that the more stable isomeride had not been decomposed. Lest it be maintained that the tetra-acetylfructose used by us was not the same y-form as is present in sucrose, we have now varied the procedure so as to ensure that this objection cannot apply.

When sucrose octa-acetate is acted on by acetyl bromide dissolved in glacial acetic acid, the disaccharide is ruptured into its components and the product consists of an equimolecular mixture of tetra-acetylglucose and tetra-acetyl-y-fructose. It might reasonably have been expected that such a mixture would represent the ideal starting material for the synthesis of sucrose, but all attempts to re-condense the constituents by the action of phosphoric anhydride have again resulted in the formation of crystalline iso-sucrose octa-acetate. As before, the reaction yielded syrupy acetates of disaccharides other than iso-sucrose and, on occasions, iso-trehalose octa-acetate was isolated, but despite numerous variations in procedure no evidence has been obtained of the formation of sucrose

---

[1] Irvine, Oldham and Skinner, THIS JOURNAL, 51, 1279 (1929).

octa-acetate in this reaction. The series of changes may be summarized in the following scheme

$$\begin{tikzcd}
 & \text{Tetra-acetylglucose} \arrow[dr] & & \\
\text{Sucrose} \arrow[ur] \arrow[dr] & & \text{\textit{Iso}-sucrose octa-acetate} \arrow[r] & \text{\textit{Iso}-sucrose} \\
 & \text{Tetra-acetyl-y-fructose} \arrow[ur] & &
\end{tikzcd}$$

The above scheme has been supplemented by using tetra-acetyl-γ-fructose derived from an entirely different source.

It will be recalled[2] that a tri-acetylanhydrofructose may be obtained from inulin tri-acetate and we find that this compound when treated with acetyl chloride and dry hydrogen chloride is converted smoothly into tetra-acetyl-7-fructose showing the correct constants. The condensation of this tetra-acetyl-y-fructose with tetra-acetylglucose by the agency of phosphoric anhydride once more gave *iso*-sucrose octa-acetate melting at 130–131°. Incidentally, this result shows that, in all probability, tri-acetylanhydrofructose contains one oxygen ring in the γ-position, and in this respect resembles the remainder of the inulin molecule.

Experimental

Action of Acetyl Bromide on Sucrose Octa-acetate.—The correct conditions for carrying out this reaction were established only after a large number of trial experiments had been made in which the concentration of the reagent and the time of the reaction were varied over wide limits. Owing to the destructive action of hydrogen bromide on fructose derivatives it is advisable to arrest the change when not more than one-half of the sucrose octa-acetate has been hydrolyzed.

A 5% solution of sucrose octa-acetate in glacial acetic acid containing 15% of acetyl bromide was maintained at the temperature of the room; the optical rotation increased steadily in the dextro-sense and at the end of approximately fifty hours the reaction was arrested by cooling in ice, diluting largely with acetic acid and thereafter adding powdered ice with active stirring. When all or the acetyl bromide was decomposed a solution of sodium acetate was added in slight excess of that required to neutralize the hydrogen bromide and the mixture was then warmed at 60° for forty-five minutes. Blank experiments showed that this treatment converts acetobromoglucose quantitatively into tetra-acetylglucose.

The cold solution was then extracted six times with chloroform, the material extracted being isolated, dissolved in benzene and the benzene solution thereafter extracted with water. The aqueous extract contained the desired mixture of glucose and fructose tetra-acetates, while unaltered sucrose octa-acetate remained in the benzene.

TABLE I

DATA SHOWING THE RELATIVE YIELDS UNDER DIFFERENT CONDITIONS

Concentration of sucrose octa-acetate, 5%; of acetyl bromide, 15%

No.	Acetate g.	Duration of expt , hours	Final $[\alpha]_D$	Total prod., g.	Extracted by C_6H_6, g.	Extracted by Water, g.
I	50	67	+123.8°	43.9	16.9	23.9
II	50	43	+104.2°	48.5	27.5	19.2

The procedure of Experiment II was adopted as the most satisfactory practical method.

---

[2] Irvine and Stevenson, THIS JOURNAL, 51, 2197 (1929).

Examination of the Mixed Acetates of Glucose and Fructose.—On extracting the aqueous solution with chloroform and subsequent removal of this solvent, the mixed acetates remained as a colorless, viscous sirup. The acetyl content was 48.6%; calcd., *49.3%;* in chloroform solution $[\alpha]_D = +58.0'$ for $c = 3.068$. From these results it is possible to calculate the relative proportions of tetracetyl-y-fructose and tetra-acetylglucose in the mixture. The activity of tetracetyl-7-fructose in chloroform shows slight variation but the average value for $[a]_D$ is $+34.5°$. Applying this figure the above mixture should contain

Tetra-acetyl-γ-fructose	49.2%
Tetra-acetylglucose	50.8%

This composition was confirmed. A weighed quantity of the mixture (about 0.5 g.) was dissolved in water containing a little acetone and, after cooling in ice, a slight excess of *2 N* sodium hydroxide was added. Twenty minutes later sufficient acid was added to make the solution approximately *N*/10 and the rotation was determined. Under the conditions specified the solution, which contained glucose and fructose, gave $[\alpha]_D = -17.7°$. Control experiments established that under the same conditions tetra-acetyl-γ-fructose gives the end-point $[\alpha]_D = -89.4°$, while that for tetra-acetylglucose is $[\alpha]_D$ +50.3°. It follows that the mixture of acetates under examination contained *48.57'* of tetra-acetyl-y-fructose as against *49.2%* determined by the direct method.

Condensation of the Hexose Acetates.—This was carried out by the action of phosphoric anhydride as previously described.' The total product of the condensation showed the usual reducing action on Fehling's solution and from the mixture iso-sucrose octa-acetate (m. p. 129–131° $[\alpha]_D$ in chloroform +19.3°) was the only crystalline compound obtained. The identity of this product with the iso-sucrose octa-acetate previously described by us was confirmed.

Conversion of Triacetylanhydrofructose into Tetra-acetyl-γ-fructose.—Seven and four-tenths grams of crystalline triacetylanhydrofructose was dissolved in *74* cc. of acetyl chloride saturated with dry hydrogen chloride. The solution was preserved at the temperature of the room for six weeks, the rotation being determined at intervals until the darkening of the liquid interfered with accurate reading. The initial value, $[\alpha]_D$ +4.3°, increased to the approximate maximum of $55 2°, at which stage the acetyl chloride was removed in a vacuum. On taking up the product in glacial acetic acid, powdered ice was added and thereafter water, the system being kept homogeneous if necessary by the addition of more acetic acid. After extensive dilution with water the liquid was extracted six times with chloroform and, on removal of the solvent and thorough drying of the residue at 100° in a vacuum, the product was taken up in benzene. When the benzene solution was extracted with water, unchanged tri-acetylanhydrofructose (weight = *1.8* g.) remained behind and *4.09* g. of tetra-acetyl-γ-fructose passed into the solution, from which it was isolated in the usual way. Found: CH_3CO, 50.0%; n_D *1.4652;* $[\alpha]_D$ in benzene +38.1° for c = *4.9%;* after alkaline hydrolysis in the cold, $[\alpha]_D$ calculated on the weight of hexose formed was *−89.0".* The corresponding values for tetra-acetyl-7-fructose prepared by other methods are: CH_3CO, 50.8% (calcd., 49.4%), n_D *1.4645;* $[\alpha]_D$ in benzene +38.7° for $c = 5.4\%$; specific rotation on cold alkaline hydrolysis *−89.4'.* No description of the condensation of this specimen of tetra-acetyl-γ-fructose with tetra-acetylglucose is necessary as the procedure and results were the same as in former experiments.

Summary

1. Sucrose octa-acetate has been converted into an equimolecular mixture of tetra-acetylglucose and tetra-acetyl-y-fructose.

2. This mixture when subjected to the condensing action of phosphoric anhydride has not yielded sucrose octa-acetate, the only crystalline product obtained being the octa-acetate of iso-sucrose.

3. Tri-acetylanhydrofructose has been converted into tetra-acetyl-γ-fructose, thereby proving that one oxygen ring in the former is in the same position which it occupies in the remainder of the inulin molecule.

4. Tetra-acetyl-y-fructose obtained as described in 3 above has been condensed with tetra-acetylglucose. In this case also, iso-sucrose octa-acetate was the only crystalline derivative isolated.

5. In none of the condensations now described has any evidence been forthcoming that sucrose derivatives are formed.

PREPARATION OF AMINO-ACETAL

BY JOHANNES S. BUCK AND SAMUEL N. WRENN

RECEIVED JULY 19. 1929 PUBLISHED DECEMBER 11, 1929

Amino-acetal, $NH_2CH_2CH(OC_2H_5)_2$, on account of its reactivity and versatility, is a synthetic reagent of considerable importance. A search of the literature revealed only three reasonably promising methods, the reduction of nitro-acetal[1] by sodium and alcohol, the reduction of glycine ester by sodium amalgam to amino-acetaldehyde and the conversion of this into amino-acetal,[2] and the action of ammonia on the halogen acetals, which has been investigated by several different workers.[3]

No record was found of attempts to prepare amino-acetal in quantity. For this purpose the action of ammonia on the halogen substituted acetals was investigated. The authors have made use of a steel autoclave of 1100-cc. capacity, fitted with a special ammonia gage and having a working pressure of 1000 pounds. Provision was made for connecting the apparatus to an ammonia tank. With this apparatus a number of runs were made, using chloro-, bromo- and iodo-acetal, and varying the amount of ammonia, the time of heating and the temperature. Chloro- and bromo-acetal proved to be unsatisfactory on account of the low yield and the amount of tarry matter produced; iodo-acetal gave good results.

Experimental

Iodo-acetal was prepared by iodinating acetal in the presence of iodic acid, substantially as described by Hesse[4] and employed by Losanitsch.[5]

[5] Losanitsch, *ibid.*, 42, 4044 (1909).

Amino-acetal and **Iodo-acetal.**—In the autoclave were placed 108 g. of iodo-acetal and 600 cc. of alcoholic ammonia, saturated at 0°, and further ammonia was introduced by connecting the autoclave with an ammonia tank for six hours. A pressure of 150 pounds was registered. The cylinder was disconnected and the autoclave heated directly for eleven hours at 110–125°. During the heating period the pressure rose to 375400 pounds and then fell slowly. After allowing the apparatus to cool and releasing any remaining pressure, the reaction mixture was removed, filtered and the alcohol and ammonia distilled off. The residue was taken up in a little water and extracted several times with ether to remove any unchanged iodo-acetal and higher bases. The ether extract thus obtained was dried over solid potassium hydroxide for twelve hours. The aqueous solution was saturated with potassium carbonate and the oil which separated removed. As a precaution the aqueous solution was extracted with ether. The extract was added to the oil and the whole dried over potassium hydroxide for twelve hours, the ether removed and the residue distilled under reduced pressure to remove tar. The distillate was then fractionated at atmospheric pressure, the amino-acetal being collected between 162 and 165°, and the higher-boiling residue worked up as below.

The ether extraction of the reaction mixture, after removal of the ether, was fractionated under reduced pressure, two fractions being obtained (a) up to 125° (10 mm.), (b) 125–140° (10 mm.). The higher fraction, combined with the high-boiling residues from the amino-acetal, gave on refractionation 7 g. of diacetalamine, b. p. 130–138° (10 mm.). The low-boiling fraction was redistilled and the portion boiling at 162–165" (760 mm.) combined with the amino-acetal previously obtained and redistilled several times. In this way 21 g. of amino-acetal, b. p. 162–163°, was obtained.

No unchanged iodo-acetal was found and comparatively little tar was present. The preparation could doubtless be substantially improved by pouring Babbitt metal between the shell and liner of the autoclave and heating the latter in a bath or by steam. Stirring would probably help matters. The temperature of heating should not exceed 125°, as much tar forms above this temperature. The duration of heating should be such that all of the halogen acetal is changed; otherwise general decomposition takes place on distilling the product. As large an excess of ammonia as practicable should be employed, to avoid the formation of secondary and tertiary products.

Amino-acetal from **Chloro-acetal.**—Thirty-five grams of chloro-acetal and 700 cc. of alcoholic ammonia, saturated at 0°, were placed in the autoclave and treated in a manner similar to the previous preparation. The combined yield of amino-acetal, boiling at 160–165°, from four preparations was 12 g. (11.1%).

Amino-acetal from **Bromo-acetal.**—In this preparation 188 g. of bromo-acetal and 400 cc. of saturated alcoholic ammonia were used, and the heating was continued for fourteen hours at 110–115°. From this experiment 24.5 g. of amino-acetal, b. p. 162–166°, and 27 g. of diacetalamine, b. p. 130–140° (8 mm.), were obtained.

Summary

The preparation of amino-acetal is conveniently carried out in a steel autoclave, using iodo-acetal. Iodo-acetal is far superior to chloro- and bromo-acetal and may be readily prepared.

DURHAM, NORTH CAROLINA

[Contribution from the Chemical Laboratory of Northwestern University]

KETENE FROM ACETIC ACID

By Charles D. Hurd and Kenneth E. Martin

Received July 19, 1929 Published December 11, 1929

The thermostability of acetic acid was noted many years ago by Cahours[1] and by Berthelot.[2] Nef,[3] however, was the first to study its decomposition in a detailed manner. He reported methane, carbon dioxide, carbon monoxide, ethylene, hydrogen, carbon and acetone as reaction products when the acid vapors were passed over pumice at 500°. Still more recently, these substances and also acetic anhydride were observed by Peytral,[4] who passed acetic acid through an 11-cm. platinum tube at 1150°. She postulated three reactions to explain the results

$$2CH_3CO_2H \longrightarrow H_2O + (CH_3CO)_2O$$
$$CH_3CO_2H \longrightarrow CO_2 + CH_4$$
$$2CH_3CO_2H \longrightarrow 2CH_2O + 2CO + C_2H_4$$

The acetic anhydride reaction has recently been made the subject of patents.[5] The peculiarity of such anhydride formation may not be self-evident. However, almost no other monocarboxylic acid behaves in this manner. Some unusual feature, therefore, must be present in this case.

To provide an interpretation of the mechanism of pyrolysis of acetic acid, the "methane system" has proved useful and interesting. Just as the hydroxyl group serves in the *water system,* or the amino group in the *ammonia system,* so the methyl group is the analog in the *methane system.* On this basis carbonic acid, acetic acid and acetone are structurally similar. The known equations for the decomposition of carbonic acid and of acetone,[6] namely, $HO—CO—OH \longrightarrow H_2O + O{=}C{=}O$, and $CH_3—CO—CH_3 \longrightarrow CH_4 + CH_2{=}C{=}O$, provide a basis for the analogy that acetic acid should break down primarily both into "carbon dioxide + methane" and into "ketene + water." Thus

$$CH_3—CO—OH \longrightarrow H_2O + CH_2{=}C{=}O$$
$$CH_3—CO—OH \longrightarrow CH_4 + O{=}C{=}O$$

In confirmation of this prediction, search for ketene in the reaction products of the acetic acid pyrolysis revealed its presence in appreciable amounts. Ketene unquestionably is the precursor of acetic anhydride, because of its reaction with acetic acid

$$CH_2{=}C{=}O + CH_3CO_2H \longrightarrow (CH_3CO)_2O$$

Furthermore, it serves to explain the origin of the ethylene and the carbon monoxide: $2CH_2{=}C{=}O \rightarrow C_2H_4 + 2CO$.

Experimental Part

Estimation of **Ketene.**—The following plan was adopted for the determination of the "acetic acid, acetic anhydride, ketene" mixture which was produced by passing acetic acid through a heated tube. The hot effluent vapors were conducted upward through a vertical bulb condenser to remove the bulk of the acid and the acetic anhydride. Remaining traces of these substances were condensed in two ice-cooled U-tubes, which were connected in series at the top of the condenser? From the second U-tube, the gases were conducted into a flask containing an excess of a measured volume of aniline, wherein the available ketene content was quantitatively removed as acetanilide. This value for ketene is certainly lower than the true value because of the fact that some ketene is removed In the condensers either by simple solution or by reaction either with water or with acetic acid.

A series of experiments was carried out to demonstrate that the acetanilide originated largely or entirely from the ketene. In the first place, it was ascertained that acetic acid mixes with aniline with almost no diminution in volume. Thus 9 cc. of aniline and 1.1 cc. of acetic acid gave 10.1 cc. of mixture. Since the increase in volume in the aniline flask was negligible when the ketene vapors (generated from 85 to 600 cc. of glacial acetic acid) were admitted, this is evidence that negligible quantities of acetic acid were introduced. In no case was the increase more than 1 cc. Secondly, it was definitely established by the following tests that acetic acid does not convert aniline in the cold into acetanilide under the conditions of the experiment. (a) One cc. of acetic acid was mixed with an excess of aniline and left for two hours. Then the acid was neutralized with a dilute solution of sodium bicarbonate, extracted with ether, the ether evaporated and the aniline distilled to 200°. There was no trace of residual acetanilide (b) A repetition of (a) with similar results, except that 20 cc. of acid and 20 cc. of aniline were used. (c) Similar to (b) except that 5 g. of acetanilide was purposely admixed at the start. At the conclusion of the experiment 4.8 g of acetanilide was recovered. Finally, since acetanilide may be formed by the interaction of acetic anhydride and aniline in the cold, it was proved that the quantity of acetic anhydride which could have been present was quite insufficient to produce the acetanilide which was isolated. To prove this, the acetic acid and acetic anhydride condensate from Run 4 below was analyzed for the anhydride content by Whifford's method,[8] and was found to contain 0.11 g. of acetic anhydride per cc. of the condensate. Since the total increase in volume of the aniline through which the ketene passed was only one cc., the maximum amount of acetanilide caused by acetic anhydride would be 0.27 g. Presumably even less than this would be formed from this source since acetic anhydride possesses a lower vapor pressure than acetic acid and would tend, therefore, to remain more completely in the condensate. Actually, 4 g of acetanilide was isolated in this run. In Run 6 no acetic anhydride could be detected, yet 3.5 g. of acetanilide was isolated. Its origin must have been from ketene.

Reagents and Apparatus.—Glacial acetic acid was purified by crystallization. The acid was frozen at 15°, filtered off, melted and distilled. The fraction boiling between 115 and 118° was taken. A sample of this fraction melted at 17°. The aniline was also freshly distilled.

---

[7] From 600 cc. of original acetic acid in one run at 800°, 480 cc. was recovered by the condenser, 4 cc. by the first U-tube and none by the second.

[8] Whitford, THIS JOURNAL, 47, 2939 (1925).

The apparatus for the pyrolysis was essentially similar to that previously described[9] for the preparation of ketene from acetone. A quartz tube was generally used because of the high temperature required (800°), although similar results were also obtained with a Bohemian glass tube. Porcelain chips were used as packing in both. The temperature was recorded inside the tube by a thermocouple which was sheathed by a small pyrex tube. The quartz reaction tube was heated by the longest unit (16 inches) of an ordinary 3-segmented electric combustion furnace. The acetic acid vapors flowed first through the hot reaction tube, then through a vertical bulb condenser and two ice-cold U-tubes, and finally through a flask which contained 30 cc. of aniline. The remaining gases were inflammable (probably CH_4, CO, C_2H_4) and also contained carbon dioxide (white precipitate with lime water), but they were not otherwise examined.

Pyrolysis.—It was established that little or no decomposition of acetic acid occurred as it was vaporized (by rapid boiling) and passed through a tube at 600° or at 700°. Thus, at 700°, from an original 100 cc. there was almost complete recovery and no trace of acetanilide (*via* ketene) was isolable. At 800°, however, the acid decomposed and ketene was evident in the products. The results of six selected representative experiments are summarized in Table I.

TABLE I

PYROLYSIS OF ACETIC ACID AT 800°

Orig. acetic acid, cc.	Recov. vol., cc.	Acid consumed, cc.	Acrtanilide, g.	Equiv. % yield of ketene
100	80	20	0 6	1.2
100	75	25	0.7	1.2
85	60	25	2	3.4
600	440	160	4	1.1
600	480	120	2.5	0.9
400	280	120	3.5	1.2

The aniline was searched for acetanilide in the following manner. It was washed with a dilute solution of sodium bicarbonate and extracted with ether. Both aniline and ether were distilled off up to 200°, and the residue was dissolved in boiling water, filtered and allowed to cool, These acetanilide crystals were collected on a filter, dried and weighed. In general, the percentage yield of available ketene was 1–2%. Unquestionably, as explained above, the true yield of ketene was greater than this.

Summary

At 800° or higher acetic acid undergoes a reaction of dehydration into ketene as well as a reaction of demethanation into carbon dioxide. These are the primary reactions, but the reactivity of ketene sponsors other effects. Such secondary processes include addition with water or with acetic acid (giving acetic acid and acetic anhydride, respectively) or

pyrolysis into carbon monoxide and ethylene. The concept of the "methane system" has been adapted to explain these results.

TREMETOL, THE COMPOUND THAT PRODUCES "TREMBLES" (MILKSICKNESS)

BY JAMES FITTON COUCH

RECEIVED JULY 22, 1929 PUBLISHED DECEMBER 11, 1929

Tremetol is the active principle of two plants, richweed and rayless goldenrod, both of which cause the disease known as trembles. This disease is also known as milksickness, especially by the medical profession. Richweed or white snakeroot (*Eupatorium urticaefolium*) is responsible for the disease in the Central States; rayless goldenrod or jimmy weed (*Aplopappus heterophyllus*,) occurs in the Southwestern section of the United States, where it produces the same disease.

Extensive pharmacological study, the results of which have been published in other places[1] has demonstrated that the active constituent of these plants is a substance to which the name tremetol has been applied. This paper contains the results of the chemical study of tremetol.

To prepare tremetol the following procedure has been used successfully. The plant material should be fresh in the case of richweed; rayless goldenrod is still poisonous when dried but appears gradually to lose toxicity. Old dried richweed does not produce trembles. The plant is comminuted and extracted with alcohol. The solvent is distilled from the extract, best under diminished pressure, and the greenish fatty residue is extracted with boiling water as long as anything dissolves. The insoluble material is collected and thoroughly extracted with boiling 50% alcohol. The solvent is removed from this solution and the thick resinous mass that separates is allowed to cool and harden, when the watery portion of the residue may be poured off it. The resinous mass is now thoroughly extracted with boiling 30% alcohol and the solution is filtered hot from the insoluble matter. On cooling the filtrate crude tremetol ester separates. A further crop may be obtained by evaporating the alcohol from the mother liquors. The combined crops are now hydrolyzed by boiling with 5% alcoholic potash for four hours, the alcohol is distilled off and the residue is dissolved in water. The free tremetol is extracted from this solution with successive portions of ether. The ether solutions are united, concentrated to convenient volume and washed, first with dilute sodium hydroxide solution and then with water, to remove possible phenols and resin acids. The purified ether solution is now mixed with 4 volumes of petroleum ether, filtered from any precipitate and allowed to evaporate. The solution in ether and reprecipitation with petroleum ether should be repeated twice to insure purity. On removal of the solvent tremetol remains as a straw-yellow, thick oil of pleasant aromatic odor distantly reminiscent of clove and nutmeg. Should solid, waxy particles separate, the substance has not been thoroughly separated from a sterol that accompanies it in richweed

and the 50 and 30% alcohol steps should be repeated. Criteria of purity are the optical rotation, index of refraction and molecular weight.

Properties of Tremetol.—Tremetol is a straw-yellow thick oil of aromatic odor. It has not been obtained in crystalline condition and decomposes when attempts to distil it are made, even when the pressure is reduced to 3 mm. It is slowly volatile in steam and appears to suffer some alteration during the process. Tremetol is insoluble in water, acids and alkalies. It is readily soluble in alcohol and the common organic solvents, less soluble in petroleum ether but readily in mixtures of that solvent with ether. It occurs in the plant in combination with a resin acid the chemical composition of which has not been determined. Tremetol readily oxidizes in the air, losing its characteristic odor and developing a rancid and acetous odor.

The analytical figures for tremetol indicate either of two formulas, $C_{16}H_{22}O_3$ or $C_{17}H_{24}O_3$, agreeing better with the latter. Molecular weight determinations, bromine absorption and molecular refractivity data agree closely with the requirements of the first formula and this has been chosen as the more likely. The high percentages of carbon and hydrogen found by analysis are considered to be due to small amounts of petroleum ether remaining in the tremetol, which cannot be driven off without decomposing the substance itself.

Tremetol absorbs four atoms of bromine per molecule at room temperature. Inasmuch as the formula indicates the presence of five double bonds, it may be concluded that the substance contains a phenyl nucleus and a side chain containing two double bonds. The function of the oxygen atoms has not been determined. Phenolic hydroxyls and alkoxyl groups are not detected by the appropriate tests. No crystalline oxime or hydrazone has been obtained. Aldehyde and carboxyl groups are absent. A study of the constitution of the substance is in progress.

Anal. Calcd. for $C_{16}H_{22}O_3$ (262.17): C, 73.24; H, 8.45. Calcd. for $C_{17}H_{24}O_3$ (274.18): C, 73.87; H, 8.75. Found: (substance from richweed) C, 73.89, 73.89, 73.33; H, 8.89, 8.58, 8.60; mol. wt., 257, 259; (substance from rayless goldenrod) C, 73.54, 73.72, 73.57; H, 8.66, 8.83, 8.94; mol. wt., 237, 262, 258. ***Optical activity.*** 2.9020 g. in enough alcohol to make 100 cc. rotated the plane of polarized light an average of 0.98° to the left when examined in a 10-cm. tube at 30°: whence $[\alpha]^{30}_{D}$ $-33.82°$.

Bromine Absorption.—In carbon tetrachloride solution 0.3882 and 0.4359 g. of the substance absorbed 0.4531 and 0.5466 g. of bromine at room temperature, or 1.167 and 1.254 g. of bromine per gram of substance (mol. wt. 262.17). One molecule of substance **with two** active double bonds reacting with four atoms of bromine requires 1.22 g. of halogen per gram; d^{25}_{4} 1.0787, n^{30}_{D} 1.5345, mol. refr. calcd. for $C_{16}H_{22}O_3$ (F_5), 76.12; for $C_{17}H_{24}O_5$ (F_5), 79.65. Found: 75.62.

Summary

Tremetol, the substance present in richweed and in rayless goldenrod, which produces the diseases known as milksickness and trembles is a straw yellow oil, $C_{16}H_{22}O_3$, levorotatory, insoluble in water, acid and alkaline solutions, and soluble in the common organic solvents.

RELATIONS BETWEEN ROTATORY POWER AND STRUCTURE IN THE SUGAR GROUP. XXI. BETA-THIOPHENOL GLYCOSIDES OF GLUCOSE, XYLOSE, LACTOSE AND CELLOBIOSE[1,2]

BY CLIFFORD B. PURVES

RECEIVED JULY 22, 1029 PUBLISHED DECEMBER 11, 1929

Although the glycosides of the hydroxy alcohols form a numerous group which has been submitted to detailed study and whose optical properties have been classified through the work of Hudson,[3] too few of the thioglycosides have been prepared to render possible a similar mathematical examination of their molecular rotations. Apart from the *a*- and β-glucosides of methyl, ethyl, propyl and benzyl mercaptan described by Schneider and his co-workers,[4] the only other simple members of the series found recorded in the literature are β-thiophenol glucoside and β-thiophenol lactoside, which together form the subject of a paper by Fischer and Delbrück.[5] The thioglycosides, nevertheless, are of interest from an optical point of view, for they differ from their oxygen analogs in containing a bivalent and therefore unsaturated sulfur atom directly united to the first asymmetric center of the carbohydrate residue. It is impossible to predict the nature and the extent of the changes which this difference may bring about in their behavior toward plane-polarized light and, in consequence, the present investigation is one of several designed to gain information on this subject by experimental methods. This article is mainly concerned with four glycosides of thiophenol and with their acetylated derivatives.

At an early stage in the research it became apparent that an acetobromo sugar in ethereal or benzene solution reacted very slowly and sometimes incompletely with sodium thiophenate dissolved in water. This was the

---

method used by Fischer and Delbrück[5] for preparing the acetylated derivatives of thiophenol glucoside and lactoside, but its tedious nature and somewhat uncertain outcome led to its abandonment in the present work. The acetobromo sugars studied, however, swiftly condensed with potassium thiophenate when means were taken to render the system homogeneous, and the yield of the acetylated thioglycosides was satisfactory when the alkalinity of the solution was low. These conditions were readily obtained by adding the acetobromo sugar, dissolved in chloroform, to an equal bulk of 95% alcohol containing one equivalent of potassium hydroxide and a 10 to 15% excess of the mercaptan, an excess which was sufficient to render the alcoholic solution neutral to litmus and to phenolphthalein. After the reaction had been completed by heating, the clear liquor was washed free of potassium bromide, alcohol and thiophenol by very dilute aqueous sodium bicarbonate and the product was recovered in an almost pure condition from the chloroform residue. It will be seen that this procedure was very similar to that adopted by Schneider, Sepp and Stiehler[4] but differs from it in that a reacetylation of the glycoside was unnecessary. This was due to the strongly acidic nature of thiophenol and to the particular excess of the reagent which was used. Moreover, the acetobromo derivative was prepared from the fully acetylated sugar by the action of hydrogen bromide dissolved in a mixture of glacial acetic acid and chloroform. After the substitution of bromine for acetyl was complete, washing with water removed the free acids and the residual chloroform, containing almost the theoretical amount of the acetobromo sugar, was run into the solution of alcoholic potassium thiophenate without previous drying. This simplification rendered it possible to obtain a 70% yield of the β-thiophenol glycoside acetate from the crude, fully acetylated sugar in the course of six hours.

Five new compounds are described in the experimental portions: the β-thiophenol and the β-*p*-thiocresol glycosides of cellobiose together with the acetate of the former; β-thiophenol xyloside triacetate and β-thiophenol xyloside itself. In addition, it was necessary to repeat the work of Fischer and Delbruck on the thiophenol derivatives of glucose and lactose, partly to confirm and to extend the optical data which they record for these substances and partly to make sure that the new method gave products identical with those formerly described. All of the thioglycosides examined were crystalline and a summary of their physical properties will be found below.

A simple way of analyzing the molecular rotations of the fully acetylated thioglycosides is to adopt the method used by Hudson[6] to calculate the rotation, A_{Cl}, of the potentially reducing asymmetric carbon atom of the acetochloro sugars. Assuming, as a first approximation, that substitution

---

[6] Hudson, This Journal, 46, 462 (1924).

in this position does not affect the optical rotatory power of the other asymmetric centers in the molecule, the combined molecular rotation in chloroform of the latter may be denoted by B. The values of B for the various acetylated sugar residues were obtained by the above author from his study of the α- and @-acetates themselves and are listed in the table below. Then if A_{SPh} be the molecular rotation due to the asymmetric carbon atom to which the thiophenyl radical is attached, $B-A_{\mathrm{SPh}}$ is the observed molecular rotation of the β-thiophenol glycoside acetate and the magnitude of A_{SPh} may be calculated in each case. These values, together with those quoted from the work of Hudson for A_{Cl}, the sum A_{SPh} plus A_{Cl} and the difference, A_{SPh} minus A_{Cl}, are also given.

TABLE I

COMPARISON OF THE QUANTITIES A_{SPh} AND A_{Cl}, THE MOLECULAR ROTATIONS, RESPECTIVELY D# TO THE TERMINAL ASYMMETRIC ATOM IN THE β-THIOPHENOL GLYCOSIDE ACETATES AND IN THE ACETOCHLORO DERIVATIVES Ob THE SUGARS

Sugar	$B-A_{\mathrm{SPh}}$	B	A_{SPh}	A_{Cl}	$A_{\mathrm{Cl}}-A_{\mathrm{SPh}}$	$A_{\mathrm{Cl}}+A_{\mathrm{SPh}}$
Xylose	−21,670	10,200	−31,870	38,500	70,370	6,630
Cellobiose	−20,740	8,800	−29,540	39,000	68,540	9,460
Lactose	−14,270	16,900	−31,170	38,100[7]	69,270	6,930
Glucose	− 7,700	20,700	−28,400	40,200	68,600	11,800
		Mean value M_D	−30,500	38,950	69,200 in $CHCl_3$	

Inspection of the data shows that A_{SPh}, like A_{Cl}, is an almost constant quantity and that the greatest deviation from the mean value occurs with tetra-acetyl thiophenol glucoside. This error corresponds to less than 5° in specific rotation and the agreement may be considered fair. Thiophenol glycoside acetates, therefore, obey the regularities discovered by Hudson for other similar series of sugar derivatives and the possession of an unsaturated sulfur atom does not necessarily render invalid the principle of optical superposition on which such regularities are founded. It is worthy of note that the molecular rotation of the p-thiocresyl group, M_D *29,580* as obtained from that of hepta-acetyl β-*p*-thiocresol cellobioside, M_D *−20,780* in chloroform, is practically the same as that of A_{SPh}, as might have been expected from the close structural similarity between these two radicals.

While it is true that A_{SPh} is approximately constant, the deviations from the average value would individually be zero if the law of optical superposition were obeyed with rigor. This is obviously not the case and different substituents occasion varying small but definite changes in the rotation of the rest of the molecule. The remarkable constancy of the sum $A_{\mathrm{Cl}}+A_{\mathrm{SPh}}$, as compared with the gross variations in their difference, $A_{\mathrm{Cl}}-A_{\mathrm{SPh}}$, indicates that in the former case the secondary

---

[7] Hudson and Kunz, THIS JOURNAL, 47,2052 (1925).

deviations were largely compensated and were, therefore, very similar in magnitude and opposite in sign. As the thiophenyl glycoside acetates, from their method of preparation, possessed the β-configuration and were therefore contrary in this respect to the acetochloro sugars, it may be concluded that the thiophenyl group very closely resembles a chlorine atom in its effect upon the rotation of an acetylated sugar molecule as a whole. Indeed, an exhaustive series of similar calculations showed that this parallelism between thiophenyl, p-thiocresyl and chlorine substituents in the reducing position of the four sugar acetates studied was as close as that between chlorine and iodine in the acetohalogen derivatives, much better than that between chlorine and bromine, chlorine and α-methoxy or β-thiophenyl and β-methoxyl. In a word, the molecular rotations of the thiophenol glycoside acetates in chloroform are appropriately compared with those of the acetochloro derivatives and not with the acetylated glycosides of the hydroxy alcohols.

While the acetylated thiophenol glycosides display the normal relationship to each other in their optical behavior, no such claim can be made for the β-glycosides themselves. The following data are based throughout upon measurements made in water, while a_{SPh} and b have their old significance but with respect to the new solvent. An article by Hudson[8] furnished the data from which the value of b was calculated from the molecular rotations of the β-sugars in the usual way. It will be seen that the variation in the magnitude of a_{SPh} is very great.

TABLE II

VALUE OF THE QUANTITY, a_{SPh}, THE ROTATION OF THE END ASYMMETRIC CARBON ATOM FOR β-THIOPHENOL GLYCOSIDES

Sugar	M_D in water $b - a_{SPh}$	M_D b	M_D a_{SPh}
Xylose	−17,130	7,250	24,380
Cellobiose	−25,690	13,970	39,660
Lactose	−17,060	20,470	37,530
Glucose	−19,180	11,870	31,050

If the very probable assumption be made that the deacetylation of the acetylated thioglycosides by means of alcoholic ammonia was accompanied by no other structural change in the molecule, only two explanations seem to be able to account for the inconstancy of a_{SPh}. The first of these would postulate that the unsaturated sulfur atom in the thioglycoside formed an unstable addition compound with an hydroxy group in the carbohydrate residue or with the elements of the water used as a solvent in the optical determinations. In this case the experimental observations could be attributed to the constitutional dissimilarity of the compounds studied. On the other hand, the anomalies may be due to the failure of

---

[8] Hudson, THIS JOURNAL, 47, 268 (1925).

the principle of optical superposition to apply even approximately to **the** glycosides of thiophenol, but it then becomes difficult to understand why the same irregularities are not more marked among the rotations of the fully acetylated derivatives. **The** exploration of this possibility would involve the study of reducing sugars substituted in the first position by other highly acidic radicals such as chlorine in the unknown chloro sugars. In the meantime, however, it is unsafe to make use of an optical property as a guide to the stereochemical arrangement of the unsubstituted thioglycosides.

Experimental

The Preparation of **Triacetyl β-Thiophenol Xyloside.**—A solution of 10 g. of pure β-xylose tetra-acetate in 25 cc. of dry chloroform was made up to 50 cc. with glacial acetic acid saturated with hydrogen bromide. The optical rotation of the mixture increased to a constant value within thirty minutes, when the substitution of bromine for the acetyl group on the first carbon atom of the molecule was taken to be complete. After three successive washings with ice water had removed acetic acid and hydrogen bromide, the residual chloroform solution of acetobromoxylose, together with small chloroform extracts of the aqueous liquors, was added at room temperature and without drying to the equivalent amount (51 cc.) of 0.612 *N* alcoholic caustic potash in which 3.5 cc. or a 10% excess of thiophenol had previously been dissolved. Warming on the water-bath for thirty minutes rendered the condensation complete, after which the clear liquor, with its deposit of crystalline potassium bromide, was repeatedly washed in a separatory funnel with a dilute aqueous solution of sodium bicarbonate until the odor of the thio-alcohol became faint. The chloroform layer, after being finally extracted with water and dried over anhydrous calcium chloride, was evaporated under diminished pressure to a thin sirup, from which an 80% yield of triacetyl-β-thiophenol xyloside was precipitated by the cautious use of light petroleum. The product, which occurred as small, well-formed prisms, was readily recrystallized by adding petroleum ether to its ethereal solution and after two such purifications possessed a specific rotation in chloroform of $[\alpha]_D$ −58.71° (0.2566 g. in 25 cc. rotated plane-polarized light 1.205° to the left when a 2-dm. tube was used). Another recrystallization failing to change this value appreciably (found, $[\alpha]^{20}_D$ −59.0"; 0.3758 g. in 25 cc. of chloroform gave an observed reading of 1.774" to the left when in a 2-dm. tube), the specific rotation of pure triacetyl-β-thiophenol xyloside in chloroform was accepted as $[\alpha]^{20}_D$ −68.9'. The compound was readily soluble in all of the usual organic solvents save petroleum ether and melted sharply at 78°.

