The writers wish to express their indebtedness to Dr. Irving Langmuir for his kindness in discussing this work with one of them.

Summary

The partial vapor pressures of six binary liquid systems containing an alcohol as one component are measured. The results are found to deviate considerably from the behavior required by Langmuir's theory of molecular surface energies. The deviations are explained in terms of the interaction of the electric doublets contained in the molecules. It is concluded that, as this interaction is dependent upon not only the electric moments of the doublets but also their locations in the molecules and the sizes and shapes of these molecules and, probably, the constraints upon the electrons in them, no generally valid quantitative formulation of the effect is possible at present.

THE CONDUCTANCE AND TRANSFERENCE NUMBER OF THE CHLORIDE ION IN MIXTURES OF SODIUM AND POTASSIUM CHLORIDES

BY DUNCAN A. MACINNES, IRVING A. COWPERTHWAITE AND THEODORE SHEDLOVSKY

RECEIVED MARCH 22, 1929 PUBLISHED SEPTEMBER 5, 1929

The transference numbers of the ion constituents in mixtures of sodium and potassium chlorides have been investigated by various workers, including Braley and Hall,[1] Schneider and Braley,[2] and Dewey.[3] In the first two papers mentioned the authors presented what they thought was evidence that there are ionic complexes in these mixtures. These conclusions were called in question by MacInnes[4] and Bjerrum,[5] who could find evidence, in the experimental work, for simple ions only. This conclusion was later accepted by Braley and Rippie[6] on repeating some of the experimental results of Schneider and Braley.

The question of ionic complexes has been raised again by McBain and Van Rysselberge.[7] They have concluded from transference number measurements made on 0.05 N salts containing divalent ions, to which rather large amounts of salts had been added, that complex ions occur in such mixtures.

Since the moving boundary method appears to be capable of greater precision than the Hittorf method, at least as usually carried out, it seemed desirable to test the applicability of the method in the case of mixtures. Purthermore, it seemed possible that, since McBain and Van Rysselberge's work, if confirmed, indicates large amounts of complexes in the solutions they worked with, precise measurements might show at least a small amount in mixtures of potassium and sodium chlorides.

It is not, however, possible, with the moving boundary method, to determine the separate transference numbers of the two positive ion constituents in these mixtures. The determinations were therefore carried out on the chloride ion constituent, which is common to both salts. The measurements described below are on the transference numbers and conductances of mixtures of potassium and sodium chlorides at a total (volume) concentration of 0.1 N, at 25°.

Theoretical

If we let x represent the proportion of potassium chloride in the mixture

of potassium and sodium chlorides, the transference number T_{Cl} of the chloride ion will be

$$T_{\text{Cl}} = \frac{\Lambda_{\text{Cl}}}{x\Lambda_{\text{K}} + (1 - x)\,\Lambda_{\text{Na}} + \Lambda_{\text{Cl}}} \tag{1}$$

This formula assumes that we are dealing with solutions containing only simple ions. If the equivalent conductances Λ_{Cl}, Λ_{K}, Λ_{Na} of the ion constituents are independent of the values of x, or, in other words, if the mobilities of the ions are the same in the various mixtures as they are in the solutions of the pure salts at the same total salt concentration, the equivalent conductance of the mixtures should vary linearly with values of x. This, we will see below, is nearly but not exactly true. Since it follows from these assumptions, and has been found experimentally, that for these solutions $N\Lambda_{\text{KCl}} = N'\Lambda_{\text{NaCl}} = \Lambda_{\text{Cl}}$, in which N and N' are the transference numbers of the chloride ion for 0.1 N solutions of pure potassium and sodium chlorides, Equation 1 can be put in the form

$$T_{\text{Cl}} = \frac{N\Lambda_{\text{Cl}}}{x(1 - N)\Lambda_{\text{KCl}} + (1 - x)(1 - N')\Lambda_{\text{KCl}}\,N/N' + N\Lambda_{\text{KCl}}} \tag{2}$$

which can readily be rearranged to

$$T_{\text{Cl}} = \frac{N'}{x\left(\frac{N'}{N} - 1\right) + 1} \tag{3}$$

which gives the transference numbers of the chloride ion in the mixtures in terms of the transference numbers of the pure salts. Any large deviation from values of transference numbers in mixtures computed from Equation 3 would tend to indicate the presence of complexes in the solutions.

Experimental

The Moving Boundary Measurements.—The technique of the moving boundary measurements followed that described in previous papers.[8] The only substantial addition to the procedure is an automatic device for initially forming the boundary. Since, as may be recalled, the rate of motion of the boundary was found to be influenced by vibration, the apparatus was placed in a thermostat which was mounted on a modified Julius suspension. The weakness of this arrangement was, however, that the initial turning of the plate-glass disks over each other in forming the boundary could not be carried out while the vibration-free support was effective. It was necessary to extend the springs so that the thermostat rested on a table, after which the disks could be turned by hand. Vibrations could thus disturb the boundary at its moment of formation, and there was a possibility of further disturbance on releasing the springs. Although recent work has shown that the result of slight mixing or diffusion is overcome, in time, by the potential gradients acting around the boundary,[9] an occasional run showed

[8] (a) MacInnes and Smith, THIS JOURNAL, **45**, 2246 (1923); (b) Smith and MacInnes, *ibid.*, 46, 1398 (1924); (c) MacInnes and Brighton, *ibid.*, **47**, 994 (1925); (d) Smith and MacInnes, *ibid.*, **47**, 1009 (1925); (e) MacInnes, Cowperthwaite and Blanchard, *ibid.*, **48**, 1909 (1926); (f) MacInnes, Cowperthwaite and Huang, *ibid.*, 49, 1710 (1927).

[9] MacInnes and Cowperthwaite, *Proc. Nat. Acad. Sci.*, *15*, *18* (1929).

variations which indicated more mixing than could be rectified in this manner. It was, therefore, decided to make the boundary formation take place without disturbing the vibration support. The arrangement adopted is shown in Fig. **1.** In order to form the boundary the electrode tube **A** must swing around the pivot P until the lower opening of **A** is directly over the measuring tube D. This is accomplished by means of the spring S which is mounted on the upright of the support. By means of a sprocket, E, and chain the motion of this spring is transmitted to the upper disk B carrying the electrode vessel **A.** The chain carries a projection which fits into a hole in the disk. The procedure for forming a boundary is as follows. After filling the measuring tube and electrode vessel as described in previous papers, the disks are placed approximately as shown in the figure. The spring S is then given a number of turns by means of the milled head and is locked with the pin Q. The chain is next adjusted over the sprocket and disk and the pin Q is raised. This causes the disk B to swing through a small angle so that the edge of the sector I is resting against the projection of the rod R through the guide K. The whole apparatus is then placed in the thermostat on the vibration-free support and electrical connection is made to the electrodes and to the terminals of the solenoid M. Now if the circuit is closed through this solenoid the rod R is raised and the disk turns until the projection H encounters the edge of the guide K and the electrode vessel **A** is directly over the tube D. The projection H is arranged eccentrically around the screw fastening it to the brass sector I in order that the final position of the disk B can be adjusted exactly. Due to the viscosity of the lubricant between the two glass disks the turning takes place smoothly with no jerk at the end. The procedure as described causes a sharp boundary to form between the solution under investigation in the measuring tube D and the "indicator" solution in the electrode vessel **A.**

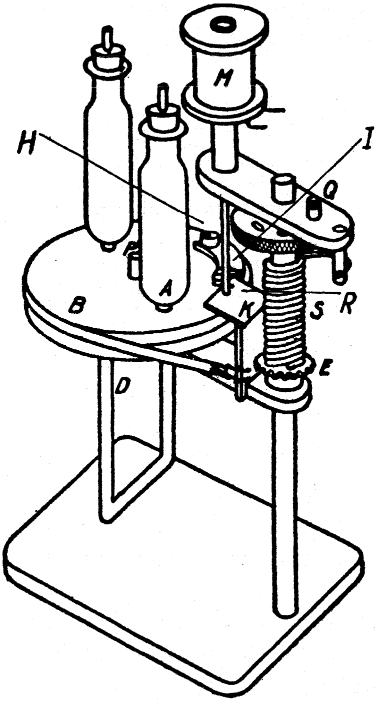

Fig. 1.

The Results of the **Moving** Boundary Experiments.—As already stated the transference numbers measured in this series of determinations were those of the chloride ion in potassium chloride–sodium chloride mixtures. As "indicator" solutions mixtures of potassium and sodium acetates were used, having in each case the same ratios of the positive ion constituents. Surrounding the silver–silver chloride electrode in the (closed) cathode chamber was a strong solution of potassium acetate. The results of the transference number measurements are given in Table I. It will be seen that for each proportion of potassium chloride the transference number obtained is independent of the indicator concentration, within the range studied, showing that adjustment was obtained in each case. This observation is supported by an earlier series of determinations which were made in order to test the possibility of measurements of the type here described. In this earlier series the range of indicator concentrations was still wider than that given in Table I. It should, further, be emphasized that each transference number in the table is the average of six figures rarely if ever differing more than 0.1% from the average. Each of these figures is the result of a measurement in which the boundary has moved eight or more centimeters.

TABLE I

TRANSFERENCE NUMBERS OF CHLORIDE ION IN 0.1 *N* POTASSIUM CHLORIDE–SODIUM CHLORIDE MIXTURES AT 25°

Transference number	Indicator concn.	Transference number	Indicator concn.	Transference number	Indicator concn.
0.25 Potassium Chloride		0.50 Potassium Chloride		0.75 Potassium Chloride	
0.5839	0.068	0.5560	0.064	0.5311	0.068
.5838	.068	.5557	.066	.5313	.070
.5828	.068	.5566	.066	.5314	.072
.5832	.068	.5560	.068		
.5831	.070				

The figures in Table I have been corrected for the volume change at the electrode as described by Lewis.[10] This correction is —0.0009 and —0.0002 to the observed transference numbers of pure 0.1 *N* sodium and potassium chloride solutions. The values for the mixtures have been interpolated from these figures.

The Conductance Measurements.—Conductance measurements were made on the solutions whose transference numbers had been determined, as well as on the 0.1 N solutions of the pure salts. Since it is intended to describe the bridge used in these measurements in some detail in a later article, only the more essential facts concerning the results will be given here. The Washburn pipet cell used was calibrated with "demal" solution prepared as described by Parker and Parker.[11] The resistance box used was calibrated against a box which had been standardized by the Carey Foster method against B. of S. standard resistances. During the measurements the cell was placed in an oil thermostat, a description of which will also be deferred. This maintained a constant temperature within 0.002°, as shown by a platinum-resistance thermometer.

The results of the measurements are given in the appropriate column in Table II. We feel that all variables that may affect the accuracy of these measurements have been controlled at least within 0.02%. Our A values for the pure salts (106.69 for NaCl and 128.86 for KCl) are not far from the values (106.71 and 128.82, respectively) given in Noyes and Falk's[12] compilation, which are based on Bray and Hunt's, and Melcher's

---

[10] Lewis, THIS JOURNAL, 32, 862 (1910).

[11] Parker and Parker, *ibid.*, 46, 312 (1924).

[12] Noyes and Falk, *ibid.*, 34, 454 (1912).

work. The latter figures have been corrected for a change of —0.14% in the constants used in calibrating the cells since Parker and Parker[1'] have shown that Kohlrausch's value for the conductance of the 0.1 N calibrating potassium chloride solution used by these authors is in error by that amount. For the mixtures the only earlier conductance work with which comparison can be made is that of Stearn,[13] which is not of sufficient accuracy for our purpose.

Preparation of Solutions and Purification of Material. -The solutions were prepared on a volume normal basis, *i. e.*, 0.1 mole of the fused salt, or mixture of salts in the desired proportions, in a liter of solution at 25°, in carefully calibrated pyrex volumetric flasks, using conductivity water. The best obtainable samples of potassium and sodium chloride were first crystallized from concentrated solution with hydrogen chloride gas, after which they were recrystallized several times from conductivity water.

Discussion of Results

The results and conclusions of our measurements are outlined in Table II. In the second column, under the heading "transference numbers observed," are given the averages of the values from Table I, and also the transference numbers for the two pure salts from earlier moving boundary measurements. The next column contains the transference numbers of the mixtures as computed from Equation **3.** In the fourth and fifth columns are given the conductivity data for the pure salts and the mixtures, and also the conductance values computed on the basis of a simple linear variation of these values with the proportion of potassium chloride in the mixture.

TABLE II

TRANSFERENCE NUMBERS AND EQUIVALENT CONDUCTANCES OF 0.1 N KCL–NACL MIXTURES AT 25°

KCl, %	Transference numbers, T_{Cl} Observed	Transference numbers, T_{Cl} Computed	Equivalent conductance, Λ Observed	Equivalent conductance, Λ Computed	Chloride-ion conductance $T_{Cl}\Lambda$
0	0.6137	...	106.69	....	65.48
25	.5834	0.5832	112.13	112.23	65.42
50	.5563	.5553	117.67	117.78	65.45
75	.5313	.5309	123.25	123.32	65.48
100	.5080	...	128.86	....	65.46

In the last column will be found the product of the observed transference numbers and the observed conductances. If simple ions only are present this is the equivalent conductance of the chloride-ion constituent in the mixtures and in the pure salts. As can be seen, this product is a constant well within the experimental error. It is an interesting fact that the observed transference numbers are all slightly larger than the computed

---

[13] Stearn, THIS JOURNAL, 44, 670 (1922).

values, whereas in the case of the equivalent conductances the reverse is true. This would follow if the chloride ion has the same mobility in the mixtures as in the solutions of the pure salts and one or both of the mobilities of the positive ions are slightly lowered in the solutions of the mixed salts. However, the effect, though definite, is all within 0.1%. There is, quite obviously, no evidence whatever of complex ions in these solutions.

Summary

An addition to the moving boundary apparatus for determining transference numbers is described, with the aid of which the boundary can be formed without disturbing the apparatus while it is mounted on a vibration-free support.

Transference numbers of the chloride-ion constituent in tenth-normal mixtures of sodium and potassium chlorides have been determined. Accurate conductance measurements have been made on the same solutions.

Within the experimental error chloride-ion conductance is the same in the mixtures as in the solutions of the pure salts. There is no evidence of complex ion formation.

A LABORATORY OZONIZER

BY ALBERT L. HENNE

RECEIVED MARCH 28, 1929 PUBLISHED SEPTEMBER 5, 1929

It is of general knowledge that ozone is by far the most suitable reagent for the oxidation of double linkages; there is also a general impression that this method requires special and expensive equipment as well as a trained operator. The purpose of this note is to show that the method is exceedingly simple and to give practical information concerning the installation and the cost of the equipment.

L. I. Smith[1] has described an ozonizer which is very satisfactory from the stand-point of the ozone yield. The present apparatus is a simplification of that described by Smith. The purposes of the alterations were to eliminate the use of mercury, which renders the apparatus heavy, expensive and liable to breakage, to modify slightly the shape of the ozone tubes in order to simplify the glass-blowing and to allow the use of sulfuric acid as an electrode, to eliminate the litharge joints, which always have a tendency to expand and break the glass tubes and to render the building of the unit a much shorter and less complicated task. All these features substantially decrease the cost.

---

[1] L. I. Smith. THIS JOURNAL, 47, 1844 (1925).

Figure 1, which shows one of the ozone tubes, is self-explanatory. A lead wire dipping in dilute sulfuric acid is used as one of the electrodes; the lead wire (six fuse-wires twisted together) remains straight and centered by virtue of its own weight, so that sparking is prevented. As in the apparatus of Smith, three tubes are sealed in series and almost completely immerged in a bath of water in a battery jar. The water is used as a second electrode and as a cooling medium. Since no mercury is used and since the weight of the tubes is nearly counterbalanced by the weight of the water displaced, it is unnecessary to have an elaborate device to maintain the tubes in position. All that is needed to support the weight is a plate of bakelite blocked 3 cm. from the bottom of the battery jar and fitted with slots to accommodate the lower extremities of the tubes. The lid of the battery jar is fitted with corresponding slots (except that the diameter of the holes is 4 cm. instead of 3.5 cm.); this is quite sufficient to maintain the tubes in position. The tension (10,000 v.) between the electrodes is furnished by a $^{1}/_{4}$-kw. transformer. The maximum cost of the whole outfit can be established as follows: transformer, \$10; battery jar, \$7; material and labor for three ozone tubes, \$10. A good glass-blower can make a tube in about an hour and a half, and spoils less than one tube out of four.

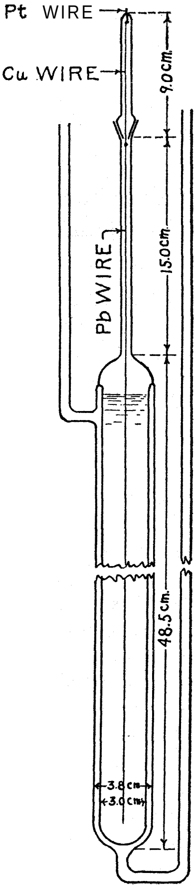

Fig. 1.

The operation of the ozonizer is essentially that indicated by Noller and Adams.[2] It should be remembered that complete drying of the oxygen is a very important feature. Despite the modifications, the yield of ozone is substantially the same as that indicated by Smith; the percentage weight of ozone will be about 14%, 8% and 3% when oxygen is delivered at the rate of 4, 20 and 100 liters per hour, respectively. This corresponds to an hourly output of 0.7, 3.6 and 4.6 g. of ozone.

The inexpensive material used for radio panels is suitable for the bottom plate and for the battery jar lid. A T2355 Thordarson transformer, type RS Cat. 135, and an Exide 21 X 31 × 42.5 cm., type I?-9, battery jar were used.

STUDIES ON THE THERMOCHEMISTRY OF THE COMPOUNDS OCCURRING IN THE SYSTEM $CaO–Al_2O_3–SiO_2$. I. THE HEAT OF SOLUTION OF CALCIUM OXIDE IN HYDROCHLORIC ACID[1]

BY T. THORVALDSON, WELDON G. BROWN[2] AND C. R. PEAKER[2]

RECEIVED MARCH 28, 1929 PUBLISHED SEPTEMBER 5, 1929

The immediate reason for undertaking the work described in this paper was that a reliable value for the heat of solution of calcium oxide in hydrochloric acid was required for the calculation of the heats of formation of the calcium aluminates from the heats of solution of these substances.

The values obtained by Berthelot[3] and Thomsen[4] were 46.06 and 46.03 calories per mole of CaO, respectively. From three determinations (46.03, 46.14 and 46.33), Backstrom[5] arrived at the weighted mean 46.20 calories (24°) per mole for the heat of solution of calcium oxide in normal hydrochloric acid at 25°. For our calculations a value for the heat of solution in more dilute acid was required.

Apparatus

The calorimeter used was of the adiabatic type developed by Richards[6] and his collaborators with certain slight modifications. A gold calorimeter vessel was used and the stirring of the liquid in the calorimeter vessel was effected by a motor-driven rotary stirrer made of an alloy of 80% of gold and 20% of copper. The stirrer was insulated from its shaft by a rod of hard rubber. The shaft made an air-tight joint where it passed through the brass tube in the cover of the calorimeter jacket so that diffusion of air between the calorimeter and the environment was eliminated. The rate of stirring was controlled by an external resistance so as to be constant as shown by a revolution counter attached to the shaft of the stirrer. A rate of 290 revolutions per minute was found to be sufficient to prevent thermal stratification in the calorimeter. This rate gave a rise of temperature of 0.001° per minute.

Two series of determinations of the thermal leakage of the calorimeter under a thermal head of 0.010 ± 0.001° and 0.020 ± 0.001°, respectively, were made. After the system was in equilibrium (water equivalent, 600 cal.) the calorimeter stirrer was stopped for ten-minute intervals and then started again. In each case the rise in temperature due to thermal leakage during the ten-minute interval was less than 0.0005°.

---

[1] The work described in this paper was made possible by bursaries awarded to Mr. Brown and Mr. Peaker by the National Research Council of Canada. The authors wish to express their appreciation of this assistance.

[2] This paper represents part of the theses presented by W. G. Brown and C. R. Peaker in partial fulfilment of the requirements for the degree of M.Sc. in Chemistry at the University of Saskatchewan.

[5] Bäckström, THIS JOURNAL, 47, 2443 (1925).

[6] (a) Richards, Henderson and Forbes, *Proc. Am. Acad.*, **41,** 3 (1905); (b) Richards, Rowe and Burgess, THIS JOURNAL, 32, 1176 (1910).

The Beckmann thermometers employed had been calibrated at the U. S. Bureau of Standards. A careful comparison with a Beckmann thermometer which had been calibrated by one of us by a thermochemical method[7] gave an agreement within 0.001" over the whole range of the thermometer scale The actual centigrade temperatures were obtained by comparison with a calibrated standard, the ice-point being taken at the same time.

The large discrepancies often found between thermochemical results from different laboratories indicate the importance of the elimination of constant errors. It was therefore considered advisable to carry out some measurements of well-known thermochemical constants, with this apparatus, before proceeding with the determination of the heat of solution of calcium oxide. Two determinations were chosen: the first involving a temperature rise of 4°, *i. e.*, the neutralization of sulfuric acid using special vessels and solutions identical with those used by Richards and Rowe;[8] the second involving a very small rise of temperature (about 0.15") *i. e.*, the heat of dilution of $HCl\cdot 20H_2O$ to $HCl\cdot 200H_2O$ according to the method of Richards, Rowe and Burgess.[6b] In both cases the method of stirring described above was used.

A series of six determinations of the heat of neutralization of sulfuric acid gave the values 16,979, 16,997, 16,990, 16,972, 16,982 and 16,984 or a mean of 163,984 calories per $^1/_2$ H_2SO_4 at 20° as compared with 16,982 calories given by Richards and Rowe[8] Ten determinations of the heat of dilution of $HCl\cdot 20H_2O$ to $HCl\cdot 200H_2O$ gave a mean value of 552 calories per mole, the highest value being 556 and the lowest 549, as compared with 556 calories obtained by Richards, Rowe and Burgess,[6b] 549 calories reported by Richards and Rowe and 552 calories calculated from dilution results by Richards and Thorvaldson.[10] The agreement between the results is all that could be expected and indicates an absence of constant errors affecting the temperature measurements.

Materials

Hydrochloric Acid.—The purest acid of commerce was diluted and redistilled with a quartz condenser, the middle portion of the distillate being collected in quartz flasks. This was then diluted with water freshly redistilled with a block tin condenser and adjusted to $HCl\cdot 200H_2O$, the concentration being checked both by titration with pure sodium carbonate and by gravimetric determinations of chloride.

Calcium Oxide.—The procedure used for eliminating impurities from the calcium salts was essentially similar to that recommended by Richards and Hönigschmid.[11]

The water and the reagents used, such as acids, ammonia, ammonium carbonate and ammonium oxalate, were all purified by redistillation or recrystallization immediately before use. The calcium salts to be purified were in each case, to begin with, of the highest quality obtainable ("for analysis," "special," "analyzed"). The mother liquors were separated from the recrystallized products by means of high-speed power centrifuges. Precipitations of calcium carbonate and calcium oxalate were made from solutions containing 5 g. of CaO per liter. The precipitates were washed by decantation with large volumes of redistilled water, time being given for diffusion of impurities from the solid, and the final wash water was separated by aid of the centrifuge. Calcium oxide was finally obtained from the carbonate or oxalate by ignition in platinum crucibles in an electric muffle. While determinations of the heat of solution in hydrochloric acid were made on eighteen different samples of calcium oxide, the data recorded in this

paper in Table II represent the values obtained with four of the most carefully purified samples prepared from calcium salts from three widely different sources. Although the original materials contained only very small amounts of impurities, the process of purification in each case increased the heat of solution materially.

Sample A.—Calcium nitrate was recrystallized twice in vessels of fused silica. Calcium carbonate was then precipitated as calcite at room temperature with ammonium carbonate.

Sample B.—Calcium carbonate was dissolved in nitric acid. The neutral solution was treated with excess of bromine and milk of lime, boiled, filtered and the calcium nitrate recrystallized three times in vessels of fused silica. The calcium was precipitated as the carbonate by ammonium carbonate. The thoroughly washed and centrifuged calcium carbonate was dissolved in hydrochloric acid and precipitated as calcium oxalate.

Sample C.—A solution of recrystallized calcium chloride was treated with excess of bromine and milk of lime, boiled, filtered and changed to the nitrate by repeated evaporation with excess of nitric acid. The nitrate was then recrystallized five times in glass, three times in platinum vessels and the calcium precipitated as calcium carbonate (calcite) by ammonium carbonate.

Sample D.—A portion of the calcium nitrate obtained after the eighth recrystallization of Sample C was precipitated by ammonium carbonate at the boiling point, crystals of aragonite being obtained.

Experimental Procedure

The experimental technique of adiabatic calorimetry is well known[6,8,9,10] and will not be described here. The method of introduction of the calcium oxide into the calorimeter should, however, be described. The calcium oxide, freshly ignited to constant weight, was dropped into the calorimeter vessel through a glass tube which reached through the cover of the calorimeter jacket. To the lower end of the glass tube there was attached a tube of gold foil which just made contact with the surface of the liquid in the calorimeter. It was found that any spattering of the liquid was caught by the gold tube. As soon as the calcium oxide had been introduced the gold tube was released and dropped into the acid solution, where it was held suspended from the cover to prevent it from interfering with the stirrer. The glass tube was then removed and the weight of any lime adhering to its inner surface, which generally did not exceed two or three milligrams, was determined by titration with standard

TABLE I

acid. The original weight of calcium oxide was then corrected for the amounts remaining in the crucible and adhering to the tube. The calcium oxide dissolved very rapidly, a constant stirring correction being usually reached in from six to eight minutes. A thermal head of 0.010 ± 0.005° was maintained between the jacket and the calorimeter vessel during the experiments.

All weights were corrected to vacuum. The calcium oxide was introduced at the final temperature of the reaction (20") and is therefore not included in the heat capacity.

14	D	2.7087	19.93	3.757	829.2
		Average	20.00	4.005	828.6

[a] These values are corrected for (1) stirring, (2) stem exposed, (3) setting of thermometer and (4) variation in temperature of CaO from 20° at time of introduction into the calorimeter.

[b] Heat capacity in Expt. 5 was 607.8 cal./deg.

Discussion of Experimental Results

The average value from Table II represents the isothermal heat of reaction at the final temperature 20.00°, expressed in terms of the mean calorie between 16 and 20".

One further correction should be applied to this value. The volume of air enclosed in the calorimeter system was about 500 cc., one-half of which was included in the calculated heat capacity of the system. Assuming that this volume of air was completely saturated with water vapor both at the beginning and at the end of an experiment, the heat absorbed by evaporation would be 1.1 calories, which is equivalent to approximately 0.4 calorie per gram of calcium oxide. As thermal equilibrium is attained rather rapidly at the end of the run, it would probably be more nearly correct to apply three-fourths of the calculated correction.

Applying a correction of 0.3 calorie per gram, the final value for the isothermal heat of solution of calcium oxide in $HCl\cdot 200H_2O$ at 20° becomes 828.9 calories per gram (mean calorie 16 to 20°). This is equivalent to 194.4 kj. or 46.50 $cal.^{20°}$ per mole.

The samples of calcium oxide used in Expts. 9 and 10 were heated at 1200" for three hours after being brought to constant weight in the usual way at 800 to 900°. In another case a sample was heated at 1200° for twenty-four hours without giving an appreciable change in the heat of solution. The results indicate that the heat of solution is not materially affected by the temperature of ignition between the limits 800 and 1200°.

Summary

The heat of solution of calcium oxide in $HCl\cdot 200H_2O$ at 20" was found to be 194.4 kilojoules or 46.50 $cal.^{20°}$ per mole. The heat of solution was found not to be materially affected by the temperature of ignition between 800 and 1200".

THE IODOMETRIC DETERMINATION OF IRON

BY ERNEST H. SWIFT

RECEIVED APRIL 3, 1929 PUBLISHED SEPTEMBER 5, 1929

Introduction

In the course of an investigation the demand arose for a rapid, fairly accurate method of determining iron in a precipitate of ferric hydroxide. A review of the various volumetric processes for determining iron was therefore made. Oxidation methods, using standard permanganate or dichromate solutions, involve the preliminary reduction of the ferric solution. In the reduction methods solutions of stannous chloride or of a titanous salt are commonly used, but both of these solutions are so unstable as to require frequent standardization or elaborate precautions in storage. The use of sodium thiosulfate for the direct titration of a ferric salt has been investigated,' but the conditions under which accurate results can be obtained are apparently very strictly limited.[2] An iodometric method, in which iodide is added to a ferric salt solution and the liberated iodine titrated with thiosulfate, was originally proposed by Mohr.[3]

The iodometric method appeared to offer great advantages, provided a simple process giving exact results could be found. However, experiments

by procedures found in standard texts were unsatisfactory, and statements at variance with these procedures were found in the literature. Thus 'fieadwell-Hall[4] directs that "the greater part of the acid" be neutralized, that five grams of potassium iodide be used, that the air in the flask be removed by carbon dioxide and finally that the reaction be allowed to proceed for twenty minutes. Sutton[5] "nearly neutralizes" the acid, adds "an excess of strong solution of potassium iodide" and heats in a closed flask at 50 60° for about twenty minutes before cooling and titrating. Joseph[6] states that "fair accuracy" can be obtained without taking "any special precautions" if to the ferric solution acidified with hydrochloric acid, "whose amount does not seem to be of any great importance" is added a few grams of potassium iodide and the iodine liberated is titrated "at once." His duplicate analyses show variations as great as 2%. Kolthoff[7] found that accurate results were obtained upon adding 1.5 g. of potassium iodide to 10 ml. of ferric chloride solution which contained 2.5 millimoles of iron and which was 0.1 molal in hydrochloric acid, and then allowing this to stand for five minutes and titrating. The same author also states that more concentrated hydrochloric acid seemed to retard the reaction as well as to cause considerable air oxidation. Kurt Bottger and Wilhelm Bottger[S] carried out a series of experiments in which to 20 ml. of a solution 0.1 molal in sulfuric acid and containing 1.6 millimoles of ferric sulfate they added 10 ml. of a 15% hydrochloric acid solution and allowed this solution to react with 3–4 g. of potassium iodide in a total volume of about 60 ml. for various lengths of time up to one hour. These experiments gave results from 1–2% high. A corresponding series of experiments in which oxygen of the air was eliminated gave correct results. They did not mention the work of Kolthoff. Very recently Grey[g] has studied this method and states: "Numerous experiments have shown that 5.5 moles of potassium iodide are required per atom of iron, and the concentration in the titrated liquid should be adjusted to about $M/7.5$, and the acid concentration should be $N/3$–$3N$. In such a case the liberation of iodine will be strictly proportional to the iron present, within the limits 0.056–56 mg. of iron in 10–50 cc. of liquid." The experimental results are not shown. It is further stated that "the solution after titration by thiosulfate may be shaken violently with air for two hours without any return of the blue color, even when the acidity is that of N hydrochloric acid." This is surprising in view of the observed air

oxidation of iodide in acid solutions which have been reported by others;[10] likewise the possibility that such oxidation may occur previous to the thiosulfate titration is apparently not considered.

Approximate calculations of the equilibrium which should be attained when a ferric salt and iodide react have been made by Bottger and Bottger[8] and by Fales.[11] These calculations indicate that with an excess of iodide, and especially upon reduction of the liberated iodine with thiosulfate, the reaction should be complete within the usual limits of error of volumetric work. Studies of the rate of the reaction between ferric salts and iodide have been made by Schukarew,[12] by Bronsted and Pedersen,[13] by Sasaki,[14] and by Wagner;[15] while the reverse reaction, the oxidation of a ferrous salt by iodine, has been investigated by Banerji and Dhar.[16] Although these investigations were principally concerned with the mechanism of the reactions involved, the results of the rate measurements would seem to indicate difficulty in forcing the reaction to completion within a short time.

In view of this situation, a study of the method was undertaken, especially as to the effect of the acid concentration upon the reaction between the iodide and the ferric salt, as to the amount of "oxygen error" occurring when the titration is carried out in air under various conditions and as to the amount of potassium iodide necessary.[17]

Preparation of the Solutions.—An approximately 0.1 molal solution of ferric chloride was prepared by dissolving an "Analyzed" brand of $FeCl_3 \cdot 6H_2O$ in approximately 0.1 molal hydrochloric acid. Tests for ferrous salt with potassium ferricyanide solution gave negative results. This solution was standardized as to iron content by two different methods. The first three values given below were obtained using the Zimmermann–Reinhardt method; the other values by displacing the chloride in the solution with sulfuric acid, reducing the ferric sulfate with aluminum and titrating the reduced solution with permanganate. An atmosphere of carbon dioxide was maintained during

[17] A preliminary investigation of this method was made by Mr. Willard A. Findlay. The detailed experimental study was carried out as a group problem by the honor students of a class in quantitative analysis. Experiments numbered 1, 2, 3, 4 and 5 of Table I were performed by S. C. Dorman, R. P. Coleman, R. E. Morris, W. A. Findlay, and J. B. Hatcher, respectively. Experiments 1, 2, 3, 4 and 5 of Table II were carried out by L. E. Kinsler, T. R. White, W. F. Eberz, C. H. Gregory, and G. M. Webb, respectively. The results shown are representative of a larger number of experiments than those actually recorded.

the reduction and titration. The permanganate solution had been standardized against sodium oxalate obtained from the Bureau of Standards. The results of the standardizations of the ferric chloride solution in millimoles per liter were as follows: 99.15, 99.18, 99.15, 98.91, 98.99, 98.91, 99.24, 99.14, 98.95; mean, 99.07.

The sodium thiosulfate solution used was standardized against the same permanganate solution under the conditions recommended by Bray and Miller.[18] Referring the thiosulfate and ferric chloride solutions to the same permanganate solution eliminated the need of knowing the exact absolute value of the permanganate.

Effect of Hydrochloric Acid and of Air.—In order to test the effect of the hydrochloric acid concentration and also the effect of the presence of the oxygen of the air, experiments were carried out as follows: 25-ml. portions of the ferric chloride solution were pipetted into a 250-ml. glass-stoppered conical flask; the amount of hydrochloric acid present was then adjusted to the value shown in the second column of Table I, 3.0 g. of solid potassium iodide was introduced, the solution mixed and the reaction mixture allowed to stand for five minutes in the stoppered flask. The volume of the solution was approximately 30 ml. This solution was then diluted to approximately 100 ml. and immediately titrated with the standard sodium thiosulfate solution, the usual starch indicator being used.

The results are given in Table I. The third column shows the volume of thiosulfate used when this first end-point was obtained. The time

[18] Bray and Miller, THIS JOURNAL, 46,2204 (1924).

required for this titration varied from five to ten minutes. To test the stability of this end-point, the solutions were in all cases allowed to stand for two five-minute intervals in the stoppered flask, and if any further iodine color developed it was titrated. The fourth and fifth columns show the total volume of thiosulfate used when more was required. Weight burets or calibrated' volume burets were used in making the titrations. The calculated volume of thiosulfate was 25.33 ml.

In the experiments in which the air was excluded the ferric chloride solution was brought just to boiling for three minutes and then cooled while a rapid stream of carbon dioxide gas was passed above the solution. The potassium iodide was then introduced and the solution allowed to stand for five minutes under a slight pressure, but no appreciable flow, of the carbon dioxide. The solution was then diluted to 100 ml. with water that had been saturated by passing a vigorous stream of carbon dioxide through it and then was titrated. The results of these experiments are shown in Table II. Although the solutions were allowed to stand for two five-minute intervals after obtaining the first end-point, in no case did further iodine color develop after the first five-minute interval. The calculated volume of thiosulfate was 25.33.

Effect of the Iodide Concentration.—To determine the effect of varying the potassium iodide used, experiments were carried out by Mr. Willard A. Findlay in air and with conditions similar to those in Table I, using 12 milli-equivalents of hydrochloric acid and the amount of potassium iodide indicated in the first column of Table III. The calculated volume of thiosulfate was 34.68 ml.

TABLE III

EFFECT OF EXCESS OF IODIDE WHEN USING HYDROCHLORIC ACID

5.0	34.67	34.67	34.67

Effect of the Presence of Sulfuric Acid and of the Iodide Concentration.—A brief study was made by Mr. W. A. Findlay of the reaction between iodide and ferric sulfate in sulfuric acid solution. An approximately 0.1 molal ferric sulfate solution which was 0.25 molal in sulfuric acid was used. The procedure was the same as with the hydrochloric acid solutions in the presence of air with the exception that 4 g. of potassium iodide was added. The effect of the amount of sulfuric acid present is shown in Table IV. The calculated volume of thiosulfate was 29.31 ml.

TABLE IV

EFFECT OF SULFURIC ACID IN THE PRESENCE OF AIR

H_2SO_4 present, milli-equivalents	1st end-point	Ml of thiosulfate after five minutes	After ten minutes
Neutralized	27.35	27.72	27.77
6	29.12	29.19	29.25

72	29.49	29.49	29.51

The experiments shown in Table V were made to show the effect of the excess of iodide present when using sulfuric acid. The procedure was the

TABLE V

EFFECT OF EXCESS OF IODIDE WHEN USING SULFURIC ACID

KI used, g.	1st end-point	Ml. of thiosulfate after five minutes	After ten minutes
0.5	13	14	15
1.0	22.6	23.5	24.0
2.0	28.80	28.92	29.30
3.0	29.18	29.26	29.26
4.0	29.28	29.29	29.29
8.0	29.36	29.36	29.37

same as that above, 18 milli-equivalents of sulfuric acid being present. The calculated volume of thiosulfate was 29.31 ml.

Discussion of the Results

The experiments given in Table I, which were carried out in the presence of air, show that under the conditions of the procedure used permanent end-points and results consistent to 0.2% can be obtained when there are present 0.25 to 12 milli-equivalents of hydrochloric acid in 30 ml. of solution. If the solution is nearly neutralized unstable end-points and low results are obtained. This is to be expected because of the hydrolysis of the ferric chloride under these conditions. With more than 24 milli-equivalents of hydrochloric acid the "oxygen error" becomes pronounced, as shown by the unstable end-points and high results. The experiments given in Table II, carried out under carbon dioxide, show that the accuracy obtained in the presence of air when less than 12 milli-equivalents of acid was present is at least partly due to compensating errors, namely, to a negative error, probably caused by insufficient acid to prevent hydrolysis of the ferric chloride, and a positive "oxygen error." When 12 milli-equivalents of hydrochloric acid are present during this reaction between iodide and ferric chloride, or the acid is approximately 0.5 mold, the values obtained in carbon dioxide reach a maximum. The decrease observed in the values for the first end-point as the acid is increased above 12 milli-equivalents, while possibly a rate effect, is in accord with the decrease in the potential of the ferric-ferrous electrode which has been observed by Carter and Clews[19] and by Popoff and Kunz,[20] as the hydrochloric acid in the solution is increased. This effect is attributed by these authors to complex formation between the hydrochloric acid and the ferric chloride. When air is present this effect is overcome by a greater oxygen error. It is indicated that the oxygen error is at a minimum when the hydrochloric acid concentration is most favorable for the reaction between the ferric chloride and iodide. The experiments given in Table III show that 3 g. of potassium iodide is the minimum amount permissible under the conditions of these experiments. The experiments of Tables IV and V indicate that the effect of sulfuric acid is to increase the amount of acid and of iodide necessary and to make the end-point less stable. The above results are confirmatory of the experiments and conclusions of Kolthoff.

Test Analyses

In order to test this method the following analyses were carried out by Mr. C. H. Gregory. A sample containing 2.3667 g. of "Sibley" Iron Ore, Standard Sample No. 27 of the Bureau of Standards and containing ac-

---

cording to the average of the Bureau of standards determinations 69.26% iron, was weighed out. This was treated with hydrochloric acid and the insoluble residue was filtered out and treated with hydrofluoric acid in a platinum crucible; the hydrofluoric acid was expelled by adding sulfuric acid and evaporating this just to dryness. The residue remaining was dissolved in hydrochloric acid and added to the first solution. Dilute permanganate solution was added to this cold solution until the first perceptible pink color was noted and the solution then evaporated until the volume was about 5 ml. Five ml. of 6 molal hydrochloric acid was then added, the solution diluted to 250 ml. in a weighed flask and the flask and solution weighed. Two approximately 25-ml. portions of this solution were then weighed into conical flasks and treated by the same procedure as was used in obtaining the results shown in Table I. Two other samples were then treated by the same procedure, except that the air was displaced by carbon dioxide in the manner previously described. Weight burets were used in the titrations. The results of these analyses are shown in Table VI.

TABLE VI

ANALYSIS OF IRON ORE NO. 27 OF THE BUREAU OF STANDARDS

Method	Air not removed	Air not removed	Under CO_2	Under CO_2
Fe found, %	69.23	69.19	69.16	69.16
Fe present, %	69.26	69.26	69.26	69.26

Summary

The conditions determining the reliability of the simple iodometric determination of ferric iron originally suggested by Mohr have been studied. Experiments have been described which show that an accuracy of 0.2% is obtained when the reaction between the ferric chloride and iodide is allowed to take place in a closed flask for five minutes in about 30 ml. of a solution which contains 3 g. of potassium iodide and from 0.25 to 25 milli-equivalents of hydrochloric acid, and this solution is then diluted to approximately 100 ml. and titrated with thiosulfate. Permanent end-points are obtained under these conditions. The accuracy of this procedure has also been confirmed by test analyses.

Experiments carried out under carbon dioxide show that this accuracy is in most cases partly the result of compensating errors—an incomplete reaction and an "oxygen error."

When sulfuric acid is used more acid is required, a higher concentration of iodide is necessary and the end-points are not as permanent.

STUDIES RELATING TO BORON'. I. REACTION OF BORON TRIFLUORIDE WITH AMMONIA AND ALKYLAMINES

BY CHARLES A. KRAUS AND EARL H. BROWN

RECEIVED APRIL 6, 1929 PUBLISHED SEPTEMBER 5, 1929

I. Introduction

The chemistry of boron is of particular interest in the light of the modern atomic theory. Seemingly, boron has a marked tendency to form compounds corresponding to a valence greater than might be expected from its position in the periodic system. This is best seen in the simplest hydride whose composition corresponds to the formula BH_3 but whose molecular weight corresponds to the formula B_2H_6.[1] The tendency of boron to function with a higher valence than **3** also appears in other compounds. Thus Krause,[2] in reducing triphenylboron with the alkali metals in ether, obtained a salt corresponding to the formula $NaB(C_6H_5)_3$. The electron due to sodium is evidently associated with the triphenylboron group, but it is not held very firmly since it is reduced by triphenylmethyl. Triphenylboron also forms remarkably stable compounds with one molecule of ammonia or an amine.[3] When these compounds are reduced by means of the alkali metals in suitable solvents,[4] they add an atom of metal to form compounds of the type $NaB(C_6H_5)_3{\cdot}NH_3$. Trimethylboron also combines with various hydroxides[5] and triphenylboron combines with the amides[6] of the alkali metals. These compounds are now under investigation and will be reported later.

The boron trihalides appear to have a marked tendency to combine with ammonia or amines. In particular, boron trifluoride combines with ammonia with the evolution of a great deal of heat to form a seemingly stable solid compound. Unfortunately, it is not easy to distinguish between an addition compound and a mixture of compounds due to ammonolysis. It is the purpose of the present investigation to determine definitely whether or not boron trifluoride is capable of adding ammonia or an amine directly without ammonolysis. As the results will show, this is the case, although, at the same time, there is clear evidence that, when boron trifluoride is dissolved in ammonia or an amine, it is ammonolyzed to an appreciable extent.

The reaction between boron trifluoride and ammonia was first observed

by Gay-Lussac.[7] The reaction was further studied by J. Davy.[8] Neither of these investigators definitely established whether or not an addition compound is formed. Davy, in particular, showed that the initial solid compound is soluble in excess of ammonia.

According to Mellor,[9] the solid compound is probably monoammino-boron trifluoride, $BF_3 \cdot NH_3$, while the products containing greater quantities of ammonia are mixtures of ammonium fluoride and boron amides.

Mixter[10] prepared monoammino boron trifluoride by passing boron trifluoride into dry ammonia gas. He analyzed this product for ammonia and found values approximating that required for the formula $BF_3 \cdot NH_3$. He determined the molecular weight of the vapor of this material by the Victor Meyer method at temperatures above the melting point of zinc. The values found lay in the neighborhood of 46, or approximately one-half that of monoammino boron trifluoride, indicating practically complete dissociation of the compound into its constituents.

Joannis[11] studied the interaction between boron trichloride and liquid ammonia and concluded that the chloride is completely ammonolyzed. This might lead one to infer that a similar reaction occurs in the case of boron trifluoride. It should be noted, in this connection, that the weight of the final product gives no safe indication of whether or not ammonolysis has occurred. Thus, reaction might take place as follows

$$2\ BF3 + 2\ NH3 = NH_4BF_4 + BF_2NH_2$$

If boron trifluoride ammonolyzes with the formation of ammonium fluoride, the latter compound might well combine with boron trifluoride to form ammonium borofluoride. The resulting mixture would have the same composition as a compound of the formula $BF_3 \cdot NH_3$.

As indicating a marked tendency of boron trifluoride to form addition compounds, it might be mentioned that Gasselin[12] found that it combines readily with one molecule of ether to form a comparatively stable product boiling at 125°. An ether solution of boron trifluoride was found very useful in the present investigation in preparing pure compounds of boron trifluoride with ammonia and various amines.

II. Preparation and Properties of Monoammino Boron Trifluoride

Materials.—Boron trifluoride was prepared by heating a mixture of ammonium borofluoride with a slight excess of boric oxide in concentrated sulfuric acid.

Ammonium borofluoride was prepared by dissolving boric acid in a slight excess

of aqueous hydrogen fluoride and neutralizing with ammonium hydroxide. The solution was concentrated, filtered and allowed to cool, when fine colorless crystals separated.

Preparation of $BF_3 \cdot NH_3$.—A reliable method for the preparation of monoammino boron trifluoride was not found in the literature. Accordingly, four different methods were tried out, of which the last proved the most convenient. These methods were: (1) to pass a mixture of dry nitrogen and boron trifluoride through liquid ammonia, (2) to introduce alternately small quantities of boron trifluoride and ammonia into an evacuated bulb at room temperatures, (3) to bubble pure boron trifluoride into liquid ammonia from underneath a surface of mercury, (4) to saturate an ether solution of boron trifluoride with ammonia.

Methods 1 and 2 were quite unsatisfactory. Method 3 proved fairly convenient but the presence of mercury was disadvantageous. Method 4 proved satisfactory and may be described in some detail. The desired quantity of boron trifluoride, dissolved in ether, is saturated with ammonia at zero degrees by passing a stream of ammonia vapor over the surface of the solution under constant agitation. Monoammino boron trifluoride is precipitated as a fine, white solid. The supernatant liquid is decanted and adhering solvent removed by means of a pump.

Properties of $BF_3 \cdot NH_3$.—Monoammino boron trifluoride is soluble in liquid ammonia, ethylamine and diethylamine. It is practically insoluble in ether, benzene and petroleum ether. When heated in an evacuated tube, it sublimes at temperatures above 180°, leaving only a slight residue. Fusion sets in at 180°, an opaque pasty mass resulting. This seems to indicate that under these conditions the material is not homogeneous.

Monoammino boron trifluoride, dissolved in liquid ammonia, is appreciably ammonolyzed, since, when treated with metallic sodium, hydrogen is evolved. The reaction takes place in several stages, indicating that not all the fluorine atoms are hydrolyzed with equal ease. The fact that the corresponding ethylamine derivative can be completely ammonolyzed by means of lithium in ethylamine leaves no doubt that an analogous reaction occurs in liquid ammonia.

Analysis of Monoammino Boron Trifluoride.—The compound prepared by passing ammonia through an ethereal solution of boron trifluoride was analyzed for ammonia and boron. To determine the ammonia, an alkaline solution of the compound was distilled, the distillate being collected in an excess of 0.1 N hydrochloric acid which was titrated back with 0.1 N sodium hydroxide.

Anal. Subs., 0.3151, 0.4147: 36.33, 48.01 cc. of 0.1021 N HCl. Calcd. for $BF_3 \cdot NH_3$: N, 16.47. Found: N, 16.48, 16.54.

In analyzing for boron, weighed samples were dissolved in water containing a slight excess of sodium hydroxide. The resulting solutions were neutralized with 0.1 *N* hydrochloric acid, using methyl red as indicator. When the end-point was reached, about 1 g. of mannitol was added and the boric acid titrated with 0.1 N sodium hydroxide, using phenolphthalein as indicator.

Anal. Subs., 0.1829, 0.2949, 0.5671: 21.98, 31.66, 62.65 cc. of 0.10727 *N* NaOH. Calcd. for $BF_3 \cdot NH_3$: B, 12.95. Found: B, 14.25, 12.65, 13.00.

The nitrogen content of the compound is in good agreement with the formula $BF_3 \cdot NH_3$ but the boron analyses are less satisfactory. In fact, unless conditions can be carefully controlled, it is extremely difficult to get entirely satisfactory results for boron by any of the usual analytical methods.

As will be shown below, boron trifluoride combines with triethylamine to form the compound $BF_3 \cdot N(C_2H_5)_3$. When this compound is treated with ammonia, a product is formed which has the properties of monoammino boron trifluoride. Its solubility, melting point and other properties correspond closely with those of the compound directly precipitated by passing ammonia into an ethereal solution of boron trifluoride. The product formed by the treatment of the triethylamine derivative with ammonia was analyzed for nitrogen, as described above.

Anal. ($BF_3 \cdot NH_3$ precipitated from triethylamine). Subs., 0 0394, 0.0275: 4.54, 3.19 cc. of 0.1021 *N* HCl. Calcd. for $BF_3 \cdot NH_3$: N, 16.47. Found: N, 16.46, 16.52.

It was found that monoammino boron trifluoride is soluble in triethylamine in the presence of excess ammonia. When the excess ammonia is slowly removed, the ammonia derivative crystallizes from the solution. A quantity of this material was prepared and analyzed for nitrogen.

Anal. (Recrystallized $BF_3 \cdot NH_3$). Subs., 0.1192, 0.0947: 13.88, 11.01 cc. of 0.1021 N HCl. Calcd. for $BF_3 \cdot NH_3$: N, 16.47. Found: N, 16.63, 16 61.

The analyses show that the product formed on passing ammonia through an ethereal solution of boron trifluoride has a mean composition corresponding to the formula $BF_2 \cdot NH_3$. Either a compound corresponding to this formula exists or the product consists of a mixture of BF_2NH_2 and NH_4BF_4. Since the compound prepared by the action of ammonia on a triethylamine solution of boron trifluoride is identical with that obtained from an ethereal solution and since, moreover, the product formed in ethylamine is completely soluble in this solvent in the presence of excess ammonia and can be recrystallized from this solvent, and since, further, the crystallized product, on analysis, shows a composition corresponding to the formula $BF_3 \cdot NH_3$, it follows that the original product formed by the action of ammonia on the ethereal solution of boron trifluoride is, in fact, an addition compound $BF_3 \cdot NH_3$. Triethylamine is a very indifferent solvent for salt-like substances, being inferior even to ether in this respect. It is inconceivable that ammonium borofluoride would be soluble in such a mixture. Furthermore, in the process of recrystallization, there is no evidence of a second product. Accordingly, it may be concluded that boron trifluoride combines with one molecule of ammonia to form the compound $BF_3 \cdot NH_3$.

III. Triethylammino Boron Trifluoride

Preparation.—The interaction between boron trifluoride and triethylamine is of particular interest since ammonolysis cannot well take place in this solvent. The compound was first prepared by introducing a known quantity of triethylamine into a weighed reaction tube cooled to liquid ammonia temperatures, into which an excess of boron trifluoride was then introduced. When the reaction was completed, the excess fluoride was pumped off and the reaction tube was weighed. Thus the amount of boron trifluoride combined with the amine could be found.

The product formed was a solid melting at room temperatures and turning brown upon standing for a comparatively short time. In three experiments the following results were obtained: 3.125, 0.534, 1.565 g. of amine combined with 1.924, 0.392, 0.928 g. of BF_3. These data yield for the ratio $BF_3/(C_2H_5)_3N$ the values 0.951, 1.076, 0.877.

In other words, approximately 1 mole of boron trifluoride was found to combine with one mole of triethylamine. It was found that the product is soluble in the presence of excess ammonia and that it is reprecipitated in crystalline form as the ammonia is removed. The resulting crystalline material appeared to be identical with monoammino boron trifluoride.

In one experiment ammonia was added to the triethylamine derivative, after which the tube containing the material was pumped to constant weight at $-33°$. Under these conditions the excess ammonia, as well as the triethylamine formed in the reaction with ammonia, was removed. It was found that 2.4821 g. or 0.0246 mole of amine initially combined with 1.6805 or 0.0247 mole of BF_3 and, after treating with ammonia, the weight indicated the presence of 0.4389 g. or 0.0258 mole of NH_3. From these data it is seen that 1 mole of boron trifluoride combines with 1 mole of triethylamine which, in turn, may be substituted quantitatively by ammonia. The final product obtained in this reaction was analyzed for ammonia, the data being given on page 2693.

A second and more satisfactory method of preparing triethylammino boron trifluoride consists in treating an ethereal solution of the trifluoride with an excess of triethylamine at liquid ammonia temperatures. The amine (in excess) was condensed on the ethereal solution of BF_3 and when the two layers were mixed, a white precipitate was formed. This precipitate melted at room temperatures and rapidly acquired a brown tint, indicating some decomposition. After removing all excess materials, the product was finally distilled at a temperature of 80° under a pressure of 3 mm. The liquid which distilled over solidified in the colder portions of the apparatus. This compound proved to be triethylammino boron trifluoride $(C_2H_5)_3N{\cdot}BF_3$.

Analysis and Molecular Weight.—The nitrogen content of the redistilled material was determined by adding water and boiling off the amine in an evacuated two-legged tube. The distillate was titrated with standard hydrochloric acid.

Anal. Subs., 0.0783, 0.0688: 5.13, 4.41 cc. of 0.09077 *N* HCl. Calcd. for $(C_2H_5)_3N{\cdot}BF_3$: N, 8.27. Found: N, 8.32, 8.14.

The fluorine content of the compound was determined as lead chlorofluoride. The sample was dissolved in water and 16 drops of concentrated hydrochloric acid were added, after which the solution was made slightly acid with nitric acid and 10 drops of acetic acid were added. Lead chlorofluoride was precipitated on the addition of a 10% solution of lead acetate.

Anal. Subs., 0.0389, 0.0889: PbClF, 0.1751, 0.4068. Calcd. for $BF_3{\cdot}(C_2H_5)_3N$: F, 33.69. Found: F, 32.67, 34.38.

The analyses for fluorine are not entirely satisfactory but, as is well known, it is extremely difficult to obtain satisfactory analyses for this element, particularly with the small quantities of material available. There can be no doubt, however, that the compound involves a single molecule each of triethylamine and boron trifluoride. This was further borne out by its molecular weight in benzene as determined by the freezing-point method.

Molecular weight of $BF_3{\cdot}(C_2H_5)_3N$ in benzene: solute, 0.1262, 0.2312, 0.3574 g.; solvent, 22.69, 22.69 g.; *At,* 0.170°, 0.300°, 0.437°; mol. wt. found, 163.5, 169.8, 180.1; mol. wt. calcd. for $(C_2H_5)_3N{\cdot}BF_3$, 169.2.

As may be seen from the data given, the molecular weight of the compound in benzene solution corresponds closely to that required.

Properties.—Triethylammino boron trifluoride melts sharply at 29.5°. It decomposes slowly, especially at room temperatures, turning brown and giving off amine. It is very soluble in alcohol, benzene, ether and hot petroleum ether. It is difficultly soluble in water, but if first dissolved in a small quantity of ether the resulting solution is completely soluble in water. The compound, when dissolved in triethylamine, is not affected by freshly cut sodium or lithium.

IV. Diethylammino Boron Trifluoride

Preparation.—Monoammino boron trifluoride was dissolved in diethylamine, the excess amine removed with a pump, the product washed with ether and the last traces of solvent were removed with a pump. The product was a white solid which melted at 150–151°.

Anal. Subs., 0.0672, 0.0817: 5.31, 5.96 cc. of 0.09077 N HCl. Calcd. for $BF_3\cdot(C_2H_5)_2NH$: N, 9.91. Found: N, 10.41, 8.27.

In one experiment 0.9648 g. (0.0113 mole) of $BF_3\cdot NH_3$ was treated with diethylamine in a weighed reaction tube. After exhausting, the product weighed 1.6054 g. Assuming that the ammonia was replaced by diethylamine, the weight of amine present corresponded to 0.0118 mole, which agrees fairly well with 0.0113, the number of moles of boron trifluoride present.

In another preparation diethylamine was distilled into an ethereal solution of boron trifluoride at liquid ammonia temperatures. A white crystalline solid was formed, the supernatant liquid was decanted and the solid was washed several times with ether. It was then dried rapidly on a filter paper. It melted at 165° but not sharply.

Anal. Subs., 0.1360, 0.1113: 9.34, 9.69 cc. of 0.09077 N HCl. Calcd. for $BF_3\cdot(C_2H_5)_2NH$: N, 9.91. Found: N, 8.72, 8.79.

On analyzing this material for boron by the lead chlorofluoride method, there were obtained, respectively, 46.33 and 45.00% of fluorine against 40.36 required.

In another preparation an ethereal solution of boron trifluoride was added drop by drop to diethylamine cooled in ice water. The resulting product was dissolved in alcohol and ether was added to precipitate the compound. After washing, the product was dried on a pump and analyzed.

Anal. Subs., 0.0613, 0.0812: 3.73, 4.84 cc. of 0.1083 N HCl. Calcd.: N, 9.91. Found: N, 9.23, 9.04.

Several analyses for fluorine yielded 50% in place of 40.36% required for the compound $BF_3\cdot(C_2H_5)_2NH$. None of the analyses, either for fluorine or nitrogen, is entirely satisfactory. The first preparation gave, on the whole, the most satisfactory results. Seemingly the compound loses diethylamine fairly readily. This is further borne out by the fact that the melting points obtained were variable and in general not sharp.

Properties.—Diethylammino boron trifluoride is practically insoluble in ether, benzene and petroleum ether. It is very soluble in diethylamine, alcohol and water. It melts in the neighborhood of 160°. The high melting point is quite unexpected as the triethylamine derivative melts at 29.5° while the ethylamine derivative melts at 89°.

V. Ethylammino Boron Trifluoride

Preparation.—The ethylamine derivative was prepared by condensing a quantity of ethylamine on monoammino boron trifluoride in one leg of a two-legged tube. Any undissolved material was allowed to settle out, after which the supernatant liquid was decanted into the second leg of the tube. The excess of amine was then distilled and the last traces were removed by means of a pump.

The compound was also prepared by adding an excess of amine to an ethereal solution of boron trifluoride and distilling off the ether and excess amine.

Analyses.—Products prepared as described above were analyzed for nitrogen in the usual manner.