An acetyl determination was carried out by the method of Kunz;[9] 0.3174 g. required 26.13 cc. of decinormal alkali in place of the theoretical amount, 25.88 cc., for triacetyl thiophenol xyloside. In the estimation of sulfur the accurate and expeditious method due to Waters[10] was adopted: 0.3566 g. gave 0.2346 g. of Ba_2SO_4. Calcd.: S, 8.70. Found: S, 9.02.

Hepta-acetyl-β-thiophenol Cellobioside.—Pure β-cellobiose octa-acetate, 30 g., was allowed to stand for three hours at room temperature in chloroform (90 cc.) and glacial acetic acid containing 20% by weight of hydrogen bromide (75 cc.). Occasional shaking had enabled the acetate to dissolve completely and a solution of the acetobromo sugar in chloroform was isolated from the mixture as described in the preceding pare-

---

[9] Kunz and Hudson, THIS JOURNAL, 48, 1982 (1926).

[10] Waters, *J. Ind. Eng. Chem.*, 12,482 (1920).

graph. The condensation of the acetobromocellobiose with the theoretical amount (96 cc.) of 0.455 *N* alcoholic caustic potash and with 4.8 cc. (10% excess) of thiophenol was also carried out exactly as in the case of triacetyl thiophenol xyloside and, on isolation, a 78% yield of crude crystalline acetylated thioglycoside was obtained. A single recrystallization from 16 times its weight of hot alcohol lowered the specific rotation of the preparation to $[\alpha]^{20}_{\mathrm{D}}$ —26.57' in chloroform but this method did not succeed in eliminating all of the impurities. The crude material, which contained no halogen and displayed little reducing power on hot Fehling's solution, was eventually dissolved in 100 cc. of warm chloroform and was fractionally recrystallized as minute needles by the cautious addition of hot absolute alcohol. This procedure gave a small first fraction with a specific rotation of $[\alpha]^{16}_{\mathrm{D}}$ —27.2" in chloroform (0.2485 g. in 25 cc. had a —0.541° in a 2-dm. observation tube) and a large second fraction with $[\alpha]^{16}_{\mathrm{D}}$ —28.5° (0.4633 g. in 25 cc. of chloroform gave an observed reading of 1.056° to the left in a 2-dm. tube). The specific rotation of the latter fraction did not change appreciably on repeated purification in the same manner; after the first recrystallization, $[\alpha]^{17}_{\mathrm{D}}$ —28.33° (0.5428 g. in 25 cc. of chloroform had a —1.230° in a 2-dm. tube); after the fourth, $[\alpha]^{18}_{\mathrm{D}}$ —28.58" (0.5421 g. gave an observed reading of 1.230° to the left); and after the fifth, $[\alpha]^{20}_{\mathrm{D}}$ —28.20° (0.5343 g. had a —1.205" observed in 25 cc. of chloroform with a 2-dm. tube). Accordingly, $[\alpha]^{20}_{\mathrm{D}}$ —28.5° was accepted as the true specific rotation of hepta-acetyl-β-thiophenol cellobioside in chloroform. The compound decomposed in the neighborhood of 295° and dissolved freely in chloroform and acetone, was sparingly soluble in hot alcohol and was almost insoluble in ether or petroleum ether.

In an acetyl estimation, 0.2287 g. required 21.8 cc. of decinormal alkali, the amount calculated for the same weight of thiophenol cellobioside acetate being 22.0 cc. The preparation contained 4.57% of sulfur in place of the theoretical amount, 4.40% (0.5349 g. gave 0.1785 g. of $BaSO_4$).

Hepta-acetyl-β-*p*-thiocresol Cellobioside.—The method used to obtain hepta-acetyl-β-thiophenol cellobioside was also adopted in the preparation of the analogous p-thiocresol derivative and gave rise to the product as long, silky needles in a yield which was 80% of the theoretical. The specific rotation of the crude product was $[\alpha]^{21}_{\mathrm{D}}$ —22.8' in chloroform (0.3323 g. in 25 cc. had a —0.606" in a 2-dm. tube) but two recrystallizations from alcohol reduced this figure to $[\alpha]^{20}_{\mathrm{D}}$ —28.2° (0.3438 g. gave an observed reading of 0.776° to the left). No change occurred after the next purification (found, $[\alpha]^{20}_{\mathrm{D}}$ —27.75°; 0.3385 g. in 25 cc. of chloroform gave an observed reading of 0.751° to the left) and $[\alpha]^{20}_{\mathrm{D}}$ —28.0° was taken to be the correct rotation of hepta-acetyl-β-*p*-thiocresol cellobioside in this solvent. The substance melted sharply at 217°.

In an acetyl estimation 0.2726 g. required 25.04 cc. of decinormal alkali, the theoretical amount being 25.15 cc.; 0.4923 g. also gave 0.1529 g. of $BaSO_4$. Found: S, 4.26; hepta-acetyl thiocresol cellobioside requires, S, 4.31.

Hepta-acetyl-β-thiophenol Lactoside.—The acetylated thioglycoside was prepared from 40 g. of crude lactose octa-acetate, free from inorganic salts but not recrystallized, exactly as in the case of the same derivative of cellobiose, and the yield of the crude crystalline product averaged 70% of the theoretical. Recrystallization from 130 cc. of hot 95% alcohol reduced the specific rotation to $[\alpha]^{20}_{\mathrm{D}}$ —19.25' (0.3552 g. had a reading of 0.547' to the left in 25 cc. of chloroform and a 2-dm. tube), while after the next purification a value of $[\alpha]^{20}_{\mathrm{D}}$ —19.6" was observed (0.2916 g. in 25 cc. with a 2-dm. tube gave 0.457' to the left). The product from the third recrystallization had $[\alpha]^{20}_{\mathrm{D}}$ —19.72° (0.3270 g. gave a reading of —0.516") and $[\alpha]^{20}_{\mathrm{D}}$ —19.6" was the specific rotation of pure hepta-acetyl-β-thiophenol lactoside in chloroform solution at a concentration of about 1.5%.

Fischer and Delbrück[5] quote $[\alpha]^{20}_{\mathrm{D}}$ —17.7° as the specific rotation of the substance in a 7.165% chloroform solution; the present preparation gave an observed reading of 2.599' to the left in a 2-dm. tube under the same conditions and therefore possessed a specific rotation of $[\alpha]^{20}_{\mathrm{D}}$ −18.14° at this concentration. The compound melted at 155–156°.

In an acetyl estimation, 0.1652 g. required 15.88 *cc.* of decinormal alkali while the value demanded by the same weight of acetylated thiophenol lactoside is 15.85 cc. The sulfur estimation on 0.4831 g. gave 0.1567 g. of $BaSO_4$. Found: S, 4.46; calcd., S, 4.40.

Tetra-acetyl-β-thiophenol Glucoside.—The substance was prepared by the above method in 70% yield from crude crystalline glucose penta-acetate and was recrystallized from 95% alcohol as long needles with a specific rotation of $[\alpha]^{20}_{\mathrm{D}}$ −22.25' in chloroform (0.1653 g. in 25 cc. had an observed reading of 0.294° to the left in a 2-dm. tube). Two fractions were obtained in the third recrystallization with rotations of $[\alpha]^{19}_{\mathrm{D}}$ −17.5" and $[\alpha]^{20}_{\mathrm{D}}$ −17.38°, respectively (0.6482 g. had a −0.907"; 0.6786 g. had α −0.943" under the usual conditions) and the next recrystallization did not change the determination (found, $[\alpha]^{20}_{\mathrm{D}}$ −17.63°; 0.6745 *g.* had α −0.951"). Pure tetra-acetyl-β-thiophenol glucoside, therefore, had a specific rotation in chloroform of $[\alpha]^{20}_{\mathrm{D}}$ −17.8" for a concentration of about 2.5%.

Fischer and Delbriick[5] made an observation in toluene of $[\alpha]^{20}_{\mathrm{D}}$ −40.1° for a concentration of 4.6784%; two determinations in this solvent, carried out under comparable conditions, gave values of $[\alpha]^{21}_{\mathrm{D}}$ −40.85" and $[\alpha]^{21}_{\mathrm{D}}$ −40.7° for the specific rotation, or a mean value of $[\alpha]^{21}_{\mathrm{D}}$ −40.8°, in good agreement with the earlier observations (0.1696 *g.* in 25 cc. of toluene had α −3.828"; 1.1410 g. in 25 cc. had α −3.699").

β-Thiophenol Xyloside.—Pure triacetyl-β-thiophenol xyloside was dissolved in six times its weight of methyl alcohol which had previously been saturated at room temperature with dry ammonia gas. After standing overnight the evaporation of the solvent left a sirup which was repeatedly extracted with warm dry ether to remove acetamide. The product then crystallized in almost quantitative yield as stout prisms with a specific rotation in water of $[\alpha]^{20}_{\mathrm{D}}$ −69.7° after a single purification from alcohol (0.2905 g. in 25 cc. gave a reading of 1.621° to the left in a 2-dm. tube). A second recrystallization gave a product with $[\alpha]_{\mathrm{D}}$ −71.0" (0.2748 g. had α −1.562") which was not changed by the third or by the fourth (found, $[\alpha]^{20}_{\mathrm{D}}$ −70.5" and $[\alpha]^{20}_{\mathrm{D}}$ −71.0"; 0.2933 g. gave a reading of 1.654°, 0.3420 g. one of 1.943" to the left in a 2-dm. tube when dissolved in 25 cc. of water). β-Thiophenol xyloside thus possessed a specific rotation of $[\alpha]^{20}_{\mathrm{D}}$ −70.8° in a 1.4% aqueous solution. In acetone the optical property was very different (0.1581 g. in 25 cc. of the pure solvent gave an observed reading of 1.101" to the left in a 2-dm. tube and $[\alpha]^{20}_{\mathrm{D}}$ was −87.05"). The compound melted sharply at 144° and in addition to a ready solubility in water and alcohol it dissolved freely in acetone and ethyl acetate.

In an estimation of sulfur, 0.1951 g. gave 0.1894 g. of $BaSO_4$. Found: S, 13.33; calcd. for thiophenol xyloside, S, 13.23.

β-Thiophenol Cellobioside.—After the deacetylation of the pure hepta-acetate with methyl alcoholic ammonia and the removal of acetamide with ether, the addition of a little alcohol caused the glycoside to crystallize in a yield of 67% of the theoretical. The minute crystals separated over the course of days from methyl alcohol containing a little ether and possessed a rotation of $[\alpha]^{16}_{\mathrm{D}}$ −54.7 in water (0.2584 g. in 25 cc. had α −1.131"). Two similar recrystallizations raised this value to $[\alpha]^{16}_{\mathrm{D}}$ −59.0° (0.3836 g. gave a reading of α −1.811°), which was not changed by further purification (found $[\alpha]^{17}_{\mathrm{D}}$ −59.3'; 0.4020 had α −1.907'). β-Thiophenol cellobioside, therefore, had a specific rotation of $[\alpha]^{17}_{\mathrm{D}}$ −59.2° in water for a 1.5% solution. The melting point was sharp at 230°.

The sulfur estimation, carried out on 0.3696 g., gave 0.2029 g. of $BaSO_4$. **Found:** S, 7.54; calcd., S, 7.37.

β-Thiophenol Lactoside.—By the deacetylation of the pure acetate, crystalline thiophenol lactoside was obtained in 80% of the theoretical yield. Two recrystallizations from 95% alcohol rendered the compound nearly pure (found, $[\alpha]^{19}_{D}$ −38.45°; 0.2477 g. in 25 cc. of water had α −0.762"). After the third, the specific rotation was $[\alpha]^{19}_{D}$ −39.45" (0.2436 g. rotated plane-polarized light 0.786' to the left under the usual conditions), while no significant change was observed after the fourth purification (found, $[\alpha]^{19}_{D}$ −39.13"; 0.2345 g. in 25 cc. of water had **a** −0.734' when observed in a 2-dm. tube). The specific rotation of pure β-thiophenol lactoside in about 1% aqueous solution was thus $[\alpha]^{19}_{D}$ −39.3°. At a higher concentration, 6.5632%, the rotation of this glycoside was $[\alpha]^{19}_{D}$ −40.36" (1.6408 g. in 25 cc. of water gave a reading of 5.296" to the left in a 2-dm. tube), in good agreement with the value, $[\alpha]^{20}_{D}$ −40.1 °, obtained by Fischer and Delbrück[5] under the same conditions. β-Thiophenol lactoside melted sharply at 220°.

In a sulfur estimation, 0.5004 g. gave 0.2651 g. of $BaSO_4$. Found: S, 7.28; calcd. for thiophenol lactoside, S, 7.37.

β-Thiophenol Glucoside.—The sirupy mixture of acetamide and thioglucoside which remained from the deacetylation of pure tetra-acetyl-p-thiophenol glucoside was dissolved in 7 times its weight of warm ethyl acetate and 86% of the theoretical amount of thiophenol glucoside crystallized as the solution cooled. After two further recrystallizations from ethyl acetate containing a little methyl alcohol, the product had a rotation of $[\alpha]^{20}_{D}$ −70.34° in water (0.5352 g. in 25 cc. had an observed rotation of 3.012" to the left in a 2-dm. tube) and melted sharply at 133°. These values were not changed on further purification (found, $[\alpha]^{19}_{D}$ −70.75"; 0.5323 g. had **a** −3.012°) and the specific rotation of β-thiophenol glucoside in a 2% aqueous solution was regarded as $[\alpha]^{19}_{D}$ −70.5". When the concentration was 9.774%, the rotation fell to $[\alpha]^{19}_{D}$ −72.15' (observed in a 2-dm. tube, 14.76° to the left) in good agreement with the values of $[\alpha]_D$ −72.3" and $[\alpha]_D$ −72.5" found by Fischer and Delbrück for the same solution.

The author desires to thank the Commonwealth Fund of New York for the Fellowship which made possible the carrying out of this research. He also expresses his deep indebtedness to Dr. C. S. Hudson for many valuable suggestions.

Summary

1. The specific rotations of the following thioglycoside acetates have been measured in chloroform solution: triacetyl-β-thiophenol xyloside, m. p. 78°, $[\alpha]^{20}_{D}$ −58.9°; hepta-acetyl-β-thiophenol cellobioside, decomposition point about 295°, $[\alpha]^{20}_{D}$ −28.5°; hepta-acetyl-β-*p*-thiocresol cellobioside, m. p. 217', $[\alpha]^{20}_{D}$ −28.0'; hepta-acetyl-β-thiophenol lactoside, m. p. 155–156°, $[\alpha]^{20}_{D}$ −19.6°; tetra-acetyl-p-thiophenol glucoside, m. p. 117°, $[\alpha]^{20}_{D}$ −17.5°.

2. It has been shown that the molecular rotation of the potentially reducing carbon atom in the above acetylated thioglycosides, A_{SPh}, is approximately constant at M_D 30,500. The deviations from this value in the case of individual sugars are similar in magnitude but opposite in sign to those of A_{Cl}, the molecular rotation of the terminal asymmetric atom of the acetochloro derivatives.

3. The following specific rotations were measured with precision in aqueous solution; β-thiophenol xyloside, m. p. 144°, $[d]_D^{20}$ −70.8°; β-thiophenol cellobioside, m. p. 230°, $[\alpha]_D^{17}$ −59.2°; β-thiophenol lactoside, m. p. 220°, $[\alpha]_D^{19}$ −39.3" and β-thiophenol glucoside, m. p. 133°, $[\alpha]_D^{19}$ −70.5°.

4. The molecular rotations in water of the above four β-thiophenol glycosides displayed irregularities which could not be explained. In consequence, optical data cannot at present be safely used as an aid in determining the stereochemical configuration of the thioglycosides.

RELATIONS BETWEEN ROTATORY POWER AND STRUCTURE IN THE SUGAR GROUP. XXII. EVIDENCE CONCERNING THE RINGED STRUCTURE OF BETA-THIOPHENOL CELLOBIOSIDE AND OF BETA-THIOPHENOL LACTOSIDE[1,2]

BY CLIFFORD B. PURVES

RECEIVED JULY 22, 1929 PUBLISHED DECEMBER 11, 1929

A noteworthy property of the β-thioglycosides which serves to distinguish them from the isomeric a-forms, and also from the glycosides of the hydroxy alcohols, may be seen in their great stability toward acid hydrolysis.[3] The glycosidic unions in β-thiophenol lactoside and cellobioside are no exceptions to the general rule and the comparative indifference of the thio linking in such derivatives of the disaccharides makes possible a simple way of examining their constitution. For example, if thiophenol lactoside be submitted to the action of aqueous acid under conditions just sufficiently drastic for the complete hydrolysis of the disaccharide itself, the union of thiophenol with the potentially reducing carbon atom of the sugar residue is largely preserved and galactose and a thiophenol glucoside may be expected to form the main products of the reaction. The former component may readily be modified before its examination, either as regards the position of the oxygen ring or otherwise, and the isolation of galactose of the ordinary type therefore provides no evidence concerning its original state in the disaccharide molecule. It is otherwise

[2] The author has arranged with Dr. C. S. Hudson, under whose direction the research was carried out, that it will be included as No. XXII in his series entitled "Relations between Rotatory Power and Structure in the Sugar Group." No. XXI was published in THIS JOURNAL, 51,3619 (1929).

[3] Schneider, Sepp and Stiehler, *Ber.*, 51,220 (1918).

with the thioglycosidic component, for here the reducing position is shielded by the stable thiophenol radical and a change in the structure of this unit of thiophenol lactoside during the experiment may be discounted with some confidence. Thiophenol lactoside and cellobioside have accordingly been submitted to the action of aqueous acid and the specimens of thiophenol glucoside so obtained have been examined in order to see whether they were of the normal or gamma type.

After making certain that thiophenol glucoside itself was very nearly stable under the experimental conditions to be employed in the hydrolyses, thiophenol lactoside was heated with normal sulfuric acid for one and three-fourths hours. The trace of thiophenol set free during this operation was readily removed by chloroform and it was possible to determine the final specific rotation of the solution to be $[\alpha]_D$ −10.66". An equimolecular mixture of galactose and β-thiophenol glucoside possesses the closely similar rotation of $[\alpha]_D$ −9.56" in distilled water. Ethyl acetate separated the non-reducing product from the crystalline galactose, which was also identified, and the extract was found to contain 75.4% of the theoretical amount of β-thiophenol glucoside in one experiment and 84% in a second. The physical constants of the product, m. p. 125–128°, $[\alpha]_D$ −65.9° in water, although improved by subsequent recrystallization, could not be made to agree with those of pure β-thiophenol glucoside, m. p. 133°, and $[\alpha]_D$ −70.5" and the impure specimen was acetylated. A tetra-acetyl-β-thiophenol glucoside was thus obtained in 90% yield which possessed the same crystalline form, melting point and specific rotation as a standard preparation from glucose itself. Fischer and Delbrück[4] also carried out this hydrolysis with a similar result but unfortunately the scale of their experiment was too small to permit of the rigorous characterization of the particular type of thioglucoside which had been formed. It was therefore necessary to repeat their work.

The partial hydrolysis of β-thiophenol cellobioside was carried out in precisely similar fashion and yielded glucose, identified as glucosazone, and slightly impure β-thiophenol glucoside of the ordinary variety, identified as such and also as the pure tetra-acetate, m. p. 117°, $[\alpha]_D$ −17.84" in chloroform. Although the hydrolysis of the thiocellobioside was discontinued when the specific rotation of the solution had increased to $[\alpha]_D$ −23.0°, that is, in close agreement with that of an equimolecular mixture of glucose and β-thiophenol glucoside, $[\alpha]_D$ −21.5" in water, the yield of thiophenol glucoside extracted by ethyl acetate was only 51% of the theoretical. The easy separation of amorphous galactose from thiophenol glucoside by the same solvent stands in contrast to this observation.

From the foregoing, thiophenol lactoside and thiophenol cellobioside may be regarded as thiophenol glucosides of the normal ringed type substi-

tuted by galactose and by glucose residues, respectively. This conclusion is entirely in accord with the commonly accepted constitution of the corresponding methyl glycosides due to Haworth and his collaborators[5] whose publications include a comprehensive review of the literature. As these authors examined the structure of methyl lactoside and cellobioside by the methylation method, the present work provides a direct and independent confirmation of an important part of their findings.

Experimental

Stability of B-Thiophenol Glucoside toward Aqueous Acid.—A solution of the glucoside in 0.5 *N* sulfuric acid had an initial observed reading of −3.005° in a 2-dm. tube and, after heating for two hours at 80° and for one hour at 100°, the liquid remained perfectly clear and did not smell of thiophenol. On cooling, the observed rotation was —2.995" and thiophenol glucoside was therefore stable under these conditions.

When the thioglucoside was boiled under a reflux condenser with sulfuric acid of normality 0.8 N, an initial reading of −1.240° changed to one of −1.222° in the course of three hours, while the solution acquired a faint odor of thiophenol. As complete hydrolysis to glucose and thiophenol required a change in the observed reading from −1.240 to 0.611°, that which occurred was of the order of 1%.

Thiophenol Glucoside from Thiophenol Lactoside.—Five grams of the thiophenol lactoside was dissolved in normal sulfuric acid and the solution, volume exactly 50 cc., was heated for an hour on the water-bath. The specific rotation increased during this time from $[\alpha]_D$ −38.3° (observed in a 2-dm. tube, the rotation was 7.65" to the left) to $[\alpha]_D$ −19.1° (observed **a** —3.81") but subsequent determinations were made uncertain by the presence of thiophenol. After continuing the heating for forty-five minutes, the cloudy solution was neutralized with aqueous alcoholic caustic soda and after a filtration was found to turn plane-polarized light 0.96° to the left when in a 2-dm. tube. As the total volume was now 116 cc., the observation corresponds to a specific rotation of $[\alpha]_D$ −10.66°, corrected on the assumption that the change to galactose and β-thiophenol glucoside had been quantitative. The theoretical rotation for such an equimolecular mixture is $[a]_D$ −9.56°, measured in distilled water.

The solvents were removed by evaporation under diminished pressure, the dry residue was repeatedly extracted with ethyl acetate and 2.4137 g. of fine needles was recovered from the concentrated extracts by the cautious addition of ether. The crude product, melting at 125–128° and with a specific rotation in water of $[\alpha]_D^{20}$ —65.91° (0.2105 g. in 25 cc. had α —1.115" when observed in a 2-dm. tube) was therefore recovered in 75.4% of the theoretical yield. After two recrystallizations from ethyl acetate, the preparation had a melting point of 130–132°, of 132–133° when mixed with an authentic specimen of pure β-thiophenol glucoside and a specific rotation of $[\alpha]_D^{19}$ −69.2° in water. The constants for pure β-thiophenol glucoside are m. p. 133" and $[\alpha]_D^{20}$ −70.5° in water.

Acetic anhydride and anhydrous sodium acetate acetylated the material and tetra-acetyl-β-thiophenol glucoside was recovered in 90% yield after being recrystallized from alcohol. The physical constants, m. p. 117° and $[\alpha]_D^{17}$ —18.0" in chloroform (0.6701 g. in 25 cc. had an observed reading of 0.965' to the left in a **2-dm.** tube), were in excellent agreement with those accepted as correct for tetra-acetyl β-thiophenol glucoside, m. p. 117" and $[\alpha]_D^{20}$ −17.5" in the same solvent. **A** mixture of the two specimens also melted at 117°.

[5] Haworth and Long, J. Chem. *Soc.*, 131, 544 (1927); Haworth, Long and Plant, *ibid.*, 2809 (1927).

The residue from the hydrolysis which was insoluble in ethyl acetate was extracted with methyl alcohol to recover the reducing sugar, which slowly crystallized from the extract after the alcohol had been replaced by a little glacial acetic acid; yield, 0.826 g., or 41% of the theoretical. The crystals were those of or-galactose and without further purification displayed a mutarotation in water of $[\alpha]_D$ 140' (extrapolated) to an equilibrium rotation of $[\alpha]_D$ 77.35°, in fair agreement with the constants accepted for the pure sugar, $[\alpha]_D$ 144° to $[\alpha]_D$ 80.5' (0.4929 g. in 25 cc. gave a final observed reading of 3.051° to the right in a 2-dm. tube).

Thiophenol Glucoside from Thiophenol Cellobioside.4.7926 g. of pure β-thiophenol cellobioside was dissolved in normal sulfuric acid and the solution, volume exactly 100 cc. and having an observed rotation in a 2-dm. tube of —5.29", was heated on a steam-bath for three hours. At the end of that time the liquid was cooled, made up to its original bulk with water and shaken with a few cc. of chloroform to dissolve a trace of thiophenol and a small orange precipitate. The optical rotation of the aqueous portion had then increased to —2.29°, corresponding to a specific rotation of $[\alpha]_D^{17}$ —23.0' when calculated on the basis that the hydrolysis to glucose and thiophenol glucoside had been quantitative. The theoretical specific rotation for this mixture is $[\alpha]_D^{20}$ —21.5°, measured in distilled water.

After removing the free acid as barium sulfate, the solution was evaporated to dryness under diminished pressure and the residue was extracted ten times in succession with boiling ethyl acetate. The thiophenol glucoside isolated from the extract and once recrystallized weighed 1.505 g. or 50% of the theoretical, melted at 125–127°, at 128–129° when mixed with authentic β-thiophenol glucoside and had a specific rotation in water of $[\alpha]_D^{26}$ —65.13' (0.4578 g. in 25 cc. had an observed reading in a 2-dm. tube of 2.386" to the left). It was thus impure and was acetylated in the usual way to give an almost quantitative yield of tetra-acetyl-β-thiophenol glucoside whose melting point of 117° was not depressed by admixture with the standard substance. The specific rotation of $[\alpha]_D^{18}$ —18.25" in chloroform (0.3051 g. in 25 cc. had α —0.445' in a 2-dm. tube) was reduced to $[\alpha]_D^{18}$ —17.84' by a recrystallization from alcohol (0.4737 g. in 25 cc. of chloroform had or —0.676" in a 2-dm. tube) and thus agreed well with the standard rotation of $[\alpha]_D^{20}$ —17.5° for tetra-acetyl-β-thiophenol glucoside.

The residue from the ethyl acetate extractions failed to crystallize but yielded an osazone, decomposing at 204° when heated on the water-bath with phenylhydrazine and acetic acid. After a purification from aqueous pyridine, 0.1 g. was made up to 5 cc. with ethyl alcohol containing 40% by volume of pyridine and the solution was examined polarimetrically after having stood for eighteen hours in a 0.5-dm. tube. The observed rotation, —0.40°, was identical with that possessed by an authentic sample of glucosazone in the same circumstances.[6]

The author wishes to thank Dr. C. S. Hudson for his interest in the research and for many valuable suggestions. He also expresses his great indebtedness to the Commonwealth Fund of New York for the Fellowship which made the research possible.

Summary

1. β-Thiophenol lactoside and β-thiophenol cellobioside, on partial hydrolysis with aqueous acid, yielded a β-thiophenol glucoside identical in all respects with a specimen prepared from glucose itself.
2. It was concluded from the above evidence that the glucose resi-

RELATIONS BETWEEN ROTATORY POWER AND STRUCTURE IN THE SUGAR GROUP. XXIII. THE PREPARATION AND THE STRUCTURE OF BETA-THIOPHENOL MALTOSIDE AND OF ITS HEPTA-ACETATE[1]

BY CLIFFORD B. PURVES

RECEIVED JULY 22, 1929 PUBLISHED DECEMBER 11, 1929

β-Thiophenol cellobioside and β-thiophenol lactoside, according to the evidence presented in the preceding paper,[2] may be regarded as derivatives of a β-thiophenol glucoside of the normal ring structure. The two compound thioglycosides were submitted to the action of aqueous acid in such a way that glucose, or galactose, and thiophenol glucoside formed the main products of the partial hydrolysis. On examination, the specimens of thiophenol glucoside so prepared were found to be identical in all respects with one derived from acetobromoglucose and potassium thiophenate. It was this fact which led to the above conclusion, although it will be noticed that the reasoning involved the assumption that the relatively great stability of the thioglycosides toward acid hydrolysis precluded any change in their ring structure during the course of the experiment.

The examination of maltose in similar fashion was beset with the difficulties found in obtaining an adequate supply of hepta-acetyl-β-thiophenol maltoside in a pure condition. These were largely due to the unsatisfactory nature of the reaction between hydrogen bromide in glacial acetic acid-chloroform solution and maltose β-octa-acetate, which fails to result in a crystalline acetobromo derivative. This compound formed the starting point in the preparation of the thiophenol glycoside acetate. When *the* action of the hydrogen bromide solution was limited to two and one-half hours at 0°, 60% of the octa-acetate was recovered unchanged after the remainder had been condensed with potassium thiophenate, in spite of the fact that a 500% excess of the gas had been used and that similar acetates, such as those of glucose or cellobiose, give almost quanti-

[2] The author has arranged with Dr. C. S. Hudson, under whose direction the research was carried out, that it will be included as No. XXIII in his series entitled "Relations between Rotatory Power and Structure in the Sugar Group." No. XXII was published in THIS JOURNAL, 51,3627 (1929).

tative yields of the acetobromo sugars under the same conditions. On another occasion a solution of maltose acetate and a 600% excess of hydrogen bromide were allowed to stand in solution at 20° for forty-eight hours with the result that twenty-six per cent. by weight of the acetate used was recovered as pure tetra-acetyl-P-thiophenol glucoside. The experimental conditions finally adopted for the preparation of acetobromo maltose were intermediate to those described above and were very similar to those used by Irvine and Black,[3] although the small scale to which the authors restricted the reaction was found to be unnecessary. When the directions cited in the experimental portion were adhered to with rigor, a chloroform solution of the amorphous derivative was obtained which gave a reliable yield of 49.5% by weight of crude, crystalline hepta-acetyl-β-thiophenol maltoside when condensed with potassium thiophenate in the usual way.

The crude acetylated glycoside could not be purified readily by recrystallization from chloroform and ether, and the fractions which separated from these solvents displayed a specific rotation which varied capriciously from $[\alpha]_D$ 43° to $[\alpha]_D$ 52" in chloroform. Reacetylation failed to give a homogeneous product and showed that the irregularities were not due to the partial removal of acetyl groups from the thioglycoside during the condensation. As sulfur and acetyl estimations tended to be high and low, respectively, the presence of tetra-acetyl thiophenol glucoside was inferred but whatever the nature of the impurity was, it was eventually eliminated by the careful fractional crystallization of the crude hepa-acetyl-β-thiophenol maltoside from absolute alcohol. The constants of the pure compound were found to be m. p. 93–95" and $[\alpha]_D^{27}$ $-49.0°$ in chloroform.

The molecular rotation of hepta-acetyl β-thiophenol maltoside, M_D 35,660 in chloroform, may be expressed in the manner of Hudson[4] as $B - A_{SPh}$, where B refers to the rotation of the acetylated basal chain and has the value M_D 62,700. From this the rotation of the terminal asymmetric carbon atom, A_{SPh}, in the thioglycoside acetate is seen to be of a magnitude M_D 27,040 in chloroform, which is considerably lower than the average value of M_D 30,500 deduced from the molecular rotations of the fully acetylated β-thiophenol glycosides of glucose, xylose, lactose and cellobiose.[5] In the same article, moreover, it was shown that the deviations from the mean value of A_{SPh} for these four sugars were opposite in sign but similar in magnitude to those encountered in the quantity A_{Cl}, the rotation due to the terminal asymmetric center in the corresponding acetochloro derivatives. The sum $A_{SPh} + A_{Cl}$ was therefore remarkably constant throughout the series examined and amounted to M_D 69,200 in chloro-

form. β-Thiophenol maltoside acetate and acetochloro maltose supply a further illustration of the principle. for the sum $A_{\mathrm{Cl}} + A_{\mathrm{SPh}}$ (41,400[4] + 27,040) is M_{D} 68,440 in this case and agrees well with the former value.

Two attempts were made to prepare a crystalline β-thiophenol maltoside from the hepta-acetate, alcoholic ammonia being used as the deacetylating agent on one occasion and sodium methylate on the other, but both methods yielded an amorphous white solid which could not be crystallized and which was not fermented by yeast. The specific rotation of the impure thioglycoside was of the order of $[\alpha]_{\mathrm{D}}^{27}$ 38° in water but its extremely hygroscopic nature caused the determination to be of doubtful accuracy.

As thiophenol maltoside possessed such unsatisfactory physical properties, the crystalline acetate was submitted in its place to a partial hydrolysis with dilute sulfuric acid and yielded glucose and a thiophenol glucoside. This amorphous mixture was not readily separated by means of acetone or ethyl acetate and the amount of the thioglucoside recovered by the use of these solvents was only 55% of the theoretical yield. The insoluble portion was therefore fermented with yeast in order to remove the reducing sugar and when this was done a further quantity of β-thiophenol glucoside could be isolated, the total thus being increased to 71% of the theoretical. Acetylation of the material gave a pure tetra-acetyl-β-thiophenol glucoside, which was characterized with precision and found to be identical with a specimen prepared from acetobromoglucose.

β-Thiophenol maltoside, then, as well as the same derivative of cellobiose, must be regarded as β-thiophenol glucoside of the normal structure substituted in one hydroxy group by a second glucose residue. Haworth and his collaborators[5] have very recently elucidated the constitution of β-methyl maltoside by the methylation method and with the same result Their more extended investigation shows that the methyl glycosides of cellobiose and maltose differ in a stereochemical sense only in that the former is a β-glucosido-glucoside while the latter possesses the a-configuration. Such a conclusion is in full accord with the properties of the glycosides of the two disaccharides but fails to explain the sharp distinction to be observed in the behavior of their acetates toward hydrogen bromide. The amorphous nature of acetobromo maltose, together with the low yields of crystalline β-glycosides which may be prepared from it, suggests that it is the product of a more complex reaction than that which results in acetobromo cellobiose. The reason for this anomalous behavior remains obscure.

Experimental

Preparation of β-Thiophenol Maltoside Acetate.—A 50-cc. graduated glass-stoppered flask held exactly 10 g. of pure β-maltose octa-acetate, 20 cc. of chloroform and 20 cc. of a glacial acetic acid solution which contained 340 g. of hydrogen bromide

[5] Haworth and Peat, J. *Chem. Soc.*, 3094 (1926).

per liter. After standing in a constant temperature room for eight hours at 20°, the mixture was made up to the mark with chloroform, shaken and found to have a positive reading of 74.1' on the polarimeter when observed in a 2-dm. tube. The specific rotation of the acetobromomaltose was therefore $[\alpha]_D$ 180.1°, when calculated on the basis that its formation from the octa-acetate had been quantitative. The acids were then removed from the solution by washing, thrice repeated, with ice water and the wet chloroform residue containing the acetobromo sugar was run into a mixture of 1.65 cc. (10% excess) of thiophenol and 21 cc. of 0.7 N alcoholic potassium hydroxide (the theoretical amount). Warming on the water-bath for forty minutes completed the condensation. After washing potassium bromide, thiophenol and alcohol from the liquor with very dilute aqueous sodium bicarbonate, the chloroform solution was dried over calcium chloride and evaporated to a thin sirup, which was straightway taken up in 30 cc. of cold alcohol. Hepta-acetyl-β-thiophenol maltoside readily crystallized in the presence of a nucleus when 5 to 6 cc. of water was added and the solution was steadily scratched; yield, 4.95 g., m. p. 90–93°, $[\alpha]^{19}_D$ 44.64' (0.3170 g. in 25 cc. of chloroform gave an observed reading of 1.132° to the right when in a 2-dm. tube).

In order to purify the thioglycoside acetate, the product from several condensations, 13 g., was allowed to separate from an initial volume of 160 cc. of absolute alcohol in five fractions, the properties of which were as follows.

FRACTION 1.—Slender felted needles, apparently homogeneous; weight, 5.31 g.; 0.3223 g. required 30.06 cc. of decinormal caustic soda in an acetyl determination, the calculated value being 30.99 cc.; 0.2942 g. gave 0.0984 g. of barium sulfate; found, S, 4.59.

FRACTION 2.—Similar in crystalline form to the above; weight, 4.40 g.; 0.3233 g. took 31.27 cc. of decinormal alkali in an acetyl estimation where theory demands 31.09 cc.; 0.5534 g. gave 0.1795 g. of barium sulfate; found, S, 4.46.

FRACTION 3.—Similar in crystalline form to the above; weight, 2.04 g.; 0.2841 g. required 27.56 cc. of decinormal alkali in place of 27.32 cc.

FRACTION 4.—A mixture of slender needles with shorter, stouter prisms; weight, 0.65 g.; 0.3065 g. took 27.74 cc. of decinormal alkali in place of 29.47 cc. required by theory; 0.3033 g. gave 0.1120 g. of barium sulfate; found, S, 5.07.

FRACTION 5.—A small, discolored residue which crystallized completely as short, pointed prisms some weeks later. Hepta-acetyl thiophenol maltoside requires S, 4.39.

Fractions 2 and 3, which possessed satisfactory analytical figures, also agreed in their specific rotation (found, $[\alpha]_D$ 48.83°, 48.85" in chloroform; 0.3072 *g.* in 25 cc. had *a* 1.200'; 0.2966 g. had *a* 1.159° to the right in a 2-dm. tube). These fractions were therefore recrystallized together from alcohol as fine clusters of square-ended very slender prisms, soluble in petroleum ether, readily so in other organic solvents and with a specific rotation in chloroform of $[\alpha]^{27}_D$ 49.09°, or substantially the same as before (0.2213 g. in 25 cc. gave an observed reading of 0.869' to the right in a 2-dm. tube). Pure hepta-acetyl-β-thiophenol maltoside therefore possessed a specific rotation in chloroform of $[\alpha]^{27}_D$ 49.0°.