Subs., **0.0736, 0.0756, 0.2250, 0.2315: 6.40, 7.31, 19.51, 20.16** cc. of **0.1021** *N* HCl. Calcd. for $BF_3\cdot(C_2H_5)NH_2$: N, 12.38. Found: N, **12.43, 13.82, 12.39,** 12.45.

The product was likewise analyzed for fluorine by the lead chlorofluoride method.

Subs., **0.0782, 0.0920:** PbClF, **0.559, 0.6851.** Calcd. for $BF_3\cdot(C_2H_5)NH_2$: F, **50.39.** Found: F, **51.60, 51.94.**

The molecular weight of the ethylamine derivative was determined in ether by a modification of the Cottrell method.

Subs., **0.3253, 0.1505, 0.0704;** ether, 33.06, **29.23, 40.37;** *At,* 0.141°, 0.1079°, **0.029'.** Calcd. for $BF_3\cdot(C_2H_5)NH_2$: mol. wt., **113.1.** Found: mol. wt., **147.0, 137.5, 133.3.**

Properties.—Ethylammino boron trifluoride melts sharply at 89°. It decomposes rapidly when heated in air above its melting point. It is soluble in benzene and slightly soluble in ether, from which solvents it may be recrystallized. Its reaction with lithium in ethylamine solution will be described in a subsequent paper.

Taking into account the results of analysis and molecular weight determinations, as well as the fact that the compound may be recrystallized from various solvents, there can be little doubt that ethylamine forms an addition compound with boron trifluoride corresponding to the formula $BF_3\cdot(C_2H_5)NH_2$.

Summary

1. Several methods for the preparation of monoammino boron trifluoride, $BF_3\cdot NH_3$, are described. This compound has been characterized and some of its properties determined.

2. Boron trifluoride combines with triethylamine to form the compound $BF_3\cdot(C_2H_5)_3N$, which melts at 29.5°. The method of its preparation and its properties are described.

3. Boron trifluoride combines with diethylamine to form the compound $BF_3\cdot(C_2H_5)_2NH$, which melts in the neighborhood of 160°. This compound is relatively less stable than other ammino derivatives and has not been so well characterized.

4. Boron trifluoride combines with ethylamine to form the compound $BF_3\cdot C_2H_5NH_2$, which melts at 89°. The properties of this compound are described and methods of preparation are given.

THE DECOMPOSITION OF THALLIC OXIDE[1]

BY A. B. F. DUNCAN

RECEIVED APRIL 9, 1929 PUBLISHED SEPTEMBER 5, 1929

In studies of the thermal decomposition of metallic oxides, relatively little attention has been paid to the influence of particle size on the equilibrium oxygen pressures. L. Wöhler,[2] in a study of the decomposition of several oxides, observed that the equilibrium pressure of a sample at a fixed temperature was not constant but gradually fell. A. J. Allmand[3] attributed this to changes in particle size during heating, while Wohler claimed that solid solutions of the products with the original oxide were formed. The influence of particle size on the decomposition of carbonates and mercuric oxide has been studied by Centnerszwer and co-workers[4]

If a sample of oxide is prepared by precipitation in cold solution, or from a hydroxide by dehydration at low temperatures, the sample would usually contain a large proportion of very small particles. If the oxide loses oxygen at low temperatures, at which there is a slow rate of growth of the particles to larger ones, we may obtain apparent equilibrium values which are in error due to the fact that the original solid was not in a thermodynamic steady state. By varying the conditions of precipitation and dehydration we get samples which give different equilibrium pressures at the same temperature. If a quantity of oxygen is withdrawn after the equilibrium pressure is reached and a lower equilibrium pressure is obtained at the same temperature, it cannot be decided whether a solution has been formed or whether a change in the degree of dispersion of the solid has taken place.

Matters are somewhat simplified when we can work with oxides above their melting points. The size of the particles no longer enters the question and any lowering of the decomposition pressure must show solution. Milan has recently studied[5] the decomposition of vanadium pentoxide above its melting point and found that small quantities of the lower oxide, V_2O_4, lowered the decomposition pressure of pure V_2O_5 by large amounts.

Experiments on the loss of oxygen by thallic oxide have been made by Lamy,[6] T. Carnelley and J. Walker,[7] and O. Rabe.[8] The behavior of this

oxide on being heated seems to depend on its method of preparation. If the oxide is prepared from the hydrate, $Tl_2O_3 \cdot H_2O$, it loses oxygen below 100°, before all the water is removed. The brown crystalline modification loses oxygen below 500°, but according to Rabe[9] the black crystalline modification may be heated for hours at 500° without change. The behavior of Tl_2O_3 heated in a vacuum has not been studied. The decomposition of the oxide is thus seen to depend on the method of preparation, but the brown forms change over to the black by melting under a pressure of oxygen sufficient to prevent decomposition.

Two experimental difficulties are met in the study of the decomposition of thallic oxide. The oxides are chemically active and attack fused quartz, forming silicates, and dissolve platinum and silver. In addition, thallous oxide is somewhat volatile at the temperatures used and would distil into cooler parts of the apparatus, changing the composition of the residue, or react with the fused quartz, leaving an excess of oxygen. In this work a vessel of pure fused magnesium oxide[10] was found to be satisfactory since it was not attacked chemically and apparently not dissolved by the oxides. The pure oxide was molded, sintered at a high temperature and finally heated at 2500° in the induction furnace. The surface was well glazed. The second difficulty was avoided by enclosing the crucible and oxide in a vacuum-tight vessel of pure silver. At high temperatures oxygen quickly diffused through the walls but the thallous oxide could not, so it was all kept at constant temperature. Details in regard to the construction of this vessel are given in the following section.

Apparatus

The apparatus consisted of the fused quartz reaction tube, a water jacketed gas buret, a manometer, a McLeod gage and a mercury vapor pump backed by an oil pump. The pumps could be cut off from the apparatus by a mercury trap.

The manometer was a U-tube, both arms being one meter long. The top of one arm was connected to the reaction tube and gas buret and the other arm led to the McLeod gage and pumps. At the bottom of the U was sealed a tube 80 cm. long, carrying rubber hose and leveling bulb. With the mercury bulb lowered the manometer, reaction vessel and gas buret could be put in connection with the pumps and McLeod gage. By raising the mercury the manometer gave direct pressure readings provided a high vacuum was maintained over the arm connected to the pumps. The manometer and scale to which it was fixed was calibrated. The fused quartz reaction tube is shown in Fig. 1. The platinum–platinum-10% rhodium thermocouple was in the inner fused quartz tube and the hot junction about three millimeters from the silver cup, well in the zone of constant temperature of the furnace. Temperatures were measured on a Leeds and Northrup portable potentiometer, and are considered accurate to 3°. The platinum furnace has been described.[11] The gas buret and fused quartz tube were connected to

[11] Morse and Frazer, *Am. Chem. J.*, **32**, 93 (1904).

the manometer by graded seals. The volume was made as small as possible by the use of capillary pyrex tubing. The space within the quartz–pyrex graded seal was taken by a closely fitting glass tube sealed at both ends.

The silver cup was designed so that it could be filled with oxygen at atmospheric pressure and sealed in that condition. The silver was specially purified in this Laboratory. The bottom cylindrical cup was 5 cm. high, 2.5 cm. in diameter, 0.17 mm. thick and was spun in one piece. The top, also spun in one piece, had a rim projecting upward 1.5 cm., and fitted closely in the cup. In the center of the top was a cone which had a small hole in the tip.

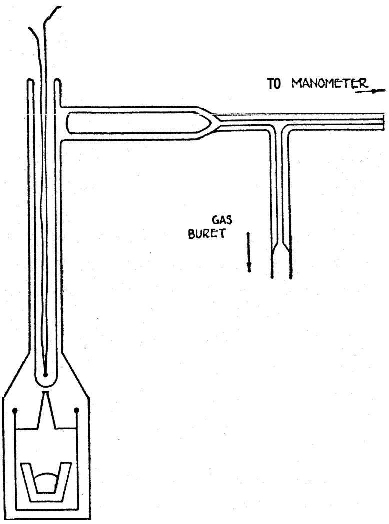

Fig. 1.

Sealing the Silver Cup.—A weighed sample of thallic oxide was placed in the magnesia crucible which was placed in the silver cup. The top was put in place and fused to the cup with a small oxygen–gas flame, without the use of solder. During this operation, the cup was partly immersed in water.

After sealing, the cup was placed in the pyrex tube shown in Fig. 2, which was sealed to the manometer and gas buret. Then with the lower stopcock closed and the upper opened the apparatus, including the interior of the silver cup, was thoroughly pumped out. Then the volume of the apparatus was found by admitting a known quantity of air and measuring the pressure. The air was pumped out and oxygen (99.8%) was admitted to atmospheric pressure. Then a rapid stream of oxygen was started from a tank through a rubber tube. The upper stopcock was closed. The rubber tube was fitted on the lower stopcock, which was quickly opened and the ground joint disconnected. With oxygen rapidly passing upward around the cup the hole was closed as tightly as possible by pressing the tip of the cone with pliers. Then the cup was taken out and the tip sealed by melting in the oxygen–gas flame. The cup was replaced in the pyrex tube, the apparatus pumped out and the volume of the apparatus again determined. The volume was shown to be much less and the decrease in volume minus the volumes of silver, magnesia and thallic oxide gave the oxygen inclosed.

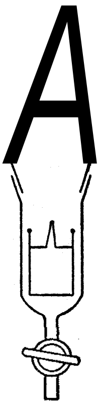

Fig. 2.

Preparation of Thallic Oxide.—The method of preparing black crystalline thallic oxide given by Rabe[8] was used with slight modification. The product was washed with 5 N nitric acid, then with hot water until free from acid and dried at 120". It was later fused under an oxygen pressure greater than the decomposition pressure. The product used consisted of well-defined black needles.

Experimental Procedure

The silver cup after sealing was sealed inside the fused quartz container shown in Fig. 1. This was packed in the furnace and then sealed to the apparatus. The total volume of the reaction system was found by admitting a known quantity of air and reading pressure after the mercury had been raised above the gas buret to a mark on the capillary tubing.

The reaction tube was evacuated for several days with the furnace heated to 450°. The furnace was brought to 750° and oxygen admitted from the gas buret to 760 millimeters' pressure. After heating at this temperature and pressure for several hours, the furnace was slowly cooled, the oxygen pressure being kept constant at 760 millimeters. The system was pumped out. The mercury was raised above the stopcock of the gas buret and the manometer set; then the following experiments were made.

The oxygen pressures at five different temperatures were measured. To insure equilibrium the temperature was kept constant until there was no further change in pressure. The temperature was increased for a time and then changed to its former value, at which the pressure also assumed its former value. Pressures were measured to the nearest millimeter. After cooling very slowly to room temperature the pressure remaining was less than one millimeter.

The furnace was heated and the mercury drawn back into the gas buret. When a sufficient quantity of oxygen had collected, a definite volume at known temperature and pressure was withdrawn from the system by closing the stopcock of the buret. The mercury was raised above the stopcock and the furnace slowly cooled. The melt contained a mixture of thallic and thallous oxides and the composition was fixed by the oxygen removed.

The oxide mixture was heated at the same temperatures that were used previously and measurements of the equilibrium pressures were obtained. At the conclusion another definite quantity of oxygen was removed. Four series of pressure measurements were made, representing the decomposition of the pure oxide and three different mixtures of the two oxides.

During the fifth series of measurements erratic results were obtained and after a short time the reaction tube broke. It was found that the melted oxides had crept over the sides of the magnesia crucible, made a hole in the bottom of the silver cup and then a hole in the quartz glass. Thallous oxide vapor does not attack silver, for the upper part of the cup was quite clean.

The total volume of the apparatus from the zero mark of the manometer was known to be 57.94 cc. The volume outside the furnace was measured by filling with mercury and weighing. It was found to be 8 cc. The volume in the hot portion was then 49.94 or 50 cc. One centimeter of the manometer contained 0.135 cc. The total volume at room temperature was then 8 + 0.135 times the pressure reading.

Results

In Table I are recorded the oxygen pressures at different temperatures. From the temperatures and volumes of the different parts of the apparatus the number of moles of oxygen at the equilibrium pressures may be calculated. The moles of oxygen will give directly the Tl_2O present, and since the original weight of Tl_2O_3 is known, the mole fraction of Tl_2O may be calculated.

As an example is shown the calculation of the moles of oxygen in equilibrium with a mixture of thallic and thallous oxides at 676°, after the first quantity of oxygen had been withdrawn.

At the beginning of the work, the cup was full of oxygen at atmospheric pressure, which was 0.000692 mole. The first oxygen withdrawn from the system totaled 0.00175 mole. Then actually the difference, 0.001058 mole, was removed from the Tl_2O_3. There was originally 0.01567 mole of Tl_2O_3 present. Then the composition of the mixture before heating to 676° was Tl_2O_3, 0.014612 mole; Tl_2O, 0.001058 mole. At the temperature under consideration the oxygen present was given by the expression

$$N_{O_2} = \frac{p_{O_2}}{R}\left(\frac{V_h}{T_h} + \frac{V_c + V_m}{T_r}\right)$$

where v_h is the volume in the furnace, v_c that outside the furnace up to the zero mark of the manometer, v_m the volume in the manometer, T_h the furnace temperature, T_r the prevailing room temperature and p_{O_2} the oxygen pressure in atmospheres.

$$N_{O_2} = \frac{3.9}{76 \times 82.07}\left(\frac{50}{949} + \frac{8 + 0.527}{295.5}\right) = 0.000051$$

$$\text{Moles of } Tl_2O = 0.000051 + 0.001058 = 0.001109$$

$$\textbf{Mole fraction of } Tl_2O = \frac{0.001109}{0.01567} = 0.0708$$

Thus a solution 7.08 mole per cent. of Tl_2O is in equilibrium with oxygen at a pressure of **3.9** cm. at 676".

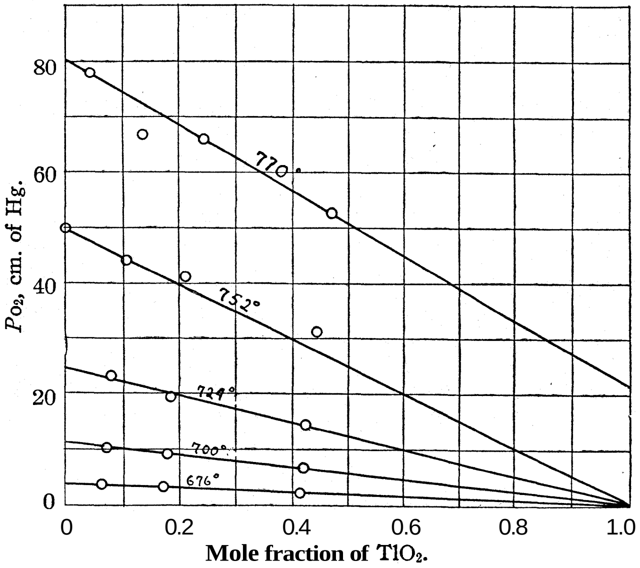

Fig. 3.

From the calculated values of the mole fraction of Tl_2O a pressure–composition diagram was plotted, which is shown in Fig. **3.** The isotherms are apparently straight lines over a long pressure range. By extrapolating these lines to zero mole fraction of Tl_2O, the decomposition pressures of pure Tl_2O_3 are obtained. These values are given in Table II.

The equilibrium constant for the reaction $Tl_2O_3 = Tl_2O + O_2$ may be calculated from these pressures at different temperatures since K_p under these conditions is equal to the oxygen pressure over pure Tl_2O_3. Values of K_p are given. Pressure–temperature curves for any mixture of the two oxides could be constructed from values read from the pressure–composition curves.

1025	0.3432	.000977	77,000	352
1043	−0.10138	.000958	....	−106

The heat of the reaction within the temperature range studied may be found by plotting $-R \ln K$ against $1/T$, shown in Fig. 4. Four of the five points fall on a straight line. The slope of the line at any point gives the heat of the reaction at that temperature. From the equilibrium constants the free energy of the reaction at certain temperatures was calculated. Values of the heat of the reaction and the free energy are given in Table III.

The Melting Point of Thallic Oxide

Reference to the composition–pressure diagram shows that unless Tl_2O_3 melts below 715–710°, the melting point cannot be determined in air, since the decomposition pressure at 720" is 25.5 cm., while the partial pressure of oxygen in air is about 16 cm. This shows that former determinations must be in error due to the presence of Tl_2O. In addition, former determinations were made in glass, and the silicates formed must have contaminated the oxide.

The determinatioq was carried out in the apparatus illustrated in Fig. 5. This was joined to the system used in the study of the decomposition pressures in the place formerly occupied by the reaction vessel. About 6 g. of black crystalline thallic oxide was placed in a fused magnesia crucible, which had been sealed previously inside a fused quartz bulb. The bulb was joined to the rest of the apparatus by a graded seal. The hot junction of the platinum–platinum-rhodium thermocouple was immersed in the oxide. The wires were insulated by fused quartz beads and led out of the apparatus through seals of de Khotinsky wax.

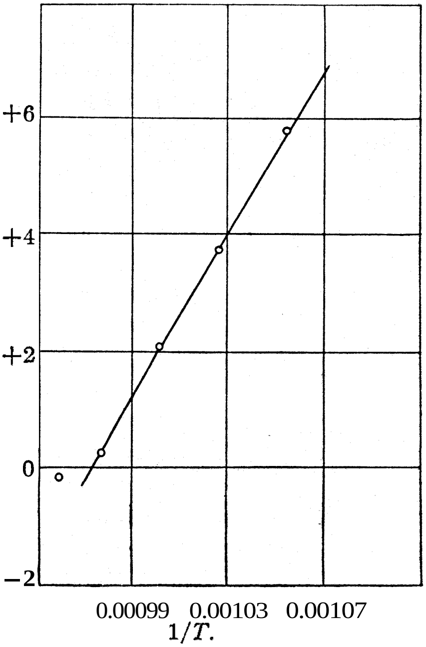

Fig. 4.

An oxygen pressure of one atmosphere was maintained over the oxide during the measurements. Readings of temperature and time were taken and cooling curves plotted. Five determinations were made. The first curve, because of too rapid cooling, showed no break. The next three showed breaks at 715, 717 and 717°. The last showed two breaks, one at 718°, and an indefinite break at about 730". The melting point is considered to be 717 ± 5°.

At the end of the fifth determination the fused quartz tube cracked and the thermocouple wires were found to be badly attacked. This probably accounts for the irregularity observed in the fifth determination.

Discussion

From the results obtained it is evident that the oxygen pressures are dependent not only on the temperature but also on the composition of the mixed oxides in equilibrium with the oxygen. If this were not the case the isotherms would have all been parallel to the composition axis. In this respect the decomposition of thallic oxide differs from the decomposition of silver oxide, mercuric oxide and cupric oxide, in which two condensed phases are present. The decomposition of ferric oxide, barium peroxide and vanadium pentoxide[12,5] gives only one condensed phase, a solid or liquid solution, depending on the temperature. Thallic oxide is to be classed with these latter oxides.

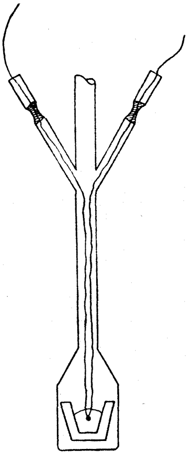

Fig. 5.

It is interesting to note that the isotherms on the pressure-composition diagram are straight lines over large variations in composition. If we apply Raoult's law to this system we find that the ratio of p_{O_2} (which is directly related to the vapor pressure of Tl_2O_3) to the mole fraction Tl_2O_3 is almost constant at constant temperature. Raoult's law seems to be obeyed in this case. This may be due to chemical similarity of the two oxides. Both are basic and show no acidic properties. Although both are polar compounds, the fields of force about the two kinds of molecules may not be different enough to cause wide departures from Raoult's law. In contrast, V_2O_5 is more acidic than basic and V_2O_4, the lower oxide formed by its decomposition, is basic. In the study of the decomposition of V_2O_5 wide variations from Raoult's law were found. We have no evidence that these oxides are associated or dissociated in solution. We have calculated the composition curve assuming that for every mole of oxygen in the gas phase there dissolves one mole of Tl_2O in Tl_2O_3. If either oxide were polymerized, the oxygen pressures would be the same but the mole fractions of Tl_2O differ, giving a different pressure–composition diagram. There seems to be no special reason why this should be the case, but it must be admitted as a possibility.

An examination of the 770° isotherm shows that the best straight line does not cut the 100 mole per cent. Tl_2O line at $p = 0$, as do the other

[12] Lewis, THIS JOURNAL, **28**, 139 (1906); Keyes and Hara, *ibid.*, **44**, 479 (1922); Hulett and G. B. Taylor, *J. Phys. Chem.*, 17, 567 (1913); Smyth and Roberts, THIS JOURNAL, **42**, 2582 (1920); Sosman and Hostetter, *ibid.*, 38, 807 (1916); Hildebrand, *ibid.*, *34*, 246 (1912).

isotherms. The line may be correct as drawn, indicating dissociation of the lower oxide. There are no data on the dissociation of Tl_2O at these temperatures. Or the line may cut the composition axis at mole fraction $Tl_2O = 1$, and the observed equilibrium values displaced from the true ones because of volatilization of the lower oxide from the solution at this high temperature, which would make the solution less concentrated in Tl_2O than is determined from the oxygen pressures. In general, the 770° isotherm does not seem to be as dependable as the other four. Furthermore, the value of the equilibrium constant obtained from the extrapolation of this curve does not fall on the straight line with the other four as shown in Fig. 4.

It is unfortunate that the heat of reaction and free energy values cannot be extrapolated to low temperatures with any degree of accuracy, but these quantities change very rapidly with temperature and an accurate knowledge of the specific heats and their variation with temperature is needed. Values for Tl_2O_3 could perhaps be determined using a sufficient pressure of oxygen to prevent decomposition, but the determination of the values for Tl_2O at these high temperatures does not seem practicable.

One of the handicaps to this work has been the lack of information about the physical and chemical properties of pure Tl_2O. Indeed, it is doubtful whether pure dry Tl_2O has ever been prepared. Its preparation, purification and any subsequent transference must be carried out in the absence of oxygen and carbon dioxide. This, coupled with its volatile nature at high temperatures, makes a study of the pure oxide very difficult.

In conclusion, the author wishes to express appreciation to Dr. J. C. W. Frazer and to Dr. W. A. Patrick, who suggested this study and under whose direction it was done.

Summary

The equilibrium pressures of oxygen over thallic oxide and mixtures of thallous and thallic oxide have been determined, from which a pressure–composition diagram has been constructed.

The equilibrium pressures of oxygen depend both on the temperature and the composition of the mixture of oxides.

Thallous oxide dissolves in thallic oxide, forming solid and liquid solutions.

The solutions of the oxides appear to obey Raoult's law over the concentration range investigated.

The melting point of thallic oxide has been redetermined, and found to be 717 ± 5°.

Values for the heat of the reaction and the free energy change are calculated for several temperatures.

THE THERMAL DECOMPOSITION OF GASEOUS ETHYLENE OXIDE

BY WINFIELD W. HECKERT AND EDWARD MACK, JR.

RECEIVED APRIL 10, 1929 PUBLISHED SEPTEMBER 5, 1929

To the rapidly increasing number of homogeneous unimolecular gaseous reactions described in the recent literature, it is the purpose of the present paper to add another, namely, the decomposition of ethylene oxide. This reaction is particularly noteworthy because of the ease with which it lends itself to accurate study, and also because the course of the reaction seems to find an adequate explanation in terms of Christiansen and Kramers' hypothesis.[1]

According to this hypothesis in exothermic reactions the energy with which the freshly formed product molecules are loaded, consisting of the heat of reaction as well as the energy corresponding to the original heat of activation, may be transmitted by collision to unactivated reactant molecules, and thereby maintain a supply of activated reactant molecules, replacing those that have undergone chemical change. An obvious objection to such a mechanism is that the increasing accumulation of inert product molecules, as the reaction progresses, or the introduction of an inert gas into the system, would result in reducing the share of energy obtained by the reactant molecules from the freshly formed product, and hence would cause a much more rapid decrease in velocity than that characteristic of a unimolecular reaction.[2]

As far as the present authors are aware, no unimolecular reaction affected appreciably in this manner by inert product or foreign gas has hitherto been observed. In the case of the decomposition of diethyl ether, Hinshelwood[3] has found that helium and nitrogen have little or no effect, although the reaction products in considerable excess had a slight retarding influence.

Nature of the Reaction.—The decomposition and isomerization (to acetaldehyde) of ethylene oxide in the presence of various catalysts have been studied by Krasussky,[4] Ipatiew and Leontowitsch,[5] Nef[6] and Peytral[7] but in all of these cases the reactions have probably been heterogeneous. We have found that thermal decomposition of ethylene oxide in a pyrex

chamber at 380–444° is a strictly homogeneous gas reaction. This is shown by the data of Table I. The ratio of surface to volume, S/V, was varied more than six times by introducing fragments of pyrex glass tubing into the reaction chamber, without affecting the velocity of the reaction. Furthermore, the reproducibility of the velocity constants indicates clearly that the reaction is homogeneous.

TABLE I

DATA SHOWING THE HOMOGENEITY OF THE REACTION

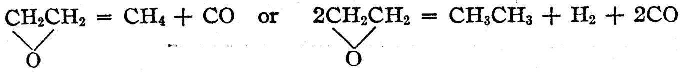
Expt.	P_{av}	Temp., °C.	k_1	S/V	H_2, %
100L	72	443.5	0.0727	8.33	6.6
101L	65	443.5	.0704	8.33	. . .
102L	82	443 5	.0710	8.33	9 9
94–98m, 104–105m, 109–110, 112m	84.5 av.	443 5 av.	0 0720 av.	1 32 av.	7.4 av.

An attempt was made to determine whether acetaldehyde could be isolated from the partially decomposed gases, by passing ethylene oxide through a long tube heated with sulfur vapor. The boiling point of the product was taken by a micro method. The last portions of the product to boil off had a strong aldehyde odor, though hardly that of acetaldehyde. We must conclude that nearly all of the aldehyde, if it is formed at all, is immediately decomposed.

The decomposition of the ethylene oxide was carried on in an apparatus to be described shortly. The product gases were analyzed in a gas analysis apparatus according to the following scheme: dilute sulfuric acid treatment to remove excess ethylene oxide; potassium hydroxide for carbon dioxide; copper oxide at 300° to oxidize hydrogen and carbon monoxide (decrease in volume equals the volume of the hydrogen); potassium hydroxide to remove the carbon dioxide; combustion pipet. The following are some typical analyses.

	Expt. 85K	Expt. 93M	Expt. 87K
H_2, %	6.2	7.8,	7.9
C_2H_6, %	6.6	7.7	7.0
CH_4, %	37.5	35.1	35.3
CO, %	49.6	49.0	49.9

Analyses were also made for hydrogen with palladium black. These checked with the above. Ammoniacal cuprous chloride was used to determine the carbon monoxide in some cases. The ethane was not identified, and all higher hydrocarbons were calculated as ethane. The percentage of hydrogen varied somewhat, but an average of ten experiments gave 7.4. No factor, surface, temperature, pressure, etc., could be found which determined the percentage of hydrogen. It would appear, therefore, that the reaction occurs in two ways with perhaps acetaldehyde as an intermediate compound.

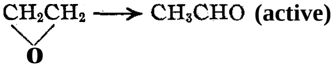


$$\underset{O}{CH_2CH_2} = CH_4 + CO \quad \text{or} \quad 2\underset{O}{CH_2CH_2} = CH_3CH_3 + H_2 + 2CO$$

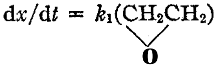
In any case, at the completion of the reaction, the pressure is just doubled.

	Expt. 107M	Expt. 108M
Initial pressure, cm.	30.92	23.21
Final pressure, cm.	61.86	46.42

There is considerable evidence that the decomposition of ethylene oxide is not as simple as it is represented above. There is a perceptible induction period. This lasts for a period of about one and one-half minutes at 444°, and for nearly fifteen minutes at 400°. During this time the velocity increases. The induction period is followed by a period when the unimolecular law holds quite accurately. At still later stages the velocity falls off due to the accumulation of reaction products, methane and carbon monoxide. Other inert gases are shown to have a similar retarding effect. The fact that ethylene oxide isomerizes so readily to give off 23,300 cal.[8] per mole, together with the facts above, leads us to postulate the following mechanism.

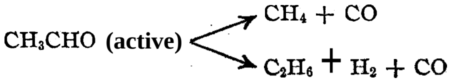


$$\underset{O}{CH_2CH_2} \longrightarrow CH_3CHO \text{ (active)} \qquad (1)$$



$$dx/dt = k_1(\underset{O}{CH_2CH_2})$$

$E = 52{,}000$ cal.
$Q = 23{,}300$ cal.
75,300 cal.

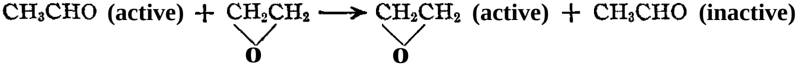


$$CH_3CHO \text{ (active)} \begin{cases} \nearrow CH_4 + CO \\ \searrow C_2H_6 + H_2 + CO \end{cases} \qquad (2)$$

$$dx/dt = k_2\ (CH_3CHO)\ \text{(active)}$$

E and Q very small

$$CH_3CHO\text{(active)} + X \longrightarrow CH_3CHO \text{ (inactive)} + X \text{ (energy-laden)} \qquad (3)$$



$$CH_3CHO \text{ (active)} + \underset{O}{CH_2CH_2} \longrightarrow \underset{O}{CH_2CH_2} \text{ (active)} + CH_3CHO \text{ (inactive)}$$

$$2CH_3CHO \longrightarrow 2CH_4 + 2CO \qquad (4)$$

Hinshelwood and Hutcheson[9] have shown that acetaldehyde decomposes bimolecularly in the neighborhood of 444°. The energy of activation was found to be 45,500 cal. for two moles. Acetaldehyde molecules, if formed by the above mechanism, would have about 75,000 cal. per mole, or more than three times the amount necessary for activation. They would probably decompose unimolecularly under these conditions, and collisions with inert molecules would tend to cause them to lose some of their large load of energy. According to the theory of Rice and Ramsperger, or that of

---

[8] Estimated from the heats of combustion given by Berthelot: for ethylene oxide, 6870 cal./g., *Ann. chim. phys.*, [5] 27, 374 (1882); for acetaldehyde, 6338 cal./g., *Compt. rend.*, 129, 920 (1899).

[9] Hinshelwood and Hutcheson, *Proc. Roy. Soc. London*, 118A, 380 (1926).

Kassel, the loss of this energy would lower their rate of decomposition until finally the reaction would be of the second order. Collision with ethylene oxide molecules would perhaps result in the activation of the latter. This would not reduce the rate.

If we consider the first two reactions above and integrate the differential equation for the successive reactions, we obtain the following equation

$$\frac{a - x}{a} = \frac{k_2}{k_2 - k_1} e^{-k_1 t} - \frac{k_1}{k_2 - k_1} e^{-k_2 t}$$

where $a - x$ is the partial pressure of the ethylene oxide at the time t. The application of this equation is somewhat difficult. However, in the present case k_2 is large and k_1 is small. Hence, immediately following the induction period, the second term on the right drops out and we obtain the following expression for k_1

$$\frac{a - x_1}{a - x_2} = e^{-k_1 t_1}/e^{-k_1 t_2}$$

$$k_1 = \frac{2.303}{t_2 - t_1} \log \frac{a - x_1}{a - x_2}$$

This may then be used to calculate k_2

$$k_2 = \frac{k_1 Y_2}{Y_2 - e^{-k_1 t_2}},\quad Y_2 = (a - x_2)/a$$

The time t_2 must be taken such that $k_1 e^{-k_2 t_2}/(k_2 - k_1)$ has become vanishingly small.

Having obtained a value for k_2, it is now possible to calculate values for k_1 over the entire interval.

$$k_1 = \frac{2.303}{t} \log \frac{A}{Y_t + Be^{-k_2 t}}$$

where

$$A = k_2(k_2 - k_1),\quad B = k_1(k_2 - k_1)$$

The values of k_1 calculated in this manner and shown in Table II and IIA are very satisfactory. Without this treatment of the decomposition as a two-stage reaction, the constant k_3, calculated directly from the pressure data by the classical unimolecular equation, is found to vary by several hundred per cent., at least at those lower temperatures where the induction period is long enough to be followed.

It is possible to consider the induction period as merely due to the building up of a number of "reaction chains" as demanded by the Christiansen-Kramers theory. On such an hypothesis the energy-laden products would activate ethylene oxide molecules by collision with them. Such a picture, as previously indicated, would agree qualitatively with the experimental data. It seems certain that an intermediate state of some nature occurs during the reaction.

Measurement of Reaction Velocity.—A number of different samples of ethylene oxide were used, all of which gave the same velocity constant. Most of the samples were prepared by distilling an Eastman Kodak product at least three times over freshly burned calcium oxide. Low-boiling fractions were retained, giving a final sample boiling from 9.95–10.00° (corrected). This is two degrees lower than the boiling point reported in the literature.

The sample was kept in the dark in Bulb B in cold water, Fig. 1. Ethylene oxide was found to decompose slowly at room temperature. A sample taken from an old iron tank was 18% unabsorbed by sulfuric acid; this unabsorbed portion analyzed 50% of carbon monoxide. To avoid any error due to such decomposition, the storage tank S was pumped out before each run.

The apparatus, shown in Fig. 1, was the conventional set-up. Constant temperature was secured by boiling sulfur in the jacket J, where the pressure was controlled by the height of the water in the tube N. The five-gallon carboy G was connected to a pump which operated at a rate sufficient to pull an occasional bubble through the tube N. The outer jacket was heated by an auxiliary electric furnace, maintained at about 300°. The sulfur was boiled with a Fischer burner. The upper end was cooled with an air blast and several turns of lead pipe supplied with cold water. The whole lower part was enclosed in an asbestos box.

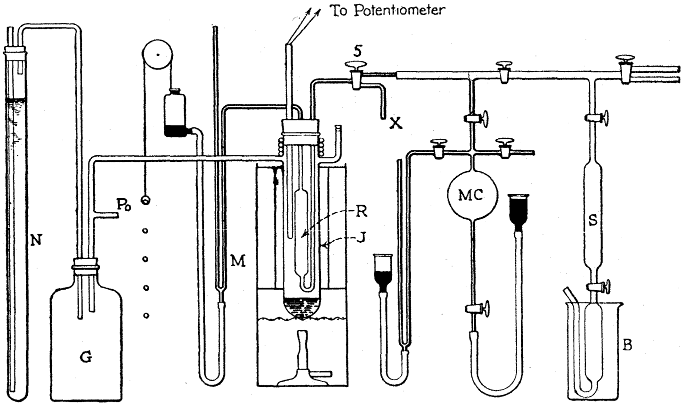


Fig. 1.

The temperature was measured with a calibrated chromel–alumel thermocouple and a potentiometer. It was possible to measure changes in temperature of 0.1°. The absolute temperatures are probably correct to within 0.5°.

The reaction chamber R was blown from pyrex tubing. It was connected to the stopcock 5 by means of 1-mm. tubing, and to the manometer M with 1.5-mm. capillary. The manometer M was made from 2-mm. capillary. The left arm was 2 meters long; the right, 1 meter long. The mercury leveling bulb was maintained at such a height that the right column could be read within 10 cm. of the top of the manometer arm. Thus the total dead space varied between 0.6 and 0.9 cc. This usually represented about 0.3% of the volume of the reaction chamber. The meter stick in the manometer was compared with a standard meter stick. The apparatus was frequently cleaned by pumping hot chromic acid through it. It was washed with distilled water, acetone and ether. A vaseline–paraffin mixture was used on all of the stopcocks. Stopcock 5 was enclosed in a metal container and surrounded with water maintained at a suitable temperature.

For experiments dealing with the effect of inert gases, a chamber, MC, was attached, in which it was possible to mix the gases thoroughly before passing them into the reaction chamber. A water jacket, not shown in the drawing, maintained a constant temperature while filling the mixing chamber.

The procedure in making a run was briefly as follows. The reaction chamber was evacuated with an oil pump and stopcock 5 was closed. The chamber S and the connecting tubes were evacuated and filled with ethylene oxide. Stopcock 5 was opened and zero time was counted (with a stop watch) when one-half of the desired amount of ethylene oxide had entered. The bulb was raised until the mercury stood within a few centimeters of the top of the right arm of the manometer. Readings on both arms were taken as desired. If it was desired to analyze the gases, they were removed at X. The temperature and barometric pressure were read at frequent intervals.

The total pressure P_1 was calculated from the manometer readings. From this the total pressure P_2, if there had been no dead space, was calculated by means of the equation

$$P_2 = P_1(1 + vT_R/VT_m)$$

where v is the dead space to the top of the mercury, V is the volume of the chamber, T_m is the temperature of the manometer and T_R that of the

reaction chamber. Since the pressure just doubles, the final pressure would be $2P_2$, providing all of the ethylene oxide in the manometer were to decompose. In order to estimate the partial pressure P_0 of the ethylene oxide actually in the chamber, the following equation was used

$$P_0 = 2(P_2)_0 - P_2\frac{3v_0T_R}{2VT_m} - (P_2)t$$

At best this is an approximation. However, the error probably at no time exceeds $0.5v_0T_R/VT_m \cdot P_2$, which represents an error of 0.5% or less.

Ethylene oxide is not associated in the vapor phase.

Order of Reaction.—The decomposition of ethylene oxide is a first-order reaction without question. Table III gives values of k_1 taken over a large range of pressures.

TABLE III

VELOCITY CONSTANT k_1 AT DIFFERENT PRESSURES

Expt.	Temp.. °C.	P_{av}., cm.	k_1	$k_1(444)$
142m	443.1	90.5	0.0707	0.0739
145m	443.1	96.0	.0709	.0741
146m	443.5	64.7	.0716	.0735
147m	443.6	59.9	.0719	.0736
155m	444.0	28.5	,0666	.0666
162m	443.7	2.42	.0617	.0627

If the reaction were bimolecular, k_1 calculated at an interval averaging a pressure of 2.42 cm. would be enormously smaller than at 96.0 cm- These constants were calculated over the two to five-minute interval immediately following the induction period.

The induction period becomes more noticeable as the temperature is lowered. It is impossible to evaluate k_2 at 444'. At 394° values can be calculated, but the error is large.

TABLE IV

VELOCITY CONSTANT k_2 AT DIFFERENT PRESSURES (T = 394.3°)

Expt.	P_{av}.	k_1	k_2
169m	83.9	0.00486	0.353
170m	41.5	.00474	.472
171m	21.3	.00471	609
172m	11.8	.00464	Too large to calculate
250m	52.9	.00473	.495
251m	31.8	.00475	.654
253m	17.1	.00454	Too large to calculate

Apparently k_2 becomes larger with decrease in pressure. This is in agreement with the mechanism advanced, since the decomposition of activated acetaldehyde molecules is more likely to take place when there is a greater time between deactivating collisions.

In Fig. 2 the results of a number of experiments at approximately 444° are shown. The logarithm of the partial pressure of the ethylene oxide is plotted against time, with the logarithm scale shifted to bring all of the experiments together. The falling off of the rate with accumulation of products is clearly shown. This is not proportional to the pressure of the products, but more nearly to the ratio of their pressure to that of the ethylene oxide. After a steady state has been reached, the pressure of activated acetaldehyde molecules will be nearly proportional to the partial pressure of the undecomposed ethylene oxide. Since the first point on these graphs must be estimated, the nature of the induction period at this temperature must remain unknown.

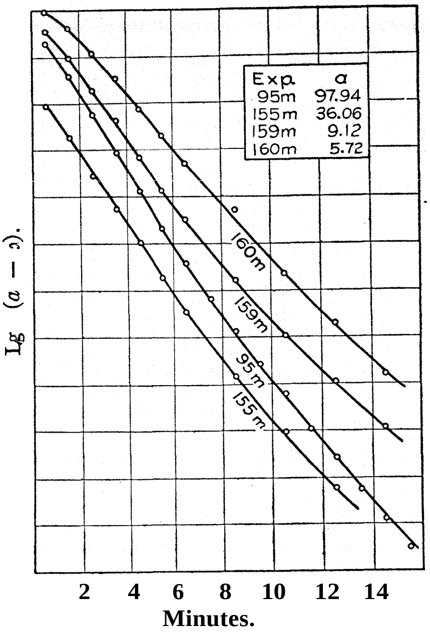

Fig. 2.

Energy of Activation.—Table V gives a summary of the data (at the higher pressures) from which the energy of activation may be calculated. Figure 3 shows a plot of $-\log k_1$ against $1/T$. The usual straight line is obtained. The energy of activation E, calculated by equating the slope of this line to $E/2.303R$, is 52,000 cal.

TABLE V

The Effect of Inert Gases.—It was thought that a study of the rate of decomposition of ethylene oxide in the presence of a number of inert gases would yield some interesting information with regard to the exchange of energy during collision. Table VI gives a summary of the experimental data. Traces of oxygen interfere with the observation of the induction period and give false values for k_2.

In Table VI $P_{\text{av.}}$ is the average partial pressure of the ethylene oxide during the interval in which k_1 was calculated. The column headed P_g is the partial pressure of the inert gas. The column P_{CO} is one-half of the average pressure of the products during the interval. All of the experiments are corrected over short temperature intervals to 394.3°.

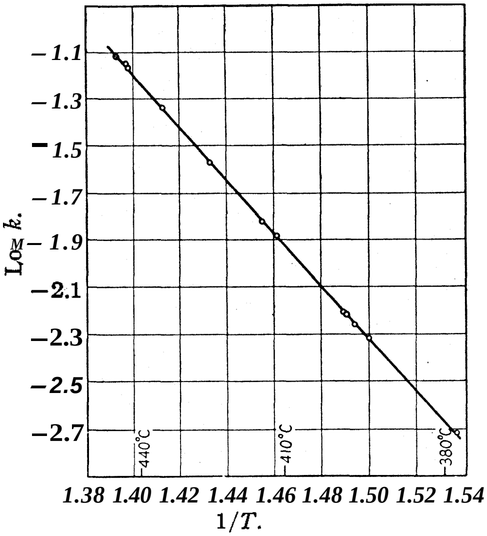

Fig. 3.

In addition to those listed in the table, ethylene, ammonia, methyl bromide, n-butane and isopentane were tried. In the first case there was probably a polymerization of the ethylene and a combination with the ethylene oxide. Ammonia apparently reacted somewhat with the oxide while in the mixing chamber, and the resulting compound dissociated during the first several minutes of the experiment. This suggests that the decomposition of aminoethyl alcohol might yield another unimolecular reaction. Methyl bromide, n-butane and isopentane were found to "crack" in the presence of ethylene oxide. The velocity of "cracking" was greater in the presence of ethylene oxide than in its absence, which suggests that these substances were obtaining energy of activation from the ethylene oxide decomposition.

The two sets of experiments on carbon dioxide indicate that within the limits of experimental error the depression of k_1 is proportional to the ratio of pressure of the inert gas to that of the ethylene oxide.

In the case of the hydrocarbons, it is at once apparent that the depression of the velocity constant is related to the complexity of the molecule. The isosteres, nitrogen and carbon monoxide, both cause the same depression. Carbon dioxide, with several more degrees of freedom and a larger collision area, though with a smaller velocity of translation, exhibits a slightly greater depression.

Argon and neon depress the rate less than any of the other gases. Their collisions are perhaps the most elastic and they have but three degrees of

freedom (translational). Helium, however, depresses the rate considerably.

The **Effect** of Hydrogen.—While investigating the decomposition of di-ethyl ether at low pressures, Hinshelwood and his students have shown that the presence of sufficient hydrogen will restore the high pressure rate of decomposition. They attributed this to the fact that hydrogen, traveling at high velocities and making many collisions, was peculiarly fitted for maintaining the Maxwellian distribution of energy among the decomposing molecules. No other gas was found to have this effect.

TABLE VII

THE EFFECT OF HYDROGEN

Expt.	Temp., °C.	$P_{av.}$	P_{H_2}	k_1	k_2

E = 51,500 cal.

Table VII shows a number of results of experiments with ethylene oxide in the presence of about one atmosphere of hydrogen. The rate is increased about 40% at each temperature. The heat of activation calculated on the basis of these experiments is 51,500 calories, the same as before within the limits of experimental error.

Study of the decomposition of ethylene oxide is being continued at much lower pressures to collect sufficient data for testing the validity of the Rice and Ramsperger equations.

We wish to express our gratitude to the E. I. du Pont de Nemours Company for a Fellowship grant which made this investigation possible.

Summary

It has been shown that the thermal decomposition of ethylene oxide is a strictly homogeneous unimolecular reaction, exhibiting an induction period and a decrease in rate of decomposition in the presence of inert gases. The velocity of decomposition may be represented by the equation

$$\ln k_1 = 34.02 - 52{,}000/RT$$

A mechanism for the decomposition has been advanced involving a unimolecular isomerization to acetaldehyde molecules of high energy content and their subsequent unimolecular decomposition into carbon monoxide and methane. Collision of activated acetaldehyde molecules with inert gases and the consequent interference with the Christiansen-Kramers mechanism for activation, have been regarded as the cause of the damping effect of inert gases. A study of the velocity of decomposition has been made in the presence of ten inert gases. The fact that the presence of hydrogen increases the velocity of decomposition, together with a slight falling off of the velocity constant with decrease in pressure, has been cited as evidence that the reaction at ordinary pressures is in a process of change from a unimolecular reaction to a bimolecular reaction.

THE IONIZATION CONSTANT OF PARA-CYANOBENZOIC ACID

BY EDGAR P. VALBY AND HOWARD J. LUCAS

RECEIVED APRIL 16, 1929 PUBLISHED SEPTEMBER 5, 1929

It has been pointed out by one of us[1] that from the ionization constants of the para-substituted benzoic acids it is possible to obtain an approximate value of the relative electron attractions of radicals. It has been assumed that in such acids the substituent groups are so far removed in space from the carboxyl group that their effect upon the latter is largely the result of electron displacements through the benzene ring and not of electrostatic influences operating across space. It is therefore desirable to know the ionization constants of all of the para-substituted benzoic acids. In this paper are described the methods by which *p*-cyanobenzoic acid was prepared and its ionization constant determined.

In the process of replacing amino by cyano it is necessary to avoid, first, the formation of *anti*-diazocyanide,[2] second, the decomposition of the sodium cuprous cyanide when the acid, which is present in the diazotized solution, is added and, third, the hydrolysis of the cyano group in the final product. As the replacement reaction is not especially rapid it was found necessary to maintain a temperature of 50–60°. Since *syn*-diazotates may at this temperature change to the stable anti-forms, it was thought best to keep the diazo solution acid until it could react with the cuprous cyanide. The addition of sodium carbonate to the cuprous cyanide solutions,[3] following a procedure which had been developed previously in this Laboratory in connection with other work,[4] seemed to overcome these difficulties fairly well, since the yield of crude *p*-cyanobenzoic acid, m. p. 206–210° (uncorr.), was 45%, and of the pure acid, m. p. 218.5–219° (corr.), after five crystallizations from hot water was 30%.[5]

From measurements on the conductance of aqueous solutions of the pure p-cyanobenzoic acid the ionization constant has been found to be

---

[1] Lucas, THIS JOURNAL, 48, 1837 (1926).

[2] Hantzsch and Schulze, *Ber.*, 28, 666 (1895), showed that the anti-diazocyanides are stable and do not readily decompose to yield nitriles.

[3] "Organic Syntheses," John Wiley and Sons, 1925, Vol. IV, p. 69. In the preparation of the tolunitriles sodium carbonate is added to the cold solution of the diazotized amine. The modification here described is more convenient.

[4] E. D. Stewart, "Senior Thesis," California Institute of Technology, 1925.

[5] Sandmeyer, *Ber.*, 18, 1497 (1885), reported that the acid is unstable and changes into terephthalamide upon crystallization from hot water. However, Kattwinkel and Wolffenstein, *ibid.*, 34, 2423 (1901), showed that the cyano acid can be prepared by the Sandmeyer method and can be recrystallized from hot water to give a product melting at 219°.

3.1×10^{-4}, the calculation being made according to the usual expressions

$$K_A = \frac{c\gamma^2}{1 - \gamma}$$

where $\gamma = \Lambda_c/\Lambda_0$, Λ_0 = the conductance at zero concentration and Λ_c = the conductance at the concentration c.

A comparison of the ionization constant of this acid with those of other para-substituted benzoic acids indicates that CN has a lower electron attraction than NO_2 and a greater one than SO_2NH_2, since the constant of *p*-$C_6H_4NO_2COOH$ is 4.0×10^{-4} and that of *p*-$C_6H_4SO_2NH_2COOH$ is 2.6×10^{-4}.

The solubility of p-cyanobenzoic acid is approximately 0.12 g. in 100 g. of water at 20° and 4 g. at 100°.

Terephthalamide, produced by the action of hydrogen peroxide on *p* cyanobenzoic acid,[6] has such a low solubility that no measurements of its conductivity were undertaken.

***p*-Cyanobenzoic** Acid.—An alkaline solution of sodium cuprous cyanide is first prepared by adding the cuprous chloride obtained from 160 g. of copper sulfate[7] to a solution of 80 g. of sodium cyanide in 125 ml. of water,[3] followed by the addition of 60 g. of anhydrous sodium carbonate. To the resulting liquid, maintained at a temperature of 50–60°, is added during the course of ten to fifteen minutes the diazotized solution obtained from 40 g. of *p*-aminobenzoic acid, 70 g. of concd. hydrochloric acid (*c.* P.), 100 g. of water, 300 g. of ice and 20 g. of sodium nitrite (in 50 g. of water). The mixture is maintained at 50–60° for about half an hour, by which time the evolution of nitrogen has practically ceased. It is then cooled and concd. hydrochloric acid is added until no more precipitate comes down. The solid, consisting of p-cyanobenzoic acid and cuprous cyanide, is filtered off, washed and treated with about 75 ml. of concd. ammonium hydroxide, which forms the soluble ammonium salt of the organic acid. The solution is filtered from insoluble copper salts and the p-cyanobenzoic acid is precipitated as a brown mass on the addition of hydrochloric acid to the filtrate. The product has a melting point of 206–210°; yield, 45%.

Five crystallizations from hot water to which animal charcoal has been added give white plates melting at 218.5–219° (corr.); yield, 30%.

The equivalent weight of the acid was determined by titration of 40.00 ml. of a solution made by dissolving 0.5006 g. in 500 ml. of water at 20° against 0.01660 N barium hydroxide. The mean of five titrations gave 16.457 ml. of the base, from which the calculated equivalent weight is 146.6. The theoretical value is 147.1.

The Conductance Measurements.—These were determined by the method of Kohlrausch, employing, however, an a. c. galvanometer for detecting balance instead of a telephone receiver. The cell was immersed in a thermostat at 25°. The results obtained are shown in the accompanying table.

Calculation of the Ionization Constant. In using the equivalent conductance at zero concentration we have adopted the value of 377 reciprocal ohms, which is the one previously found for *m*-cyanobenzoic

---

5	.002059	755.3	119.6	.3172	30.4
6	.0008235	1347.0	167.7	.4448	29.4
				Mean	30.9

acid.[8] The assumption that isomeric m- and *p*-cyanobenzoic acids have the same equivalent conductance at zero concentration is warranted from a comparison of other isomeric *m*- and p-substituted benzoic acids.[8] If we take the equivalent conductance of hydrogen ion at 25° to be 350 reciprocal ohms,[9] the equivalent conductance of p-cyanobenzoic ion is then 27, a value which checks well with that of caproate ion, 27.4.[10]

Summary

By a 'modification of the Sandmeyer method p-cyanobenzoic acid may be obtained in satisfactory yields from p-aminobenzoic acid.

The ionization constant of p-cyanobenzoic acid as determined by conductivity measurement has a mean value of 3.1×10^{-4} at 25°.

On the assumption that the ionization constants of *p*-substituted benzoic acids are directly related to the electron attraction of radicals, the electron attraction of CN is greater than that of SO_2NH_2 and less than that of NO_2.

THE DETERMINATION OF ALUMINUM IN PLANTS. I. A STUDY OF THE USE OF AURINTRICARBOXYLIC ACID FOR THE COLORIMETRIC DETERMINATION OF ALUMINUM[1]

BY O. B. WINTER, W. E. THRUN AND O. D. BIRD

RECEIVED APRIL 22, 1929 PUBLISHED SEPTEMBER 5, 1929

Two types of methods, colorimetric and spectrographic, have been used for determining very small amounts of aluminum. The latter is of very recent origin. It has one decided advantage over other methods in that it requires no chemical reagents, a point which is particularly important in the estimation of aluminum since this element contaminates nearly all reagents. Unfortunately the necessary apparatus is so expensive that but few laboratories can afford to possess it.

Though known for many years, colorimetric methods for estimating aluminum have only recently assumed importance as the increased demand for micro methods has aroused interest in colorimetric methods in general. While affording many chances for inaccurateness, they can be used wherever a colorimeter is available and hence have tempted chemists to work for their perfection. Several such methods have been proposed, the most promising of which is the one making use of the ammonium salt of aurintricarboxylic acid—the dye commercially known as aluminon. Lundell and Knowles[2] used it for the detection of small amounts of aluminum in certain non-ferrous materials; Myers and co-workers[3] used it for the determination of aluminum in blood and animal materials, while Yoe and Hill[4] studied the reaction of aluminum with the dye under different experimental conditions and discussed its application to the colorimetric determination of aluminum in water. Some time previous to the above, Hammett and Sottery[5] studied the behavior of some of the common elements and ions with the dye, and Middleton[6] and Corey and Rogers[7] studied its behavior with some of the less common elements.

Yoe and Hill showed that during the formation of the aluminum lake intensity of color increased, within certain limits, with rise in tempera-

ture, length of time of standing and with the increase in the quantity of aluminum, dye, hydrochloric acid or ammonium acetate present. They also showed that the color decreased with increase in volume of solution and with the amount of ammonium hydroxide or carbonate added, and that the use of protective colloids made it possible to increase the concentration of the lake without having it precipitate.

Several attempts at determining aluminum in plants by the modifications of the method used by these investigators showed that none was entirely satisfactory in our, hands. The following difficulties were encountered.

(1) The results of duplicate determinations did not always agree. (2) The color of some samples faded rapidly. (3) The necessity of having the amount of aluminum in the standard nearly the same as that in the sample required the preparation of several standards whenever a number of determinations were to be made. This wasted much time.

Hence it was decided to make a further study of the reaction between aluminum and the dye in an attempt to overcome these difficulties and if possible to adapt the method to our problem. Special emphasis was placed on determining suitable conditions (1) for the formation of a lake of maximum color intensity and (2) for destroying the color of the excess dye while retaining the lake color. Considerable time was also given to working out a procedure whereby the relationship between the amount of aluminum in a sample and the colorimeter readings could be represented by a curve. This would enable the analyst to compare all of the samples run at one time with one standard and to read the amount of aluminum directly from this curve.

Experimental Part

Apparatus and Reagents.—The lakes were developed in 50-cc. volumetric flasks. The colors were compared in a Duboscq type of colorimeter using a daylight lamp in a dark room or ordinary daylight. The reagents used in the preliminary work were not standardized but were approximately as follows: (1) hydrochloric acid, 1.5 N; (2) ammonium acetate, 5 *N;* (3) ammonium carbonate, 3 *N;* (4) ammonium hydroxide, N and 5 N; (5) 10% ammonium carbonate in ammonium hydroxide (1–2); (6) ammonium salt of aurintricarboxylic acid, 0.1 and 0.2%; (7) standard aluminum solution. This was prepared by dissolving 1.0000 g. of aluminum metal (99.976% Al) in as little hydrochloric acid as possible, diluting to 1 liter with distilled water, taking 10 cc. of this solution and again diluting to 1 liter. Each cc. of this final solution contained 0.01 mg. of aluminum. The reagents used in the later work were standardized and were as follows: (1) hydrochloric acid, 1.5 *N;* (2) ammonium acetate, 5 *N;* (3) ammonium carbonate, 3.2 *N;* (4) ammonium chloride, 5 *N;* (5) standard aluminum solution, same as above.

Color Development

The Dye.—Before attempting to find the optimum conditions under which a lake of maximum color could be obtained, it was deemed advisable to make a similar study of the dye alone.

To ascertain the effect of acidity on the dye several samples of varying *PH* were prepared by adding hydrochloric acid to distilled water, then adding 2 **cc.** of 0.1% dye to 25 cc. of these solutions and allowing them to stand for forty-five minutes for the color to develop. The *PH* of each solution was determined colorimetrically using phenol red, the color intensities were compared with the standard described above and calculated to a uniform basis giving the standard an arbitrary value of 100. The results are shown in Table I.

TABLE I

COLOR INTENSITY OP DYE AT DIFFERENT PH READINGS

Solution	1	2	3	4	5	6	7	8	9
PH	6 9	6.0	5 5	4 9	4 5	3 9	**3.3**	*2.8*	1 8
Colorintens.	54	65	100	118	143	169	126	Yellow	Dyeppted.

The data in Table I show that the color intensity of the dye increased with the acidity of the solution until approximately *PH* 4.0 was reached and that the dye was precipitated at about *PH* 1.8.

Work on the other factors which, according to Yoe and Hill, influenced the intensity of the lake, showed that the intensity of the color reached a maximum and the dye separated at a slightly higher *PH* in the presence of ammonium acetate. It also showed that the intensity of color increased with increase in temperature or dye concentration.

The Aluminum Lake.—In order to determine the *PH* and quantity of ammonium salts that would produce the maximum color of the lake, a number of solutions were prepared, each of a different *PH* and containing a different amount of ammonium acetate. These were adjusted to *PH* 0.0, 5.0, 4.5 and 4.0 with hydrochloric acid. To 25 cc. of each at room temperature were added **3** cc. of the aluminum solution and 2 cc. of 0.1% dye, both having first been adjusted to the same *PH* as the solution to which they were added. After standing for forty-five minutes for the color to develop they were compared. The relative color intensity was also determined on a check containing 5 cc. of 5 *N* ammonium acetate, 2 cc. of 0.1% dye but no aluminum. The concentrations of ammonium acetate, the *PH* readings and the relative color intensities calculated as in Table **I** are given in Table II.

TABLE II

EFFECT OF VARYING *PH* AND CONCENTRATION OF AMMONIUM ACETATE ON COLOR INTENSITY

		Relative color intensity			
Soln.	**$(NH_4)_2C_2H_3O_2$, cc.**	***PH* 6 0**	**PA 5 0**	**PH 4 6**	***PH* 4.0**
1	Check	8[a]	15"	19"	yellow[b]
2	None	23	55	74	Yellow
3	*2*	24	*64*	75	Yellow
4	5	26	66	77	Lake pptd.
5	7	27	67	76	Lake pptd.

[a] These readings are only approximate. The colors differed from the standard.

[b] These differed so much from the standard that no attempt was made to read them.

The data in Table II show that the color intensity due to the lake and the excess dye which did not enter the lake increased with the acidity of the solution until the point was reached where the lake separated which, in the presence of 5 cc. of 5 *N* ammonium acetate, was at about PH 4.0. Since the color of the dye was only a small part of the total color, the above phenomenon was caused mostly by the lake. The data also show that the intensity of the color increased slightly with the addition of ammonium acetate until about 5 cc. had been added. Therefore this concentration of the salt should be used for making aluminum determinations.

To show the temperature at which maximum color was produced, two solutions, each containing 5 cc. of 5 N ammonium acetate for every 25 cc., were prepared and adjusted to PH 5.0 and 4.5, respectively. Three cc. of the aluminum solution and *2* cc. of the 0.1% dye were added to 25-cc. portions and, after holding the solution at given temperatures for ten minutes, the color intensities were compared. The figures for the PH of the solution, the temperature at which the color was developed and the relative intensities calculated as before are given in Table III.

TABLE III

EFFECT OR VARIATION IN TEMPERATURE ON COLOR INTENSITY

Solution		**1**	**2**	**3**	**4**	**5**	**6**
Temp.. °C.		**27**	**65**	**80**	**85**	**Boil 1 min.**	**Boil 3 min.**
Rel. color intensity	*PH* 5.0	**87**	**107**	**112**	**111**	**112**	**112**
	PH 4.5	**94**	**114**	**120**	**121**	**120**	**121**

Table III shows that under the conditions of the experiment maximum color intensity was obtained when the solution was heated to about 80° for ten minutes or when boiled for one minute.

The effect of the time of standing at room temperature on the development of the color was shown by adjusting a number of solutions to PH 5.0 as in the preceding experiment, developing the colors and comparing their intensities after standing for different lengths of time. The results are shown in Table IV, which gives the relative color intensity expressed in percentage of maximum intensity (obtained by boiling for one minute) corresponding to each different length of time the solution was allowed to stand.

TABLE IV

EFFECT OX VARIATION IN LENGTH OF TIME OF STANDING ON COLOR INTENSITY

Soln.	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**
Temp., °C.	**27**	**27**	**27**	**27**	**27**	**27**	**27**	**Boiling**
Standing, hrs.	**$^1/_6$**	**0.25**	**0.5**	**1**	**1.5**	**18**	**60**	**1 min.**
Col. intens.	**63**	**64**	**66**	**69**	**73**	**90**	**92**	**100**

Table IV indicates that with the given amount of dye and aluminum approximately 64% of the possible maximum color (obtained by boiling for one minute) was developed in fifteen minutes, that it continued to develop at a decreasing rate but that the maximum color obtainable was not reached in sixty hours. Other experiments showed that with a sufficient increase in the dye concentration it was possible to obtain maximum color at room temperature in about twenty-four hours.

From the work done on color development it appeared that maximum intensity of color was obtained when the lake was developed in the presence of 5 cc. of 5 N ammonium acetate in 25-cc. solution at PH 4.5 and allowed to stand for ten minutes at 80° or to boil for one minute.

Decolorization of Excess Dye and Permanency of Lake **Color.**—Since the color of the dye alone in acid solution and that of the lake are quite similar, it was found impracticable to make quantitative determinations of aluminum by comparison of the intensity of the color of the unknown with that of the standard until after the solution was neutralized and the excess dye decolorized. Hence the next step in this work was to try to find optimum conditions for destroying the color of the unused dye while retaining the color of the lake.

The Dye.—In order to determine the PH at which the dye decolorized and the effect of ammonium salts on this PH, several solutions of 25 cc. each were prepared containing salts as shown in Lines 2 and *3* in Table V. Hydrochloric acid to give a *PH* of 4.5 and 2 cc. of 0.1% dye were added to each of these and they were allowed to stand for forty-five minutes for the color to develop. Ammonium carbonate[8] was now added slowly until the color began to fade, after which the addition of small amounts of the carbonate was continued at intervals until the color entirely disappeared. The *PH* was then determined colorimetrically. The results are given in Table V.

TABLE V

EFFECT OF AMMONIUM SALTS ON THE PH AT WHICH DYE DECOLORIZED

Sample	1	*2*	3	4
5 N NH_4Cl, cc.	0	5	0	5
5 N $NH_4C_2H_3O_2$, cc.	0	0	*5*	5
Average PH	8.0	6.9	7.0	7.0

The figures in Table V indicate that the dye was decolorized at a lower *PH* in the presence of ammonium salts and that under these conditions the dye decolorized at *PH* **6.9–7.0.** It should also be stated that the use of a larger quantity of dye or the development of the color at a higher temperature had no effect upon the *PH* at which the color changed.

The Lake.—The maximum *PH* at which the lake color would remain was determined by preparing several solutions containing 5 cc. of 5 *N* ammonium acetate, 2 cc. of 0.1% dye and **0.03** mg. of aluminum and

---

[8] Similar results were obtained when dilute ammonium hydroxide or 10% ammonium carbonate in ammonium hydroxide (1–2) was used.

developing the colors as in the preceding experiment. An equal number of similar solutions was prepared but with the dye omitted. The quantity of neutralizing agent necessary to bring each of these latter solutions, respectively, to PH 7.0, 7.1, 7.2, 7.3, 7.4 and 7.5 was carefully determined and these amounts were added to the solutions containing the dye. After standing for thirty minutes for the excess dye to decolorize, the color changes were noted at intervals over a period of two hours and are recorded in Table VI.

TABLE VI

EFFECT OR PH OR SOLUTION ON PERMANENCY OF LAKE COLOR

Sample	**1**	**2**	**3**	**4**	**5**	**6**
PH	*7.0*	*7.1*	**7.2**	*7.3*	*7.4*	*7.5*
Color intens.	Const.	Const.	Const.	**Faded v. sl.**	**Faded sl.**	**Faded rapidly**

Prom Table VI it will be seen that the lake color remained practically constant until after the solution was raised above PH 7.3 and that it decolorized more rapidly as the PH increased above this point. Other experiments showed that the quantity of dye used or the temperature at which the lake was developed had no effect upon this.

Now it seemed important to know whether or not the PH of the solution at which the lake color was developed had any effect on the final color intensity of the lake after the dye had been decolorized. Therefore, a number of solutions were prepared as in the preceding experiment, the lakes developed at PH 5.5, 5.0 and 4.5 and after standing for forty-five minutes the solutions were brought to PH 7.2 with ammonium carbonate. After these neutralized solutions had stood for thirty minutes to allow the excess dye to decolorize, they were compared. The relative color intensities are given in Table VII where *a*, b and *c* under each number represent similar solutions each adjusted to the corresponding PH shown in the table.

TABLE VII

EFFECT OF DEVELOPING THE LAKE AT THREE: DIRFERENT *PH*'S ON THE FINAL INTENSITY OF COLOR

Sample	*la*	*lb*	1*c*	2*a*	2*b*	2*c*	3*a*	3*b*	3*a*
***Pa* of col. dev.**	*5.5*	*5.0*	*4 5*	**5.5**	*5.0*	*4.5*	*5.5*	**5.0**	*4.5*
Rel. final intens.	*90*	*100*	*101*	*115*	*130*	*129*	*90*	*100*	*97*

The results in Table VII show that the lakes developed at PH 4.5–5.0 gave rise to maximum final color intensity.

Other experiments not reported here showed that increasing the amount of dye used in developing the lake increased the color intensity of the final solution and made it possible to increase the concentration of the lake without having it separate. However, the yellow color formed when the excess dye was neutralized gave rise to varying tints which made reading **the colorimeter** very difficult; therefore, the data on this work are omitted.

From the work done thus far it appeared that the maximum final color intensity for practical purposes was obtained when the lake was developed in the presence of 5 cc. of 5 N ammonium acetate at PH 5.0 heated at 80° for ten minutes or boiled for one minute and neutralized to PH 7.1–7.3. It was found that 5 cc. of 1.5 N hydrochloric acid added to the solution gave the desired acidity (PH 5.0). In neutralizing the solution with ammonium hydroxide it was found necessary to use a dilute solution (about 1 N) and add it very slowly with vigorous shaking in order to get concordant results. Apparently a more concentrated solution (5 N) gave rise to localities of momentary high PH where some lake color was destroyed. There appeared to be no advantage in adding the ammonium hydroxide–ammonium carbonate solution which some analysts have used. It was found that 5 *N* ammonium carbonate could be used without loss of color if added slowly (about 5 cc. in 20 sec.) with gentle shaking. Ammonium chloride has a slight buffer effect in the range near PH 7.2 and the addition of 5 cc. of a 5 N solution of this salt before neutralizing made it possible to control more easily the acidity of the solution at this point. Therefore, ammonium chloride and ammonium carbonate were used in the remainder of this work and it was found that 5 cc. of a 3.2 N solution of the carbonate brought the lake to PH 7.2. The formation of carbon dioxide bubbles on the prisms of the colorimeter and occasionally in the bottom of the cups was sometimes quite annoying. This was largely avoided by allowing the cups to stand a few moments after the solution had been poured into them. The presence of bubbles could easily be recognized by the altered color of the solution.

The procedure developed thus far was now used for making a number of determinations on synthetic aluminum solutions. The results of these determinations are given in Table VIII, which also shows the percentage error.

The data in Table VIIIA show that the method gave good results providing the amount of aluminum in the standard was very nearly the same as that in the sample. Otherwise the results were not good, as is more emphatically shown by the determinations in Part B, for which several standards were chosen differing considerably in composition from the samples. These results show that the color intensity is not a linear function of the amount of aluminum present, that when the standards contain more aluminum than the sample the results are high and vice *versa* and that the greater the difference between the amount of aluminum in the standard and the sample, the greater is the error.

Now it appeared safe to assume that if the variable factors in the method (temperature, time, quantity of reagents, etc.) were carefully controlled and if the colorimeter readings of the standard were kept constant, the relation between the colorimeter readings and the amount of aluminum

TABLE VIII

DETERMINATION OF ALUMINUM IN SYNTHETIC SOLUTIONS

present might be represented by a curve plotted to show this relationship. Furthermore, it should be possible to read directly from this curve the quantity of aluminum present in unknowns.

In order to determine the correctness of this assumption, several series of determinations were made, taking solutions containing 0.005, 0.01, 0.02, 0.03, 0.04, 0.05, 0.06 and 0.07 mg. of aluminum for each series and reading each of these against 0.03 mg. of aluminum as the standard. The readings were made with the standard set at 30 or when this was not practical they were calculated to this value. The results are shown in Table IX, which gives the amount of aluminum in the solution, the corresponding colorimeter readings and the averages of these readings.

TABLE IX

COLORIMETER READINGS OP SIX SERIES OP SYNTHETIC ALUMINUM SOLUTIONS

Al, mg.	Colorimeter readings 1	2	3	4	5	6	Av.
0.0050	102.6	106.0	102.6	100.1	..	..	103.1
.0100	58.8	59.5	58.1	54.6	61.5	60.4	58.8
.0200	38.8	39.1	39.3	38.6	40.0	40.0	39.3

.0700	16.9	17.1	..	17.0	16.9	17.0	17.0

Figure 1 shows the relation between the aluminum and average colorimetric readings expressed in Table IX in the form of a graph.

Aluminum determinations were now made on several synthetic solutions by reading the results directly from the curve in Fig. 1. These data are given in Table X, which shows the colorimeter readings, the amount of aluminum present, the amount found and the percentage error.

The values in Table X show that aluminum can be determined colorimetrically by comparing the color intensities of the unknowns with that of one standard and reading the results directly from a curve which shows the relation between the colorimeter reading and the amount of aluminum present. These also show that the method is applicable to solutions containing from 0.0050–0.0700 mg. of aluminum and that the method is accurate to within about 5%. Other determinations which are not recorded here show this to be approximately the limit of error of the method. The result for Solution 7 in Table X indicates that if the curve were continued nearer the zero point for aluminum the method might be useful for solutions containing less than 0.0050 mg. of aluminum. In this case a fair approximation may be made but the color is very faint and if accurate results are desired it is better to make up a standard containing 0.0050 mg. of aluminum and calculate the results.

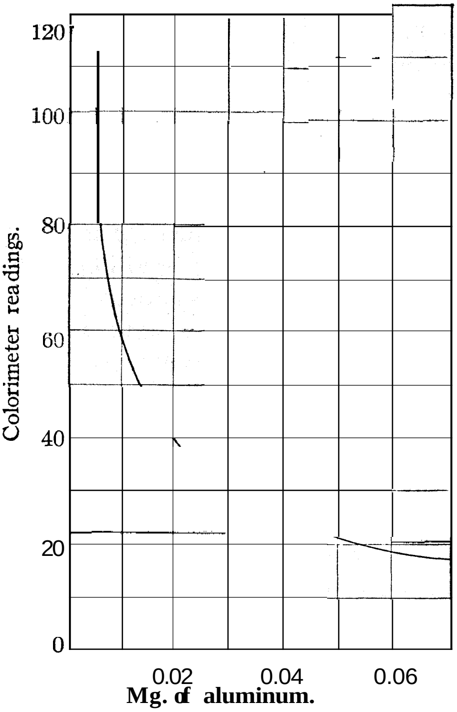

Fig. 1.—Relation between the colorimeter readings and the amount of aluminum.

TABLE X

ALUMINUM DETERMINATIONS READ FROM CURVE IN FIG. 1

Soln.	Colorimeter reading	Aluminum Present, mg.	 Found, mg.	Error, %

6	100.9	.0050	.0052	−4.0
7	176.4	.0030	?	

The Method

The procedure recommended for making aluminum determinations is as follows: transfer the solutions, which should be slightly acid, to 50-cc. volumetric flasks and to each add water to make a volume of about 20 cc.; then add 5 cc. of 5 N ammonium acetate, 5 cc. of 1.5 N hydrochloric acid and 2 cc. of 0.1% dye and place in a water-bath at about 80° for ten minutes. Add 5 cc. of 5 N ammonium chloride, cool to room temperature, add 5 cc. of 3.2 N ammonium carbonate while shaking gently, fill to the mark with distilled water and mix. At this point the reactions should be P_H 7.1–7.3 and the red color of a blank should disappear in about fifteen minutes. (The exact concentration of the reagents is not important, but the final P_H is, and the amount of ammonium carbonate necessary to bring the solution to the above P_H should be determined by neutralizing similar solutions without adding the dye.) Simultaneously with the above, run a standard (or standards if necessary) containing a given quantity of aluminum. After standing for twenty minutes for the excess dye to decolorize, compare the color intensities and read the amount of aluminum from a curve plotted as described in the following paragraph.

When only a small number of determinations are to be made, prepare four standards containing 0.0100, 0.0300, 0.0500 and 0.0700 mg. of aluminum, respectively, and run these with the samples. Compare all of these solutions with the standard containing 0.0300 mg. of aluminum and calculate the results to a colorimeter reading of 30 for this standard. Arbitrarily give 0.0050 mg. of aluminum a reading of 100 and with this and the four readings on the standards plot a curve similar to Fig. 1. Read the quantity of aluminum in each sample from this curve. If a large number of determinations are to be made extending over a period of time, it is advisable to make determinations on several series of standards and plot a curve from the average of these results, as was done in obtaining the curve in Fig. 1. Having done this it is necessary to run only one standard each time determinations are to be made and read the results from the curve.

Summary and Conclusions

1. The colorimetric method in which aurintricarboxylic acid is used for determining aluminum has been modified so that samples ranging from 0.0050 to 0.0700 mg. of aluminum may be compared with one standard and the amount of aluminum in each sample may be read directly from a curve. The results are accurate to within about 5%.

2. Maximum color intensity was obtained in the presence of 10% of 6 N ammonium acetate when the solution was at approximately P_H 4.0 and held at a minimum temperature of 80° for about ten minutes.

3. In the presence of 5 cc. each of 5 N ammonium acetate and ammonium chloride the dye changed color at about P_H 7.0. A neutral or

alkaline solution of 2 cc. of 0.1% dye in a volume of 50 cc. was very nearly colorless.

4. The lake color remained sufficiently permanent for making determinations until the solution was raised to PH 7.4.

5. The presence of ammonium acetate and chloride as buffers was found advantageous for controlling the PH of the solution.

6. Ammonium carbonate was found more suitable for decolorizing the excess dye than either ammonium hydroxide or a solution of ammonium carbonate in ammonium hydroxide.

PHOTOCHEMICAL STUDIES. IX. URANYL SULFATE AS SENSITIZER FOR THE PHOTOCHEMICAL DECOMPOSITION OF OXALIC AND MALONIC ACIDS

BY WILLIS CONWAY PIERCE

RECEIVED MAY 1, 1929 PUBLISHED SEPTEMBER 5, 1929

The photochemical decomposition of malonic acid, both in the presence and absence of uranyl salts, has been the subject of a previous study,[1] while the decomposition of oxalic acid has been repeatedly investigated.[2] The results indicate that the mechanisms of the sensitized decompositions of the two acids may be different and the present work was undertaken in order to obtain a more thorough comparison between the two.

I. Temperature Coefficient

There is some discrepancy in the values given for the quantum efficiency of the oxalic acid decomposition but the generally accepted value seems to be one.[3,4] Various workers have reported a temperature coefficient of unity. The quantum efficiency for the decomposition of 0.05 M malonic acid with 0.0025 M uranyl sulfate was found[1] to be about 0.25, and to be in some degree at least independent of wave length. Buchi[3] attributed the effect of uranyl sulfate to complex formation in the case of oxalic acid. Müller,[5] on the other hand, has attributed the effect to collisions of the second kind between activated uranyl ions and oxalic acid molecules or oxalate ions. A somewhat similar explanation was suggested[1] for the

uranyl sulfate–malonic acid reaction, although it was said that complex formation was not definitely ruled out.

It seemed that the temperature coefficient might furnish evidence as to the applicability of the two explanations and this was determined for uranyl sulfate with malonic acid and uranyl sulfate with oxalic acid. A value of one was found for the oxalic acid, confirming the results of Bruner and Kozak[6] and Bacon.[7] The sensitized decomposition of malonic acid showed a temperature coefficient of 1.13 ± 0.02 between 3 and 73°.

Experimental

A quartz mercury arc lamp was mounted vertically and two quartz water jackets surrounding quartz test-tubes were placed parallel to the lamp at a distance of two centimeters. The solutions were placed in the test-tubes and were kept at the desired temperature by a rapid flow of water through the jackets. The system was tested for uniformity by exposing similar samples of a uranyl sulfate–oxalic acid solution in the two vessels and measuring the decomposition by titration with permanganate. Malonic acid solutions were analyzed by titration with carbonate-free sodium hydroxide solution with phenolphthalein indicator. Results are given in Table I.

TABLE I

TEMPERATURE COEFFICIENT.[a] $KMnO_4$, 0.105 N. NaOH, 0 05 N

[a] By "temperature coefficient" is meant the ratio of the rates. $R_{t+10°}/R_t$.

These results confirm a large number of previous runs in which but a single sample was exposed.

II. Absorption Spectra

The absorption coefficients of uranyl salts are greatly enhanced by the presence of organic acids. Henri and Landau[8] first described this for oxalic acid and uranyl sulfate and their work was cited by Büchi as evidence for complex formation. It was stated in the previous paper that no such effect was found with malonic acid, but a further investigation at higher

[8] Henri and Landau, *Compt. rend.*, **158**, 181 (1913).

frequencies (using more dilute solutions) showed that in the range 220 mμ to 320 mμ the absorption coefficients are increased by the presence of malonic acid. The effect is not so marked at longer wave lengths. Ghosh and Mitra[9] assumed that this enhancing effect is due to the formation of a complex between the uranyl salt and the organic acid and used the absorption coefficients to calculate the degree of formation. Both oxalic and malonic acids were investigated by them. They based their calculations on the assumptions that (1) one molecule of the organic acid unites with one molecule of the uranyl salt to form a molecular complex, (2) the mass law applies to this combination and (3) the complex molecule has a definite absorption coefficient for each wave length. They found the equilibrium constants

$$\left(K = \frac{[\text{complex}]}{[\text{uranyl salt}]\,[\text{organic acid}]}\right)$$

K = 115 for oxalic acid–uranyl sulfate complex and K = 80 for malonic acid–uranyl sulfate complex. According to these values oxalic and malonic acids form complexes of about the same degree of stability but the absorption of the oxalic acid complex is much greater than that of the malonic acid complex.[10]

The work of Müller,[5] Jette and West,[11] and West, Müller and Jette[12] suggested that the increase in the absorption might be due to quenching the fluorescence of the uranyl ion. They found that chloride ion was effective in quenching the fluorescence and that sulfate ion had relatively little effect. The absorption coefficients were determined for uranyl sulfate with these added ions. Neither had an appreciable effect in dilute solution but 0.001 M uranyl sulfate in saturated potassium chloride or potassium sulfate showed practically the same absorption coefficients as when dissolved in 0.01 M oxalic acid. From these results and the fact that Beer's law is obeyed for dilute solutions of uranyl salts it was concluded that the quenching of the fluorescence is probably not the reason for the enhancing of the absorption. The peculiar enhancing by saturated salt solutions may be due to the formation of very unstable complexes but no attempt was made to investigate these.

III. Effect of Concentration on the Rate of Reaction

(a) Uranyl Sulfate.—It was stated in the previous paper that the rate of reaction varied with the concentration of uranyl sulfate when it was

---

[9] Ghosh and Mitra, *J. Indian Chem. Soc.*, *4*, **353** (1927).

[10] Absorption coefficients were determined for oxalic and malonic acids and for their solutions with uranyl sulfate before noting the above work. The results were in qualitative agreement with the work of Ghosh, although the difference in the enhancing due to oxalic and malonic acids was not so great as that found by Ghosh.

[11] Jette and West, *Proc. Roy. Soc. London*, **121A,** *300* (1928).

[12] West, Muller and Jette, *ibid.*, **121A,** *294* (1928).

less than 0.0025 M and was independent of concentration in the range 0.0025 to 0.01 M. This was for reactions carried out in vessels exposing a layer of solution one to two centimeters in depth. All of the previous work was done with only one exposure at a time and was open to error in accidental variation in the light intensity. A new series of experiments was carried out with all the samples of varying concentration lighted simultaneously on a rotating motor-driven turntable. The results are listed in Table II. They are in agreement with the previous results.

TABLE II

VARIATION OF RATE WITH CONCENTRATION OF URANYL SULFATE

10-cc. samples lighted in open porcelain crucibles. Depth of liquid, 1.5 cm. Malonic acid, 0.05 M. NaOH, 0.0528 *N*.

Concn. UO_2SO_4	Amt. decomp. (cc. NaOH) I	II	Relative rate 2.72 = 1	8.15 = 1
0.0000	0.50	1.71	0 18	0.21
.0005	1.75	5.05	0 64	0 62
.0010	2.29	6.03	0 84	0.74
.0015	2.38	6.76	0 88	0 83
.0025	2.75	7.58	1 01	0.93
.0050	2.63	8.39	0 97	1 03
.0075	2.86	8.47	1 05	1 04
.0100	2.64	8.15	0.97	1 00

(b) Malonic Acid.—It has previously been shown that with 0.01 M uranyl sulfate the rate varied with the concentration of malonic acid. The effect is most marked at small concentrations of acid. The importance of this led to a reinvestigation, using a greater variety of mixtures. All samples were lighted simultaneously on the rotating apparatus, thus eliminating errors due to fluctuations in the light intensity. The total reaction had to be kept small in order to prevent complete decomposition of the samples having small amounts of malonic acid, and on this account the experimental error was quite large. Averages taken from a large number of determinations gave sufficient accuracy to determine the trend of the rate curve. Results of two typical runs are given in Table III.

TABLE III

VARIATION IN RATE WITH CONCENTRATION OF MALONIC ACID

Uranyl sulfate, 0.0116 M. 20-cc. samples used. NaOH, 0.0528 N

	2 5-Hour run				5.8-Hour run			
Init. concn. malonic acid	0.0048	0.0092	0.023	0.040	0.0092	0.023	0.046	0.092
Molar ratio = x	0.4	0.8	2.0	4.0	0.8	2.0	4.0	8.0
Amt. dec., cc. of NaOH	1.30	1.59	1.95	2.60	2.97	4.91	5.58	6.18
Rel. rate, x = 8, for unity	0.45	0.55	0.67	0.90	0.48	0.79	0.90	1.00
Av. molar ratio, $\bar{x}$	0.25	0.61	1.8	4.0−	0 4	1.5	4.0−	8.0−

The two series of runs were calculated to the same relative rate of unity for samples having a molar ratio of 8. Since the concentration changed during a run, an average value of x (molar ratio) was calculated and used as the effective molar ratio. This does not accurately represent the effective concentrations during a decomposition but it may be taken as a first approximation.

IV. Discussion of Results

Some points of difference are noted in the catalyzed decompositions of oxalic and malonic acids. For example, the temperature coefficient of the former is one while that of the latter is 1.13. The quantum efficiency of the former is given as one, but for the latter a value of about 0.25 was found. On the other hand, many points of similarity lead to the conclusion that the function of the uranyl sulfate is the same in both cases. It seems that both reactions may be satisfactorily explained by the assumptions of Biichi that a light-sensitive complex is formed by the uranyl ion and the organic acid, and that decomposition is caused only by the light absorbed by this complex. There is, however, some evidence for the alternative theory that the uranyl ion transfers energy to the acid molecule by collisions of the second kind. Indications of complex formation to be found are: (1) The conductivity of uranyl salts was shown by Dittrich[13] to be lowered by the addition of sodium oxalate.

(2) The quantitative work of Ghosh and Mitra on the absorption spectra seems to point to complex formation.

(3) The variation in rate with the concentration of acid may be in agreement with the "complex" theory. Büchi showed that for oxalic acid the rate is nearly constant when the molar ratio is greater than one (acid in excess). This is difficult to explain by collisions of the second kind unless the activated uranyl ions have a very long life and may be deactivated only by collision with oxalic acid molecules. It is, however, in harmony with the "complex" theory if the complex has such large absorption coefficients that practically all of the effective light is absorbed by it, and if the complex is so stable that when a molar ratio of unity is reached practically all of the uranyl ions are combined. Both of these assumptions are necessary to account for a quantum yield of unity, as found by Biichi.

These assumptions, however, are not in agreement with the values of Ghosh[8] for the stability of the complex and its absorptive power. Buchi used 0.0167 M uranyl sulfate solutions with equimolar oxalic acid. Ghosh found an equilibrium constant of 80 for this reaction. This value leads to a calculated concentration of complex of 0.006 M for the above solution. The relative absorption for a given frequency is given by the relation

$$\text{Fraction of light absorbed by complex} = \frac{k_1c_1}{k_1c_1 + k_2c_2}$$

---

[13] Dittrich, *Z. physik. Chem.*, **29**, **449** (1899).

where k_1 and k_2 are absorption coefficients of complex and uranyl ion, respectively, and c_1 and c_2 are their concentrations. In order for the complex to absorb most of the light its absorption coefficient must be very much greater than those of the uranyl ion if the relative concentrations are as given by the calculation. It seems then that (1) the complex may be more stable than postulated by Ghosh, (2) it may have larger absorption coefficients, or **(3)** energy absorbed by the uranyl ions may be transferred to the complex by collisions of the second kind of very high efficiency.

The case of malonic acid is much the same. The increase in rate beyond a molar ratio of 1 is very much less than when the uranyl sulfate is in excess. The reaction may be satisfactorily interpreted as due to the absorption of light by the complex and decomposition of the activated complex. The steady rise in rate with increasing acid concentration may be due to the formation of more of the complex, thus increasing the fraction of the light absorbed by the complex.

This interpretation does not conflict with the observation that in 0.05 M malonic acid solutions the rate is independent of the uranyl salt concentration in the range 0.0025 to 0.01 M. At such concentrations absorption of the effective light is undoubtedly nearly complete even in very shallow layers, and increase in the complex concentration should not cause an increase in rate. Further, increase in the concentration of uranyl ion decreases the molar ratio so that the fraction of the uranyl ion converted to complex becomes smaller as its total concentration is increased, and less of the light is available for the reaction. A calculation of the fraction converted may be made using the equilibrium constant of 115 as determined by Ghosh. At initial concentrations of $UO_2SO_4 = 0.0025$ and malonic acid $= 0.05$ M the concentration of complex is 0.00217 M, or 86.7% of the ion has reacted. For 0.01 M UO_2SO_4 and 0.05 *M* malonic acid the complex concentration is 0.00827 M, corresponding to 82.7% reaction. Since the absorption coefficients of the complex are higher than those of the uranyl ion, the fraction of the light absorbed by the complex does not change greatly over this range of concentration of uranyl ion.

(4) The temperature coefficient of unity may be in harmony with either mechanism for oxalic acid. If the reaction is a zero order decomposition of a complex, it appears that the activation of any molecule may lead to decomposition, and that thermal activation is not necessary. It would seem that temperature changes have little effect on the stability of the complex since the reaction rate is independent of temperature. If, on the other hand, the reaction is brought about by collisions of the second kind, all absorbed quanta must be utilized in activating oxalic acid molecules and rise in temperature should cause no change in rate.

It is significant that the temperature coefficient of the malonic acid reaction is so much larger, but this fact as well as the quantum efficiency may agree equally well with either explanation.

Collisions of the second kind do not seem to offer an adequate explanation of the enhancing of absorption when organic acids are added to uranyl sulfate solution. On the other hand, complex formation does not seem to explain the observation of Müller[5] that addition of certain ions to a uranyl sulfate–oxalic acid solution lowers the rate of reaction. He found that the order of effectiveness of chloride, bromide and thiocyanate ions is the same as their order of effectiveness in quenching the fluorescence of uranyl ions. Both effects are ascribed to the ability of the added ions to deactivate the uranyl ions on collision. If such a deactivation occurs, the effectiveness of added ions in reducing the rate of oxalic acid decomposition should depend (a) on the effectiveness of transfer of energy from the uranyl ion to retarder and to reactant, and (b) the relative number of collisions of each with the activated uranyl ions. These assumptions have been used to calculate the rate of decomposition of 0.1 M oxalic acid in the presence of various retarders. The experimental results are those given by Müller.[5] Results are summarized in Table IV. The assumed effectiveness of the deactivation per collision with a retarding ion is: chloride ion, **0.228;** bromide ion, **0.5;** thiocyanate ion, **1.0.** It is significant that the inhibitor having the greatest effect has an efficiency of deactivation of unity.

Table IV

Inhibiting Effect of Added Ions

Concn. of added ion	Calcd. rate Cl	Obs. rate Cl	Calcd. rate Br	Obs. rate Br	Calcd. rate SCN	Obs. rate SCN
0.02	26.9	27.1	25.6	26.2	23.3	23.0
.05	25.8	26.1	23.3	24.2	18.7	18.5
.10	(24.8)	24.8	21.0	22.3	14.0	13.8
.20	23.7	24.2	18.7	19.4	9.3	8.6

The excellent agreement obtained lends support to this theory.

Each theory then may account for many of the observed facts, and it seems that further work is needed in order to establish either one. A third possibility is that the reaction is brought about by both complex formation and collisions of the second kind.

V. Summary

1. The temperature coefficient is **1.13 ± 0.02** for the photolysis of malonic acid in presence of uranyl sulfate. It is unity for oxalic acid–uranyl sulfate, as reported by previous workers.

2. The rate of the reaction varies with the concentration of uranyl sulfate and approaches a constant value. The rate varies with the concentration of malonic acid. This effect is greatest when the molar ratio of malonic acid to uranyl sulfate is less than unity. At ratios greater than unity the change in rate with concentration is small.

3. The oxalic and malonic acid reactions seem to be similar although they show a marked difference in their temperature coefficients and quantum efficiencies.

4. Two mechanisms are discussed. The reaction may be due to the decomposition of an intermediate uranyl ion–acid complex, or it may be explained by collisions of the second kind between activated uranyl ions and acid molecules.

THE HEAT CAPACITY OF TOLUENE FROM 14°K. TO 298°K. THE ENTROPY AND THE FREE ENERGY OF FORMATION

BY KENNETH K. KELLEY[1]

RECEIVED MAY 6, 1929 PUBLISHED SEPTEMBER 5, 1929

Very few low temperature thermal measurements on aromatic hydrocarbons have been made. The only true specific heats which have been published are those of Nernst[2] for benzene but even these data are very scanty and do not agree well among themselves.

This paper presents specific heat, heat of fusion and temperature of fusion data for toluene. The specific heat measurements were carried down to 14°K. The methods and apparatus and the accuracy of measurement have been discussed elsewhere.[3]

One change in the apparatus was made before starting this work. Due to an unfortunate explosion the portable hydrogen liquefier, previously used, was demolished. A new liquefier, similar to that described by Latimer and Greensfelder,[4] was built in as a permanent unit. Both of these liquefiers were designed by Mr. G. F. Nelson of this Laboratory and built under his supervision.

Material.—The toluene was the best product of the Eastman Kodak Company (sulfur free). Treatment of a sample with concd. sulfuric acid gave no coloration in ten minutes. The material was dried for several days with fused calcium chloride, decanted off, and carefully fractionated three times. The middle portion used had a volume of 200 cc. and a boiling range of 0.03". The density, d_4^0, 0.88456, compares favorably with the Leiden measurement: d_4^0, 0.88445, and with that of Biron,[6] d_4^0, 0.88450. The fusion curves indicated exceptional purity.

The Measurements.—The specific heat results are given in Table I and shown graphically in Figure 1. No abnormal behavior was noted in either the crystals or liquid.

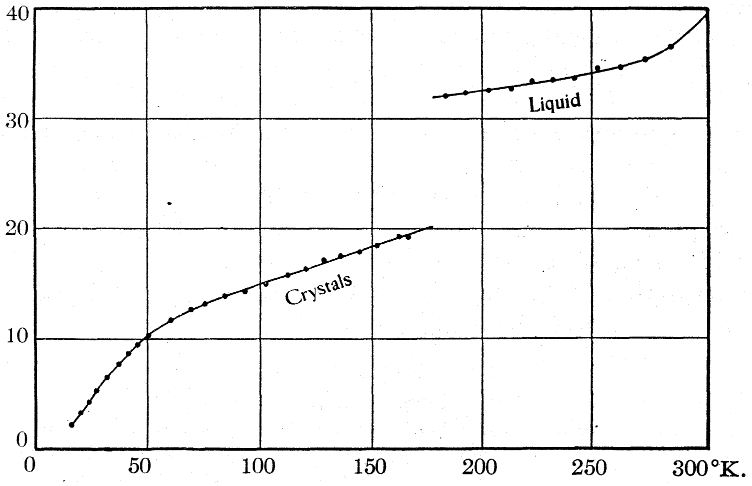

Fig. 1.—The heat capacity of toluene in calories per mole.

The heat of fusion and temperature of fusion data appear in Table II. The fusion temperature of toluene recorded here is almost exactly (to 0.01°) the same as that obtained at Leiden.[5]

TABLE II

FUSION DATA

T, °K.	Heat of fusion in cal per mole 1st result	 2nd result	Mean
177.95	1584	1579	1582

The Entropy.—The entropy was calculated in the usual manner. The extrapolation below the initial temperature of the lowest measurement was made by means of the Debye function with $\Theta = 91$. Table III contains the results of the entropy calculation.

TABLE III

ENTROPY OF TOLUENE

0–14 °K. (extrap.)	crystals	= 0.52
14–177.95	crystals	= 25.50
1582/177.95	fusion	= 8.89
177.95–298.1	liquid	= 17.46
$S_{298.1}$ for 1 mole of liquid toluene =		52.4 ± 0.3 E. U.

Preliminary Measurements on *m*-Xylene.—Similar measurements were carried out on m-xylene. However, the fusion curves revealed a considerable amount of impurity and for that reason the specific heat data are not worthy of publication. The entropy value obtained, namely 60.3 E. U. per mole, is probably not in serious error and has been checked by Parks and Huffman,[7] who also unfortunately did not have a pure sample.

Free Energy Calculations and Discussion.—The free energy of formation from the elements was calculated by means of the equation, $\Delta F = \Delta H - T\Delta S$. The heat of combustion data of Richards and co-workers[8] were used, corrections being made to 15° calories and to the standard of temperature used here, 298.1 °K. The heats of formation of carbon dioxide and water and the values for the entropies of the elements were those adopted in previous work.[3] For the purpose of comparison the free energy of benzene has also been calculated, using the value of 42.4 E. U. for its entropy at 298.1 °K.[9] Table IV contains the resulting thermal data, the 15° calorie being used throughout.

TABLE IV

THERMAL DATA

Substance	Heat of combustion	$\Delta H_{298.1}$	$\Delta S_{298.1}$	$\Delta F_{298.1}$
Benzene	781,700	11,120	−54.2	27,300
Toluene	935,100	1,930	−75.1	24,300
m-Xylene	1,090,500	−5,260	−98.1	24,000

From the entropy of benzene and the values given for toluene and m-xylene in this paper it may be seen that the entropy difference between benzene and toluene is 10.0 units and between toluene and m-xylene 7.9 units. These differences are of the same order of magnitude as the value associated with a CH_2 increment in the homologous series of primary

---

[7] Parks and Huffman, personal communication.

[8] Richards and Barry, THIS JOURNAL, 37, 993 (1915); Richards and Davis, *ibid.*, 42, 1599 (1920).

[9] This value was obtained by Parks and Huffman of Stanford University from their unpublished measurements. From Nernst's data a value of 42.2 E. U. may be calculated.

saturated aliphatic alcohols,[10] which has been shown to be 7.7 E. U. In the case of the alcohol series the free energy of formation changed by about 500 cal. per CH_2 group added. No similar definite statement can be made in the present case partly because the heats of combustion utilized in spite of their high percentage accuracy may be in error by a few hundred calories due to their magnitude.

Summary

1. Specific heat measurements on toluene covering the temperature range from 14 to 298°K. have been made.
2. The heat of fusion and temperature of fusion were measured.
3. The entropy and free energy of toluene at 298°K. have been calculated. Preliminary values on m-xylene are also included.

THE MOVEMENT OF GASES AROUND ELECTRICALLY HEATED WIRES

BY SAM LENHER AND GUY B. TAYLOR

RECEIVED MAY 11, 1929 PUBLISHED SEPTEMBER 5, 1929

In conducting some experiments on the kinetics of the catalytic oxidation of sulfur dioxide by the hot wire method in which the pressure change was being followed on a mercury manometer, it was observed that the mercury meniscus oscillated slightly, indicating a periodic pressure change. Further investigation showed that this periodic effect was not a catalytic phenomenon since it occurred in air and other gases where no chemical reaction was possible.

Platinum wires, 0.25 mm. in diameter and 10 cm. or more in length, were sealed in glass cylinders 3 to 6 cm. in diameter. When the wire was heated electrically to any temperature from about 300° to a white heat, a small periodic pressure change could be detected on a sensitive manometer. The fluctuations occurred from 50 to 100 times per minute and were synchronized with a minute change in the heating current. The current fluctuation was detected by putting the secondary of a small transformer in series with the storage battery used for heating the wire and connecting the primary with a high sensitivity galvanometer. The same effects were observed with wires sealed in spherical glass vessels.

The magnitude of the pressure change at a pressure of one atmosphere when the wire was either nearly vertical or horizontal was a fraction of a centimeter of water. As the tilt of the vessel was increased the periodic

---

[10] Kelley, THIS JOURNAL, 51, 779 (1929).

fluctuation became more pronounced, until at a tilt angle of 45° the change became several centimeters of water.

The periodic pressure change was observed with a nearly horizontal wire in air, nitrogen, argon and carbon dioxide but not in hydrogen or helium. The effect, with air, decreased with decrease of pressure from two atmospheres to one-quarter atmosphere, where in this particular experiment the periodic phenomenon stopped.

It appeared probable that the periodic phenomena were connected with convection currents in the gas; this was confirmed by experiment. A platinum wire was sealed vertically in a cylindrical glass vessel with a tungsten weight on the lower end dipping into mercury. The vessel was immersed in a large water thermostat and a gas along with a thin mist of sulfuric acid or titanium hydroxide was introduced. The white mist made the movements in the gas due to convection actually visible. The vessel was illuminated from the side by light from a Pointolite lamp. When the wire was heated electrically a zone was observed around the wire which was free from mist in sharp contrast to the body of gas. This zone appears to be the conduction zone postulated by Langmuir[1] and others.[2]

Langmuir, in studying the energy losses from hot wires, assumed that the transfer of heat from a hot body to a gas in contact with it took place across a thin film of gas next to the heated body through which heat was transferred principally by conduction and radiation. The mist-free zone

TABLE I

DIAMETER OF MIST-FREE ZONE AROUND A HOT PLATINUM WIRE (WIRE DIAMETER, 0.25 MM.)

[1] Langmuir, *Phys. Rev.*, 34, 401 (1912); *Trans. Am. Inst. Elec. Eng.*, 31, 1011 (1912); *Trans. Am. Electrochem. Soc.*, 23,299 (1913).

[2] For the early literature on the conduction zone theory of convection *see* Dalby, *Proc. Inst. Mech. Eng. (London)*, 921 October (1909).

observed in the present experiments followed the behavior of the conduction zone postulated by Langmuir in all respects except one important one. As Langmuir observed, the diameter of the zone was greater in hydrogen and helium than for air at the same wire temperature. Its diameter increased with decrease in pressure as observed with the conduction zone by **Kennelly.**[1,3]

However, the zone observed here was not independent of the wire temperature. This is shown clearly by the data in Table I giving the relation of the diameter of the zone to the wire temperature and the gas pressure for several gases. Resistance of the wire measured as E/I was used as a criterion of equal temperature in the gases. At the high resistances the wire was white hot and at the lower resistances it was not visibly red. The dependence of the zone diameter on the wire temperature was also demonstrated under conditions where the body of the gas was not appreciably heated by the hot wire. A platinum wire was placed vertically in a large glass vessel containing a dilute titanium hydroxide mist in air. The air 1 cm. away from the glowing wire was only 10° above room temperature, but the increase in the diameter of the mist-free zone with increase of wire temperature was the same as that given in the experiments summarized in Table I.

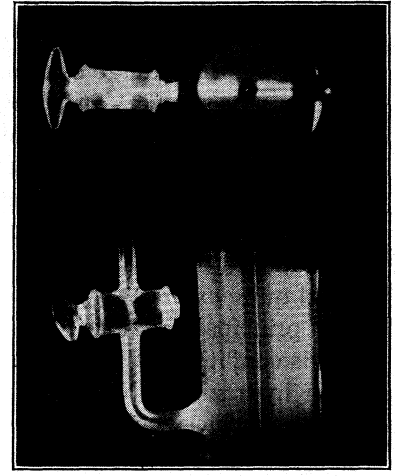

Fig. 1.

In hydrogen and helium the convection currents in the body of the gas outside the zone around the wire were streamline in character while in the other gases the currents tended to become turbulent, periodic and to break into the zone. The periodic pressure change synchronized with a clearly marked visible periodic turbulence in the convection currents.

Figure 1 shows the mist-free zone around a hot wire viewed from the side and from above through a plane window.

Summary

1. A periodic pressure change has been observed in vessels containing an axially placed electrically heated wire. The periodic pressure change has been found to be synchronized with a corresponding fluctuation in the heating current.
2. A mist-free zone around a hot wire in a gas containing a dilute mist

---

[3] Kennelly, *Trans. Am. Inst. Elec. Eng.*, *28*, 363 (1909).

has been noted. It has been shown that this zone behaves like the conduction film assumed to exist around a heated body.

3. It has been shown that the diameter of the mist-free zone is dependent on the wire temperature.

STUDIES ON HYDRAZINE. THE AUTO-OXIDATION

BY E. C. GILBERT

RECEIVED MAY 11, 1929 PUBLISHED SEPTEMBER 5, 1929

The strength of dilute solutions of hydrazine hydrate decreases rapidly in the presence of air. It has been shown[1] that this is due to oxidation by atmospheric oxygen. The reaction between oxygen and hydrazine has been studied also by Browne and Shetterly[2] who passed oxygen and ozone through hot hydrazine solutions, acid, neutral and alkaline. They found no products except nitrogen and in one case a trace of hydronitric acid. The oxidation of hydrazine in the presence of platinum black has been studied quite extensively[3] but this procedure as will be shown removes one of the principal products of the reaction. It is possible, though the evidence is conflicting, that platinum black also effects a catalytic decomposition of hydrazine. None was able to find a mathematical expression for the rate at which the hydrazine is oxidized.

The present work represents a study of the rate of oxidation of hydrazine hydrate in dilute solution by pure oxygen and by air. One of the most interesting developments was the discovery that considerable quantities of hydrogen peroxide are formed in the reaction. This is, of course, a concomitant of many auto-oxidations but hydrazine is a very powerful reducing agent and under some conditions at least reacts readily with peroxide. The presence of peroxide is of particular interest because it interferes seriously with many methods of determining hydrazine. In addition to this the velocity of oxidation under the conditions adopted has been found to follow a simple mathematical expression over a wide range of concentration, temperature and alkalinity.

Experimental Part

(1) **Procedure.**—The apparatus consists of an inverted Erlenmeyer flask into the mouth of which is fitted, by a ground joint, a Jena Gooch crucible containing a medium porous fritted glass disk through which oxygen may be passed into the solution. A hole made in what was formerly the bottom of the flask serves for the introduction of the

stirrer and for the withdrawal of samples. The reactions are carried out at constant temperature. For the work described here, the interior of the flask was coated with paraffin, as was also the stirrer. The solution was stirred at a constant rate just sufficient to ensure uniformity of concentration; too rapid stirring drew the bubbles of oxygen into the stirrer. In some runs stirring was omitted for periods of thirty minutes at a time with no noticeable effect. It was, however, necessary at the start, Oxygen passed through at the rate of five liters per hour as measured by a calibrated flowmeter. Some runs were made at 6.5 liters per hour but no difference was found. Too rapid flow of gas causes an unduly large loss of hydrazine by volatilization

At the beginning of a run, water and sodium hydroxide (total volume 100 cc.) were introduced into the reacting vessel and saturated with oxygen. The proper amount of hydrazine hydrate (Eastman Kodak Company 50% solution) was added and after one minute a sample (2 cc.) was withdrawn for analysis. At further intervals of five minutes or more samples were withdrawn alternately for the determination of hydrazine and peroxide. Hydrazine was determined by the iodic acid method.[4] Peroxide interferes seriously with this method and must be removed. Both hydrazine and peroxide are reducing agents but peroxide is also an oxidizing agent so the following procedure was adopted, after trial. The sample of hydrazine containing peroxide is run into 6 N sulfuric acid and a few drops of sulfurous acid added. The peroxide is destroyed and so far as could be detected under these conditions the hydrazine is unaffected, The solution was boiled for five to ten minutes to remove excess sulfur dioxide and the hydrazine determined as usual. A test (containing no peroxide, however) went as follows:

Sample of hydrazine sulfate, *cc.*	H_2SO_3, *cc.*	HIO_3, *cc.*	$Na_2S_2O_3$, *cc.*
2.00	1.0	10.00	5.45
2.00	0.0	10.00	5.45

Peroxide could always be detected if present since the final starch–iodine end-point is not permanent if peroxide is present. Peroxide was determined as follows, though no great precision can be claimed for the method. The sample (2 cc.) was run into 3 cc of 6 *N* sulfuric acid in a glass-stoppered flask and carbon dioxide passed through for at least five minutes to remove oxygen from the solution and flask. Potassium iodide was added and after standing for ten to fifteen minutes the liberated iodine was titrated with 0.005 N thiosulfate. In the presence of acid of this concentration hydrazine should react so slowly with iodine that the error would be negligible. Tests by this method on peroxide solutions of known concentration with and without hydrazine. proved its suitability.

The concentration of sodium hydroxide was varied from 0.0 to 0.46 *M*, the initial concentration of hydrazine from 0.07 to 0.27 M and the temperature from 20 to 25 and 30°. Air was used in place of oxygen only to determine the effect of oxygen pressure, as the rate of oxidation was much more rapid with pure oxygen. Runs were made in the presence of ammonia, hydronitric acid, hydrogen peroxide and sand, and with various rates of stirring and oxygen flow.

In the light of the results of Browne and Shetterly it was thought that hydronitric acid might be present but none could be found, though the tests are extremely sensitive. The solution also gave a negative test for nitrite and nitrate. Peroxide was shown to be present by the ether–dichromate test and also by the color reaction with titanium sulfate. The gases were tested for hydrogen with a palladium absorption tube but none could be found. In the early part of the work a small amount of ammonia was found in the more alkaline solutions. The amount was so small that it was not tested for in later runs.

An entirely different procedure was also used, shaking the solution in a bottle in

the presence of oxygen, and the results are apparently of a different character. This report deals only with the bubbling method.

(2) Results.—In Fig. 1 is shown a series of characteristic curves for the auto-oxidation of hydrazine and the accompanying curves for the formation of peroxide. Data for some of the curves are given in Table I. For the sake of brevity the major part of the results is merely summarized (Table II).

(3) Discussion. (a) The Effect of Hydrazine Concentration.—The curves all show for the oxidation of hydrazine a characteristic double inflection, with a period of "induction" at the beginning followed by a rapid change of slope, after which they assume a slight concavity to the horizontal axis. After the first period of irregular change all, covering a fourfold increase in hydrazine concentration, may be formulated by the equation developed by Bodenstein[6] for certain gas reactions and adapted by MacInnes[6] to a heterogeneous reaction in solution whose rate is governed by the adsorption of the reactants, or diffusion

$$-\frac{dC}{dt} = k\cdot C^{\frac{1}{n}}$$

Since it is not possible to begin the calculations with zero time, it is necessary to calculate the constants from point to point or better to adopt some one point as a basis. In either case

$$k = \frac{1}{(t_2 - t_1)(1 - 1/n)}\left(C_1^{(1 - 1/n)} - C_2^{(1 - 1/n)}\right)$$

A value of 2 for "*n*" proved to satisfy the conditions satisfactorily over the whole range of temperature and concentration. It might be expected that a different value would be required at different temperatures, but a similar small variation of "*n*" with temperature has been noted in another similar heterogeneous reaction.[7] A certain drift should be expected in these constants because there is unavoidably some loss of hydrazine by volatilization. This is a variable quantity depending upon duration of experiment and alkalinity of solution but present in all cases. Rough experiments using hydrogen instead of oxygen indicated a maximum loss of 2% an hour. This being a heterogeneous reaction it was difficult to obtain results which agreed as closely as 2% and no correction was made for the loss. Duplicates run at periods of three to six months agreed in quite a satisfactory manner, as may be seen from the tables.

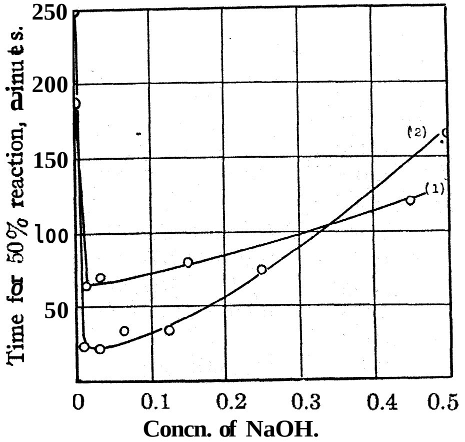

Fig. 2.—Comparison of effect of NaOH on auto-oxidation of hydrazine (1) and on the catalysis of hydrogen peroxide by colloidal platinum (2).

(b) The Effect of OH– Concentration.—The effect of increasing the hydroxyl-ion concentration is first to accelerate oxidation and then to retard it. The maximum rate of oxidation is found when the sodium hydroxide concentration is 0.01–0.03 M. An interesting coincidence occurs here. Inspection of Fig. 2 shows that the effect of sodium hydroxide on this reaction is practically the same as its effect on the catalysis of hydrogen peroxide by colloidal platinum.[8] It is difficult to ascribe this effect to some

particular part of the phenomenon, because the maximum rate of oxidation is attended by a minimum formation of peroxide (see paragraph c). Whether the smaller amount of peroxide is present at this concentration (NaOH = 0.01–0.03 M) because this represents the optimum condition for the decomposition of peroxide (Fig. 2) is not certain. It is fairly certain, however, that the amount of peroxide present is the resultant of two reactions, one of formation and one of decomposition, since in some cases the amount passes through a maximum and decreases (see Run 68, Fig. 1).

A possible explanation of the effect of sodium hydroxide on the oxidation is this. The molecule N_2H_4 may be the oxidizable material. Low concentrations of NaOH serve to repress the ionization of hydrazine hydrate, thus increasing the concentration of the N_2H_4 molecules. It also combines with the peroxide formed. High concentration may alter conditions such as hydration, association, etc., so as to reduce the actual number of reactive molecules. It might be thought that the formation of peroxide would reduce the hydroxyl-ion concentration to an extent sufficient to affect the course of the reaction. A rough calculation shows this not to be the case.

$$\frac{N_2H_5^+ \times OH^-}{N_2H_4} = 1.5 \times 10^{-6}$$

In a solution where NaOH = 0.03 M, as a first approximation then

$$\frac{N_2H_5^+}{N_2H_4} = 5 \times 10^{-5}$$

The hydrazine is practically un-ionized. At the end of two hours the peroxide concentration was about 0.015 M. Assuming that the sodium salt is not hydrolyzed, the effective OH^- is still 0.015 and the ratio is

$$\frac{N_2H_5^+}{N_2H_4} = 1 \times 10^{-4}$$

Since the molecule is presumably the reactive form, this difference in ratio can have no detectable effect on the reaction from the standpoint of hydrazine concentration.

(c) The Effect of Peroxide Concentration.—It has not been found possible to formulate any satisfactory expression for the increase of peroxide with time, probably because it is the difference between formation and decomposition. Run 76 in which standard Ottawa sand was added shows a lower amount of peroxide than usual, substantiating this theory. The amount of peroxide varies with the initial concentration of hydroxyl ion almost in inverse ratio to the rate of oxidation, *i. e.*, slow oxidation, high peroxide and *vice versa* as may be seen by comparing companion curves in Fig. 1. It does not necessarily follow that the peroxide is low because it is reacting or has reacted with hydrazine, thereby accelerating the rate, because when air is used instead of oxygen, the rate of oxidation falls to one-fifth, but the amount of peroxide does not decrease accordingly. In Run 64, however, in which 0.0167 M peroxide was added at the start, the oxidation seems to run slightly faster, but the interesting thing is that the peroxide formed in the run is less than 30% the normal amount formed in a similar run with no added peroxide.

As judged by the amount of peroxide formed when 0.05 mole of hydrazine has been oxidized, see Col. 4, Table II, it seems probable that in the absence of NaOH the ratio Moles peroxide formed/Moles hydrazine oxidized = 1:2. In the presence of low OH– (0.012–0.03) the ratio is 1:4 and in strong NaOH (0.15–0.46) the ratio is 1:3. Since, however, different time intervals are required in the several cases for this amount of oxidation, no very close distinctions may be drawn. It should be stated that the formation of peroxide is not a function of this apparatus or procedure. It is formed by simple exposure of an alkaline solution of any hydrazine salt, or hydrazine hydrate, on a watch glass to air, though, of course, not so rapidly as with pure oxygen.

(d) The Temperature Effect.—In 0.03 N NaOH, k for the oxidation increases from 0.0032 at 20° to 0.0056 at 30°, giving a coefficient of 1.75 for this ten-degree interval. This corresponds more closely to that of a chemical reaction at a surface than to a diffusion process.[9]

(e) The Active Surface.—The data so far obtained indicate, therefore, a reaction at a surface, but it is not certain what this surface may be. The walls and stirrer were coated with paraffin, upon which very little reaction would be expected. The fritted glass disk falls under suspicion, but addition of sand which should increase such surface cuts the velocity in half. The bubbles of oxygen were extremely fine but they passed through the solution rather rapidly. The temperature coefficient and indeed the expression for the velocity constant correspond to a micro-, rather than macro-heterogeneous reaction, so it is possible that this is a reaction catalyzed by dust particles.[10] In preliminary experiments it was found that variously prepared samples of hydrazine sulfate gave very great differences in rate, most easily explained by this same hypothesis.

(f) The Effect of Oxygen Pressure.—When air was used the rate was so slow that the curve was practically a straight line after an initial drop. The slope of this line was 0.0002 as compared with a slope of 0.00107 for a similar solution using oxygen. This ratio is within the limit of experimental error 1:5. In other words, the reaction rate is directly proportional to the partial pressure of oxygen. A 30% increase in oxygen flow above that ordinarily used had no detectable effect on the rate of oxidation.

(g) The Effect of Added Impurities.—Ammonia (0.015 M) was added in two runs. No effect could be noted. Two runs with small amounts of hydronitric acid added likewise showed no difference from the ordinary. These two substances were added because they are the most common prod-

ucts of oxidation of hydrazine with the exception of nitrogen itself. Qualitatively it was found that the reaction, like other auto-oxidations, is affected by substances like acetanilide, aniline, hydroquinone, etc.

Summary

1. The auto-oxidation of hydrazine in alkaline solution has been studied by the procedure of passing oxygen through a fritted glass disk into the solution.

2. With this procedure the reaction is heterogeneous and the rate may be expressed by the equation $-dC/dt = k \times p_{O_2} \times C^{1/n}$, being governed by the rate of adsorption of hydrazine on the active surface.

3. Hydrogen peroxide is formed under all conditions when hydrazine in dilute alkaline solution is exposed to the action of oxygen.

4. The rate of oxidation passes through a maximum, in the presence of sodium hydroxide, with increasing concentration of hydroxide. The optimum concentration corresponds with that for the maximum rate of decomposition of hydrogen peroxide by colloidal materials, indicating that the auto-oxidation is also a micro-heterogeneous reaction.

OZONIZATION AND INTERACTION OF OXYGEN WITH NITROGEN UNDER ALPHA RADIATION

BY S. C. LIND[1] AND D. C. BARDWELL[2]

RECEIVED MAY 22, 1929 PUBLISHED SEPTEMBER 5, 1929

The following experiments were made about three years ago as a part of our general study of chemical reactions produced by alpha rays. Detailed publication[3] was delayed in the hope that the work could be made more complete in certain respects. Recent results of others for the same reactions, but using high-speed cathode rays, which will be fully discussed later, indicate that maximum yields per ion pair can be approached only with such high rates of gas flow and with such low intensity of discharge that it appears uninviting to attempt with alpha radiation to push farther in either of these directions than has already been done. The results given here for the formation of oxides of nitrogen, although rather incomplete, represent the first ionic yields to be reported for this important reaction.

Ozonization.—The production of ozone is studied both in pure oxygen and in mixtures with nitrogen. This was begun as a continuation

---

[1] Director of the School of Chemistry, University of Minnesota.

[2] Research Chemist, Atmospheric Nitrogen Corporation, Syracuse, New York.

[3] Brief mention was made of the results in "Chemical Effects of Alpha Particles and Electrons," Chemical Catalog Co., New York, 1928, 2d ed., pp. 83 and 92.

of the earlier work of Lind[4] whose results showed considerable fluctuation in yield, believed to have been due to accidental small amounts of mercury in the ozonizing chamber, which caused high and variable de-ozonization.

More recently D'Olieslager[5] has reported new results in ozonization by alpha rays. In a static system of oxygen mixed with radon he found little or no ozone, but upon adopting the original method of Lind[4] of flowing oxygen past an alpha ray bulb and measuring ozone chemically in the effluent gas, he was able to obtain a yield of ozone of 1 molecule per ion pair, or twice the maximum obtained by Lind. He furthermore made the important observation that the yield is a function of the flow and of the intensity of radiation so that owing to de-ozonization by the alpha rays the net yield per ion pair is highest for the lowest concentration of ozone.