Fraction 1, after recrystallization and rejection of the first portion of 1 g. to separate, also yielded the pure thioglycoside acetate with the correct melting point of 93–95" and an accurate specific rotation (found, $[\alpha]^{22}_D$ 48.59'; 0.5217 g. in 25 cc. of chloroform gave an observed reading of 2.028' to the right in a 2-dm. tube). Thus 10.4 g. of pure hepta-acetyl thiophenol maltoside was obtained from 13 g. of the crude material, or from 26.3 g. of pure maltose octa-acetate. The yield was therefore about 37% of the theoretical.

Thiophenol Glucoside from **Hepta-acetyl β-Thiophenol** Maltoside. —Exactly 4 g. of the acetate was heated at 90° in a 100-cc. flask with 50 cc. of normal sulfuric acid and about 30 cc. of alcohol, which was just sufficient to give a clear solution. As the acetyl groups were removed during the hydrolysis, it was possible to replace this alcohol with distilled water as it evaporated, without causing the solution to become cloudy. Eight hours of heating sufficed to hydrolyze the thioglycoside, whereupon the volume was increased to the 100-cc. mark with water, a trace of thiophenol was extracted from the cold, cloudy solution with 1 cc. of chloroform and the clear aqueous portion was found to have a rotation of $-0.66°$, observed in a 2-dm. tube. This reading corresponds to a specific rotation of $[\alpha]_D$ $-13.3°$ on the assumption that the hydrolysis to β-thiophenol glucoside and glucose had been quantitative and may be compared with the theoretical rotation of $[\alpha]_D$ —21.5" for this mixture, measured in distilled water.

After the neutralization of the free acids with calcium carbonate, the filtered liquor was evaporated to complete dryness at 60° and the residue was extracted three times with acetone. The extract deposited a stiff sirup when concentrated and the portion which remained dissolved was crystallized from ethyl acetate after its recovery; 0.823 g. of crystalline β-thiophenol glucoside was so obtained m. p. 121–127°, raised to 129–131° by several purifications from ethyl acetate. A mixture of the substance with authentic thiophenol glucoside, m. p. 133°, melted at 131°, while its specific rotation was $[\alpha]_D$ —64.0" in water (0.2016 g. in 25 cc. had α $-1.032°$ when a 2-dm. tube was used). The whole of the original product which was not soluble in ethyl acetate was then united, freed from inorganic salts as far as possible by solution in methyl alcohol and fermented with yeast in 20 cc. of water after all traces of organic solvents had been removed. No glucose remaining in the solution four days later, a filtration through charcoal and a clarification with basic lead acetate were followed by the evaporation of the liquor to dryness under diminished pressure and by the extraction of the residue with ethyl acetate. The thiophenol glucoside which crystallized from the extract weighed 0.25 g. and increased the total yield of the crude material to 1.073 g., or 71.7% of the theoretical.

The acetylation of the thiophenol glucoside with acetic anhydride and pyridine, followed by recrystallization of the acetate from 95% alcohol, gave an almost quantitative yield of pure tetra-acetyl-β-thiophenol glucoside of the usual variety, m. p. 116"; mixed m. p. with an authentic specimen, 116° and $[\alpha]^{20}_D$ —18.4' in chloroform (0.4585 g. in 25 cc. and in a 2-dm. tube had a levorotation of 1.070°), thus agreeing with the standard constants, m. p. 117°, and $[\alpha]^{20}_D$ $-17.5°$, for this substance.

β-Thiophenol Maltoside.—A solution of 0.05 g. of metallic sodium in 5 cc. of absolute methyl alcohol was added to one of 8 g. of pure hepta-acetyl-p-thiophenol maltoside dissolved in 20 cc. of the same solvent.[7] The odor of methyl acetate was strong two days later, when the solution was evaporated to leave a colorless sirup which would not crystallize. The amorphous product was extremely soluble in water, methyl and ethyl alcohols, but dissolved sparingly in ethyl acetate and in cold propyl alcohol. Prior to analysis the β-thiophenol maltoside was heated at 100° (0.1 mm.) for several hours and assumed the form of an extremely hygroscopic glass with a specific rotation of $[\alpha]^{27}_D$ 38.12' in water (0.2339 g. in 25 cc. gave an observed reading of 0.357' to the right in a 1-dm. tube).

The author desires to thank the Commonwealth Fund of New York for the Fellowship which made possible his participation in the work. He also expresses his deep indebtedness to Dr. C. S. Hudson for many valuable suggestions.

Summary

1. Hepta-acetyl-β-thiophenol maltoside was synthesized from acetobromomaltose and potassium thiophenate and the constants of the pure compound were found to be m. p. 93–95" and $[\alpha]^{27}_D$ 49.0" in chloroform.

---

[7] Zemplén and Pacsu, *Ber.*, 62, 1613 (1929).

2. When submitted to a partial hydrolysis with aqueous acid, hepta-acetyl-β-thiophenol maltoside yielded glucose and β-thiophenol glucoside of the normal ring structure. β-Thiophenol maltoside may accordingly be regarded as ordinary β-thiophenol glucoside substituted by a second glucose residue.

3. β-Thiophenol maltoside was obtained as a very hygroscopic glass with an approximate specific rotation of $[\alpha]_D^{27}$ 38° in water.

PREPARATION OF BENZOYLACETIC ESTER

BY R. L. SHRINER AND A. G. SCHMIDT

RECEIVED JULY 25, 1929 PUBLISHED DECEMBER 11, 1929

The usual method given for the preparation of benzoylacetic ester is the Claisen condensation[1] of ethyl acetate with ethyl benzoate. A yield of 33% is reported but all attempts to duplicate this yield have failed. A study of this condensation was made by Marvel and Shiao[2] who found that the best yield obtainable by this method was 18%. In many runs the reaction mixture turned brown, puffed up and decomposed entirely giving very little or no product at all. A similar condensation with methyl piperonylate[3] gave yields ranging from 20 to 35%.

Since benzoylacetic ester would be an extremely useful reagent if it were readily obtainable, a search was made for other methods of preparation. The present communication is a report on the preparation of benzoylacetoacetic ester and its partial hydrolysis to benzoylacetic ester.

Benzoylacetoacetic ester was prepared in the usual way by the reaction between benzoyl chloride and the sodium derivative of acetoacetic ester. It was found possible to raise the yield of product from 50 to 75% and to shorten the time materially by using a slight excess of benzoyl chloride in benzene as the medium for the reaction.

The primary hydrolysis of benzoylacetoacetic ester may take place in three different ways

$$\left.\begin{matrix}C_6H_5CO\\ CH_3CO\end{matrix}\right\rangle CHCOOC_2H_5 + H_2O \longrightarrow \begin{cases} C_6H_5COCH_2COOC_2H_5 + CH_3COOH \\ CH_3COCH_2COOC_2H_5 + C_6H_5COOH \\ CH_3COCH_2COC_6H_5 + C_2H_5OH + CO_2 \end{cases}$$

Complete hydrolysis, of course, will lead to the formation of benzoic acid, acetophenone, acetone or acetic acid and the final products obtained will depend on the conditions of hydrolysis, which evidently must be carefully adjusted in order to favor the first reaction.

The different methods reported in the literature for accomplishing this

hydrolysis were tried. The most promising one was a short time hydrolysis with ammonia and ammonium chloride.[4] Claisen carried out this hydrolysis on the crude sodium salt obtained by the action of benzoyl chloride on acetoacetic ester and sodium ethylate. In the present study the pure benzoylacetoacetic ester was isolated first and then subjected to hydrolysis under the influence of varying concentrations of ammonia and ammonium chloride. The results of these experiments are summarized in Table I.

TABLE I

EFFECT OF VARYING CONCENTRATIONS OF AMMONIA AND AMMONIUM CHLORIDE ON THE HYDROLYSIS OF BENZOYLACETOACETIC ESTER

Run	Benzoyl-acetoacetic ester, g.	Water, cc.	NH_4Cl, g.	NH_4OH, cc. (sp. gr. 0.9)	Temp., °C.	Time, min.	Yield of benzoyl-acetic ester g.	%
1	40.0	100	9	10	40	10	11	34.3
2	58.5 (0.25 mole)	150	16	20	40	10	23	47.9
3	58.5	150	16	40	40	10	21	43.8
4	58.5	150	32	20	40	10	29	60.3
5	58.5	150	32	10	40	10	37.5	78.1
6	58.5	150	32	none	40	10	..	..

Run No. 1 was made according to Claisen's directions and resulted in a yield of 34%, although Claisen[5] claims 64–67% yields. A comparison of Runs 2 and 3 indicates that an increase in the ammonia concentration decreases the yield. An increase in ammonium chloride is beneficial up to a certain point. Run No. 6 resulted in the production of large quantities of benzoic acid. The optimum conditions are those given in No. 5. It was also found that the use of a higher temperature or longer time of hydrolysis resulted in lower yields.

It is evident that this same method can be applied to the preparation of substituted benzoylacetic esters.

Experimental

Preparation of Benzoylacetoacetic Ester.—Claisen[4] prepared this compound by adding benzoyl chloride slowly to a solution of acetoacetic ester in a sodium ethylate solution. Other investigators[6] have prepared the benzoylacetoacetic ester by adding metallic sodium to an ether solution of acetoacetic ester and then adding benzoyl chloride. The first method is objectionable because considerable amounts of ethyl benzoate are formed and the second requires a long time because of the slowness with which the sodium reacts with the acetoacetic ester. By using benzene and warming the mixture the time of preparation is considerably shortened. The optimum conditions are as follows.

In a 5-liter flask fitted with a mechanical stirrer and reflux condenser were placed

---

[4] Claisen, *Ann.*, 291, 71 (1896).

[5] From a consideration of Claisen's experimental data it is evident that two runs were combined in order to obtain the above yield. Attempts to duplicate Claisen's work by several different workers have given yields ranging from 29 to 34%.

[6] Bonné, *Ann.*, 187, 1 (1877); Fischer and Bülow, *Ber.*, 18, 2131 (1885); Nef. *Ann.*, 266, 99 (1891); Pechmann, *Ber.*, 25, 1046 (1892).

4.5 liters of dry benzene, 260 g. (2 moles) of acetoacetic ester and 46 g. (2 moles) of sodium. The mixture was stirred and allowed to reflux gently for twenty-four hours. The solution was then cooled slightly and 350 g. (2.5 moles) of benzoyl chloride added slowly over a period of three hours. The mixture was refluxed with stirring for eight hours. It was then cooled to room temperature and 500 g. of cracked ice added. After shaking thoroughly the benzene layer, which contains the benzoylacetoacetic ester, was separated and the benzene distilled. The residue was then distilled from a Claisen flask with modified side-arm and the fraction boiling at 177–181° at 20 mm. collected; yield, 350 g. or 74.8% of the theoretical.

Hydrolysis of Benzoylacetoacetic Ester.—The first hydrolysis recorded in Table I was made according to Claisen's directions.[4] The remaining hydrolyses were made in accordance with the procedure outlined below, the only variables being the amounts of ammonia and ammonium chloride. The amounts stated in the following procedure are those of Run 5 which represents the optimum conditions.

Thirty-two grams (0.6 mole) of ammonium chloride was dissolved in 150 cc. (8.3 moles) of water and 10 cc. (0.10 mole) of ammonia (sp. gr. 0.9) added. The solution was warmed to 40° and 58.5 g. (0.25 mole) of benzoylacetoacetic ester added. The solution was kept at 40° for ten minutes and then cooled rapidly by placing the flask in an ice-bath. It was extracted twice with 100 cc. of ether and the ether solution dried with anhydrous magnesium sulfate. The ether was distilled and the residue distilled in *vacuo;* yield, 37.5 g. (78.1% of the theoretical) of benzoylacetic ester boiling at 165–169° at 20 mm.; sp. gr. at 20°, 1.1098; n_{D}^{20} 1.5498.

Summary

The preparation and partial hydrolysis of benzoylacetoacetic ester to give benzoylacetic ester have been studied and optimum conditions worked out.

IDENTIFICATION OF AMINES.
V. DERIVATIVES OF TERTIARY AMINES

BY C. S. MARVEL, E. W. SCOTT AND K. L. AMSTUTZ

RECEIVED JULY 26, 1929 PUBLISHED DECEMBER 11, 1929

Solid derivatives of tertiary amines suitable for identification purposes are not always available. The methiodides, picrates, chloroplatinates, chloro-aurates and simpler salts such as the hydrochlorides, hydrobromides, etc., are at times useful but no one derivative is generally applicable to a wide number of amines. These derivatives have the common fault of melting with some decomposition and the temperature of decomposition is usually dependent on the rate of heating.

The most characteristic reaction of tertiary amines is the formation of quaternary ammonium compounds by addition to the nitrogen atom. It is generally true that the greater the proportion of the hydrocarbon part of the molecule in a quaternary ammonium salt, the more likely the compound is to have a sharp melting point. With this idea in mind, the addition of benzyl chloride, *p*-nitrobenzyl chloride and phenacyl chloride to a large number of tertiary amines was tried. The results were disappointing. Benzyl chloride reacted with four common amines to give new derivatives which were easily prepared and crystallized, but many products were too difficult to purify. *p*-Nitrobenzyl chloride was not at all satisfactory. Phenacyl chloride reacted with pyridine and α-picoline to give quaternary ammonium salts melting at 113 and 157°, respectively, but did not seem to show promise of general usefulness.

Several cases of the formation of quaternary ammonium compounds from tertiary amines and esters of arylsulfonic acids have been reported. A patent[1] describes the addition products of several quinoline derivatives with methyl and ethyl *p*-toluenesulfonates, and ethyl p-bromotoluenesulfonates. The melting points of these derivatives were reported as follows: 1-ethyl-2-methylquinolinium p-toluenesulfonate, 105°; 1-ethyl-2,6-dimethylquinolinium p-toluenesulfonate, 120°; 1,2-dimethylquinolinium *p*-toluenesulfonate, 134'; 1-ethyl-2-methylquinolinium p-bromotoluenesulfonate, 142°. More recently Simon and Frerejacques[2] observed that the methyl esters of several complex arylsulfonic acids combined with hexamethylenetetramine and some other complex tertiary amines to give products with sharp melting points. Rodionow[3] has described trimethylphenylammonium benzenesulfonate, m. p. 180–181°; dimethylethylphenylammonium p-toluenesulfonate, m. p. 48-49 °; trimethylphenylammonium p-toluenesulfonate, m. p. 160–161°, and the methyl *p*-toluenesulfonate derivatives of several alkaloids.

The properties of these addition products suggested that methyl p-toluenesulfonate might prove to be a general reagent for use in identifying tertiary amines. A number of compounds of this type have been prepared and characterized. The reagent was found to be particularly useful with ring nitrogen compounds. Practically all of the pyridine and quinoline derivatives which were prepared, were well suited for identification purposes. However, it is less useful for the other types of amines studied as too many derivatives failed to crystallize.

Other experiments were made in the use of methyl *p*-bromobenzenesulfonate and methyl methanesulfonate. Each of these reagents gave some crystalline derivatives but none was useful where the methyl *p*-toluenesulfonate was unavailable,

Experimental Part

The addition compounds which are described in the tables were all prepared by mixing 1 g. of the amine and 2 to 3 g. of the reagent (benzyl

chloride, methyl p-toluenesulfonate, methyl *p*-bromobenzenesulfonate or methyl methanesulfonate) in 10 cc. of dry benzene. The mixture was heated to boiling for about thirty minutes, cooled and filtered. The product was recrystallized by dissolving in the least amount of boiling ethyl alcohol and adding ethyl acetate until the material began to precipitate. The melting points given in the table were taken on compounds which had been purified to constant melting point.

Dimethylaniline	*p*-Bromobenzene	218–220	8.60	8.23
Dimethylaniline	Methane	192° (dec.)	13.85	14.00

[a] This melting point is higher than that recorded in the patent literature **(Ref. 1)**. [b] This product seemed to soften somewhat at 95°. [c] Ref. 3. [d] The amount available was not great enough to permit crystallization to constant melting point.

Methyl p-toluenesulfonate gave oily products with the following amines: diethylaniline, di-n-propylaniline, di-isopropylaniline, ethylbenzylaniline, diethylallylamine, di-n-butylallylamine and nicotine.

Summary

1. Benzyl chloride, p-nitrobenzyl chloride, phenacyl chloride, methyl p-toluenesulfonate, methyl p-bromobenzenesulfonate and methyl methanesulfonate have been investigated as reagents for use in the preparation of derivatives for the identification of common tertiary amines.

2. Methyl p-toluenesulfonate has been found to be a fairly general reagent and to be particularly useful in the case of ring nitrogen compounds.

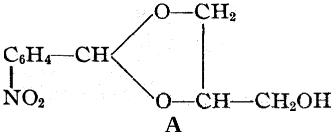
STUDIES ON REACTIONS RELATING TO CARBOHYDRATES AND POLYSACCHARIDES. XXIV. RING MIGRATION IN THE GLYCEROL CYCLIC ACETALS. BEHAVIOR OF PARA-NITROBENZYLIDENE GLYCEROL[1]

BY HAROLD HIBBERT, MURIEL E. PLATT AND NEAL M. CARTER

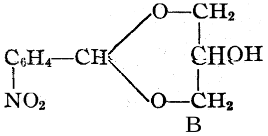
RECEIVED JULY 27, 1929 PUBLISHED DECEMBER 11, 1929

The close structural relationships existing between cyclic acetals on the one hand and carbohydrates, anhydro sugars and polysaccharides on the other has been emphasized frequently in this series of communications.[2] The present investigation deals with the interconversion of the 5- and 6-membered p-nitrobenzylidene glycerols



A

and



B

It has been found, in accordance with previous work carried out on the benzylidene and methylidene glycerols,[3,4] that in the presence of a trace of dry hydrochloric acid gas the six-membered derivative (B) is readily converted into an equilibrium mixture of the five- and six-membered isomers. By carrying out the reaction at 100° for one and a half hours, an equilibrium is apparently reached in which the proportion of 6:5-membered acetals is represented by 1:2.

In a second series of experiments, carried out by heating the crystalline six-membered acetal (B) with dilute hydrochloric acid ($N/10$) in a sealed tube at 100° for varying lengths of time, it was found that after about an hour an equilibrium mixture was obtained in which the six- and five-membered rings were present in the ratio of 0.37:1. In this series of experiments certain discrepancies came to light in that, for example, discordant results were obtained if the crystalline 6-membered acetal recovered

---

[4] Hibbert and Carter, *ibid.*, 50,3120 (1928).

from one equilibrium experiment was used, without complete purification, for the following one. The explanation of this is probably to be found in the fact that the *p*-nitrobenzylidene glycerols exist in cis and trans forms. It was also found that while equilibrium was established after approximately a one-hour period, that this was far from being realized when the time interval fell slightly below sixty minutes. Using, however, the same pure, crystalline, p-nitrobenzylidene six-membered isomer (m. p. 93.5°) for each experiment, values were found as represented graphically on the accompanying curve.

The results obtained indicate the pronounced tendency of each of the two rings to pass over into an equilibrium mixture in presence of acid, and serve not only as a further illustration of "Michael's Partition Principle," but also for the necessity of avoiding acid media when conducting experiments designed to throw light on the structure of glycerol acetals, and by analogy, on carbohydrates, anhydro sugars and polysaccharides.

Experimental

Preparation of **1,3-*p*-Nitrobenzylidene** Glycerol (2-p-Nitrophenyl-5-m-dioxanol).—The procedure adopted for the preparation of this compound was that developed by Hibbert and Carter.[5] A mixture of 50 g. of p-nitrobenzaldehyde, 33.1 g. of glycerol (3% excess over the theoretical amount) and three drops of 40% sulfuric acid as catalyst gave 29.3 g. of the 1,3-*p*-nitrobenzylidene glycerol melting at 93°; yield, 58 8%.

Interconversion of the 5- and 6-Membered Rings by the Action of Dry Hydrogen Chloride.—Two-gram samples of freshly recrystallized 1,3-*p*-nitrobenzylidene glycerol were mixed with 0.01% of their weight of dry hydrogen chloride in sealed tubes and allowed to stand for one and a half hours at 100° The product, in each case, was then cooled to room temperature, diluted with 20 cc. of benzene and the acid neutralized with fused pstassium carbonate. The solvent was removed under reduced pressure. The weight of the mixture of 1,3- and 1,2-acetals recovered was 1.2 g. The mixture was taken up in benzene and allowed to crystallize at 0° in order to isolate the 6-membered isomer. The weight of the crystalline unchanged 1,3-material was 0.4 g. The ratio of 6- to 5-membered acetal thus obtained is approximately 1:2. The low yields are presumably due to ring scission and formation of p-nitrobenzaldehyde and glycerol, as shown later in the experiment with $N/10$ hydrochloric acid.

Interconversion of the 5- and 6-Membered Cyclic Acetal Rings by Very Dilute Hydrochloric Acid.—Five-gram samples of 1,3-*p*-nitrobenzylidene glycerol, to which had been added 0.4 g of $N/10$ hydrochloric acid (thus introducing the theoretical quantity of water necessary for hydrolysis of the sample) were shaken vigorously and continuously in sealed ampules at 100° for varying lengths of time. This was carried out as follows. The crystalline isomer was melted before the acid was added, the ampule sealed and then placed in the shaking apparatus. At the expiration of the given time interval, the ampule was immediately plunged into a cooling bath (—12") to prevent further reaction. Those samples which had been heated for periods of fifteen and thirty minutes, respectively, solidified on cooling, while those heated for a longer period of time yielded a very viscous oil, thus indicating a partial conversion to the liquid isomer. The contents in each case were dissolved in 250 cc. of benzene, the trace of acid present was neutralized by shaking with 1 cc. of a dilute solution of potassium

---

[5] Hibbert and Carter, THIS JOURNAL, **50**, 3376 (1928).

bicarbonate, the benzene solution cooled to 10° (to prevent any change in the equilibrium) and then shaken with a cold saturated solution of sodium bisulfite to remove the *p*-nitrobenzaldehyde. The formation of an addition product indicated that some of the latter had been formed during the reaction. The free glycerol, which is insoluble in benzene, remained in the mother liquor. After drying the benzene solution over solid potassium carbonate, the solvent was removed under diminished pressure and the total amount of the 5- and 6-membered acetals determined.

The separation of the two isomers was carried out by dissolving the product in 25 cc. of warm benzene and cooling the solution for two hours at −12°. The frozen mixture was allowed to stand at room temperature for half an hour, the crystals of the 6-membered acetal filtered off at room temperature, dried and weighed. The weight of the 5-membered acetal formed was determined by difference and the ratio of 6- to 5-membered acetal calculated. The solubility of the 6-membered acetal in benzene at 22° is slight, namely, one part in one hundred and fifty.

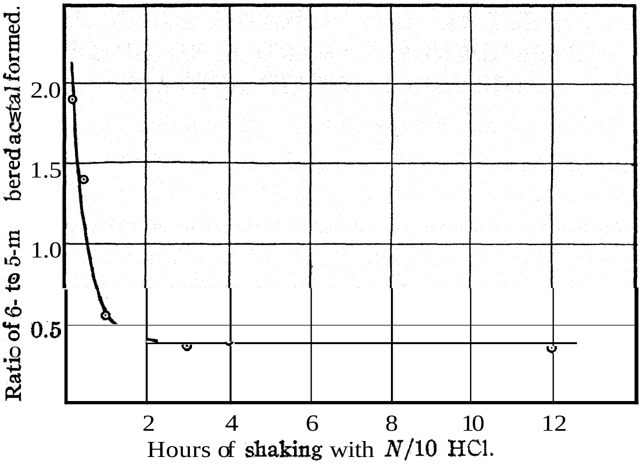

Fig. 1.

The results of the experiments are given in Table I and shown graphically on the accompanying curve (Fig. 1).

Table I

5-Membered acetal, g.	1.15	1.3	2.3	2.4	2.45	2.6	2.3
Equil. ratio, 6:5 rings	1.9:1	1.4:1	0.56:1	0.37:1	0.38:1	0.38:1	0.35:1

Summary

1. The six-membered cyclic acetal, *p*-nitrobenzylidene glycerol, is converted, in the presence of dry hydrochloric acid gas at 100°, into an equilibrium mixture of itself with the five-membered isomer, the ratio of the former to the latter being 1:2.

2. Under similar conditions but using dilute hydrochloric acid at 100°, an equilibrium is obtained after about one hour in which the ratio of six- to five-membered acetal is 0.37:1.

3. The results indicate the ease of transformation of oxygen rings in cyclic acetals and, by analogy, point to similar conditions in the case of furanose and pyranose rings in carbohydrates, anhydro sugars and polysaccharides.

STUDIES OF REACTIONS RELATING TO CARBOHYDRATES AND POLYSACCHARIDES. XXV. METHYLATION PROCESSES AND TENDENCY TOWARD RING SHIFT IN GLYCEROL CYCLIC ACETALS

BY HAROLD HIBBERT, MURIEL E. PLATT[1] AND NEAL M. CARTER

RECEIVED JULY 27, 1929 PUBLISHED DECEMBER 11, 1929

In the methylation of sugars and their derivatives two methods have been employed: (1) the use of silver oxide and methyl iodide, as first originated by Purdie and developed with so much success by Irvine,[2] and (2) the use of dimethyl sulfate and sodium hydroxide, developed by Denham and Woodhouse[3] in the methylation of cellulose, and later applied by Haworth[4] in the methylation of sugars.

The silver oxide method has had a very wide application, the reaction being carried out in neutral solvents. Thus methylated aldosides, obtained by treating glucosides dissolved in methyl alcohol, with methyl iodide and dry silver oxide yielded on hydrolysis the methyl ethers of the respective aldoses.

It has been established that under these mild experimental conditions profound changes, such as racemization, the Walden Inversion or the interconversion of glucosides (α- and β-forms) do not occur. On the other hand, conclusive evidence, to some extent, is lacking as to the total absence of (a) the migration of a methyl group and (b) ring scission and ring migration.

The employment of the expensive alkyl iodides and silver oxide, as well as the necessity for finding a suitable solvent for the carbohydrate in the initial stages of the reaction, prevented a wide and general application of

the process, and restricted the further study of the alkylated disaccharides. Haworth, therefore, applied the dimethyl sulfate method, which Denham and Woodhouse had used with cellulose, to the sugars with satisfactory results. Inasmuch as Haworth states,[5] "There are eight available hydroxyl groups in a dihexose. These may be protected by simple methylation with methyl sulfate and dilute alkali, but the conditions must be so chosen that when the disaccharide is sensitive to acids, as is sucrose, the alkali should always be present in excess. On the other hand, since other disaccharides are adversely affected by alkali, it is necessary to ensure, particularly during the earlier stages of the methylation process, that alkalinity does not develop. These conditions can be controlled by maintaining an excess of methyl sulfate during the addition of dilute alkali solution," . . . it is evident that he assumes no ring scission or ring shift (for example, a furanose into a pyranose derivative) in the presence of an acid medium. The various researches carried out by Hibbert and co-workers on cyclic acetal formation indicate clearly, however, the very labile character of such rings and the remarkable ease with which one is transformed into the other in the presence of a trace of acid. It is, therefore, of considerable interest to ascertain whether in the case of a cyclic acetal characterized by ease of ring scission and ring migration, such changes occur during the process of methylation by means of dimethyl sulfate under varying conditions of acidity and alkalinity.

It is now known that in the condensation of acetone with glucose in the presence of a small amount of hydrochloric acid, a ring shift actually occurs[6] and, since benzylidene glycerol is very similar to an acetone sugar with regard to its ease of hydrolysis in acid media, series of methylation experiments on crystalline 1,3-benzylidene glycerol, using dimethyl sulfate and alkali as the methylating agent, were undertaken with a view of determining: (a) the yield of crystalline 1,3-benzylidene-glycerol-2-methyl ether and (b) the possibility of ring shift with consequent formation of the *liquid*, isomeric 1,2-benzylidene-glycerol-3-methyl ether.

The structure of both of these ethers has been definitely determined.[7] The methylation of the 1,3-derivative was carried out under two sets of conditions: (a) in a reaction mixture containing at the start an excess of dimethyl sulfate, that is, in an acid medium, and (b) in a reaction mixture which was kept distinctly alkaline at all stages.

Reaction in Acid Medium.—The only product obtained when an excess of dimethyl sulfate was used was a small amount of benzaldehyde formed by hydrolysis of the 1,3-benzylidene glycerol by the dimethyl sulfate.

Reaction in Alkaline Medium.—Under these conditions 1,3-benzylidene-

[7] Hibbert and Carter, THIS JOURNAL, 50, 3376 (1928).

glycerol-2-methyl ether and unchanged original product were obtained when the methylation was carried out in the presence of alkali at 30°, but no 1,2-benzylidene-3-methyl ether could be detected.

At lower temperatures small amounts of unchanged original product only were recovered.

A distinct odor of benzaldehyde was noticed in all the reaction mixtures, indicating that the sensitive acetal ring undergoes hydrolysis even under these conditions; this is probably the reason for the low yields of total recoverable crystalline products. Some of the benzaldehyde may also have been oxidized to benzoic acid, which would have been retained as the sodium salt, although none of the acid was obtained on neutralization and extraction of the aqueous reaction mixture. An attempt to isolate the *liquid* 1,2-benzylidene glycerol isomer (formed by ring shift of the 1,3-isomer) from the mother liquor, obtained after removal of the crystalline 6-membered form, through the formation of its *p*-nitrobenzoate,[8] was unsuccessful, no evidence being obtained of its formation in the methylation process.

The results of these experiments would seem to indicate that, with an alkali-insoluble acetal such as 1,3-benzylidene glycerol, methylation does not take place readily, but that no ring shift occurs under alkaline conditions. However, extensive hydrolysis to glycerol and benzaldehyde readily occurs in both acid and alkaline media.

Experimental

Preparation of 1,3-Benzylidene Glycerol.—Benzylidene glycerol was prepared from benzaldehyde and glycerol by the method previously described.[7] One hundred thirty-eight grams of benzaldehyde, 131 g. of glycerol and six drops of concentrated hydrochloric acid yielded 145 g. of a mixture of isomeric benzylidene glycerols. The 1,3-isomer isolated had a melting point of 80°.

Methylation of 1,3-Benzylidene Glycerol with Dimethyl Sulfate Solution.—To 14 g. of freshly recrystallized 1,3-benzylidene glycerol, dissolved in 62.5 g. (five times the theoretical amount) of dimethyl sulfate at 0°, 90 cc. of a 40% sodium hydroxide solution (five times the theoretical amount) was added slowly through a buret. After five hours of constant stirring at 0°, two layers separated, after which the mixture was stirred for two hours at room temperature. The aqueous layer which separated out was strongly alkaline. The mixture was extracted with ether, the ether extract separated from the aqueous layer and the latter then extracted several times. The combined ether extracts were dried over fused potassium carbonate and the ether distilled off. The residue on fractionation yielded 3 cc. of benzaldehyde. No crystals could be obtained from the residue when it was taken up in benzene–petroleum ether (2:1), this being the method usually employed for the separation of these isomers.

Methylation of 1,3-Benzylidene Glycerol with Dimethyl Sulfate in Alkaline Solution. Methylation at 0°.—To 13.9 g. of the freshly recrystallized 6-membered acetal dissolved in 20 cc. of methyl alcohol and cooled to 0°, 90 cc. of a 40% sodium hydroxide solution (a little more than five times the theoretical amount) and 62.5 g. of dimethyl

---

[8] Hibbert and Carter, THIS JOURNAL, 50, 3120 (1928).

sulfate (five times the theoretical amount) were added slowly from different burets, using phenolphthalein as an indicator, in order to be certain that the mixture remained slightly alkaline A precipitate which was present from the start proved to be sodium sulfate, which was insoluble in the aqueous alcoholic solution. After stirring for four hours at 0°, the product was filtered, the filtrate extracted with ether and the extract dried over potassium carbonate. On evaporation of the solution to about 15 cc. and cooling, crystals separated out. The product was taken up in benzene–petroleum ether (2:1) and cooled. Two grams of crystals (14.5% of original) was separated with a melting point of 80°, that is, the melting point of the original acetal.

Methylation at 30°.—The above experiment was repeated at 30° using 49 g. of the 1,3-acetal, 160 g. of sodium hydroxide (in 40% solution) and 175 g. of dimethyl sulfate. After stirring for four hours, a stream of carbon dioxide was bubbled through the mixture for two hours in order to change any sodium derivative of the unchanged acetal which might have been formed during the reaction back to the ether-soluble free acetal. The product was then extracted with ether and the ether removed under reduced pressure. The residue was taken up in a mixture of benzene and petroleum ether in the proportion of 2:1 and the following crops of crystals were obtained as the result of an exhaustive fractional crystallization of the solution: (1) unchanged 1,3-benzylidene glycerol (m. p. 83°), yield 2 g.; (2) unchanged 1,3-benzylidene glycerol (m. p. 80°), yield 2 g.; (3) 1,3-benzylidene-glycerol-2-methyl ether,? (m. p. 51°), yield 9 g.; (4) unchanged 1,3-benzylidene glycerol (m. p. 78°), yield 0.5 g.; (5) a residual oil, weight 4.5 g. The residual oil was investigated for the presence of the isomeric 1,2-benzylidene glycerol and of its methyl ether, but with negative results. The original 1,3-benzylidene glycerol apparently undergoes extensive hydrolysis to glycerol and benzaldehyde under these conditions.

p-**Nitrobenzoylation** of the Oil Obtained in the Previous Experiment.—Four and one-half grams of Fraction V (the above residual oil) was added with shaking to 4.5 g. of p-nitrobenzoyl chloride dissolved in 19.8 g. of pyridine. After standing overnight at 20°, the mixture was poured into 400 cc. of water, the precipitate which formed filtered off and dissolved in benzene–petroleum ether (2:1). The crystals which separated on cooling were recrystallized from ethyl acetate and then had a melting point of 153–154° (melting point of 1,3-benzylidene glycerol-2-p-nitrobenzoate, 156°).[7] Four successive crops of crystals were obtained from the mother liquor, all having a melting point of 153–154°. Ligroin (30–50°) was then added to the mother liquor until the solution became murky. On cooling a last crop of crystals was obtained with a melting point of 152°. 1,2-Benzylidene-glycerol-3-*p*-nitrobenzoate, which would have been present had ring shift occurred during methylation, melts at 91°.[7] There was thus no evidence of any ring change.[9]

---

[9] The evidence submitted in this and the preceding paper renders it highly improbable that any "ring shift" or "wandering of a methyl group" occurs during the methylation of glucosides, anhydro sugars and polysaccharides, except in the isolated cases where the product in question undergoes ready hydrolysis by water, thus involving ring scission.

On the other hand, abnormal results are to be expected in the methylation of the free sugars in alkaline solution, since in these cases (that is, where a free carbonyl group is present) there is the possibility of a "Lobry de Bruyn–van Ekenstein transformation" involving conversion of the sugar into an equilibrium mixture of different carbohydrates or polyoses.

That other deep-seated changes are involved is indicated by the decrease in the rotation of a 0.25 M glucose solution to practically zero, in twelve hours, under the influence of 0.85 N potassium hydroxide [J. Groot, *Biochem.* Z., 146, 72 (1924)].

The low yield of β-methyl glucoside when prepared by the action of dimethyl

Summary

1. Methylation of 1,3-benzylidene glycerol, using dimethyl sulfate and sodium hydroxide under acid and alkaline conditions, has been described.

2. Attention has been drawn to the difficulty of methylating the 1,3-benzylidene glycerol under non-alkaline conditions. In the presence of an excess of dimethyl sulfate (that is, in an acid medium), 1,3-benzylidene glycerol undergoes ring scission into benzaldehyde and glycerol. It was not found possible to isolate any monomethyl ether of either the five- or the six-membered ring isomers.

3. Under alkaline conditions methylation takes place more readily, with formation of the corresponding methyl ether. The methylation is not accompanied by ring migration, as is evidenced by the absence of any 1,2-benzylidene-glycerol-3-methylether, although extensive hydrolysis occurs.

4. The necessity for great care in drawing conclusions from methylation experiments carried out on cyclic acetals, carbohydrates and polysaccharides in acid media is pointed out.

sulfate and sodium hydroxide on glucose [Maquenne, *Bull. soc. chim.*, [3] 33, 260, 469 (1925); Schlubach and Maurer, *Ber.*, 57, 1686 (1924)] would also seem to indicate the existence of other reactions in an alkaline medium.

For these reasons there would seem to be some doubt as to the presence of a new "active or gamma-sugar" formed under the conditions indicated in the recent paper of Whitnah [THIS JOURNAL, 51, 3490 (1929)].

It is, however, to be expected that the nature of the glucoside formed in *neutral* and very *slightly* acid solutions of carbohydrates such as glucose, will vary markedly both with regard to the number and type of ring isomers formed, in accordance with the PH value of the medium used. This has been pointed out repeatedly by the senior author in the last few years and is now found to be the case experimentally. The results are to be published in the near future and the reservation of this field (glucoside formation in neutral and faintly acid media) in view of long years of previous preparation is courteously requested for a short period. PREPARATION, PROPERTIES AND REACTIONS OF LEAD MERCAPTIDES[1]

P. BORGSTROM,[2] L. M. ELLIS, JR.,[3] AND E. EMMET REID[4]

RECEIVED JULY 29, 1929 PUBLISHED DECEMBER 11, 1929

Lead mercaptides have been known for a long time and have been used primarily for the removal of mercaptans from solution or in synthetic work for the introduction of the mercapto group. In the last few years the petroleum industry has also become interested in the properties of the lead mercaptides in connection with the "sweetening" of petroleum by the use of sodium plumbite.[5] In studying the properties of these mercaptides, there is a lack of information on the purity and solubility. In this paper certain lead mercaptides will be discussed as to methods of preparation, their analyses, solubility and some reactions.

TABLE I

PREPARATION AND ANALYSES OF LEAD MERCAPTIDES

Mercaptan	Percentage of lead Calculated	Found	Preparation
Ethyl	62.92	62.84, 62.89	Recrystd. from EtOH
n-Propyl	58.02	57.66, 58.41	Washed thoroughly, vacuum dried
Isopropyl	58.02	57.99, 57.98	Washed thoroughly, vacuum dried
n-Butyl	53.79	53.41, 53.35, 53.36	Recrystd. from *n*-BuOH or EtOH
Isobutyl	53.79	54.03, 54.26	Recrystd. from EtOH
Iso-amyl	50.10	50.13, 50.42	Recrystd. from MeOH
Benzyl	45.72	45.55, 45.55	Washed and vacuum dried
Thiophenol	48.70	48.72, 48.96	Washed and vacuum dried
y-Hydroxypropyl	53.21	53.13, 53.15	Recrystd. from 50% EtOH

Experimental

Preparation of Lead Mercaptides.—The desired mercaptan dissolved in 6 to 10 parts of ethyl alcohol was added to a warm 50% alcoholic solution of $M/4$ lead acetate until a cloudiness appeared. It was then heated to boiling (more alcohol added if necessary to obtain a clear solution), allowed to cool and crystallize. The crystals were washed several times by decantation, then thoroughly on the filter and finally dried in a vacuum desiccator. Whether it is desirable to recrystallize is questionable, for the analyses given in Table I of different mercaptides show no improvement in purity for the recrystallized samples. Recrystallization may even be detrimental, for unrecrys-

tallized n-propyl, isopropyl and thiophenol mercaptides were more stable than iso-amyl, benzyl arid γ-hydroxypropyl which were recrystallized. If, in preparation of the mercaptides, the concentration of lead acetate and mercaptan was too great, the lead mercaptide often separated as an oil which solidified on cooling. This occurred with n-butyl and iso-amyl. n-Butyl mercaptide can be recrystallized from n-butyl alcohol as well as ethyl alcohol, but if the oil or crystals became slightly superheated, immediate darkening occurred and decomposition began. This happened with the n-butyl readily. *Iso*-amyl mercaptan in oily form was slightly soluble in acetone, n-butyl alcohol, ethyl alcohol and methyl alcohol. It was finally recrystallized from methyl alcohol, which was a slow process due to low solubilities. The lower mercaptides, that is, ethyl, n-propyl and isopropyl separated very readily in the crystalline form when prepared and therefore were analyzed as prepared.

To obtain lead mercaptides that have a constant melting point on recrystallization was impossible. On recrystallizing there probably is a slight decomposition due to reaction with the alcohol and this slight impurity may be the cause of the indefinite values found. For instance, one sample of ethyl lead mercaptide recrystallized from *95%* ethyl alcohol coalesced at 119° and blackened at 124° and on an attempted second recrystallization had undergone decomposition and did not melt up to 170°. *A* second sample of this coalesced at 104°, and pronounced change occurred at 110° turning deep red. Another sample dried in *vacuo* for twenty-four hours darkened at 110–112°.[6] With n-propyl lead mercaptide the usual temperature at which a first change appeared was 89–90° when softening occurred; it melted at about *9496";* but even this was not at all satisfactory. Isobutyl mercaptide changed to a wax-like substance at *66°* and melted at *71°*. On recrystallization it became wax-like at *60–61"* and was not completely molten at 130°. Benzyl mercaptide began to coalesce at 98° and decomposed without melting at *100–101°*.

An attempt was made to determine qualitatively the solubility of the lead mercaptides after they had been once recrystallized, washed and thoroughly dried in a vacuum desiccator. Ethyl mercaptide recrystallized from ethyl alcohol and n-butyl mercaptides recrystallized from n-butyl alcohol were used as samples with carbon tetrachloride; both turned dark within twenty-four hours. With acetone (C. P.) the mercaptide became white. With ethyl alcohol there was a change similar to that with acetone but not as marked. With n-butyl alcohol there was some solubility, for when the solutions were heated to 50° and then cooled again crystals of the yellow mercaptide separated. This was especially true for n-butyl lead mercaptide. With a carefully purified low-boiling hydrocarbon there was practically no solubility, as the naphtha was colorless and on evaporating *25* cc. no stain was found in the beaker. There was no visible decomposition in the same time in which decomposition appeared with carbon tetrachloride. Using C. P. benzene freshly distilled from sodium there was no visible decomposition.

Reactions.—To *C.P.* benzene freshly distilled from metallic sodium, and the recrystallized mercaptides, in *50-cc.* sample bottles, small amounts of C. p. sulfur (powdered) were added. With ethyl mercaptide there was an immediate darkening, sometimes first brown and then to black. With benzyl and n-amyl there was the same darkening. With n-butyl it became red first and then dark. The reaction was very rapid. Using the same benzene and mercaptides and adding some of this same benzene saturated with dry hydrogen sulfide there appeared immediately a brown to black color with ethyl, n-amyl and benzyl. With n-butyl a reddish color first appeared at first, which then changed to brown and finally black. This color play has been noted with the "doctor"

---

[6] R. Otto, *Ber.*, 13, 1290 (1880), gives the melting point for lead ethyl mercaptide as 150°.

solution and naphthas using sodium plumbite and sulfur.[7] Whether the color play in both cases is due to the same original compound is not proved by these experiments.

An attempt was made to use the titration with iodine in benzene represented by the equation $Pb(SR)_2 + I_2 \longrightarrow PbI_2 + (SR)_2$ as an analytical method, but this was not very successful. The reaction was rapid at first, slow after half of the iodine had been absorbed, and toward the end very slow. The benzene used was freshly distilled from sodium. The lead iodide formed was filtered into a Gooch crucible, washed, dried and weighed. The results are given in Table II.

TABLE II

RESULTS OF ANALYSES

		Mg. of iodine			PbI_2		
$Pb(SR)_2$	G.	Calcd.	Abs.	%	Calcd.	G.	%
Ethyl	0.3664	282.4	272.2	96.39	0.5129	0.5058	98.61
n-Amyl	.2558	157.1	154.5	98.34	.2854	.2750	96.36
Benzyl	.3788	212.1	178.5	84.16	.3853	.3500	90.83

Summary

Lead mercaptides have been prepared and analyzed and some of their properties noted.

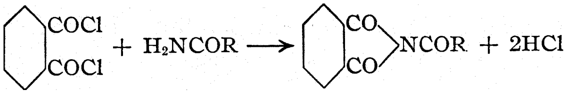
THE REACTION OF PHTHALYL CHLORIDE WITH AMIDES

BY THEODORE W. EVANS AND WILLIAM M. DEHN

RECEIVED JULY 29, 1929 PUBLISHED DECEMBER 11, 1929

Acetylphthalimide[1] and benzoylphthalimide[2] are the only examples of substitution of the imino hydrogen of phthalimide by acid radicals. The acetyl derivative was prepared by the action of acetic anhydride on phthalimide, also by dehydration of acetylphthalamic acid; the benzoyl derivative was prepared by the action of benzoyl chloride on phthalimide in pyridine solution, also by dehydration of benzoylphthalamic acid.

Because compounds of this type were required in another study, we have investigated different methods for their preparation, and have found that phthalyl chloride reacts normally with amides



giving good yields[3] which were free from other products, especially such as

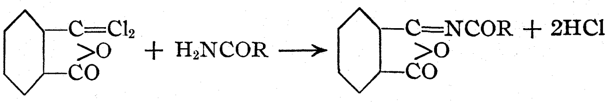
[1] Aschan, *Ber.*, **19**, 1400 (1885).

[2] Titherley and Hicks, *J. Chem. Soc.*, **89**, 708 (1906). For a general discussion of methods of acylation of amides, see Titherley, *ibid.*, **85**, 1679 (1904).

[3] Titherly concluded that the action of an acyl chloride on amides is "a poor method, applicable only to the primary amides of the aliphatic series."

might be expected if the isomeric form of phthalyl chloride reacts in accordance with the equation



When equivalents of the phthalyl chloride and the amide were heated, either without a solvent or in toluene until no more hydrogen chloride was evolved, the products could be purified by one crystallization. This method was invariably successful but other methods failed.

For example, p-tolylsulfonylphthalimide was easily prepared by this method, but could not be prepared by any of the following methods: heating phthalic anhydride and p-toluenesulfonamide, heating potassium phthalimide with p-toluenesulfonyl chloride or heating phthalimide with p-toluenesulfonyl chloride in pyridine. Also, heating benzenesulfonamide and phthalic acid to 230° failed to give benzenesulfonylphthalimide, easily obtainable from phthalyl chloride and benzenesulfonamide.

PARA-BROMOPHENYL-4-SEMICARBAZIDE[1]

BY ALVIN S. WHEELER

RECEIVED AUGUST 3, 1929 PUBLISHED DECEMBER 11, 1929

This paper is a continuation of studies[2] in this Laboratory on semi. carbazides as ketone reagents. *p*-Bromophenylurea, from which the semicarbazide was prepared, has not been satisfactorily characterized. We prepared it by three different methods: **(1)** by the action of bromine on phenylurea in glacial acetic acid solution;[3] (2) by the action of bromine on an alcoholic solution of phenylurea; **(3)** by the action of potassium cyanate on p-bromo-aniline hydrochloride in hot water solution. Each method has its advantages. The impure product behaved so erratically on heating that much time was lost in arriving at a pure product. If heated rapidly, it melts; if slowly, it does not melt, In either case it decomposes at an elevated temperature. The statement of Pinnow that it decomposes at about 260° evidently is incorrect.

The semicarbazide was prepared according to the method of Curtius[4] and Burkhardt, who prepared phenylsemicarbazide. p-Bromophenylurea was heated for fifty hours with an excess of hydrazine hydrate. The pure product melts at **252** and at 254° decomposes to a claret-colored liquid.

Semicarbazones were obtained by treating alcoholic solutions of the semicarbazide with the following ketones: acetone, methyl ethyl ketone monochloro-acetone, *α*,y-dichloro-acetone, acetophenone and benzophenone.

Experimental

p-Bromophenylurea, $C_6H_4BrNHCONH_2$.—This compound was first made by Pinnow.[3] He treated a glacial acetic acid solution of phenylurea with bromine. Two of the workers in this research (Pritchard and Andrews) preferred an alcoholic solution, while the others preferred a very different method, *i. e.*, the action of potassium cyanate on *p*-bromo-aniline hydrochloride in hot water. The product may be purified by hot water (soluble in 200 parts); hot alcohol (soluble in 7 parts); glacial acetic acid (soluble in 5 parts) or from benzene If alcohol or acetic acid is used, the solution is poured into cold water. It crystallizes in long colorless needles which behave peculiarly on heating. If the rate of heating is 50° per minute or faster, the substance melts at 220°, resolidifies about 225° and decomposes at about 296" to a black rubber-like substance. When heated slowly no apparent change occurs until decomposition takes place at 296°. Pinnow states that decomposition without melting occurs at 260°.

[3] Pinnow, Ber., 24, 4172 (1891).

[4] Curtius and Burkhardt, J. prakt. *Chem.*, 58,205 (1898).

We have never observed any such behavior of the many preparations which we have made.

Anal. Calcd. for $C_7H_7ON_2Br$: Br, 37.20. Found: (Paul R. Bryan) 37.23; (W. N. Pritchard, Jr.) 37.37.

p-Bromophenyl-4-semicarbazide, $C_6H_4BrNHCONHNH_2$.—The semicarbazide was prepared by boiling an absolute alcoholic solution of bromophenylurea with hydrazine hydrate. Many variations of proportions of materials were tried. The time of boiling was also varied. The best yield was obtained by J. G. Park: 5.4 g. of bromophenylurea, 30 cc. of absolute alcohol and 7.5 g. of 42% hydrazine hydrate (2.5 equivalents) were boiled under a reflux condenser for fifty hours. After determining that an excess of hydrazine hydrate was necessary, it was found that prolonging the time of heating increased the yield. A gradually diminishing undissolved portion remained for eighteen hours, complete solution then occurring. The product was finally poured into a beaker, evaporated to one-half of its original volume and cooled. Dense crystallization took place. Water was added to effect complete separation and the yield of the crude product was 4.8 g. It was purified by adding it to 20 cc. of alcohol and 20 cc. of concd. hydrochloric acid and boiling. It was then cooled and the precipitate filtered off. Any unchanged phenylmea was isolated by boiling the product with 200 cc. of water to extract the semicarbazide hydrochloride. The insoluble bromophenylurea was filtered off and the semicarbazide in the filtrate precipitated by adding caustic potash solution. One gram of bromophenylurea was recovered. Bromophenylsemicarbazide crystallizes in small needles from hot alcohol. It is insoluble in cold water and cold alcohol. It decomposes with effervescence at 254° to a claret-colored liquid.

Anal. Calcd. for $C_7H_8ON_3Br$: Br, 34.78. Found: (Pritchard) 35.12.

Semicarbazones

p-Bromophenyl-4-semicarbazone of Acetone, $C_6H_4BrNHCONHN(CH_3)_3$.—0.25 g. of the semicarbazide was dissolved in 15 cc. of hot alcohol and an excess of acetone added. The mixture was boiled for twelve hours. Upon cooling the solution very beautiful prismatic crystals separated. The crystals had three wide faces and three narrow ones and the ends formed pyramids.

The product melts sharply at 174° (corr.) to a colorless liquid. It is insoluble in cold water or cold alcohol but dissolves in hot alcohol.

Anal. Calcd. for $C_{10}H_{12}ON_3Br$: Br, 29.62. Found: (Pritchard) 29.40.

TABLE I

SEMICARBAZONES

	Ketone	Crystal form	M. P.,[a] °C.	Time of heating
1	Methyl ethyl ketone	Rect. plates	175	1 Hour
2	Chloro-acetone	Needles	182 dec.	5 Min.
3	α,γ-Dichloro-acetone	Needles	196 dec.	5 Min
4	Acetophenone	Bulky needles	218	5 Hours
5	Benzophenone	Bulky needles	205	10 Hours

[a] All temperatures are corrected except that for acetophenone.

	Formula	Bromine, % Calcd.	Bromine, % Found
1	$C_{11}H_{14}ON_3$	28.14	27.98
2	$C_{10}H_{11}ON_3ClBr$	26.24	25.90
3	$C_{10}H_{10}ON_3Cl_2Br$	23.58	23.68
4	$C_{15}H_{14}ON_3Br$	24.07	24.00
5	$C_{20}H_{16}ON_3Br$	20.28	20.15

This reaction was also carried out in the cold, using a vacuum to concentrate the solution.

Other semicarbazones are indicated in Table I. All were prepared by J. G. Park except No. 4, which was prepared by W. N. Pritchard, Jr. In all cases the reacting compounds were dissolved in alcohol and the products were recrystallized from alcohol.

Summary

The preparation of *p*-bromophenylurea by three methods is described and procedure is given for its conversion into *p*-bromophenyl-4-semicarbazide. The usefulness of the semicarbazide as a ketone reagent has been tested by the preparation of several semicarbazones.

IV. THE CHEMICAL EFFECTS OF ELECTRICAL DISCHARGE IN BUTANE. FRACTIONATION OF THE LIQUID PRODUCT[1]

BY S. C. LIND[2] AND GEORGE GLOCKLER[3]

RECEIVED AUGUST 5, 1929 PUBLISHED DECEMBER 11, 1929

Introduction

In a former paper[4] it was shown that butane, as well as other hydrocarbons, yields liquid condensates when subjected to the semi-corona electrical discharge. At the same time, however, it was found that solid condensation products are also formed on the inner walls of the discharge tubes. From previous experience it was known that this solid formation does not occur in an all-glass ozonizer, or at least that such action is very slow.

Since the *object of the present work was the production of a fairly large amount of liquid condensate from butane gas by electrical means and its fractional distillation,* it was decided to build an all-glass ozonizer apparatus consisting of twelve ozonizers connected in parallel as to gas flow and as to electrical wiring. This apparatus is shown in Fig. 1. It may be said at once that indeed the solid formation just mentioned was quite negligible and only near the upper ends of the ozonizers toward the close of the long experiment was there any solid product formed.

---

[1] This paper includes part of an investigation of "The Effect of Electrical Discharge upon Gaseous Hydrocarbons," Project No. 8 of American Petroleum Institute research. Financial assistance has been received from the research fund of the American Petroleum Institute, donated by the Universal Oil Products Company. This fund is administered by the Institute with the coöperation of the Central Petroleum Committee of the National Research Council.

[4] Lind and Glockler, THIS JOURNAL, 51, 2811–22 (1929).

Experimental Procedure

The ozonizers were supplied with about 20,000 volts from the secondary of a Thordarson transformer using a primary current of about 12 amperes and a primary voltage of about 110 volts. During the initial stages of the experiment the machine was kept in operation during the daytime only, in order to study its behavior. On account of the possibility of breakdowns and fires resulting therefrom it was necessary to watch the apparatus and when the run was finally made continuous during the twenty-four hours of a day it was necessary to have a watch maintained at all times. The apparatus was run for 659.2 hours at a gas flow of 3.46 liters of butane (25°, 1 atm.) per hour. There were then used 5420 g. of butane which yielded 1041 cc. of liquid condensate weighing 832.8 g., having a density of 0.804. These figures show that 15.37% by weight of the butane used was converted into liquid condensate. The temperature of the apparatus was about 50° due to the electrical energy consumed (356 k. w. h.), since the twelve ozonizers were protected by asbestos boards (not shown in Fig. 1). This higher temperature was found to aid the run-off of the liquid condensate as previously noted.[5] The performance of the apparatus was followed by noting daily the amount, color and index of refraction of the liquid product. Its average index of refraction was 1.4600 and its average molecular weight in benzene by the freezing-point method was found to be 178. The color on the arbitrary scale of the Union Oil Co. colorimeter was about 2.75 scale readings. The exit gases have not been analyzed since the primary interest in this present research was concerned with the production and fractionation of the liquid condensate.

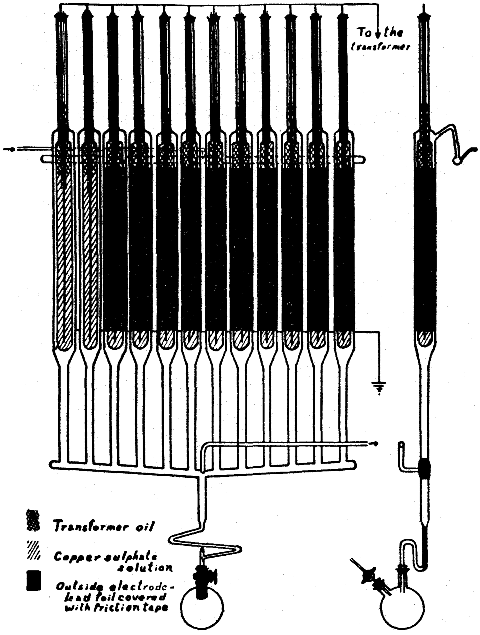

Fig. 1.—Twelve ozonizer tubes in parallel.

Fractionation of the Liquid Condensate.—In order to carry out the fractional distillation of the liquid hydrocarbons obtained from butane, a small chain-still[6] was built having an 18-inch column filled with iron chain (about $^1/_8$-inch link). With this still the liter of liquid product was distilled at low pressure (using liquid–air traps to avoid loss) and was separated into three main fractions, as shown in Table I.

The Middle Fraction 11.—The fractions noted in Table I are still complex mixtures of liquid hydrocarbons and they were in turn subjected

[5] Lind and Glockler, THIS JOURNAL, 50, 1767 (1928).

This still was built after a drawing obtained from Dr. E. W. Washburn, Bureau of Standards, Washington, D. C. We wish to thank Dr. Washburn for much valuable information regarding distillation problems which was obtained from him during a visit at the Bureau.

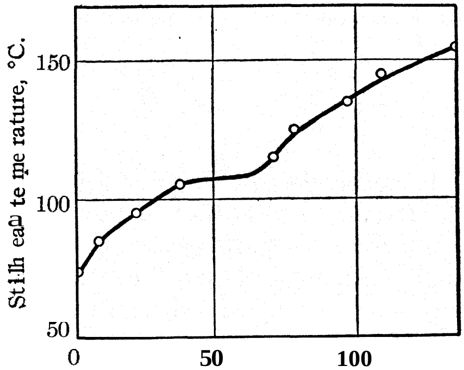
TABLE I

EXPERIMENTAL DATA

No	Fraction	Vol., cc.	Density	Wt. g.	B. p., range °C.	B. p., range mm.	Index of refraction
I	Light (liq.-air trap)	450	0.740	335	0–160	740	1.3713–1.4334
II	Middle (cond. at room temp.)	117	.795	93	78–112	5	1.4386–1.4558
III	Heavy (rem. as residue)	465	.872	405	230	10^{-4}	1.4855
		1032	0.804	833			

to further fractional distillation. The middle fraction (II) was thus separated (at 5-mm. pressure) into five sub-fractions boiling between 90 and 98° with a large residue of 38 g. These sub-fractions were again distilled at low pressure in a smaller still of the same design into 14 further small fractions. The range of boiling points now widened to 78–112°. The amounts of the fractions were now rather small and further attempts of separating "middle fraction II" will be made at a later date when more of this material is available for investigation.

The Heavy Fraction III.—This material is the residue which remained in the distilling flask. It is very viscous and has an index of refraction of 1.4855. Beyond the fact that the material is a mixture nothing has been found out about it. It was possible to distil from this heavy oil a much lighter yellow oil at about 230°, using a Nickel-Shot Bath and a very low pressure (10^{-4} mm.). It is hoped to study this heavy fraction in greater detail later.



Grams of distillate (light fraction I).

Fig. 2.

The Light Fraction, I.—This low-boiling section is the material caught in the liquid-air trap and contains, of course, a great deal of dissolved butane. This gas was removed and collected and its boiling point determined. The total amount of butane (147 g.) was distilled at 0° with exception of a few cubic centimeters which remained as a residue and which must represent slightly higher hydrocarbons. The next material that came over on distilling the "light fraction I" was separated into eleven sub-fractions by making cuts every 10°. The details of this fractionation are shown in Table II; Fig. 2 gives the distillation curve.

It is seen that Fraction I-6 is the largest fraction boiling within a ten-degree interval. This fraction was, therefore, redistilled into five sub-sub-fractions boiling between 105 and 117°.

TABLE II

FRACTIONATION OF THE "LIGHT FRACTION I" INTO ELEVEN SUB-FRACTIONS (BAROMETER 740 MM.)

I-11	160.0–	1.4334	53.0	188.0
			188.0	

TABLE III

FRACTIONATION OF SUB-FRACTION I-6 INTO FIVE SUB-SUB-FRACTIONS (BAROMETER, 744.2 MM.)

No.	Temp. of still-head, °C.		Distillate, g.
I-6-1	105.0–110.0	1.4004	0.5
I-6-2	110.0–113.0	1.4021	8.0
I-6-3	113.0–115.0	1.4029	6.0
I-6-4	115.0–117.0	1.4036	2.0
I-6-5	117.0–	1.4118	10.0
			26.5

Identification of Fraction I-6-2.—On comparing the boiling point of this fraction and its index of refraction with known hydrocarbons (I. C. T.), it was found that two octanes fit closest in these two properties. They are 2,4-dimethylhexane and 2-methyl-3-ethylpentane. Several properties of this unknown hydrocarbon were therefore determined, such as density, carbon–hydrogen ratio, molecular weight by the freezing-point method in benzene and halogenation number. At the same time these methods were checked on a sample of pure heptane available in the laboratory.

The properties are given in Table IV. The freezing-point determination was checked with pure naphthalene; the combustions were carried out with 0.200-g. samples in an enclosed system;[7] the halogenations were performed by the iodine-bromide-in-CCl_4 method[8] and checked against cyclohexene and cymene.[9]

It is at once seen that the unknown material I-6-2 is not a system of

saturated octanes but the halogenation and combustion data show the presence of unsaturated substances. Since the molecular weight, density and index of refraction are very closely those of octanes, it may be assumed that the unsaturation found is due to octylenes.

Discussion of Results.—It is believed that in this work the largest quantity of liquid condensate ever produced from a gaseous hydrocarbon by electrical means has been made. Furthermore, the fractional distillation of this material has been carried to a more detailed extent than has been accomplished by previous investigators. For instance, Pryanishnikow[10] has studied the liquid condensation products obtained from ethylene by electrical discharge, but his fractionation involves cuts covering much larger temperature intervals than is the case in the work reported here. Of course, the identification presented here has therefore a better basis. It would require a still larger amount of liquid condensate to push the separation still further. This would involve the identification of isomeric octanes and octylenes and this problem has not been solved completely even with ordinary hydrocarbon materials.

The distillation curve of the "light fraction I" (Fig. 2) shows that the Fraction I-6 (33 g.) is the largest fraction obtained. From the range of boiling points of this fraction obtained upon further fractionation and from the detailed study of Sub-Fraction I-6-2 it appears that these materials are octanes. Octanes or at least 8-carbon atom materials of molecular weights near octanes are then relatively most abundant in this final liquid product. This result seems to follow quite simply from the cluster theory of ionic gas reactions as proposed by one of us.[11] On this theory the reactions leading to condensation by doubling are as follows.

---

[10] D. N, Pryanishnikow, Ber., 61B, 1358-1363 (1928).

[11] S. C. Lind, "The Chemical Effects of Alpha Particles and Electrons," Chemical Catalog Co., Inc., New York, 2d ed., 1928, p. 100.

$$C_4H_{10} \longrightarrow C_4H_{10}^+ + E^- \text{ (Ionization)}$$
$$C_4H_{10}^+ + C_4H_{10} \longrightarrow (C_4H_{10}\cdot C_4H_{10})^+ \text{ (Clustering)}$$
$$(C_4H_{10}\cdot C_4H_{10})^+ + E^- \longrightarrow C_8H_{18} + H_2 \text{ (Neutralization of cluster and rearrangement of bonds)}$$

Since any butane ions formed would meet with neutral butane molecules most frequently because of the greater concentration of butane, it is to be expected that octanes would be formed relatively in greatest amount. Of course, other possible hydrocarbons would be built by continued and successive actions of the type referred to and since decomposition would also take place it is readily understood that probably all possible combinations of radicals take place in such a manner as to produce a most complex mixture of hydrocarbons.

Just which of the isomeric octanes would be produced in greatest amount would depend upon the reactivity of the various carbon–hydrogen bonds of the butane molecule, and, since it has not been possible to identify the isomers of octane formed, this question must await further experimentation. The octylenes found can be thought to be formed by splitting off two hydrogen molecules upon reaction and rearrangement as typified in Equation **3** above.

In future work it is hoped to carry on the study and identification of some of the other larger fractions as obtained from the present series of distillations and to produce still greater quantities of the original mixture for a more detailed fractionation.

The authors wish to thank Mr. J. L. Wilson, who has assisted in this work as American Petroleum Institute Research Assistant.

Summary

A quantity of liquid hydrocarbons (1041 cc.) has been prepared from gaseous butane by condensation in an electrical discharge. A system of twelve all-glass ozonizers was used for the purpose. The liquid product obtained was separated into 40 fractions by fractional distillation at various pressures. These fractions consist of very light, medium and also very viscous oils. One of the light fractions was studied in detail and found to have the following properties: b. p. 110–114.0°; index of refraction, 1.4021; density, 0.708; molecular weight, 114.7; percentage of carbon, 84.55; percentage of hydrogen, 15.45; empirical formula, $C_8H_{17.4}$; unsaturation by halogenation, 22.5 mole per cent. These properties serve to identify this material as a mixture of octanes and octylenes. It is interesting to note that this largest fraction of the lighter oils consists of eight-carbon-atom molecules which can be produced from butane by simple doubling according to theory.

DERIVATIVES FOR THE IDENTIFICATION OF MERCAPTANS[1]

BY E. WERTHEIM

RECEIVED AUGUST 6, 1929 PUBLISHED DECEMBER 11, 1929

For the identification of mercaptans the preparation of lead or mercury salts has been recommended in the literature. These are reported to be easy of preparation and purification and to have definite melting points. Reid[2] has advocated the use of 1.5-butyl-anthraquinone-sulfone sodium sulfonate. Prom this compound he has prepared derivatives of mercaptans having high and sharp melting points. So far as the writer is aware this compound is not on the market and would need to be prepared for individual use.

On account of the growing importance and availability of the mercaptans, it seemed of interest to review the subject of their identification and to fill the gaps in the literature regarding mercaptans now available.

The literature reports of lead and mercury salts are very scanty; the inference is that all of them have not been prepared. In this work the salts were made by adding 6 drops of the mercaptan to about 2 cc. of ethanol, subsequently adding an excess of lead acetate solution (20%) or mercuric cyanide solution (10%). After shaking and cooling the mixture for a few minutes the resulting precipitates were separated by filtration and dried in the air for a short time on a porous plate. They were purified by one recrystallization from the appropriate solvent, The mercury salts were crystallized from ethanol. The solvents used for the lead salts are shown in the following table. The melting points of the lead and mercury salts are given in Table I. The values shown in parentheses were obtained from the literature.

TABLE I

MELTING POINTS OF LEAD AND MERCURY SALTS OF MERCAPTANS

Alkyl	Lead salt, °C.	Mercury salt, °C.
Methyl	. . .	(175)

[a] Solvent, ethanol. [b] Solvent, chloroform and ethanol. [c] Solvent, benzene.

---

[1] This problem was originally assigned to C. H. Adams for a Master's thesis. However, owing to a combination of circumstances, he was unable to continue the work. I wish to thank Mr. Adams for the preparation of several of the compounds described.

[2] Reid, THIS JOURNAL, 45, 1837 (1923).

It will be noted that several of the lead salts are not reported. These precipitated as gummy masses which did not harden for some time and were deemed unsuitable for the purpose at hand. The melting points of the mercury compounds are seen to lie within a small range and several are practically identical.

In this work mercaptan derivatives were also prepared from 3,5-dinitrobenzoic acid and from 3-nitrophthalic anhydride, both of these compounds having proved of value for the identification of alcohols.

Preparation of Derivatives of **3,5-Dinitrobenzoic Acid.**—3,5-Dinitrobenzoyl chloride was prepared as directed by Mulliken[3] from 4 g. of 3,5-dinitrobenzoic acid and 5.5 g. of phosphorus pentachloride. Two grams (one mol) of the resulting acid chloride was placed in a test-tube with 1.5 mols of the mercaptan. The reaction was catalyzed by the addition of 4 drops of pyridine. The tube was then gently heated from time to time until the fumes of hydrogen chloride ceased to appear. In most instances the reaction was complete in about ten minutes; where this was not the case the tube was placed in hot water until the reaction had been completed.[4] A few drops of water were added to the mixture, then pyridine was added dropwise until the odor showed an excess of this reagent. Upon vigorous stirring the mass within the tube quickly solidified. It was brought upon a filter, washed with water and then placed upon a porous plate. One or two recrystallizations of the dried product from dilute alcohol or dilute acetic acid usually gave compounds of constant melting point.

On the small scale (for identifications) 0.2 g. of acid chloride, 6 drops of the mercaptan and 1 or 2 drops of pyridine were treated essentially as described above. For the preparation of the amyl and iso-amyl derivatives it was necessary to use an excess of the acid chloride.

The pure compounds are colorless or very faintly yellow and are odorless. They were made in lots of several grams as indicated above and analyzed

TABLE II

DERIVATIVES OF MERCAPTANS WITH 3,5-DINITROBENZOIC ACID

---

[3] Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York, 1911, Vol. I, p. 168.

[4] If the odor at this time proves the presence of a considerable excess of mercaptan, more of the acid chloride should be added and the heating continued. This may occur with the higher less volatile mercaptans.

in order to make sure that the reaction took the same course in each instance. The melting points and analytical data are given in Table II.

The melting points of the derivatives with 3,5-dinitrobenzoic acid are closer than would be desired and are, moreover, rather low.[5] Mixed melting points were taken for all compounds whose melting points lie within a few degrees of each other; a depression of melting point was observed in every such instance.

The use of 3-nitrophthalic anhydride for the identification of alcohols has been recommended by Nicolet and Sacks.[6] The compounds secured are especially convenient because they contain a free carboxyl group and may, accordingly, be titrated to secure the neutralization equivalent and thus the equivalent weight of the alkyl radical concerned.?

The derivatives of mercaptans and 3-nitrophthalic anhydride are exceptionally easy of preparation. The yields are good and these compounds may be recommended for the identification of mercaptans (excepting methyl mercaptan).

Preparation of Derivatives of Mercaptans with 3-Nitrophthalic **Anhydride.—**3-Nitrophthalic anhydride was prepared from the corresponding acid as directed by Nicolet and Bender.[8] Two grams (one mol) of the anhydride was treated in a test-tube with 1.5 mols of the mercaptan. After heating with a free flame for about one-half minute the tube was set aside. When cool about 20 drops of 10% sodium hydroxide solution was added in several portions. The tube was vigorously shaken between additions of the base and subsequently. It was cooled from time to time in an ice-bath if necessary. The mixture quickly assumed a plastic or oily consistency. About 10 drops of 5% hydrochloric acid solution was added and the tube again vigorously shaken. The solid was separated by filtration and dried on a porous plate. One or two recrystallizations from aqueous acetone or dilute acetic acid sufficed to give products of constant melting point.

For identifications 0.2 g. of the anhydride was treated with 6 drops of the mercaptan and approximately proportional amounts of sodium hydroxide and hydrochloric acid solutions. The products secured are colorless or very faint yellow; they are odorless. Analytical data and melting points are reported in Table III. The neutralization equivalents for several of these compounds were obtained and are also reported in the table.

---

[5] It was to be predicted that these melting points would be lower than those of the known oxygen compounds. Part of the reason for their preparation was to see how much this difference would be.

[6] Nicolet and Sacks, THIS JOURNAL, 47,2348 (1925).

[7] McKenzie has shown (reference in Nicolet and Sacks' paper" that of the two possible mono-esters formed by the reaction of certain alcohols with 3-nitrophthalic anhydride, one is present in very small amount. Nicolet and Sacks' work indicates that this trace must be removed during the purification process. If in the reaction with mercaptans two mono-esters are produced it must again be true that one of them is lost during the purification, for the evidence given by the melting points of the compounds secured is that they are chemical individuals and not mixtures of isomers.

The melting points given were secured when the bath was previously heated to about 100° and the temperature quickly raised to within about 10° of the true melting point. They are higher than those obtained when the compound is slowly heated from room temperature. The majority of the compounds show a slight decomposition at the melting point, liberating a gas. In identifications these compounds should be prepared from known samples of mercaptans, and the melting points of the known and unknown compounds should be taken together along with a mixed melting point.

Observation of the results given in the table will show that the melting points of these compounds again lie within a small range as Nicolet and Sacks noted for the oxygen compounds. Mixed melting points were taken for all pairs of compounds having melting points within a few degrees of each other. In every case a depression of the melting point was noted.

Summary

Derivatives of mercaptans have been prepared from lead and mercuric ions and from 3,5-dinitrobenzoic acid and 3-nitrophthalic anhydride. Their melting points and some other properties are reported. 3-Nitrophthalic anhydride is recommended for the identification of mercaptans (with the possible exception of methyl mercaptan, for whose identification the mercury salt appears to be preferable). Twenty-eight of the compounds reported are new.

THE ACTION OF THIONYL CHLORIDE UPON CHOLESTEROL AND CERTAIN OTHER ALCOHOLS[1]

BY PAUL J. DAUGHENBAUGH AND JAMES B. ALLISON

RECEIVED AUGUST 9, 1929 PUBLISHED DECEMBER 11, 1929

Halogen derivatives of cholesterol, substituted monosaccharides and certain other alcohols were desired for further synthetic work. The isomerization, polymerization, reduced yields of the halide and sometimes destructive action which may result from the treatment of alcohols with the halogen derivatives of phosphorus has been pointed out by Darzens.[2] The reaction of diacetone-glucose with phosphorus pentachloride yielded 75% of compounds containing phosphorus.[3] Thionyl chloride acts as a milder reagent and does not cause the Walden inversion of certain optically active alcohols.[4] Darzens[2] offers a general method for the preparation of halogen derivatives of the aliphatic alcohols with good yields by the use of thionyl chloride or thionyl bromide in the presence of an organic base such as pyridine.

However, while attempting to prepare fenchyl chloride by the treatment of fenchyl alcohol with thionyl chloride in the presence of pyridine, Ruzicka and Liebl[5] obtained difenchyl sulfite. There was no chlorination. Richter[6] and Badische[7] have prepared a series of aryl sulfites in a similar manner. A study of the reaction indicated that an alcohol treated with the theoretical amount of thionyl chloride in the presence of pyridine would yield the organic ester of sulfurous acid. By this method the sulfurous acid esters of cholesterol, diacetone-glucose, ethyl alcohol, butyl alcohol and phenol have been prepared. There was no chlorination. These esters were also prepared by treating their sodium salts in petroleum ether or ethyl ether with the theoretical amount of thionyl chloride. This method was described in a previous paper for the preparation of *bis*-(diacetone-glucose)-sulfite.[3]

If a large excess of thionyl chloride is used on the alcohol in the presence of a small amount of pyridine, the reaction evidently goes according to Equation I. When refluxed, sulfur dioxide is eliminated according to Equation II.

$$ROH + SOCl_2 \longrightarrow R{-}O{-}S(=O){-}Cl + HCl \qquad (I)$$

$$R{-}O{-}S(=O){-}Cl \longrightarrow RCl + SO_2 \qquad (II)$$

McKenzie and Clough[4] obtained an intermediate product, d-amyl chlorosulfinate, from which sulfur dioxide was eliminated according to Equation II. An excess of thionyl chloride was used in this reaction. Cholesterol, in the presence of an excess of thionyl chloride, with or without the addition of a small amount of pyridine, yielded cholesteryl chloride almost quantitatively. When an excess of pyridine was used and the reaction was carried out in ether, a small amount of *bis*-cholesteryl sulfite was also formed. When an excess of thionyl chloride is added to diacetone-glucose in ether and in the presence of an excess of pyridine, little or no sulfur dioxide is eliminated upon refluxing the reaction mixture. When poured into water which is kept slightly alkaline with sodium carbonate, the compound which is formed is hydrolyzed and diacetone-glucose is immediately regenerated. Green[8] has isolated a reactive intermediate product, dichlorothionyl quinol, from which sulfur dioxide was not eliminated by heat under the conditions of the reaction.