Experimental

The present experiments were made also using the original method except for elaborate precautions against the presence of mercury in the ozonizing chamber or flow system. While the new results (Table II and Fig. 1) are not without some fluctuation, they show great improvement over the original ones. They confirm D'Olieslager's claim of dependence of yield on ozone concentration, and under the best conditions show yields considerably higher than his. This point will be discussed further.

D'Olieslager[5] first suggested a method of calibrating the alpha-ray bulb system for ionization by means of a reaction of known M/N ratio. The failure in employing acetylene polymerization ($M/N = 20$) and the later success with $2C0 + O_2 = 2CO_2$ ($M/N = 6$) have been discussed elsewhere by one of us.[6] The latter method was employed for standardization in the present work. Electrolytic gas ($2H_2 + O_2 = (2H_2O)$; $-M/N = 6$) may be employed even more conveniently, but preferably at double the

[6] Lind, ref. 3, p. 90.

pressure of the $2CO + O_2$ mixture on account of the lower stopping power of hydrogen for alpha rays. The pressure of either mixture should be so regulated that the ionization produced by an alpha particle in traversing the radius of the reaction sphere shall fall in the same range as that of the gas to be experimented with. As the first example of the employment of this method of calibration, a set of data is given in Table I.

Taking **794.5** as the best value for the volume change per curie, the number of molecules reacting per curie is

$$7.945 \times 10^2 \times 2.705 \times 10^{19} = 21.5 \times 10^{21}$$

Taking

$$\frac{-M_{(CO+O_2)}}{N_{(CO+O_2)}} = 6 \quad \text{or} \quad \frac{+M_{CO_2}}{N_{(CO+O_2)}} = 4$$

the number of ions produced in the gas per curie would be

$$\frac{21.5 \times 10^{21}}{6} = 3.58 \times 10^{21}$$

Using Bragg's value of **1.13** of k for O_2 and **1.015** for CO, the number of ions would be **1.13** X **3.4** X 10^{21} = **3.85** X 10^{21}.

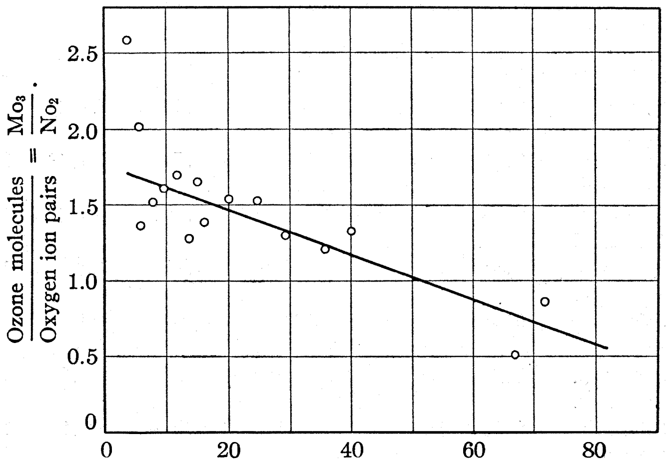

Fig. **1.**

Examination of Table II and Fig. 1 will show that the M/N ratio varies from **0.5** to about **1.7** as the ozone concentration decreases from about **70** parts per million to **10** parts per million. There is one value of 2.6 for M/N and another of **2.0,** but these two values are probably not consistent with the others. Values of M/N have been plotted against concentration of ozone. The values are quite irregular but there is a definite trend toward higher values of M/N as the concentration of ozone approaches zero.

Discussion of Results on **Ozonization.**—At present it is not possible to

predict *a priori* the yield per ion pair for a given reaction. Empirical rules have been established[7] by analogy for certain classes of reactions, but since ozonization represents a unique class, namely, a system of a single component with supposed affinity for free electrons, we have no guiding precedent. Evidently, unlike the case of components with no electron affinity, we must consider negative as well as positive ions. The negative ions

---

[7] Ref. 3, Chapter 5.

would be molecular and if we assume that the positive ions are also mainly molecular,[8] the following might represent some of the possibilities.

TABLE III

THEORETICAL O_3 YIELD

	Reactions		Per ion pair	Remarks
	No ion clustering			
1	$O_2^+ + O_2^- = O_3 + O$	rare	$>1 <2$	The O atom in (1) must have high velocity to carry away the heat of the ion recombination, to prevent decomposition of O_3
1a	$O +$ 0 2 $= O_3$			
1b	$O + O_3 =$ 202			
1c	$O + O = O_2$			
	Bimolecular clusters			
2	$O_2^+ \cdot O_2 + O_2^- \cdot O_2 = 2O_3 + O_2$		2	Improbable that $2O_3$ and O_2 would all remain intact
2a	$O_2^+ \cdot O_2 + O_2^- \cdot O_2 = 2O_3 +$ 2 0		$>2<4$	
	Stoichiometric clusters			
3	$O_2 \cdot O_2^+ \cdot O_2 + O_2 \cdot O_2^- \cdot O_2 = 4O_3$		<4	Improbable that all 4-03 molecules would remain intact

If any such reactions take place as those indicated above, yields could be expected in the range 1 to 4 molecules of O_3 per ion pair in oxygen. Although Mund and D'Olieslager[9] deduced from experiments in the presence of mercury that the maximum theoretical yield does not exceed about 1, the present results show it cannot be less than 1.5, is more probably nearer 2, while results of less certainty indicate it to be as high as 2.0 to 2.6. Undoubtedly secondary de-ozonization plays the controlling part, but it does not appear possible that it is caused by direct collision of alpha particles with O_3 molecules as has been suggested. We know the action of alpha particles is not in the least selective and therefore the chance of de-ozonization by this means at low concentration of O_3 is practically negligible. Evidently we must resort to a de-ozonizing action of activated oxygen either as ions or as atoms (see Reaction lb).

Owing to the great difficulty of working at yet lower ozone concentration or of extrapolating, since the experimental results become progressively less accurate in that direction, it is not possible to set an upper limit to the yield, but there is no indication from alpha ray results that it would exceed 3–4 molecules of ozone per ion pair in oxygen.

Using high velocity cathode rays from a Coolidge tube, Busse and Daniels[10] have recently obtained results which confirm the ionic yields obtained with alpha rays. Since they could not measure nor calculate ionization directly, they employed the indirect method of measuring calorimetrically the energy received in their reaction chamber. Assuming it to be wholly expended in producing O_2^+ ions by electron collision, with a loss of 15 volts (the ionization potential of O_2) they obtained a yield of $M_{O_3}/N = 1$.

[10] Busse and Daniels, THIS JOURNAL, 51, 3271–3286 (1929).

The earlier work of Krüger[11] with cathode rays accorded with the alpha ray results and hence with the new results of Busse and Daniels, but in later work Krüger and Utesch,[12] measuring the ionization by a supposed saturation current method, obtained much higher yields, 12 to 40 molecules of O_3 per ion pair in O_2. If, however, Krüger and Utesch were misled in believing they secured saturation current, as seems very probable on *a priori* grounds,[13] their ionization measured was too low, and hence their calculated yield too high. That this was probably the case is indicated by the fact that both Busse and Daniels and Marshall[14] have attempted to obtain saturation current under conditions similar to those of Krüger and Utesch without any indication that saturation was approached. There remains then every reason to believe that the law of equivalence of ionization and chemical action, first established for alpha rays, holds in the same way for Lenard rays. Busse and Daniels' calorimetric method of arriving at an M/N ratio is an important step in making such comparisons possible.

Interaction of Nitrogen and Oxygen. (Preliminary Experiments.)—It is rather striking that in all the gaseous reactions under alpha radiation that have been investigated, no results have been reported of the combination of oxygen and nitrogen under its influence, except a note by Soddy[15] who found that the collection of pure radon by condensation at low temperature is impossible if air is present in the gases, owing to the production of N_2O, which is also condensed at liquid-air temperature. The first compound formed in the arc process and in the oxidation of NH_3 is NO. The NO is oxidized to NO_2 (in equilibrium with N_2O_4) rather slowly in the presence of excess O_2. If NO_2 is dissolved in H_2O, HNO_2 and HNO_3 are formed in solution and some NO is liberated. This NO will oxidize to NO_2 in the presence of O_2, so that eventually all of the nitrogen is oxidized to nitrate.

Study of the combination of nitrogen and oxygen by alpha rays is greatly complicated by the simultaneous formation of ozone. A flow system was adopted like that recently used for ammonia synthesis.[16] Owing to the difficulty of determining the oxides of nitrogen and ozone separately in a flow system, the device was adopted of making alternate measurements of the total acidity by passing the gases for a time through standard alkali and then of the combined power to liberate iodine from a potassium iodide

solution. The oxides of nitrogen dissolving in alkali form nitrites and nitrates. The neutralizing capacity of the gas is thus a measure of the acid oxides formed and does not exceed one molecule of acid for each atom of nitrogen in the oxides. The capacity to liberate iodine is a measure of the combined oxidizing power of ozone and nitrogen oxides. All oxides of nitrogen are oxidized to N_2O_5 by ozone providing the latter is in sufficient excess. That the concentration of ozone was not always high enough to oxidize completely the nitrogen oxides to N_2O_5 in the time allowed before absorption seemed to be indicated by the results for air in which there was a marked "after-bluing" in the thiosulfate titration—in some cases amounting to 25% of the total titration. In mixtures of air and oxygen the extent of "after-bluing" became less for increasing O_2 content.

The ratio of oxygen to nitrogen was varied from that in air to about 4 O_2:-1N_2 by the addition of oxygen to the stream. The total oxidizing power is found to be equivalent to 2.4 molecules of ozone per pair of ions (total) in air and decreases slightly as the mixture becomes richer in oxygen. The results are shown in Table IV.

TABLE IV

It is quite apparent that the formation of acidic oxides falls off as the N:O ratio in the flowing gases is diminished. Apparently this might mean that nitrogen ions, but not oxygen ions, are responsible for this reaction. If the ionization potential of nitrogen is higher than that of oxygen, then ionization by collision of the second kind[17] could take place only in the direction $N_2^+ + O_2 = N_2 + O_2^+$ which would explain at once why nitrogen oxide formation diminishes while total oxidation remains relatively little changed,

---

[17] G. P. Harnwell, Phys. *Rev.*, 29, 683, 830 (1927).

since the latter represents both ozone and oxides of nitrogen. In the static experiment with 28.5 millicuries of radon decaying in a 4 O_2:1 N_2 mixture, very little acid was produced.

The special experiment on the production of nitrous oxide in air confirmed Soddy[15] in its formation, although the yield was only 0.076 molecules per pair of ions, much lower than that of the acid-forming oxides.

The nitrous oxide was separated from the air by use of liquid air and was subsequently pumped off at $-100°$ into a miniature eudiometer tube. That the gas so separated was nitrous oxide was confirmed by explosion with a measured volume of pure hydrogen. The volume contraction corresponded approximately to that for the reaction $N_2O + H_2 = N_2 + H_2O$ (liq.).

Summary

1. Ozonization in oxygen flowing past an alpha-ray bulb is higher (per ion pair) the faster the rate of flow and the lower the intensity of ionization, that is, higher the lower the ozone concentration from either influence, owing to de-ozonization. This confirms D'Olieslager's results.
2. The maximum yields of ozone obtained per ion pair (M_{O_3}/N_{O_2}) was not less than 1.5 and may be as high as 2–2.5.
3. De-ozonization appears to be due to a secondary effect of oxygen ions (or atoms), not to a primary impact with an alpha particle.
4. In mixtures of nitrogen and oxygen both ozone and acid-forming oxides of nitrogen are simultaneously formed; also a smaller amount of nitrous oxide (confirming Soddy). Nitrous oxide formation was investigated only for air.
5. The yield of acid-forming oxides diminishes with decreasing N_2:O_2 ratio, while the total oxidizing power toward potassium iodide solution is little influenced. A theory is proposed for this.

NOTES

An Application of the Thiocyanate Method for the Precipitation of Copper in the Confirmatory Tests for Cadmium and Antimony.—The use of the thiocyanate anion as a means for the separation of copper from cadmium, after first having reduced the copper with sulfurous acid, has been suggested by Crookes.[1] This method has also been used for the quantitative determination of copper, but to the knowledge of the author it has not hitherto been applied to the qualitative scheme of analysis. The insolubility of cuprous thiocyanate in dilute sulfuric and hydro-

---

William Crookes, "Select Methods in Chemical Analysis," Longmans, Green and Company, London, 1886, p. 332.

chloric acids and the ease of precipitation makes it well suited for this application.

The means for the separation of copper from cadmium in the confirmatory test for cadmium given by Noyes[2] has been found to be not quite satisfactory for class use due to the fact that many times the student does not obtain a thorough separation of the copper.

The thiocyanate method has been used in the classes in the Qualitative Laboratory of the University of New Hampshire and has been found to give very satisfactory results.

The procedure for this method is as follows. To the part of the ammonium hydroxide solution remaining after the ferrocyanide test has been made for the confirmation of copper add dilute sulfuric acid until acid to litmus, then 5 cc. of a normal solution of potassium thiocyanate. A brown coloration will result due to the formation of cupric thiocyanate. Heat to boiling, add about 0.5 g. of dry sodium sulfite and continue boiling for about one minute until the white precipitate of cuprous thiocyanate has coagulated. Filter off the precipitate and saturate the clear filtrate with hydrogen sulfide. If cadmium is present the characteristic yellow precipitate of cadmium sulfide will form.

This reagent has also been used to advantage to avoid the interference of copper in the test for antimony as given by Noyes,[3] which occurs in some instances when sodium polysulfide is used and very often when ammonium polysulfide is employed for the separation of the copper and tin groups. The above procedure may be used after the antimony and tin have been separated from the arsenic by concentrated hydrochloric acid, and the solution has been diluted to the proper acid concentration for the precipitation of the antimony sulfide.

unpreventable draining of these solutions into the gas buret during the absorption process. Even in the hands of an expert an exact gas analysis apparatus becomes badly fouled in the course of a single complete analysis of a gas mixture such as water gas.

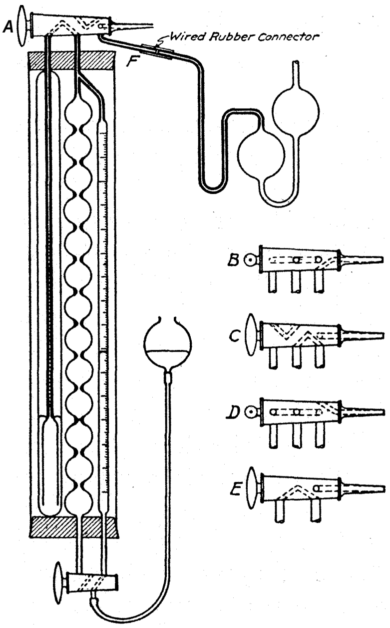

Fig. 1.

This difficulty is eliminated by the use of the special stopcock shown attached to a bulbed exact gas analysis apparatus[1] equipped with a single leg compensator[2] in Fig. 1. By placing the outlet to which the absorption pipet is attached below instead of above the stopcock barrel, it is possible to bring the absorbent solution slowly up to the bore of the cock without any danger of spilling over into the buret. During the absorption of any constituent the solution adhering to the walls of the stopcock outlet then drains down away from the stopcock and buret. Four views of the stopcock are shown at A, B, C and D, each a quarter turn in the clockwise direction from the preceding position as shown in the sketches. In the case of an uncompensated buret such as is used in technical analyses the simpler stopcock shown at E suffices.

ACYL DERIVATIVES OF ORTHO-AMINOPHENOL. V

BY R. E. NELSON AND H. S. ROTHROCK

RECEIVED NOVEMBER 7, 1928 PUBLISHED SEPTEMBER 5, 1929

When diacyl derivatives of o-aminophenol are prepared by the usual methods, it is found in most cases that the order of introduction of the two different acyl groups has no influence upon the formation of the diacyl, identical products being isolated from the two acylations. The position of the acyl groups in the molecule can be determined by removing the group attached to oxygen by saponification with dilute alkali, and determiningfrom the physical constants of the remaining mono-acylated product the group attached to the nitrogen. The identical diacyls mentioned above are found to saponify to yield identical products, as would be expected.

The formation of identical rather than isomeric products on reversing the order of acylation indicates that during acylation a rearrangement must have occurred in one of the two cases. It is found that certain acyl groups have more power than others to bring about this migration, weight and acidity of the group being considered to have the predominating influence in their obtaining a position in the more basic amino group in preference to the phenol group.

Previous work on this subject by Ransom,[1] Ransom and Nelson,[2] Nelson and others,[3] and Raiford and others[4] is discussed in the literature.

The work of Ransom and of Ransom and Nelson indicated that, in the cases observed, carbalkoxy (COOR) groups had the power to displace carbonyl (COR) groups from their position on the nitrogen atom during the introduction of the second acyl group. Nelson, Shock and Sowers[5] found, however, that the n-carbopropoxy group, *n*-C_3H_7OCO, was displaced from the nitrogen atom by the benzoyl group, while the *iso*carbopropoxy group, *iso*-C_3H_7OCO, was able to displace the benzoyl group from the nitrogen. This peculiar action was also investigated by the present authors and the results were confirmed. It was found in addition, however, that rearrangement was not complete and that both possible monoacyls were produced on saponification. The identical diacyls may then have been either identical equilibrium mixtures or the same pure compound, in which last case rearrangement must have occurred during saponification.

[5] Nelson, Shock and Sowers, THIS JOURNAL, 49, 3129 (1927).

This investigation was undertaken with the view of determining whether any other differences in the action of *iso*- and n-acyl groups could be found, and to study a number of other carbalkoxy-benzoyl diacyl derivatives of o-aminophenol.

When o-benzoylaminophenol was acylated with *n*-butylchlorocarbonate, the same diacyl was obtained as when n-butyl-o-hydroxycarbanilate was acylated with benzoyl chloride. Saponification yielded in both cases n-butyl-o-hydroxycarbanilate, proving that in the diacyl the *n*-carbobutoxy group must have been attached to the nitrogen. In the first acylation, therefore, the benzoyl group rearranged to the oxygen.

In the same way, when o-benzoylaminophenol was acylated with *iso*-butylchlorocarbonate, the same diacyl was produced as when *iso*butyl-*o*-hydroxycarbanilate was acylated with benzoyl chloride. Here again saponification showed that the diacyl had the benzoyl group attached to the oxygen. In this case there is no difference in the action of the two pairs of isomeric carbalkoxy groups used against the benzoyl group.

Other structurally isomeric aliphatic acyl groups were next studied with the same purpose in mind. When o-benzoylaminophenol was acylated with n-valeryl anhydride, a diacyl, o-benzoylaminophenol n-valerate, was formed, while on treating o-n-valerylaminophenol with benzoyl chloride, an isomeric diacyl o-n-valerylaminophenyl benzoate, resulted. Saponification of each of these produced only o-benzoylaminophenol, indicating that in the latter case migration of the benzoyl group from the oxygen to the nitrogen must have occurred.

Similar results were obtained with the groups isovaleryl and benzoyl. Acylation of o-benzoylaminophenol with isovaleryl chloride produced a diacyl, o-benzoylaminophenyl isovalerate. Acylation of *o*-*iso*valerylaminophenol with benzoyl chloride produced a diacyl, *o*-*iso*valerylaminophenyl benzoate. Saponification of the first product yielded only *o*-benzoylaminophenol, while saponification of the latter yielded largely *o*-benzoylaminophenol and a small amount of o-isovalerylaminophenol. In this last case rearrangement is not quite complete during saponification. Obviously, however, the reaction is quite similar to that occurring in the case of the n-valeryl group.

When methyl o-hydroxycarbanilate was acylated with benzoyl chloride the same diacyl was produced as when o-benzoylaminophenol was acylated with methyl chlorocarbonate. Saponification of the diacyl yielded mainly o-benzoylaminophenol with a small amount of methyl *o*-hydroxycarbanilate.

The investigations up to this time on the benzoyl-carbalkoxy diacyl derivatives of o-aminophenol may be summarized in the following table.

The action of the carbomethoxy group may be explained as due to the difference in weight between it and the benzoyl group, but this does not

Summary

1. A study has been made of the diacyl derivatives of o-aminophenol, using the benzoyl group against a series of carbalkoxy groups. It is found that the carbalkoxy group is able in most cases to displace the benzoyl group from the nitrogen. Where, however, there is a large difference in the weights of the two groups, as in the case of carbomethoxy (CH_3OCO) and the benzoyl (C_6H_5CO) groups, the benzoyl group is able to displace the lighter group completely, though the reverse takes place when the next heavier (C_2H_5OCO) group is used.

2. No evidence of differences in the action of *normal* and iso-acyl groups when used against the benzoyl group is observed in the case of the *n*- and *iso*carbobutoxy (C_4H_9OCO) groups and of the n- and *iso*valeryl (C_4H_9CO) groups.

3. New mono- and diacyl derivatives of o-aminophenol have been prepared and studied.

RECEIVED NOVEMBER 26, 1928 PUBLISHED SEPTEMBER 5, 1929

In a previous paper[1] the fact was emphasized that different strains of yeast, all of which are called by the name *Saccharomyces cerevisiae,* may react quite differently toward nutrilites.[2]

Since this article was written considerable progress has been made in this Laboratory in concentrating the active material from yeast and other sources, the purification of which was the main object of our research. Before carrying the purification further we were interested to know how important the substance in question might be; whether, for example, it functions for one strain of yeast only or whether it might not be important in the nutrition of several strains of yeast. A second reason for making

[2] *See* Williams, *Science,* 67, 607 (1928).

this study, in addition to our interest in the significance of our own preparation, was that few controlled experiments have been reported in which different strains of yeast have been compared directly with each other and we deemed it important to know just how wide a variation might be expected.

The principal purpose of this paper, therefore, is to give results of experiments in which six strains of yeast (three bakers' and three brewers' yeasts) were compared with each other in their behavior toward various preparations, including the "α-Bios" and "β-Bios" of Eddy and Kerr,[3] "Bios I" (Inositol) of Lash Miller and our own concentrated material, as well as cruder preparations.

In Figs. 1–6 are given results in which crude yeast extract, prepared essentially according to the method outlined in the paper previously cited, was introduced in various amounts into our synthetic media and the growth of the different yeasts tested in the resulting solutions. The technique used was essentially that described previously, with a few minor modifications. Ten cubic centimeters of medium was used instead of 50. To it is added 1 cc. of a solution containing the material to be tested, plus 1 cc. of a yeast suspension (in sterile medium) of such concentration that the average for each large square on a Levy counting chamber was $3^1/_2$ to 4 cells. In these and other experiments in which a yeast crop was too small to weigh, the crop was estimated by visual comparison with suspensions containing known amounts of yeast. Neither this method nor that of weighing very small crops is highly accurate but they are sufficiently so for the purpose involved. In no case do we draw conclusions from small differences. In the experiments already mentioned, two sets of experiments were run in each case; one set was allowed to grow for eighteen hours and the other set for forty-eight hours.

The pure cultures of yeasts used in these tests were obtained from the following sources: Numbers **578** and **2335** from the American Type Culture Collection, Old Process Bakers' Yeast and Gebriide Mayer from the Fleischmann Company, Ruppert Brewing Yeast and Untergarige Hefe K from Dr. W. H. Eddy. "Old Process Bakers' Yeast," "Gebriide Mayer" and No. **2335** are bakers' yeasts and the others are, according to our best information, brewers' yeasts. We have been a little in doubt with regard to yeast No. 578, which has been used in this Laboratory most extensively in recent years. This culture originated in the collection of F. W. Tanner of the University of Illinois, which was handled by the American Type Culture Collection. It was first obtained with the understanding that it was bakers' yeast. In the late catalog of the American Type Culture Collection, however, it is listed as a brewers' yeast.

---

[3] See Peskett, *Proc. Soc. Exptl. Biol. Med.*, **25**, **340** (1928).

Although the various yeasts grow at different rates and show other peculiarities, the following general observations may be made.

1. The growth of all the yeasts tested is remarkably stimulated by the addition of yeast extract to our synthetic medium. In all cases the maximum yeast crops were obtained when the largest amounts of extract were added.

2. When the yeast was allowed to grow for as long as forty-eight hours, there was a striking contrast between the control cultures and those in which very small amounts of extract were added.

3. When the yeast was allowed to grow for only eighteen hours, this contrast was less marked, yet the eighteen-hour growth curves are, in general, much more regular, approximating a straight line in the lower concentrations.

We believe that these results materially strengthen the suggestion previously made that a short growth period is superior to longer growth periods for quantitative measurements of dosage. Accordingly the rest of the experiments reported in this paper were carried out using the eighteen-hour growth period.

In Table I are given results of experiments in which the six yeasts are tested on two of our preparations, each added separately and both added together. Results reported previously showed that for yeast No. 578 two complementary preparations could be obtained. One fraction is adsorbed by fuller's earth; the other is not. Both together are necessary to stimulate appreciably the growth of this yeast. The preparations used in this experiment were (1) the crude unadsorbed residue obtained by treating the yeast extract with fuller's earth and evaporating the filtrate to dryness, *(2)* a highly concentrated material (Z_2) derived from the fraction which is adsorbed by fuller's earth from yeast extract.

The method of preparation of "Z_2" will not be described in great detail since we do not claim that the material is pure in any sense, and because we have subsequently materially modified our procedure for concentrating such material. Its preparation involved the following steps: (1) The "activated" fuller's earth was extracted with baryta, the baryta removed by sulfuric acid and the filtrate evaporated to dryness. *(2)* The residue was fractionated with the following solvents: 80% alcohol, water and methanol. In this process the activity was concentrated to approximately one-fifth of its original weight by applying the solvents in the order indicated and rejecting the insoluble material in each case. The Z_2 preparation is highly soluble in water. **(3)** The remaining soluble material was fractionated, following the method of Jansen and Donath,[4] the Z_2 coming from the fraction precipitated between the P_H values 6.5

---

[4] B. C. P. Jansen and W. F. Donath, *Nededeel. Dienst Volksgezondheid Nederland, Indië*, **Part** I, 86–99 (1927).

and 7.5. Other fractions, however, also contained much activity. (4) The silver precipitate was decomposed with hydrochloric acid and carefully evaporated to dryness. The gummy residue constitutes "Z_2."

TABLE I[a]

EFFECT OF UNADSORBED RESIDUE AND Z_2 CONCENTRATE ON SIX YEASTS

Yeast	Blank	8 Mg. of U. R.	0.005 Mg. of Z_2	8 Mg. of U. R. +0.005 Mg. of Z_2
578	0.2	0.5	0.3	6.5
G. M.	.6	9.7	1.6	12.1
O. P.	.2	0.5	0.3	5.2
U. H. K.	.1	0.2	.3	1.1
2335	.1	3.5	.1	2.7
Rupperi	.15	1.2	.5	2.1

[a] In this and following tables "U. R." stands for the unadsorbed residue and "Z_2" for our concentrate, both of which are previously described. The numbers represent the yeast crops expressed in milligrams obtained in eighteen hours. The blank is our synthetic medium unless otherwise indicated.

It will be noted in this experiment that in the cases of Yeast 578, O. P. yeast, and Untergarige Hefe K, there is a marked complementary action of the two preparations. In Gebriide Mayer and Ruppert yeast the effect of the two preparations is approximately additive, while in the case of Yeast *2335* the concentrate seems to have no stimulating effect. (However, in two other experiments this preparation did have a slight stimulating effect on Yeast *2335.)*

In the cases of Yeast *2335* and Gebriide Mayer the unadsorbed residue alone is very effective. Experimenters who might be working with either of these yeasts would naturally conclude that fuller's earth treatment removes practically none of the active substance from an active solution, whereas exactly contrary results are obtained with three other yeasts.

Table II depicts experiments in which were tested, in parallel, the effects of 1-mg. doses each of our unadsorbed residue, Eddy and Kerr's "α-Bios" and "β-Bios." The latter two preparations were kindly furnished by Drs. Eddy and Kerr.

TABLE II

EFFECT OF UNADSORBED RESIDUE, "α-BIOS" AND "β-BIOS" ON SIX YEASTS

Yeast	Blank	1 Mg. of U. R.	1 Mg. of "α-Bios"	1 Mg. of "β-Bios"
578	0.1	0.5	0.1	0.4
G. M.	3.7	6.5	2.9	5.0
O. P.	0.1	0.5	0.1	0.2
U. H. K.	.15	.5	.2	.15
2335	.025	.3	.025	.025
Ruppert	.1	.3	.1	.1

In no case does the "α-Bios" appear to show distinctly stimulating effect on the yeasts when tested in this way. The "β-Bios" shows appreciable stimulation in the case of two yeasts, but in each case an equal dosage of unadsorbed residue gives a greater stimulation. It may be remarked here that Eddy and Kerr have, in their experiments, generally used a longer growth period in which case very *small* amounts of active material may cause very marked increases in the yeast crop. This effect of the longer growth period is shown very clearly in the contrast between the upper and lower curves in Figs. 1 and 2.

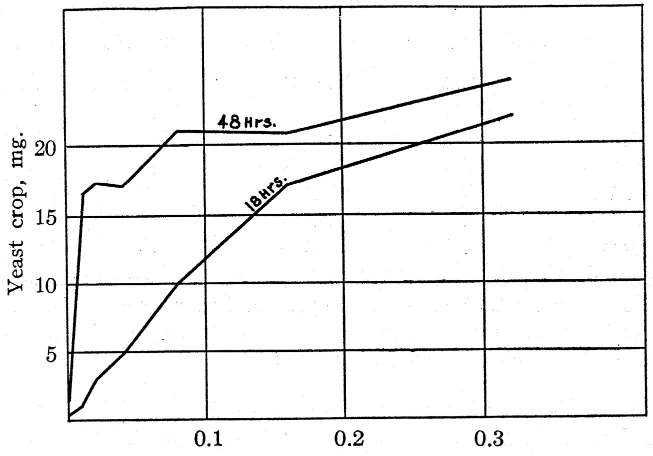

Fig. 1.—Yeast No. 578.

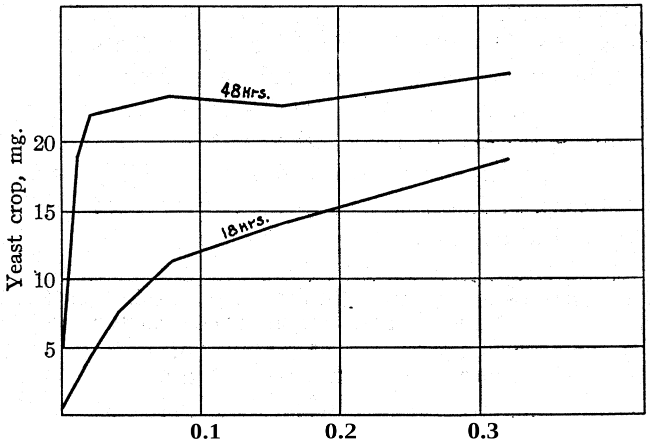

Fig. 2.—Gebriide Mayer.

In Table III are given results of tests of "a-Bios" and "β-Bios" in conjunction with our concentrate, which we have designated as "Z_2." The yeast used in this experiment was No. 578 which, it will be noted in Table I, is very slightly affected by "Z_2" alone. The purpose was to see whether either of these preparations acted as a supplement to the preparation which we obtained from material adsorbed on fuller's earth. Both "α-Bios" and "β-Bios" have been obtained from material which was not adsorbed by fuller's earth. The results of the tests are negative, that is, neither "α-Bios" nor "β-Bios" appears to supplement "Z_2" so far as yeast No. 578 is concerned.

TABLE III

EFFECT OF "α-BIOS" AND "β-BIOS" PLUS "Z_2" ON YEAST 578

Blank	0.4	0.1 mg. of "α-Bios"	0.4
1 mg. of "α-Bios"	.2	0.1 mg. of "α-Bios" +0.005 of Z_2	.4
1 mg. of "α-Bios" +0.005 of Z_2	.3	0.1 mg. of "β-Bios"	.5
1 mg. of "β-Bios"	.4	0.1 mg. of "β-Bios" +0.005 of Z_2	.5
1 mg. of "β-Bios" +0.005 of Z_2	.6		

In the experiment referred to in Table IV, yeast No. 578 was used. The amounts of "Z_2" and unadsorbed residue in the media were each varied separately, with the results indicated. It is apparent that if either component is held at a proper level, variation of the other component causes a variation of yeast crop which is roughly proportional in the lower concentrations to the amount of the preparation added. It is also apparent from the results that a dosage of "Z_2" as low as 0.0006 mg. (0.00005 mg. per cc.) causes marked stimulation in the growth of the yeast. If a langer growth period is used this same dosage will cause a much greater contrast between the crop obtained and that obtained in the control medium. Results of this sort have been obtained repeatedly. In Fig. 1 a case appears in which a dosage which causes approximately a doubling of growth in eighteen hours, causes a 33-fold increase over the blank when the forty-eight hour growths are compared.

TABLE IV

EFFECT OF VARYING "Z_2" AND UNADSORBED RESIDUE (YEAST 578)

Blank (8 mg. of U. R.)	0.6	Blank (0.0024 mg. of Z_2)	0.2
Same + 0.0006 mg. of Z_2	1.4	Same + 1 mg. of U. R.	.5
Same + 0.0012 mg. of Z_2	2.2	Same + 2 mg. of U. R.	.7
Same + 0.0024 mg. of Z_2	3.3	Same + 4 mg. of U. R.	1.8
Same + 0.0048 mg. of Z_2	5.6	Same + 8 mg. of U. R.	3.3
Same + 0.0096 mg. of Z_2	5.5	Same + 16 mg. of U. R.	3.9
Same + 0.096 mg. of Z_2	11.8	Same + 32 mg. of U. R.	4.3

The results of tests of Bios I (Inositol), discovery of which was announced[5] from Lash Miller's laboratory are shown separately in Table V because the other work had been completed before these publications appeared. The inositol used in these experiments was obtained from the Eastman Laboratories. It will be noted that in the doses used the inositol

---

[5] *Science Suppl.*, X, July 6, 1928; Eastcott, *J. Phys. Chem.*, 32, 1094 (1928).

has very little effect on the growth of any of the six yeasts either alone or in conjunction with our "Z_2" concentrate.

It may be that our "Z_2" is not the proper supplement to the inositol. However, since "Z_2" does supplement our "unadsorbed residue," inositol is evidently not the active substance in this residue. From the method of preparation of "Z_2" and the very small doses which are effective, it is clear that inositol is not the active material in the "Z_2" concentrate.

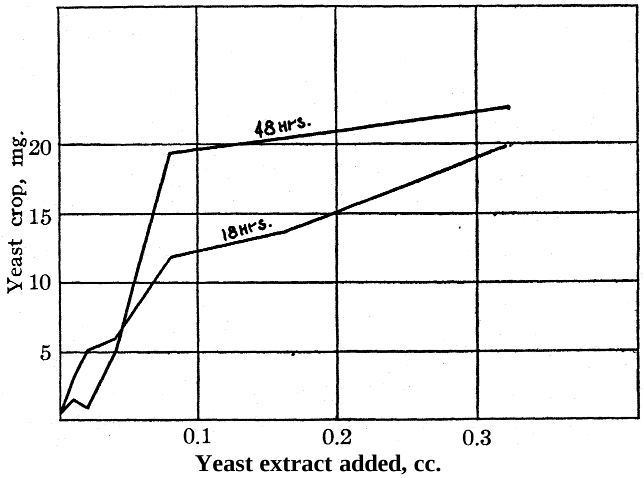

Fig. 3.—Old Process Bakers' Yeast.

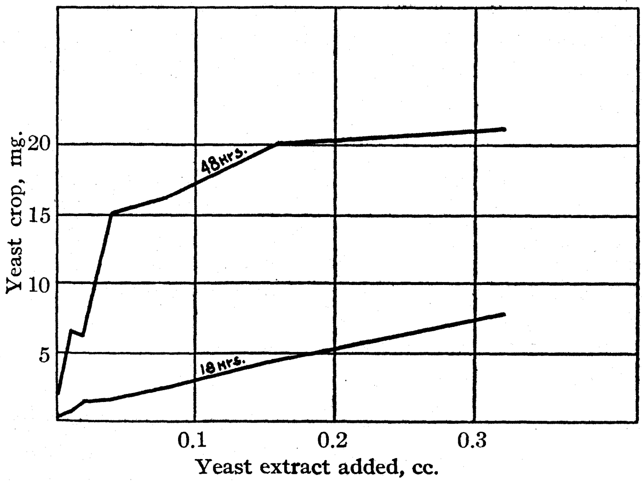

Fig. 4.—Untergärige Hefe K.

The conclusion may be drawn, therefore, that inositol does not constitute the active material in either of the two supplementary fractions which we have found to be, when used together, very stimulatory to the growth of certain yeasts.

An examination of Miss Eastcott's evidence as to the functioning of inositol in yeast growth is not reassuring. We have no reason to doubt the approximate homogeneity of the product which was obtained, but evidence seems to be lacking both as to its potency and constancy. Relatively large doses of inositol were required to cause an effect. A dosage of 0.0033 mg. of inositol per cc. is required to about treble the yeast crop which is obtained in eighteen hours when "Bios II" alone is present. By comparison with our results it may be noted in Table IV that 0.0001 mg. of "Z_2" per cc. (0.0012 mg. per 12 cc.) more than trebles the growth in eighteen hours. Yet our "Z_2" is obviously impure and recent work has indicated that it consists for the most part of inert material.

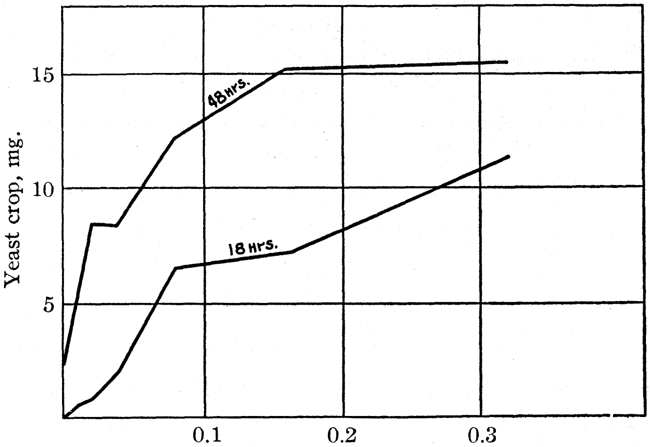

Fig. 5.—Yeast No. **2335.**

As to the constancy of the activity of inositol Miss Eastcott gives no evidence. She states that Kahlbaum's inositol and that obtained from tea showed "no difference" in behavior but no data are given to support the statement. Neither is evidence given nor even a statement made that the activity of the inositol remained constant after recrystallization. In the discussion the question as to the identity of her product with inositol is thoroughly treated but no emphasis is placed upon the question of the identity of her product with the physiologically potent substance for which she was searching.

The inositol that is on the market is obtained from a vegetable source which is probably rich in "bios," and it may be difficult to free the inositol from traces of these impurities. Even when purified on an enormous scale and in a very efficient manner, cane sugar has repeatedly been shown to contain "bios." We have also observed the occurrence of "bios" in highly purified asparagine and Kahlbaum's lactose.

The fact that the yeast crops recorded in Table V are very low as compared with the others is due, we feel sure, to the physiological state of the yeast used. This experiment was made early in the fall after a summer vacation during which the yeast cultures were not transplanted regularly.

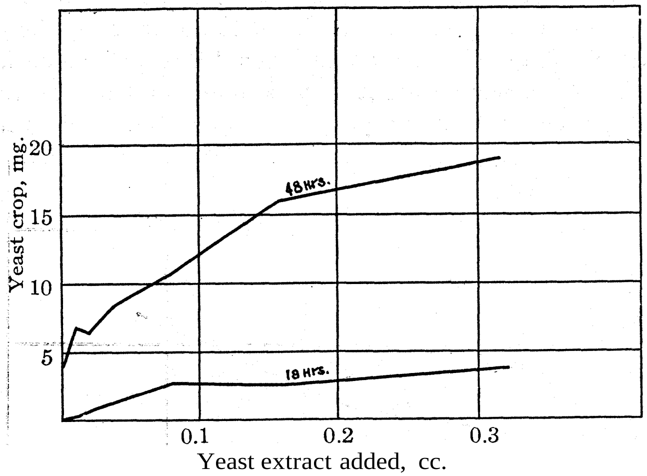

Fig. 6.—Ruppert Brewing Yeast.

After having transplanted the cultures a number of times the growths increased and in a few weeks came back and have remained at the higher level. There is no evidence that these slower-growing cultures of yeast reacted materially differently toward the preparations than the yeast used in the earlier experiments.

Our thanks are due the Research Committee of the University of Oregon for its support of this work and to the Fleischmann Company for the fellowship which they have granted and under which a portion of this work was done.

Summary

1. All six yeasts tested show a very marked stimulation of growth when varying quantities of yeast extracts are added to a synthetic medium,

2. All yeasts fail to show an "optimum" concentration of yeast extract either when an eighteen-hour or a forty-eight-hour growth period is used. That is, in every case the largest crops were obtained when the most extract was added. When toxic materials are present in the extract these results may not be obtained.

3. In the case of most, if not all six, of the yeasts studied it appears that a short growth period (eighteen hours) is much more easily adapted than a longer growth period (forty-eight hours or more) for quantitative studies on yeast nutrilites. If a long growth period is used, a very small dosage of active material may produce an inordinatkly large increase in the yeast crop. The crops are likely to be irregular and there is an unnecessary loss of time. These statements apply primarily to cases in which yeast is grown without agitation.

4. In spite of the uniformities above noted, each of several different strains of yeast (so-called *Saccharomyces cerevisiae*) reacts more or less distinctively toward different "bios" preparations. In some cases the contrast in behavior is very marked. This indicates possible deep-seated differences in the metabolic processes in different strains.

5. The results show that our most concentrated fraction (adsorbable by fuller's earth) in conjunction with the unadsorbed residue stimulates two of the yeasts markedly in very small doses and has a varying-though definite effect on the others. In the case of yeast No. 578, doses of this concentrate as low as 0.00005 mg. per cc. have a marked effect. The same-preparation has little effect on one or two of the yeasts tested and uniformly has little effect on any yeast unless the "unadsorbed residue? is also present. The dosage indicated above is, to the best of our knowledge, much smaller than that used by any other investigators in this field.

6. The effects of "α-Bios" and "β-Bios" and that of inositol on the six yeasts tested are of a lesser order and involve the presence of relatively large amounts of the substances. It seems to us within the realm of possibility that such activities as these preparations possess may be due to occluded or adsorbed impurities.

7. Miss Eastcott's conclusion as to the identity of inositol with a bios (Bios I) does not appear justified by her evidence. Until more convincing proof is offered we must tentatively regard its yeast growth stimulatory effect as probably due to impurities[6]

EUGENE, OREGON

---

[6] Miss E. V. Eastcott thanks the Editor for an opportunity to read the manuscript of Williams, Warner and Roehm and to point out that, except in their own paper, the substance to which Mr. Lucas gave the name "Bios I" and which has since been identi-

fied with inactive inosite, has never been spoken of as "a bios." It is one of the constituents into which Lucas separated Wildiers' bios; by itself it has little if any effect on the yeast crop; but if the other constituent, namely, "Bios II," be present in the culture medium, addition of inosite much increases the crop. As to the inosite from tea, Miss Eastcott's paper, *J. Phys. Chem.*, **32**, 1094 (1928), states that it was recrystallized from methyl alcohol and water and obtained in two "clear white" crystalline forms, anhydrous and the dihydrate, both of which were analyzed; also that it made no difference in the yeast crops obtained with various preparations of Bios II whether Kahlbaum's inosite was employed or that from tea. Her laboratory note-books show that the last six recrystallizations had no effect on the "activity" of the latter.

INTERACTION OF ALKYL SULFIDES AND SALTS OF MERCURY

BY W. F. FARAGHER, J. C. MORRELL AND S. COMAY

RECEIVED JANUARY 10, 1929 PUBLISHED SEPTEMBER 5, 1929

The property of organic sulfides of forming compounds with certain heavy metal salts was discovered by Loir.[1] He prepared compounds of methyl and ethyl sulfides with mercuric chloride, mercuric iodide and platinum chloride.

Some of the results reported by Loir were criticized by subsequent investigators. Blomstrand[2] found the properties of the product formed by the interaction of ethyl sulfide and platinic chloride to be different from those reported by Loir: the melting point was 70° higher. Abel,[3] who discovered ethyl sulfide in dog's urine, contested the originally reported melting point of the compound of ethyl sulfide and mercuric chloride.

Phillips[4] disputed the formula assigned by Loir to the reaction product of methyl sulfide and mercuric chloride. He found that the compound was $3HgCl_2\cdot 2(CH_3)_2S$ and not $(CH_3)_2S\cdot HgCl_2$, as stated by Loir. The reason for the conflict between reports is presented in this paper.

The compounds of alkyl sulfides and salts of platinum were quite extensively investigated by Blomstrand,[2] Blomstrand and his co-workers,[5] Klason[6] and Rây.[7]

On the other hand, the literature contains little information about the compounds of alkyl sulfides and salts of mercury. Smiles[8] reported the preparation of five addition compounds of alkyl sulfides and mercuric iodide: $(CH_3)_2S\cdot HgI_2$, $(CH_3SC_2H_5)\cdot HgI_2$, $(C_2H_5)_2S\cdot HgI_2$, $(C_5H_{11})_2S\cdot HgI_2$ and $(C_6H_5CH_2)_2S\cdot HgI_2$.

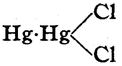
Faragher, Morrell and Monroe[9] found that alkyl and aromatic sulfides react quantitatively with powdered "normal" mercurous nitrate, $Hg_2(NO_3)_2\cdot 2H_2O$. No analysis of the products or description of the reaction was given by them since this problem was outside the scope of their work.

It was first observed in the present work that metallic mercury is formed when an alkyl sulfide reacts with a mercurous salt, e. g., mercurous nitrate. The reaction is shown by the equation

$$2R_2S + Hg_2(NO_3)_2 \longrightarrow (R_2S)_2\cdot Hg(NO_3)_2 + Hg + \text{heat}$$

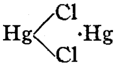
The behavior of ethyl sulfide and other organic sulfides toward the mercurous salts used was found to be analogous to the behavior of pyridine toward mercurous salts. Lang[10] found that metallic mercury is precipitated at once when mercurous nitrate is treated with pyridine. The mercuric nitrate formed reacts with the pyridine to give the compound $(C_5H_5N)_2\cdot Hg(NO_3)_2$. No quantitative results were reported. François[11] investigated quantitatively the action of aniline, phenol and alcohol on mercurous iodide at an elevated temperature and found that the decomposition of mercurous iodide was in each case limited. Lang explains the mechanism of the change by the assumption, "A state of equilibrium exists in the solution of the mercurous salt dissociated partially into mercury and mercuric salt, the number of molecules decomposing and reforming in unit time being equal; but if the equilibrium is destroyed by the removal of the mercuric salt by pyridine, etc., metallic mercury separates."

Werner[12] in discussing the constitution of the mercurous salts considers that Lang's discovery that pyridine rapidly decomposes mercurous chloride into mercury and mercuric chloride is not in accord with the formula for mercurous chloride, Cl–Hg–Hg–Cl. He says: "This behavior of mercurous chloride seems to indicate that it is an addition product of mercury and mercuric chloride, and mercury, like water, is capable of forming addition compounds; the amalgams correspond to the hydrates as was shown in such an excellent way by Forster." Accordingly, Werner proposed either of the following two formulas for mercurous chloride



$$Hg\cdot Hg\left\langle\begin{matrix}Cl\\Cl\end{matrix}\right.$$

and



$$Hg\left\langle\begin{matrix}Cl\\Cl\end{matrix}\right\rangle\cdot Hg$$

Although pyridine reacts rapidly with solid mercurous chloride, ethyl sulfide does not react, and methyl sulfide causes the formation of metallic mercury from mercurous chloride only in the presence of water. It will be shown that it cannot be predicted that because a substance reacts readily with a mercuric salt it will react with the corresponding mercurous salt; the specific reactivity of each of the reacting substances cannot be ignored.

[10] Lang, Ber., 21, 1587 (1888).

[11] Franpis, *Compt.* rend., 121, 253, 700, 880 (1895).

[12] Werner, *Z. anorg. Chem.*, 15, 5 (1897).

Usually some members in the series of alkyl sulfides are more reactive than others toward a particular mercurous salt. In some cases the solvent is an important factor. Methyl sulfide, as previously stated, does not react with mercurous chloride unless water is present; but it reacts with mercurous acetate in the absence of water. Ethyl sulfide and the other alkyl sulfides used in this investigation caused mercury to separate from mercurous acetate only in the presence of water. Thiophene does not react with powdered "normal" mercurous nitrate, but if water is added, mercury is precipitated. Methyl sulfide, ethyl sulfide and *iso*-amyl sulfide separate mercury immediately from mercurous sulfate in the absence of water. Although in some of the instances mentioned solubility may be the reason for the fact that the reaction proceeds only in the presence of water, nevertheless in the case of methyl sulfide and mercurous chloride, the compound formed is practically insoluble in water. Therefore, it is apparent that the mechanism of the reaction requires further investigation, especially when one recalls that pyridine separates mercury from solid mercurous chloride immediately and also that the sulfides separate mercury from mercurous iodide in the absence of water.

Experimental

Action of Alkyl Sulfides on Mercurous Salts. **Ethyl Sulfide and $Hg_2(NO_3)_2·2H_2O$.**—Analysis of the products of the interaction of ethyl sulfide and mercurous nitrate showed that the reaction is represented by

$$2Et_2S + Hg_2(NO_3)_2 \longrightarrow (Et_2S)_2·Hg(NO_3)_2 + Hg$$

This was shown as follows: 180 cc. of an 8% aqueous solution of mercurous nitrate (0.5% of nitric acid was added to keep the salt in solution) was treated with 2.27 g. of ethyl sulfide. The metallic mercury that separated weighed 2.51 g. or 99.6% of the theoretical weight.

When ethyl sulfide and powdered normal mercurous nitrate were used in molecular proportions, the amount of mercury weighed was 97 to 98% of the theoretical amount.

The compound, $(Et_2S)_2·Hg(NO_3)_2$, was isolated as follows. The sulfide was dissolved in hexane and treated with normal mercurous nitrate by shaking for five minutes. After standing for a few hours the hexane and the liquid reaction product were decanted from the mercury and the liquid product separated from the hexane. The sirupy reaction product was filtered twice to remove all trace of metallic mercury. The filtrate was placed under a vacuum of two cm. of mercury and after a few hours long white needles appeared. The needles were removed and kept under vacuum again for fifteen hours. They melted to a clear liquid at 63°. The crystals are very hygroscopic and if kept even for a short time in the open they absorb moisture from the air and become pasty.

Analysis of the dry crystals for mercury was made by treating them with a solution of sodium thiosulfate, using in excess of four moles to one mole of mercuric nitrate. The method of analysis was as follows. The weighed sample was added to 15 cc. of an 18% thiosulfate solution and allowed to boil for five to ten minutes. As soon as the addition compound is added even in the cold it dissociates into the organic and inorganic components; the odor of the sulfide is very pronounced. A concentrated solution of sodium sulfide was then added until an almost clear solution was obtained. If red or black mercuric sulfide was still left undissolved, the mixture was boiled until a complete solution was obtained. About 150 cc. of water and some solid ammonium nitrate crystals were added. The mixture was boiled for fifteen minutes and the precipitate collected in a Gooch crucible, washed and dried at 120° in the usual manner This procedure was found to give accurate results when mercuric chloride was treated with sodium thiosulfate solution.

The reaction between solid sodium thiosulfate and mercuric chloride was investigated by Allen and Crenshaw.[13]

The accuracy of the procedure adopted in this work can be seen from the following results: for 0.5000 *g.* of mercuric chloride, theory requires 0 4283 g. of mercuric sulfide. Found: 0.4270 and 4275 g.

When the black precipitate first formed on boiling 0.5000 g. of mercuric chloride with 1.828 g. of the thiosulfate in 15 cc. of water was weighed after washing and drying, the amounts of mercuric sulfide obtained were 0.3885 and 0.3883 g., respectively, approximately only 90% of the theoretical.

The crystals of the addition compound, $(Et_2S)_2{\cdot}Hg(NO_3)_2$, were analyzed for mercury by the procedure just described and the percentage of mercury corresponded within experimental error to that required by the formula given.

Anal. Calcd.: Hg, 39.75. Found: Hg, 39.58, 39.45.

Reaction between Alkyl Sulfides and Mercurous Salts.—The following alkyl sulfides were tested qualitatively for their behavior toward various mercurous salts: methyl sulfide, ethyl sulfide, n-propyl sulfide, n-butyl sulfide, *iso*butyl sulfide and *iso*-amyl sulfide. The results obtained are given briefly.

(1) All alkyl sulfides precipitate mercury from powdered mercurous nitrate, $Hg_2(NO_3)_2{\cdot}2H_2O$, or aqueous solution of mercurous nitrate.

(2) Only methyl sulfide precipitates mercury from mercurous chloride and it does so only in the presence of water. The other alkyl sulfides seem to have no action on this mercurous salt even in the presence of water.

(3) Methyl sulfide precipitates mercury from mercurous acetate even when water is absent. The other sulfides react likewise but only in the presence of water.

(4) All the alkyl sulfides used react with mercurous sulfate even in the absence of water.

(5) All the sulfides precipitate mercury from mercurous iodide. Methyl, ethyl and n-propyl sulfides when used in excess give solutions and metallic mercury. The other sulfides give grayish precipitates which dissolve in benzene with the separation of mercury.

Alkyl Sulfides and Mercuric Salts.—Generally speaking, the addition compounds of alkyl sulfides with salts of oxy-acids are water-soluble compounds. This phenomenon is in agreement with the analogous finding of Blomstrand[2] that the compounds of ethyl sulfide and the platinum salts of oxy-acids (except the nitrite) are water soluble.

---

[13] Allen and Crenshaw, *Am. J. Sci.*, [4] **34, 369 (1912).**

Interaction of Alkyl Sulfides and Mercuric Chloride.—Only the first two members in the series of the aliphatic sulfides had been investigated previously. The alkyl sulfides and mercuric chloride were found to give under different conditions two types of addition compounds for each sulfide, the types varying with the sulfide used. It was also found that Types 2 and 3 are in some cases easily converted into each other.

TABLE I

PREPARATION, PROPERTIES AND ANALYTICAL DATA OF ADDITION COMPOUNDS OF ALKYL SULFIDES WITH MERCURIC CHLORIDE

No.	Soln. of $HgCl_2$ in	Alkyl sulfide	Cryst. solvent	M. p., °C.
1	Alcohol	Ethyl sulfide	Alcohol	76.5–77
2	Alcohol	Ethyl sulfide	Bz or acetone	119–119.5
3	Alcohol	n-Propyl sulfide	Alcohol	87.5–88
4	Alcohol	*n*-Propyl sulfide	Benzene	121–122
5	Alcohol	Isobutyl sulfide	Alcohol	116
6	Alcohol	Isobutyl sulfide	Benzene	131
7	Alc. or water	*n*-Butyl sulfide	Benzene	112–113
8	Water	n-Butyl sulfide	......	Liquid
9	Alc. or water	Iso-amyl sulfide	Benzene	......
10	Water	*Iso*-amyl sulfide	......	Liquid

[a] White needles. If a large excess of $HgCl_2$ is used or if the product is recrystallized several times from alcohol, the higher compound, $(C_2H_5)_2S\cdot 2HgCl_2$, is formed. [b] White plates. When the product is recrystallized from alcohol it does not change. [c] Long white needles. Solvent of crystallization is important, while an excess of either of the reactants is of no moment. [d] White plates. When recrystallized from alcohol, the lower compound, $(n\text{-}C_3H_7)_2S\cdot HgCl_2$, is formed. [e] Same as for 3. [f] Same as for 4. [g] White plates. When alcohol is used as the solvent, a large excess of $HgCl_2$ is required in order to get precipitation. In water, molecular proportion of the reactants is sufficient. A clear oily liquid containing compounds 7 and 8 is formed. Addition of ether precipitates the solid. [h] Same as for 7.

Ethyl Sulfide and Mercuric Chloride.--The addition compound obtained by the interaction of ethyl sulfide and mercuric chloride was formerly considered to be an equimolecular compound of the two reacting substances. Abel[3] in disagreeing with the discoverer about the melting point of the reaction product said that Loir did not make a pure compound. Abel found that the melting point of his purified compound, which was recrystallized from alcohol and ether, was 119". Loir had reported a melting point of 90° for his product. Abel assumed that the compound melting at 119° was the same as that made by Loir. No analysis was reported by Abel, although he obtained under some conditions a product melting at 80°.

During the present investigation many experiments were made to find the reason for these discrepancies. As will be shown later, the reason was discovered to be the existence of two compounds of ethyl sulfide and mercuric chloride, $Et_2S\cdot HgCl_2$ and $Et_2S\cdot 2HgCl_2$. The two compounds have widely different melting points. They are obtained in a pure state when the proper conditions of formation as well as of recrystallization are used.

(a) **$Et_2S\cdot HgCl_2$.**—This compound is obtained when ethyl sulfide and mercuric chloride are used in an equimolecular proportion and the product is recrystallized either from absolute alcohol or from acetone containing a small quantity of ethyl sulfide.

When this crystalline compound was recrystallized from ether, a compound melting at 112–119° was obtained. This compound is a mixture of the two addition compounds. This fact explains why Abel obtained the higher-melting product, since he purified his product by recrystallization from ether.

(b) **$Et_2S\cdot 2HgCl_2$.**—This compound may be obtained pure if an excess of mercuric chloride solution is used and the product of the reaction is recrystallized once or twice from acetone or from benzene.

An acetone solution of the crude product obtained as described in section (a) was left partially covered overnight. Both types of crystals were formed. They were separated by hand-picking and were found to melt at 77° and 119.5°, respectively. Crystals of $Et_2S\cdot HgCl_2$ when recrystallized several times from either acetone or benzene are converted into $Et_2S\cdot 2HgCl_2$. The crystals thus obtained were recrystallized several times from absolute alcohol. No conversion was effected; the compound melted at 119.5".

***n*-Propyl** Sulfide and Mercuric Chloride. (a) ***n*-$Pr_2S\cdot HgCl_2$.**—When alcohol is the medium of the reaction, the crude reaction product melts invariably at 85°, even though an excess of the sulfide or of the mercuric salt is used. Also, in both cases the compounds recrystallized from absolute alcohol consist of long white needles melting at 87.5–88°.

(b) ***n*-$Pr_2S\cdot 2HgCl_2$.**—This compound is obtained by recrystallizing *n*-$Pr_2S\cdot HgCl_2$ (a) twice from benzene.

When this compound is recrystallized from alcohol, long needles of *n*-$Pr_2S\cdot HgCl_2$, melting at 87.5–88°, are invariably obtained. Thus the two compounds are convertible into each other.