Experimental Part

Bis-cholesteryl **Sulfite.**—Two grams of anhydrous cholesterol was dissolved in 50 cc. of dry pyridine. A little in excess of the theoretical amount of thionyl chloride was then added. This mixture was allowed to stand for twenty-four hours at room temperature. At the end of this period water was slowly added until no more precipitate settled out. The impure neutral sulfite ester was filtered off and extracted with a small quantity of hot alcohol to remove any unchanged cholesterol. The ester was purified by several recrystallizations from ethyl acetate; m. p. 186.5–187°. The yield was almost quantitative. Acknowledgment is made for the assistance of two senior students, Karl S. Hecht and Meyer H. Zuravin.

Anal. Calcd. for $C_{54}H_{90}O_3S$: S, 3.91. Pound: S, 4.02.

Bis-cholesteryl sulfite is soluble in cold petroleum ether, carbon tetrachloride, chloroform and ethyl ether. It is only slightly soluble in boiling methyl or ethyl alcohol and acetone. It is only slightly soluble in cold ethyl acetate but very soluble at the boiling temperature. The ester is quite stable to aqueous acid or alkaline saponification. It can be quickly hydrolyzed by boiling in 30% alcoholic potassium hydroxide with a quantitative yield of cholesterol.

This sulfite ester is partially converted into cholesteryl chloride when heated with phosphorus pentachloride in carbon tetrachloride. A small quantity of cholesterol and some unchanged sulfite were also isolated from the reaction mixture. The end-products would indicate that the reaction had gone in the same way that Michaeiis[9] found for the action of phosphorus pentachloride upon diethyl sulfite. The sulfurous acid esters of ethyl alcohol, butyl alcohol and phenol were prepared in a similar manner.

Bis-**(diacetone-glucose)-sulfite.**—Five grams of diacetone-glucose and 100 cc. of pyridine were dissolved in 50 cc. of dry ethyl ether; 0.72 cc. of thionyl chloride was added a drop at a time. The mixture was permitted to stand for three hours. The pyridine

---

[9] Michaelis, *Ber.*, 7, 1074 (1874).

hydrochloride which had separated was removed by decantation. The reaction mixture was poured into three volumes of water which was kept faintly alkaline with sodium carbonate. After complete neutralization the ether-soluble portion was separated from the water-soluble constituents. The ether solution was dried over anhydrous sodium carbonate. When the ether was removed under reduced pressure, a yellow transparent syrup remained which had all of the properties of *bis*-(diacetone-glucose)-sulfite. Tests showed the presence of sulfur but no chlorine. The product was identified by hydrolysis with 0.1 *N* alcoholic potassium hydroxide. Potassium sulfite and diacetone-glucose resulted.

Cholesteryl Chloride.—To 5 g. of cholesterol and 1 cc. of pyridine, 10 cc. of thionyl chloride was added rapidly. The reaction mixture was kept cool with running water and was refluxed for one hour. Sulfur dioxide was liberated. The mixture was cooled, poured into water and then extracted with ether. The ethereal solution was dried over anhydrous sodium carbonate. When the solvent was removed under reduced pressure a semi-crystalline product remained. This was recrystallized from alcohol and identified as cholesteryl chloride; m. p. 95–96°. The yield was almost quantitative. The reaction was repeated without the addition of pyridine with identical results.

Ethyl chloride, and butyl chloride were prepared in a similar manner. Attempts to prepare chlorobenzene from phenol by this method were unsuccessful.

Reaction of Diacetone-glucose with Excess Thionyl Chloride.—Five grams of diacetone-glucose and 10 cc. of dry pyridine were dissolved in 30 cc. of dry ethyl ether; 10 cc. of thionyl chloride was added rapidly and the reaction mixture was kept cool by immersion in ice water. It was refluxed for one hour. The pyridine hydrochloride which separated was removed by decantation and the solution poured into ice water. The ether-soluble portion was separated and dried over anhydrous sodium carbonate. When the solvent was removed under reduced pressure a semi-crystalline mass remained which contained sulfur and a trace of chlorine. Upon recrystallization from high-boiling petroleum ether about 3 g. of diacetone-glucose separated; m. p. 102°. Hydrolysis of the remaining sirup with alcoholic potassium hydroxide yielded diacetone-glucose, potassium sulfate and potassium sulfite. It is hoped that a further study of this reaction will result in the production of the chloride.

A similar reaction with cholesterol yielded about 80% of cholesteryl chloride and about 20% of *bis*-cholesteryl sulfite.

Summary

1. The synthesis of *bis*-cholesteryl sulfite is reported and some of its properties are described.

2. The action of thionyl chloride, in the theoretical amount, upon cholesterol and certain other alcohols in the presence of an excess of pyridine yields the sulfurous acid ester of the alcohol. No chlorination takes place.

3. The action of thionyl chloride, in large excess of the theoretical amount, upon cholesterol and certain other alcohols in the presence of an theoretical amount of pyridine, yields the chloride of the alcohol. Evidence is presented to indicate that an intermediate compound is formed which upon heating may break down to form sulfur dioxide and the alkyl chloride.

STUDIES IN THE CHLOROPHYLL SERIES. I. THE THERMAL DECOMPOSITION OF THE MAGNESIUM-FREE COMPOUNDS

BY J. B. CONANT AND J. F. HYDE

RECEIVED OCTOBER 31, 1929 PUBLISHED DECEMBER 11, 1929

Chlorophyll a is the magnesium derivative of phaeophytin a, which contains the groupings $—OC_{20}H_{39}$ and $—OCH_3$ presumably as ester groups. By the replacement of the phytol alcohol radical by methyl, methyl phaeophorbide *a* results, which contains, therefore, two methoxyl groups. The replacement of the phytyl group by hydrogen produces phaeophorbide a, a monobasic acid, from which by alkaline hydrolysis the dibasic acid chlorin *e* is formed. In this last reaction a deep-seated change has probably taken place in addition to hydrolysis.[1] A similar set of transformations of chlorophyll *b* yields methyl phaeophorbide *b*, phaeophorbide b and rhodin g.

We have found that all of these magnesium-free compounds lose carbon dioxide when heated in dilute diphenyl solutions to 180–250°. The process may be followed quantitatively by passing nitrogen through the solution and absorbing the carbon dioxide in the usual way. Crystalline products may be isolated by dissolving the reaction mixture in ether and fractionating with hydrochloric acid according to the Willstatter–Mieg procedure.[2] The results are summarized in Table I.

It is evident from an inspection of Table I that all the magnesium-free derivatives of both the a and the *b* series which we have examined, with the exception of the trimethyl ester of chlorin *e*, lose carbon dioxide under the conditions of our experiment. The phaeophorbides lose one molecule of carbon dioxide whereas chlorin *e* and rhodin g lose two molecules. The analyses of the crystalline products which we have isolated in the a series correspond to the loss of the number of moles of carbon dioxide noted in our quantitative decompositions. Definite but irregular amounts of water are formed in the reaction, as shown by the increase in weight of the calcium chloride absorption tube, but the blank was so large that no conclusions could be drawn from the results. It is possible that water may be eliminated and then added during the isolation of the products.

It is significant that the trimethyl ester of chlorin e does not lose carbon dioxide, whereas methyl phaeophorbide *a* loses one molecule. Since the methyl phaeophorbide contains no free carboxyl group, this carbon dioxide must come from some special grouping of the molecule. The decomposition of an ester group is made unlikely by the fact that chlorin e trimethyl ester does not lose carbon dioxide on heating. A lactone seems to be the

[a] Within the experimental error (±0.8 mg.).

The molecular weights used in calculating the number of moles of carbon dioxide are given; because of the uncertainties of the analyses these values are only approximate.

most probable explanation. As pointed out in our preliminary notice of this work,[3] these results point to the presence of some such grouping as an unsaturated lactone bridge which could lose carbon dioxide.

Methylation experiments now in progress should yield further evidence in regard to the presence of a lactone linkage or a hydroxyl group. The fact that the spectra of the parent substances and the pyro compounds are so similar suggests that the pyrrole rings are in the same condition in both compounds.

Our analytical data, as well as the recently published results of Treibs[4] and of Fischer[5] indicate that there are five or six oxygen atoms in the

[5] Fischer and Baümler, *ibid.*, 474, 65 (1929).

phaeophorbide *a* molecule. The grouping $—COOCH_3$ is clearly present in methyl phaeophorbide and, if one accepts the conclusion that a lactone group is also present, this leaves the extra methoxyl group without sufficient oxygen to constitute a carbomethoxy group if there are but five oxygens. It should be pointed out, however, that there is no clear evidence that there are two carbomethoxy groups in methyl phaeophorbide a. The second methyl group may well be present as the methyl ether of an enol, for example, the enol of a lactam. A similar interpretation is possible with chlorin *e;* indeed, the fact that it is possible to obtain the trimethyl ester by the action of diazomethane on chlorin e as shown by Treibs[4] seems to us strong evidence that the third methyl group in this instance is derived from an enol and not by the opening of a lactone or lactam ring. There seems to be no reason to believe that diazomethane would be effective in opening such groups.

Pyro-phaeophorbide a is an acid; this shows that the carbon dioxide from this compound must have resulted from some group other than the free carboxyl and that the acidic group in phaeophorbide *a* is stable at high temperatures. The final decomposition by alkali of all the compounds we have been mentioning leads to porphyrins,[1,5] which contain the very stable grouping $—CH_2CH_2COOH$; it is quite clear that it is this carboxyl group which is free in phaeophorbide a and which is, therefore, attached to the phytyl group in phaeophytin and in chlorophyll.

The two products formed by the pyrolysis of chlorin e we shall designate by the terms pyrochlorin e and pyrochlorin e-porphyrin. The former substance is green and has a spectrum somewhat similar to that of chlorin e itself, whereas the porphyrin has the general appearance, spectrum and characteristics of this very large class of substances. The two compounds are isomeric. The green pyrochlorin e is unstable and on standing for a few months undergoes a partial decomposition. By acid fractionation it is possible to obtain from the decomposed material a substance which is very similar to pyrochlorin e-porphyrin, but not identical with it. It is clear that in the pyrolysis of chlorin e we have stripped the molecule of all but one carboxyl group and in the green substance have a relatively simple representative of the chlorophyll series, which still has a spectrum similar to the more complex members. A further study of these products, as well as those from the b series and the magnesium-containing compounds, is now in progress and should throw more light on the question of the structure of the first transformation products of chlorophyll. It seems extremely probable that the carbon skeleton of the chlorophyll porphyrins as established recently by Fischer[6] is present in all the chlorophyll series, as he has indicated. The ease of transformation of our green

---

[6] Fischer and Treibs, Ann., 466, 188 (1928); Fischer and Schormüller, *ibid.*, 473, 211 (1929).

pyrochlorin e into a porphyrin is more evidence pointing in this same direction.

In connection with the analytical data given in the experimental part of this paper, it should be mentioned that it is impossible to decide at present between several possible formulas for each compound. The same difficulties have been encountered by other workers in this field as pointed out by Fischer.[4] We have given the calculated values for several different formulas in each case. Of the more probable formulas for methyl phaeophorbide *a* ($C_{36}H_{38}O_6N_4$, $C_{36}H_{38}O_5N_4$, $C_{35}H_{38}O_6N_4$, $C_{35}H_{38}O_5N_4$) we prefer the formula $C_{36}H_{38}O_6N_4$, since all our results can be best interpreted on this basis. Our analyses and quantitative results of pyrolysis are consistent in each case. At first sight, there appears to be a certain inconsistency between the formulas of the monobasic porphyrins and our pyro-compounds from chlorin e. The recent work of Fischer[6] has established that there are 31 carbon atoms and 2 oxygen atoms in the chlorophyll monobasic porphyrins, yet our substances, which should be isomeric, have at least 32 carbon atoms and 3 oxygen atoms. It would seem that our method of decomposition has left some group in the molecule which is eliminated through the usual alkaline decomposition; it will be a matter of great interest to determine the nature and position of this grouw.

Experimental Part

Preparation and Analysis of Methyl Phaeophorbide a, Phaeophorbide *a,* Chlorin e and Chlorin e Trimethyl Ester.—Phaeophytin was used for the preparation of these substances. In all cases the methods of preparation used were those described by Willstatter and Stoll.[1] The products were all obtained in a nicely crystalline condition, and agreed closely in acid number, spectrum and crystal form with the descriptions given by the same authors. In most eases, however, the yields obtained were only one-half to two-thirds of those mentioned by Willstatter and Stoll.

In the preparation of chlorin e by using the cold hydrolysis over a long period of time, the product seemed to correspond to the form described as the lactam hydrate, while in other cases, using hot hydrolysis with pyridine, the so-called anhydrous form was obtained. Chlorin e trimethyl ester was prepared both by using dimethyl sulfate according to Willstatter, and according to Treibs and Wiedemann using diazomethane.[4] Both products melted on the block at 202–204° and a mixed melting point showed no depression.

For analysis the materials were in most cases redissolved in ether and refractionated with hydrochloric acid to insure purity. In all cases the samples were dried over phosphorus pentoxide for a period of from three to five days at a pressure of 10–20 mm. The following table gives the analytical results; these and all the other results reported in this paper were obtained by the Pregl micro methods.

And. Methyl phaephorbide a: C, 70.38, 70.90, 71.21, 69.70; H, 6.23, 5.95, 6.06, 6.16; N, 9.38, 9.53, 9.33. Phaeophorbide a: C, 67.96, 68.72, 68.29, 68.00; H, 5.94, 6.10, 6.20, 6.53; N, 9.33. Chlorine: C, 67.14; H, 6.49; N, 8.81, 8.96. Chlorin e trimethyl ester: C, 69.78, 69.03; H, 7.25, 6.88; N, 8.75.

Preparation of Pyro-compounds.—The method of pyrolysis involved heating the substance in diphenyl solution to the desired temperature for the required length of time.

The apparatus consisted of a side arm U-tube made from tubing thirty millimeters in diameter, and was about 150 mm. in height. This tube contained the diphenyl solution and was heated in an oil-bath. The outlet tube was attached to a 200-mm. length of 3-mm. tubing bent in the form of a U-tube. This served as an air-condenser to assist in preventing diphenyl from being carried along in the gas stream. To this tube was attached another U-tube containing calcium chloride followed by a potash absorption bulb. The whole system was swept out during the experiment by a slow stream of dry nitrogen, which served to agitate the diphenyl solution as well as to transfer any carbon dioxide or water formed to the absorption train. By frequent weighing of the absorption tubes the progress of the decomposition could be followed. The outlet side of the reaction tube was surrounded by a small copper cooling coil to prevent the diphenyl from distilling

In starting an experiment, 20 g. of diphenyl was heated to boiling for a short time, a slow stream of nitrogen being passed through the apparatus. The absorption tubes were then weighed, replaced and the heating continued for one to three hours to determine any blank which might be involved. The blank on the carbon'dioxide tube was negligible while that on the water tube was usually about a milligram per hour. The sample (150–50 mg.) was then introduced quickly into the hot diphenyl and the heating carried out at the desired temperature.

The results of the pyrolysis experiments have been summarized in Table I; some typical results are given in more detail below. Pyrolysis of chlorine e: temp., 160–175°; time, 2.5 hrs.; 0.1137 g. yielded 0.0116 of CO_2 and 0.003 g. of H_2O after subtracting a blank of 0.002 g. (0.0008 g. per hr.). Temp. 250°; time 5 hrs.; 0.1252 g. yielded 0.0171 g. of CO_2 and 0.0024 g. of H_2O after subtracting a blank of 0.0060 g. Because of the large blank (due to the volatility of the diphenyl), not much significance can be attached to the increase in weight of the calcium chloride tube. However, some water appears to be formed and in one experiment with chlorin *e* it was condensed in a freezing mixture.

The products were all purified in the same way. The reaction mixture was dissolved in 300 to 500 cc. of ether and fractionally extracted with various concentrations of hydrochloric acid according to the method of Willstatter and Mieg. The main acid fractions were then washed twice with ether to remove any traces of diphenyl and the colored substance retransferred to ether either by dilution of the acid layer or by partial neutralization with ammonia. These ether solutions were then washed with water or with very dilute potassium hydroxide in the case of an alkali insoluble product, dried with sodium sulfate and concentrated to a small volume. Usually concentration to 10 or 15 cc. caused the material to crystallize. For purification these materials were dissolved in ether and refractionated with acid.

The yields given in the table are obviously not true measures of the amounts of the compounds formed in the reactions; the losses during purification of such small samples are very large. In no case was the formation of carbon monoxide detected. In most cases a few milligrams of black ether-insoluble residue was found in the reaction mixture. In one instance, using a 0.5-g. sample of chlorin e and adding to the cold diphenyl, 0.3 g. of this black residue was formed. It would thus seem desirable to add the sample to the hot diphenyl.

Chlorin e trimethyl ester was the only substance recovered from the reaction mixture unchanged.

Methyl Pyrophaeophorbide a.—This substance crystallizes from ether in beautiful long flat needles which tend to grow in radiating clusters. Their color is deep blue with a metallic luster. The crystals redissolve readily though slowly in ether imparting to it an olive-green to brown color, indistinguishable from that of an ether solution of pure methyl phaeophorbide a. It dissolves very readily in pyridine and rather slowly in acetone. The acid number is 15, the acid extract being colored a greenish-blue. The product is not itself extracted from ether by mild alkali but is hydrolyzed slowly in acid solution yielding a material which can be extracted with alkali. This substance is identical in acid number, spectrum and behavior toward alkali with pyrophaeophorbide *a*. The melting point of methyl pyrophaeophorbide *a* on the block is 220–225°. The spectrum by visual comparison is identical both in position and relative intensities with that of pure methyl phaeophorbide *a*. Unlike methyl phaeophorbide *a*, the pyro-compound does not give the phase test.

The spectra given below and with the other new compounds were measured in ether solution (concn. 0.1 g. per 5 liters), the thickness of the solution is given in mm. Dotted lines indicate fainter absorption.

100 mm.: 701.2---689.9—646.8; 622.9---619—601.2--597.4; (hazy) 565.6—553.5; 542.7—529.5; 519.2—491.7; 478.6—464.6; E. A. 444.6.

20 mm.: 679.5—656.3; 617.8—603.4; 540.1—531.9; 512.1—504.2---494.7; E. A. 433.

Anal. Calcd. for $C_{35}H_{38}O_4N_4$: C, 72.66; H, 6.57; N, 9.68—for $C_{35}H_{38}O_3N_4$: C, 75.00; H, 6.79; N, 9.65—for $C_{34}H_{38}O_4N_4$: C, 72.1; H, 6.72; N, 9.9—for $C_{34}H_{38}O_3N_4$: C, 74.2; H, 6.9; N, 10.2. Found: C, 74.03, 73.83, 73.93; H, 6.40, 6.04, 6.03; N, 10.14, 10.14, 9.90.

Pyrophaeophorbide a.—This substance was extracted from ether solution by 13–14% acid to give a bluish-green solution. Its acid number is between 12 and 13. It crystallizes from ether in a micro-crystalline condition, probably needles, with a steel blue luster. The ether solution is colored olive-green to brown, practically identical in color with a solution of pure phaeophorbide *a*, and possesses the same reddish fluorescence. Toward other solvents its behavior is the same as phaeophorbide *a*. With dilute alkali an ether solution gives a yellowish-brown precipitate at first which gradually redissolves in the ether as well as the water layer, imparting a brown color suggestive of the phase test. It appears to give the phase test. On the block it melts between 210 and 220°. Spectroscopically this product is identical with phaeophorbide *a*, which is in turn identical with methylpyrophaeophorbide *a*.

20 mm.: 682.0---679.7—657.6---655.0; 615.4--604.4; 549.0—531.6; 512.9—491.5; E. A. 433.7.

100 mm.: 699.1---687.3—647.5---644.0; 621.6---619—601.7; 565.5—555.9; 541.0—529.4; 517.2—491.0; 481.3—462.1; E. A. 443.6.

Anal. Calcd. for $C_{34}H_{36}O_4N_4$: C, 72.34; H, 6.38; N, 9.92—for $C_{33}H_{36}O_4N_4$: C, 71.7; H, 6.52; N, 10.13—for $C_{34}H_{36}O_3N_4$: C, 74.4; H, 6.57; N, 10.21—for $C_{33}H_{36}O_3N_4$: C, 73.88; H, 6.71; N, 10.44.

In the formation of pyrophaeophorbide *a* there was obtained as a by-product a small amount of black micro-crystalline material. It was extracted from the mother liquor by 9% acid giving a green solution, and on retransferring to ether gave a dark purple-red color which was unusually intense considering the amount of material present. The quantity was too small for careful investigation, but the spectrum is given below.

20 mm.: 670.0—661.6; 588.4--579.5; 566—557.2—546.2; 525—497.4; E. A. 441.7.

100 mm.: 675—653.0; 604---591.9—580.3---574.8; 568.1—557.1---543; 527.3—494.3; E. A. 452.7.

Pyrochlorin *e*.—Pyrochlorin e is extracted from an ether solution by 8% acid, giving a deep greenish-blue solution. Its acid number is between seven and eight. It is so soluble in ether that the small quantities available could not be crystallized from that solvent. It was, however, obtained in a micro-crystalline condition by removing most of the ether, adding a small volume of ethyl alcohol and diluting gradually (over a period of a day) with water to 50%. Prepared in this way it appears as a dark blue micro-crystalline powder. The color of its ether solution is identical with that of chlorin *e*. However, when the solution is shaken with dilute potassium hydroxide, the behavior is similar to that of an ether solution of pyrophaeophorbide *a*. A brown precipitate appears which only partially redissolves and colors both the ether and water layers yellowish-brown, a color suggesting the phase test. Its melting point is between 165–170°.

The spectrum is the same as that of chlorin e in relative intensities, but the corresponding lines are shifted slightly to shorter wave lengths, most noticeably in the red.

20 mm.: 670—649.3; 609—596.0; 532.3—525.5; 509.6—487.3; E. A. 430.8.

100 mm.: 679.6—641.1; 611.9—596.6; 560.9—550.2; 534.1—526.1; 516.5—483.4; E. A. 442.9.

Anal. Calcd. for $C_{33}H_{38}O_3N_4$: C, 73.60; H, 7.06; N, 10.40—for $C_{32}H_{36}O_3N_4$: C, 73.28; H, 6.87; N, 10.68. Found: C, 73.70, 74.14, 73.79, 73.52; H, 6.86, 6.96, 5.87, 6.04; N, 10.41, 10.26, 10.35.

Pyrochlorin e seems to be unstable; a carefully purified sample of the solid, after standing for three months, on refractionation with acid yielded a small quantity of material which was extracted with 1% acid. This material was red in ether solution and crystallized in beautiful ruby-red prismatic needles. The color of the ether solution and acid number suggest identity with pyrochlorin *e* porphyrin (isomeric with pyrochlorin *e*). The spectrum, however, seems slightly different.

50 mm.: 666.1—659.3---655.5—647; 594.1---582—574.8; 551.1—533.9; 522.3—487.2; E. A. 452.8.

Pyrochlorin e **Porphyrin.**—This substance was formed as a by-product in rather small quantities along with pyrochlorin *e*. It is extracted from the mother liquor easily with 1% acid and the acid number is between one-half and one. The acid solution is purple and gives a red ether solution on retransferring. The concentrated ether solution gives long red prismatic needles with a purplish-blue iridescence. The solubility was similar to that of phylloporphyrin. By shaking the ether solution with dilute potassium hydroxide, a rather insoluble potassium salt is formed.

20 mm.: 589.1---580.2—573.4; 548.1—533.4; 516—491.0; E. A. 433.3.

100 mm.: 665.6-657.5---651.0; 634.7—628.8; 593.4---580.9—573.5; 547.3—532.2; 519.3—487.0; E. A. 446.3.

Anal. Calcd. for $C_{33}H_{38}O_3N_4$: C, 73.60; H, 7.06; N, 10.40—for $C_{32}H_{36}O_3N_4$: C, 73.28; H, 6.87; N, 10.68. Found: C, 74.03, 74.23, 74.02; H, 6.31, 6.81, 6.73; N, 10.37, 10.67, 10.73.

Summary

1. Phaeophorbide *a*, methyl phaeophorbide *a* and chlorin *e* lose carbon dioxide on heating in dilute diphenyl solution to 180–250°. The amount of carbon dioxide evolved corresponds to the loss of one molecule with the phaeophorbides and two in the case of chlorin *e*. The analyses of the crystalline products confirm this conclusion. Two isomeric products are obtained from chlorin *e*, one a green substance the other a porphyrin.

2. The experiments with the phaeophorbides indicate that a lactone or similar grouping is the source of the carbon dioxide and that the phytol in phaeophytin is attached to the $—CH_2CH_2COOH$ group.

CAMBRIDGE, MASSACHUSETTS

NOTE

The Decomposition of Methyl-2-hexanol-2.—Recently, Edgar, Calingaert and Marker[1] have described the preparation of methyl-2-hexanol-2. The olefin formed by slow distillation of this tertiary alcohol with a trace of iodine was stated to be methyl-2-hexene-2, but the isomeric methyl-2-hexene-1 may also have been present. Hydrogenation of either of these heptenes would produce 2-methylhexane, and since this was the desired product no study was directed to identify the olefins which may have been produced.

In 1927 we studied this problem and obtained evidence to show that a single olefin, presumably methyl-2-hexene-2 (later called "Heptene-A), was formed when the alcohol was refluxed without catalyst for several hours. This decomposition always occurs to a small extent during distillation at atmospheric pressure (139–141"). Apparently, methyl-2-hexanol-2 does not undergo scission into "acetone + butane" or into "methyl butyl ketone + methane," since no ketones could be isolated from the distillate. This type of scission is known to occur in similar cases at more elevated temperatures.[2] At 58–60' and 20 mm., methyl-2-hexanol-2 may be distilled repeatedly without decomposition. When purified in this way the index of refraction was n_D^{20} 1.4187.

With a small amount of iodine as catalyst, as in the work of Edgar, Calingaert and Marker, the extent of the dehydration was found to be much greater and the nature of the "Heptene-B" thus produced differed from Heptene-A. This difference displayed itself in the refractive index and in the properties of the respective heptene dibromides. Both heptenes boiled at 92–95°.

The index of refraction values for Heptene-B were: 18.5°, 1.4098; 19.0°, 1.4091; 20.5°, 1.4088; 23.5°, 1.4054. The corresponding values for Heptene-A at 17.5 and 20.5° were 1.4049 and 1.4040, respectively. This difference is certainly large enough to be significant. The density of Heptene-B at 20° was found to be 0.7089.

The dibromides were prepared by adding the calculated quantity of pure bromine drop by drop to each of the heptenes. The reaction flasks were cooled in ice water during this addition. The dibromide of Heptene-A distilled at 99–100° (27 mm.) and the pure compound gave the following values for n_D: 18°, 1.5020; 19°, 1.5014; 19.8°, 1.5010; 22°, 1.5001.

Anal. Calcd. for $C_7H_{14}Br_2$: Br, 62.0. Found, 62.6.

This dibromide boiled with decomposition at 187–188° at ordinary pressure.

The dibromide of Heptene-B, similarly prepared, and fractionally distilled in *vacuo*, yielded a fraction boiling at 65–70' (18–19 mm.) with

[1] Edgar, Calingaert and Marker, THIS JOURNAL, 51, 1485 (1929).

[2] See Grignard and co-workers, *Compt. rend.*, 176, 1860 (1923); 182, 299 (1926); *Ann. chim.*, 2, 298 (1924).

$n_D^{17.5}$ 1.4700, and 1.6 times as much of a higher fraction, b. p. 93–97° (17–18 mm.), with $n_D^{17.5}$ 1.5022. Of these two fractions, the latter seemed identical with the dibromide from Heptene-A.

To explain these data, it is suggested that "Heptene-A" is largely or entirely methyl-2-hexene-2, and that "Heptene-B" is a mixture of methyl-2-hexene-2 and methyl-2-hexene-1, the former predominating.

Summary.—Methyl-2-hexanol-2 slowly undergoes dehydration into methyl-2-hexene-2 by refluxing. With iodine as a catalyst, the dehydration reaction proceeds more readily but methyl-2-hexene-1 also appears to be formed.

ADDITIONS AND CORRECTIONS

1921. VOLUME 43

Indirect Method of Preparation of Organic Mercuric Derivatives and a Method of Linking Carbon to Carbon, by Morris S. Kharasch.

Page 2243. The author writes as follows: ". . . Lines 22 and 34 should read '2,2′,4,4′,6,6′-hexanitro mercury diphenyl' instead of '2,2′,4,4′,6,6′-hexanitro diphenyl.' It is unfortunate that this omission of the word 'mercury' has occurred. The author intended to call attention to the very interesting fact that if the molecule of 2,4,6-trinitrophenyl mercuric chloride is treated with potassium periodide at room temperature, two simultaneous reactions take place. The first reaction is a substitution of the —HgX radical by iodine and the second reaction is a 'bridging' effect due to the potassium iodide.

"This is believed to clear up the apparent discrepancy in the article and results recorded in a recent publication [Whitmore and Thurston, THIS JOURNAL, 51, 1502 (1929)], except that since these authors refluxed the sample of 2,4,6-trinitrophenyl mercuric chloride with iodine for eight hours and did not employ potassium iodide at all, they could not have noted the formation of the 2,2′,4,4′,6,6′-hexanitro mercury diphenyl, as observed by the first author. It is the unusual speed of formation of this latter compound from 2,4,6-trinitrophenyl mercuric chloride and potassium iodide at ordinary temperature that was deemed worthy of mention."—M. S. KHARASCH.

Chemical Kinetics in Highly Dilute Solution. Bromo-acetate and Thiosulfate Ions in the Presence of Sodium Ion at 25°, by Victor K. La Mer.

Page 3341 The author writes as follows: "... An unfortunate error was made in computing the ionic strengths of the final solutions. The contribution of the sodium thiosulfate to the ionic strength was computed in terms of a normal solution of valence type $(1, -2)$, whereas the normality employed was really in terms of iodine equivalents, *i. e.*, for thiosulfate $\mu = 3$ N and not 1.5 N. The net result is that each value of μ given in the article must be multiplied by a factor $40/25 = 1.60$ and each $\sqrt{\mu}$ by $\sqrt{1.60}$ or 1.265. This correction distorts Fig. 1 slightly and thereby weakens but does not destroy the conclusions reached. Thus the limiting experimental slope $d \ln k/d \sqrt{\mu}$ for the lowest points is not equal to $0.93 Z_A Z_B$ but to about $0.75 Z_A Z_B$. In other words, the limiting theoretical slope $Z_A Z_B$ is being rapidly approached but has not been attained even for the region of dilution of $\mu = 0.002$ to 0.001, for a reaction of such comparatively simple valence type as the one employed. The values given in Table I refer to $\sqrt{\mu}$ and not to μ."—VICTOR K. LA MER.

NEW BOOKS

Lectures on Combustion. By JOSEPH PRIESTLEY, LL.D., F.R.S., and JOHN MACLEAN, M.D., Professor of Mathematics, Natural Philosophy and Chemistry in the College of New Jersey. Edited by WILLIAM FOSTER, Princeton University. Foreword by Professor Hugh S. Taylor. Princeton University Press, Princeton, N. J., 1929. vii + 116 pp. Illustrated. 13 × 21 cm.

This small volume contains, first, a brief, but interesting biography of John Maclean, M.D., the first professor of Chemistry at the College of New Jersey (Princeton) by Professor Foster; second, a reprint of Priestley's famous valedictory pamphlet published in "Northumberland in America" in defense of the doctrine of Phlogiston, and third, "Two Lectures on Combustion and an Examination of Dr. Priestley's Considerations on the Doctrine of Phlogiston" by Maclean in answer to this pamphlet.

Professor Foster's biography shows Maclean as an attractive figure;—practicing medicine successfully and a member of the Faculty of Physicians and Surgeons of Glasgow University at 21; Professor of Chemistry and Natural History at Princeton at 25; an enthusiast for the newest developments of the chemical science of his period.

Priestley's pamphlet displays the skill and clarity of presentation of the accomplished writer and also an appealing modesty; but Maclean in his two lectures points out with vigor and persistency the errors, chiefly of *fact*, on which Priestley's arguments were based.

A Foreword by Professor Taylor states that this volume was issued on the occasion of the dedication of the new chemical laboratory at Princeton. This is indeed most appropriate; the enthusiasm of Maclean for chemistry and his emphasis of the importance of experimental investigations in that science afford a splendid heritage and an inspiring tradition.

ARTHUR B. LAMB

Müller-Pouillets Lehrbuch der Physik. (**Müller-Pouillet's** Textbook of Physics.) **Lehre** von der strahlenden Energie **(Optik).** (The Science of Radiant Energy. Optics.) Eleventh edition. Volume II, second half. Edited by KARL WILHELM MEISSNER. Collaborators: Part I, E. BUCHWALD, M. CZERNY, E. GEHRCKE, G. HETTNER, H. KOHN, R. MINKOWSKI, W. PAULI; Part II, E. BACK, D. COSTER, B. GUDDEN, G. HERTZ, A. KRATZER, R. LADENBURG, L. MEITNER, F. PASCHEN, W. PAULI, R. W. POHL. Friedrich Vieweg und Sohn, Akt.-Ges., Braunschweig, Germany, 1929. Part I, xvi + 799 pp. 498 figs. Part II, xv + 684 pp. 223 figs. 15.5 X **24.5** cm. Price, unbound, R. M. 87.50; bound, R. M. 95.

Three years later than the half-volume on geometrical optics, appears this collective work upon physical optics and related subjects. The decease of Otto Lummer, the original editor, together with the amazing development of the field, provided formidable difficulties for the new editor and for the contributors, as the preface duly explains. In particular a helpful introduction to the new quantum mechanics and to wave mechanics, by Pauli, was included, but time was lacking for revision of other sections which could have been profitably handled from this standpoint. In many cases, however, pertinent references have been provided.

The first part of the half-volume deals with reflection, refraction, dispersion, polarization, the laws of radiation, photometry, spectroscopic and radiometric methods. The section on photometry, together with that on the aims and limitations of technical light production, is highly suggestive and replete with practical applications. Nearly all the other sections reflect the detachment of the pure scientist. The average chemist will seldom feel the need of additional theory, but he could justly protest upon finding rotation of the plane of polarization dismissed with the views of Fresnel and of Airy, plus a very brief list of references to later work.

The second part takes up the structure of various types of spectra, and modern interpretations of the same. Those who have struggled to extract from current physical literature, with its perversely variable notation, a fragmentary knowledge of such interpretations will find here intelligibility, compactness, adequacy, Gratitude should even overbalance exasperation when at the end of the volume, luminescence, photochemistry and photography are found all occupying the Procrustean bed of sixty pages.

Undeniably these two books, at moderate cost, can make good a deficiency which inexcusably exists in many a chemical library.

G. S. FORBES

Gmelins Handbuch der anorganischen Chemie. (**Gmelin's** Handbook of Inorganic Chemistry.) Edited by R. J. MEYER. Eighth edition. Iron. System number 59. Part **A,** Installment **1.** Issued by the Deutsche Chemische Gesellschaft. Verlag Chemie G. m. b. H., Corneliusstrasse **3,** Berlin W 10, Germany, 1929. 226 pp. 17 × 25 cm. Price, to subscribers, M. 26; singly, M. **33.**

Iron has been of such outstanding importance in human affairs since the earliest times that it is not surprising that in this comprehensive handbook two large volumes are to be devoted to this element. One volume (Part A) will contain the sections dealing with the history and occurrence of iron, the metal itself and its alloys; the other (Part B) will cover the compounds of iron. The whole will run to about 1600 pages, and will be published in separate installments of about 200 pages each. The publishers assure us that these will appear in rapid succession.

The first installment, now in hand, contains the sections on the history of iron, on its occurrence and on the preparation of pure iron. As an indication of the magnitude of the field to be covered it may be remarked that the section on the history of iron, occupying 60 pages, is exclusively and merely a tabulation of the literature of the subject. The section on the occurrence of iron (120 pages) discusses the subject both from a geological and a geographical point of view.

These volumes on iron will indeed be welcome. This element was never reached in the seventh edition of the Gmelin handbook and has not yet been reached by the treatises of Mellor or of Abegg.

An imposing array of collaborators has been secured. Those concerned in the preparation of this first installment were H. Ehrenberg, O. Meyer, E. Pietsch, P. Ramdohr and R. Wasmuth.

ARTHUR B. LAMB

Proceedings of the Seventh International Congress of Photography. Edited by W. Clark, T. Slater Price and B. V. Storr. W. Heffer and Sons, Ltd., Cambridge, England, 1929. xiii + 571 pp. Various papers illustrated. 15.5 × 24.5 cm. 25/-net.

On July 9–14, 1928, the Seventh International Congress of Photography met in London. The proceedings of this meeting together with the papers and discussions there presented are now published in full. The meeting was divided into three sections, Section 1 being further subdivided into four subsections: (la) Theoretical Aspects of Photography, in which sixteen papers were presented, ten papers were taken as read, and a report was made on the "Unit of Photographic Intensity." (lb and lc) Photographic Practice and Scientific Applications, in which seven papers were presented and eleven taken as read. (1d) Photo-engraving—ten papers were presented. Only one paper was presented, as a general lecture, in Section 2, "Pictorial Photography: The Relation of Technical Advance to Further Artistic Achievement." In Section 3, Bibliography, Record Photography, History, Patents, Copyrights *and* other Legal *Questions,* eight papers were taken as read and discussed.