Isobutyl Sulfide and Mercuric Chloride. (a) *iso*-$Bu_2S\cdot HgCl_2$.—The compound was obtained by the action of isobutyl sulfide on an alcoholic solution of the mercuric salt. The precipitate was very voluminous. Recrystallized from absolute alcohol, the crystals melted at 116° after sintering.

(b) ***iso*-$Bu_2S\cdot 2HgCl_2$.**—The compound was obtained by recrystallizing *iso*-$Bu_2S\cdot HgCl_2$ (a) twice from benzene.

Some of the crystals melting at 131° were recrystallized again from alcohol. The new crystals melted at 116". Analysis gave Hg, 47.79, instead of the theoretical value of 48.04 for *iso*-$Bu_2S\cdot HgCl_2$.

Thus isobutyl sulfide behaves like ethyl sulfide and n-propyl sulfide by forming with mercuric chloride two addition compounds; it is like n-propyl sulfide with respect to the easy conversion of one compound into the other by using different solvents for recrystallization.

***n*-Butyl** Sulfide and Mercuric Chloride.—The interaction of n-butyl sulfide and mercuric chloride yielded two types of addition compounds, one of which had not been made with ethyl, n-propyl and isobutyl sulfides. The compound, $n\text{-Bu}_2\text{S}\cdot\text{HgCl}_2$, seems to be non-existent. When the sulfide and the mercuric salt are used in the molecular proportion of 1:1 in alcohol, no precipitate is formed; but when the reacting substances are taken in the molecular proportion of 2:1, a heavy precipitation of white crystals occurs. However, if water is used as the solvent, a liquid separates when the reacting substances are taken in the molecular proportion of 1:1.[14] This liquid product when treated with a small quantity of ether yields a heavy mass of white crystals which on analysis were found to be the addition compound, $n\text{-Bu}_2\text{S}\cdot2\text{HgCl}_2$. The ether solution, when evaporated, leaves an oily residue which by analysis was found to be the addition compound, $(n\text{-Bu}_2\text{S})_2\cdot\text{HgCl}_2$.

The reactions involved may be explained as follows

$$3\,n\text{-Bu}_2\text{S} + 3\text{HgCl}_2 = \underset{\text{Solution}}{2\,n\text{-Bu}_2\text{S}\cdot1\text{HgCl}_2 + n\text{-Bu}_2\text{S}\cdot2\text{HgCl}_2} \qquad (1)$$

$$\underset{\text{(Soln.)}}{2\,n\text{-Bu}_2\text{S}\cdot1\text{HgCl}_2 + n\text{-Bu}_2\text{S}\cdot2\text{HgCl}_2} \xrightarrow{+\text{ ether}} \underset{\text{(In ether soln.)}}{n\text{-Bu}_2\text{S}\cdot2\text{HgCl}_2 + (n\text{-Bu}_2\text{S})\cdot\text{HgCl}_2} \qquad (2)$$

The compound $n\text{-Bu}_2\text{S}\cdot2\text{HgCl}_2$ is only slightly soluble in ether, while the compound $(n\text{-Bu}_2\text{S})_2\cdot\text{HgCl}_2$ is very soluble in this solvent.

(a) $\boldsymbol{n\text{-Bu}_2\text{S}\cdot2\text{HgCl}_2}$.—This compound was also obtained from 8.5 g. of mercuric chloride and 1.5 g. of n-butyl sulfide, i. e., weights in the proportion of 3 moles of the salt to 1 mole of the sulfide. When only once recrystallized from benzene, the percentage of mercury found was 55.5, but when the product was crystallized again from the same solvent, almost the theoretical value for mercury was found.

(b) $\boldsymbol{(n\text{-Bu}_2\text{S})_2\cdot\text{HgCl}_2}$.—This compound was obtained as previously described. Since Compound (a) is soluble in Compound (b), one would expect to find Compound (a) in Compound (b) as an impurity. On standing for a few days, a white precipitate was observed on the bottom of the test-tube. This change indicates the solubility of (a) in (b) as the cause of the high percentage of mercury.

***Iso*-amyl** Sulfide and Mercuric Chloride.—The addition products obtained by the interaction of iso-amyl sulfide and mercuric chloride are similar in their constitution to those obtained from n-butyl sulfide and the mercuric salt. The method of preparation is also the same.

(a) $\boldsymbol{iso\text{-Am}_2\text{S}\cdot2\text{HgCl}_2}$.—The compound may be obtained either by using an excess of mercuric chloride in alcoholic solution or by using the reacting substances in the molecular proportion of 1:1 in an aqueous medium and then treating the product with ether. The results of analysis of the compound obtained by the latter method are given here.

(b) $\boldsymbol{(iso\text{-Am}_2\text{S})_2\cdot\text{HgCl}_2}$.—This compound was obtained by using the sulfide and the mercuric salt in equimolecular proportion with water as the solvent; the product was then treated with ether. The high percentage of mercury may be explained by the solubility of Compound (a) in Compound (b).

Methyl Sulfide and Mercuric **Chloride.**—Loir[1] assigned to the reaction product of

---

[14] n-Propyl sulfide and mercuric chloride in equimolecular proportions in water as solvent yield white crystals. This behavior shows that the reaction is different for n-butyl sulfide and iso-amyl sulfide.

methyl sulfide and mercuric chloride the formula $(CH_3)_2S \cdot HgCl_2$. Phillips[4] reinvestigated the compound and in accordance with the results of his analysis for mercury, sulfur and chlorine, gave to it the formula $2(CH_3)_2S \cdot 3HgCl_2$. The compound has no definite melting point. By heating rapidly, a clear liquid is obtained at 151°. The compound is only sparingly soluble in benzene and practically insoluble in the other ordinary organic solvents. The product obtained from alcoholic mercuric chloride and an equimolecular proportion of methyl sulfide was dissolved in an excess of boiling benzene. The crystals that separated were analyzed for mercury and sulfur.

Anal. Calcd. for $2(CH_3)_2S \cdot 3HgCl_2$: Hg, 64.63; S, 6.42. Found: Hg, 63.28, 62.83; S, 6.78, 6.73.

There is a possibility that the product is a "molecular" compound made up of equimolecular proportions of $Me_2S \cdot HgCl_2$ and $Me_2S \cdot 2HgCl_2$, the two types of addition compounds that were obtained from ethyl, n-propyl and isobutyl sulfide with mercuric chloride. Were it possible to find a favorable solvent, the two types might be separated. An analogous situation was found by Rây[7] for the compound $(Et_2S)_2 \cdot PtCl_3$. On recrystallization from boiling alcohol, he succeeded in obtaining the compounds $(Et_2S)_2 \cdot PtCl_2$ and $(Et_2S)_2 \cdot PtCl_4$ from $2(Et_2S)_2 \cdot PtCl_3$.

Summary

1. The action of alkyl sulfides on mercurous salts was investigated. The reaction was found to be a conversion of the mercurous salt into metallic mercury and the corresponding mercuric salt, and the formation of an addition compound of the alkyl sulfides with the mercuric salt.

2. In some cases the reaction takes place only in the presence of water.

3. Except for methyl sulfide, the alkyl sulfides have no action on mercurous chloride.

4. The addition compounds of alkyl sulfides and mercuric salts of most oxyacids are water soluble.

5. The products of reaction of alkyl sulfides and mercuric chloride were investigated. Three types of addition compounds were found. These types are $(R_2S)_2 \cdot HgCl_2$, $R_2S \cdot HgCl_2$ and $R_2S \cdot 2HgCl_2$. Each of the alkyl sulfides formed two of the types, depending on the solvent used.

6. n-Propyl sulfide and isobutyl sulfide form with mercuric chloride two types of compounds that are easily converted into each other by recrystallization from proper solvents.

THE MERCURATION OF AURIN AND ATTEMPTS TO MERCURATE SOME OTHER TRIPHENYLMETHANE DYES

BY FRANK C. WHITMORE AND G. J. LEUCK

RECEIVED FEBRUARY 4, 1929 PUBLISHED SEPTEMBER 5, 1929

The original purpose of this study was to make organic mercury derivatives of crystal violet with the hope that they might be valuable therapeutically. This aim was not achieved. While dimethylaniline and similar substances are mercurated with the greatest ease, less basic amino compounds are not.[1]

No successful mercuration was obtained with crystal violet, N-phenyl methyl violet or malachite green. A small amount of a dimercurated product was obtained from the base of malachite green. It was too insoluble for further study. On the other hand, pararosaniline was mercurated with relative ease. The product was the acetate of triacetoxymercuri-pararosaniline. It was so insoluble that it could not be changed to the corresponding chloromercuri compound.

It was next decided to mercurate aurin. This process proved to be unusually easy, as was to be expected from the work of Wolvekamp on the corresponding tricarboxylic acid.[2] In the present study modified methods of mercuration were developed which made it possible to obtain products containing one, two or three atoms of mercury by merely modifying the solvent. In a mixture of ethyl acetate and acetic acid the mono-mercury product was obtained. In alcohol solution the chief product was the very insoluble tri-mercury compound. By using a mixture of alcohol and acetic acid and a relative excess of aurin, the di-mercury product was obtained. When the mono-acetoxymercuri-aurin was refluxed alone in alcohol, it was converted to the triacetoxymercuri compound and free aurin.

The explanation of these reactions is that the mercuration reactions are reversible. The use of alcohol removes the acetic acid formed in the mercuration reaction and favors the formation of the very insoluble tri-mercury product. An increase in the acetic acid concentration favors the di-mercury product. With ethyl acetate and acetic acid and no alcohol, the mercuration is made most difficult and only the mono-mercury compound is obtained. Further evidence for this conception is given by the conversion of acetoxymercuri-aurin to the tri-mercury compound by heating in alcohol and to the trichloromercuri-aurin by heating with sodium chloride solution.

[2] Wolvekamp, U. S. Patent 1,412,440; C. A., 16, 2199 (1922).

All of the organic mercury compounds obtained in this study were split by sodium iodide to give inorganic mercury and sodium hydroxide.[3]

Experimental

Mercuration of **Pararosaniline.**—A solution of 5 g. (0.014 mole) of pararosaniline acetate and 2 g. (0 006 mole) of mercuric acetate in 500 cc. of water containing 1 cc. of acetic acid was refluxed for three hours. The solution then gave no test for inorganic mercury. After addition of 3 g. (0.009 mole) more mercuric acetate the mixture was refluxed for five hours longer. Inorganic mercury was then present. After three more hours of refluxing only organic mercury was present. On cooling the whole mixture set to a thin jelly. This was evaporated to a volume of 200 cc. It was then filtered by suction, a process requiring several days. The residue was dried first at 50° and then at 80°. It was extracted repeatedly with 95% alcohol and dried again. The product was triacetoxymercuripararosaniline acetate.

Anal. Calcd. for $C_{27}H_{27}O_8N_3Hg_3$: Hg, 53.6. Found: Hg, 52.6, 52.5.

It is a dark brown solid very sparingly soluble in water. After thorough drying it is much more difficultly soluble. It is insoluble in other solvents. When refluxed with an excess of aqueous sodium iodide the mercury is removed quantitatively with the formation of sodium mercuric iodide, sodium hydroxide and pararosaniline base.

The preparation of the mercury compound was repeated according to several other sets of conditions without any noticeable change in the results. The products obtained contained the following percentages of mercury: 52.6, 52.7, 53.1.

Attempts to prepare mercury derivatives of pararosaniline containing one or two atoms of mercury were unsuccessful.

Attempted Mercuration of Malachite Green **and** its Base.—This substance was treated with mercuric acetate under a great variety of conditions. The solvents used included various concentrations of ethyl alcohol, acetic acid, ethyl acetate, benzene and mixtures of these. The time of heating varied from a few minutes to ten days. In no case was there any evidence of formation of organic mercury compounds. In all cases considerable amounts of mercury and mercurous compounds were formed, indicating oxidation of the dye. In one run in glacial acetic acid a small amount of dimethylaminobenzophenone, m. p. 93–94°, was obtained. In several cases addition products containing inorganic mercury were obtained.

When the mercuration was repeated at a higher temperature by refluxing the free base of malachite green for twenty hours in n-butyl acetate, oxidation was the only result, all of the mercury being converted to metal.

Attempted Mercuration of Other Basic Triphenylmethane Dyes.—Similar experiments were carried out with crystal violet (N-hexamethyl pararosaniline), N-phenyl methyl violet (N-phenyl-N-pentamethyl pararosaniline). In no case was an organic mercury compound obtained.

Acetoxymercuri-aurin.—A solution of 4.8 g. (0.16 mole) of aurin and 5.7 g. (0.18 mole) of mercuric acetate in 80 cc. of dry alcohol-free ethyl acetate containing 20 cc. of glacial acetic acid was refluxed .with stirring for six hours. No inorganic mercury remained. The precipitate was removed, washed with alcohol and dried.

Anal. Calcd. for $C_{21}H_{16}O_5Hg$: Hg, 36.5. Found: Hg, 35.8, 36.0.

A larger run using 48 g. of aurin, 58 g. of (90%) mercuric acetate, 240 g. of glacial acetic acid and 760 cc. of 90% ethyl acetate gave 83 g. of the acetoxymercuri-aurin (91% of the calculated amount). Analyses gave 36.4 and 36.5% of mercury.

---

[3] Whitmore and Middleton, THIS JOURNAL, 43,619 (1921).

If much more than one molecular equivalent of mercuric acetate was used in the above solvent mixture, inorganic mercury remained even after long refluxing.

Acetoxymercuri-aurin is a red powder soluble in alcohol, acetone and alkalies. When refluxed with sodium iodide solution the carbon–mercury linkage is split with the formation of sodium hydroxide.

Diacetoxymercuri-aurin.—A solution of 19.3 g. (0.065 mole) of aurin and 6 g. (0.17 mole) of 90% mercuric acetate in 300 cc. of 95% alcohol and 12 cc. of glacial acetic acid was refluxed for half an hour with stirring. Longer refluxing gave some of the black trimercurated product. Shorter refluxing gave a smaller yield of dimercurated product. The mixture was cooled and filtered. The product was washed with alcohol and dried at 50°. Diacetoxymercuri-aurin is a bright red powder. It is soluble in alcohol, acetone, ethyl acetate and alkalies.

Anal. Calcd. for $C_{23}H_{18}O_7Hg_2$: Hg, 49.7. Found: Hg, 49.9, 49.2, 50.0.

Triacetoxymercuri-aurin.—A solution of 14.5 g. (0.05 mole) of aurin and 32.0 g. (0.1 mole) of mercuric acetate in 300 cc. of 95% alcohol, 50 cc. of water and 15 cc. of acetic acid was refluxed with stirring for fifteen hours. No inorganic mercury remained. The greenish-black precipitate was collected on a filter, washed with alcohol and dried; wt., 22 g. A similar run using mercuric acetate and aurin in the molar ratio of 3:1 gave the same product. Mercury analyses gave 56.2 and 56.4. Triacetoxymercuri-aurin is a black powder somewhat soluble in alcohol, acetic acid and alkalies.

Anal. Calcd. for $C_{25}H_{20}O_9Hg_3$: Hg, 56.5. Found: Hg, 56.9, 56.7.

Conversion **of Acetoxymercuri-aurin** to **Triacetoxymercuri-aurin.**—A mixture of 5 g. of acetoxymercuri-aurin in 100 cc. of 95% alcohol was'refluxed for 24 hrs. The hot mixture was filtered and the red filtrate discarded. The residue was refluxed with 100 cc. more alcohol for twenty-four hours. It was again filtered, giving a yellow filtrate. The residue was washed with alcohol and dried at 90°, the product being triacetoxymercuri-aurin. It was dark red, whereas the product obtained by direct mercuration was black.

Anal. Calcd. for $C_{25}H_{20}O_9Hg_3$: Hg, 56.5. Found: Hg, 56.9, 56.9.

Trichloromercuri-aurin was prepared from the acetate and sodium chloride in alcohol by refluxing for three days.

Anal. Calcd. for $C_{19}H_{11}O_3Cl_3Hg_3$: Hg, 60.5. Found: Hg, 59.7, 60.5, 60.3.

The same product was obtained by refluxing 5 g. of acetoxymercuri-aurin and 3.5 g. of sodium chloride in 150 cc. of alcohol for three days. It gave mercury analyses of 60.0 and 59.8%.

No way was found of making chloromercuri-aurin.

Summary

1. Pararosaniline yields a triacetoxymercuri compound readily. The base of malachite green gives a small yield of a diacetoxymercuri compound.

2. Aurin gives mono-, di- and triacetoxymercuri compounds depending on the solvent used.

MERCURATED TEREPHTHALIC ACID

BY FRANK C. WHITMORE AND LLOYD L. ISENHOUR

RECEIVED FEBRUARY 19, 1929 PUBLISHED SEPTEMBER 5, 1929

The mercuration of aromatic acids converts them to amphoteric substances of weakly acid properties. The sodium salts and the chlorides are readily hydrolyzed to give the insoluble anhydro-hydroxymercuri aromatic acids. It was thought that a second carboxyl group in the molecule would give stronger acidic properties. Consequently, mercurated terephthalic acid was prepared and studied. The difference between it and mercurated benzoic acid in forming stable salts is very slight. Both are precipitated from sodium carbonate solution by carbon dioxide. In the case of mercurated terephthalic acid, however, a very careful adjustment of concentration is necessary to obtain complete precipitation. No such precaution is mentioned by the workers with mercurated benzoic acid.[1]

Anhydro-hydroxymercuriterephthalic acid seems to be more soluble in sodium acetate solution than does the corresponding anhydro-hydroxymercuribenzoic acid, although no quantitative study has been made.

The most interesting comparison of the two acids is between their n-butyl esters as regards their stability in hot 95% alcohol. Di-n-butyl chloromercuriterephthalate can be crystallized satisfactorily from hot alcohol. n-Butyl chloromercuribenzoate is hydrolyzed to anhydrohydroxymercuribenzoic acid by boiling with 90% alcohol.

Of many methods attempted for mercurating terephthalic acid only two were successful. One was to reflux an aqueous mixture of terephthalic acid, mercuric acetate, acetic acid and sodium acetate. The other was to fuse diethyl terephthalate with mercuric acetate and a trace of acetic acid at 117°. The use of higher temperatures gave large amounts of an unmanageable dimercurated product.

A method of purification applicable to other mercurated aromatic acids was developed. The mercurated acid was converted to the acid chloride and then to the n-butyl ester.[2] The ester of mercurated terephthalic acid was readily crystallized from hot ethyl or n-butyl alcohol. Since the n-butyl ester of the original acid is a liquid and that of the di-mercurated acid is very insoluble, this method of purification was very successful.

The esters of chloromercuribenzoic acid are more easily hydrolyzed and so must be crystallized from absolute alcohol.

The structure of the mercurated terephthalic acid was determined by conversion to the following mercurated derivatives, the anhydro com-

[2] Whitmore and Middleton, THIS JOURNAL, 44, 1546 **(1922).**

pound, the di-n-butyl ester, the amide and the anilide, and by replacing the mercury by bromine to form 2-bromoterephthalic acid.

The positions of the mercury atoms in the di-mercurated terephthalic acid have not been determined.

Experimental Part

Preparation of Terephthalic Acid. 1. From Commercial Xylene.—Xylene was oxidized by alkaline potassium permanganate. Isophthalic and terephthalic acids were precipitated. They were then dissolved in ammonium hydroxide and the very insoluble barium terephthalate was precipitated and then converted to the free acid; yield, 150 cc. of acid from 600 cc. of crude xylene.

2. From Commercial Cymene.—The oxidation was carried out with dilute nitric acid to give *p*-toluic acid, which was converted to terephthalic acid by alkaline permanganate.

Mercuration of Terephthalic Acid.—A solution of 34 g. (0.2 mole) of terephthalic acid in a slight excess of sodium hydroxide was mixed with a solution of 44.7 g. (0.2 mole) of mercuric oxide in a slight excess of acetic acid and 10 g. of sodium acetate and refluxed for 240 hours. At that time the mixture gave no test for inorganic mercury and was completely soluble in sodium hydroxide solution. The precipitated material was filtered off, washed and dried; wt., 102 g. The filtrate on acidification gave 10 g. of unchanged terephthalic acid. The mercurated product was digested for one hour with 1 liter of concentrated ammonium hydroxide solution and 500 cc. of water. The insoluble material was filtered off and extracted again in a similar way. The two extracts were barely acidified with acetic acid. The white precipitate was collected on a filter, transferred to a large beaker and dissolved in a very slight excess of hot saturated sodium carbonate solution. The solution was filtered from a small amount of insoluble material, cooled and treated with carbon dioxide to precipitate a mixture of the mono-mercurated acid and a little of the di-mercurated product. The mixture was digested for about one hour with 500 cc. of saturated (20°) sodium acetate solution and 1 liter of water. This treatment dissolved the mono-mercury compound. The filtrate was acidified with 40 cc. of glacial acetic acid, filtered, washed with water and alcohol and dried in *vacuo* over phosphorus pentoxide; yield of pure anhydro-2-hydroxymercuri-terephthalate, 18 g. More of the product was obtained from the various residues and mother liquors.

Anal. Calcd. for $C_8H_4O_4Hg$: Hg, 55.0. Found: Hg, 54.5.

Mercuration of Diethyl Terephthalate.—A mixture of 40 g. (0.18 mole) of diethyl terephthalate, 57.5 g. (0.18 mole) of mercuric acetate and 2 cc of glacial acetic acid was heated for seventy hours at 117° (bath of boiling n-butyl alcohol). No test for inorganic mercury was then given. The pasty mass was then steam distilled for twenty-four hours. The residue was digested with ammonium hydroxide solution, filtered and acidified. The mercurated terephthalic acid was purified as before.

Di-n-butyl 2-Chloromercuriterephthalate.—A suspension of 5 g. of the anhydro compound in 200 cc. of chloroform was treated with 20 g. of phosphorus pentachloride. Some heat was evolved. After refluxing for half an hour solution was almost complete. A slight residue was removed by filtration and the filtrate was evaporated on a water-bath to 50 cc. in *vacuo.* It was cooled in ice. The acid chloride separated in crystalline form but it was not possible to prepare it in definite purity for analysis. In its crude state it was heated with 25 cc. of anhydrous n-butyl alcohol. On cooling, fine white crystals of the ester separated. It was crystallized from 15 cc. of hot 95% alcohol and dried in *vacuo* over phosphorus pentoxide; m. p. 82–85°; yield, 70%.

Anal. Calcd. for $C_{16}H_{21}O_4ClHg$: Hg, 39.1. Found: Hg, 39.7.

2-Chloromercuriterephthalamide.—A solution of 2 g. of the ester in 300 cc. of 95% alcohol was treated with dry ammonia gas and allowed to stand for two days. The white precipitate was collected and dried at 100°; wt., 1 g. It did not melt at 300°. Analyses of several samples gave consistently 48.0 ± 0.2 for the mercury content instead of the calculated 50.1. This mercury content corresponds to a monohydrate but no water was given off even at 200°.

The amide was prepared from the crude acid chloride and dry ammonia in chloroform. It was dried in *vacuo* at 140°; yield, 90%.

Anal. Calcd. for $C_8H_7O_2N_2ClHg$: Hg, 50.1. Found: Hg, 40.5.

Anilide of 2-Chloromercuriterephthalic Acid.—The crude acid chloride from 10 g. of the anhydro compound was heated with 50 cc. of aniline. The extract was evaporated in *vacuo* to 5 cc. and treated with 10 cc. of alcohol and 400 cc. of water. The anilide was a brown, amorphous product, somewhat soluble in hot water and readily soluble in hot alcohol. It did not melt at 300°.

Anal. Calcd. for $C_{20}H_{15}O_2N_2ClHg$: Hg, 36.4. Found: Hg, 36.3.

Treatment of the Mercurated Terephthalic Acid with Bromine.—A suspension of 10 g. of the anhydro compound was treated with a solution containing 10 g. of sodium bromide and 1.5 cc. of bromine. The bromine was decolorized at once. The mixture was acidified with hydrochloric acid and the resulting precipitate crystallized from hot alcohol. It showed the properties of 2-bromoterephthalic acid and melted at 299°. Its molecular weight in alcohol as determined by the McCoy method was 269 (calcd. 245).

Purification of Anhydro-2-hydroxymercuribenzoic Acid.—A sample of the crude product containing 62.5% of mercury was converted to the acid chloride and then to the n-butyl ester. This was crystaliized from absolute alcohol. It was then hydrolyzed by boiling with 90% alcohol.

Anal. Calcd. for $C_7H_4O_2Hg$: Hg, 56.1. Found: Hg, 55.8, 55.9.

Summary

1. Terephthalic acid has been mercurated in the 2-position.
2. The salts of the mercurated terephthalic acid are only slightly less hydrolyzed than those of mercurated benzoic acid.
3. A method has been developed for purifying mercurated aromatic acids.

RELATIONS BETWEEN ROTATORY POWER AND STRUCTURE IN THE SUGAR GROUP. XX. TWO ISOMERIC CRYSTALLINE COMPOUNDS OF d-MANNOSE WITH CALCIUM CHLORIDE[1]

BY J. K. DALE[2]

RECEIVED MARCH 8, 1929 PUBLISHED SEPTEMBER 5, 1929

Crystalline compounds of the sugars with inorganic salts, a number of which are known,[3] have hitherto been of little interest in the advancement of our knowledge concerning the structures of the sugars. However, the important position which mannose holds in relation to structural studies makes the preparation and study of any of its compounds or derivatives of unusual interest. Dr. C. S. Hudson informed the author that he had observed the formation of crystals in a solution of mannose and calcium chloride and suggested that the writer prepare and investigate the compound whose existence in a crystalline state had been thus indicated. This proposal led to far more interesting results than had been anticipated. The double compound of mannose and calcium chloride which was obtained showed mutarotation, but the course of the mutarotation was of an unusual character differing from that of any known sugar. Secondly, by evaporating an alcoholic solution on a water-bath the compound was transformed into a second modification, isomeric with the original. Subsequently it was found that either isomer could be made at will from mannose and calcium chloride, or even directly from hydrolyzed vegetable ivory, depending upon the solvent and the temperature at which crystallization took place. The first isomer crystallizes from a concentrated aqueous solution of mannose and calcium chloride at room temperature while the second crystallizes from an alcoholic solution during evaporation on a boiling water-bath. The isomer crystallizing from water at room temperature showed a calcium and chlorine content, loss of weight on drying and specific rotation at equilibrium corresponding to the formula $C_6H_{12}O_6 \cdot CaCl_2 \cdot 4H_2O$. As its initial specific rotation and course of mutarotation, in the early stages at least, do not permit a correlation with either of the known forms of mannose, it will subsequently simply be designated as the "First Isomer." The second isomer, crystallizing from alcohol at the temperature of a boiling water-bath, showed a

calcium and chlorine content and specific rotation at equilibrium corresponding to the formula $C_6H_{12}O_6\cdot CaCl_2\cdot 2H_2O$. Its initial specific rotation and course of mutarotation definitely correlate it with β-mannose of initial $[\alpha]_D$ −17°; hence it will be designated as β-mannose$\cdot CaCl_2\cdot 2H_2O$.

Initial Specific Rotation and Mutarotation of the First Isomer, Mannose$\cdot CaCl_2\cdot 4H_2O$.—The first observations of the direction of the mutarotation of this compound indicated that the optically active component was α-mannose. However, an extrapolation of its mutarotation curve to zero time showed an initial specific rotation, calculated to a mannose basis, of $[\alpha]_D$ 4-20', whereas Levene[4] had found $[\alpha]_D$ +30° for a-mannose. Subsequent attempts to obtain readings more quickly after making the

solution gave the unexpected result that the anticipated normal mutarotation was preceded by an extremely rapid change from a negative value, far below even that of β-mannose, to a positive maximum. From this maximum the rotation fell at a rate comparable with that of a-mannose. At 20° in aqueous solution the initial change was too rapid to be measured accurately. At 2" it was still rapid but could be followed with sufficient precision to permit a close estimation of the initial value. In Tables I and II are recorded the mutarotation data for this compound in aqueous solution at the temperatures of 20 and 2°, respectively. The curves A and B of the figure are plotted from these readings.

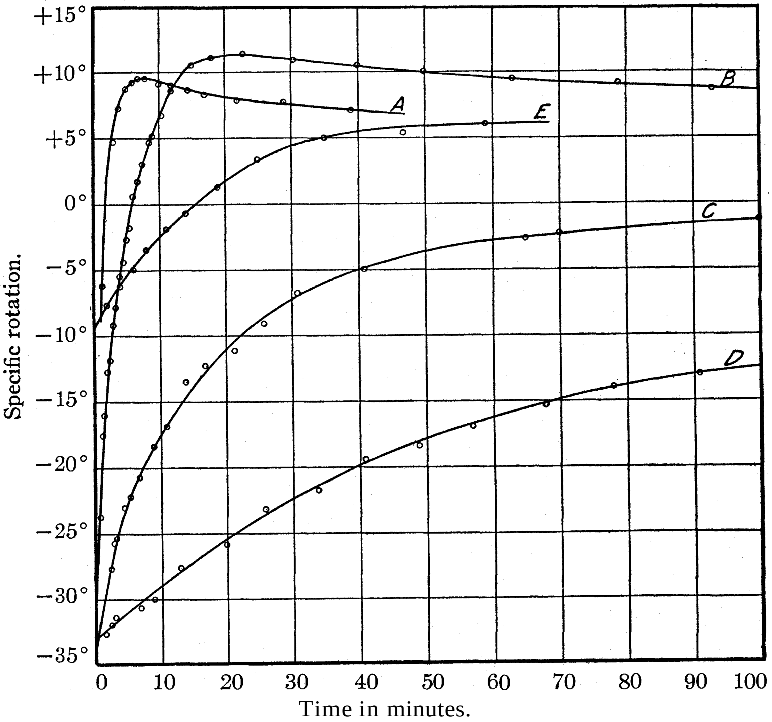

Fig. 1.—Initial stages in the mutarotation of mannose-calcium chloride compounds. Curve **A**, first isomer in water at 20°; Curve B, first isomer in water at 2°; Curve C, first isomer in methanol at 20°; Curve D, first isomer in methanol at 5°; Curve E, beta isomer in water at 20".

The later part of the mutarotation, decreasing from the maximum to an equilibrium value, appears to be unimolecular and the constant found at 20°, $k_1 + k_2 = 0.025$, is of the same order of magnitude as that given by Hudson and Sawyer for β-mannose[5] (0.019), and Levene[4] has shown that a-mannose has the same rate of mutarotation as the β-form. Fur-

[5] Hudson and Sawyer, THIS JOURNAL, **39**, 475 (1917).

thermore, if this portion of the curve is extrapolated to zero time, the initial specific rotation thus estimated is not far removed from that of a-mannose. These facts constitute evidence that this stage of the mutarotation is the passing of a-mannose to the equilibrium state of mannose solutions.

The initial rapid increase in rotation deserves special attention. The possibility exists that this change is due to a dissociation of the mannose–calcium chloride compound. This explanation appears unlikely, however, because no change in polarization due to a slow dissociation of sugar and salt has been observed in other compounds of this nature.[6] *It appears to be more likely that this change is due to a rapid rearrangement of a new form of mannose to the alpha modification.* If this is true the initial specific rotation of this new form of mannose becomes of special interest. Extrapolation of the mutarotation curve, B, to zero time shows the initial specific rotation of this compound to be about $-30°$, and hence for the mannose constituent, $[\alpha]_D$ $-60°$. Owing to the extreme rapidity of the early stages of the polarimetric change this figure is uncertain by several degrees.

The rate of the polarimetric change of the First Isomer in methanol is much slower than in water; hence in this solvent the course of the change could be followed with more precision and the initial specific rotation determined with more accuracy. Curves C and D show the early stages of the mutarotation of this compound at the temperatures of 20 and 5°, respectively. Extrapolation of these curves to zero time gives the values for the initial specific rotation at these two temperatures as -34 and $-33°$, and hence for the mannose constituent, $[\alpha]_D$ -68.6 and $-66.5°$. The final or equilibrium value for the specific rotation in this solvent was found to be $+4.0$ and $+4.8°$, an average of $+4.4°$, which calculated to a mannose basis equals $+8.9$".

C. S. Hudson[7] has produced evidence from theoretical considerations based upon the principle of optical superposition that the two known crystalline forms of mannose are not a true alpha and beta pair having the same ring structure, but that the form with an initial specific rotation of $+30°$ is the alpha form of a 1,5-ring structure, while the form showing $[\alpha]_D$ $-17°$ is the beta form of a 1,4-ring structure. He has further calculated the specific rotations to be expected for the missing members of these two-ring structures and predicts the value for the β-form of the 1,5-ring structure to be $-65°$ in water solution. The initial specific rotation of a new form of mannose, occurring as a crystalline double com-

---

[6] The author has prepared in crystalline form calcium chloride compounds of arabinose, xylose and fructose and also the well-known compound of sodium chloride and glucose. Each of these substances shows a normal mutarotation comparable with that of the sugar constituent. The data will be published in a subsequent article.

[7] C. S. Hudson, THIS JOURNAL, 48, 1425, 1434 (1926).

pound with calcium chloride is here shown to be not far from −60" in aqueous solution. The close agreement of this measured initial specific rotation of the new form of mannose with one of Hudson's calculated values, −65°, lends strong experimental support to his view that the well-known crystalline forms of mannose possess different ring structures, and as a corollary it follows that *the mannose constituent of the crystalline compound here described is the beta form of the sugar corresponding in ring structure with alpha mannose of initial specific rotation* +30°. If this view is correct, the initial mutarotation must be explained as a rapid conversion of the beta form of one ring structure to the corresponding alpha form. The subsequent slower polarimetric change must then be considered to be an establishment of equilibrium between forms of different ring structures.

Mutarotation of β-Mannose·$CaCl_2 \cdot 2H_2O$.—This compound, which was first obtained by concentrating an alcoholic solution of the First Isomer on a boiling water-bath, was characterized by a normal mutarotation in aqueous solution as shown in Table III and by Curve E. The mutarotation constant, $k_1 + k_2$, at 20° was found to be 0.024, a value essentially the same as the constant found for the latter stage of the mutarotation of the First Isomer (0.025) and slightly higher than the value, 0.019, found for β-mannose[5] at this temperature.[8] The final specific rotation, +6.73°, and

[8] The difference between the value $k_1 + k_2 = 0.024$ found for β-mannose·$CaCl_2 \cdot 2H_2O$ and the value $k_1 + k_2 = 0.019$ found by Hudson and Sawyer for β-mannose is too great to be attributed to experimental error. It is more likely that the rate of mutarotation of the mannose constituent of β-mannose·$CaCl_2 \cdot 2H_2O$ is accelerated by the presence of $CaCl_2$ in the solution. In confirmation a mutarotation experiment was made upon β-mannose dissolved in water and a second one upon β-mannose dissolved in a $CaCl_2$ solution of such strength that mannose and $CaCl_2$ were present in equimolecular proportions. Mannose in water alone showed $k_1 + k_2 = 0.020$, while in the $CaCl_2$ solution it showed $k_1 + k_2 = 0.025$.

the extrapolated initial specific rotation, −9.0°, correspond to +12.2° and −16.2°, respectively, for the mannose constituent. Thus this isomer is apparently a compound of $CaCl_2$ with the well known β-mannose of $[\alpha]_D$ −17°.

Acetylation of the Mannose·$CaCl_2$ Compounds.—β-Mannose·$CaCl_2$·$2H_2O$ may be of utility in the synthesis of mannose derivatives because it can be directly acetylated to give a good yield of β-mannose penta-acetate. This may be of timely importance, for pure β-mannose has recently become difficult to obtain, at least in some laboratories. Levene[4] states that after having once prepared a-mannose, subsequent recrystallizations of impure mannose from alcohol invariably gave this form. The author recrystallized at intervals several lots of impure mannose in the research laboratory of St. Andrews University. At first β-mannose was obtained, but unexpectedly one lot appeared as the alpha isomer and thereafter the recrystallized product always consisted of this form. It is true that alpha mannose can be acetylated[9] to give alpha mannose penta-acetate, but the yield is not more than 20% of the theoretical, which is far from satisfactory. On the other hand, 0-mannose or β-mannose·$CaCl_2$·$2H_2O$ readily yields on acetylation 60% or more of the theoretical. The First Isomer (mannose·$CaCl_2$·$4H_2O$) on acetylation with acetic anhydride and pyridine in an ice-bath gave a sirupy gum which after long standing in an ice chest yielded only a few crystals of β-mannose penta-acetate.

Experimental

Preparation of **the** First Isomer, Mannose·$CaCl_2$·$4H_2O$, from **β-*d*-Mannose.**—Twenty g. of β-mannose and 32 g. of crystallized calcium chloride dihydrate were dissolved on a boiling water-bath in 28 cc. of water. On standing overnight at room temperature the solution crystallized to a solid mass. This was thinned out with absolute alcohol, filtered on a Biichner funnel and washed with absolute alcohol. Dried at 35°, the yield was 28 g. It was recrystallized by slow evaporation of a concentrated aqueous solution in a desiccator. A solution of 25 g. of the compound in 25 cc. of cold water was filtered through an asbestos mat, followed by the addition of 10 *cc.* of water. The filtrate was placed in a crystallizing dish in a vacuum desiccator over sulfuric acid. After two weeks this solution had crystallized to a solid mass. It was triturated with absolute alcohol, filtered on a suction filter and washed with a further quantity of alcohol. Dried at 35°, the yield was about two-thirds of the original material. It was readily soluble in water, methanol and hot absolute alcohol. It dissolved slowly in cold 95% alcohol and in acetone. It melted at 101–102° corr.

Analysis.—Chlorine and calcium were determined directly in an aqueous solution of the compound. Moisture was determined by drying at 50 mm. over phosphorus pentoxide, first for six hours at 76°, then for nineteen hours at 100°. Four hours' additional drying at 110° caused no further loss in weight. Subs., 1.0197: AgCl, 0.8080. Subs., 1.0239: CaO, 0.1615. Calcd. for mannose·$CaCl_2$·$4H_2O$: Cl, 19.56; Ca, 11.02; H_2O, 19.80; $[\alpha]^{20}_D$, 6.94". Found: Cl, 19.62; Ca, 11.16; loss on drying to constant weight, 19.10; observed $[\alpha]^{20}_D$, + 6.72".

---

[9] Levene, *J. Biol. Chem.*, 57,329 (1923).

Preparation of the First Isomer, Mannose$\cdot CaCl_2\cdot 4H_2O$, from Vegetable Ivory.—A mannose sirup was prepared essentially according to the methods of Hudson and Sawyer[5] and Clark[10] though with a somewhat simplified procedure. One hundred grams of vegetable ivory meal sifted through a 48-mesh sieve was slowly added to 125 g. of 85% sulfuric acid and kneaded into a thick paste. After standing at room temperature for twenty-four hours the paste, which had by this time become liquid, was diluted to a volume of 2 liters and boiled under a reflux condenser for 3 hours, or until samples which were taken at one-half hour intervals showed a constant rotation. The dark red liquor was decolorized with 20 g. of active carbon and neutralized to Congo Red paper by slowly adding freshly precipitated, well washed barium carbonate to the boiling solution. The precipitated barium sulfate was separated by filtration with suction and well washed. The mixed filtrate and washings were acidified with 2 cc. of 5% sulfuric acid and the slight precipitate thus produced was filtered off with the addition of a further 10 g. of decolorizing carbon. This colorless liquor was evaporated to a sirup of about 90% solids as determined with a refractometer. To this sirup, while still warm, there was added a solution of 95 g. of calcium chloride dihydrate in 60 cc. of water. The mixture was stirred to a uniform solution, which was then diluted with 135 cc. of equal parts of absolute alcohol and acetone. Crystallization began almost immediately after cooling and seeding. After one night at room temperature and twenty-four hours in an ice chest, the crystals were filtered off on a Büchner funnel and washed with 400 cc. of equal parts of absolute alcohol and acetone. Dried at 35°, there was obtained 114 g. The melting point, analysis and polarization data identified this product with the First Isomer, Mannose$\cdot CaCl_2\cdot 4H_2O$, as originally obtained from crystalline 0-mannose.

Transformation of the First Isomer, Mannose$\cdot CaCl_2\cdot 4H_2O$, into β-Mannose$\cdot CaCl_2\cdot 2H_2O$.—Ten grams of the First Isomer was dissolved in 40 cc. of hot absolute alcohol and the solution was placed on a boiling water-bath. When the volume had been reduced by about one-quarter, crystals appeared. By the time the volume had been further reduced to about one-half, the solution was well filled with crystals. It was then set aside at room temperature overnight, filtered and the crystals washed with absolute alcohol. Dried at 35° there was obtained 6.5 g. The product was markedly different from the First Isomer. The crystals were well-defined, hard, triangular prisms. They were readily soluble in water and in methanol, only slightly so in cold 95% alcohol and practically insoluble in absolute alcohol. The substance melted at 159–160° (corr.) with decomposition.

Analysis.—Chlorine and calcium were determined directly in aqueous solution. The results agree with the percentages calculated for mannose$\cdot CaCl_2\cdot 2H_2O$, but holding at 50 mm. over phosphorus pentoxide at 100° for five hours caused no loss in weight.

Subs., 0.9799: AgCl, 0.8550. Subs., 1.0168: CaO, 0.1741. Calcd. for mannose$\cdot CaCl_2\cdot 2H_2O$: Cl, 21.71; Ca, 12.23; $[\alpha]^{20}_{D}$, 7.7°. Found: Cl, 21.59; Ca, 12.23; obs. $[\alpha]^{20}_{D}$, 6.73°.

Reversal of the above Transformation.—Ten grams of β-mannose$\cdot CaCl_2\cdot 2H_2O$ was dissolved in 150 cc. of boiling absolute alcohol. The solution was cooled and 1.1 cc. of water was added, just sufficient to make up the deficiency between a dihydrate and a tetrahydrate. The solution was evaporated at room temperature in a current of air to a thin sirup, then seeded with crystals of the First Isomer and placed in a desiccator. After a few days the sirup had crystallized to a semi-solid mass. After filtering, washing with absolute alcohol and drying at 35°, there was obtained 6 g. The melting point and course of mutarotation identified it as the First Isomer.

Preparation of β-Mannose$\cdot CaCl_2\cdot 2H_2O$ from β-Mannose or Directly from Vegetable Ivory.—This compound, though first prepared by transformation of the First Isomer as described above, was subsequently obtained both from crystalline β-mannose and

---

[10] Clark, J. *Biol. Chem.*, 51, 1 (1922).

from hydrolyzed vegetable ivory. In the former case 20 g. of β-mannose with 24 g. of calcium chloride dihydrate was dissolved in 12 cc. of hot water, the solution placed on a boiling water-bath, and 80 cc. of hot absolute alcohol slowly added. After remaining on the bath for one-half hour, the solution was well filled with crystals. It was cooled slowly and kept at room temperature overnight. Filtered, washed with 95% alcohol and dried at 35°, there was obtained 28 g.

The same procedure of crystallizing from strong, hot alcohol was applied to the preparation of this compound directly from an impure mannose sirup. Ten g. of a thick sirup from hydrolyzed vegetable ivory prepared as described earlier was mixed with 10 g. of $CaCl_2 \cdot 2H_2O$, previously dissolved in 3 cc. of water, on a boiling water-bath. Thirty-five cc. of warm absolute alcohol was added and the resulting solution kept on the bath until its volume had been reduced by about one-half, when a few crystals of β-mannose·$CaCl_2 \cdot 2H_2O$ were added as seed. Crystallization of the characteristic triangular prisms was soon in evidence and progressed rapidly. After a further short period on the bath and forty-eight hours at room temperature, the crystals were separated on a Biichner funnel, washed with 95% alcohol and dried at 35°. The yield was 8.5 g.

Acetylation of β-Mannose·$CaCl_2 \cdot 2H_2O$.—Ten g. of β-mannose·$CaCl_2 \cdot 2H_2O$ was added in small portions during the course of one-half hour to a mixture of 50 cc. of acetic anhydride and 65 cc. of pyridine, previously cooled in an ice-bath. The mixture was held in the ice-bath with frequent shaking for four hours and then kept in an ice chest for two days. When it was poured onto crushed ice, crystallization of β-mannose penta-acetate took place almost immediately. The crystals were filtered on a suction funnel, washed with water and dried at 35". The yield of this impure material was 5.5 g. The filtrate, after neutralizing with sodium bicarbonate and extracting with chloroform, gave a further 1.25 g. These two quantities of impure crystals were mixed and recrystallized from alcohol, yielding 6 g. of pure p-mannose penta-acetate, or 50% of the theoretical.

Summary

Two crystalline isomeric double compounds of d-mannose with calcium chloride have been prepared.

One, designated the First Isomer, shows an unusual course of mutarotation and an initial specific rotation which indicate that the sugar constituent of the double compound is a new form of mannose.

The extrapolated initial rotation of this compound shows a value for the mannose portion in good agreement with that previously calculated by Hudson for a 0-mannose of 1,5-ring structure.

A second isomer was obtained by evaporating an alcoholic solution of the first on a water-bath. This product is a double compound of the previously known 0-mannose and calcium chloride.

The preparation and study of compounds of the sugars with salts appear to offer a promising method for the discovery of new crystalline forms of the sugars.

X-RAY INVESTIGATIONS OF OPTICALLY ACTIVE COMPOUNDS

I. A PROOF OF MOLECULAR ASYMMETRY IN OPTICALLY ACTIVE PHENYLAMINOACETIC ACID[1]

BY GEORGE L. CLARK AND G. ROBERT YOHE

RECEIVED APRIL 29, 1929 PUBLISHED SEPTEMBER 5, 1929

Introduction

An investigation for the purpose of establishing the identity of the d- and l-forms of a substance capable of being resolved into these optically active antipodes, for the purpose of checking up on the similarity of the active and racemic modifications, and for the purpose of finding out whether, after all, the molecules of an optically active substance are asymmetric as first pictured by Pasteur in 1860, and by Le Bel and van't Hoff in 1874, may at first thought seem futile, since the theories concerning these things are so well established. But, as Stewart[2] says: "—— this state of affairs is not altogether healthy since it tends to repel original minds who find little interest in a subject which is apparently resting on a dead center of perfectness. At the present day it seems fashionable to suppose that certain views are so firmly established that no research into their foundations is worth the labor expended on it . . . it was supposed for many years that the composition of the atmosphere was definitely settled—and then the discoveries of Rayleigh and Ramsay showed how little was known of even this common mixture. With this object lesson before them, it is to be hoped that more organic chemists will find time to investigate some of the problems which are passed over by the bulk of workers who seem to place a label in the same category as an explanation."

The x-ray examination of optically active organic compounds is a field which is thus far practically untouched. No one has yet used the powerful rotating crystal method in a study of this type. W. T. Astbury[3] has made a study of d-tartaric acid, utilizing axial ratios and angles determined by optical methods, and measuring interplanar spacings by means of the Bragg spectrometer method. He finds that his results confirm the theory of van't Hoff and Le Bel, and that it is not possible to distinguish between the d- and l-forms of an optically active substance by means of x-ray diffraction methods.

Reis and Schneider[4] have recently presented further x-ray data for tartaric and mesotartaric acids.

There are two hundred and thirty space groups according to which crystals may be built. While most of these space groups can be built up of molecules which possess symmetry within their structure, there are a few which will admit of no molecular symmetry. If, in crystallizing, an optically active compound builds its crystalline form according to one of these space groups which will admit of no symmetry of the molecule this may be taken as direct evidence that its molecules are asymmetric. For this study a representative amino acid, phenylaminoacetic acid, was chosen in spite of the fact that no crystallographic or optical data are available in Groth's tables or elsewhere for the active or racemic forms of this compound. One of the chief purposes of the investigation was to show that a unique structural analysis can be made by means of x-ray diffraction results alone and without adopting the invariable practice of depending upon previous crystallographic information. The rotating crystal diffraction method has been made to combine goniometric orientation of crystals and the production of the fruitful layer-line patterns for rotation around three principal axes.

Experimental

A. The Phenylaminoacetic Acid Used.—Phenylaminoacetic acid was being resolved in connection with another investigation, and the d-, *l*- and dl-forms at hand were subjected to this x-ray examination.

The crude phenylaminoacetic acid was prepared at the University of Illinois by the following reactions[5]

$$C_6H_5CHO + NaCN + NH_4Cl \longrightarrow C_6H_5CHNH_2CN + NaCl + H_2O$$
$$C_6H_5CHNH_2CN + HCl + 2H_2O \longrightarrow C_6H_5CHNH_2COOH + NH_4Cl$$

It was found that the racemic amino acid could be recrystallized from hot dilute pyridine (2 volumes of water to 1 of pyridine), and that by very slow cooling of the solution well-formed crystals could be obtained. These were very small, however, the largest being about one mm. long and less than one mm. in thickness; m. p. 250–252°, uncorr.

The levorotatory form was obtained by following the procedure of Ingersoll and Adams,[6] which is essentially that of Betti and Mayer,[7] of fractional crystallization of the d-camphorsulfonate, the *l*-phenylaminoacetic acid d-camphorsulfonate being less soluble. Since the d-camphorsulfonate hydrolyzes readily in hot water, it was found best to use an excess of d-camphorsulfonic acid in this resolution. The separation of the forms was carried out as follows: 110 g. of dl-phenylaminoacetic acid, 206 g. of d-camphorsulfonic acid and 500 cc. of water were heated together, giving a clear solution which on cooling deposited crystals of the *l*-phenylaminoacetic acid d-camphorsulfonate. These were recrystallized from hot water using about 10% excess of d-camphorsulfonic acid to prevent hydrolysis and about 2 g. of Norite to decolorize the solution. The *l*-phenylaminoacetic acid was precipitated from a cold, saturated, aqueous solution of the *d*-

camphorsulfonate by adding dilute ammonium hydroxide until the solution was faintly alkaline. The crystals, after washing with water and drying, gave a rotation $[\alpha]_D^{20}$ $-152°$ in 0.133 N hydrochloric acid; $[\alpha]_D^{20}$ $-162.8°$ in 10% hydrochloric acid; $[\alpha]_D^{20}$ $-111°$ in water, this last value checking that of $-111.02°$ given by Betti and Mayer.[7] It was found that on slow evaporation of a saturated aqueous solution of the *l*-phenylaminoacetic acid, long needle-like crystals formed. One of the most perfect of these was used in the rotating crystal studies; m. p., subl. 245–248°, uncorr.; $[\alpha]_D^{20}$ (in 0.140 N hydrochloric acid) $-149°$. It may be noted here that the rotations observed varied widely with the concentration of the hydrochloric acid used as a solvent. No consistent melting point was obtained, which is in harmony with the results previously published. For example, St. Minovici[8] reports m. p. 227° (subl.); Fischer and Weichhold[9] report m. p. 305–310°; Betti and Mayer[7] report m. p. above 305°.

The d-phenylaminoacetic acid was obtained by extraction of the partially resolved (80% d-, 20% *dl*-phenylaminoacetic acid) acid precipitated from the mother liquor of the d-camphorsulfonate crystallization with ammonium hydroxide. The active form of phenylaminoacetic acid is more readily soluble in hydrochloric acid than the racemic, and is thus extracted from the racemic.[10] The d-phenylaminoacetic acid was precipitated by adding dilute ammonium hydroxide. The mother liquor from this precipitation, on standing for several days, yielded needle crystals, one of the most perfect of which was used in the x-ray work; m. p. 242–244°, uncorr.; $[\alpha]_D^{20}$ (in 0.105 N hydrochloric acid) $+147°$.

B. The **X-Ray** Equipment.—The x-ray tube used was of the Hadding–Siegbahn type equipped with a copper anticathode. It was operated at about 40 kilovolts and a current of about 12 milliamperes, the high potential being supplied by a Wappler special transformer, rectified by a Kenex rectifier. The radiation was not filtered, the K_α radiation of copper predominating to such an extent that filtration was found unnecessary.

A Müller Universal Spectrograph was used. This was equipped with a cylindrical camera of 5-cm. radius, and a goniometer head which greatly facilitated the accurate orientation of the crystal, as well as making it possible to measure the angles between the crystallographic axes by measuring the displacement necessary to bring another crystallographic axis parallel to the axis of rotation.

The time of exposure depended upon the focus of the cathode rays within the x-ray tube. A good focus giving a very intense beam of x-rays made possible the taking of good pictures in one to two hours' exposure, but for poorer focus and hence a less intense x-ray beam exposures of ten hours were necessary.

C. The Technique of Taking the Photographs.—The levorotatory form was studied first. The needle-like crystal was mounted on the goniometer mounting with a small drop of collodion so that the long axis of the crystal was perpendicular to the axis of rotation. The resulting photograph showed the crystal to be improperly aligned. The angle between

[10] Unpublished work from this Laboratory.

the two lines of interferences that cross at the position of the central beam was measured, and the crystal displaced half this angle, still keeping the long axis of the crystal perpendicular to the axis of rotation. By this means it was possible to bring the crystal into alignment so that one of the major crystallographic axes was parallel to the axis of rotation. The resulting layer line diagram is reproduced in Fig. 1. The crystal was then displaced 90°, still keeping the long axis of the crystal perpendicular to the axis of rotation. Another typical layer line diagram was thus obtained showing that another major crystallographic axis was now parallel to the axis of rotation, and that the angle between the two axes was 90°. The crystal was then displaced another 90°, this time bringing the long axis of the crystal parallel to the axis of rotation. Again a typical layer line diagram was produced showing that the third crystallographic axis was now parallel to the axis of rotation, and that the angle between this third axis and the plane of the first two must be 90°.

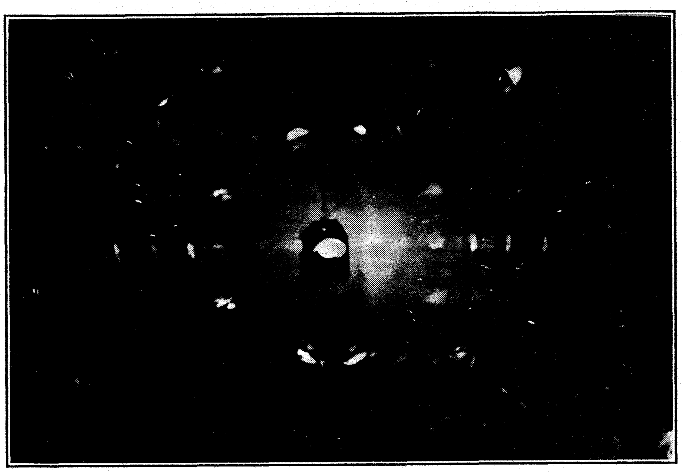

Fig. 1.

In this way the crystal was proven orthorhombic, independently of any optical data, since $\alpha = \beta = \gamma = 90°$. The layer lines of the rotation photographs make possible direct calculation of the "identity periods," or dimensions of the unit cell, and consequently the axial ratio in a manner which is verly clearly explained by Sir William Bragg.[11]

It is of interest to note the size of the crystals used in making these photographs, and others made of the dextrorotatory and racemic modifications. The dimensions of the crystal of 1-phenylaminoacetic acid were 4 mm. X 1 mm. X 0.1 mm.; those of the crystal of the d- form used were 4 mm. X

---

[11] Bragg, "An Introduction to Crystal Analysis," D. Van Nostrand Co., New York, 1929, p. 41.

0.3 mm. × 0.2 mm.; and those of the crystal of the racemic form were about 2 mm. × 1 mm. X 0.5 mm. Thus it may be seen that very small crystals can be used in work of this type; in fact it is advantageous to use small crystals since the resulting diffraction spots are sharper and can be measured more accurately. Furthermore, a small crystal is more apt to be free from imperfections.

D. Data for *l*-Phenylaminoacetic Acid.—In calculating the identity periods from the layer line photographs, use was made of the equation

$$I = \frac{n\lambda}{\sin \mu}$$

where **I** is the identity period, *n* the number of the layer line (i.e., 1st, 2nd, 3rd, ...), λ the wave length of the radiation used (λ Cu K_α = 1.54 Å.), and $\mu = \tan^{-1} e/a$, e being the distance measured on the film from the equator line to the nth layer line, a being 50 mm., the distance from the axis of rotation to the film. The following tables give the results obtained in calculating these identity periods.

TABLE I

DATA FROM FILM REPRODUCED IN FIG. 1 FOR IDENTITY PERIOD ALONG *c* AXIS

Goniometer scale readings: 13° 50′, 26° 20′

e, mm.	tan μ	sin μ	*n*	*I*, Å.
8	0.1600	0.1579	1	9.74
17	.3400	.3220	2	9.55
27	.5400	.4751	3	9.70
			Average	9.66

TABLE II

DATA FOR IDENTITY PERIOD ALONG *a* AXIS

10.5	.2100	.2056	2	15.0
15.8	.3160	.3013	3	15.3
21 8	.4360	.3996	4	15.4
			Average	15.2

TABLE III

DATA FOR IDENTITY PERIOD ALONG b AXIS

Goniometer scale readings: 103° 50′, 54° 00′

e, mm.	tan μ	sin μ	*n*	I, Å.
16	0.3200	0.3049	1	5.05

Though no more layer lines were obtained, this value of **I** checks exactly with values taken from a photograph using a flat film and stationary crystal, in which interferences corresponding to two layer lines were obtained, both values being 5.05 Å.

Thus the dimensions of the unit cell are calculated directly to be a = 15.20, b = 5.05 and *c* = 9.66 Å. (axial ratio 3.01 : 1 : 1.91) and, since the unit cell is orthorhombic, the volume of this cell is 15.20 × 5.05 × 9.66 Å.^{3} = 742 Å.^{3}

The density of the crystals was obtained by suspending them in a liquid of known density. The liquid used was petroleum ether. Although *l*-phenylaminoacetic acid is insoluble in petroleum ether within the limits of error of this determination, the precaution was taken to allow the petroleum ether to stand in contact with the I-phenylaminoacetic acid for several hours before the determination was started. The density so obtained is 1.30.

Then N, the number of molecules in the unit cell, is obtained from

$$N = \frac{(\text{volume of unit cell})\ \text{X}\ (\text{density})}{\dfrac{(\text{mass of H atom})}{(\text{molecular wt.})} \times (\text{Avogadro's number})}$$

$$N = \frac{5.05 \times 9.66 \times 15.2 \times 10^{-21} \times 1.30}{(151/1.008) \times 1.663 \times 10^{-24}} = 3.88$$

This is very nearly four, so that N, the number of molecules in the unit cell, is taken as four.

Thus it was shown that *l*-phenylaminoacetic acid is orthorhombic, and contains four molecules per unit cell. These considerations alone would narrow down the possible space groups to the following:[12] C_{2v}^1, C_{2v}^2, C_{2v}^3, C_{2v}^4, C_{2v}^5, C_{2v}^6, C_{2v}^7, C_{2v}^8, C_{2v}^9, C_{2v}^{10}, Q^1, Q^2, Q^3, Q^4, all of which are based on Rravais lattice Γ_0. In the C_{2v} space groups the a and *b* axes are interchangeable. Of these space groups, C_{2v}^1 and Q^1 are at once eliminated as they call for no abnormal spacings; in these results (see Tables IV, V and VI) it is seen that the 9.66 spacing appears only as the identity period

(Table I), not as true first order reflection, and again halved, as 4.84 (Table IX). The same is true also of the 5.05 spacing. Q^3 and Q^4 are eliminated readily since they call for the halving of both {1 0 0) and {0 1 0}, while the 15.2 spacing appears very strongly in these results. Space group C_{2v}^2 calls for halving of {0 k I] if I is odd; this condition is fulfilled (Table VIII). C_{2v}^3 requires halving of {h 0 I} if I is odd; this is not true, and C_{2v}^3 is eliminated (Table VII). In C_{2v}^4 {*h* 0 *l*} is halved if h is odd; that this is true may be seen in Table VII. C_{2v}^5 calls for halving of {h0 I} if h is odd, and halving of {0 k *l*} if *l* is odd. Tables VII and VIII show both of these conditions to be fulfilled, and since C_{2v}^2 calls for only the latter of these two, and C_{2v}^4 for only the former, these two are eliminated. C_{2v}^6 and C_{2v}^7 require that {*h* 0 *l*} be halved if h + I is odd; Table VII shows that this is not the case, thus eliminating these two. In C_{2v}^8 {0 k *l*} must be halved if k is odd; Table VIII shows that this is not the case. C_{2v}^9 and C_{2v}^{10} call for halving of {0 k I] if k + *l* is odd; that this is not the case is readily seen from Table VIII. This leaves only space groups C_{2v}^5 and Q^2. Q^2 calls for only one abnormal spacing, the halving of {0 0 1}.

That other abnormal spacings occur can be seen from Tables VII and VIII; these two tables also show remarkable agreement with the conditions required for space group C_{2v}^5. The conclusion is, therefore, that *l*-phenylaminoacetic acid belongs to space group C_{2v}^5, which by its purely geometric derivation demands four asymmetric molecules per unit cell.

TABLE VII

SPACE GROUP ASSIGNMENT

One of the conditions for space group C_{2v}^5 is that $(h0l)$ must be halved if h is odd. This condition also applies to space group C_{5v}^9. In this table Col. 3 − means that the spacing indicated should not appear, + means that it should. The observed values are taken from the photograph for which the crystal was rotated about the 5.05 axis; calculated spacings based on a = 15.2, b = 5.05.

[a] This is in a region where apparently several interferences lie close together, giving a broad diffuse spot. Using a smaller crystal of the d-form, sharper spots were obtained; one was found corresponding to d = 4.84 A. [b] Very faint. [c] Possibly Cu K_β line from spacing 2.10 Å.

Wyckoff[13] gives the following as the coordinates of the four equivalent points in space group C_{2v}^5: (x, y, z), $(\bar{x}, \bar{y}, z + 1/2)$, $(x + 1/2, \bar{y}, z)$, $(1/2 - x, y, z + 1/2)$. A drawing of the unit cell is shown in Fig. 2. Since any point on the lattice may be chosen as the origin, a different origin has been selected for each of the four points in such a way that all four points fall in

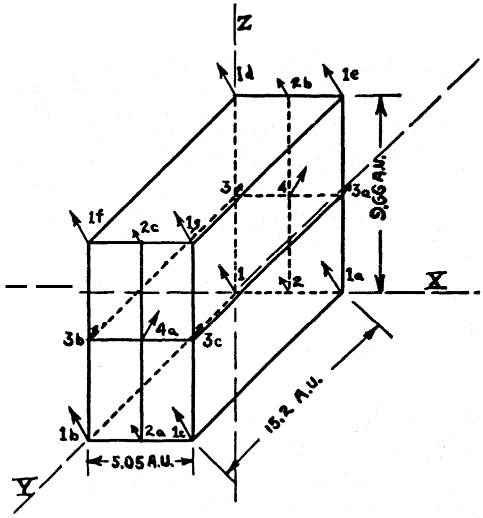
[a] See note a under Table VII. [b] See note c under Table VII.

the same unit parallelopiped. The other points that have the same relation to the lattice as these four are then placed. There are thus eight molecules at the eight corners of the cell. Since each of these is shared by eight unit parallelopiped~, one-eighth of these, or one, belongs to one unit cell. There are eight others that lie on edges of the parallelopiped. Each of these is shared by four unit parallelopiped~, whence one-fourth, or two, belong to the one unit cell. There are two more that lie in faces of the parallelopiped; since each of these is shared by two cells, one-half of these, or one, belongs to the one cell. Thus the total is four molecules per unit cell. It readily can be seen from the drawing that two of the spacings corresponding to the unit cell dimensions will be halved, while the third will not. As was observed above, the 9.66 and 5.05 Å. spacings did not appear except on the layer line diagrams, while the 15.2 Å. spacing was not halved. It may also be seen that the (0 1 0) planes are densely populated with molecules; this explains the high intensity of the reflections from these planes.

It is evident that the *c* axis (identity period 9.66 Å.) differs from the *a* and *b* axes in that it coincides with the dyad screw axis of symmetry.[12]

In explanation of Fig. 2, Arrow 1 is considered pointing behind the ZX plane and to the left of the YZ plane. Arrows 1 a, b, c, d, e, f and g are parallel to 1. Arrow 2 points in front of the ZX plane and to the left of a plane parallel to YZ. Arrows 2 a, b and c are parallel to 2. Arrow 3 points in front of the ZX plane and to the right of the YZ plane. Arrows 3 a, b and c are parallel to 3. Arrow 4 points behind the ZX plane and to the right of a plane parallel to YZ. 4a is parallel to 4. By a rotation of 180° and a translation of $c/2$, 1 will coincide with 3, 2 with 4, etc.

No attempt is made here to determine the orientation of the molecules within the unit cell other than the molecular asymmetry demanded by the space group, and the relative positions of the molecules as shown in the diagrams. To determine the relative positions of the atoms within any one molecule, and to determine just how these atoms are situated with respect to the axes requires careful measurement of the intensities of various reflections; even then many assumptions must be made. In this investigation it was considered that the intensity data were not sufficient and that the assumptions involved were not justifiable for the calculating of molecular sizes, shapes and orientations within the unit cell. Obviously the molecules must lie with their greatest length in the general direction of the *a* axis (15.2 Å.).



The four equivalent positions are shown at 1, 2, 3 and 4.

Fig. 2.—Diagram of the unit cell of active phenylaminoacetic acid, $C_6H_5CHNH_2COOH$.

It is of interest to compare the structure of active phenylaminoacetic acid  $C_6H_5-\overset{H}{\underset{NH_2}{C}}-COOH$ (I) with that of phenylacetic acid  $C_6H_5-\overset{H}{\underset{H}{C}}-COOH$ (11), recently studied by Patterson.[14]

Molecular symmetry	**None**	**Center**

The dimensions of the unit cells are remarkably similar and the comparison further verifies the correctness of the structure assigned. The presence of the basic amino and acid carboxyl groups in the same molecule affects profoundly the forces holding the molecule in the unit cell, as clearly shown by the inordinately high melting point. This is a further complication in interpretation of intensity data.

It is very important to note that the space group C_{2v}^5 admits of no possible molecular symmetry. Thus the classical theories of van't Hoff and Le Bel are confirmed, for here an examination has been made of an optically active substance, and the space group of the crystal requires that the molecule be asymmetric.

E. The Structure of d-Phenylaminoacetic Acid.—A rotation diagram of a crystal of this enantiomorph gave identically the same results as for the 1-acid. For the rotation around the b (5.05 Å.) axis the 15.2 Å. spacing shows up strongly. It is interesting to note here that the 9.66 Å. spacing appears halved, as spacing 4.84 Å., while for the levo form there was no clearly defined interference. This is due to the fact that the crystal of dextro form used was smaller, and therefore the interferences were more distinct than on the film from the 1-form, where the use of a larger crystal gave a more diffuse spot at the corresponding position. Powder photographs made with the General Electric X-Ray Diffraction apparatus, using the K_α radiation of molybdenum present further proof of the identity of the two active forms of phenylaminoacetic acid. It is thus quite clear

TABLE IX

that the structure of d-phenylaminoacetic acid is the same as that of the l-form, and that these results show that X-ray diffraction methods offer no means of distinguishing between the two.

F. Study of the Racemic Modification.—A complete analysis of the crystalline structure of the racemic modification of phenylaminoacetic acid will be presented in another paper. However, ample proof is at hand that it differs from the active forms. In the powder spectra it can be readily seen that there is no correspondence of diffraction lines between active and racemic forms. A rotating crystal photograph of the racemic form was made using the same apparatus as described above. The identity period calculated from this photograph is 4.26 Å., differing widely from any observed in the case of the active form. This evidence is sufficient to prove that the racemic form has a different crystalline structure than the active forms.

Summary

1. An x-ray examination by the rotation and powder diffraction methods has been made of the *d*-, *l*- and racemic forms of phenylaminoacetic acid. The power of the rotation method is shown by the fact that a straightforward crystal structure analysis was possible although no crystallographic or optical data were available.

2. The d- and *l*- forms are shown to crystallize in the orthorhombic system, upon Bravais lattice Γ_0, space group C_{2v}^5. The unit cell containing four molecules has the dimensions $a = 15.2$, $b = 5.05$, $c = 9.66$ Å.

3. The fact that space group C_{2v}^5 admits of no molecular symmetry confirms the classical theories of van't Hoff and Le Bel connecting molecular asymmetry with optical activity.

4. It has not been found possible to distinguish between the d- and *l*-forms by means of x-ray diffraction methods.

5. The crystal form of the racemic modification differs from that of the optically active forms.

SOME ORGANIC ACIDS OF SUGAR CANE MOLASSES

BY E. K. NELSON

RECEIVED MAY 9, 1929 PUBLISHED SEPTEMBER 5, 1929

In continuation of the work in this Laboratory on the non-volatile acids of fruits and plant products, an investigation was made of the acids of sugar cane molasses.[1] While considerable work has been done on this subject, it appeared to be worth while to determine the acids of molasses by the ester distillation method.

The organic acids of cane molasses comprise the acids naturally occurring in cane juice, chiefly aconitic acid, and the acids formed during the process of manufacture, such as formic, acetic and lactic acids. Of the amino acids formed from the hydrolysis of proteins, aspartic and glutamic acids have been found in molasses. Dark colored uncrystallizable acids are also present, but none of these is considered in the present paper.

The presence of aconitic acid in cane juice was first noted by Arno Behr,[2] who separated it in the form of an acid ammonium salt.

Malaguti[3] records that although oxygen is without influence on neutral sugar solutions, formic acid is formed in the presence of weak acids. He concluded that the acid caused partial inversion and that the formic acid resulted from the action of oxygen on invert sugar. As early as 1851, formic and acetic acids were mentioned by Michaelis[4] as being present in beet molasses, and this has been confirmed by later investigations.

It has been shown by numerous investigators, among whom may be mentioned Niedschlag,[5] Isaac[6] and Tollens,[7] that acetic and lactic acids are formed by the action of alkalies on sucrose, and Tollens states that the lime treatment of beet juice probably produces most of the lactic acid found in the products of sugar manufacture, and that this acid may amount to 0.5% of the molasses.

More recently the acids in sugar cane juice have been investigated by Yoder,[8] who found aconitic acid and a small quantity of malic acid. From 6 liters of juice Yoder isolated 3 g. of aconitic acid and 0.046 g. of malic acid. He reported the absence of tartaric, succinic and citric acids.

The material used in the investigation reported in this paper was a sample of molasses from the Central Fajardo, Porto Rico.[9] The analysis accompanying the sample was as follows: Brix, 83.90; dry substance, 83.86; apparent purity, 31.00; true purity, 36.54; glucose, 28.86; sucrose, 30.64; ash, 7.52; dye value,[10] 3373.

The alkalinity of the ash was equivalent to 57.1 cc. of normal hydrochloric acid per 100 g. of sample and the free acid corresponded to 26.0 cc. of normal hydrochloric acid per 100 g.

The volatile acids consisted of a mixture of formic and acetic acids, 0.097 g. of formic and 0.2 g. of acetic acid being recovered per 100 g. of molasses.

The predominating non-volatile acid was aconitic acid (0.8%). Small quantities of malic, citric and lactic acids were found.

Experimental

Volatile Acids.—Volatile acids were distilled from three kilos of molasses to which sufficient hydrochloric acid had been added to liberate the combined acids. The distillate was neutralized with standard barium hydroxide solution and evaporated to dryness. The dried barium salts were weighed and from the weight, taken in conjunction with the quantity of barium necessary to neutralize the distillate, the proportion of barium formate and barium acetate was calculated.

The distillate required 657 cc. of 0.25 *N* barium hydroxide to neutralize it, and the barium salts weighed 20.089 g. From these data the weight of the barium formate was calculated to be 7.195 g. and that of the barium acetate, 12.894 g.

Non-Volatile Acids.—The non-volatile acids were precipitated as lead salts from two kilos of molasses. The acids recovered from the lead salts were dissolved in water and extracted four times with ether. The ether removed 4.06 g. of a crystalline acid melting at 185 to 186° and giving no depression in melting point on admixture with aconitic acid. The aqueous solution was then evaporated to dryness, esterified in the usual manner and the esters, 7.8 g., were fractionated at 10 mm. Less than 1 cc. distilled under 150°. This distillate afforded a hydrazide crystallizing like malic hydrazide, melting at 178 to 179° and showing no depression in melting point when mixed with malic hydrazide.

Fraction **2,** when redistilled, boiled at 160° and weighed 4.5 g. As the hydrazide of aconitic acid is very hygroscopic and not easily identified, this fraction was saponified, acidified and extracted with ether, yielding pure aconitic acid. Four and one-half grams of ethyl aconitate correspond to three grams of aconitic acid.

The third fraction, boiling above 160°, measured 0.5 ec. When this fraction was treated with hydrazine hydrate, a hydrazide separated which had the appearance of citric hydrazide. It melted at 100 to 103°. Optical crystallographic examination[11] proved its identity as citric hydrazide.

In order to avoid losses by esterification, a direct, continuous ether extraction was made on the acids recovered by precipitation of three kilos of molasses with lead acetate.

---

[9] The Carbohydrate Division of this Bureau furnished material for this investigation with the analysis of the sample.

[10] Badollet and Paine, *Int.* Sugar ***Journal,*** 28, **23,** 97, 137 (1926).

[11] This examination was made by G. L. Keenan of the Food, Drug and Insecticide Administration.

The concentrated solution of the acids was extracted in a Bacon-Dunbar "perforation" outfit until only negligible quantities of extractive were removed by the ether. In this manner 23.9 g. of aconitic acid was obtained, or 7.97 g. per kilo.

The acid solution remaining after the extraction by ether was neutralized with calcium carbonate, the excess being removed by filtration. The solution, on boiling, deposited a considerable precipitate. Filtered and dried, this weighed 1.76 g. The acid isolated from this calcium salt melted at 142 to 144° and gave no depression when mixed with citric acid. Optical crystallographic examination confirmed its identity as citric acid.

A special examination of Dominican molasses was made for lactic acid. Four hundred grams of molasses was acidified, diluted with 200 cc. of water and extracted for twenty-four hours with a rapid stream of ether in a perforation outiit. The ether-soluble acids were neutralized with barium hydroxide, diluted to 100 cc. and then 200 cc. of alcohol was added. After this solution had stood overnight, the undissolved barium salts were filtered off. The filtrate was freed from barium with the required quantity of sulfuric acid, the filtrate from barium sulfate was boiled with an excess of zinc carbonate and filtered. The filtrate was concentrated to 5 cc., 15 cc. of alcohol was added and the crystalline precipitate was filtered, dried and weighed. It weighed 0.315 g., corresponding to 0.19 g. of lactic acid, or 0.05% of the molasses. Optical crystallographic examination, oxidation to acetaldehyde and the hydroxy acid test with ferric chloride established its identity as zinc lactate.

The acids recovered from the insoluble barium salt were subjected to fractional crystallization. All fractions were aconitic acid. No succinic acid or tricarballylic acid could be separated from any of the fractions or identified by optical crystallographic examinations.

Summary

The acids of molasses were found to be formic acid, about 0.1%; acetic acid, 0.2%; aconitic acid, 0.8%; lactic acid, 0.05% and small quantities of malic and citric acids. By establishing the presence of formic, acetic, aconitic, malic and lactic acids in sugar cane molasses, the results of previous investigators were confirmed. Citric acid has not previously been reported as a constituent of sugar cane molasses.

III. THE CHEMICAL EFFECTS OF SEMI-CORONA DISCHARGE IN GASEOUS HYDROCARBONS[1]

BY S. C. LIND[2] AND GEORGE GLOCKLER[3]

RECEIVED MAY 10, 1929 PUBLISHED SEPTEMBER 5, 1929

In two previous papers[4] the authors showed that when ethane is subjected to electrical discharge of various types, condensation to liquid by the elimination of hydrogen and methane always takes place. The identity of the gaseous products and of their amounts relative to those found when alpha particles act on hydrocarbons[5] led to the conclusion that the reactions are entirely similar in being due to ionization. Hence the same kind of mechanism is operative in both cases. Especially is that true of the less intense types of discharge such as in the ozonizer or Siemens tube. In corona and semi-corona discharge, while the gaseous and liquid products remain the same, formation of solid on the walls also occurs. In the semi-corona and corona the reaction rate is much more rapid because the energy is more fully expended in ionizing the gases instead of being wasted in getting through the glass wall, as in the Siemen's tube. However, this is not pure gain in the production of liquid because the solid formed in the corona types of discharge is equal in weight to the liquid. The solid hydrocarbons deposit on the glass (or metal) wall in a gummy adherent coating. Their average molecular weights remain unknown as no solvent has been found for them. Free carbon also forms on the metal electrodes in small tree-like deposits. Its amount is, however, relatively small, as will be seen in Table VIII.

In the present work eleven semi-corona tubes of pyrex glass (Fig. 1) were connected in series as to gas flow but in parallel as to electrical flow. The eleven central electrodes of $^1/_8$-inch aluminum rod were connected in parallel to an A. C. source (Thordarson transformer) with 18,000 volts on the secondary. The discharge took place across the annular space of 0.5 inch to the outer glass wall of the tubes, all of which were immersed in an electrolytic solution (sodium carbonate) which was grounded, thus constituting the other electrode. The solution was heated to 70° for the purpose of causing the first liquid droplets formed on the wall to flow off to the trap more readily, thus avoiding production of liquids of high viscosity and molecular weight by continued action of the

---

[1] This paper includes part of an investigation of "The Effect of Electrical Discharge upon Gaseous Hydrocarbons," Project No. 8 of American Petroleum Institute Research. Financial assistance has been received from the research fund of the American Petroleum Institute, donated by the Universal Oil Products Company. This fund is administered by the Institute with the cooperation of the Central Petroleum Committee of the National Research Council.

discharge on the liquid already formed (see Paper II). All eleven traps were cooled to a common low temperature suitable to each gas (Table VIII), to cause condensation and to prevent further ionization in successive tubes of heavy gas molecules which would give a still denser liquid. Gas samples were taken from beyond the last discharge tube from time to time. The liquid products were drawn off separately from each tube by cutting its fine glass tip. Solid products were removed (with difficulty) from the wall of each tube after the system had been cut apart.

The entire reaction takes place in a closed glass system (pyrex) out of access to air, so that products containing only hydrogen and carbon were obtained. The first experiment using the series flow apparatus (Fig. 1) was made with propane. These results will be described in detail, and the same procedure and apparatus were used with the other hydrocarbons, methane, ethane, butane and ethylene, data for which are also given in this paper.

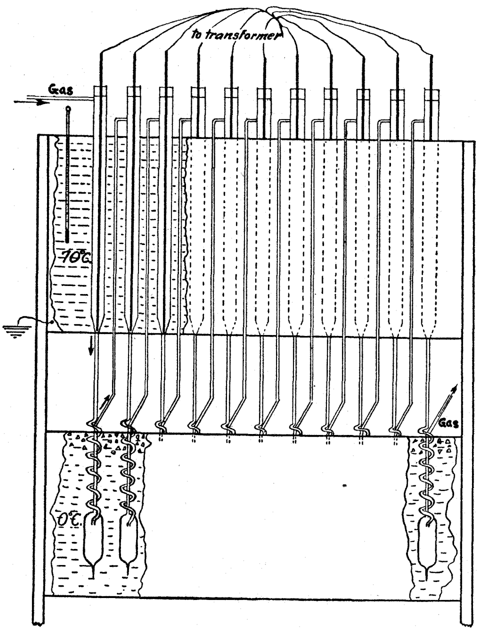

Fig. 1.—Semi-corona apparatus series gas flow.

Propane. Experiment No. 1.—In this experiment no heater was used for the discharge tubes, as it was hoped that the electrical energy applied would maintain their temperature at 60–70°. Actually the sodium carbonate electrolyte surrounding these tubes and hence controlling the temperature of their outer walls, in which we were most interested, would heat only to 35°. The accumulation of liquid in the traps being open to observation, the run was ended when any trap first became full of liquid, in this case the last one, No. 11. By collecting a sample of gas of definite volume and then condensing all gases in the sample at liquid-air temperature, only hydrogen and methane are left. Since they are always the principal gaseous products (Paper I), the course of the reaction can be followed by determining their combined partial pressure. The following data show how the reaction gradually became slower in the whole system, due to the

TABLE I

DECREASE IN REACTION RATE DUE TO DEPOSITION OF SOLID ON THE GLASS WALL

EXPERIMENT NO. 1 WITH PROPANE

Time	Pressure, mm.	Remarks

2–17–28	270.0	
2–21–28	180.0	

decrease in efficiency of each tube owing to the deposition of the solid hydrocarbons on the wall, which diminishes the current and hence the ionization and chemical action in each tube.

The distribution of liquid products in successive tubes in the series is shown in Table II. The total yield of liquid in this experiment was **37.09** g. from 550 g. of propane, using 51.5 kw. hours.

Properties of **Liquid** Condensates.—The following properties have been determined for the liquid condensate of each tube: index of refraction for sunlight at 21°, density, average molecular weight and the color (arbitrary scale of the Union oil colorimeter).

TABLE II

[a] The twelfth trap was not related to any ozonizer. It was an additional condensation **trap,** placed at the exit end of the apparatus. Its purpose was to catch any condensable material not caught in the eleventh trap.

The properties given in Table II are shown graphically in Fig. 2. It should be remembered that the liquids are all very complex. No efforts to fractionate them will be reported in the present paper. All data refer to the liquids as obtained.

Correlation of **Properties.**—Inspection of the curves of Fig. 2 shows at once that index of refraction, density, average molecular weight and color are all correlated properties and hence show similar curves when plotted in the order of the successive traps. All four properties show a marked fall when proceeding in the direction of flow. Irregularities are probably due to accidental variations in individual tubes, either wall thickness or eccentricity of the central electrode.

This fall in average molecular weight, etc., is closely but inversely related to the yield per trap. The greater the yield per tube, the faster the flow of liquid from the walls, hence the shorter the time of exposure to further discharge which has already been shown (Paper II) to be the cause of *high* condensation, average molecular weight, color, density, viscosity, etc.

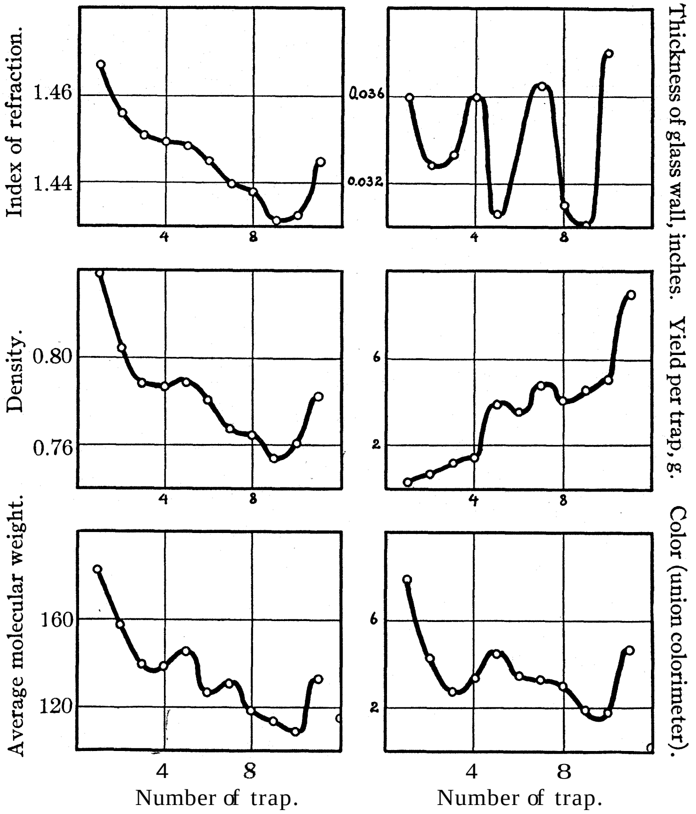

Fig. 2.—First propane run—eleven semi-coronas in series.

In order to demonstrate more clearly the correlation of index of refraction to density and to molecular weight, the data of Run No. 1 with propane have been plotted in two curves (Fig. 3). These curves have been used to obtain the density and molecular weight of the liquid product of other gaseous hydrocarbons from their indices of refraction. The agreement with values found directly by the freezing point lowering in benzene was fairly satisfactory, as is seen in Fig. 5, where the double circles show the actual check determinations in comparison with the predicted curves.

Yield per Tube.—As has just been seen the yield per trap increases on passing to successive tubes in the direction of gas flow. Three causes are to be considered: (1) a purely physical inefficiency or lag in vapor condensation, which would give an increased concentration in later tubes, further augmented by electrical generation of new condensable vapor. This effect might not be expected to increase through many tubes but to reach a steady state; however, it should be remembered that presumably the more of heavy molecules reaching a given tube, the easier it is to produce ionization there and hence more of the condensable product is formed. *(2)* The carrying over to higher tubes of molecules already condensed (chemically) but not sufficiently so to condense physically to liquid. These heavy readily ionized molecules also supplement the yield. (3) *A delayed chemical condensation* exists, as demonstrated in Paper II, p. 1771. All three of these effects work in the same direction to give more liquid in successive tubes. It is not now possible to evaluate the influences separately. It is evident that there would be a limit to this increase though it is not reached in this case, but is in propane Run 2, where, on account of a slower rate of flow and consequent earlier depletion of reactant gas, a maximum is passed. The conversion of total propane to liquid product is only 6.7% in Run 1 (see Table VII).[6]

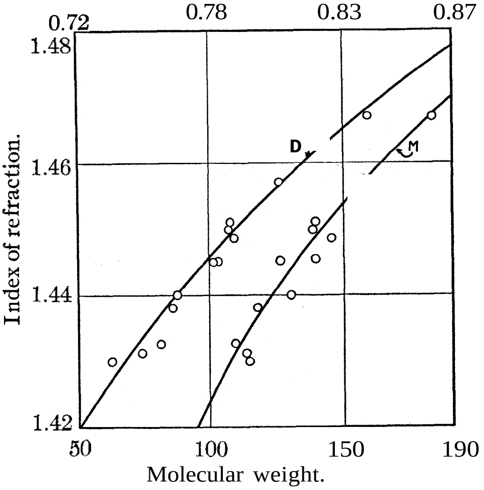

Fig. 3.—Molecular weight and density as functions of index of refraction. First propane run in eleven semi-corona apparatus.

TABLE III

EXPERIMENT NO. 1 ON PROPANE. ANALYSIS OF INITIAL AND EFFLUENT GASES

Initial gas		Effluent gas	
Permanent gases	0 12%	$H_2 + CH_4$	26.06%
C_2H_6	0 51	C_2H_6	7.05
C_3H_8	99 12	C_3H_8	64 50
C_4H_{10} (and higher)	0.42	C_4H_{10} (and higher) by difference	2.39
Total	100.17	Total	100.00

Solid Deposits.—The glass walls were covered with a resinous inert solid deposit of the character already described, the amount of which was

---

[6] The efficiencies given always refer to the amount of initial gas sent through the apparatus. The efficiency of the ozonizers decreased during the experiments (see Tables I and IV) and it was not possible to calculate the actual amount of initial gas used from the gas analysis.

not determined in this run. The aluminum rod electrodes had a deposit of carbon in tree-like formation, the amount of which was relatively small but undetermined (compare Table VIII).

Propane. Experiment 2.—The same sample of gas was used as in Experiment 1, and the same apparatus (Fig. 1), the chief difference being that the rate of flow was reduced from 1.45 in Run 1 to 0.54 liters per hour in Run 2. Due to this slower rate of flow, a number of differences are observed owing to the more rapid depletion of propane, as may be seen by comparing the following with corresponding data for Run 1.

TABLE IV

DECREASE IN REACTION RATE DUE TO DEPOSITION OF SOLID ON THE GLASS WALL

EXPERIMENT 2

3-10-28	220.0	

Owing to the higher utilization of propane (60% to solid and liquid against 6.7% to liquid or 13% estimated for liquid and solid in Run 1) the yield per trap passes a maximum at the eighth tube and then falls off in the ninth, tenth and eleventh (Fig. 4 and Table V). The data are given in Table V and plotted in Fig. 5. Inspection of the latter shows the same kind of correlation between index of refraction and color as in Run 1, and in addition a close correlation, almost equality, between the

Liquid and solid per kw. hour, g.	[a]	0.985

[a] The solid deposit was not determined in Propane Run 1, because it was first discovered there while attempting to clean the apparatus. In cleaning the apparatus with hot chromic acid copious evolution of carbon dioxide from the wet oxidation of the solid on the wall was noticed.

Results for Other Hydrocarbons—Methane, Ethane, Propane, Butane and Ethylene.—Having in the foregoing part of this paper given and explained in considerable detail the results obtained using propane as initial gas, the results for the four other hydrocarbon gases studied can be rather briefly summarized, as they are quite similar in most respects to those obtained for propane.

The eleven tube semi-corona apparatus was again used. All of the hydrocarbons examined give liquid condensates of the same general character. The relation between index of refraction, molecular weight and density is the same for the different liquid condensates, which is interpreted to mean that these liquids are all of the same type. This is supported by our ability to deduce their densities and molecular weights from their indices of refraction by using the corresponding curves from propane. Moreover, all of the condensates have a similar terpene-like odor. The results for all five gases are summarized in Table VIII.

Discussion of Results

The results for propane, butane and ethylene were obtained under quite comparable conditions. This is not equally true of the experiments with methane and ethane, for which the runs were of much shorter duration due to premature failure of the glass under discharge with the result that formation of solid on the walls had only begun; consequently the clean tubes appear unduly efficient with respect to yield of liquid per unit weight of methane or ethane used or per unit of electrical energy applied to them, in comparison with results for the other gases.

Of course, the most satisfactory basis of comparison of the reaction yields for the different hydrocarbons would be in terms of yield per ion-pair; but since the ionization can neither be measured nor calculated,[7] we must be content with relative rather than absolute comparisons. It has been shown that the reactions have the same general character as those produced in the same gases by alpha radiation, and are presumably due to ionization. In the case of ozone formation by high-speed cathode rays,

[7] Lind, *Trans. Am. Electrochem. Soc.*, **53,** 26 (1928).

Busse and Daniels[8] have recently made a satisfactory estimate of the ratio (yield/ion pair) by assuming the total energy reaching their reaction vessel to be wholly expended in producing oxygen ions. Since such a large proportion of energy in the semi-corona discharge is lost to the wall, we cannot make their assumption. It appears more plausible to assume that so much of our energy is lost to the wall that the condition is more like that of alpha particles in vessels so small that all alpha particles cross the entire gas space, and that at the same pressure the amount of reaction in different gases is proportional to the product of the specific ionization yield per ion pair (M/N)—a comparison similar to the one made[9] for the results of Hutchinson and Hinshelwood[10] for the decomposition of NH_3 and N_2O in different tubes under conditions of equal current flow. It is not implied that any single electron traverses the entire gas space, but that under conditions of equal electron flow the total ionization and chemical action in the different gases will be relatively in the proportion given by the product:[11] ks $\times$ M/N where *ks* is Bragg's specific (molecular) ionization and M/N is the yield of molecules M reacting per N ion pairs.

Two assumptions are involved: (1) that the relative specific molecular ionization by electrons is the same as by alpha particles, which seems by far more plausible than to assume, as has been sometimes done by others, that the probability of ionization by electrons is proportional to the number of molecules present, regardless of their size or nature; and (2) that the yield (M/N) is the same, or, more generally, that the chemical behavior of ions is the same, whether produced by bombardment by electrons or by alpha particles. If the ions produced are identical, this postulate must be true, other conditions being alike. Therefore, we should expect the relative yields to be roughly proportional to those shown for ks X M/N.

TABLE IX

THEORETICAL RELATIVE YIELDS OF LIQUID FROM DIFFERENT GASEOUS HYDROCARBONS UNDER ELECTRICAL DISCHARGE

Hydrocarbon	CH_4	C_2H_6	C_3H_8	C_4H_{10}	C_2H_4
ks[12]	1.01	1.97	3.05	4.02	1.65
M/N[12]	2.0	2.0	2.0	2.0	5.0
ks X M/N	1.0	1.95	3.02	3.99	4 08
Corrected	0.25	0.98	3.02	3.99	4.08

If by yield we mean *liquid* (and solid) formed, then the relative values for methane and ethane must be yet further reduced because in a reaction

of simple doubling such as $2CH_4 = C_2H_6 + H_2$ and $2C_2H_6 = C_4H_{10} + H_2$, neither of the gases can reach a condensable stage in a single step but must be acted on again (C_4H_{10} once and C_2H_6 twice), so that perhaps the actual relative values would be improved by dividing that for C_2H_6 by two and that for CH_4 by four. The higher numbers from propane up can all reach the liquid stage by a single doubling.

Some general resemblance, at least to the order given above, can be seen by inspecting the yields per kw. hr. or also per gram of gas used (Table VIII), but the picture is a very distorted one on account of the differences in the amount of solid on the different tubes, which as already mentioned was practically absent for CH_4 and C_2H_6 on account of the short time for accumulation. Hence, the relative yields from ethane and methane appear higher than they should; on the other hand, that of ethylene is depressed on account of the abnormal amount of solid formed.

It may appear strange that all of the hydrocarbons in spite of the great differences in their densities, molecular weights, etc., give liquids of about the same properties with respect to density, average molecular weight, etc. Striking as this may appear on first thought, it is a simple consequence of multiple doubling and of the experimental arrangement so as to arrest further doubling by condensing the product in low temperature traps outside of the zone of reaction. By changing the temperature of the discharge region and of the traps, the properties of the liquids could be varied at will, and all of the liquids brought to equal molecular weights of some other value in an arbitrary manner.

The authors wish to thank Mr. J. L. Wilson, who has assisted in this work as American Petroleum Institute Research Assistant.

Summary

1. Like ethane, the other lower hydrocarbons, methane, propane, butane and ethylene condense to liquid and solid hydrocarbons in semi-corona discharge (central aluminum rod in a (pyrex) glass cylinder).

2. The condensation of saturates is brought about by the elimination of hydrogen and some methane as under alpha radiation.

3. In series gas flow through a number of discharge tubes, the amount of liquid condensate increases in successive tubes. If the rate of flow be so slow that depletion of reactant becomes considerable, then a maximum of liquid yield is attained in an intermediate tube.

4. The liquid products obtained from different hydrocarbons or in different tubes from the same hydrocarbon are similar in physical properties, when obtained at the same trap temperature.

5. The liquid products are very complex. Fractionation was not attempted in the present work.

6. Solid hydrocarbons are obtained in slight amount in the Siemens

tube, in larger quantity equal to that of liquid in the corona tubes. The solid is gummy or resinous, inert toward solvents and chemical reagents except strong oxidizing reagents.

7. In corona discharge a small amount of free carbon is deposited on the metal electrode in tree-like formation.

8. A close correlation of index of refraction, molecular weight, density, color and viscosity characterizes all the liquid products. Increase in all these properties is inversely proportional to the *yield,* for which a simple explanation is given.

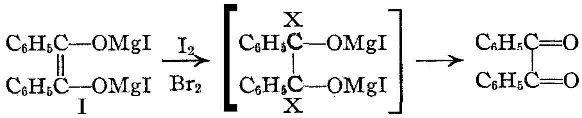
OXIDATION OF BENZOINS TO DIKETONES WITH IODINE

BY BEN B. CORSON AND ROBERT W. MCALLISTER

RECEIVED MAY 10, 1929 PUBLISHED SEPTEMBER 5, 1929

Benzoin, anisoin, piperoin, furoin, etc., are easily oxidized to the corresponding diketones by various methods. On the other hand, the conversion of aliphatic analogs of benzoin such as butyroin, $C_3H_7CHOHCOC_3H_7$, into diketones is not so convenient. We have studied the oxidizing effect of iodine, thinking that the reaction might be applicable to aliphatic acyloins. Solid aromatic acyloins were used in the investigation since they are easier to manipulate than the liquid aliphatic analogs. Although the reaction seems of no value in the preparation of aliphatic diketones, some of the results which came to light are of general interest.

The reaction is based on a recent observation of Gomberg and Bachmann[1] that benzil results from the action of iodine or bromine on stilbenediolate (I).



$$\begin{matrix}C_6H_5C\text{—}OMgI\\ \| \\ C_6H_5C\text{—}OMgI\end{matrix} \xrightarrow[Br_2]{I_2} \left[\begin{matrix} X\\ C_6H_5C\text{—}OMgI\\ | \\ C_6H_5C\text{—}OMgI\\ X\end{matrix}\right] \longrightarrow \begin{matrix}C_6H_5C{=}O\\ |\\ C_6H_5C{=}O\end{matrix}$$

I

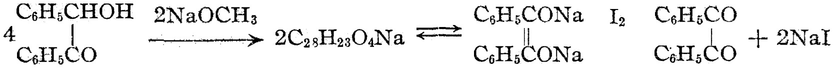
We have obtained 90–95% yields of benzil by the addition of iodine to alkaline solutions of benzoin. Benzoin was dissolved in methyl alcohol and sodium methylate was added, followed by iodine. Due to the extreme sensitiveness to oxidation of an alkaline solution of benzoin, the reaction mixture must be protected from air. This was accomplished either by working in an atmosphere of dry nitrogen or by keeping the alcohol solution boiling throughout the duration of the reaction. Similar yields of diketone (80 to 90% of the theoretical amount) were obtained from anisoin, piperoin and furoin.

It seems quite likely that the mechanism of this reaction is that described by Gomberg, namely, the removal of sodium from the dienolic

---

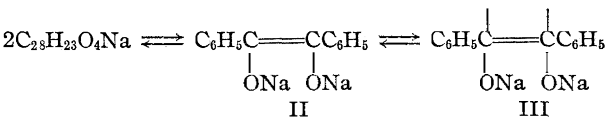
[1] Gomberg and Bachmann, THIS JOURNAL, 49,2584 (1927).

salt. However, the interaction of benzoin with sodium methylate does not yield stilbenediolate, as would be required for the above mechanism. According to Meisenheimer,[2] the product is a white salt which contains one atom of sodium per two molecules of benzoin, $C_{28}H_{23}O_4Na$. If our suggested mechanism be correct, this salt must be in equilibrium with disodium stilbenediolate.



$$4\begin{matrix}C_6H_5CHOH\\ |\\ C_6H_5CO\end{matrix}\xrightarrow{2NaOCH_3}2C_{28}H_{23}O_4Na \rightleftharpoons \begin{matrix}C_6H_5CONa\\ \|\\ C_6H_5CONa\end{matrix}\quad I_2\quad \begin{matrix}C_6H_5CO\\ |\\ C_6H_5CO\end{matrix} + 2NaI$$

A deep reddish-purple color appears immediately when sodium methylate is added to a methyl alcohol solution of benzoin. When a small amount of iodine is added, the color quickly fades to straw yellow, but in a few moments the purple color returns. Also, the admission of a small amount of air discharges the color but the original purple color quickly reappears when air is prevented from entering. Gomberg[1,3] observed a similar behavior with his unsaturated halomagnesium glycolates. He suggests that the remarkable reactivity of the latter may be due to a partial opening of the double bond. These color changes could be explained in the same manner.



$$2C_{28}H_{23}O_4Na \rightleftharpoons \underset{\text{II}}{C_6H_5\underset{ONa}{\underset{|}{C}}=\underset{ONa}{\underset{|}{C}}C_6H_5} \rightleftharpoons \underset{\text{III}}{C_6H_5\overset{|}{\underset{ONa}{\underset{|}{C}}}=\overset{|}{\underset{ONa}{\underset{|}{C}}}C_6H_5}$$

The color would be due to the free valented form (III); iodine or oxygen momentarily removes it from the equilibrium. Whatever may be the significance of the color of an alkaline solution of benzoin, it nevertheless serves as a delicate test for the latter.

Experimental Part

Oxidation of Benzoin—At first the oxidation reaction with sodium methylate and iodine was carried out in air but the benzil was always impure. In order to discover what impurities might result due to air, we carried out the following run. Twenty-one grams of benzoin was dissolved in 500 cc. of hot methyl alcohol and 7.5 g. of sodium, dissolved in 100 cc. of methyl alcohol, was added. Considerable light purplish solid separated from the dark solution. The mixture was heated to ±50° for half an hour and mechanically stirred while a stream of compressed air was blown into the flask. The solid finally disappeared; the solution was still dark colored at the end of the half hour. We isolated 2 g. of benzil and 12 g. of benzoic acid, which accounts for 60% of the original benzoin. When the oxidation of benzoin with methylate and iodine was run in an atmosphere of dry nitrogen or in boiling methyl alcohol, pure benzil was obtained in 90 to 95% yields. The conditions are described in the preparation of furil. The methyl alcohol must be free from acetone, ethyl alcohol, etc., else iodoform will contaminate the product.

Oxidation of **Furoin.**—Ten grams of furoin was dissolved in 225 cc. of boiling methyl alcohol and to the boiling solution was added a hot, freshly prepared solution of

---

[2] Meisenheimer, Ber., 38,874 (1905); cf. Garner, *Am. Chem.* J.,32,583 (1904).

[3] *Cf.* Hantzsch and Glower, Ber., 40,1519 (1907).

sodium methylate made by dissolving 2 5 g. (105% of the calculated amount, assuming the product to be a disodium derivative of dienol) of sodium in 50 cc. of pure methyl alcohol. To the boiling solution was then added, in three portions, 14 g. (106% of the calculated amount based on sodium) of iodine. The final color of the solution was brown. The heat was then removed; furil immediately began to crystallize. The mixture was allowed to cool to room temperature and filtered. A small additional yield was obtained by concentrating the mother liquor. The total yield of air-dried product, melting point 164–165° (corr.), was 8 g. (80% of the theoretical amount). The best solvent for crystallizing furil is benzene. Pure furil melts at 165 to 165.5° (corr.). When bromine is substituted for iodine, there is a resultant drop in yield of 20 to 30%.

Until recently the only practical preparation of furil was air oxidation of a cold alkaline solution of furoin as described by E. Fischer.[4] Recently a new method has been described by Nisbet[5] which involves the use of nitrobenzene as oxidizing agent.

In the oxidation of benzoin we used twice the amount of sodium methylate required to form stilbenediolate. This seemed to be the best amount. However, when this proportion of sodium was used with furoin, the yield of furil dropped 40%; with furoin the sodium methylate should be barely in excess.

Preparation of **Furoin.**—Furoin was prepared by Fischer's directions.[4] The purity of the crude product depends greatly upon the quality of the furfuraldehyde. If the latter is very impure, it is almost impossible to obtain pure furoin. We purified the crude product as follows. The crude furoin (dark brown and apt to be sticky) was air-dried and then allowed to stand for twelve hours in ether. It was filtered and then soaked in fresh ether for a second twelve hours, after which it was again filtered by suction. The ether removed a black tar. The furoin was dissolved in boiling ethyl alcohol (±150 g. per 500 cc. of alcohol) and precipitated by slowly pouring the hot alcohol solution into 5 volumes of water with rapid stirring. The solid was filtered, dissolved in alcohol and precipitated again with water. The process was repeated once more. The final product was of a light tan color and the supernatant aqueous alcohol from which it separated was clear and red. The first precipitation yielded a product which filtered slowly. However, the second and third precipitations gave a product which filtered very nicely. Finally, the furoin was crystallized from hot ethyl alcohol, filtered by suction, washed with ether and air-dried. Pure furoin melts at 138–139° (corr.).

Benzoin Color Test.—The purple color of an alkaline solution of benzoin has long been used as a color test for both benzoin and benzil,[6] but it has never been evaluated quantitatively. Using our procedure a positive color test is given by 0.0002 g. of benzoin and a weak test with 0.0001 g. This is one hundred times or so as sensitive as the test with Fehling's solution. Under the conditions of the test benzil alone gives no purple color even when the solution is warmed. However, benzil added to the test solution intensifies the benzoin color. The intensification is slight but it is unmistakable. This deepening of color would seem to be evidence of quinhydrone formation.[7]

The procedure consists in first adding to a 10-cc. test-tube 1 cc. of sodium methylate solution (4 g. of sodium in 50 cc of methyl alcohol), next 0.1 cc. of saturated benzil solution and, finally, anywhere from 0.02 to 1 cc. of the methyl alcohol solution of benzoin to be tested.

This color test can be applied to furoin and benzofuroin, the former giving a navy

[7] Scholl, *ibid.*, **32,** 1809 (1899).

blue with sodium methylate, the latter a delicate amethyst. In both cases the color is deeper in the presence of furil, benzofuril or benzil. On the other hand, neither piperoin nor anisoin give any color with methylate; neither does piperil nor anisil intensify the color of benzoins that do give color, namely, benzoin, furoin and benzofuroin.

Simple sugars are similar to benzoin inasmuch as they have a carbonyl group adjacent to hydroxyl. Levulose, however, does not respond to the color test; neither does butyroin, $C_3H_7CHOHCOC_3H_7$, a typical aliphatic acyloin.

We compared the delicacy of the color test against that of the Fehling test. The smallest amount of benzoin capable of yielding a significant precipitate of cuprous oxide in an hour was 0.01 g. An immediate color change on simple heating required 0.02 g. to 0.05 g. This is a poor test when compared with the color reaction with sodium methylate, which gives an immediate and conclusive purple color with 0.0002 g. of benzoin. The extreme limit of the Pehling test is 0.005 g. of benzoin. At this dilution the mixture must stand for two hours or more and the indication which finally results is very doubtful.

This work was aided by a grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences.

Summary

1. Various analogs of benzil can be prepared by iodine oxidation of alkaline solutions of the corresponding benzoins. A mechanism involving stilbenediolate is suggested.

2. The frequently described delicate color test with alcoholic alkali is shown to be applicable to certain benzoins but not to others. It is suggested that the color is indicative of trivalent carbon.

THE REACTIVITY OF ATOMS AND GROUPS IN ORGANIC COMPOUNDS. IX. THE VAPOR PRESSURES, DENSITIES AND REFRACTIVE INDICES OF CERTAIN BINARY MIXTURES

BY SPENCER W. PRENTISS

RECEIVED MAY 13, 1929 PUBLISHED SEPTEMBER 5, 1929

In the seventh paper of this series the velocity constants of the reaction at 25° between pyridine and ethyl iodide in a number of solvents were presented. The relative values of the constants, indicating the adjuvance of the solvents, were as follows.

TABLE I

VELOCITY CONSTANTS

Benzene	1	n-Propyl alcohol	1.11
Nitrobenzene	25	*n*-Butyl alcohol	1.11
Acetone	12.8	Isopropyl alcohol	1.07
Methyl alcohol	2.5	*Sec.*-butyl alcohol	1.00
Ethyl alcohol	1.4	*Tert.*-butyl alcohol	**0.93**

In view of the differences in chemical behavior shown by benzene, *n*-butyl alcohol and *tert.*-butyl alcohol, it was regarded as noteworthy that these compounds possessed nearly the same adjuvance. It has been suggested that adjuvance may be related more to physical forces set up between the molecules involved than to chemical attractions.

The present investigation was undertaken to test the validity of this hypothesis. If physical forces are the important factor, it seemed to us that a study of the physical properties of several binary mixtures of each reactant with a few of the more adjuvant and less adjuvant solvents might yield significant results. Specifically, we hoped to show that the adjuvance of the solvent would bear a simple relation to the deviations, from ideal solution laws, of vapor pressures, densities and refractive indices of several binary mixtures of the solvent with each reactant. No simple relationship has been found which will apply to all the cases studied. However, it is felt that the data obtained in this study possess sufficient value, apart from the above-mentioned hypothesis, to warrant their publication.

During this investigation a simple apparatus has been devised for measuring the vapor pressures of liquid mixtures where only small quantities—5 cc. or less—are available for each determination. It is hoped that adaptations of this apparatus may also be found useful in other lines of work.

Vapor Pressures.—The vapor pressures at 20° were measured by a static method. A small glass ampoule containing 3 or 4 cc. of the liquid was broken in an evacuated space of small volume and the pressure developed was measured by means of a mercury manometer. In this way the vapor pressures of pyridine, ethyl iodide, two of the more adjuvant, and two of the less adjuvant solvents, together with those of several binary mixtures of each reactant with each solvent, were obtained.

A numerical expression of the deviation, when this is small, of the observed vapor pressures from Raoult's Law is given by the exponent A in the equations[1]

$$p_1 = p_1^\circ \mathrm{N}_1 \, e^{A\mathrm{N}_2^2} \tag{1}$$

$$p_2 = p_2^\circ \mathrm{N}_2 \, e^{A\mathrm{N}_1^2} \tag{2}$$

where p° is the vapor pressure of the component and p is its partial pressure over a solution in which its mole fraction is N. Where $A = 0$ the equations become the familiar expressions of Raoult's Law; positive and negative values of A correspond, respectively, to positive and negative deviations from the law.

The values of A, which when substituted in Equations 1 and 2 yielded values of $p_1 + p_2$ in fair agreement with the observed total vapor pressures, are given in Table II. In the first line are given the solvents studied

---

[1] See Hildebrand, "Solubility," The Chemical Catalog Co., New York, 1924, p. 45.

and in Line 2 their relative adjuvance in the reaction under consideration, as found by the previous determination of velocity constants; Line 3 gives the A-values for the system solvent–pyridine, and Line 4 the A-values for the system solvent–ethyl iodide,

TABLE II

A-VALUES

Solvent	Nitrobenzene	Acetone	n-Butyl alcohol	Benzene
Adjuvance	25	12.8	1.11	1.00
***A*, Pyridine**	1 425	0 448	0.48	0.24
***A*, Ethyl iodide**	1.17	0.76	1.70	0.65

No simple combinations of the A-values for pyridine and ethyl iodide have been found which give values in any way proportional to the values found for the relative adjuvance.

Densities and Indices of Refraction.—The density and refractive index of mixtures of each reactant with nitrobenzene, acetone, *tert.*-butyl alcohol and benzene, respectively, were measured. In these instances, also, no parallelism was found between the adjuvance of a given solvent and the deviation of the measured property from the value it would have if the solution were ideal. In general the deviations were small and of opposite sign to those found in the measurements of vapor pressure. The data are given in Tables V and VI in the experimental part of this paper.

Experimental Part

The vapor pressures were measured in the apparatus shown in Fig. 1b, constructed of pyrex glass. Connections were made through Q to a Cenco Hyvac pump, through T to a Langmuir diffusion pump backed up by the Hyvac pump through R, through S to a McLeod gage and through J to a water-jet aspirator. The chamber, **O**, served to break the ampule containing the liquid under investigation. It was provided with a ground joint to permit the removal of the lower portion and to enable the latter to be turned in the fixed member. Inward pointing knobs were made, as close as possible to the top and bottom, by heating a very small spot to a bright orange and pushing in the hot spot with a small stout wire. This chamber, together with a stirrer and a Beckmann thermometer, was immersed in a water-bath contained in a Dewar flask. The water-bath temperature was controlled by a heating coil and a cooling-water tube (not shown) also immersed in the bath. The setting of the Beckmann thermometer was effected through the use of a thermometer reading from 0 to 40° which had been standardized by the Berliner Reichsanstalt. A paper scale was placed behind the manometer.

The vapor space from O and M to the mercury surface at P, approximately 30 cc., corresponded to $30/22{,}400 \times 273/293 = 0.0012$ mole. As the internal diameter of the manometer tube was approximately 0.4 cm., the vapor space was increased by $0.4^2\pi/2 = 0.25$ cc., corresponding to 0.000010 mole for each centimeter of pressure. The corrections to be subtracted from the weights of each component taken were obtained by multiplying the number of moles of vapor, as above determined, by an approximate value of the pressure fractions, p_1/p and p_2/p, respectively.

Ampules having a capacity of about 4 cc. were made from 10 mm. o.d. soft glass tubing (Fig. 1a). The tip **A** was made quite fragile, and the shank D fairly heavy, with an internal diameter of 2 or 3 mm. A 5-cc. pipet was drawn out at the tip into a small tubule, about 0.5 mm. i.d., 1 mm. o.d., and 10 cm. long; by passing this tubule down the shank of the ampule, the latter could be filled with a liquid without wetting any part of the ampule above the level C.

A determination of the vapor pressure was carried out in the following manner. The desired mixture was first made up by weight, using a 5-cc. glass-stoppered weighing bottle. Enough of this was transferred to the ampule to bring the liquid to the level C, just above the shoulder. By bringing the tip of the tubulated pipet into contact with the inside wall of the ampoule and letting the liquid flow in very slowly at first, the tip A could be filled with liquid without entrapping any air.

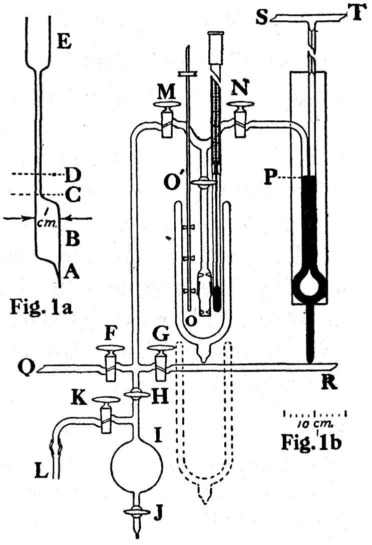

Fig. 1.

The ampule was next attached by means of the rubber tubing L, to the Bulb I, which had been previously exhausted by means of a water-jet aspirator to a pressure of from 5 to 10 mm. of mercury. The ampule and contents were chilled by immersion in ice and concentrated hydrochloric acid, Stopcock K was opened and the ampule was sealed off at a point near the top of the shank, using a hand torch. The remaining long portion of the shank was removed by sealing at a point D such that when the ampule was subsequently placed in the chamber O the upper tip would project above the upper knobs without touching the wall directly above them.

The ground joint was next very sparingly greased, the ampule placed in the lower portion with the fragile tip resting on the bottom and the chamber put together as at O (ampule not shown), with the Dewar flask lowered. The right side of the manometer having been previously evacuated to less than 0.01 mm. as shown by the McLeod gage, the rest of the apparatus was evacuated through Q as far as Stopcocks H and G, until there was no further change in the level of mercury in the left arm that could be seen with the unaided eye.

Stopcock O' was next turned so as to break the lower tip of the ampule, whereupon the liquid ran out into the chamber. The Dewar bath was placed in position and Stopcock M was closed; whereupon Stopcock O' was slowly opened by a minute amount until the bulk of the vapor had formed, when it was opened wide. After the establishment of equilibrium, shown by repeatedly and slowly approaching the temperature, 20°, alternately from above and below, the vapor pressure was read and recorded.

Tables III and IV give the data thus found. Table III gives the vapor pressures of the individual components, in mm. of mercury, observed at 20.00°. In Table IV, Cols. 1 and 2 give the number of moles, X 100, of each component in the solution, as determined by weight; Col. 3 gives the mole fraction, N_2, of pyridine or ethyl iodide, corrected for vaporization; Cols. 4 and 5 give, respectively, the observed vapor pressure and that calculated from Equations 1 and 2, using the value of *A* given in the table for each system.

Densities and Refractive Indices.—The densities of the pure components had been measured with especial care using a Sprengel pyknometer, yielding values which are believed fairly to indicate the degree of purity of the substances used (see below). However, for the purpose of comparing the densities of the binary mixtures studied, all that was required was a rapid, fairly accurate method which would give reproducible results. A pyknometer patterned after that described by Mulliken[2] was found to fulfil these requirements perfectly. Accordingly, the densities of the mixtures were measured and those of the pure components remeasured, at 25.0°, using this instrument. No excessive care was used in its calibration and no buoyancy corrections have been included in the density values as given. Nevertheless, it is evident from an inspection of the data that the main purpose of the density measurements—namely, a determination of the deviations from ideal solution laws—has been adequately fulfilled.

The refractive indices were measured at the same temperature, 25.0°, using an Abbé refractometer. The density and refractive index of the pure components and of 2 to 1 and 1 to 2 molecular mixtures of each reactant with each solvent were measured. The mixtures were made up by volume, in duplicate, and the number of moles of each component was calculated using the observed density of the latter. One determination of each property of each mixture was made. The agreement in the case of the pure components was within 1 or 2 units in the last decimal, for both properties. From the respective property and the mole fraction of each pure component were calculated the molecular volume and the molecular refraction of ideal solutions having the composition indicated, using the formulas

$$MV = \frac{1}{D}(M_1N_1 + M_2N_2), \text{ and } MR = \frac{n^2 - 1}{n^2 + 2} \times MV$$

where MV = molecular volume, MR = molecular refraction, D = mass/volume at 25.0°, M = molecular weight, N = mole fraction and n = refractive index at 25.0° using the D line. Tables V and VI give the data thus found.

TABLE V

distilled. Nitrobenzene was repeatedly frozen and distilled *in vacuo.* Acetone from the bisulfite compound was first refluxed with permanganate, then repeatedly with anhydrous carbonate of potash and then fractionally distilled. The alcohols were purified in general by the procedures used in this Laboratory in previous investigations. Benzene (thiophene free) was shaken with concentrated sulfuric acid, alkali and water, then refluxed with sodium and distilled from flasks containing this metal.

Table VII gives the physical constants of the materials used. The figures represent the maximum and minimum values of the constants for the different compounds used, and not the variation in the property for the individual compound. The boiling range, for example, was usually 0.1 or 0.2° for 90% distilled.

[a] The melting point was not determined for all the samples used.

The author is indebted to Professor J. F. Norris for his continued interest in this work, and to Professor George Scatchard for many helpful suggestions and criticisms, and especially for indicating the applicability of the Duhem–Margules equations to the problem in hand.

Summary

1. The vapor pressures of several binary mixtures of nitrobenzene, acetone, n-butyl alcohol and benzene with pyridine, and with ethyl iodide, have been measured at 20° by a static method.

2. The densities of similar mixtures of nitrobenzene, acetone, *tert.*-butyl alcohol and benzene with pyridine, and of nitrobenzene and benzene with ethyl iodide, and the refractive indices of mixtures of nitrobenzene and benzene with pyridine and with ethyl iodide, have been measured at 25°.

3. For the reaction between pyridine and ethyl iodide an attempt has been made to show that the adjuvance of the solvent, reported in paper No. VII of this series, would bear some relation to the deviation, from ideal solution laws, of vapor pressures, densities or refractive indices of binary mixtures of the solvent with each reactant. No such correlation, however, has been observed.