To review each individual paper and the discussions which follow them is not possible in the space allotted here. Suffice it to say that the subjects dealt with cover almost every phase of photographic science and practice. "Probably few people reflect," said Mr. Renwick in his opening address, "on the vast changes which have taken place in the methods and in the applications of photography" since the first International Congress in 1899. Who can read these Proceedings, however, without realizing that tremendous strides have been made, and the very great importance of photography in our every-day life and its many connections and ramifications in the various fields of science?

Appendices are included giving the officers of the Congress, the organizing and other committees, regulations, and a list of members and associate members. The whole forms a compact and well arranged presentation of the Congress proceedings.

E. P. WIGHTMAN

Lumineszenz-Analyse im filtrierten ultravioletten Licht. (Analysis by Means of Luminescence in Filtered Ultraviolet Light.) By Professor Dr. P. W. DANCKWORTT, Hannover. Second, enlarged edition. Akademische Verlagsgesellschaft m. b. H., Leipzig, Germany, 1929. viii + 147 pp. 56 figs. 16 X 23.5 cm. Price, unbound, R. M. 8.40; bound, R. M. 9.50.

In his preface to the second edition the author emphasizes his continued self-restraint, evidenced by omission of all theoretical discussions. As a result, the thirty-two additional pages deal exclusively with new apparatus, methods and data. This estimate does not include new material replacing that which has become obsolete since July, 1928. No part of the book remains unchanged, but apparatus, organic compounds, oils and alkaloids receive the most attention. A detailed discussion of porphyrins is added to the biological section. The recording, by photographic methods, of ultraviolet fluorescence has now become important. Its possibilities are illustrated by exposures comparing various textiles and adhesives by reflected daylight, by visible fluorescence light and by ultraviolet fluorescence light. One hundred and twenty new references fortify the bibliography. In every respect the revision has been painstaking and successful.

G. S. FORBES

Die Korrosion, unter Berücksichtigung des Materialschutzes. Vol. I. General and Theoretical Part. (Corrosion, with a Consideration of the Protection of Materials.) By Professor Dr. O. KRÖHNKE, O., Professor Dr. E. MAASS and D. W. BECK. S. Hiizel, Königstrasse 2, Leipzig, Germany, 1929. viii + 208 pp. 43 figs. 15 × 22.5 cm. Price, unbound, M. 16; bound, M. 17.50.

This monograph is to consist of two volumes; the one now at hand, which discusses in general the theory of the corrosion of metals and the protective coatings of metals; and Volume II, which is to discuss in detail the corrosion of the most important technical metals and alloys.

The preparation of this monograph was prompted, according to the Preface, by the lack of such a treatise in the German language and by the inadequate treatment in the English and American treatises of the German literature on corrosion.

The first hundred pages deal with the mechanism of the dissolution of metals, with passivity and with the external causes of corrosion. The presentation is relatively clear, straightforward and non-mathematical. It is particularly valuable for its full discussion of the German investigations in this field.

The next thirty pages contain an account of metallic and non-metallic protective coatings. It is difficult to see how so cursory and superficial a treatment of this subject can be of value to anyone.

The final sixty pages are occupied with indexes and a bibliography.

The book is open to criticism in that while it mentions meticulously the investigators responsible for the various researches, it does not give direct references to their publications. There is, to be sure, the bibliography, but this has no general index, so it is all but impossible to look up the specific research referred to in the text.

ARTHUR B. LAMB

Statistical Mechanics. The Theory of the Properties of Matter in Equilibrium. By R. H. FOWLER, M.A., Fellow and Lecturer of Trinity College and Stokes Lecturer in Mathematics in the University of Cambridge. The University Press, Cambridge, England, 1929. Sole American Agents, The Macmillan Company, 60 Fifth Avenue, New York City. viii + 570 pp. 28 figs. 18.5 X 27 cm. Price, $10.50.

The volume contains a very clear and complete exposition of the equilibrium theory of Statistical Mechanics growing out of the author's study of the physical state of matter along the lines suggested by the announcement for the Adams Prize Essay for 1923.

Chemistry has hitherto been quite content to use thermodynamics as practically the sole basis for correlating its facts pertaining to the chemical equilibrium of substances. During the past two decades, however, there has been an increasing need of supplementing the purely thermodynamical treatment by the methods of the Kinetic or Statistical theory. It cannot, of course, be denied that in pre-quantum times there did not exist a sufficiently general theory adequate for the treatment of the somewhat complicated problems of chemical science. The development of the quantum theory has, however, already supplied, at least in principle, the elements needed to surmount many of the difficulties of the classical statistical theory. Professor Fowler in attempting a practically complete exposition of the theory under the trying conditions presented by the rapidly developing quantum theory, deserves special thanks from those devoted to chemistry. It is to be noted that the new quantum mechanics were established after the manuscript was completed but the changes introduced thereby are, on the whole, insignificant. The final chapter, though terse, indicates sufficiently (perhaps only for the present) the nature of the modifications imposed by the most recent position of the quantum theory.

There have been two earlier expositions of statistical theory published, those by Herzfeld and Smekal following Ehrenfest and Trkal's 1920 paper. Professor Darwin and the author some years ago (1922) developed a new and elegant method of treating statistical problems which has been employed in the present systematic treatment. The method avoids the usual indiscriminate use of Stirling's formula for factorials and, moreover, permits an examination of the average state of an assembly. To be sure the "average state" and "the most probable state" are the same, but the average energy of the assembly may be evaluated by the new method and the partition related to temperature without using Boltzmann's theory relating entropy to probability. The latter process has always been somewhat unsatisfactory, and unconvincing.

The average state is calculated by the use of the multinomial expansion theorem together with a theorem from complex variable theory. In the more general applications multiple complex integrals appear but no special difficulty is created on this account. The new mathematical method has the advantage of precision, power and rigor, and in dealing with the relation of statistical mechanics to thermodynamical principles sheds new light on the nature of entropy. Especially illuminating is the author's criticism of that much mistreated concept "thermodynamical probability" which in the hands of many has sometimes been woefully twisted out of the shape into which it was originally cast by Boltzmann.

The first and second chapters set out and discuss the ideas and mathematical methods which are to be employed in the presentation. There follows a succinct chapter on the heat capacity of gases in which the author takes care to indicate the provisional nature of the theory of the specific heat of gases. The theory has complete quantitative success only in the case of hydrogen.

Before the treatment of chemical dissociation, and evaporation, the theory of the properties of crystals is given. The Born theory of the solid state is sketched and a generous amount of comparison between deduction and experiment is shown in the case of the heat capacity for solids. The equation of state for solids is derived on the basis of Born's "lattice theory."

The chapter on dissociation and evaporation, which will be of particular interest to chemists, is necessarily rather difficult reading. The treatment in its essential aspects is based on the 1920 work of Ehrenfest and Trkal with the restriction of "fully excited" or "completely unexcited" degrees of freedom removed. This chapter also includes the application of the theory to the vapor pressure of crystals.

The discussion of the relation of the statistical equilibrium theory to thermodynamics constitutes one of the most ably written sections of this noteworthy book. The proof that the laws of thermodynamics hold true for the assemblies is carried out by the use of analogies in pretty much the same manner as adopted by Gibbs in his "Mementary Principles of Statistical Mechanics." In the course of the discussion the fundamental basis of the statistical theory is critically reviewed, giving evidence of the painstaking thought that has been given to the difficult question of "weight" (*a priori* probability). The section of this chapter on entropy and Boltzmann's probability hypothesis is particularly well written.

Nernst's heat theorem and related topics, which can only be discussed in detail from the point of view of statistical mechanics, is sketched in an all too brief chapter. The theorem of Nernst, as originally derived, is wholly empirical and certainly "proves too much." The statement of the theorem by Lewis and Randall is drawn with the proper reservations. The author points out, however, that the extra hypothesis required to obtain the theorem (identity of weights of the lowest quantum states of all condensed systems) may not be true, as evidenced by the case of hydrogen.

The theory for imperfect gases represents a brave attempt but scarcely carries the problem beyond the old status. The limitations of the statistical method and the nature of the difficulties emerge clear-cut and definite, which in itself is a notable achievement in a field where an extraordinary amount of illusory theory has been written. When the need of considering the potential energy due to long range forces (case of ions in solution, for example) becomes important, difficulties arise due to the fact that the relative coordinates of the molecules or ions are insufficient to define the effects on the distribution expression. The problem has assumed much immediate importance since the papers of Debye and Hiickel on ionic solutions. Professor Fowler's able discussion of the character of the theoretical pitfalls inherent in the latter theory will be all too brief for those interested in the properties of solutions. The further discussion of dilute solutions and comparisons with experiment are given in a later chapter.

Considerable space is given to the theory as worked out for assemblies of atoms, ions and electrons, a condition of matter at very high temperatures. The dissociation theory given earlier is revised here in order to introduce terms representing essentially corrections for the potential due to electrostatic forces. The theory is also compelled to give attention to many details of atomic structure in order to develop a plausible set of rules for assigning "weights." With these details settled the analysis proceeds to develop the partition functions and finally encounters the same difficulties that beset Debye and Hiickel in the case of ionic solutions.

The development of the theory is of great importance and is carried as far as seems reasonably possible in view of the difficulties, mathematical and physical, inherent for the moment in the general situation. Applications of the equations (involving, as the author indicates frankly, certain speculative approximations) are made to the problems of stellar atmospheres and interiors. The theoretical side of the problem, it may be emphasized, is of pronounced interest in chemistry.

The general theory of molecular interaction or collision precedes a statement of the theory of gaseous chemical reaction velocity and radiative processes. The book ends with an excellent chapter on statistical mechanics based on the new quantum theory (wave mechanics).

The author makes gracious acknowledgment of the assistance of an unusually large number of very able collaborators who have contributed generously to the sustained excellence of this scholarly work. The book is really a masterpiece of critically presented scientific theory.

FREDERICK G. KEYES

Handbuch der biologischen Arbeitsmethoden. (Handbook of Biological Methods.) Edited by Professor Dr EMIL ABDERHALDEN. Section I. Chemical Methods, Part 2, 2d Half. Number 2. Chemische Reaktionen organischer Körper im ultravioletten Licht und im Licht der Sonne. (Chemical Reactions of Organic Compounds in Ultraviolet Light and in Sunlight.) By FRANZ BACHÉR, Rostock. Number 3. Sulfonieren. (Sulfonation.) By JOSEF HALBBRKANN and FRITZ FRETWURST, Hamburg. Biologisch wichtige Reaktionen und Reagenzien. By EDUARD STRAUSS and KARL KOULEN, Frankfort-on-Main. Number 4. Darstellung metallorganischer Verbindungen. (Preparation of Organometallic Compounds.) By EMIL KLARMANN, Bloomfield, New Jersey. Urban and Schwarzenberg, Friedrichstrasse 105B, Berlin N 24, Germany, 1928, 1929. No. 2, 630 pp. 25 figs. No. 3, 180 pp. No. 4, 159 pp. 3 figs. 17.5 × 25.5 cm. Price, No. 2, R. M. 32; No. 3, R. M. 10; No. 4, R. M. 8.

Abderhalden's Manual of Biological Methods deals with so many and such diverse topics, fundamental as well as applied, is so ambitious in aim and so comprehensive in scope, that it ranks as a new phenomenon in scientific publication. In view of the great diversity of subjects and the number of collaborators—six hundred—it was to be expected that the various installments would be very dissimilar in character. They are. And they are also very unequal in quality.

The three installments that are reviewed here all belong to the sub-section dealing with general chemical methods. The earliest one—number 254—is, doubtless, the most extensive treatise on the photochemistry of organic compounds that is available. Beginning with excellent chapters on "the photochemical reaction," "experimental procedures," "reaction participants," and the treatment of the products of the reaction," it passes on to a survey of the behavior of all the various classes of organic compounds that have been exposed to ultraviolet light or to direct sunlight and ends with a special section in which all known cases are tabulated with respect to: substances exposed, source of the light, nature of the process and character of the products. While the author here and there hints that a process is especially interesting to the biochemist, the text would probably be exactly the same if he had prepared it especially for the organic chemist.

This installment is invaluable to anyone who is interested in, or has occasion to examine, the photochemical behavior of an organic compound. The survey is complete, including references to the original literature; the material is well organized, and the judgments are critical. As a part of a larger volume the number has no separate index, but a very detailed table of contents in a great measure makes up for the lack of it.

The other two installments under review deal with similar subjects—the one the preparation of sulfonic and sulfuric acids, the other the preparation of organometallic compounds. These installments are very unequal in quality. The author of number 287 discusses the principles underlying the various methods of sulfonation, explains why methods that give admirable results with one class of substances must be modified before they are applicable to other closely related classes, and cites abundant examples for illustration. The author of number 294 contents himself with transcripts of the various directions that are to be found in the literature for preparing metal organic compounds. This method of treatment may be useful to an occasional biochemist to whom the sources are not accessible; the organic chemist will prefer the more critical and comprehensive treatises that are available.

E. P. KOHLER

Die Kiinstlichen Harze. (Artificigl Resins.) By JOHANNES SCHEIBER, Dr. Phil., Professor at the University of Leipzig, and KURT SÄNDIG, Dr. phil. Wissenschaftliche Verlagsgesellschaft m. b. H., Stiittgart, Germany, 1929. xv + **376 pp.** *29* **figs.** 16.5 X 25 cm. Price, unbound, M. 26; bound, M. 28.

This book is divided into three parts—general, theoretical and special. The general part contains a discussion of the nature of the resinous state and the molecular conditions responsible for its existence. The theoretical part contains a systematic discussion of the types of compounds and the kinds of reactions which lead to resin formation, together with a consideration of such information as is available concerning the structures of the molecules present in resins and the mechanisms by which they are formed. The third part is concerned with commercial methods of preparation, the properties, uses and the methods of testing the most important types of artificial resins. The authors have carefully surveyed the voluminous literature of this difficult subject up to the middle of 1928. The book is provided with subject, author and patent indexes.

This monograph will be indispensable to chemists who are directly interested in artificial resins, and the theoretical part especially will be useful to all chemists who are interested in the broader field of natural and synthetic polymers of high molecular weight.

WALLACE H. CAROTHERS

Praktikum der Färberei und Druckerei. By Dr. KURT BRASS, Professor at the Technical Nigh School of Prague. Second, revised edition. Julius Springer, Linkstrasse 23–24, Berlin W 9, Germany, 1929. viii + 104 pp. 5 figs. 14 × 21 cm. Price, R. M. 5.25.

This little work by Dr. Brass is an excellent example of what a laboratory manual should be. It presupposes a reasonably good knowledge of what dyestuffs are, and how divided into groups according to their generally most prominent chemical character, though it seems as though one who did not possess this preparatory knowledge to any great extent might work his way into the art of dyeing, so skilfully is the book constructed, and with such accommodation to the student "who did know, but has forgotten for the time being." It is not a mere set of directions for getting a piece of fabric or a lot of material dyed to a certain color, but a distinctively scientific introductory manual for the use of a serious student taking up training in dyeing operations for the first time.

Introductory sections cover such matters as the description of the different textile fibers, and their determination and distinction, the various classes of dyestuffs from both the practical and the structural side, the general methods of dyeing—preparation of the material, the solution, the bath, the apparatus, etc.—and pass into the main portion of the work—general methods of dyeing and practical examples in detail under each group of dyestuffs, with examples of after-treatment, when such exist. The final section deals in the same full way with the operations of printing. Appended to the section on dyeing is a chapter on the different standard methods for examining the fastness of the dyed material toward the various influences which affect it—light, washing, chlorine, etc.

The book is well printed, with arrangement and styles of type calculated to make instant reference to a particular point easy. It is properly bound instead of wired, and so will stay open and flat without one's having to bend and stretch the pages, or weight down each side of the open book as it lies upon the work-bench or desk. We wish very much that laboratory manuals of equally high excellence in all points were available for other branches of laboratory work, whether in German or English.

FREDERICK S. BEATTIE

Lehrbuch der Seifenfabrikation. (Textbook of Soap Manufacture.) BY DR. J. DAVIDSOHN. Gebrüder Borntraeger, W 35 Schöneberger Ufer 12 a, Berlin, Germany, 1928. xxiv + 731 pp. 105 figs. 16 × 24.5 cm. Price, unbound, M. 36.

This book is intended as a textbook of soap manufacture, addressed both to the academic chemist and to the practical soap chemist, showing the relation between theory and practice. It treats of the raw materials and methods of testing them (160 pages), plant commonly used (40 pages), theory (*23* pages), practice of soap boiling (**124** pages), manufacture of each of seven main classes of soap (**236** pages), methods of testing and analysis (*30* pages), and the by-products, lyes and glycerine (*22* pages), with a brief Appendix devoted to statistics and governmental regulations.

The book describes German manufacturing usage but contains little or nothing that is new or original. It does not, of course, attempt to compete with standard reference works such as Ubbelohde–Goldschmidt or Hefter, and it will not be widely used by American readers who have access to such existing books in English as those of Lewkowitsch–Warburton, Webb or Lamborn. On the theoretical side the book is decidedly lacking, the author ignoring the work of several of the leading schools in Germany, not to mention those of other countries. On the other hand, the author's practical experience as a consultant is reflected in numerous details he gives as to methods of testing and analysis.

JAMES W. MCBAIN

Kraemer's Scientific and Applied Pharmacognosy. Third edition, revised by E. N. Gathercoal, morphology; E. B. Fischer, constituents; L. K. Darbaker, literature and index; E. L. Newcomb, editor-in-chief, supervision. John Wiley and Sons, Inc., 440 Fourth Ave., New York, 1928. 405 illustrations. xxxvii + 893 pp. 15.5 × 23.5 cm. Price, $7.50.

The book is "intended for the use of students in pharmacy, as a handbook for the pharmacists and as a reference book for botanists, chemists, food and drug analysts, and pharmacologists."

Kraemer's undertaking was an ambitious attempt toward a comprehensive standard work for this country.

The revisers have evidently given most attention to the morphological descriptions and the book will continue to be very helpful in that respect.

Authoritative information on applied pharmacognosy, occurrence and especially on adulteration, requires such an intimate contact with the industry and thorough knowledge of present field and trade conditions that equal perfection is very difficult to attain.

Considerable further revision, addition and deletion are needed to bring the information given up to date. The same general suggestion is made in connection with statements referring to chemical composition, identification and evaluation, if the book is to serve as a "hand and reference book."

Subject Index to Volume LI, 1929[1]

ABSORPTION (of rays), ultraviolet absorption of p-aminobenzoic esters in water soln. 484

Acetaldehyde, condensation of, with methylmalonic ester. 2535

Acetals, benzoinanilanilide and benzoin-*p*-tolyl-*p*-toluide as ammono benzoin, 269; comparison of tendencies of satd. and unsatd. aldehydes toward formation of cyclic, 611; action of metallic Na on brominated cyclic, 1509; methylation processes and tendency toward ring shift in glycerol cyclic. 3644

Acetamide, equil, in aq. soln. between $AcONH_4$, water and. 1106

Acetic acid, heat of diln. of, and its bearing on heat capacity and heat of neutralization, 712; heat of neutralization of, 737; velocity of sapon. of Me ester of, by NaOH at 25°, 1959; ketene from, 3614; analysis of mixts. of EtOH, AcOEt, H20 and, (correction). 3676

Acetoacetic acid, acetoacetic ester condensation. 3124

Acetone, heat capacities of isopropyl alc. and, from 16 to 298°K. and the corresponding entropies and free energies, 1145; equil. between hydrazine and. 3394

Acetoxymercuric chloride. 2589

Acetylene, kinetics of the polymerization of. 3470

Acids, polyhydric alc.-polybasic acid reaction, 509; ω-hydroxy aliphatic, 625, 3450; NCl_3 and unsatd., 937; ketonic decompn. of β-ketocarboxylic, 2098; some org., of sugar cane molasses, 2808; hydrolysis of HCN by. 3368

Acridine, synthesis of certain compds. of. 816

Activation, energy of, in synthesis of water with a Ag catalyst, 7; of O by electron impact. 2367

Activity, detn. of, of one substance from that of another by a cell with a liquid junction, 223; of molten alloys of Tl with Sn and with Pb, 462; influence of the H-ion, upon the stability of the hemocyanin of *Helix pomatia*. 550

Activity coefficients, of diacetone alc. in aq. salt solns., 984; of ions in very dil. MeOH solns., 1112; of $CdCl_2$ and $CdBr_2$, 2597; of electrolytes. . .,2622, 2632

Acyl groups, wandering of, in glycerol esters. 1601

Adsorbents, platinized Pt as. 2888

Adsorption, of $Ca(OH)_2$ by basic Ca phosphate and by $Ca_3(PO_4)_2$, 1097; by pure C from non-aq. binary systems, 1637, 1643; use of dichlorofluorescein as an, indicator for the argentometric titration of chlorides, 3273; exptl. tests of the Gibbs theorem. 3534

Air, effect on the potential of the $Hg\text{-}Hg_2SO_4$ electrode. 1752

Albumins, Elektrizität und, insbesondere des Zellplasmas (Pfeiffer, book review). 2846

Alcohols, inhibitive action of, on the oxidation of Na_2SO_3, 90; polyhydric alc.-polybasic acid reaction, 509; amino, 2262; promoter action with oxide catalysts for the decompn. of, 2449; reduction with, of cinnamaldehyde to β-phenylpropionaldehyde, 2589; mol. orientation and the partial vapor pressures of binary systems contg. an alc., 2660; regularities in the m. ps. of some cryst. derivs. of various aliphatic, 3424; action of thionyl chloride upon certain. 3665

Aldehydes, comparison of tendencies of satd. and unsatd., toward cyclic acetal formation, 611; mechanism of formation of β-aryl-β-amino fatty acids by the condensation of aromatic, with malonic acid and its derivs., 841; near infrared absorption spectra of some. 1384

6-Aldehydocoumarin, and dyes derived from it, (correction). 3677

Aldonic acids, improvements in the prepn. of. 2225

Alginic acid, from *Macrocystis pyrifera*. 1914

Alizarin, reaction of $(AcO)_2Hg$ and. 1951

Alkali metal alkyls, reaction with quaternary phosphonium halides. 3496

Alkaline earth germanates, gels of. 2029

Alkylamines. See *Amines*.

Alkyl bromides, alternating properties of normal. 1576

Alkyl halides, action of H_2SO_4 in the prepn. of certain, 225; relationship of the constitution of certain, to the formation of nitroparaffins and alkyl nitrites. 279

---

[1] This index was prepared in the Editorial Offices of Chemical *Abstracts* through the courtesy of Dr. E. J. Crane and under his direction.

Alkyl nitrites. relationship of the constitution of certain alkyl halides to the formation of 279

Alkylresorcinols. mercuration of 479

Alkyl sulfides. interaction of Hg salts and 2774

Alkylxanthines. synthesis of some 2245

Allomucic acid. prepn. of. and certain of its derivs 2167

Allyl alcohol. reactions of. over Al and Zn oxide catalysts 2430

Alumina. reactions of allyl alc. over. catalyst. 2430; thermochemistry of the compds. occurring in the system: $CaO-SiO_2-$ 2678

Aluminum. confirmatory test for. 1165; detn. in plants. 2721. 2964; in plant materials 2964

Aluminum chloride. catalytic activity of. 576; reactions of vinyl chloride and C_6H_6 in the presence of 2978

Amalgams. Ca. electrode in dil. aq. solns 1345

Amides. reaction of phthalyl chloride with 3651

Amines. formation of primary. from Grignard reagents and monochloroamine. 567; cleavage of diethyl α,α'-dibromoadipate by secondary amines, 599. 1536; modification of the Curtius synthesis of primary. 1202; identification of. 1272; phenyl and o-tolyl isothiocpanates as reagents for primary aromatic. 1909; reaction of BF_3 with NH_3 and alkyl, 2690; identification of—derivs. of tertiary 3638

Aminoacetal. prepn. of 3612

Amino acids. aniline in the prepn. of 2277

Amino alcohols 2262

p-Aminobenzoic acid. ultraviolet absorption of esters of. in water soln., 484; 1-alkyl-4-piperidyl esters of 922

Aminohydroxyphenylarsonic acid. derivs. of 527

Aminonaphthols. prepn. of 1766

o-Aminophenol. condensation of. and oxalic acid. 1243; acyl derivs. of 2761

2-Aminoresorcinol dimethyl ether. bromination of 524

Ammonia. thermal decompn. of. on Fe catalysts. 688; soly. in the gaseous phase. especially in the system: $NH_3(l)-NH_3(g)$, $H_2(g)$, $N_2(g)$, 1026; reduction of isoprene by Na—. 1293; chem. reactions of dried substances—P_2O_5 and. 2121; products obtained by the reducing action of metals upon salts in liquid. soln., 2127; reaction of BF_3 with. 2690; reaction of triphenylsilicane with Na in liquid. 3067; removal of. from the coordination sphere in complex compds 3520

Ammonium acetate. equil. in aq. soln. between acetamide, water and 1106

Ammonium chloride. vapor pressure and vapor d. of intensively dried 748

Ammonium molybdotellurates 171

Ammonobenzoin acetals. benzoinanilanilide and benzoin-p-tolyl-p-toluide as 269

Amyloses. disruption of the corn starch granule and its relation to the constituent. 294; characterization of certain starches and their 3431

Analysis. quant. gas. by high dispersion infra-red spectroscopy. 377; Anleitung zur Chem. Gesteinsanalyse (Jakob. book review). 955; Lumineszenz, im filtrierten ultravioletten Licht (Danckwortt. book review). 958. 3681; ceric sulfate in volumetric. 1128. 1449; Volumetric. Vol. I. Theoretical Principles of Volumetric (Kolthoff. Menzel. book review). 1615; Vol. II. Practical Volumetric (Kolthoff. Menzel, book review). 2591; Analytical Chemistry. Vol. II. Quant. (Treadwell. Hall. hook review). 2593; Photometric Chem. (Yoe. Kleinmann. book review). 2593; Theory and Technique of Quant. (Farnsworth, book review). 3173; adaptation of the diphenylcarbazide test for Hg to the scheme of qual 3351

Anesthetics. local. derived from 2-(β-hydroxyethyl)-piperidine, 915; new series of. —acylaniline derivs 2570

Anhydrofructose. isolation of a new 2197

Aniline. nitration of substituted. 505; action of bases on mercurated derivs. of. 894; double salts of. hydrohalides with metal halides. 1167; effect on cellulose triacetate, 1810; in the prepn. of amino acids. 2277; acyl derivs. of 2570

Anisotropic liquids. See ***Liquid*** crystals.

Anthracene (Houben, Pischer. book review) 1620

Anthraquinonedicarboxylic acids. mercuration of 856

Anthraquinones (Houben. Fischer. book review) 1620

Antimony (Mellor. book review). 1614; at. wt. of. from different sources. 1745;

estn. of minute amts. of. in As_2O_3, 2416; pptn. of Cu in the confirmatory test for 2758
Aphanizomenon flos aquae. mol. wt. of phycocyan from 3573
l-Arabinose, isolation from cholla gum 3441
Arsenic (Mellor. book review) 1614
Arsenic oxides. action of aromatic Grignard reagents on As_2O_3, 1558; prepn. of Sb-free As_2O_3 and the estn. of minute amts. of Sb in As_2O_3 2416
Arsine oxides. action of aromatic Grignard reagents on aryl- 3479
β-Aryl-β-aminoethane-α,α-dicarboxylic acids. synthesis of 847
β-Aryl-β-amino fatty acids. mechanism of formation of. by the condensation of aromatic aldehydes with malonic acid and its derivs. 841
Arylguanidines 476
Atmosphere, interpretation of the atm. absorption bands. 1436; isotope of O in. 3528
Atomic kernels, repulsion of. as a factor in org. rearrangements 3185
Atomic weights. 35th annual rept. of the Comm. on—detns. published during 1928 647
Atomistics. Principles of Modern (Gerlach. book review) 1953
Atoms. Atomstruktur und Atombindung (Stark. book review). 641; At. Structure as Modified by Oxidation and Reduction (Reynolds. book review). 958; optical rotation and dimensions of. 1820; Principles of Modern Atomistics and Exptl. Results of At. Investigation (Gerlach, book review). 1953; polarization of liquids 2051
Aurin, mercuration of 2782
Aurintricarboxylic acid. use for the colorimetric detn. of Al 2721
Azibenzil. pyrochem. decompn. of 3583
Azides. mechanism of the azide rearrangement 2436

BACILLUS. bactericidal action of certain octadecanoic acids toward B. *leprae* 1261
Bacteria. bacteriol. cond. culture cell and some of its application 166
Bactericidal action. of certain chloro and bromo derivs. of 2,4-dihydroxydiphenylmethane and .ethane. 605; of certain octadecanoic acids toward *B. leprae*, 1261; of diaryl-sulfide phenols 1526
Bananas. quant. changes in the chloroplast pigments in the peel of. during ripening 2439
Bandrowski's base. constitution of 1587
Barbituric acids. identification of alkyl-, 288; direct substitution on the N of 5,5-dialkyl- 316
Barium. crystal structure of 1709
Barium chloride. heat of diln. and sp heat of solns. of. 794; transference no. of. as a function of the concn., 1073; viscosity of aq. solns. of 2950
Barium oxide. system: $BaO–P_2O_5–H_2O$ at 25° 1091
Bases. action of. on certain mercurated anilines, 894; constitution of Randrowski's. 1587
Beckmann rearrangement. See *Rearrangements.*
Bence-Jones protein. mol. wt. of 3594
Benzaldehyde. pyrolysis of 1197
1,2-Benz-3,4-anthraquinone 3141
Benzene. oxidation of benzoyl-*o*-toluidine at a water. interface. 965; shift in the 1.14μ absorption band of some. derivs., 1750; reactions of vinyl chloride and. in the presence of $AlCl_3$ 2978
Benzeneazophenol. effect of position isomerism on the absorption spectra of Me derivs. of 1204
Benzene ring. orientation in the 524
Benzoic acid. γ-pyrrolidino- and γ-pyrrolinopropyl esters of. 887; l-alkyl-4-piperidyl esters of. 922; pyrolysis of benzyl ester of 1197
Benzoinanilanilide, as ammonobenzoin acetal 269
Benzoins, oxidation of. to diketones with I 2822
Benzoin-*p*-tolyl-*p*-toluide, as ammonobenzoin acetal 269
Benzophenoneanil. forced reaction with PhMgBr 2252
Benzoquinone. photochem. decompn. of. in H_2O and in alc 3549
Benzoxazoleguanidine 2522
Benzoylacetic acid. prepn. of ester of 3636
o-Benzoylbenzoic acid. dehydration of 310
Benzoyl-*o*-toluidine, oxidation of. at a C_6H_6–water interface 965
Benzyl alcohol. pyrolysis of benzoic acid ester of 1197
Benzylmagnesium chloride. formation of di-p-tolyl incidental to the prepn. of 1571

Biographies, of Edgar Fahs Smith, *Proc.* 55, 57; Das Buch der Grossen Chemiker (Bugge, book review).. 3171

Boron, studies relating to 2690
Boron trifluoride, reaction with NH_3 and alkylamines 2690
Brines. Industrial Development of Searles Lake (Teeple. book review) 2594
Bromide ion. preferential removal of, from the coördination sphere 3523
Bromides. detn. of chloride in 1065
Bromination. 2-aminoresorcinol dimethyl ether. 524; of pyridine. 863; of desylacetophenone 3591
Bromine. Budde effect in. 1395; potentiometric detn. of. in HBr solns., 1695; action on certain mixed ethers 1776
Bromoacetate ion. chem. kinetics in highly dil. soln.—thiosulfate ion and. in the presence of Na ion at 25°, 3341. (correction) 3678
p-Bromodiethylaniline, reaction of $(AcO)_2Hg$ with 1952
Bromoguaiacolcarbonate 3072
2-Bromopentane, pentene-2 from 3034
3-Bromopentane, pentene-2 from 3023
p-Bromophenyl-4-semicarbazide 3653
Bromotrimethylstannane. action of Zn on 2403
Budde effect. in Br and Cl 1395
Buffer systems. for the PH region of 5.2 to 6.8 1754
Burets. improved stopcock for gas analysis 2759
Butane. action of S on normal. 1566; characteristics of the non-explosive oxidation of. 1839; pyrolysis of. 3353; chem. effects of elec. discharge in 3655
2-Butenes, synthesis of the isomeric 2528
Butyl alcohol. dielec. polarization of 3312
Butylmagnesium bromide. prepn. of normal 1861

CADMIUM. pptn of Cu in the confirmatory test for 2758
Cadmium bromide. activity coeff. of. 2597; transference nos. of 2605
Cadmium chloride. activity coeff. of. 2597; transference nos. of 2605
Cadmium oxide. oxide cell of 194
Calcite. soly. in certain aq. solns. at 25° 2082
Calcium alloys. Ca amalgam electrode in dil. aq. solns 1345
Calcium aluminate. crystal structure of tri- 2283
Calcium carbonate. soly. in certain aq. solns. at 25° 2082
Calcium chloride. heat of diln. and sp. heat of solns. of. 794; two isomeric cryst. compds. of d-mannose with 2788
Calcium hydride. reduction reactions with 2936
Calcium hydroxide. adsorption by basic Ca phosphate and by $Ca_3(PO_4)_3$ 1097
Calcium oxide. See *Lime*.
Calcium phosphate, basic, and the adsorption of $Ca(OH)_2$ by basic, and by tri-Ca phosphate 1097
Calcium sulfate, soly. of, from 0 to 200° 360
Calcium tellurate, prepn. of H_2TeO_4 from 3229
Calcium tellurite, oxidation of, by heating 3229
Calculations, Problèmes et calculs de chimie générale (Hocart, book review) 1298
Calycanthine, isolation from *Meratia paecox* 1836
Capillaries, crit. temp. measurements on CO_2 in small 1360
Carbohydrates. reactions relating to, 302, 611, 620, 3115, 3641, 3644; micropotentiometric detn. of reducing 1356
Carbon, adsorption by pure, from non-aq. binary systems, 1637, 1643; indirect method of prepn. of org. mercuric derivs. and a method of linking C to C, (correction) 3676
Carbon compounds. (See also *Organic compounds.)* Electron displacement in, 248; heat of dissocn. of CH 2374
Carbon dioxide, simple app. for the detn. of, 222; crit. temp. measurements

on, in small capillaries, 1360; soly. of $MgCO_3$ in water at pressures of, up to 1 atm. 2093
Carbon monoxide, equil. between MeOH, H and 129
Carbon tetrachloride, intensively dried, 2948; transition temp. of, as a fixed point in thermometry 3517
Carbonyl compounds, action of the Grignard reagent on highly branched 1227
Carboxyl, replacement of, by Hg in certain 3-substituted phthalic acids 602
Carboxylic acids. See *Acids.*
Casein, rate of hydrolysis of, in acid solns. as measured by the formation of amino N 836
Catalysis, activity of $AlCl_3$, 576; effect of Ru salts on the reduction of $HClO_4$ by HBr, 786; decompn. of triarylmethyl carbonates in presence of Cu, 2157; in reduction of α-diketones and their derivs., 2163; basic, in the decompn. of diacetone alc. 3215
Catalysts, synthesis of water with a Ag--energy of activation and mechanism, 7; Cu, prepd. from pptd. hydroxide, 61, 187; thermal decompn. of NH_3 on Fe, 688; pyridine as, in production of dimethyl-a-naphthylamine, 1555; reactions of allyl alc. over Al and Zn oxide, 2430; promoter action with oxide, for the decompn. of alcs., 2449; effect of temp. on the reduction rate of furfural with the, from $PtO_2.H_2O$ 3384
Cellobiose, β-thiophenol-glycoside of, 3619; evidence concerning the ringed structure of β-thiophenol 3627
Cells, animal, Elektrizitat und Eiweisse, insbesondere des Zellplasmas (Pfeiffer, book review) 2846
Cells, electrolytic, bacteriol. cond. culture cell and some of its applications, 166; inexpensive pyrex cond. cell 2419
Cells, plant, isolation of xylan and cellulose from the cell walls of corn seedlings 2506
Cells, voltaic, oxide, of Cd, Cu, Sn and Pb, 194; detn. of the activity of one substance from that of another by a, with a liquid junction, 223; Messungen elektromotorischer Krafte galvanischer Ketten mit wasserigen Elektrolyten (Drucker, book review), 2280; polarization in standard, 2327; hysteresis in standard cells 2345
Cellulose, action of fatty acids on, 274; structure of, 1820; isolation from the cell walls of corn seedlings 2506
Cellulose triacetate, effect of aniline on tri- 1810; fractional pptn of, and some properties of the fractions 3095
Ceric ion, potentiometric study of the reaction between ferrocyanide ion and 1128
Ceric sulfate, as a volumetric oxidizing agent, 139, 149; prepn. and stability of solns. of, 149; applications in volumetric analysis, 1128, 1449; oxidation of H_2O_2 by 1449
Cesium, influence on the detection of K by Zr sulfate, 1062; at. wt. of, (correction). 3677
Chalcones, synthesis of some 1267
Charcoal, heat of adsorption of O on 2019
Chaulmoogric acid, new phenolic combinations obtained by coupling, with resorcinol, 1503; synthesis of, from hydnocarpic acid 1515
Chemical compounds, complex—removal of NH_3 from the coordination sphere 3520
Chemical constitution, relation between the absorption spectra and, of certain azo dyes, 1204; relations between, and taste of pungent principles, 1911; relations between rotatory power and, in the sugar group, 2225, 2788, 3619, 3627, 3631; effect of, of org. halides on their rate of reaction with inorg. halides 3409
Chemistry, Kurzes Lehrbuch der, in Natur und Wirtschaft (Matula, Oppenheimer, book review), 640; College (Gordon, book review), 954; Chem. Publications, their Nature and Use (Mellon, book review), 959; Pharmaceutical and Medical (Sadtler, et *al.*, book review), 962; Annual Survey of American (West, book review), 1296; Symbols and Formulas in (Caven, Cranston, book review), 1297; Problèmes et calculs de chimie générale (Hocart, book review), 1298; Origins and Growth of (Marsh, book review), 1613; Chem. Fachworterbuch für wissenschaft Technik, Industrie und Handel (Mayer, book review), 1614; A Comprehensive Treatise on Inorg. and Theoretical (Mellor, book review), 1614; Collection of Czechoslovak Chem. Communications (Votoček, Heyrovský, book review), 1953; Leçons sur la Chimie Générale (Dubrisay, book review), 1953; Guide to the Literature of (Crane, Patterson, book review), 1956; Introductory Theoretical (Cartledge, book review), 2843; modern concepts in physics and their relation to 2847

Chemists. Das Buch der grossen (Bugge, book review).......................... 3171
Chloride ion. conductance and transference no. of the. in mixts. of NaCl and KCl. 2671
Chlorides. detn. in bromides. 1065; adsorption indicator for the argentometric titration of... 3273
Chlorination. of phenylbutadiene. 2496; induced. of $C_2H_4Cl_2$—effect of O upon the reaction between C_2H_4 and Cl.. 3082
Chlorine. Budde effect in. 1395; effect of O upon the reaction between C_2H_4 and. 3082
Chloroacetic acids. reaction with Zn... 852
Chloroamine, formation of primary amines from Grignard reagents and......... 567
Chlorophyll series. studies in... 3668
Chloroplasts. quant. changes in the pigments in the peel of bananas during ripening...2439
γ-Chloropropyl ketimines, formation of pyrrolines from 1174
5-Chlorovanillin. Schiff bases derived from.................................. 2586
Cholesterol. action of thionyl chloride upon................................ 3665
Choline. phosphoric acid ester derivs. of.................................... 953
Cholla gum. compn. of... 3441
Chromic acid. action upon some gossypol derivs.............................. 1475
Chromic ion. reduction of permanganate ion by. in acid soln.................. 345
Chromium. detn. in the presence of Mn. Fe and V.............................. 139
Cinnamaldehyde. reduction with alcs. of. to β-phenylpropionaldehyde........... 2589
Cinnamic acids, mechanism of Knoevenagel's synthesis of...................... 847
Cinnamylidene glycerols. isomeric... 620
Circulator. brine. for cooling condensers.................................... 475
Claisen ester condensation. with Et thiolacetate............................. 1567
Coal. Gesammelte Abhandlungen zur Kenntnis der (Fischer. book review)...... 2844
Cobalt. equil. in the system: $Co–H_2O–CoO–H_2$—free energy changes for the reaction $CoO + Hz = Co + H_2O$ and the reaction $Co + {}^1/_2O_2 = CoO$ ... 3249
Cobalt. oxide. equil. in the system: $Co–H_2O–CaO–H_2–$, —free energy changes for the reaction $CoO + H_2 = Co + H_2O$ and the reaction $Co + {}^1/_2O_2 = CoO$.. 3249
Cocaine. polarized light and. decompn... 808
Colloidal state. L'État Colloidal et l'Industrie (Kopaczewski. book review)..... 961
Colloid Chemistry (Svedberg. Tiselius, book review).......................... 3175
Colloids. conductance-diffusion method for studying the coagulation of colloidal Fe_2O_3, 1154; germanate gels of the alk. earths. 2029; Dispersoidanalyse (Hahn. bookreview).. 3516
Color. dissocn. and. of free radicals... 1163
Columbium (Mellor, book review). 1614; fusion of rare metal ores—detn. of..... 122
Combustion. Lectures on (Priestley, Maclean, book review).................. 3678
Compressibility. velocity of sound in some org. liquids and their............. 759
Condensation. general theory of. polymers.................................... 2548
Condensers. brine circulator for cooling..................................... 475
Condition equation. for gaseous mixts—application to mixts. of CH_4 and N...... 19
Conductivity. electric. diffusion-. method for studying the coagulation of colloidal Fe_2O_3, 1154; temp.-conductance curves of solid salts. 1331; measurement of the. of electrolytes—improvements in the oscillator and detector. 2407; inexpensive pyrex cond. cell. 2419; of the chloride ion in mixts. of NaCl and KCl, 2671; abs. measurement of the surface. near the boundary of optically polished glass and solns. of KCl.. 3294
Cooling. brine circulator for. condensers..................................... 475
Coordination sphere. removal of NH_3 from. in complex compds., 3520; preferential removal of bromide ion from the...................................3523
Copper. catalysts prepd. from pptd. hydroxide. 61. 187; at. wt. of. from the Lake Superior region and from Chile. 400; as a standard in iodimetry. 1299; single potential of the. electrode. 1315; catalytic decompn. of triarylmethyl carbonates in the presence of. 2157; pptn. of. in the confirmatory tests for Cd and Sb.. 2758
Copper oxides. oxide cells of. 194; heat capacities at low temps. of........... 215
Corn. chem. compn. of seedlings—isolttion of xylan and cellulose from the cell walls. 2506; chem. decompn. of. seedlings—isolation of a dextrin similar to the trihexosan obtained by the thermal depolymerization of potato starch...... 2516
Corn cobs. destructive distn. of lignin from................................. 2420
Corn starch. disruption of granule of. and its relation to the constituent amyloses. 294
Corona. chem. effects of semi-. discharge in gaseous hydrocarbons............. 2811

Corrosion (Kröhnke, Maass, Beck. book review). 3681; of Metals (I) General Theory (Palmaer, book review) 3172
Corrosive systems. modified Pirani gage for use in 804
Creatinine. new derivs. of 3074
Cresol red. use of. in acid solns 1458
Crotonic acid. oxidation of 228
Crystals. Physics of (Joffe. book review). 318; principles detg. the structure of complex ionic. 1010; single. of Ag 1134
Crystal structure. of Ba. 1709; of tricalcium aluminate. 2283; of m-iodobenzoic acid 2880
Curtius synthesis. modification of. of primary amines 1202
Cyanides. detn. in small amts 1171
p-Cyanobenzoic acid. ionization const. of 2718
Cyclobutane. new synthesis of. derivs 1536
Cyclobutane acids. synthesis of 614
Cyclohexanol. and the 3rd law of thermodynamics 1400
Cyclopropyl ketimines, formation of pyrrolines from 1174
Cyclose. from redwood 3139
p-Cymene, studies 3079. 3135
p-Cymylhydrazine-2, and derivs 3135
2-*p*-Cymyl-4-semicarbazide, and certain derivs 3079
Cytosine. test for thymine and 5-methylcytosine in the presence of 1237

DECAMETHYLSTANNOBUTANE 2403
Decolorizing agents. Anorg. und Org. (Singer. book review) 2595
Density. vapor. of intensively dried NH_4Cl, 748; detg. vapor ds. at room temps., 1165; of certain binary mixts 2825
Density bulbs. vacuum contraction of 2042
Desylacetophenone. bromination of 3591
Detonation. effect of $PbEt_4$ and the relation of oxidation to engine 2213
Dextrin. isolation from corn seedlings of a. similar to the trihexosan obtained by the thermal depolymerization of potato starch 2516
Diacetone alcohol. activity coeff. of. in aq. solns., 984; basic catalysis in the decompn. of 3215
3.3'-Diaminodimesityl. resolution of 630
Diaminohydroxyphenylarsonic acid. derivs. of 527
Diaryl sulfides. germicidal activity of diaryl-sulfide phenols 1526
α,α'-Dibromoadipic acid. cleavage of diethyl ester of. by secondary amines . . . 599, 1536
2.5-Dibromonitrobenzene. derivs. of 2539
Dichloroamine 2112
Dichloroethanes. solubilities of. 2362; induced chlorination of 3082
Dichlorofluorescein. use of. as an adsorption indicator for the argentometric titration of chlorides 3273
Dichloropropanes. solubilities of 2362
Dichromate. kinetics of the oxidation of iodide ion by acid. solns. in presence of a neutral salt 1973
Dictionary. Chem., für wissenschaft Technik, Industrie und Handel (Mayer. book review) 1614
Dicyanic acid 1806
Diffusion. conductance-. method for studying the coagulation of colloidal Fe_2O_3 . . 1154
Difurylethylene 1270
2.4-Dihydroxydiphenylethane. prepn. of certain chloro and bromo derivs. of. and their germicidal action 605
2.4-Dihydroxydiphenylmethane. prepn. of certain chloro and bromo derivs. of. and their germicidal action 605
4-(3.4-Dihydroxyphenyl)-thiazoles. synthesis of 1815
Diketones. See Ketones.
Diketopiperazine. new derivs. of 3074
Dimethylethylacetaldehyde. 1246. (correction) 3677
Dimethylethylacetic acid. esters of 1950
Dimethylketazine. hydrolysis of 3394
Dimethyl-a-naphthylamine. pyridine as catalyst in production of 1555
Dimethyloctadiene 1294
β,β-Dinaphthyl sulfide, as a by-product in the prepn. of β-naphthoic nitrile 2277

β,β-Dinaphthylsulfone, reduction with NaCN.......... 2277
Dinitrothiophene.......... 2147
Diolefins, aliphatic.......... 2266
Diphenic acid series, studies in.......... 583
Diphenyl compounds, stereoisomerism of.......... 630
α,β-Diphenylglutaric acids, isomeric.......... 2833
Diphenyl lead dichloride, prepn. of.......... 3112
Diphenylmethane, some thiophene analogs of, compds.......... 2143
Diphenyl oxide, some alkoxy derivs, of.......... 3447
Diphenyltetra-*tert.*-butylethynylethane, sym.......... 932
Distillation apparatus, automatic cut-off device for a gas fired lab. Hg.......... 3349
Di-*p*-tolyl, formation of, incidental to the prepn. of benzylmagnesium chloride.......... 1571
Dixanthyls, dissocn. into free radicals of substituted.......... 1925
Dried substances, chem. reactions of, 2121; intensively dried CCl_4.......... 2948
Dühring's rule, vapor pressures of related compds.—application of, 116; app. for testing, for corresponding b. ps.......... 3262
Durene, f. p. diagram of mixts. of isodurene and.......... 3001
Dyeing, Praktikum der (Brass, book review).......... 3687
Dyes, relation between the absorption spectra and chem. constitution of certain azo, 1204; leuco bases of a new class of, contg, pyrimidine rings, 1274; mercuration of some triphenylmethane, 2782; cleavage of azo, by means of sulfites, 2986, 3483; 6-aldehydocoumarin and, derived from it, (correction).......... 3677

EDESTIN, mol. wt of.......... 2170
Electric discharge, O_3 formation in, at pressures below 3 mm., 30; chem. effects of semi-corona discharge in gaseous hydrocarbons, 2811; chem. effects of. in butane.......... 3655
Electricity (Gerlach, book review), 1953; und Eiweisse, insbesondere des Zellplasmas (Pfeiffer, book review).......... 2846
Electric moments, some applications of, to electronic theories of valence.......... 2380
Electrodes, oxidation-reduction potentials—the ferric-ferrous, 382; simple reference, for potentiometric titrations, 471; single potential of the Cu, 1315; Ca amalgam, in dil. aq. solns., 1345; potential of inert, in solns. of H_3SO_3, 1409; single potential of the Ni, 1429; effect of air on the potential of the Hg_2SO_4 electrode, 1752; PbO_2-$PbSO_4$ electrode, 2009; AgCl, 2901; measurement of e.m.f. in dil. aq. solns.—Pb, 2905; PH measurement with the glass, and vacuum tube potentiometer, 3266; normal potential of the I-iodide, (correction).......... 3677
Electrolysis, of metallo-org. compds.......... 638
Electrolytes, Uber Losungs- und Verdünnungswärmen einiger starker (Lange, book review), 642; thermochem. behavior of weak, 740; Messungen elektromotorischer Krafte galvanischer Ketten mit wasserigen (Drucker, book review), 2280; measurements of the conductance of, 2407; activity coeffs. of, 2622, 2632; viscosity of aq. solns. of strong, with special reference to $BaCl_2$.......... 2950
Electromotive force. See ***Potential, electric.***
Electrons, displacement in C compds., 248; activation of O by electron impact.......... 2366
Electron theory, some applications of elec. moments to, of valence, 2380; electronic interpretation of oxidation and reduction.......... 2391
Elements, Atlas der letzten Linien der wichtigsten (Löwe, book review).......... 641
Emulsification, by high frequency sound waves.......... 1724
Emulsions, stability, area per mol. in the interfacial film, distribution of sizes and the oriented wedge theory, 1674; Theory of, and their Tech. Treatment (Clayton, book review).......... 2845
Energy (Gerlach, book review), 1953; of activation in synthesis of water with a Ag catalyst, 7; heat capacity of MeOH from 16 to 298°K., and the corresponding free, 180; heat capacities of ethyl and hexyl alcs. from 16 to 298°K., and the corresponding free, 779; heat capacities of isopropyl alc. and acetone from 16 to 298°K., and the corresponding free, 1145; free, of 19 org. compds., 1969; heat capacity of toluene from 14 to 298°K., and the free, 2738; free, changes for the reaction $CoO + H_2 = Co + H_2O$ and the reaction $Co + {}^1/_2O_2 = CoO$, 3249; iodide, I, triiodide equil. and the free, of formation of AgI, (correction), 3676; Lehre von der strahlenden Energie (Meissner, *et al.*, book review).......... 3679
Engines, effect of $PbEt_4$ and the relation of oxidation to detonation in.......... 2213

Entropy. of MeOH, 180; of ethyl and hexyl alcs., 779; of isopropyl alc. and acetone. 1145; of HI from spectroscopic data. 1441; of 19 org. compds., 1969; theoretical evaluation of the. of aq ions. 2293; of O from spectroscopic data. 2300: of toluene. 2738; of NO from spectroscopic data. 3194

Enzymes. Enzyme Actions and Properties (Waldschmidt-Leitz, book review). . . 2282

Ephedrine. synthesis of. and structurally similar compds. 580, 1906, 2269

Epichlorohydrin. reaction of EtMgBr with. 3390

Equation of state. See *Condition equation*.

Equilibrium. between methanol. CO and H. 129; in aq. soln. between $AcONH_4$, acetamide and water. 1106; between the carbonates and bicarbonates of Na and K in aq. soln. at 25°, 1626; in the system: $Co-H_2O-CoO-H_2$, 3249; between hydrazine and acetone. 3394; iodide. I. tri-iodide. and the free energy of formation of AgI, (correction). 3676; Statistical Mechanics—The Theory of the Properties of Matter in (Fowler. book review). 3652

Esters. near infra-red absorption spectra of some. 1384; polymerization and ring formation—poly-. 2560

Ethers. near infra-red absorption spectra of some. 1384; action of Br on certain mixed. 1776

Ethyl acetate. analysis of mixts. of EtOH, AcOH, H_2O and. (correction). 3676

Ethyl alcohol. heat capacities of. from 16 to 298°K. and the corresponding entropies and free energies, 779: dielec. polarization of. 3312; analysis of mixts. of AcOEt, AcOH, H_2O and. (correction). 3676

Ethylene. detn. of. 1463; reactions of H. the satd. hydrocarbons and. under the influence of excited Hg. 2922; effect of O upon the reaction between. and Cl. . 3082

Ethylene oxide. kinetic studies on derivs. of. 428; thermal decompn. of gaseous. . 2706

Ethylfluorescein. dibromo and monomercury derivs. 1773

Ethyl iodide. dielec. polarization of. 3312

Ethylmagnesium bromide. reaction with epichlorohydrin. 3390

3-Ethyl-2-pentene. addn. of HCl to. 248

Extraction. micro. method. 474

FATTY ACIDS. action on cellulose. 274; mechanism of formation of β-aryl-β-amino. by the condensation of aromatic aldehydes with malonic acid and its derivs.. 841; assocd. with rice starch. 2185

Ferrocyanide ion. potentiometric study of the reaction between ceric ion and. . . . 1128

Films. area per mol. in the interfacial. in emulsions. 1674

Fluoresceins. absorption spectra of some halogenated. 1769

Formulas. in Chemistry (Caven. Cranston. book review). 1297

Fossilized wood. compn. of. 1187

Fructose. condensation of glucose and. 1279; coupling of glucose and γ-,. 3609

Furazan oxides. structure of. 1592

Furfural, reaction with liquid H_2S, 803; effect of temp. on the reduction rate of. with the catalyst from $PtO_2 \cdot H_2O$. 3384

α-Furfuryl chloride. and its derivs. 3131

d-GALACTOSE, isolation from cholla gum. 3441

Gallic acids. prepn. of some methylated. 2193

Gallium. rapid concn. of Ge and. contained in ZnO carrying them. 1459

Gases. equation of state for gaseous mixts., 19; quant. analysis of. by high dispersion infra-red spectroscopy. 377; stopcock in which contamination by grease is prevented and its application to a problem in gas technique. 2132; Technische (Muhlert. Drews. book review). 2280; heat of absorption of. by solids. 2608; movement of. around electrically heated wires. 2741; improved stopcock for gas analysis burets. 2759; mechanism of homogeneous reactions of. 3190; app. for detn. of the sorption of. by solids at elevated temps. 3560

Germanates. germanate gels of the alk. earths. 2029

Germane. halogen substitution products of mono. 2321

Germanium. 1151. 2321. rapid concn. of Ga and. contained in ZnO carrying them. 1459

Germanium dichloride. 1151

Gibbs. J. Willard. Collected Works of (Longley, Van Name. book review). 639

Gibbs adsorption theorem. exptl. tests of. 3534

Glass. PH measurement with the electrode and vacuum tube potentiometer 3266

Glucic acid. properties and chem. constitution of. 830

β-Glucochloralose, structure of. 519

Glucosazone, new conditions for the formation of.......... 3161

d-Glucose, condensation of, and fructose, 1279; acetate of the free aldehyde form of, 2188; coupling of, and γ-fructose, 3609; β-thiophenol-glycoside of....... 3619

Glycerides, synthetic,—prepn, and m. ps. of, of known constitution. 866

Glycerol, (Lawrie, book review), 962; reaction with phthalic anhydride, 509; wandering of acyl groups in, esters, 1601; synthesis and properties of hydroxy alkylidene derivs. of.......... 3115

Glycerol cyclic acetals, ring migration in, 3641; methylation processes and tendency toward ring shift in.......... 3644

Glycerol-dichlorohydrin, "non-existence" of a migratory Me group in conversion of, into glycerol monomethyl ether.......... 1943

Glycerol methyl ether, prepn., properties and identification of β-, 302; "non-existence" of a migratory Me group in the conversion of glycerol-dichlorohydrininto mono-.......... 1943

Glycols (Lawrie, book review), 362; synthesis and properties of hydroxy aikylidene.......... 3115

Glycosides, β-thiophenol-, of glucose, xylose, lactose and cellobiose.......... 3619

Gold, soly. in Hg.......... 1703

Gossypol, action of chromic acid upon some derivs. of, 1475; action of boiling HI as used in the Zeisel method upon, and some of its derivs........... 1479

Grignard reaction, reaction between aromatic nitro compds. and organo-Mg halides, 821; forced reaction of phenyl isocyanate, phenyl isothiocyanate and benzophenoneanil with PhMgBr, 2252; possible interchange of radicals on heating a mixt. of an $R'X$ and an RMgX compd........... 2840

Grignard reagents. (See also Magnesium compound.) Formation of primary amines from, and monochloroamine, 567; action of, on highly branched carbonyl compds , 1227; action of aromatic, on As_2O_3, 1558; probable preliminary formation of free radicals in the prepn. of, 1571; yields of some, 1576; effect of rapid addn. of halide on the yields of some, 1583; constitution and the dissocn. of, 3149; coupling org. radicals by means of the, 3375; reducing action of aliphatic, 3378; prepn. of Hg diphenyl by use of, 3387; action on arylarsine oxides.......... 3479

Guaiacol carbonate, estn. of.......... 3072

Guanidine, monoaryl derivs........... 476, 2522

Gum arabic, compn. of.......... 1519

Gums, compn. of cholla gum.......... 3441

HALIDES, e.m.fs. of uni-univalent, in concd. aq. solns., 416; double salts of aniline hydrohalides with, 1167; reaction of org. Hg compds. with org., 1491; effect of rapid addn. of, on the yields of some Griguard reagents, 1583; systems formed by certain tetra-, 2910; effect of structure of org., on their rate of reaction with inorg. halides.......... 3409

Halogenation, series arrangement of org. groups as detd. by, of mixed stannanes. . 3065

Heat, capacity of MeOH, 180; capacities at low temps of the oxides of Sn and Pb, 207; capacities at low temps. of "ferrous oxide," magnetite, Cu_2O and CuO, 215; capacities in aq. salt solns., 323; heats of diln. of NaOH, AcOH and AcONa, and their bearing on, capacities, 712; capacities of HCl solns., 727; capacities of ethyl and hexyl alcs., 779; capacities of isopropyl alc. and acetone, 1145; capacity of HI, 1441; partial molal capacities and relative partial molal, functions in solns. of molten metals, 1711; thermal data on org. compds., 1969; capacity of 0,2300; capacity of toluene, 2738; capacity of NO.......... 3194

Heat of adsorption, of O on charcoal, 2019; of gases by solids.......... 2608

Heat of dilution, Über, einiger starker Elektrolyte (Lange, book review), 642; of NaOH, AcOH and AcONa, and their bearing of heat capacities and heat of neutralization, 712; of HCl solns., 727; of Ba and Ca chloride solns....... 794

Heat of dissociation, of the mols., CH, NH, OH and HF.......... 2374

Heat of neutralization, heats of diln. of NaOH, AcOH and AcONa, and their bearing on, 712; of AcOH.......... 737

Heat of solution, Über, einiger starker Elektrolyte (Lange, book review), 642; of CaO in HCl.......... 2678

Heat of vaporization, of HI, 1441; of 0, 2300; of NO.......... 3194

Helix *pomatia*, influence of the H-ion activity upon the stability of the hemocyanin of........... 550

Hemimellitic acid. mercuration of 3352

Hemocyanin, mol. wt. of. of *Limulus polyphemus*. 539; influence of the H-ion activity upon the stability of. of *Helix pomatia* 550

Heptanes, prepn. and properties of the isomeric. 1483. 1540; action of S on normal. 1566

Δ-1,5-Hexadiene, prepn. and some phys. consts of 2266

Hexamethylbenzene, m. p. of 3001

Hexyl alcohol. heat capacities of. from 16 to 298°K. and the corresponding entropies and free energies 779

Hexylfluorescein, dibromo and monomercury derivs 1773

Homologous series. investigation of surface tension consts. in. from the point of view of surface orientation 153

Hormones. und Innere Sekretion (Laquer, book review) 322

Hydantoin-1-acetic acid. synthesis of polypeptide-hydantoins from 1784

Hydantoins, synthesis of polypeptide. from 2-thiohydantoin-3-acetic acid. 254; synthesis of polypeptide. from hydantoin-1-acetic acid 1784

Hydnocarpic acid. synthesis of chaulmoogric acid from 1515

Hydrazine. photosensitized and photochem. decompn. of. 2059; auto-oxidation of, 2744; studies on—equil. between acetone and 3394

Hydrazine hydrate. concn. of solns. of 265

Hydrazoic acid. thermal decompn. of 2134

Hydriodic acid. heat capacity of. and its heat of vaporization—the entropy from spectroscopic data. 1441; action of boiling. as used in the Zeisel method upon gossypol and some of its derivs.. 1479; prepn. of anhyd 2389

Hydrobromic acid. catalytic effect of Ru salts on the reduction of $HClO_4$ by. 786; potentiometric detn. of Br, octavalent and quadrivalent Os in. solns 1695

Hydrocarbons. prepn. of Zn alkyls and their use in the synthesis of. 594; chem. effects of semi-corona discharge in gaseous. 2811; reactions of C_2H_4, H and the satd., under the influence of excited Hg, 2922; pyrolysis of. 3353. 3561; direct introduction of S into aromatic 3428

Hydrochloric acid. addn. to 3-ethyl-2-pentene, 248; heats of diln. and heat capacities of solns. of. 727; photosynthesis of. at low pressures. 770; heat of soln. of CaO in 2678

Hydrocyanic acid. hydrolysis by acids 3368

Hydrofluoric acid. heat of dissocn. of 2374

Hydrogen. equil. between MeOH, CO and. 129; soly. in the gaseous phase. especially in the system: NH_3 (l)–NH_3 (g), H_2 (g). N_2 (g). 1026; rate of recombination of at., 1985; reactions of C_2H_4, the satd. hydrocarbons and. under the influence of excited Hg, 2922; 1,6-addn. of. to unsatd. 1,4-diketones, 3008; equil. in the system: Co–H_2O–CoO–H_2–, —free energy change for the reaction $CoO + H_2 = Co + H_2O$, 3249; permeability of hot metals to. 3278; some reactions of at 3286

Hydrogenation. competitive 3418

Hydrogen compounds. heats of dissocn. of CH, NH. OH and HF 2374

Hydrogen-ion concentration. Na maleate—a buffer for the PH region of 5.2 to 6.8, 1754; measurement of. in unbuffered solns., 2888; PH measurement with the glass electrode and vacuum tube potentiometer 3266

Hydrogen ions. influence of activity of. upon the stability of the hemocyanin of *Helix pomatia*, 550; Detn. of (Clark. book review) 1618

Hydrogen peroxide. properties of pure. 674; absorption spectrum and decompn. of. by light. 1371; oxidation of. by ceric sulfate 1449

Hydrogen sulfide. reactions in liquid 803, 1453

Hydrolysis. rate of. of casein in acid solns. as measured by the formation of amino N 836

3-Hydroxy-6-aminotoluene, reactions of, and of certain of its derivs 900

4-Hydroxyazobenzene-5-carboxylic acid. cleavage of 3483

Hydroxybenzoic acids. identification of *o*-. m- and *p*- 1947

ω-Hydroxybutyric acid. prepn. of the Na salt of 260

w-Hydroxycaproic acid. prepn. of the Na salt of 260

w-Hydroxydecanoic acid. conversion to chain poly-intermol. esters and to a dimeric cyclic ester 3450

2-(β-Hydroxyethyl)-piperidine, local anesthetics derived from 915

Hydroxyhydroquinolsulfonephthalein. and derivs 1466

3-Hydroxyisocrotonic acid. oxidation of the lactone of 228

6-Hydroxypiperonylic acid. synthesis of. and incidental compds 532

Hydroxytriarylcarbinols, tautomerism of 1889
ω-Hydroxyvaleric acid. prepn. of the Na salt of 260
Hysteresis. in standard cells 2345

ILLINIUM, extu. of com. rare-earth residues with a view to the concn. of 2107
Indicators. use of crcsol red in acid solns., 1458; use of dichlorofluorescein as an adsorption. for the argentometric titration of chlorides 3273
Inorganic chemistry. (Matula. book review). 640; Gmelins Handbuch der (Meyer. book review). 1296. 1297. 3679; A Comprehensive Treatise on (Mellor. book review) 1614
Interferometer, sonic 759
Inulin, mol. structure of 2197
Iodide, I-triiodide equil. and the free energy of formation of AgI, (correction), 3676; normal potential of the I-, electrode 3677
Iodide ion, oxidation of, by persulfate ion, 1034, 1048; kinetics of the oxidation of. by acid dichromate solns. in presence of a neutral salt 1973
Iodimetry, studies in,—Cu as a standard in 1299; studies in,—$KMnO_4$ as a standard in 1307
Iodine. detn of traces of,—in vegetables, 894; oxidation of benzoins to diketones with. 2822; potato as an index of, distribution, 2942; -iodide-triiodide equil. and the free energy of formation of AgI, (correction), 3676; normal potential of the. -iodide electrode. (correction) 3677
Iodine cyanide, reactivity of, in different org solvents 1999
m-Iodobenzoic acid. crystal structure of 2880
Ionization, electrolytic, consts. of H_3PO_4, 1004; and color of free radicals 1163
Ions, electrolytic, principles detg. the structure of complex ionic crystals, 1010; activity coeffs. of, in very dil. MeOH solns., 1112; modification of the moving boundary method for the detn. of transference nos., 1656; theoretical evaluation of the entropies of aq., 2293; complex—preferential removal of bromide ion from the coordination sphere 3523
Iron (Meyer, book review). 3679; thermal decompn. of NH_3 on, catalysts, 688; detn. of ferrous, in silicate rocks, 2117; iodometric detn. of 2682
Iron compounds. ferrous nitroso compds 1323
Iron oxides, heat capacities at low temps. of "ferrous oxide" and magnetite, 215; conductance-diffusion method for studying the coagulation of colloidal Fe_2O_3 1154
Iron salts, oxidation-reduction potentials—the ferric-ferrous electrode 382
Iron sulfide, system: Na_2S– 3241
Isoamylcyclopentane, synthesis of 2591
Isobutane, characteristics of the non-explosive oxidation of, 1839; pyrolysis of .. 3353
Isobutylene, pyrolysis of 3561
Isocrotonic acid, oxidation of 228
Isocyanic acid, action of Ph ester of, on urethans, ureas and thioureas, 2220; forced reaction of Ph ester of, with PhMgBr 2252
Isodurene, f. p. diagram of mixts. of durene and 3001
Isoelectric point, of cryst. urease 1255
Isomerism, effect of position, on the absorption spectra of Me derivs. of benzeneazophenol, 1204; tautomerism of hydroxytriaryl-carbinols 1889
Isoprene, reduction by $Na–NH_3$ 1293
Isopropyl acetate. vapor pressure of 1623
Isopropyl alcohol, heat capacities of acetone and, from 16 to 298°K. and the corresponding entropies and free energies 1145
Isosucrose, synthesis of an, 1279; conversion of sucrose into 3609
Isothiocyanic acid. phenyl and o-tolyl esters of, as reagents for primary aromatic amines, 1909; forced reaction of Ph ester of, with PhMgBr 2252
Isotopes, Ra and its (Erbacher, book review), 1297; of O 1436, 3528
Isouracil, and its derivs.—methods of synthesis 873

JACOBSEN REACTION. with pentamethylbenzene 2994

KETENE, from AcOH 3614
Keto acids. ketonic decompn. of β-ketocarboxylic acid 2098
Ketones. near infra-red absorption spectra of some. 1384; ketonic decompn. of β-ketocarboxylic acids. 2098; catalytic reduction of α-di-, and their derivs.,

2163; reduction of aromatic 1,2-di-, by the binary system MgI_2 (or $MgBr_2$) + Mg, 2238; new synthesis of o-di-, 2269; new condensations of, with phenols, 2426; oxidation of benzoins to di-, with I, 2822; 1,6-addn. of H to unsatd. 1,4-di- 3008

Ketyl radicals, $R_2(IMgO)C$-, formation of 2229, (correction) 3677

Ketyls, structure of metal—Schmidlin formula 1856

Kinetics, of the oxidation of iodide ion by acid dichromate solns. in presence of a neutral salt 1973

LACTIC ACID, photochem. decompn. of 3165

Lactones, oxidation of the, of 3-hydroxyisocrotonic acid 228

Lactose, β-thiophenol-glycoside of 3619

Lactoside, evidence concerning the ringed structure of β-thiophenol 3627

Lanthanum iodate, soly. in aq. salt solns., and the principle of sp. interaction 2632

Laws, vapor pressures of related compds.—application of Duhring's, 116; Das, der chem. Massenwirkung (Lorenz, book review), 957; cyclohexanol and the 3rd law of thermodynamics, 1400; app. for testing Duhring's, for corresponding b. ps 3262

Lead, indirect detn, of, 1449; measurement of e.m.f. in dil. aq. solns.—Pb electrodes 2905

Lead alloys, activities of molten Tl- 462

Lead compounds, prepn. of Ph_3PbCl and Ph_2PbCl_2 3112

Lead mercaptides, prepn., properties and reactions of 3649

Lead oxides, oxide cells of PbO_2, 194; heat capacities at low temps. of, 207; PbO_2-$PbSO_4$ electrode, 2009; oxidation of SeO_2 and of TeO_2 with PbO_2 3225

Lead phosphates, solubilities of 997

Lead sulfate, PbO_2-, electrode 2009

Lead tetraethyl, effect of, and the relation of oxidation to engine detonation 2213

Leuco bases, of a new class of dyestuffs contg. pyrimidine rings 1274

Light, polarized, and cocaine decompn., 808; absorption spectrum and decompn. of H_2O_2 by, 1371; photosensitized and photochem. decompn. of hydrazine, 2059; uranyl sulfate as sensitizer for the decompn. of oxalic and malonic acids by, 2731; decompn. of lactic acid by, 3165; decompn, of benzoquinone in H_2O and in alc. by, 3549; Chem. Reaktionen org. Korper im ultravioletten Licht und im Licht der Sonne (Bachér, book review), ... 3685

Light, ultraviolet, absorption of *p*-aminobenzoic esters in water soln., 484; Lumineszenz-Analyse im filtrierten (Danckwortt), 958, 3681; Chem. Reaktionen org. Korper im (Bachér, book review) 3685

Lignin, chemistry of,—destructive distn. of, from corn cobs 2420

Lime, thermochemistry of the compds. occurring in the system: Al_2O_3, SiO_2 and,—heat of soln. of, in HCl 2678

Limulus polyphemus, mol. wt. of the hemocyanin of 539

Liquid crystals, (Oseen, book review) 3174

Liquids, sonic studies of the phys. properties of, velocity of sound in some org., and their compressibilities, 759; dielec. polarization of, 1736, 2051, 3312, 3330; detn. of the soly. of slightly sol., in H_2O 2362

Literature, Chem. Publications, Their Nature and Use (Mellon, book review), 959; Guide to the, of Chemistry (Crane, Patterson, book review) 1956

Lithium, influence on the detection of K by Zr sulfate 1062

Luminescence, Lumineszenz-Analyse im filtrierten ultravioletten Licht (Danckwortt, book review) 958, 3681

MACROCYSTIS PYRIFERA, alginic acid from 1914

Magnesium, reduction of phenyl naphthyl ketones by the binary system: MgI_2 +, 306; influence on the detection of K by Zr sulfate, 1062; sensitive test for, 1456; reduction of aromatic 1,2-diketones by the binary system MgI_2 (or $MgBr_2$) +. 2238

Magnesium bromide, reduction of aromatic 1,2-diketones by the binary system Mg + ... 2238

Magnesium carbonate, soly in water at 25° and pressures of CO_2 up to 1 atm... 2093

Magnesium compounds. (See also Grignard reagents.) Reaction between aromatic nitro compds. and organo-Mg halides, 821; improvements in the method for the prepn. of Hg dialkyls from organo-Mg halides, 928; formation of di-*p*-tolyl incidental to the prepn. of benzylmagnesium chloride, 1571; prepn. of normal-butylmagnesium bromide, 1861; forced reaction of Ph isocyanate, Ph isothiocyanate and benzo-phenoneanil with PhMgBr, 2252; possible interchange of radicals on heating a mixt. of an R'X and an RMgX compd., 2840; reaction of EtMgBr with epichlorohydrin, 3390; some rearrangement reactions of a-naphthylmethylmagnesium chloride, 3475; prepn. of CPh_3MgCl, 3493; reaction between sulfochlorides and organomagnesiumhalides.... 3501

Magnesium iodide, reduction of phenyl naphthyl ketones by the binary system: Mg +, 306; reduction of aromatic 1,2-diketones by the binary system Mg 4. 2238

Magnetite, heat capacities at low temps of.... 215

Maleic acid, Na salt of, a buffer for the *P*H region of 5.2 to 6.8.... 1754

Maleic anhydride, oxidation of.... 228

Malic acid, effect of heat on.... 1276

Malonic acid, photochem. decompn. of, both in the presence and absence of uranyl sulfate, 80; mechanism of formation of β-aryl-β-amino fatty acids by the condensation of aromatic aldehydes with, and its derivs., 841; condensation of acetaldehyde with Me ester of, 2535; uranyl sulfate as sensitizer for the photochem. decompn. of.... 2731

Maltose, halogeno-hepta-acetyl derivs. of.... 1820

Maltoside, prepn. and structure of β-thiophenol, and of its hepta-acetate.... 3631

Manganese, electrometric titration of, by the Volhard method.... 39

d-Mannose, two isomeric cryst. compds. of, with $CaCl_2$.... 2788

Manometers, modified Pirani gage for use in corrosive systems, 804; new differential.... 2378

Mass action, Das Gesetz der (Lorenz, book review).... 957

Matter, (Gerlach, book review), 1953; Statistical Mechanics—The Theory of the Properties of, in Equil. (Fowler, book review).... 3682

Measurement, (Block, book review).... 1616

Mechanics, Statistical (Fowler, book review).... 3682

Medicine, Pharmaceutical and Medical Chemistry (Sadtler, *et al.*, book review).... 962

Melibiose, halogeno-hepta-acetyl derivs. of.... 1820

Melting points, regularities in, of some cryst. derivs. of various aliphatic alcs.... 3424

Menthol, esters, of the 2-nitro-4-carboxyphenylarsonic and phenylarsenious acids. 1462

Meratia praecox, isolation of calycanthine from.... 1836

Mercaptans, derivs. for the identification of.... 3661

Mercaptides, prepn., properties and reactions of Pb.... 3649

Mercuration, of resorcinol and some alkylresorcinols, 479; of anthraquinonedicarboxylic acids, 856; of naphthalic acids, 1831; in alk. soln., 2196; of aurin and attempts to mercurate some other triphenylmethane dyes, 2782; of hemimellitic acid, 3352; of naphthoic acids.... 3363

Mercury, replacement of carboxyl by, in certain 3-substituted phthalic acids, 602; soly. of **Au** in, 1703; effect of air on the potential of the Hg_2SO_4-, electrode, 1752; measuring the partial pressure of, at room temps., 2398; reactions of C_2H_4, H and the satd. hydrocarbons under the influence of excited, 2922; automatic cut-off device for a gas-fired lab., still, 3349; adaptation of the diphenylcarbazide test for, to the scheme of qual. analysis.... 3351