THE ISOMERIC ALPHA,BETA-DIPHENYLGLUTARIC ACIDS[1]

BY S. AVERY AND W. D. MACLAY

RECEIVED MAY 17, 1929 PUBLISHED SEPTEMBER 5, 1929

Part I. The Optically Inactive Acids

Introduction

An acid of this group was first synthesized by Avery and McDole[2] through the addition of benzyl cyanide to cinnamic ester and the hydrolysis of the product formed. The acid crystallized as needles. The corrected melting point was 226–228°. In this paper it will be referred to as "the higher-melting acid." The possibility of the presence of a lower-melting isomeric acid formed along with the higher-melting acid was considered by Avery and McDole in a discussion, of which the following is an abbreviation: "By working over the mother liquors a substance was obtained melting at 205" (uncorr.). However, careful work showed the presence of a small amount of nitrogen in the supposed isomeric acid and when this compound was placed in a sealed tube with hydrochloric acid and heated, the compound obtained in every case was the diphenylglutaric acid melting at 224° (uncorr.)." The nitrogen just referred to was actually due to a very minute trace of the monoamide of diphenylglutaric acid.[3] The 205" compound was in reality the nearly pure isomeric glutaric acid to be described in this paper as "the lower-melting acid," the melting point of which is 208–210° (corr.). It forms nearly square or oblong flat plates, beveled plates or prisms. The crystals formed under different conditions vary considerably in superficial appearance.

Substituting phenylacetic ester for phenylacetonitrile (benzyl cyanide), Borsche[4] effected the synthesis of the higher-melting acid. He describes a very satisfactory method for preparing the esters of this acid, and the acid itself, but makes no mention of the lower-melting acid which is formed in considerable quantity when the ester of the higher-melting acid is hydrolyzed by potassium hydroxide in the usual way.

By oxidizing 1,2-diphenylcyclopentene-3, Kishner[5] obtained a mixture of acids which he converted into their methyl esters and separated by fractional distillation. He thus obtained a methyl ester melting at 87° having the same percentage composition as the known methyl ester (143°) of α,β-diphenylgutaric acid. By saponifying this ester he obtained an

acid in the form of needles melting at 200–201°, which he called the maleinoid form, designating the higher-melting acid as the fumaroid form.

By oxidizing β,γ-diphenylvalerolactone, Meerwein and Dott[6] obtained in the form of prisms an acid melting at 203–204°. It formed a methyl ester apparently identical with the "maleinoid" ester of Kishner. The acid, however, with its higher melting point and different crystalline form does not closely correspond to the latter's "maleinoid" acid.

The investigators referred to were in fairly close agreement in so far as the higher-melting acid is concerned. All reported needles melting above 220°, the exact temperature depending on the rapidity of heating. All reported a methyl ester melting sharply at about 143°. On the other hand, the only close agreement in regard to the lower-melting acid is the fact that two of the investigators report a methyl ester melting at 87°.

In view of the uncertainty in regard to the lower-melting acid, the authors of this paper regarded a thorough study of the subject as desirable.

Experimental Part

The Anhydride of the Lower-Melting Acid.—Five grams of the higher-melting acid was heated in a sealed tube with approximately 10 g. of acetyl chloride at 140° for four hours. The product of the reaction was treated with 50 cc. of petroleum ether. An oil separated out and became crystalline on stirring. After an hour the crystals were filtered off; yield, 4 g. The anhydride was purified by recrystallizing from hot tertiary amyl alcohol and gave plates, m. p. 124°, by dissolving in chloroform, adding absolute alcohol and condensing in a current of cold, dry air; by dissolving in chloroform and precipitating with petroleum ether, m. p. 126.5°.

Anal. Calcd. for $C_{17}H_{14}O_3$: C, 76.7; H, 5.3. Found: C, 76.6; H, 5.4.

That this body is the anhydride of the lower-melting acid is shown by its reacting readily to form this acid (and its esters), and not the higher-melting acid from which it was prepared. It also deports itself as an anhydride in forming the acid amide, the imide and the anilic acid.

This anhydride was formed almost quantitatively by treating the lower-melting acid with an excess of acetyl chloride, evaporating on the steam-bath and allowing the residue to crystallize.

The Lower-Melting α,β-Diphenylglutaric Acid.—This acid is gradually formed when the anhydride just described is treated with boiling water. It is formed more readily by dissolving the anhydride in an alkaline carbonate solution and precipitating with strong acid. It was first isolated in pure condition, however, by the following method: 30 g. of the methyl ester, m. p. 143°, was saponified by boiling with 15 g. of potassium hydroxide in 100 cc. of 95% alcohol. As the potassium salt precipitated out, water was added and the boiling continued for two hours. The solution was then evaporated to dryness, dissolved in water and added gradually to an excess of a 10% solution of hot hydrochloric acid. After cooling, the white crystalline mass was filtered off and washed well with water; yield, approximately 25 g. This was dissolved in hot 95% alcohol; boiling water was then added to incipient turbidity. On cooling, needles of the nearly Pure higher-melting acid separated; yield, approximately 15 g. The filtrate was condensed to about one-third of its previous volume and cooled. The mix-

---

[6] Meerwein and Dott, *J. prakt. Chem.*, 97, 264–268 (1918).

ture of the higher and lower acids formed was then filtered off; yield of mixed acids, approximately 10 g. The needles of the higher-melting acid and the beveled plates or short prisms of the lower-melting acid appeared to be present in about equal amounts when seen through the microscope. About 1 g. of the pure lower acid was obtained by repeated recrystallization from dilute acetic acid.

For practical purposes, however, the mixed acids are converted into the pure anhydride by heating with acetyl chloride at 140°. The anhydride in turn passes readily into the pure lower-melting acid as has just been stated.

The lower-melting acid formed by the oxidation of 1,2-diphenylcyclopentene-3 as described by Kishner, but purified by dissolving out the benzoic acid with benzene and recrystallizing the residue by dissolving in as small an amount of ethyl acetate as possible, adding benzene and condensing in a current of dry, cold air, is readily obtained in a pure condition.

The three samples just described have the same crystalline form, the same solubility relations and the same melting point, 208–210° (corr.). Melting points of mixed samples showed no variation.

Anal. Calcd. for $C_{17}H_{16}O_4$: C, 71.8; H, 5.7. Found: C, 71.6; H, 5.7. Titration: 0.1225 g. required 8.6 cc. of $N/10$ NaOH. Calcd.: 8.6 cc.

Except for the higher melting point obtained, the results just given are so closely in agreement with the conclusions of Meerwein and Dott that the synthesis of the acid by their method for the sake of comparison seemed unnecessary.

The Monoamide of α,β-Diphenylglutaric Acid.—Two grams of the anhydride dissolved in chloroform was treated for some time with dry ammonia gas. The white powder formed suspended in chloroform was shaken with concentrated ammonium hydroxide solution and evaporated to dryness. The residue recrystallized from 50% alcohol melted at 200–205° with decomposition and the evolution of ammonia. It was found to be identical with the monoamide of diphenylglutaric acid from β,γ-diphenyl-γ-cyanobutyric acid.[3] This fact is of interest as indicating that the cyano derivatives through which Avery and McDole first synthesized the higher-melting acid belong to the series of the lower-melting acid and that the series of the higher-melting acid is reached only in the final hydrolysis.

The Imide of the Lower-Melting α,β-Diphenylglutaric Acid.—The monoamide of the lower-melting acid on boiling with a mixture of 95% alcohol and concd. hydrochloric acid gives the corresponding imide as coarse, hair-like crystals; m. p. 225–229° without evolution of ammonia.

The imide may also be made as follows: β,γ-diphenyl-γ-cyanobutyric methyl ester is treated with strong alcoholic potash and evaporated almost to dryness over the open flame. Water is added and the process repeated. The mass is then dissolved in glacial acetic acid, concd. hydrochloric acid added and it is again evaporated over the open flame till a mass of coarse, hair-like crystals separate out. More hydrochloric acid is added, the mass again concentrated, then diluted with water, filtered and washed; yield, nearly quantitative. Recrystallized out of 80% alcohol it melts at 225–229°.

Anal. Calcd. for $C_{17}H_{15}O_2N$: C, 76.9; H, 5.7; N, 5.3. Found: C, 76.8; H, 5.6; N, 5.2.

The Anilic Acid.—2.26 g. of the anhydride of the lower-melting α,β-diphenylglutaric acid was dissolved in benzene, 0.93 g. of aniline in benzene was added and the solution warmed. A crystalline precipitate formed which after heating at about 80° for ten minutes was filtered off and washed with benzene; the yield of the crude product was nearly quantitative. Recrystallized three times from 50% alcohol, the anilic acid showed a constant melting point of 201–202°. The crystals appeared in the form of needles or rods.

Anal. Calcd. for $C_{23}H_{21}O_3N$: C, 76.8; H, 5.9; N, 3.9. Found: C, 76.5; H, 5.8; N, 3.8. Titration: 0.109 g. required 3.0 cc. of *N*/10 NaOH. Calcd.: 3.0 cc.

Transformation: The Higher Series $\rightleftarrows$ the Lower.—Concentrated hydrochloric acid diluted with an equal volume of water appears not to change compounds of the higher into those of the lower-melting series at any temperature,

Below 150° cyano derivatives are hydrolyzed by hydrochloric acid to a mixture of the amide and the lower-melting acid; at 150° to a mixture of the two acids, the higher-melting acid predominating as the temperature rises.

Below 180° the esters of the lower acid are hydrolyzed by hydrochloric acid with little transformation. Above 180° esters of the lower acid (and at 200° the acid itself) are transformed more or less completely into the higher-melting acid.

Saponification by alcoholic potassium hydroxide leads to the corresponding acid, mixed, however, with a varying amount of the isomeric compound. This action appears to explain why Kishner on saponifying the pure (87°) lower-melting methyl esters secured needles melting at 200–201°. He appears to have isolated a mixture of the acids.

As Kishner pointed out, the lower-melting acid is in part transformed into the higher by heating above its melting point.

The method of proceeding from the higher (or mixed acids) to the lower through the anhydride route has made it possible to prepare the lower-melting acid in quantity without excessive cost and effort.

Optical Properties.—Both acids are optically inactive.

Summary to Part I

The work previously published on the higher-melting acid, in so far as this paper relates to it, is confirmed in all essential points.

The lower-melting acid has been prepared in a pure condition by different methods, its crystalline habit noted and its melting point determined.

A mixture of the higher and lower-melting acids has been separated by fractional crystallization.

The higher-melting acid has been transformed into the anhydride of the lower. This anhydride has been isolated in pure form and used practically in preparing the lower acid.

The methyl ester (m. p. 143°), the ethyl ester (m. p. 93.3°) and the acid (m. p. 226–228°) belong to what we have termed the higher-melting series; the methyl ester (m. p. 87°), the ethyl ester 76° (as pointed out by Kishner) and the acid (m. p. 208–210") belong to the lower-melting series.

The cyano and monoamide derivatives,[7] the imide (m. p. 225–229°) and the anilic acid (m. p. 201–202") described in this paper, also appear to be members of the lower melting series.

To use the phraseology sometimes employed, but generally accepted with mental reservations when applied to saturated dibasic acids, the members of the higher-melting series might be termed "*trans*" or "fumaroid" compounds; while those of the lower-melting series would be designated as "*cis*" or "maleinoid" forms. Though these terms are freely used in the literature of the dimethyl- and diethylglutaric acids, they help to classify rather than to explain this and similar cases of stereoisomerism. Hence in

---

[7] Avery, THIS JOURNAL, 50, 2515–2516 (1928).

the hope of throwing more light on the real difference in stereo structure between the two series, the authors next undertook to resolve each acid into its optical isomers.

Part II. The Optically Active Acids

Introduction

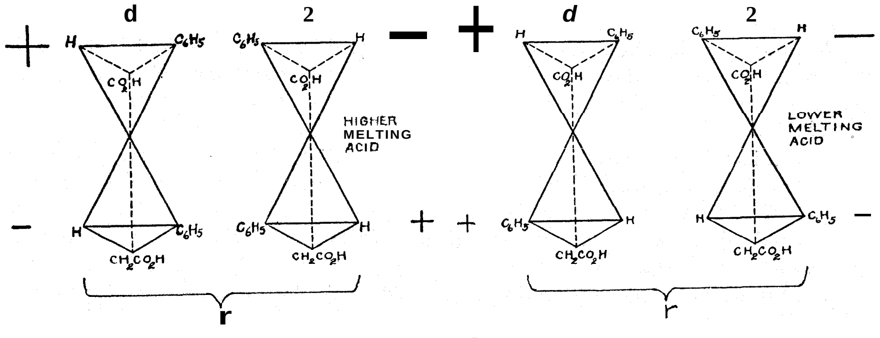
The general formula of all isomeric α,β-diphenylglutaric acids, $HOOCCH_2CH(C_6H_5)CH(C_6H_5)COOH$, shows two asymmetric carbon atoms of unequal effect on polarized light. The α-atom has without question the greater capacity for specific rotation.[8] Indicating this optical difference by the size of the signs employed, we have the following possibilities

$$HOOCCH_2CH(C_6H_5)CH(C_6H_5)COOH$$

$$\left.\begin{array}{lcc} d & \text{\Large$+$} & - \\ l & \text{\Large$-$} & + \end{array}\right\} r \qquad \left.\begin{array}{lcc} d & \text{\Large$+$} & + \\ l & \text{\Large$-$} & - \end{array}\right\} r$$

The higher-melting acid (m. p. 226–228°), as the experimental part of this paper will show, has been resolved, through fractional crystallization of the brucine salt, into isomers, one showing a d-rotation of 58.7°, and one showing a similar l-rotation.

The lower-melting acid (m. p. 208–210°) has also been resolved into isomers, one showing a l-rotation of 140.7°; the other showing a d-rotation of approximately the same amount. Hence it follows that the higher-melting acid (m. p. 226–228°) is a racemic form of the $\text{\Large$+$}\ -$; $\text{\Large$-$}\ +$ type. The lower 208–210° acid is a racemic acid of the $\text{\Large$+$}\ +$; $\text{\Large$-$}\ -$ type. The conclusion is then that there are in all six isomers, two inactive and four active. These may be expressed in another way, as indicated.



Experimental Part

Resolution of the Higher-Melting Acid.[9]—Thirty grams of finely powdered α,β-

Compare $C_6H_5CH(OH)COOH$, +157°, Ber., 37,3176 (1904), with $C_6H_5CH(OH)CH_2COOH$, 4-19, *ibid.*, 39, 790 (1906).

Compare Wren and Still, *J. Chem. Soc.*, 107,444 (1915).

diphenylglutaric acid (226–228°) was thoroughly mixed with 82.8 g. of anhydrous brucine and stirred with 6000 cc. of water on a boiling water-bath until practically all of it had gone into solution. The temperature of the solution was kept below 80°. After filtration, the solution was allowed to cool. At the end of four days the crop was filtered and allowed to dry on a porous plate; yield, 67.5 g.

This material was recrystallized from hot water, 30 cc. of the solvent being used for each gram of the salt. The course of the resolution was followed by determining the specific rotation of the acid obtained from the successive filtrates. The values for the rotations of these filtrates made in acetone solution were as follows: −12.5°, −4.2°, +36.3°, +45.4°, +50.6°, +56.4°, +57.0°.

The crop from which the last filtrate was obtained, consisting of long well-defined prisms with pointed ends and weighing 5.5 g., was dissolved in hot water and decomposed with hydrochloric acid. 1.5 g. of *d*-α,β-diphenylglutaric acid was isolated, the specific rotation in acetone solution being as follows: $[\alpha]_D^{20}$, +58.7° (1 g. in 25 cc. of soln. gave, in a 1-dcm. tube, +2.35°). The rotation of this acid remained unchanged after further recrystallization.

d-α,β-Diphenylglutaric acid crystallizes from dilute ethyl alcohol in fine, hair-like crystals with a melting point of 224–226°. It is slightly soluble in hot water and benzene, and exceedingly soluble in ethyl alcohol, methyl alcohol, acetone and ethyl acetate. The solubilities shown by this acid are much greater than those of the inactive acid.

The brucine salt of the *l*-α,β-diphenylglutaric acid being more soluble than the salt of the *d*-α,β-diphenylglutaric acid, the usual difficulties were encountered in obtaining the acid in a pure form. However, a levorotatory acid that was practically pure was obtained in the following manner: the filtrate from the first crop of brucine salt was concentrated under reduced pressure to 3000 cc. and allowed to crystallize. The crop was filtered, the filtrate concentrated to 1000 cc. in the same way and again allowed to crystallize; 34 g. of the crude levorotatory brucine salt was thus obtained. This salt was recrystallized from hot water until when viewed through the microscope it was found to be uniform in crystalline structure. The crystals were short, well-formed prisms with beveled edges. The crop was dissolved in water and decomposed with hydrochloric acid. The acid was recrystallized from dilute ethyl alcohol and gave a specific rotation in acetone solution as follows: $[\alpha]_D^{20}$, −58.0° (0.172 g. in 25 cc. soln. gave in a 1-dcm. tube −0.40°). The rotation of this acid remained unaltered with further recrystallization.

l-α,β-Diphenylglutaric acid recrystallizes from dilute ethyl alcohol in fine hair-like crystals similar to those of the d-acid. It also exhibits solubility properties analogous to those of its antipode. The melting point of the l-acid was slightly lower than that of the d-acid.

Racemization of the Active Acids.—Equal quantities of the d- and *l*-α,β-diphenylglutaric acids were placed together and recrystallized several times from dilute ethyl alcohol. The acid crystallized in long needles with a melting point of 226–228°. It was optically inactive and exhibited all the properties of the acid from which its component parts were originally derived.

Resolution of the Lower-Melting Acid.—The procedure was in general similar to that employed in resolving the isomer. The brucine salt of the l-acid first separates out in the form of diamond-shaped plates. On condensing the mother liquor after the plates have been filtered off, the brucine salt of the d-acid appears in the form of prisms.

Twenty grams of the impure plates containing a small percentage of prisms and some coloring matter was dissolved in 5% alcohol, boiled with charcoal and filtered. On cooling, colorless plates nearly free from prisms separated out. These were dissolved again in hot dilute alcohol and permitted to crystallize. The process was repeated about twenty times from dilute alcohol and finally several times from water until samples of acid recovered from successive filtrates showed no change in rotation.

The acid was recovered from the filtrates by condensing to a small volume, acidifying with hydrochloric acid, extracting with ether and recrystallizing from very dilute alcohol slightly acidulated with acetic acid.

The samples of acid from the first few filtrates appeared as prisms, then as scales without definite form and later as flattened needles. The specific rotation passed rapidly with the successive recrystallizations from +12° to −130°, still more slowly to −140°, where it remained practically constant. There now remained 5 g. of the brucine salt, which was converted into the acid and recrystallized from dilute alcohol slighty acidulated with acetic acid.

l-α,β-Diphenylglutaric acid thus prepared gave a specific rotation in acetone as follows: $[\alpha]^{20}_{D}$, **−140" (1.0 g.** in **25** cc. of soln. gave in a 1-dcm. tube **−5.63").** It crystallizes from hot dilute alcohol or acetic acid as long, flattened needles; m. p. 202°. The solubilities shown by this acid are much greater than those of the inactive acid from which it was resolved.

Titration of the E-acid: **0.1006** g. required **7** cc. of $N/10$ NaOH. Calcd.: **7.1** cc.

The corresponding d-acid was prepared as follows: **10** g. of the brucine salt, mostly prisms, previously mentioned as coming from the first filtrate after the first crop of diamond-like plates had been filtered off, was recrystallized from water until an admixture of diamond-shaped plates could no longer be detected by the microscope.

At this point the filtrates from the later recrystallizations were in turn decomposed and recrystallized as in the case of the I-acid. This process was repeated until a specific rotation of about +140° was observed in several successive samples. These latter samples were in turn recrystallized from dilute alcohol containing a drop of acetic acid. The d-acid thus obtained recrystallized in long flattened needles giving a melting point of **202".** *d*-α,β-Diphenylglutaric acid thus prepared gave a specific rotation in acetone as follows: $[\alpha]^{20}_{D}$ +140.6° **(0.2188** g. **in 25** cc. of solution gave in a **1-dcm.** tube **+1.23").**

Titration of the d-acid: 0.1848 g. required **12.9** cc. of $N/10$ NaOH. Calcd.: **13 ce.**

The I-acid recrystallized with an equal weight of the d-acid showed all the properties of the 208–210° form from which the 1- and the d-acid were resolved.

Acknowledgments.—To Dr. F. W. Upson we are especially indebted for suggesting the resolution, into their optical isomers, of the acids under consideration and for constructive criticism. Mr. R. M. Sandstedt has rendered us the favor of making the nitrogen determinations. Mr. Clifford Carr has greatly assisted in laboratory work generally and has made the combustions and titrations.

Summary of Part II

Both of the stereoisomeric acids considered in Part I have been resolved into optically active acids. Names for the six acids, now all definitely known, are suggested as follows.

PROPOSED NAMES

For the higher-melting acid (226–228°)		For the lower melting acid (208–210")	
$\alpha d,\beta l$ − $\alpha l,\beta d$-Diphenylglutaric acid (*i*), the r form of		$\alpha l,\beta l$ − $\alpha d,\beta d$-Diphenylglutaric acid (i), the r form of	
$\alpha d,\beta l$-Diphenylglutaric acid	(*d*) and	$\alpha l,\beta l$-Diphenylglutaric acid	(*l*) and
$\alpha l,\beta d$-Diphenylglutaric acid	(*l*)	$\alpha d,\beta d$-Diphenylglutaric acid	(*d*)

A STUDY OF THE POSSIBLE INTERCHANGE OF RADICALS ON HEATING A MIXTURE OF AN R'X AND AN RMgX COMPOUND

BY HENRY GILMAN AND HAROLD L. JONES

RECEIVED MAY 27, 1929 PUBLISHED SEPTEMBER 5, 1929

Introduction

In connection with studies on the comparative reactivity of RX compounds toward magnesium in ether, combinations of two RX compounds have been allowed to compete for a quantity of magnesium insufficient to react with both halides.[1] It would be necessary to assume in such studies that there is no interchange of radicals, as follows

$$\mathrm{RX} + \mathrm{Mg} \longrightarrow \mathrm{RMgX} \qquad \text{(I)}$$

$$\mathrm{R'X} + \mathrm{RMgX} \longrightarrow \mathrm{R'MgX} + \mathrm{RX} \qquad \text{(II)}$$

Obviously, if an interchange of radicals as illustrated in Reaction II occurred then the quantity of R'MgX compound formed would not be solely a measure of the rate of reaction between the R'X compound and Mg, but also a measure of any R'MgX compound that might have formed in accordance with Reaction II.

The assumption of no interchange of radicals appeared altogether reasonable prior to some studies by Gilman and Fothergill[2] on the probable dissociation of some Grignard reagents. Accordingly, the present study was undertaken to determine definitely whether the interchange pictured in Reaction II actually takes place under our particular experimental conditions. We have found that no such interchange of radicals occurs.[3]

The method used was to add carbon dioxide to a mixture of R'X and RMgX compounds subsequent to refluxing in an ether–toluene or ether–benzene mixture for a few hours. If no interchange took place, the acid formed after carbonation should be pure RCOOH. If some interchange occurred, then some R'COOH and RCOOH would result. In each of the several cases studied only one acid was obtained, namely, the acid corresponding with the RMgX initially present.

---

[1] The results of another aspect of this problem have already been reported by Giman and Van der Wal, Bull. *soc. chim.*, *45* (1929). See, also, Rudd and Turner, *J. Chem. Soc.*, 687 (1928), and Gilman and Zoellner, THIS JOURNAL, 50, 2520 (1928)

[2] Gilman and Bothergill, *ibid.*, 51 (1929). An account of this investigation was presented at the May, 1929, meeting of the American Chemical Society held at Columbus, Ohio.

[3] We mean this statement to be confined to the specific combinations used in this study. We consider it likely that special combinations like triphenylmethylmagnesium chloride and bromotriphenylchloromethane will show an interchange. Studies of such combinations of R'X and RMgX compounds, each of which has a tendency to dissociate, are in progress.

Depending on the lability of the halogen in the R'X compound, a reaction takes place between the halide and the RMgX compound, as follows

$$R'X + RMgX \longrightarrow R'R + MgX_2 \qquad \text{(III)}$$

With some R'X compound, Reaction III goes to completion.[4] In order to have some RMgX present at the end of the preliminary refluxing with R'X, an insufficient quantity of the latter was used. The chief products obtained, therefore, were the RCOOH from the RMgX, and the RR coupling product. However, in the reaction between triphenylchloromethane, $(C_6H_5)_3CCl$, and phenylmagnesium bromide a very unusual product resulted, in addition to a small quantity of tetraphenylmethane, $(C_6H_5)_4C$, which would be expected in accordance with Reaction III. This unexpected product was obtained in a 47.4% yield and was identified as p-phenyl-triphenylmethane, p-$C_6H_5C_6H_4C(H)(C_6H_5)_2$. This compound was unexpected because it was not reported by a number of other investigators[5] of this particular reaction between triphenylchloromethane and phenylmagnesium halides. A study is in progress of this and related reactions concerned with the rearrangement of halides and organomagnesium halides,[6] and free radicals formed from them.[7]

Experimental Part

With the exception of triphenylmethylmagnesium chloride,[8] the Grignard reagents were taken from stock solutions of known titration value. The RMgX solutions were free from magnesium. After refluxing the ether–toluene or ether–benzene mixtures of RMgX and R'X compounds for about three hours and at a temperature of about 60°, the cooled mixture was treated with carbon dioxide after the procedure of Gilman and Parker.[9]

Subsequent to hydrolysis the acids were extracted with dilute alkali and then recovered in a customary manner by acidification. None of the acids was purified by crystallization. Instead the "crude acid" obtained directly on acidification (after carefully extracting the alkaline solution with ether to remove all non-acidic compounds) was dried to constant weight. With the acid obtained in this manner a melting-point

Together with Reaction III another coupling reaction can occur: $2RX + 2R'MgX \longrightarrow R{\cdot}R + R'{\cdot}R' + 2MgX_2$. This reaction has been discussed in detail by Fuson, THIS JOURNAL, 48, 830,2681,2937 (1926).

determination, a mixed melting-point determination with an authentic specimen and **a** neutralization equivalent were made.

Where the possible mixtures of acids were benzoic and phenylacetic acids (see the first two experiments in Table I) the method of mixed melting points is highly accurate. This was established by the melting-point determinations of a series of authentic mixtures of these two acids. From these preliminary melting-point determinations it was shown that *less* than 0.5% of either acid mixed with the other acid would give an unmistakable softening and depression of the melting point. This method of melting point of mixtures is not sufficiently sensitive with acids whose melting points are considerably removed from each other. An illustration is the third experiment given in Table I. In this case a distinctly high percentage of benzoic acid is required to depress the melting point of triphenylacetic acid. For this reason the purity of triphenylacetic acid was measured by the neutralization equivalent. Neutralization equivalents were also made of the acids in the fourth and fifth experiments (see Table I).

The non-acidic products were recovered in the usual manner from the ether–toluene or ether–benzene layer after alkaline extraction. These products were less carefully examined in this preliminary study because our chief interest was with the acids. Some details concerning the several experiments are given in the footnotes accompanying Table I.

TABLE I

REACTION BETWEEN R'X AND RMGX COMPOUNDS

		R'X								
		Used		Recovered						
		G.	Mole	G.	%	RMgX	Mole	RCOOH	G.	%
1	C_6H_5Br[a]	23.5	0.15	19.0	80	$C_6H_5CH_2MgCl$	0.25	$C_6H_5CH_2COOH$	15.2	44.7
2	$C_6H_5CH_2Cl$[b]	20.0	.15	14.0	70	C_6H_5MgBr	.25	C_6H_5COOH	10.6	34.7
3	C_6H_5Br[c]	4.0	.025	3.3	82.5	$(C_6H_5)_3CMgCl$	.04	$(C_6H_5)_3CCOOH$	6.1	51.2
4	$(C_6H_5)_3CCl$[d]	27.8	.1	..	..	$C_6H_5CH_2MgCl$	.25	$C_6H_5CH_2COOH$	3.2	9.4
5	$(C_6H_5)_3CCl$[e]	20	.072	..	..	C_6H_5MgBr	.25	C_6H_5COOH	11.6	38

[a] The phenylacetic acid obtained in this experiment melted at 77°, and a mixed melting-point determination with an authentic specimen of phenylacetic acid which melted at 77° showed no depression.

[b] The temperature during the three-hour period of heating was 64°. The benzoic acid obtained here melted at 121° and showed no depression in a mixed melting-point determination with an authentic specimen.

[c] This is the only experiment in which an ether–benzene mixture was used. In all others an ether–toluene mixture was used. Refluxing for three and one-half hours was carried out in an inert atmosphere by means of the special apparatus of Gilman and Hewlett, *Rec. trav. chim.*, 48 (1929). The neutralization equivalent of the triphenylacetic acid was 289; the calculated value is 288. There were also obtained 0.3 g. of triphenylcarbinol and 0.4 g. of triphenylmethane.

[d] A flocculent orange-colored precipitate formed on the addition of the Grignard solution, and the stirred and refluxed mixture later assumed an opaque light yellow color. The phenylacetic acid showed no depression in a mixed melting-point determination with an authentic specimen. Its neutralization equivalent was 137.6, whereas the calculated value is 136. There was also obtained 25.1 g. or a 75.2% yield of 1,1,1,2-tetraphenylethane, $(C_6H_5)_3CCH_2C_6H_5$.

[e] On the addition of the Grignard reagent the solution assumed a deep cherry-red color. The benzoic acid showed no depression in a mixed melting-point determination with an authentic specimen. Its neutralization equivalent was 120.1, whereas the calculated value is 122.

In addition there was obtained 0.2 g. or a 0.63% yield of tetraphenylmethane, the identity of which was confirmed by a mixed melting-point determination with an authentic specimen.

The non-acidic fractions also gave 10.9 g. or a 47.4% yield of *p*-phenyltriphenylmethane which after several crystallizations from hot absolute alcohol melted at 111°.

Anal. Calcd. for $C_{25}H_{20}$: C, 93.69; H, 6.31. Found: C, 93.20; H, 6.48. Mol. wt.: calcd., 320; found, 311.4.

The identity of this hydrocarbon was confirmed by a mixed melting-point determination with an authentic specimen melting at 111–112° and prepared in accordance with the directions of Schlenck, Weickel and Herzenstein, *Ann.*, 372, 18 (1909).

Summary

In connection with rate studies, series of mixtures containing an R'X and an RMgX compound have been heated to determine whether there is an interchange of radicals. No such interchange was observed. In the reaction between triphenylchloromethane and phenylmagnesium bromide an unusual product, p-phenyl-triphenylmethane, was obtained in a 47% yield.

AMES, IOWA

NEW BOOKS

Introductory Theoretical Chemistry. BY G. H. CARTLEDGE, Associate Professor of Chemistry, The Johns Hopkins University. Ginn and Company, 15 Ashburton Place, Boston, Massachusetts, 1929. xiv + 523 pp. 71 figs. 14 X 21 cm. Price, $3.60.

In the order of treatment, the author has followed the plan of his earlier "Inorganic Physical Chemistry."

Part I, pp. 1–202, The Nature of Matter, gives an interesting résumé of the historical development of the various laws relating to the gaseous, solid and liquid states. The kinetic theory, Avogadro's law, the determination of atomic weights, radioactivity, atomic structure and surface tension are carefully treated. Numerous examples and references are given to classical experiments, such as Black's quantitative study of chalk and lime, and Landolt's research into the conservation of mass. An abstract (7 pages) from "A Revision of the Atomic Weights of Sodium and Chlorine," Richards and Wells, serves to stimulate interest in original work.

Part II, pp. 203–294, deals with the nature of solutions. Here also the historical development is emphasized. Perfect solutions and Raoult's law are illustrated by the method of vapor pressure lowering. The molecular weight of dissolved substances is determined in accordance with the older ideas (van't Hoff factor *i*) instead of by application of modern thermodynamic methods. **A** whole chapter (16 pages) is devoted to osmotic pressure. The electrical properties of solutions are given **38** pages with emphasis upon the Arrhenius theory and the degree of ionization. Colloidal solutions are treated in 10 pages.

Part III, pp. 295–466, deals with the nature of reactions. The author first devotes a chapter to the speed of reactions. The equilibrium constant is then introduced as the quotient of two rate constants. The phase rule, equilibrium in gaseous reactions, the Ostwald dilutions law, with emphasis upon the concentration of the ions, valence equilibrium (oxidation, reduction and electromotive force), energy and free energy are treated in this section. The activity concept is given a third of a page.

Part IV, pp. 467–543, is an application of the foregoing principles to special ionic equilibria: solubility products, indicators, hydrolysis, complex ions.

An outline at the beginning of each chapter and many excellent exercises increase the usability of the book. Altogether the author has given us an interesting book, quite free from errors. The reviewer feels that this work will find favor as a text in a chemistry curriculum in which the ideas of Physical Chemistry are reserved to special courses. The theoretical chemistry which should be given college freshmen is reviewed, so that the book should be a valuable reference work for advanced students.

MERLE RANDALL

Organic Laboratory Methods. By the Late Professor LASSAR-COHN (Konigsberg). Authorized translation from the general part of the fifth revised edition. BY RALPH E. OESPER, PH.D., Associate Professor of Analytical Chemistry in the University of Cincinnati. Edited by ROGER ADAMS and HANS T. CLARKE. The Williams and Wilkins Company, Baltimore, Md., 1928. xi + 469 pp. 186 figs. 15.5 × 23.5 cm. Price, $6.50.

Lassar-Cohn's "Arbeitsmethoden für Organisch-Chemische Laboratorien" appears in the original German in two volumes, the first of which deals with laboratory technique, and the second with fundamental organic reactions such as nitration, etc. The present work is a translation of volume one. Its appearance is timely in that there are not many handbooks, written in English, which adequately cover this important subject.

There is a fairly broad diversity of topics, which include among others, distillation, dialysis, passage of vapors through hot tubes, evaporation, decolorization and clarification, extraction, filtration, crystallization, solvents and diluents, dehydration and comminution. It contains many useful suggestions, and should prove of especial value to graduate students majoring in organic chemistry. The stilted form which unfortunately characterizes so many translations is largely absent from this work. As a whole, then, it impresses the reader very favorably.

A. J. HILL

Gesammelte Abhandlungen zur Kenntnis der Kohle. (Assembled Scientific Papers on Coal.) Vol. 8, by DR. FRANZ FISCHER, Director of the Kaiser Wilhelm Institute for Research on Coal. Gebruder Borntraeger, Berlin, Germany, 1929. viii + 790 pp. Price, bound, $18.50.

This volume, like the preceding ones, consists of a collection of papers, for the most part previously published, dealing with the origin, constitution and utilization of coal. The papers included in the present volume give the results of researches carried out at the Institute during the years 1924 to 1927 inclusive. There are 111 in all, and of these 90 have appeared in *Brennstoff-Chemie,* 8 in various other periodicals and 13 are published here for the first time. A considerable proportion of the researches covered had for their objective the conversion of coal into oils, particularly by hydrogenation of carbonization products and by catalytic synthesis from water gas. The following titles will serve to illustrate the nature of this work: "The Reducibility of Cresols by the Bergius Method," "Petroleum Synthesis at Ordinary Pressures from the Gasification Products of Coal," "The Reduction and Hydrogenation of Carbon Monoxide," "Equilibrium Conditions in the Formation of Hydrocarbons and Alcohols from Water Gas." Bitumens extractable from coal and their relation to cokability are covered by several articles, and some experimental evidence is offered in support of the Fischer-Shrader lignin theory of the origin of coal. This book as well as the other seven volumes of the series will be found to be a valuable adjunct to libraries of those interested in coal research. They would be more readily usable if an index were provided.

JOSEPH D. DAVIS

Jahrbuch der Organischen Chemie. (Yearbook of Organic Chemistry.) BY Professor Dr. JULIUS SCHMIDT, Stuttgart. Franz Deuticke, Vienna, Austria, 1929. 17.5 × 25.5 cm. xviii + 256 pp. Price, unbound, M. 21; bound, M. 24.

The thirteenth volume of the Jahrbuch deals with investigations that were completed in 1926. For this tardy appearance which materially diminishes the value of such an annual, the author disclaims all responsibility, and he also gives assurance that, hereafter, the Jahrbuch will appear with its pre-war promptness and regularity. The general plan remains the same and there has been but little change in scope. The mechanical work of the new publisher is excellent.

E. P. KOHLER

The Theory of Emulsions and their Technical Treatment. By WILLIAM CLAYTON, D.Sc., F.I.C. Foreword by Professor F. G. Donnan, C.B.E., M.A., Ph.D., D.Sc., F.R.S. Second edition. P. Blakiston's Son and Company, 1012 Walnut St., Philadelphia, 1928. xi + 283 pp. 42 figs. 14 X 22.5 cm.

In writing the second edition the author has held to the same context as in the earlier book (160 pp., 1923). Theories of the formation of emulsions are discussed in great detail. A brief chapter on technical emulsions has been included.

Appendix I, written by W. Ramsden on the "Theory of emulsions stabilized by solid particles," might well have been elaborated as in the discussion on the important physical factor, "angle of contact," clarity appears to have been sacrificed for brevity.

Some condensation of the chapters on the theories of emulsions and elaboration of the chapters on de-emulsification and technical emulsions would probably have been welcomed by industry.

The comprehensive review of the literature presented by Clayton guarantees that a thorough knowledge of the subject may be obtained from this source. Mayonnaise is discussed with less than a page and no mention is made of the non-colloidal emulsifying agents. Yet many interesting ideas are included. Ayres' use of a solid fat, more readily wetted by oil than by water, as a water-in-oil emulsifying agent is worth noting. So is Schou's proposal to gelatinize soya bean oil at 250° and to mix it when cooled to 100° with twice its volume of cold soya bean oil in order to prepare an excellent water-in-oil emulsifying agent. The two-page list of emulsifying agents is especially useful.

Thirty-two pages of classified references are found in the Appendix.

The book contains much valuable information for workers in diverse fields. Biologists, pharmacists, chemical manufacturers and dairy chemists especially may profit.

HARRY N. HOLMES

Elektrizität und Eiweisse, insbesondere des Zellplasmas. (Electricity and Albumins, especially of the Cell Plasma.) By Dr. HANS PFEIFFER, Bremen. Theodor Steinkopff, Residenzstrasse **32,** Dresden-Blasewitz, Germany, 1929. xii + 149 pp. 7 figs. *15.5* X *22* cm. Price, unbound, R. M. 10; bound, R. M. 11.50.

This book is Volume XXI of a series, "Wissenschaftliche Forschungsberichte, naturwissenschaftliche Reihe," edited by R. E. Liesegang. The object of these monographs, as stated by the editor in an introductory note, is to offer in condensed form a selection of the most important accomplishments since about 1914, at home and abroad, in some single branch of natural science. This volume is concerned with a part of the field of electrophysiology, taking up (1) electrical properties of colloids, (2) electrical and colloidal properties of proteins, and **(3)** attempts to interpret the behavior of living cells from electrical measurements, and from the colloidal behavior of the cell proteins, It presents a very condensed abstract of the work of a large number of authors. (Over a thousand names are included in the author index.) It is evident that in so small a book the discussion of any one among so many papers must be extremely brief. Many of the references, indeed, are not mentioned in the text.

There is a subject as well as an author index. An improvement would be a list of the books and periodicals reviewed. An appendix gives a brief report of the symposium on Electrostatics in Biochemistry, at Basle, October 8–12, 1928.

VOL. 51 OCTOBER, 1929 No. 10

PRESIDENT'S ADDRESS[1]

MODERN CONCEPTS IN PHYSICS AND THEIR RELATION TO CHEMISTRY

BY IRVING LANGMUIR

Only about 35 years ago, during the nineties of the last century, knowledge of the physical sciences had advanced to such a point that many of the foremost physicists and chemists began to believe that the rate of progress of fundamental knowledge must be slowing up. The concepts of length, mass, time, energy, temperature, electric and gravitational fields, etc., had been given precise meanings and were regarded as having an absolute existence quite as certain as that of matter itself. The phenomena of nature were explainable in terms of natural laws expressing relations between these absolute quantities. It seemed that the most important of these laws of physics and chemistry had already been discovered and that the work that remained to do was largely a matter of filling in the details and applying these great principles for practical purposes.

The laws of mechanics had been verified experimentally with a high degree of precision so no one doubted that they were rigorous laws of nature. Back in about 1830, Hamilton had succeeded in generalizing these laws in a few simple equations which seemed to contain all the essential truths of mechanics. It was only necessary to know how the kinetic and potential energy of any given system varied with the momentum and the coordinates of its parts in order to have at least a formal solution of the way in which the system would behave at all times. Thus all future work in mechanics need only be considered an application of Hamilton's equations.

Complete knowledge of the nature of light presented more difficulties. Hamilton, about 1820, showed that all the known laws of geometrical optics could be explained quantitatively in terms of either a corpuscular theory of light or a wave theory. The experiments of Fresnel on the interference of light, which were made about this time, seemed to disprove Newton's

---

[1] Presented before the 78th meeting of the American Chemical Society, Minneapolis, Minnesota, September 11, 1929.

corpuscular theory, so that Hamilton's proof of the complete analogy between waves and corpuscles in the case of geometrical optics became only of academic interest. Through the study of the phenomena of interference, diffraction, polarization and absorption of light, the wave theory of light became firmly established. Light was supposed to consist of waves in some sort of an elastic medium which was called the ether.

About 1830, Faraday developed clear conceptions regarding the electric and magnetic fields and Maxwell, about 1860, by applying exact mathematical methods evolved the electro-magnetic theory of light according to which light waves consisted of fluctuating electric and magnetic fields which are propagated through space at a speed which could be calculated from electric and from magnetic measurements in a laboratory.

Although the acceptance of Maxwell's views came slowly one could not long remain skeptical after the production of electro-magnetic waves of relatively great wave length by Hertz in 1884. It may almost be said that Maxwell's theory was essentially an application of the mathematical methods which Hamilton had originated in his treatment of the laws of mechanics, to Faraday's concepts of electricity and magnetism.

Thus in 1895, the physicists seemed to have some justification for the attitude that the most important laws had been discovered. The laws of mechanics had not been improved upon in 65 years. Faraday and Maxwell had brought in precise conceptions of electric and magnetic phenomena and had shown that by classical methods like those which had been so successful in mechanics, all the laws of optics could be derived from those of electro-magnetism.

In chemistry a somewhat similar state had been reached. After the evolution of the conception of the elements and of combining proportions based upon an atomic theory, rapid progress was made in accumulating data regarding the elements and their compounds. Faraday's laws of electrolysis and new methods for the accurate determination of atomic weights began to provide the chemist with quantitative laws almost as precise as those of the physicists. The work of J. Willard Gibbs had brought into chemistry rigorous laws as fundamental in their field of application as were those of Hamilton and Maxwell in physics.

These remarkable advances on the quantitative side seemed to overshadow in importance the more qualitative results that had previously been obtained through the stimulus of the atomic theory. Under the leadership of Ostwald, chemists began to adopt a much more critical attitude and began to distinguish carefully between what they considered experimental facts and hypotheses based upon these facts. Ostwald, although he recognized the convenience of the atomic theory, believed it must always remain impossible to prove the existence of atoms or molecules. He therefore urged that chemists avoid as far as possible the use of such hypotheses. Perhaps the chief result of this attitude was to lead physical chemists to neglect those parts of chemistry where the atomic theory would have been most helpful and to devote themselves more specially to the fields in which energy relationships and thermodynamics were directly applicable.

Physicists in general did not doubt the existence of atoms and molecules, but had by means of this theory developed the kinetic theory of gases which had led to many new quantitative laws, verified by experiment. However, the physicists in general had little to do with atoms and molecules but were more concerned with the ether, in which they believed unreservedly, although direct knowledge of the ether was far harder to obtain than knowledge of atoms and molecules.

Perhaps one of the main reasons why the physicists were so sure of the ether and the chemists so doubtful of the atoms and molecules was an unconscious belief in the respectable old adage "Natura non facit saltum," Nature makes no jumps. Certainly in those fields of physics and chemistry in which rigorous quantitative laws had been found applicable no discontinuities or jumps such as those implied by the atomic theory had been found.

The discovery of x-rays by Roentgen, in 1905, marked the beginning of an extraordinary revolution which is today still in progress. This sensational event revealed to the physicist that great and fundamental discoveries were still possible even in the field of radiation where physics had had such complete success. It immediately caused great numbers of physicists to study the phenomena of electric discharges and to look for other sources of radiation. The-discovery of radium and radioactivity by Becquerel and the Curies soon showed the importance of these new forms of radiation to the chemist as well as to the physicist.

Although Stoney in 1874 had seen that Faraday's laws of electrolysis together with the atomic theory required that electricity should also have an atomic structure, and although in 1891 he proposed the name electron for these atoms of electricity, J. J. Thomson should be regarded as the discoverer of the electron. He was able to show that electrons were contained in all forms of matter and found that the electron must weigh only about $^1/_{1800}$ as much as a hydrogen atom.

The studies of radioactivity, largely by Rutherford and his students, showed that radium spontaneously disintegrated to form helium and proved to the chemist that atoms were not indestructible and even that transmutation of elements was possible.

By the application of thermodynamics to radiation processes Boltzmann proved that the total radiation, of all wave lengths, within a cavity in a heated body must increase in proportion to the fourth power of the absolute temperature; this law had already been found empirically by Stefan. By a further development of thermodynamic methods Wien, in 1896, derived an important law, known as Wien's law, by which the intensity of radiation of any particular wave length could be calculated in terms of the wave length and temperature. This law was found to agree with experiment in the case of visible radiation from incandescent solids, but serious discrepancies were observed when an attempt was made to calculate the intensity of infra-red radiation or heat waves. Lord Rayleigh and Jeans, in 1900, using what seemed to be unimpeachable methods based on the electro-magnetic theory of light, arrived at an entirely different relation between the intensity of radiation and the temperature and wave length. This equation agreed excellently with experiments on the radiation of heat where Wien's law had failed but led to absurd results when applied to the shorter wave lengths of the visible spectrum. In fact, if the total radiation including all wave lengths were calculated from the Rayleigh-Jeans equations an infinite radiation density was obtained even at low temperatures. Thus by means of the classical theories of radiation it was found on the one hand by Boltzmann that the radiation increased with the fourth power of the temperature, and on the other by Rayleigh–Jeans, that the radiation was infinite at all temperatures.

It was shown in 1905, by Planck, that this paradox could only be solved by assuming an essential discontinuity in the energies or motions of electrons whose vibrations caused the radiation. This gave birth to the Quantum Theory, which within recent years has grown to be one of the most important theories of physics and chemistry. In 1906, Einstein showed that the photo-electric effect and many photochemical reactions could be explained in terms of the Quantum Theory if light itself consisted of discrete particles of energy or quanta, now usually called photons. Although such a corpuscular theory of light seemed utterly incompatible with the accepted wave theory, an increasing number of phenomena were discovered in which it seemed necessary to resort to this corpuscular theory. The really rapid development of the Quantum Theory, however, dates from 1913, when Bohr began to develop his theory of atomic structure by applying the Quantum Theory to Rutherford's more or less qualitative theory of the nuclear atom.

Relativity Theory.—Among all the changes in the ways of thinking which were being forced upon physicists at this time, the most important by far was that which resulted from Einstein's relativity theory, first stated in 1905. In 1895, as we have seen, electromagnetic waves and matter were thought to be manifestations of the properties of an all pervading ether.

As an example of the way that the physicists thought of the ether I will quote from the preface to Lord Kelvin's "Baltimore Lectures." This preface was written in 1904, but the lectures were those that were delivered at Johns Hopkins University in 1884.

"I chose as subject the 'Wave Theory of Light' with the intention of accentuating its failures; rather than of setting forth the admirable success with which this beautiful theory had explained all that was known of light before the time of Fresnel and Thomas Young, and had produced floods of new knowledge splendidly enriching the whole domain of physical science. My audience was to consist of Professorial fellow-students in physical science. . . . I spoke with absolute freedom and had never the slightest fear of undermining their perfect faith in ether and its light-giving waves: by anything I could tell them of the imperfection of our mathematics; of the insufficiencyor faultiness of our views regarding the dynamieal qualities of ether; and of the overwhelmingly great difficulty of finding a field of action for ether among the atoms of ponderable matter. We all felt the difficulties were to be faced and not to be evaded; were to be taken to heart *with the hope of solving them if possible.* . . . It is in some measure satisfactory to me and I hope it will be satisfactory to all my Baltimore coefficients still alive in our world of science, when this volume reaches their hands to find in it dynamical explanations of every one of the difficulties with which we were concerned from the first to the last of our twenty lectures of 1884. All of us will, I am sure, feel sympathetically interested in knowing that two of ourselves, Michelson and Morley, have by their great experimental work on the motion of ether relatively to the earth, raised the one and only serious objection against our dynamical explanations."

.This Michelson and Morley experiment of 1887, through the theoretical investigations of Lorentz and others, kept growing in importance until it finally stimulated Einstein to evolve his relativity theory.

According to this theory space and time cannot be considered as existing independently of each other. They cannot in any sense be regarded as absolute but are both dependent upon the point of view of the observer. For example, Einstein showed that it has no meaning to say that two events which took place at a great distance apart occurred simultaneously. Some observers knowing of both events would have to say that event A occurred before B, while other observers moving at a different velocity from the first observers would conclude that B occurred before A.

It is not my plan to try to explain the relativity theory to you even if I knew how to do so, but it is rather to discuss the way in which this theory and others of **a** somewhat similar nature have gradually brought about profound changes in the viewpoint of the physicists and how similar changes are beginning to occur in the attitude of the chemists. The importance of Einstein's work thus lies not so much in the facts or phenomena that can be explained by the relativity theory, but in the discovery of a new way of thinking as applied to physics. Somewhat similar methods of thought had, it is true, been used in some branches of mathematics and sometimes in philosophy, but Einstein subjected our elementary conceptions of space, time, mass, energy, etc., to a searching analysis quite new in the history of physics.

Concepts Involve Operations.—Professor P. W. Bridgman of Harvard University has recently written a popular book entitled "The Logic of Modern Physics," in which he analyzes the changes in our concepts that have resulted primarily from Einstein's work. Bridgman's thesis is that *physical concepts have meaning only in so far as they can be defined in terms of operations.* He shows that this new attitude toward our fundamental conceptions is perhaps one of the greatest changes that has been brought about by Einstein's work. There is no question in my mind but that the recent remarkable advances in quantum mechanics that have been made by such men as Bohr, Heisenberg, Schroedinger and Dirac have been stimulated by the desire to formulate all concepts in terms of operations. Bridgman has not originated this method, but he, more than anyone else, perhaps, has been conscious of its widespread application in modern physics.

I should like to outline to you the way in which Bridgman develops this thesis and to consider how well it applies to the most recent changes that have taken place in physics and in chemistry. I believe the chemist can derive great benefit from the conscious application of a similar critical attitude in his own science.

Bridgman points out that "hitherto many of the concepts of physics have been defined in terms of their properties." An excellent example is Newton's concept of absolute time. The following quotation from Newton's "Principia" is illuminating.

"I do not define Time, Space, Place or Motion, as being well known to all. Only I must observe that the vulgar conceive those quantities under no other notions but from the relation they bear to sensible objects. And thence arise certain prejudices, for the removing of which, it will be convenient to distinguish them into Absolute and Relative, True and Apparent, Mathematical and Common.

"(1) Absolute, True and Mathematical Time, of itself, and from its own nature flows equally without regard to anything external, and by another name is called Duration."

Thus, according to Newton, time and space have properties of a very abstract kind and are looked upon as "things" which exist independently of all other things. There is, however, as Bridgman says, "no assurance whatever that there exists in nature anything with properties like those assumed in the definition, and physics, when reduced to concepts of this character, becomes as purely an abstract science and as far removed from reality as the abstract geometry of the mathematicians." Nevertheless, these conceptions of space and time prevailed until the relativity theory was proposed.

In the development of his theory Einstein, in analyzing the concepts of space and time, considered what means are available by which an observer can measure distances between two points on a rapidly moving object. For example, imagine two planets moving past each other at high velocity and two observers, one on each planet, provided with means for observing each other and communicating with each other; such means, for example, as light signals. Einstein asks, what are the operations by which the two observers could compare their units of length and time? He finds that each observer would logically conclude that the other observer's unit of length is shorter than his own, and that the other's unit of time is longer than his own. Einstein thus proved that there can be no such thing as absolute length or time, or rather proved that the concept of absolute time has no meaning, for we have not been able to conceive of any method for determining the absolute time of any event.

In order to illustrate his thesis Bridgman considers in detail the concept of length. Probably one of the earliest concepts of length was obtained by counting the number of unit lengths that can be placed end to end between two given objects. For example, the number of paces are counted in walking from one object to another. An extension and refinement of this method is employed today when the standard meter at the Bureau of Standards is compared with a steel tape and this is then used to lay off a base line for a survey by triangulation.

As Bridgman suggests, it was one of the greatest discoveries of the human race to find that these operations performed with a measuring rod afford a useful and convenient means of describing natural phenomena.

During the transition from the earliest pacing of distances, to our modern refined measurements with the meter stick, the concept of length itself must have undergone radical modifications since the operations involved had been modified. For example, if distances are to be paced, it has no meaning to consider distances of $^1/_{1000}$ of a pace unless the concept is modified to include arbitrarily chosen methods by which a length equal to $^1/_{1000}$ of a pace may be determined. In our modern measurements with a steel tape we must measure the temperature of the tape and the force used in holding the tape taut, and then by means of the coefficient of expansion and the coefficient of elasticity, apply corrections to the observed length. It is hard to see what methods primitive man could have used in applying such corrections to his distances measured by pacing.

Why do we now apply such corrections? Merely because it has been found by experiment that the result that we get by applying such corrections is a quantity which proves to be more useful in describing natural phenomena than the results we get without these corrections. We must not think that we do it in order to obtain the "true" or "absolute" length.

Today we have many other methods of measuring length than by use of measuring rods or steel tape. For example, we use optical instruments and measure distances by triangulation, we measure heights in the atmosphere by means of a barometer, we measure the distances of spiral nebulae by measuring the brightness of the Cepheid variables observed in them by our most powerful telescopes, we measure the lengths of molecules by finding the area of a water surface over which a given amount of oil will spread, we calculate the diameters of molecules by measurements of the viscosity of gases by means of the kinetic theory, or we use x-ray diffraction patterns or, finally, we calculate the diameter of an electron from its mass and charge by means of the electro-magnetic theory assuming that all the energy of an electron lies in the electric field outside of its surface.

Now each of these measurements of length involves an entirely different set of operations and, therefore, fundamentally, according to Bridgman, we should regard them as different concepts; logically, in fact, they should all have different names. It has, however, been found as a matter of experiment that two or more of these methods when applied to the measurement of the same distance give results which agree more or less with one another. This, then, is our justification for calling all these concepts by the same name, length.

We may, if we wish, extrapolate and predict that by applying suitable corrections to each of these methods of measuring lengths we may be able to get better and better agreement between them. Such methods of extrapolation may be useful and stimulating but we must always expect that sooner or later we will be unable to obtain agreement between these methods with more than a limited degree of accuracy. This may not be due merely to experimental difficulties but may often result from unavoidable fuzziness in the concept itself. Such concepts as the diameter of a complicated molecule, or the mean free path of a molecule in a gas are inherently fuzzy conceptions and can mean not much more than when we speak of the diameter of a tree or of the length of the waves during a storm at sea.

Perhaps the strongest reason for the general belief in the existence of an absolute space lay in the apparently perfect agreement between our measurements of length and the theorems of Euclidian Geometry. During the last century, however, mathematicians began more and more to realize that Euclidian Geometry was only one out of many possible logical geometries, and since all of these were based solely on certain axioms or postulates none of them had any real or necessary connection with physics. The apparent agreement between our physical observations and Euclidian Geometry, therefore, does not prove that space must have the properties postulated in Euclid's axioms.

Models.—As chemists we are all more or less familiar with various models of atoms and molecules that have been proposed within recent years. The structural formulas which the organic chemists have used for a good part of a century are another example of an extremely useful type of model. I want to discuss later some of the models which the physicists have used in giving more concrete forms to their theories. Logically, I believe, we should regard Euclidian Geometry as a model devised primarily to help us "explain" natural phenomena.

Observation of nature reveals great complexity. We receive enormous numbers of impressions simultaneously and if we are to make progress in understanding phenomena we must concentrate on certain aspects of the things we see about us and thus discard the less important features. This involves a process of replacing the natural world by a set of abstractions which we have become very skilful in choosing in such a way as to aid us in classifying and understanding phenomena. Thus it was found useful to develop concepts or abstractions such as shape, position, distance, etc., and separate these characteristics of the phenomena from others such as color, hardness, etc. Euclidian Geometry was found useful in correlating these concepts of shape, position, etc.

Physicists and chemists have usually felt that they understood a phenomenon best when they could explain it in terms of a model or concrete picture. The chemist explained the law of multiple combining proportions in terms of atoms which combine together to form molecules. The heat conductivity, viscosity, etc., of gases was explained in terms of the kinetic theory, with molecules making elastic collisions with one another according to the law of probability.

When we use the atomic or molecular theories to explain phenomena in this way, we assign to the atoms and molecules only those properties which seem needed to accomplish the desired result, we do not consider what the atom is made of nor what its structure is, but usually feel justified in assuming properties which are as simple as possible. For example, in the elementary kinetic theory it is assumed that the molecules are hard, elastic spheres, not because anyone really believes that molecules have these properties, but merely because these are the simplest properties we can think of which are consistent with the known facts.

What we really do, therefore, is to replace in our minds the actual gases which we observe and which have many properties which we do not fully understand by a simplified model, a human abstraction, which is so designed by us that it has some of the properties of the thing we wish to displace.

There is thus a difference of degree rather than of kind between the adoption of a mechanical model and the development of a mathematical theory such as Euclidian Geometry. When the mathematical physicist develops an abstract theory of actual phenomena, for example, Hamilton's equations to summarize the laws of mechanics, he is in reality constructing a mathematical model. Mathematical equations have certain definite properties or rather they express certain relationships between the symbols which enter them. In a mathematical theory of physical phenomena the equations are so chosen that the relation between the symbols corresponds in some simple way to that which is observed between measurable physical quantities which are the bases of our concepts of physics.

Within recent years, especially in the development of the relativity and quantum theories, physicists have been making increasing use of mathematical forms of expression, and have been giving less attention to the development of mechanical models. The older generation of physicists and chemists and those among the younger men who are less skilled in the use of mathematics are inclined to believe that this is only a temporary stage and that ultimately we must be able to form a concrete picture or model of the atom, that is, to get a picture of what the atom is really like. It seems to be felt that a mechanical model whose functioning can be understood without the aid of mathematics, even if it only gives the qualitative representation of the phenomena in question, can represent the truth in some higher sense than a mathematical theory whose symbols perhaps can be understood only by a mathematician.