Mercury acetate, reaction of alizarin and $(AcO)_2Hg$, 1951; reaction of $(AcO)_2Hg$ with p-bromodiethylaniline.... 1952

Mercury chloride, thermal reaction between $K_2C_2O_4$ and $HgCl_2$.... 1716

Mercury compounds, Hg derivs. of halogen compds. of resorcinsulfonephthalein, 804; action of bases on certain mercurated anilines, 894; reaction of org., with org. halides, 1491; derivs. of ethyl- and hexylfluorescein, 1773; acetoxymercuric chloride, 2589; mercurated terephthalic acid, 2785; indirect method of prepn. of org. mercuric derivs. and a method of linking C to C, (correction). 3676

Mercury dialkyls, improvements in the method for the prepn. of, from organo Mg halides.... 928

Mercury di-isobutyl, factors involved in the prepn. of, by the reaction of Frankland and Duppa.... 291

Mercury diphenyl, prepn. of, by use of the Grignard reagent.... 3387

Mercury salts, interaction of alkyl sulfides and.... 2774

Mercury sulfate, effect of air on the potential of the Hg_2SO_4 electrode.... 1752

Mesityl oxide, condensation products of monohydroxybenzenes and.... 2426

Metals. (See also ***Corrosion***) Partial molal heat capacities and relative partial molal heat functions in solns. of molten, 1711; products obtained by the

reducing action of. upon salts in liquid NH_3 soln., 2127; permeability of hot, to H 3278
Methane, equation of state for mixts. of N and 19
Methanesulfonamides 1272
Methanol, equil. between CO, H and 129; heat capacity of, and the corresponding entropy and free energy, 180; activity coeffs of ions in very dil.. solns 1112
Methoxyl group, semi-micro Zeisel method for 1479
Methyl acetate, velocity of sapon. of, by NaOH at 25° 1959
Methyl alcohol. See *Methanol.*
Methylation, with methyl bromide, 2535; processes and tendency toward ring shift in glycerol cyclic acetals 3644
Methyl azide, thermal decompn. of 2134
Methyl bromide, methylations with 2535
Methylcytosine, synthesis of a new 1590
5-Methylcytosine, new test for, in the presence of uracil and cytosine, 1237; examn. of yeast nucleic acid for 1779
Methyl fluoride. purification of 377
Methyl-2-hexanol-2. decompn. of 3675
3-Methyl-4-hydroxyazobenzene-5-carboxylic acid, cleavage of 3483
Methyl isopropyl di-imide, prepn. of, 918; thermal decompn. of—a homogeneous unimol. reaction 2134
Methyl isopropyl hydrazine, prepn. of sym 918
α-Methylxyloside, structure of 2443
Milksickness, tremetol, the compd. that produces 3617
Mixtures, mol. orientation and the partial vapor pressures of binary, 2646, 2660; vapor pressures ds. and refractive indices of certain binary 2825
Molasses, some org. acids of sugar cane 2808
Molecular asymmetry, proof of. in optically active phenylaminoacetic acid 2796
Molecules, investigation of surface tension consts. in an homologous series from the point of view of surface orientation, 153; area per mol. in the interfacial film of emulsions, 1674; Polar (Debye, book review), 2279; heat of dissocn. of CH, NH, OH and HF, 2374; mol. orientation and the partial vapor pressure of binary mixts , 2646, 2660. mol. structure of the tungstosilicates and related compds., 2868; isomeric octyl alcs. and orientation of 3330
Molybdenum, grav. method for micro. detn. of 376
Muscle, sepn. of the sol. proteins of rabbit 880

NAPHTHALIC ACIDS. mercuration of 1831
Naphthoic acids. mercuration of 3363
β-Naphthoic nitrile, β,β-dinaphthyl sulfide as a by-product in the prepn of 2277
α-Naphthoxyl group. effect in org. halides on their rate of reaction with inorg. halides 3409
β-Naphthoxyl group. effect in org. halides on their rate of reaction with inorg. halides 3409
α-Naphthylmethylmagnesium chloride. some rearrangement reactions of 3475
Nephelometry, (Yoe, Kleinmann, book review) 2593
Nesquehonite, soly. in water at 25° and pressures of CO_2 up to 1 atm 2093
Nickel. single potential of the. electrode. 1429; comparison of the at. wts. of terrestrial and meteoric 1729
Nickel bromide. analysis of 1729
Nitration. of substituted anilines 505
Nitriles, salts of aromatic 262
p-Nitrobenzylidene glycerol 3641
Nitrobiuret, dearrangement of. and its application in synthesis 1801
2-Nitro-4-carboxyphenylarsonic acid. menthyl esters of 1462
Nitro compounds. reaction between aromatic. and organo-Mg halides 821
Nitrogen. equation of state for mixts. of CH_4 and. 19; active—influence of surface on the afterglows in O and. 654; active.—mutual effect of O and. on their respective afterglows. 665; soly. in the gaseous phase. especially in the system: NH_3 (l) –NH_3 (g). H_2 (g). N_2 (g), 1026; ozonization and interaction of O with. under α-radiation 2751
Nitrogen compounds. heat of dissocn. of NH 2374
Nitrogen oxides. mechanism of the photochem. decompn. of N_2O_5, 109; ds. of coexisting liquid and gaseous N_2O, 2002; absorption spectrum of N_2O_5 and its

method of decompn., **3190;** heat capacity of NO from **14°K.** to the b. p. and the heat of vaporization—vapor pressures of solid and liquid phases—entropy from spectroscopic data.................................... **3194**

Nitrogen trichloride, and unsatd. acids.................................... **937**

Nitroparaffins, relationship of the constitution of certain alkyl halides to the formation of.. **279**

Nitroso compounds, ferrous.. **1323**

Nitrothiophene.. **2147**

Nitrourea, dearrangement of, and its application in synthesis.................. **1790**

Norpinic acid.. **614**

Nucleic acid, examn. of yeast, for 5-methylcytosine.......................... **1779**

OCTADECANOIC ACIDS, prepn. of certain, and their bactericidal action toward *B. leprae*.. **1261**

Octanes, the vapor phase oxidation of isomeric—normal octane, **1875;** vapor phase oxidation of isomeric—octanes with branched chains, **2203;** vapor phase oxidation of isomeric—effect of $PbEt_4$ and the relation of oxidation to engine detonation.. **2213**

Octanesultone... **2969**

Octyl alcohol, dielec. polarization of, **3312;** isomers of, and mol orientation.... **3330**

Onium compounds, basis for the physiol. activity of.......................... **953**

Optical rotation, and at. dimension, **1820;** relations between, and structure in the sugar group, **2225, 2788, 3619, 3627, 3631;** x-ray investigations of optically active compds... **2796**

Optics (Meissner, *et al.*, book review)...................................... **3679**

Ores, fusion of rare metal ores.. **122**

Organic chemistry (Oppenheimer, book review), **320, 640;** Gesammelte Abhandlungen (Kehrmann, book review), **644;** Elementary (Adkins, McElvain, book review), **645;** A Brief Introductory Course (Conant, book review), **1619;** Richter-Anschiitz Chemie der Kohlenstoffverbindungen oder, Vol. **1.** Aliphatic Compds. Oscillator, improvements in.. **2407**

Osmium, potentiometric detn. of octavalent, **175;** potentiometric detn. of octavalent and quadrivalent, in HBr soln.................................... 1695

Oxalic acid, condensation of o-aminophenol and, **1243;** uranyl sulfate as sensitizer for the photochem. decompn. of.. **2731**

Oxidation, inhibitive action of alcs. on, of Na_2SO_3, **90;** of unsatd. compds.—of crotonic and isocrotonic acids, of the lactone of 3-hydroxyisocrotonic acid and of maleic anhydride, **228;** promoted by ultrasonic radiation, **370;** reduction potentials, **382;** of tribromoresorcinol, **493;** At. structure as Modified by (Reynolds, book review), **958;** of benzoyl-*o*-toluidine at a C_6H_6-water interface, 965; of iodide ion by persulfate ion, **1034, 1048;** of H_2O_2 by ceric sulfate, **1449;** characteristics of the non-explosive, of propane and the butanes, **1839;** mechanism of the vapor phase, of isomeric octanes, **1875;** kinetics of the, of iodide ion by acid dichromate solns. in presence of a neutral salt, **1973:** vapor phase, of isomeric octanes—octanes with branched chains, **2203;** vapor phase, of isomeric octanes—effect of $PbEt_4$ and the relation of, to engine detonation, **2213;** electronic interpretation of, **2391;** auto-, of hydrazine, **2744;** of benzoins to diketones with I, **2822;** of SeO_2 and of TeO_2 with PbO_2, **3225;** of Ca tellurite by heating.......................... **3229**

Oxides, promoter action with oxide catalysts for the decompn. of alcs.......... **2449**

Oxidizing agents, ceric sulfate as a volumetric, **139;** H_3SO_3 as................ **1409**

Oxygen, influence of surface on the afterglows in N and, **654;** mutual effect of N

and. on their respective afterglows. 665; isotopes of. 1436. 3528; heat of adsorption of. on charcoal. 2019; heat capacity of. from 12°K. to its b. p. and its heat of vaporization—entropy from spectroscopic data. 2300; activation of. by electron impact. 2367; ozonization and interaction of. with N under α-radiation. 2751; effect upon the reaction between C_2H_4 and Cl. 3082; free energy changes for the reaction $Co + {}^1/_2O_2 = CoO$ 3249
Oxygen compounds. heat of dissocn. of OH 2374
Ozone. formation of. in the elec. discharge at pressures below 3 mm 30
Ozonization. and interaction of O with N under or-radiation 2751
Ozonizer, lab 2676

PARAFFINS. m. ps. of normal 2487
Particles. Dispersoidanalyse—DieMethoden der Teilchengrossenbestimmung und ihre theoretischen Griindlagen (Hahn. book review) 3516
Patents. Chem. Patents Index (Worden, book review) 960
Pentamethylbenzene. Jacobsen reaction with. 2994; m. p. of 3001
2-Pentanol. pentene-2 from 3034
3-Pentanol. pentene-2 from 3023
2-Pentene. from 3-hromopentane and from 3-pentanol. 3023; from 2-bromopentane and from 2-pentanol. 3034; isomers of—ultraviolet absorption spectra. 3041. (correction) 3677
Perchloric acid. catalytic effect of Ru salts on the reduction of. by HBr 786
Permanganate ion. reduction by chromic ion in acid soln 345
Permeability. of hot metals to H 3278
Persulfate ion. oxidation of iodide ion by 1034, 1048
Petroleum. new. by-product. octanesultone 2969
Pharmaceutical Chemistry (Sadtler. *et al.*. book review) 962
Pharmacognosy. Kraemer's Scientific and Applied (Newcomb. *et al.*, book review). 3688
Phenanthrene. sulfonation of 2460, 2471
1.2-Phenanthrenequinone 1896
3.4-Phenanthrenequinone. derivs. of 940
Phenanthrenequinones. related to alizarin and purpurin, 1935; reduction potentialsofvarious 3101
Phenolhalophthaleins. 1865. (correction) 3677
Phenols. new phenolic combinations obtained by coupling chaulmoogric acid with resorcinol. 1503; germicidal activity of diaryl-sulfide, 1526; new condensations of ketones with 2426
Phenylacetonitrile. K 262
Phenylaminoacetic acid. proof of mol. asymmetry in optically active 2796
N-Phenyl-β-aminopropionamide-4-arsonic acid. and related compds 3158
Phenylarsenious acid. menthyl esters of 1462
Phenylation. Sn tetraphenyl as reagent for 1922
Phenyl bromide. vapor phase hydrolysis of 2489
Phenylbutadiene. chlorination of 2496
Phenyl chloride. vapor phase hydrolysis of 2489
Phenyl ether. synthesis in the di-. series—prepn. of some simple derivs 2581
or-Phenylguanidine 476
β-Phenylisobutylmethyl ketone. and its derivs 2542
or-Phenylisovalerianic acid. synthesis of 2542
β-Phenylisovalerianic acid, synthesis of 2542
Phenylmagnesium bromide. forced reaction of phenyl isocyanate. phenyl isothiocyanate and benzophenone-anil with 2252
Phenyl naphthyl ketones. reduction of. by the binary svstem: $Mg + MgI_2$ 306
Phenylnitromethane 2151
Phenylpropanolamine 2262
β-Phenylpropionaldehyde, reduction with alcs. of cinnamaldehyde to 2589
Phenylthio group. effect in org. halides on their rate of reaction with inorg. halides. 3409
Phosphenyl chloride. prepn. of 1406
Phosphonium halides. reaction of quaternary. with alkali metal alkyls 3496
Phosphoric acid. ester derivs. of choline—basis for the physiol. activity of -onium compds.. 953; ionization consts. of 1004
Phosphorus pentoxide. systems: $SrO–H_2O–$, and $BaO–H_2O–$, at 25°, 1091; chem. reactions of dried substances—NH_3 and 2121
Photochemistry. photochem. decompn. of malonic acid both in the presence and

absence of uranyl sulfate. 80; mechanism of the photochem. decompn. of N_2O_5, 109; uranyl sulfate as sensitizer for the photochem. decompn. of oxalic and malonic acids 2731
Photography. Proceedings of the Seventh Intern. Congress of (Clark. Price. Storr. book review) 3680
Photosynthesis. of HCl at low pressures 770
Phthaleins. absorption spectra of some, of the trihydroxyphenols. 1755
Phthalic acids. replacement of carboxyl by Hg in certain 3-substituted 602
Phthalic anhydride, reaction with glycerol 509
Phthalyl chloride. reaction with amides 3651
Phycocyan, mol. wts of. from *Porphyra tenera* and from *Aphanizomenon flos aquae* 3573
Phycoerythrin, mol. wt. of. from *Porphyratenera* 3573
Physical chemistry. Physikalisch-chem. Praktikumsaufgaben (Eucken, Suhrmann. book review). 956; A Comprehensive Treatise on Inorg. and Theoretical Chemistry (Mellor, book review). 1614; Introductory (Cartledge. book review). 2843; Elements of (Bell. Gross. book review) 3175
Physics. Introduction to Modern (Richtmyer, book review). 1955; modern concepts in. and their relation to chemistry. 2847; Müller-Pouillets Lehrbnch der (Meissner. *et al.*, book review) 3679
Pigments. plant. quant changes in the chloroplast. in the peal of bananas during ripening 2439
Pinacols. halogen-substituted aromatic. 2229. (correction) 3677
Pinene. apparent racemization of 3464
Piperidine. derivs 922
Pirani gage. modified. for use in corrosive systems 804
Plants. detn. of Al in 2721, 2964
Platinum. adsorbent properties of platinized 2888
Platinum oxide. effect of temp. on the reduction rate of furfural with the catalyst from $PtO_2 \cdot H_2O$ 3384
Polarization. electric. dielec., of liquids. 1736. 3312. 3330; dielec., of liquids—at. polarization. 2051; in standard cells 2327
Polymerization. studies on ring formation and. 2548. 2560; kinetics of. of C_2H_2.. 3470
Polymers. general theory of condensation 2548
Polymethylbenzenes 2994, 3001
Polypeptide hydantoins. synthesis of. from 2-thiol~ydantoin-3-aceticacid. 254; synthesis of. from hydantoin-1-acetic acid 1784
Polysaccharides. reactions relating to 302, 611. 620. 3115. 3641. 3644
Porphyra tenera, mol. wts. of phycocyan and of phycoerythrin from 3573
Potassium. influence of Li, Rb. Cs and Mg on the detection of. by Zr sulfate. 1062; detection of traces of. in the presence of Zr 3238
Potassium carbonates. equil. between the carbonates and bicarbonates of Na and K in aq. soln. at 25°, 1626; system: $NaHCO_3$–H_2O–$KHCO_3$. 2352; system: K_2SO_4, H_2O and. at 25° 2396
Potassium chloride. conductance and transference no of the chloride in mixts. of NaCl and. 2671; abs. measurements of the surface cond. near the boundary of optically polished glass and solns. of 3294
Potassium halides. temp.-conductance curves of solid 1331
Potassium hydroxide. sp. heat of solns. of 707
Potassium oxalate. thermal reaction between $HgCl_2$ and 1716
Potassium permanganate. as a standard in iodimetry 1307
Potassium sulfate. system: K_2CO_3, water and. at 25° 2396
Potato. as an index of I distribution 2942
Potential. electric. oxidation-reduction. 382; of uni-univalent halides in concd. aq. solns., 416; single. of the Cu electrode. 1315; of inert electrodes in solns. of H_2SO_3, 1409; single. of the Ni electrode. 1429; effect of air on the. of the Hg-Hg_2SO_4 electrode. 1752; Messungen elektromotorischer Krafte galvanischer Ketten mit wasserigen Elektrolyten (Drucker. book review). 2280; measurement of. in dil. aq. solns., 2905; reduction. of various phenanthrenequinones. 3101; normal. of the I-iodide electrode. (correction) 3677
Potentiometer. vacuum tube. for rapid e.m.f. measurements. 1; PH measurement with the glass electrode and vacuum tube 3266
Praseodymium oxides. higher 42
Prehnitene. prepn. of 2994
Pressure gage. See *Manometers*.

Printing, Praktikum der (Brass, book review) 3687
Promoter action, with oxide catalysts for the decompn. of alcs. 2449
Propane, characteristics of the non-explosive oxidation of 1839
Proteins, thermodynamic activities of, 696; sepn. of sol., of rabbit muscle, 880; mol. wt. of Bence-Jones 3594
Protoplasm, Elektrizitat und Eiweisse, insbesondere des Zellplasmas (Pfeiffer, book review) 2846
Pungent principles, relations between constitution and taste of 1911
Pyrethrum, flowers—detn. of the active principles 3054
Pyridine, bromination of, 863; as catalyst in production of dimethyl-α-naphthylamine 1555
Pyrimidines 873, 1237, 1274, 1779
Pyrolysis, of benzaldehyde and of benzyl benzoate, 1197; of C compds. (Hurd, book review), 2596; of hydrocarbons 3353, 3561
γ-Pyrrolidinopropyl alcohol, benzoate of 887
Pyrrolines, formation of, from γ-chloropropyl and cyclopropyl ketimines 1174
γ-Pyrrolinopropyl alcohol, benzoate of 887

RACEMIZATION, apparent, of pinene 3464
Radiation, test of the radiation hypothesis, 54; oxidations promoted by ultrasonic, 370; hypothesis of chem. reaction, 974; Lehre von der strahlenden Energie (Meissner, *et al*, book review) 3679
Radicals, dissocn. and color of free, 1163; probable preliminary formation of free, in the prepn. of Grignard reagents, 1571; dissocn. into free, of substituted dixanthyls—rate of dissocn., 1925; possible interchange of, on heating a mixt. of an R'X and an RMgX compd., 2840; Beckmann rearrangement in the presence of free, 2982; series arrangement of org., as detd. by the halogenation of mixed stannanes, 3065; coupling org. by means of the Grignard reagent 3375
Radium, and its Isotopes (Erbacher, book review) 1297
Rare earths, 42; extn. of com. rare-earth residues with a view to the concn. of Il. 2107
α-Rays, ozonization and interaction of O with N under α-radiation 2751
Rays, Rontgen, investigations of optically active compds. 2796
Reactions, kinetic studies on ethylene oxides, 428; polyhydric alc.-polybasic acid, 509; in liquid H_2S, 803; radiation hypothesis of, 974; with very large apparent temp. coeffs, 1136; in liquid H_2S with org. compds., 1453; mechanism of org., 1601, 1943; chem., of dried substances, 2121; thermal decompn. of methyl isopropyl di-imide, a homogeneous unimol., 2134; principle of sp. interaction in mixts. of high valence electrolytes, 2622; solubilities of La and thallous iodates in aq. salt solns. and the principle of sp. interaction, 2632; mechanism of homogeneous gas, 3190; Chem. org. Korper im ultravioletten Licht und im Licht der Sonne—Biologisch wichtige, (Bachér, Strauss, Koulen, bookreview) 3685
Reaction velocity, oxidation of benzoyl-*o*-toluidine at a C_6H_6-water interface with special reference to the temp. coeff. of the, 965; oxidation of iodide ion by persulfate ion—effect of tri-iodide ion formation on, 1034; oxidation of iodide ion by persulfate ion—effect of removing the products of the reaction on, 1048; chem. kinetics in highly dil. soln, 3341, (correction), 3678; effect of structure of org. halides on their, with inorg. halides 3409
Reactivity, of atoms and groups in org. compds. 2825
Reagents, Biologisch wichtige (Strauss, Koulen, book review) 3685
Rearrangements, Mol. (Porter, book review), 1619; mechanism of the azide, 2436; Beckmann, in the presence of free radicals, 2982; repulsion of at. kernels as a factor in org. 3185
Reducing agents, H_2SO_3 as 1409
Reduction, of phenyl naphthyl ketones by the binary system Mg + MgI_2, 306; of permanganate ion by chromic ion in acid soln., 345; oxidation-, potentials, 382; catalytic effect of Ru salts on, of $HClO_4$ by HBr, 786; At. Structure as Modified by (Reynolds, book review), 958; of isoprene by Na–NH_3, 1293; products obtained by the reducing action of metals upon salts in liquid NH_3 soln., 2127; catalytic, of α-diketones and their derivs., 2163; electronic interpretation of, 2391; reactions with CaH_2, 2936; potentials of various phenanthrenequinones, 3101; reducing action of aliphatic Grignard reagents, 3378; effect of temp. on the, rate of furfural with the catalyst from $PtO_2 \cdot H_2O$ 3384
Redwood, sequoyite from 3139

Refraction. dependence of molar. upon concn. in mixts. 1736

Refractive indices. of certain binary mixts. 2825

Resins. Die Künstlichen (Scheiber. Sandig. book review) 3686

Resorcinol, mercuration of. 479; phenolic combinations obtained by coupling chaulmoogric acid with 1503

Resorcinsulfonephthalein. Hg derivs. of Halogen compds. of 804

l-Rhamnose, isolation from cholla gum 3441

Rice. fatty acids assocd. with. starch 2185

Rings. polymerization and formation of 2548, 2560

Rocks. Anleitung zur Chem. Gesteinsanalyse, (Jakob, book review). 955; detn. of ferrous Fe in silicate 2117

Rotatory power. See *Optical rotation.*

Rotenone. reduction products of 2574

Rubber. natural and synthetic—products of the destructive distn. of natural. 1215; natural and synthetic 1293. 1294

Rubidium. influence on the detection of K by Zr sulfate 1062

Ruthenium salts. catalytic effect of. on the reduction of $HClO_4$ by HBr 786

SABINIC ACID. synthesis of 625

Salts. heat capacities in aq. solns. of. 323; activity coeff. of diacetone alc. in aq. solns. of. 984; temp.-conductance curves of solid. 1331; kinetics of the oxidation of iodide ion by acid dichromate solns. in presence of a neutral. 1973; products obtained by the reducing action of metals upon. in liquid NH_3 solns., 2127; Industrial Development of Searles Lake Brines (Teeple, book review). 2594

Saponification. velocity of. of AcOMe by NaOH at 25° 1959

Schiff bases. derived from 5-chlorovanillin 2586

Searles Lake. Industrial Development of. Brines (Teeple, book review) 2594

Secretions. Hormone und Innere (Laquer, book review) 322

Selenic acid. prepn. of. and its salts 1457

Selenium compounds. salts of triphenylselenonium hydroxide 3587

Selenium dioxide. pptd.. 3177; oxidation of. with PbO_2 3225

Sequoia sempervirens, sequoyite from 3139

Sequoyite 3139

Silica. therniochemistry of the compds. occurring in the system: $CaO-Al_2O_3$—. 2678

Silicates. Sol.. in Industry (Vail, book review) 644

Silicon tetrachloride. systems formed by certain tetrahalides 2910

Silicotungstic acid. prepn. of 1057

Silver. synthesis of water with a Ag catalyst—energy of activation and mechanism. 7; single crystals of 1134

Silver chloride. electrode 2901

Silver iodide. iodide. I. tri-iodide equil. and the free energy of formation of 3676

Smith. Edgar Fahs, biography of, ***Proc.*** 55; his contributions to science. Proc. 57

Soaps. Lehrbuch der Seifenfabrikation (Davidsohn. book review) 3688

Sodium (Meyer. book review). 1296; reduction of isoprene by NH_3-, 1293; action of metallic. on brominated cyclic acetals, 1509; direct detn. of. 1664; new qual. reagent for. 1965; action of. upon $Zn(CN)_2$ in liquid NH_3, 2127; reaction of triphenylsilicane with. in liquid NH_3, 3067; gravimetric detn. of. by the uranyl Zn acetate method in the presence of Rb, Cs, K, Li, phosphate or arsenate **3233**

Sodium acetate. heats of diln. of. and its bearing on heat capacity and heat of neutralization 712

Sodium carbonates. equil. between the carbonates and bicarbonates of Na and K in aq. soln. at 25°, 1626; system: $KHCO_3-H_2O-NaHCO_3$.. 2352

Sodium chloride. conductance and transference no. of the chloride ion in mixts. of KCl and 2671

Sodium cyanide. reduction of *β,β*-dinaphthylsulfone with 2277

Sodium ethyl. thermal decompn. of 588

Sodium hydroxide. sp. heat of solns. of. 707; heat of diln. of. and its bearing on heat capacity and heat of neutralization. 712; thermochem. behavior of solns. of. 731; velocity of sapon. of AcOMe by. at 25° 1959

Sodium ion. chem. kinetics in highly dil. soln.—bromoacetate and thiosulfate ions in the presence of. at 25°, 3341. (correction) 3678

Sodium sulfide. system: FeS– 3241

Sodium sulfite, inhibitive action of alcs. on the oxidation of.................. 90

Solids, heat of adsorption of gases by.................................... 2608

Solubility regular solns., 66; in the gaseous phase, especially in the system: NH_3(1) –NH_3(g), H_2(g), N_2(g), 1026; detn. of the, of slightly sol. liquids in water and the solubilities of the dichloro-ethanes and -propanes....... 2362

Solutions, soly.—regular solns., 66; heat capacities in aq. salt, 323; e.m.fs. of uni-univalent halides in concd. aq., 416; activity coeff. of diacetone alc. in aq. salt, 984; Ca amalgam electrode in dil. aq., 1345; chem. kinetics in highly dil., 3341; structure of the surface of ordinary.................... 3534

Sorption, app. for detg. the, of gases and vapors by solids at elevated temps..... 3560

Sound, sonic studies of the phys. properties of liquids—sonic interferometer—velocity of, in some org. liquids and their compressibilities, 759; chem. effects of high frequency, waves—emulsifying action..................... 1724

Specific heats, of Na and K hydroxide solns., 707; of Ba and Ca chloride solns... 794

Specific interaction, principle of, in mixts. of high valence electrolytes, 2622; solubilities of La and thallous iodates in aq. salt solns. and the principle of.. 2632

Spectroscopy, quant. gas analysis by high dispersion infra-red................. 377

Spectrum, Atlas der letzten Linien der wichtigsten Elemente (Löwe, book review), 641; relation between the absorption, and chem. constitution of certain azo dyes—effect of position isomerism on the absorption, of Me derivs. of benzeneazophenol, 1204; absorption, and decompn. of H_2O_2 by light, 1371; near infra-red absorption, of some aldehydes, ketones, esters and ethers, 1384; interpretation of the atm. absorption bands of, 1436; shift in the 1.14μ absorption band of some C_6H_6 derivs., 1750; absorption, of some phthaleins of the trihydroxyphenols, 1755; absorption, of some halogenated fluoresceins, 1769; ultraviolet absorption, of the isomeric 2-pentenes, 3041; (correction), 3677; absorption, of N_2O_5.. 3190

Standard solutions, of ceric sulfate.. 149

Standard substances, Cu as a, in iodimetry, 1299; $KMnO_4$ as a, in iodimetry... 1307

Stannanes. (See also *Tin compounds.)* Series arrangement of org. groups as detd. by the halogenation of mixed.. 3065

Starches, disruption of granule of corn, and its relation to the constituent amyloses, 294; fatty acids assocd. with rice, 2185; characterization of certain, and their amyloses... 3431

Stereoisomerism, of diphenyl compds... 630

Stopcock, in which contamination by grease is prevented and its application to a problem in gas technique, 2132; improved, for gas analysis burets........ 2759

Strontium oxide, system: $SrO–P_2O_5–H_2O$ at 25°.............................. 1091

Strontium phosphate, basic.. 1097

Sucrose, conversion into isosucrose.. 3609

Sugar group, relations between rotatory power and structure in.. 2225, 2788, ...3619, 3627, 3631

Sugars, structure of methylated.. 3490

Sulfates, rapid detn. of S in insol... 2936

Sulfites, cleavage of azo dyes by means of........................... 2986, 3483

Sulfochlorides, reaction between, and organomagnesium halides............... 3501

Sulfonation (Halberkann, Fretwurst, book review), 3685; of phenanthrene 2460, 2471

Sulfonephthaleins, new series of................................... 562, 2278

Sulfur, action on normal-heptane and normal-butane, 1566; rapid detn. in insol. sulfates, 2936; direct introduction of, into aromatic hydrocarbons....... 3428

Sulfur dioxide, surface tension of liquid...................................... 410

Sulfuric acid, action of, in the prepn. of certain alkyl halides................. 225

Sulfurous acid, potential of inert electrodes in solns. of, and its behavior as an oxidizing and reducing agent.. 1409

Surface tension, investigation of, consts. in an homologous series from the point of view of surface orientation, 153; of liquid SO_2....................... 410

Symbols, in Chemistry (Caven, Cranston, book review)....................... 1297

Syringic acid, and its derivs... 569

Systems, ternary, 2396; conjugated.. 2496

TANTALUM (Mellor, book review), 1614; fusion of rare metal ores—detn. of.. 122

Taste, relations between constitution and, of pungent principles............... 1911

Tautomerism. See *Isomerism.*

Telluric acid, prepn. of, from Ca tellurate.................................. 3229

Tellurium dioxide. oxidation of. with PbO_2 3225
Temperature. reactions with very large apparent coeffs of. 1136; -conductance curves of solid salts. 1331; crit., measurements on CO_2 in small capillaries, 1360; transition. of CCl_4 as a fixed point in thermometry 3517
Terephthalic acid. mercurated 2785
Tetraaryldiarsyls 2272
Tetrabromobutyraldehyde 1551
Tetrabromoethyl ether. sym 1551

Tetramethylene glycol 2503
Tetramethylethylene sulfide 3508
Tetraphenylmethane. some thiophene analogs of. compds 2143
Thallic oxide. decompn. of 2697
Thallium alloys. activities of molten. with Sn and with Pb 462
Thallium halides. temp.-conductance curves of solid 1331
Thallous iodate. soly. in aq. salt solns. and the principle of sp. interaction 2632
Thermochemistry, thermochem. behavior of NaOH solns., 731; thermochem. behavior of weak electrolytes. 740; of the compds. occurring in the system: $CaO–Al_2O_3–SiO_2$ 2678
Thermodynamics. Collected Works of J. Willard Gibbs (Longley, Van Name. book review). 639; thermodynamic activities of the proteins. 696; Das Gesetz der chem. Massenwirkung—Seine Thermodynamische Begründung und Erweiterung (Lorenz, book review). 957; cyclohexanol and the 3rd law of. 1400; Fundamentals of Chem. (Butler. book review) 1954
Thermometry. transition temp. of CCl_4 as a fixed point in 3517
2-Thiohydantoin-3-acetic acid. synthesis of polypeptide hydantoins from 254
Thiolacetic acid. Claisen ester condensation with Et ester of 1567
Thionyl chloride. action of. upon cholesterol and certain other alcs. 3665
Thiophene analogs. some. of di-. tri- and tetraphenylmethane compds. 2143
p-Thiophenol. glycosides of glucose. xylose. lactose and cellobiose. 3619; evidence concerning ringed structure of. cellobioside and of. lactoside. 3627; prepn. and structure of. maltoside and of its heptaacetate 3631
Thiosulfate ion. chem. kinetics in highly dil. solns.—bromoacetate ion and. in the presence of Na ion at 25°, 3341. (correction) 3678
Thioureas, derived from vanillylamine. 1911; action of phenyl isocyanate on 2220
Thymine. test for. in the presence of uracil and cytosine 1237
Tin. quant. analysis of. in org. compds. 1213
Tin alloys. activities of molten Tl- 462
Tin compounds. (See also Stannanes.) Methyl tin derivs.. 2403; alkyl 3605
Tin oxides. oxide cells of. 194; heat capacities at low temps. of 207
Tin tetraphenyl. as a phenylating reagent 1922
Titanium tetrachloride. systems formed by certain tetrahalides 2910
Titration. simple reference electrode for potentiometric. 471; differential potentiometric 1119
Toluene. heat capacity of. from 14 to 298°K.—the entropy and the free energy of formation 2738
p-Tolylpropanolamine 2262
Transference numbers. of $BaCl_2$ as a function of the concn., 1073; modification of the moving boundary method for the detn. of. 1656; of $CdCl_2$ and $CdBr_2$, 2605; of the chloride ion in mixts. of NaCl and KCl 2671
Transition temperature. of CCl_4 as a fixed point in thermometry 3517
Trembles. tremetol, the compd. that produces 3617
Tremetol 3617
Triarylmethyl carbonates. catalytic decompn. in the presence of Cu 2157
Tribromoresorcinol. oxidation of 493
2′,4′,5′-Trihydroxybenzoylbenzene-5-sulfonic acid. and derivs. 1466
Trihydroxyphenols, absorption spectra of some phthaleins of the 1755
Tri-iodide, iodide-I-. equil. and the free energy of formation of AgI, (correction) 3676
Trimethylacetaldehyde. 1246, (correction) 3677
Trimethylethylstannane, some derivs. of 892
Trimethylethylthiophene 3511
α,β,β-Trimethylglutaric acid. supposed. of Noyes and Skinner 930

Trimethylphenoxystannane ... 2403
Trimethylthiophene ... 3511
Trimethyl tin hydroxide. properties of ... 3605
Triphenyl lead chloride prepn. of ... 3112
Triphenylmethane. some thiophene analogs of. compds. ... 2143
Triphenylmethylmagnesium chloride. prepn. of ... 3493
Triphenylselenonium hydroxide. salts of ... 3587
Triphenylsilicane, constitution of. and its reaction with Na in liquid NH_3 ... 3067
Tungstosilicates, mol. structure of. and related compds. ... 2868

ULTRASONIC RADIATION. oxidations promoted by ... 370
Unsaturated compounds. oxidation of ... 228
Uracil. test for thymine and 5-methylcytosine in the presence of ... 1237
Uranyl sulfate. photochem. decompn. of malonic acid both in the presence and absence of. 80; as sensitizer for the photochem. decompn. of oxalic and malonicacids ... 2731
Ureas. derived from vanillylamine, 1911; action of phenyl isocyanate on ... 2220
Urease. isoelec. point of cryst. ... 1255
Urethans. action of phenyl isocyanate on ... 2220

VACUUM. simple lab. regulator ... 3347
Valency. Atomstruktur und (Stark. book review). 641; some applications of elec moments to electronic theories of ... 2380
Vanadium (Mellor. book review). 1614; volumetric detn. of. by means of KIO_3 ... 1366
Vanillylamine. some ureas and thioureas derived from ... 1911
Vapor density. See *Density*
Vapor pressure. of related compds.—application of Dühring's rule. 116; of intensively dried NH_4Cl, 748; of isopropyl acetate. 1623; of mononitro-and dinitrothiophenes. 2147; measuring the partial. of Hg at room temps., 2398; mol orientation and the partial. of binary mixts., 2646. 2660; of certain binary mixts.. 2825; of solid and liquid phases of NO ... 3194
Vapors. app. for detn of the sorption of. by solids at elevated temps ... 3560
Vegetables. I in ... 394
Vinyl chloride. reactions of C_6H_6 and. in the presence of $AlCl_3$ ... 2978
Vinyl phenyl ketone. addn. reactions of ... 2151
Viscosity. of aq. solns. of strong electrolytes with special reference to $BaCl_2$ ... 2950

WATER. synthesis of. with a Ag catalyst—energy of activation and mechanism. 7; oxidation of benzoyl-o-toluidine at a C_6H_6-, interface. 965; systems: SrO–P_2O_5–, and BaO–P_2O_5–, at 25°, 1091; equil. in aq. soln. between $AcONH_4$, acetamide and. 1106; system: $NaHCO_3$–$KHCO_3$–, 2352; system: K_2CO_3, K_2SO_4, and at 25°, 2396; equil. in the system: Co–CoO–H_2–, —free energy change for the reaction $CoO + H_2 = Co + H_2O$, 3249; app. for detn. of. in solids. 3560; analysis of mixts. of EtOH, AcOEt, AcOH and. (correction) ... 3676
Water vapor. reactions of dissocd. ... 3290
Weighing (Block. book review) ... 1616
Wires. movement of gases around electrically heated ... 2741
Wood. processes involved in the decompn. of. with reference to the chem. compn. offossilizedwood ... 1187

XANTHINES. synthesis of some alkyl- ... 2245
Xylan. isolation from the cell walls of corn seedlings ... 2506
Xylose. β-thiophenol-glycoside of ... 3619

YEAST. examn. of. nucleic acid for 5-methylcytosine, 1779; effect of various prepns. on the growth of bakers' and brewers' ... 2764

ZINC. reaction of chloroacetic acids with. 852; action on trimethyl tin bromide ... 2403
Zinc alkyls. prepn. of. and their use in the synthesis of hydrocarbons ... 594
Zinc cyanide. action of Na upon. in liquid NH_3 ... 2127
Zinc oxide. rapid concn. of Ge and Ga contained in. carrying them. 1459; reactions of allyl alc. over. catalyst ... 2430
Zirconium. 1062. 3238; pptn. by phosphates ... 1311
Zirconium tetrachloride. systems formed by certain tetrahalides ... 2910