There is, I believe, no adequate justification for this attitude. Mechanical models are necessarily very much restricted in scope. The relationships of their parts are limited to those that are already known in mechanics (or in electricity or magnetism). Mathematical relationships are far more flexible; practically any conceivable quantitative or qualitative relationship can be expressed if desired in mathematical form. We have no guarantee whatever that nature is so constructed that it can be adequately described in terms of mechanical or electrical models; it is much more probable that our most fundamental relationships can only be expressed mathematically, if at all.

In analyzing our attempts to describe nature, we have discussed concepts, models and mathematical theories. We find that they are all alike in that they represent human abstractions which are found convenient in describing nature. Going back a step further we must recognize that *words* themselves constitute elementary concepts. They are, it is true, much more vaguely defined than our concepts of physics and chemistry, but qualitatively they are very much like the latter; in fact, most of our misunderstandings in science arise from assigning reality to concepts whose main reason for existence is the fact that they are represented by a word. Logically we should aim to define our words in terms of operations. We should have in mind specifications by which we can test whether or not the word is properly applicable.

The progress of science depends largely upon (1) giving to words meanings as precise as possible; (2) definition of concepts in terms of operations; (3) development of models (mechanical or mathematical) which have properties analogous to those of phenomena which we have observed.

Meaningless Questions.—A great deal of time and effort is wasted in scientific circles as well as in the world at large through failure to give sufficiently definite or useful definition of words and concepts. Bridgman emphasizes this in connection with his discussion of "Meaningless Questions."

In some cases questions fail to have meaning because of the more or less inherent fuzziness of the concepts involved. For example, if we compare two trees of about the same size it may have no meaning to ask which tree has the larger diameter, for no one has defined the diameter of a tree with the necessary precision.

A more important class of meaningless questions arises when there are no conceivable operations that could be performed to arrive at a decision. For example, what is the meaning of the question, "Would the United States have ended the World War if the Lusitania had not been sunk?" Such a question may be a good subject for a school debating society, but no one is apt to think that the question has thereby been answered.

A study of meaningless questions may serve a very useful purpose in science. A statement that a certain question has no meaning may be equivalent to stating a fundamental law of nature; for example, to say that the question "What is the true velocity of the north star through space?" has no meaning is a fairly good statement of at least a part of the relativity theory.

In some cases it may have no meaning to ask whether or not there is a magnetic field in a certain portion of space. For example, suppose an observer, stationary on the earth, studies an electron in motion. The motion of an electron constitutes an electric current and experimentally he will observe the characteristic magnetic field surrounding this electron corresponding to this current. If another observer moves along with the electron, it will appear to him to be at rest, and, of course, he can observe no magnetic field. Otherwise, the presence or absence of a magnetic field around an electron or group of electrons could be used to determine absolute motion through space, which would be contrary to the relativity theory. The relativity theory thus requires that a magnetic field can have no real existence in any absolute sense.

We have seen that there are fundamentally as many different concepts of length as there are different ways in which length may be measured; nevertheless, we find approximate agreement between different ways of measuring the diameter of molecules and therefore are justified in assigning some *reality* to the concept diameter of molecule. When, however, we ask what is the diameter of an electron, we find that the question is practically without meaning. It is true that we can calculate, a diameter by assuming that the electron behaves like a charged sphere and that the classical laws of electrodynamics can be applied in this case. However, since we have no independent way of measuring this diameter, the process is one which involves reasoning in a circle.

There are many meaningless questions which afflict the chemist. It clearly has no meaning to ask what is the molecular weight of sodium chloride in a crystal. It is very doubtful whether it has any meaning to ask what is the molecular weight of water in liquid water. There are many cases where the concept of temperature has no definite meaning. Strictly speaking, temperature acquires meaning in terms of operations only in so far as an approach is made to equilibrium conditions. When the motions of molecules or atoms follow Maxwell's Distribution Law, that is, a random or probability distribution of velocity among the molecules, the concept of temperature becomes very definite. If, however, we deal with mercury vapor streaming into a high vacuum, or the conditions near a hot tungsten filament in a gas of low pressure, temperature has very little meaning. The same is true of the conditions frequently existing in an electric discharge tube such as a mercury arc, where the electrons act as though they had a temperature of perhaps 50,000°, whereas the atoms have motions corresponding to far lower temperatures. Strictly speaking, neither the electrons nor atoms have well-defined temperatures, for the conditions are far removed from equilibrium.

In much of the recent discussion of the Radiation Hypothesis of chemical reactions, chemists have been discussing meaningless questions usually without realizing it. At first it was proposed that the radiation is absorbed by the reacting gas to form excited molecules in accordance with Einstein's photochemical law. When this is found not to be in accord with experiment, the concept of radiation is altered repeatedly as new experimental facts are found so as to make the modified theory continue to fit the facts. After this process has been carried on sufficiently, it no longer has any meaning to ask whether the reaction is caused.by radiation or whether the radiation hypothesis is true.

In the studies of the properties of liquids, questions of the degree of ionization and of association and in some cases of internal pressures have been discussions of questions without meaning. A great deal of such discussion might be simplified or even avoided entirely if chemists would agree in defining these concepts in terms of operations.

Theories of valence within recent years have been afflicted with 'the same difficulties. As long as chemists deal with the ordinary valence rules of organic chemistry, they are dealing with concepts of valence which are actually defined in terms of operations; that is, the organic chemists know how to conduct experiments to prove that the valence of nitrogen in dimethylaniline is 3. The types of operations needed to establish the valence of magaesium in magnesium chloride are in many ways quite different, and they are still different if we consider the case of so-called quinquevalent nitrogen in ammonium chloride or heptavalent chlorine in perchloric acid. I believe that the chemist has much to learn from the physicist in regard to the proper method of attacking. such problems as these.

The electrochemist has been troubled in locating the source of electromotive force in cells. The physicist has similar difficulty in finding the origin of the contact potential between metals. Fundamentally it must be recognized that unless or until there are methods by which these quantities can be measured, questions involving them have no meaning.

A practical example of the meaninglessness of some questions involving electric potential has recently arisen in the numerous proposals that have been made to construct a speed indicator for airplanes which will give the speed with respect to the earth's surface independently of that of the wind surrounding the plane. It is reasoned that since the plane is moving through the earth's magnetic field a potential will be set up between the ends of a wire stretched between the wing's tips. It is only necessary to measure this potential difference in order to calculate the speed of the plane with respect to the earth. Careful analysis shows that the concept of the potential difference under these conditions is meaningless except with reference to a particular reference system. If this system is referred to the plane itself, this potential difference is zero quite regardless of what the speed of the plane may be with reference to the earth. A contrary result would conflict with the relativity theory.

Meaningless questions will assume far greater importance in future years. We shall see that the latest forms of the quantum theory now give us the best of reasons for believing that the identity of separate electrons within atoms or molecules may be partly or wholly lost, so that it may have no meaning to ask whether a particular electron we find as a result of experiment is the same electron which has previously produced an observed phenomenon. Even more far-reaching in its consequences is the Bohr-Heisenberg Uncertainty Principle according to which it has no meaning to ask what is the precise position and velocity of an electron or atom. An electron may have a definite position or a definite velocity but it cannot in any exact sense have both. This doesn't mean merely that there are experimental difficulties in measuring them, it means that the concepts themselves (position and velocity) are relative to one another in a sense somewhat analogous to that of time and space in the relativity theory.

One's instinctive reaction when first questioned as to the objective reality of space, time, position, velocity, etc., is to object to such consideration on the grounds that they are too metaphysical. The recent advances in physics demonstrate that these methods of thinking are eminently practical; they represent, in fact, an attempt to get away from the metaphysical character of much of our thinking in the past. Instead of taking for granted objective realities corresponding to our concepts, we now deal with things which can be measured in the laboratory, the concrete data that we have to start from.

It is, however, very useful to retain the concept of reality. Bridgman suggests that reality should be measured by the number and the accuracy of the independent ways in which we arrive at similar measures of the concept in question. For example, owing to the fact that we have so many concordant methods of measuring the distance between the ends of a base line used for triangulation, we attribute great reality to the concept of length or, rather, to those concepts of length which are applicable in cases of this kind. We thus have some justification in saying that two points are really one kilometer apart. We do not attribute, however, much reality to the concept of the diameter of an electron.

Thirty years ago the physical chemist doubted the existence of atoms or believed the concept was useless if not pernicious. A few years later the leader of this movement, Ostwald, in the preface of one of his books stated that he believed that the existence of atoms had been proved experimentally beyond question, although in previous books he had stated that there are always an infinite number of hypotheses that could be advanced to explain any given set of experimental facts.

Today, what can we say in answer to the question "Does matter really consist of atoms?" Must we say that this is one of those meaningless questions?

Of course, the amount of meaning that can be attached to any such question depends upon the definitions of the words and concepts which it contains. If we mean by atoms indivisible and indestructible infinitely hard, elastic spheres, we are compelled to answer the question in the negative. In accordance with modern usage, however, we do not attribute any such properties to the atom. If, by the use of the word atom, we mean to imply principally the concept that matter consists of discrete particles which can be counted by the various methods which are now known for this purpose, we have the very best of reasons for answering the question in the affirmative. If in om studies of nature we discover evidences of discontinuities or of the presence of discrete natural units which can be correlated in a definite way with the numerical integers, we have come, it would seem, about as close to something absolute in nature as we can hope to get. Einstein in the relativity theory has taught us to look upon the intersections of world lines as the data upon which our observations of nature rest. Such points of intersections, which can be called events, are essentially discontinuities. In general they are all unlike one another. When we find in nature discrete units which in many respects appear to be identical with one another, and we can count these units, it would seem that the number of these units which obtain as a result is apt to be independent of our system of reference; therefore, they have in general, a certain kind of absolute significance.

In this respect, therefore, it seems that the atomic theory and the quantum theory in which integers play such a fundamental role may be considered as representing reality to a higher degree than almost any other of our physical and chemical theories.

Skepticism in regard to an absolute meaning of words, concepts, models or mathematical theories should not prevent us from using all these abstractions in describing natural phenomena. The progress of physical chemistry was probably set back many years by the failure of the chemists to take full advantage of the atomic theory in describing the phenomena that they observed. The rejection of the atomic theory for this purpose was, I believe, based primarily upon a mistaken attempt to describe nature in some absolute manner. That is, it was thought that such concepts as energy, entropy, temperature, chemical potential, etc., represented something far more nearly absolute in character than the concept of atoms and molecules, so that nature should preferably be described in terms of the former rather than the latter. We must now recognize, however, that all of these concepts are human inventions and have no absolute independent existence in nature. Our choice, therefore, cannot lie between fact and hypothesis, but only between two concepts (or between two models) which enable us to give a better or worse description of natural phenomena. By better or worse we mean, approximately, simpler or more complicated, more or less convenient, more or less general. If we compare Ostwald's attempts to teach chemistry without the use of the atomic theory with a good modern course based upon the atomic theory, we get an understanding of what should be meant by better or worse.

The more recent advances in atomic theory which have resulted from the development of the quantum theory and which have given us our present knowledge of atomic structure, afford us interesting applications of the new methods of thought, first introduced into physics and chemistry by the relativity theory.

The older atomic and molecular theories of the chemists took on more definite form through the development of the kinetic theory of gases, and through the electron theory and the study of radioactivity developed to a point where the atom is conceived of as consisting of a definite number of electrons revolving around the nucleus. The atom ceased to be indestructible and was no longer the smallest particle of matter which could take part in a chemical reaction. The nucleus, rather than the atom, became characteristic of the chemical elements. The chemical properties of the atom, however, depended upon the number and arrangement of electrons.

Bohr, in 1913, developed a marvellous new theory of the atom by combining Planck's quantum theory with a relative theory of the nuclear atom. He evolved several new quantitative mathematical relationships with new concepts such as energy levels, quantum states, etc., and showed how the spectra of elements could be explained in terms of these new concepts. He also gave a mechanical model consisting of electrons revolving in orbits about the nucleus according to laws which were partly classical and partly inconsistent with classical laws. This model enabled him to derive certain mathematical equations from which he was able to calculate the frequencies corresponding to the different lines in the spectra of hydrogen and other elements, these frequencies being obtained from fundamental quantities such as the charge and mass of the electron and the quantum constant h, and did not involve any quantities dependent on the properties of the elements in question. The agreement between the theory and experiment was practically perfect, often enabling the frequency to be calculated with an accuracy of one part in two hundred thousand.

Such remarkable success made most physicists and chemists believe that Bohr's model, for the hydrogen atom at least, was substantially correct. That is, they believed that Bohr's work proved that in a normal hydrogen atom the electron really described a circular orbit around a nucleus having a diameter and a frequency given by Bohr's model. Bohr himself never attached any such importance to the mechanical model, realizing that the important steps that he had taken consisted mainly in the introduction of new concepts and more particularly in the mathematical equations by which the observed frequencies in the spectral lines could be calculated.

Within recent years, largely through the work of Bohr himself and his students, and Sommerfeld, Schroedinger, and others, this theory of the hydrogen atom has undergone changes. According to Bohr's original model the radiation of energy corresponding to a spectral line resulted from transition in which the electron passed from one stationary orbit to another. No physical picture of this transition seemed possible. To account for the known phenomena it seemed necessary that the transition should occur so rapidly that the electron would have to move from one orbit to another with a velocity greater than that of light, and yet the train of waves in the resulting radiation lasted for relatively long periods of time, about 10^{-8} seconds. Radiant energy could be absorbed by the atom only if the frequency was just that which was capable of transferring an electron from one orbit to another definite orbit. Thus only one frequency could be absorbed at a time by an atom. It was found, however, that the frequencies corresponding to many lines could be scattered by a single atom. This seemed to require the presence within any given atom of a number of oscillators as great as the number of lines in the spectrum. One of the greatest arguments in favor of the original Bohr theory was that it avoided just this sort of complication in the atom.

To get rid of difficulties such as these, Heisenberg and Born realized that it was necessary to sweep out of the theories of atomic structure the many concepts which were characteristic of the mechanical models that had been proposed and to develop a mathematical theory of the atom which would involve only concepts that were definable in terms of operations. That is, the theory was one that dealt more directly with measurable quantities such as the frequencies of spectral lines. New methods of matrix calculus had to be evolved, a kind of calculus of discontinuities or discrete quantities instead of the calculus of continuous quantities which had characterized classical mechanics.

Only a little later Schroedinger, by developing DeBroglie's wave theory of quantum phenomena, was able to build up a theory that we will now refer to as the wave mechanics, according to which the whole atom with all its electrons can be looked upon as a wave phenomenon. The electrons are no longer considered to be moving in orbits. For example, the hydrogen atom is found to have spherical symmetry instead of the axial symmetry of the old Bohr model of the atom. Yet this theory leads to identically the same equations for the frequencies of the lines in the hydrogen spectrum. We must not say that Bohr's theory of the hydrogen atom has been overthrown. Bohr's *mechanical* model has been superseded, but the more important model which is represented by the equations and the concepts which he evolved is even better today than it was when it was first proposed.

. The wave mechanics which involves the calculus of continuous variables is not now in conflict with the Born matrix calculus of discrete quantities. The two theories are essentially merely different mathematical methods applied to a single fundamental problem. The resulting mathematical equations always agree with one another. One begins to believe that the mathematical theory is a far better model of the atom than any of the mechanical models which are possible.

The long-standing conflict between the wave theory of light and the corpuscular quantum theory now disappears with the new wave mechanics, the two aspects of light being somewhat analogous to the two aspects of the quantum theory, the wave mechanics and the matrix mechanics. In fact, the quantum theory now indicates that the electron itself can be regarded as a particle, or as a wave, just as light can be thought of as a photon or a wave. Whatever remained of the conflict between the wave and corpuscular theory of light and of the electron seems now to be fundamentally removed by the Bohr-Heisenberg Uncertainty Principle. To ask whether an electron is a particle or a wave is a meaningless question; the same is true of the question whether light consists of corpuscles or waves. One must answer that both of these are particles or waves according to the kind of operations that we may perform in observing them. If we make an experiment which proves that an electron has a very definite position, then it would seem to prove that it is a particle. In that case, however, according to the Uncertainty Principle, we are not able to determine accurately the velocity and therefore cannot predict where the particle will go.

Bohr has emphasized that the essential reason that the classical theory falls down in any detailed description of atomic phenomena is that our knowledge of such atomic systems can only be obtained through an act of observation which makes the observer inherently a part of the system. On the classical theory we assume that we could have knowledge of a completely closed system as though it were possible to know anything of what would go on in a strictly closed system. In order to make an observation some signal must be transmitted from the system to ourselves, and if we take this interaction completely into account we are forced to the quantum theory with its Uncertainty Principle.

An interesting feature of this new quantum mechanics is that the original conception of the relation between cause and effect which was universally accepted in science has lost its meaning. Atomic processes seem to be governed fundamentally by the law of probability. It has no meaning to ask when a particular radium atom will disintegrate, for no operation is conceivable by which such an event could be predicted. The same is true of every individual quantum process. We have no guarantee whatever that the expulsion of an a-particle from an atom of radium has any immediate cause. In chemistry the formation of nuclei in supercooled liquids, etc., must be essentially quantum phenomena in which no cause can be assigned for the formation of the individual nucleus. By varying the conditions we may alter the probability that a nucleus will appear at a given point, but in no absolute sense can we ever make a nucleus form through a direct cause.

By a deeper analysis of this question of causality Bohr concludes that we have an option of two alternative descriptions of natural phenomena. If we choose to describe phenomena in terms of ordinary space and time then we must abandon causality. We may, however, retain the conception of causality if we are willing to describe atomic phenomena in terms of what the mathematician calls configuration space. Consider, for example, a helium atom with its two electrons. If we attempt to give the position of both of these electrons in space we would need a set of three coördinates, x, y, z, for each of the electrons, that is, six coördinates in all, three of which belong to one and three to the other electron. The mathematician, however, finds that the two electrons in general could also be described by one point in six-dimensional space, for such a point **has** six coordinates. This is a representation of two electrons as a single point in a configuration space of six dimensions. Now it turns out from Schroedinger's theory that the motion of electrons, or rather of the waves corresponding to them, can be completely described in the case of the helium atom by a quantity which has a particular value at each point in this six-dimensional space or configuration space. The helium atom, however, can be described in terms of the motion of two electrons in three-dimensional space if we are content merely to know the probabilities that the electrons may be found at any point in this space.

These matters undoubtedly seem very abstract to those of you who have not previously become familar with them. I give them here mainly in order to illustrate how far the modern concepts of physics differ from those of twenty years ago.

If we must thus abandon our ordinary ideas of cause and effect, it may be asked why have the physicist and chemist so long believed that the whole teaching of science gave proof that every phenomenon resulted inevitably from the causes that led to it. I think the answer is that in the past scientists chose as the subjects for their investigations almost wholly those phenomena in which such definite relations as cause and effect could be found. These phenomena are those in which such enormous numbers of individual quantum phenomena are grouped together that the result is determined only by their averages. For example, when we study the variation of the pressure with the volume of a gas, the forces that we measure result from the impacts of great numbers of molecules, the average force remaining steady and definite. If, however, we only had one molecule in a small volume, the pressure exerted on the walls would be zero except for those instants at which the molecules struck the wall. It would then be impossible to predict in advance what the pressure would be at a particular time.

I think in trying to estimate the reliability of any of our scientific knowledge we should keep in mind that the whole complexion of a science may be made to change by the psychology of the investigators which governs the choice of the subjects that are investigated.

Our best knowledge of time and its relation to other concepts is that which we have obtained through Einstein. Yet in the whole relativity theory there is nothing to distinguish between positive and negative time, that is, between future and past, any more than there is between different directions in space, such as right and left. There thus appears to be something curiously incomplete in our knowledge of time, for every one of us knows the vast practical diierence between past and future. Eddington, in his recent book, "The Nature of the Physical World," discusses the "arrow of time" at some length. He suggests that the second law of thermodynamics is the only fundamental law of nature which provides us with any distinction between future and past. One way of stating this law is that all spontaneous processes that occur in nature involve an increase in entropy. Eddington thus proposes that the positive direction of time can be defined as that direction in which the entropy increases. If we had a system in absolute equilibrium the entropy would be constant, and there would then be no arrow of time. This is in accord with the fact that in such a system there are no changes with time.

It is improbable that there are two independent fundamental factors which provide an arrow for time, so that it would seem that Eddington in having found one such factor has found the only one. There are, however, grave difficulties with this view. An arrow is a vector quantity which should have magnitude as well as direction. Now the rate of change of entropy does not seem to give us any measure of time. For this purpose we use phenomena which are as nearly reversible as possible, such as the swinging of a pendulum in a vacuum.

Fundamentally entropy is a measure of randomness. A random distribution of molecules in space and velocity is a system having the maximum entropy. If we throw a pack of cards out of the window and collect them from the ground they have become effectively shuffled. We would not expect by this process, starting with a shuffled pack of cards, to find them at the end in the order in which they come from the manufacturer. The direction in which the randomness increases thus provides an arrow for time. This arrow is, however, equivalent to that involving the increase of entropy.

It is still an open question, however, whether processes directed by intelligent beings may not involve a decrease in entropy. In fact it seems conceivable that the evolution of organic life on the earth is in some measure fundamentally contrary to the second law of thermodynamics. The inherent tendency of evolution seems to be to bring about an ordered rather than a random arrangement of parts, and in the future perhaps forms of life may evolve which cause a decrease of entropy on a large scale. Are we then to have some parts of the universe in which the arrow of time points in the opposite direction from that in neighboring parts?

Such speculations may seem fantastic, It is, however, I believe, of the utmost importance for the chemists and the physicists to evolve fundamentally sound conceptions of such things as time and entropy.

The profound changes in physical thought, particularly those represented by the Quantum Theory, are rapidly bringing about a revolution in physical chemistry. The third law of thermodynamics involving chemical constants has changed radically our methods of studying chemical equilibria. The application of the Quantum Theory to band spectra promises to be of the utmost importance in chemistry. By enabling us to determine the moments of inertia of chemical molecules, the actual distances between the nuclei of the atoms in molecules can be found. Apparently our most accurate determinations of the heats of dissociation of elementary gases can be obtained from the band spectra through a knowledge of the energy levels of the various possible states of the molecules. In recent numbers of the "Journal of the American Chemical Society," particularly in the paper of Giauque and Johnston, we see the beginnings of what promises to be the most accurate and fertile source of knowledge of chemical equilibria. From a detailed knowledge of the spectrum, for example, of oxygen, and without recourse to any other experimental determinations, the specific heat at all temperatures can be calculated, and the entropy of oxygen at all temperatures is thus found. This, together with the heats of reactions, which may be found by a similar method, makes possible the calculation of the degree of dissociation of oxygen and will ultimately make possible the calculation of all chemical equilibria.

The remarkable work of Dennison, Bonhoeffer and Eucken in predicting and isolating para-hydrogen should prove to the chemist how many of his chemical discoveries will be obtained in the future by the application of these new theories of physics.

Gurney and Condon have recently derived from the wave mechanics an explanation of the fundamental law of radioactivity. Similar methods will probably before long enable us to understand the processes involved in chemical reactions far better than we ever have before.

Physics and chemistry are being inevitably drawn closer together. It seems that there has never been a time when we can predict with such certainty rapid progress in fundamental chemistry, for the new theories of physics have as yet scarcely begun to be applied in the field of chemistry. The physicist on the other hand has much to learn from an increased knowledge of chemical phenomena which should provide him with a richness of experimental data far greater than any he has yet had an opportunity to use.

Unfortunately, although theoretical physics and chemistry are thus supplementing each other and in many respects are being merged into a new science, there are remarkably few men as yet that have received adequate training in both sciences. Before long, I hope, sharp distinctions between physics and chemistry will no longer exist, but at present there seems to be a very practical distinction.

In order to find approximately how many chemists are also active as physicists and *vice versa,* I have selected at random 100 pages of the fourth edition of American Men of Science (1927) which contains the names of 13,500 American scientists. Of these, approximately 2700 are classed as chemists and 760 as physicists. Of the chemists 87% are members of the American Chemical Society, while only 2.5% belong also to the American Physical Society. Seventy-seven per cent. of the physicists are members of the American Physical Society, while 3.3% are also members of the American Chemical Society. Thus only about 3% of the physicists and chemists of the United States, whose names are given in the American Men of Science, belong to both of the national societies. This leaves far too small a number of men who are capable or are properly prepared to carry on the important work of bringing these two sciences closer together.

To pave the way for the coming revolutionary changes in chemistry we must be prepared to modify our methods of thinking, probably along lines now so prevalent in physics. But above all we must urge young chemists in the universities and after graduation to become thoroughly well trained in mathematics and in modem physics.

THE MOLECULAR STRUCTURE OF THE TUNGSTOSILICATES AND RELATED COMPOUNDS

BY LINUS PAULING

RECEIVED SEPTEMBER 5, 1928 PUBLISHED OCTOBER 5, 1929

1. Introduction

The molecular structure of the heteropolyacids[1] such as 12-tungstosilicic acid, $H_4SiW_{12}O_{40}\cdot xH_2O$, has long been the subject of speculation. A structure based upon Werner's coordination theory, suggested by Miolati,[2] has been developed and extensively applied in the systematization of heteropolyacids by Rosenheim,[3] and now is generally used in the discussion of these acids.[4] The Miolati-Rosenheim conception is, however, far from satisfactory. It provides no explanation for the characteristic properties of these acids and their salts, and the single definite pre-

diction which it makes, concerning the number of acid hydrogen atoms, is in disagreement with the results of experiment.

By applying the principles which have been found to underlie the formation of coordinated structures in crystals, I have deduced a structure which accounts for all of the characteristic properties of the heteropolyacids; namely (1) the existence of a series of stable and eminently crystallizable compounds such as $H_4SiW_{12}O_{40}\cdot 31H_2O$ differing greatly in properties from the acids H_2WO_4, $H_2W_2O_7$, etc.; (2) the number of replaceable hydrogen atoms in these acids; (3) the number of molecules of water of crystallization in crystals of the acids and their salts; (4) the crystal form of the acids and their salts; and (5) the tendency of the 12-acids to condense to similar acids, such as $H_3PW_9O_{31}\cdot xH_2O$, in which the number of tungsten or molybdenum atoms per central atom is less than twelve; and which further leads to a number of predictions regarding the attributes of these substances which can be tested by means of the experiments that they suggest.

2. The Classification of the Molybdenum and Tungsten Polyacids. **The** Miolati-Rosenheim Theory

It was pointed out by Rosenheim[6] that there are two classes of heteropolyacids of molybdenum and tungsten, differentiated by their physical and chemical properties. Examples of the so-called 12-class are $H_4SiW_{12}O_{40}\cdot xH_2O$, $H_3PW_{12}O_{40}\cdot xH_2O$, etc.; of the 6-class $H_5I(MoO_4)_6$, etc. These acids, with 12 or 6 tungsten or molybdenum atoms per central atom, are called saturated 12-acids or 6-acids. Other members of each class exist in which the number of tungsten or molybdenum atoms per central atom is less than 12 or 6, respectively, but no well authenticated compound exists in which this ratio is greater than that for the saturated acids.

Copaux[6] prepared and analyzed a number of borotungstates, and observed the existence of isomorphism between borotungstates, silicotungstates, phosphotungstates and metatungstates, in the following cases

$5BaO\cdot B_2O_3\cdot 24WO_3\cdot 54H_2O$ $6BaO\cdot 2H_2O\cdot 24WO_3\cdot 53$ or $54H_2O$[7]	Orthorhombic, pseudocubic
$4H_2O\cdot 24WO_3\cdot 53H_2O$ $2H_2O\cdot 2SiO_2\cdot 24WO_3\cdot 50H_2O$ $3H_2O\cdot P_2O_5\cdot 24WO_3\cdot 48H_2O$	Trigonal, pseudocubic
$6K_2O\cdot 2H_2O\cdot 24WO_3\cdot 37H_2O$ $5K_2O\cdot B_2O_3\cdot 24WO_3\cdot 36H_2O$ $4K_2O\cdot 2SiO_2\cdot 24WO_3\cdot 36H_2O$	Hexagonal
$6(NH_4)_2O\cdot 2H_2O\cdot 24WO_3\cdot 46H_2O$ $5(NH_4)_2O\cdot B_2O_3\cdot 24WO_3\cdot 52H_2O$ $5H_2O\cdot B_2O_3\cdot 24WO_3\cdot 61H_2O$	Tetragonal, pseudocubic

---

[5] A. Rosenheim, *Z. anorg. Chem.*, *96*, 139 (1916).

[6] H. Copaux, Ann. *chim. phys.*, [8] *17*, 217 (1909).

[7] See H. Copaux, *Z. anorg. Chem.*, *74*, 351 (1912). The exact water content of some of these substances is doubtful.

In addition he formed a series of solid solutions between potassium metatungstate and potassium silicotungstate. As a result of these observations he concluded that the metatungstates are to be considered as 12-tungstoacids in which water plays the role of the central group.

Rosenheim and Felix[8] similarly classified the tetra- and octomolybdates as 12-molybdates.

Salts representative of the 12-class and 6-class are tabulated below.

12-class		6-class	
$K_6H_2W_{12}O_{40}\cdot 18\frac{1}{2}H_2O$	$K_3PW_9O_{31}\cdot 7H_2O$	$K_5I(MoO_4)_6$	$K_3H_6R^{+3}(MoO_4)_6$
$K_5BW_{12}O_{40}\cdot 18H_2O$	$K_4SiMo_{12}O_{40}\cdot 18H_2O$	$K_6Te(MoO_4)_6$	$R^{+3} = Al^{+3}$, Fe^{+3}
$K_4SiW_{12}O_{40}\cdot 18H_2O$	$K_3AsMo_9O_{31}\cdot 14H_2O$	$K_4H_6Ni(MoO_4)_6$	Cr^{+3}, Mn^{+3}
$Na_3PW_{12}O_{40}\cdot 21H_2O$	etc.	$K_3AsO(MoO_4)_3$	etc.

The members of the 12-class are all similar to metatungstates; the free acids are easily prepared, very stable, and very easily crystallizable. The molybdenum compounds are almost without exception deep yellow in color. The members of the 6-class, on the other hand, show the reactions of the molybdate or tungstate ion, $[MoO_4]^{--}$ or $[WO_4]^{--}$. The molybdates are colorless when the central ion is colorless.

There is no doubt that Rosenheim has assigned the correct structures to the members of the 6-class. The complex anions are composed of MoO_4 or WO_4 tetrahedra. By sharing one corner, two of these tetrahedra form the ion $[Mo_2O_7]^{--}$, etc. By sharing a corner of each MoO_4 tetrahedron with the AsO_4 group, the ions $[AsO_3(MoO_4)]^{-3}$, $[AsO_2(MoO_4)_2]^{-3}$, $[AsO(MoO_4)_3]^{-3}$, $[As(MoO_4)_4]^{-3}$ may be formed. Similarly a central ion with coordination number of six can form an octahedron, all six corners of which may be shared with MoO_4 tetrahedra.

The Miolati-Rosenheim conception of the 12-acids is that they are similarly derived from the central groups $[H_2O_6]^{-10}$, $[BO_6]^{-9}$, $[SiO_6]^{-8}$, $[PO_6]^{-7}$, etc., by replacing the oxygen atoms by Mo_2O_7 or W_2O_7 groups. The corresponding acids are then written $H_{10}[H_2(W_2O_7)_6]$, metatungstic acid; $H_9[B(W_2O_7)_6]$, 12-tungstoboric acid; $H_8[Si(W_2O_7)_6]$, 12-tungstosilicic acid; $H_7[P(W_2O_7)_6]$, 12-tungstophosphoric acid; and similarly for the 12-molybdoacids. But the acids do not have the large number of replaceable hydrogen atoms indicated by these formulas. Their salts indicate that the true basicities are four less than this. Very many neutral salts corresponding to the formulas $H_6[H_2W_{12}O_{40}]\cdot xH_2O$, $H_5[BW_{12}O_{40}]\cdot xH_2O$, $H_4[SiW_{12}O_{40}]\cdot xH_2O$ and $H_3[PW_{12}O_{40}]\cdot xH_2O$ have been prepared, but only a few salts in which four more hydrogen atoms are replaced. These formulas, accepted by most investigators in this field,[9] no doubt represent correctly the number of replaceable hydrogen atoms, so that the Miolati-Rosenheim theory leads to incorrect results in this

[8] A. Rosenheim and J. Felix, *Z. anorg. Chem.*, 79,292 (1913).

[9] H. Copaux, *ibid.*, 74, 351 (1912); F. Kehrmann, *ibid.*, 39, 98 (1904); G. Wyrouboff, Bull. *soc. franc. min.*, 28, 239 (1905); etc.

respect. Rosenheim has contended that the ordinary salts are really acid salts, and he did succeed in replacing seven hydrogen atoms in 12-molybdophosphoric acid and 12-tungstophosphoric acid with guanidine. In other cases, however, guanidine replaces fewer hydrogen atoms than correspond to the Miolati-Rosenheim theory, so that the theory is not supported. Some salts of heavy metals also are known in which more hydrogen atoms are replaced than in the ordinary salts; these we consider to be basic salts.

The Miolati-Rosenheim theory offers no explanation of the characteristic properties of the 12-acids; for it involves the coordination about a central atom of six Mo_2O_7 or W_2O_7 groups, which are evidently identified with the bimolybdate and bitungstate ions, $[Mo_2O_7]^{--}$ and $[W_2O_7]^{--}$, and are hence composed of two MoO_4 or WO_4 tetrahedra with one corner shared. Accordingly they would be expected to show the reactions of the $[MoO_4]^{--}$ or $[WO_4]^{--}$ ion, and to belong to the same class as the 6-acids. In order to account for the pronounced differences between the 12-acids and the 6-acids there is needed a radical difference in structure, and this is not provided by the Miolati-Rosenheim theory.

3. The Structure of the 12-Tungstosilicate Ion and Related Ions

A set of principles underlying the formation of coordinated structures in crystals has been formulated and discussed in a previous paper.[10] These principles are also applicable in general to atom groups of finite extent. The following discussion illustrates their use in the deduction of the structures of highly complex ions.

Molybdenum and tungsten form tetrahedral ions, $[MoO_4]^{--}$ and $[WO_4]^{--}$, in which they have a coordination number of four. (It is probable that the metal–oxygen bonds in these ions are all of the shared electron pair type.) But the crystal radii[11] of the ions Mo^{+6} and W^{+6} are both about 0.62 Å., so that it is possible to group six oxygen ions, of crystal radius 1.35–1.40 Å., about one ion Mo^{+6} or W^{+6} at octahedron corners (Fig. 1). It is to be expected, then, that such an arrangement will also occur; and it has actually been shown to exist[12] in crystals of ammonium oxyfluomolybdate, $(NH_4)_3MoO_3F_3$, in which three oxygen ions and three fluorine ions are grouped about each molybdenum ion.

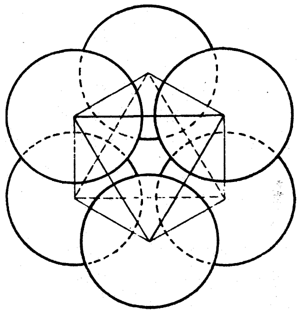

Fig. 1.—Six oxygen ions arranged at the corners of a regular octahedron about a tungsten or molybdenum ion.

Stable complexes may then be formed by arranging MoO_6 or WO_6 octahedra in such a way that they share corners with each other. The

strength of the electrostatic bond from a hexavalent cation[13] to each corner of the octahedron of anions about it is 1, so that each oxygen ion will tend to be shared between two octahedra. On account of the large electric charge of the cations, the octahedra will share corners only, and not edges or faces.

A structure satisfying these requirements is shown in Fig. 2. Each octahedron shares three corners with adjoining octahedra, and has three unshared corners. The double negative charge of the oxygen ions at the unshared comers is not satisfied by the single molybdenum or tungsten electrostatic bond, of strength 1; in order that it be satisfied, each of these 36 oxygen ions must take up a hydrogen ion. The resultant $Mo_{12}O_{18}(OH)_{36}$ group is electrically neutral.

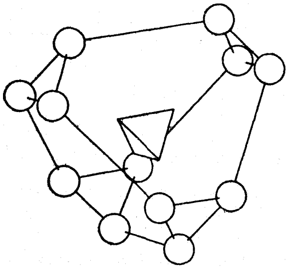

Fig. 2a.—Diagrammatic representation of a structure composed of twelve tungsten or molybdenum octahedra. Each octahedron is replaced by a circle. The lines connecting circles indicate that the corresponding octahedra are united through the possession of a common corner (an oxygen bond),

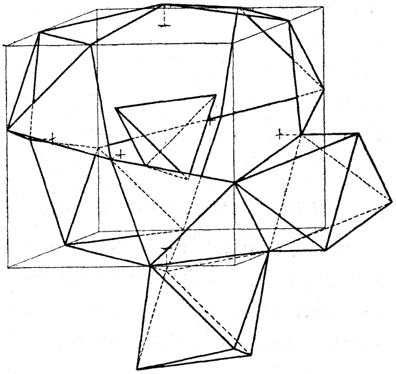

Fig. 2b.—The structure composed of twelve octahedra. Two octahedra are completely drawn. The face defined by the shared corners is shown for each of the others.

As a result of the strong repulsion between the adjacent highly charged cations the octahedra composing the group will be distorted. The distortion will take place in such a way that the Mo–O or W–O distance will remain approximately constant. The oxygen-oxygen distance determining the length of an octahedron edge is usually 2.70–2.80 Å., but may be as small as 2.50 Å. The mutual repulsion of the molybdenum or tungsten ions in the structure we are discussing will lengthen the three edges of each octahedron determined by the shared corners, the other edges being correspondingly shortened. In the crystals in which octahedron edges are shortened to 2.50 Å. (rutile, brookite, anatase, corundum),

---

[13] Throughout this paper use will be made of the word ion, although it is recognized that the bonds may not approach the limiting case of purely ionic bonds very closely.

four edges at the most are so affected. In the MoO_6 and WO_6 octahedra nine edges are shortened by deformation, so that all of the oxygen ions are brought close together; it is probable that these nine edges will not be shorter than about 2.60 Å. If the metal-oxygen distances remain 2.00 Å. throughout, the other three edges are then about 3.10 Å. long, and the distorted octahedron has the appearance shown in Fig. 3.

As a result of this deformation, an additional oxygen ion at one corner of the tetrahedron of Fig. 2 would be reasonably close to three molybdenum or tungsten ions; in fact, if it remained at a distance of about 2.7 Å. from the oxygen ions at the shared corners of the octahedra, it would be about **3.0** Å. from the three metal ions. each of charge +6. These positions, in regions of positive potential, are accordingly stable ones for oxygen ions.

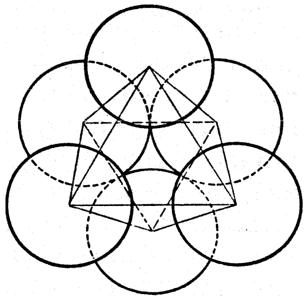

Fig. 3.—The distorted octahedron of oxygen ions about a tungsten or molybdenum ion.

It is also to be anticipated that the position in the region of negative potential at the center of the tetrahedron formed by these four oxygen ions would be stable for a small positive ion, such as B^{+3}, Si^{+4}, P^{+5}, As^{+5}, etc., with crystal radii 0.21, 0.41, 0.34 and 0.47 Å., respectively. For the strength of the electrostatic bond from Mo^{+6} or W^{+6} at the distance 3.0 Å. may be about $^1/_2$, in which case the three metal ions would not satisfy the charge of the oxygen ion and another positive ion would be required. If no other positive ion is available for this purpose, hydrogen ions would be used. The experimental observation that metatungstic acid is hexabasic indicates that two hydrogen ions are required for the four oxygen ions.

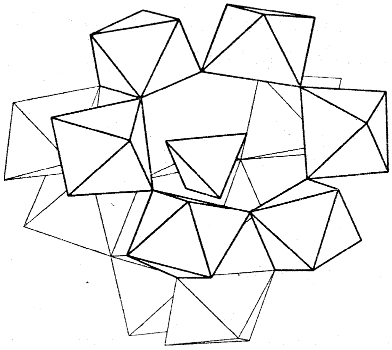

Fig. 4.—The structure of the 12-tungstosilicate ion and related ions. Twelve distorted octahedra (Fig. 3) are combined by sharing corners as shown. The tetrahedron represents the $[SiO_4]^{-4}$ ion. The complete structure has the composition $[SiO_4 \cdot W_{12}O_{18}(OH)_{36}]^{-4}$, and has the point-group symmetry T_d.

The completed complex ion, shown in Fig. 4, can now be described in the following way. Twelve molybdenum or tungsten octahedra combine by sharing corners occupied by oxygen ions (eighteen altogether). Each of the thirty-six unshared oxygen ions takes up a hydrogen ion to satisfy its negative charge. The resultant neutral structure is then stabilized by a central tetrahedral group $[RO_4]^{-3}$, with R = H_2^{++}, B^{+3}, Si^{+4}, P^{+5}, As^{+5}, etc. The central stabilizing group increases the stability of the complex not only by introducing negative ions in regions of large positive potential, but also by completing a structure which approximates close-packing of the large ions, each of the central oxygen ions being in contact with nine oxygen ions.

A first test of the possibility of existence of this structure is the investigation of the dimensions of the group of twelve octahedra to determine whether or not there is room for an RO_4 group within. In the $[SiO_4]^{-4}$ ion the oxygen-oxygen distance is about 2.60 Å., the silicon–oxygen distance being about **1.59 Å.**[14] The $[BO_4]^{-5}$, $[PO_4]^{-3}$ and $[AsO_4]^{-3}$ ions have about the same dimensions. Assuming three edges of each octahedron to be lengthened to **3.10 Å.**, each oxygen ion of the central RO_4 group will be about **2.85 Å.** from six oxygen ions in the surrounding structure. There is accordingly just room enough for the central tetrahedron. *A structure composed of less than twelve octahedra could not be built about the* R04 *group.*

A study of the structure has led to the conclusion that the deformation of the octahedra is not so great as that estimated to be the maximum possible. The nine short edges are probably about **2.65 Å.**, and the three long edges about **3.02 Å.** long. Each R04 oxygen ion is then about **2.77 Å.** from six oxygen ions of the surrounding structure, and about **3.14 Å.** from three W^{+6} or Mo^{+6} ions. The corresponding atomic positions are given by the following set of coordinates relative to orthogonal axes

1Si, B, P or As at 0 0 0

$\bar{x}\,\bar{y}\,z,\ \bar{z}\,\bar{x}\,y,\ \bar{y}\,\bar{z}\,x,\ \bar{y}\,\bar{x}\,z,\ \bar{x}\,\bar{z}\,y,\ \bar{z}\,\bar{y}\,x$
with $x = 0.02$ Å., $y = 5.28$ Å., and $z = 1.90$ Å.

4. The Properties of the 12-Tungsto- and Molybdoacids

The structure proposed for the 12-tungsto- and molybdoacids, in which the tungsten and molybdenum atoms have a coordination number of six, requires, in agreement with experiment, that these substances have

---

[14] These distances *are* in agreement with those found experimentally for orthosilicates.

distinctly different properties from the ordinary tungstic and molybdic acids, with coördination number four.

Formulas for the tungsten acids corresponding to the proposed structure are

$H_6[H_2O_4{\cdot}W_{12}O_{18}(OH)_{36}]$, metatungstic acid
$H_5[BO_4{\cdot}W_{12}O_{18}(OH)_{36}]$, 12-tungstoboric acid
$H_4[SiO_4{\cdot}W_{12}O_{18}(OH)_{36}]$, 12-tungstosilicic acid
$H_3[PO_4{\cdot}W_{12}O_{18}(OH)_{36}]$, 12-tungstophosphoric acid

Similar formulas are to be ascribed to the molybdenum acids. *The numbers of replaceable hydrogen atoms given by these formulas are exactly those found experimentally.* This is a consequence of the fact that the coordinated structure surrounding the central RO_4 group is electrically neutral, so that the complex anion has the same charge as the RO_4 group itself; in other words, the heteropolyacid has the same number of replaceable hydrogens as the acid from which it was derived.

A further notable feature of the proposed structure is the large amount of water of constitution, amounting to $18H_2O$ per molecule, aside from the replaceable hydrogen of the acids and the central hydrogen of the metatungstates and the corresponding molybdates. This explains the high water content characteristic of these compounds, which had long been an unsolved puzzle. The water content of the heteropolyacids was studied by Rosenheim and Jaenicke,[3f] who found the results given in Table I. There is some doubt as to the exact amount of water in many cases; for example, previous investigators had assigned $31H_2O$ to the series of crystals corresponding to the first column, instead of $30H_2O$.

TABLE I

WATER CONTENTS OF HETEROPOLYACIDS

$H_6[H_2W_{12}O_{40}]$	..	$24H_2O$	14–17 H_2O (?)
$H_5[BW_{12}O_{40}]$	$30H_2O$	$\boxed{24}$	12
$H_4[SiW_{12}O_{40}]$	30	24	$\boxed{22}$
$H_3[PW_{12}O_{40}]$	30	24	21
$H_4[SiMo_{12}O_{40}]$	30	..	14
$H_3[PMo_{12}O_{40}]$	30	24	14 (?)

The 30- and 24-hydrates are compatible with our formulas. We would say that eighteen molecules of water is water of constitution, and that $12H_2O$ or $6H_2O$ only is water of crystallization, that is, water which fills the interstices which result from piling together the large constituent groups in the construction of the crystals. It is to be expected that usually there will be some water of crystallization, on account of the shape of the complex anions.

Four[15] of the hydrates of the third column contain less than $18H_2O$.

---

[15] Two of these could not be identified with certainty as distinct compounds.

These substances are, however, different from the others in their properties. Rosenheim and Jaenicke state that they dehydrate on heating without melting, whereas the others show definite melting points. They can be prepared only under dehydrating conditions—by crystallizing out of concentrated nitric acid, or by heating the higher hydrates to constant weight at temperatures above their melting points. These properties are to be expected from the proposed structure, assuming that dehydration consists in the sharing of corners between octahedra in different complexes, with the elimination of $1H_2O$ for each shared corner. The coordination bonds introduced between the complexes in this way tie the whole crystal together, and prevent it from melting at a low temperature. The presence of compounds with over $18H_2O$ in this column is not surprising; they contain less than 18 molecules of water of constitution, and in addition some water of crystallization.

The 30-hydrates are all isomorphous, and so are the 24-hydrates, with the exception of the tungstoboric acid. This tungstoboric acid and the tungstosilicic acid of the third column are isomers of the ordinary heteropolyacids; their structure is discussed in the following section.

The existence of 18 molecules of water of constitution is further indicated by the data on salts, most of which crystallize with $18H_2O$ or more. For example, Groth[16] lists seventy-seven salts of 12-tungstosilicic acid which have been subjected to crystallographic examination. Of these all but thirteen contain $18H_2O$ or more, the exceptional ones having $13–17H_2O$.

The 12-heteropolyacids and their salts have a pronounced tendency to form cubic or pseudocubic crystals; thus about two-thirds of the 12-tungstosilicates with $18H_2O$ or more are cubic or pseudocubic (Table 11), and the other acids and their salts crystallize similarly. The structure proposed for these complex anions has the symmetry of the cubic point-group T_d. Accordingly cubic crystals of simple structure, containing as little as one complex anion in the unit of structure, can be built of these groups, and such crystals would be expected to occur. If, on the other hand, the complex anion did not possess cubic symmetry, a very large unit of structure would be required in a cubic crystal, and these crystals would be the exception and not the rule. It is also significant that salts with less than $18H_2O$ are all triclinic or monoclinic and show no pseudocubic development. Further similar evidence for 18 molecules of water of constitution and for the cubic point-group symmetry of the complex anions is provided by the three tungstophosphates listed by Groth.[17] The salt with less than $18H_2O$, $Na_3PW_{12}O_{40}\cdot 15H_2O$, is triclinic, while $Na_3PW_{12}O_{40}\cdot 21H_2O$ and $Ba_3(PW_{12}O_{40})_2\cdot 48H_2O$ form cubic crystals.

[17] Groth, Ref. 16, Vol. II, pp. 883–884.

TABLE II

CRYSTALLINE FORM OF 12-TUNGSTOSILICATES

No.		
1	Triclinic or monoclinic	$Na_4X \cdot 20H_2O$ ($X = [SiW_{12}O_{40}]^{-4}$) $R_2X \cdot 18H_2O$; R^{+2} = Ca, Mg, Mn, Ni, Co, Zn $Pb_2X \cdot 21H_2O$ $Sr_2X \cdot 23H_2O$ $Cd_2X \cdot 22H_2O$ $InHX \cdot 20H_2O$ $R_4X_3 \cdot 60H_2O$; R^{+3} = Al, Cr, Ga, Bi $In_4X_3 \cdot 63H_2O$ $RHX \cdot 18H_2O$; R^{+3} = La, Ce, Di, Gd $RHX \cdot 24\frac{1}{2}H_2O$; R^{+3} = Y, Tb, Yb
2	Hexagonal—$a:c$ = 1:0.6585	$K_4X \cdot 18H_2O$
3	Tetragonal—$a:c$ = 1:1.0117 (pseudocubic)	$H_4X \cdot 30$ or $31H_2O$
4	Trigonal—a! = 86° 26′–89° 8′ (pseudocubic)	$Li_4X \cdot 24H_2O$ $R_2X \cdot 24H_2O$; R^{+2} = Ca, Ba $H_4X \cdot 24H_2O$
5	Trigonal[a]—α = 75° 43′–77″ 18′	$R_4X_3 \cdot 78H_2O$; R^{+3} = Nd, Di, Sm, Gd, Y, Tb, Yb
6	Trigonal—a = 56° 4′–57° 30′ (pseudocubic)	$R_2X \cdot 27H_2O$; R^{+2} = Ca, Sr, Mg, Mn, Ni, Co, Cu, Zn, Cd $Be_2X \cdot 29H_2O$ $R_4X_3 \cdot 87H_2O$; R^{+3} = Al, Cr, Ga $R_4X_3 \cdot 81H_2O$; R^{+3} = La, Ce, Di, Sm, Gd $Gd_4X_3 \cdot 90H_2O$ $ThX \cdot 27H_2O$ $ThX \cdot 30H_2O$
7	Cubic	$Be_2X \cdot 31H_2O$ $R_4X_3 \cdot 93H_2O$; R^{+3} = Al, Cr, Fe, Ga, In

[a] These crystals, while not pseudocubic in their face development, have axial ratios in the neighborhood of 1:3, and so may have a pseudocubic structure.

5. Iso-12-Tungstosilicic Acid and Iso-12-Tungstoboric Acid

There exist in addition to the 12-acids just discussed acids of the composition $H_4(SiW_{12}O_{40}) \cdot xH_2O$ and $H_5(BW_{12}O_{40}) \cdot xH_2O$ which differ from them in their reactions, and are called iso-12-acids. Iso-12-tungstosilicic acid and its salts were discovered and investigated by Marignac.[18] Iso-12-tungstoboric acid, previously studied by Copaux,[19] was assigned its accepted formula and further studied by Rosenheim.[20] The iso-acids retain their identity on solution and recrystallization, and on conversion into salts and again into acids. They are prepared by heating solutions of the normal acids to dryness and are also formed to some extent in the preparation of the normal acids and their salts.

The Miolati-Rosenheim theory[Z1] has been made to account for the existence of two forms of 12-tungstosilicic and 12-tungstoboric acid by

---

[18] C. Marignac, *Ann. chim. phys.*, [4] 3, 5 (1864).

[19] H. Copaux, ibid., [8] 17, 217 (19C9).

[20] A. Rosenheim, Z. anorg. *Chem.*, **70**, 418 (1911); A. Rosenheim and J. Jaenicke, *ibid.*, **101**, 235 (1917).

[21] A. Rosenheim and J. Jaenicke, *ibid.*, 100, 304 (1917); P. Pfeiffer, *ibid.*, **105**, 26 (1918).

assuming a difference in character of some of the six positions about the central atom and the others.

The method of formation of the iso-acids by heating the normal acids suggests a condensation of the normal complex anions with the liberation of water of constitution. The ease of solution and reprecipitation of the iso-acids requires that the constituent coordinated groups be not too large. A structure satisfying these requirements is obtained by combining two $[RO_4W_{12}O_{18}(OH)_{36}]^{-z}$ groups in such a way that six octahedra of one group share one corner apiece with six octahedra of the other group. The resultant anion is shown in Fig. 5. The acids would then have the formulas

$$H_8[(SiO_4)_2W_{24}O_{42}(OH)_{60}] \text{ or } H_4[SiW_{12}O_{40}]\cdot 15H_2O$$
$$H_{16}[(BO_4)_2W_{24}O_{42}(OH)_{60}] \text{ or } H_5[BW_{12}O_{40}]\cdot 15H_2O$$

The amount of water of constitution, $15H_2O$, required by this structure is compatible with the observed hydration of the acids, $24H_2O$ and $22H_2O$ (Table I), for it is to be expected that some water of crystallization will also be present.

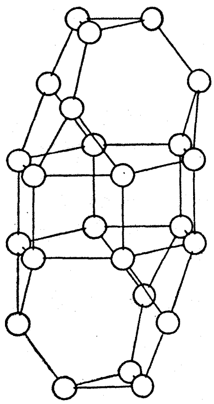

Fig. 5a.

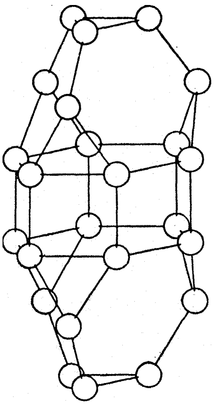

Fig. 5b.

Fig. 5a.—A possible structure for the iso-12-polyacid ion, made from two ions of Fig. 4 by the elimination of $6H_2O$ and the formation of six oxygen bonds. Point-group symmetry D_{3d}.

Fig. 5b.—The probable structure of the iso-12-polyacid ion. Point-group symmetry D_{3h}.

The salts of these acids also usually crystallize with over $15H_2O$. The well-investigated crystals $K_4SiW_{12}O_{40}\cdot 9H_2O$ (rhombic) and $Na_4SiW_{12}O_{40}\cdot 12H_2O$ (trigonal) are exceptions. It is probable that further dehydration, with the accompanying sharing of octahedron corners between the iso-anions, has taken place here.

The iso-anion $[(RO_4)_2W_{24}O_{42}(OH)_{60}]^{-2z}$ has the symmetry of the point-group D_{3d} (Fig. 5a), or, more probably, D_{3h} (Fig. 5b). Verification of the proposed structure will be attempted through the investigation with x-rays of the hexagonal bipyramidal crystals of iso-12-tungstoboric acid, $H_5[BW_{12}O_{40}]\cdot 24H_2O$.

6. The Unsaturated or Condensed Heteropolyacids

There also exist heteropolyacids, similar in their reactions to the saturated 12-heteropolyacids, in which the number of tungsten or molybdenum atoms per central atom is less than twelve. It is probable that the anions of these acids are formed from the 12-anions by the sharing between two groups of some complete octahedra. The 12-octahedra groups are of such a nature that two can combine by sharing six octahedra, as shown in Fig. 6, or by sharing two octahedra.

The acids formed from the 12-acids of phosphorus or arsenic would have formulas of the type

$$H_6[(PO_4)_2W_{18}O_{30}(OH)_{48}] \text{ or } H_6[P_2W_{18}O_{62}]\cdot 24H_2O$$

These acids should then have six replaceable hydrogen atoms and contain 24 molecules of water of constitution.

Phosphorus and arsenic form 9-acids with both molybdenum and tungsten very easily.[22] (It is, indeed, reported to be difficult to prepare salts of the saturated arsenic acids, and the acids themselves are unknown.) Most of the salts of these acids are formed by replacing six hydrogen atoms, although in a few twelve hydrogen atoms are replaced. The basicity of the acids accordingly agrees with the structure suggested.

The crystallized free acids, of composition $H_6[P_2W_{18}O_{62}]\cdot 39H_2O$, $H_6[As_2W_{18}O_{62}]\cdot 39H_2O$, $H_6[P_2Mo_{18}O_{62}]\cdot 33$ or $37H_2O$ and $H_6[As_2Mo_{18}O_{62}]\cdot 25$ or $29H_2O$, all possess some water of crystallization in addition to the water of constitution. This is true also of a majority of the salts; in the exceptional cases the amount of constitutional water is diminished by the sharing of corners of octahedra in different complex anions.

The anions of formula $[(PO_4)_2W_{18}O_{30}(OH)_{48}]$, etc., have the symmetry of the point-group D_{3d}. Verification of this should be possible through the examination with x-rays of the dihexagonal bipyramidal crystals $K_6P_2W_{18}O_{62}\cdot 28H_2O$, $K_6As_2Mo_{18}O_{62}\cdot 28H_2O$ and $Na_6As_2Mo_{18}O_{62}\cdot 30H_2O$.[23]

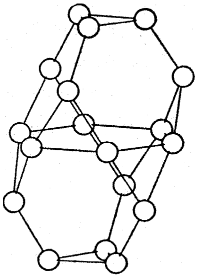

Fig. 6.—The probable structure of the 9-polyacid ion, formed from two ions of Fig. 4 by the sharing of six octahedra. Point-group symmetry D_{3d}. The structure of point-group symmetry D_{3h} (the analog of Fig. 5b) is probably unstable.

It is possible that each anion of the compounds with 11:1 as the ratio of the number of molybdenum or tungsten atoms to the number of central atoms is formed from two 12-anions with two octahedra in common, and that the anions of the compounds reported with ratios 10:1, 21:2 and 17:2 are composed of more than two 12-anions combined by sharing octahedra. In these cases, however, the confident assignment of specific structures must follow further experimental investigation.

Summary

There is described a structure for the 12-heteropolyacids of molybdenum and tungsten derived by the application of the principles under-

---

[22] A. Rosenheim and J. Jaenicke, *Z. anorg. Chem.*, 101,235 (1917); A. Rosenheim and A. Traube, *ibid.*, 91, 74 (1915).

[23] Groth, Ref. 16, Vol. II, p. 879.

lying the formation of coordinated structures in complex crystals. The proposed structure, shown in Fig. 4, may be represented by formulas such as $H_4[SiO_4 \cdot W_{12}O_{18}(OH)_{36}]$. It correlates the characteristic differences between the properties of the 12-molybdo- and tungsto-acids and those of the $[MoO_4]^{--}$ and $[WO_4]^{--}$ ions with the existence of molybdenum and tungsten atoms with coordination numbers 6 and 4, respectively, in these two types of compounds. It leads to a number of replaceable hydrogen atoms in agreement with experiment, and accounts for the large water content of the acids and their salts. The cubic point-group symmetry of the suggested structure for the complex anions explains the tendency of these compounds to form cubic or pseudocubic crystals.

The iso-12-tungstosilicate and iso-12-tungstoborate ions are ascribed the structure shown in Fig. 5, in which two 12-anions are combined through the formation of oxygen bonds.

A structure for one class of unsaturated acids, corresponding to formulas such as $H_6[(PO_4)_2 \cdot W_{18}O_{30}(OH)_{48}]$, is also suggested, involving the combination of two 12-anions as shown in Fig. 6. Possible structures for other unsaturated acids are indicated.

Among the predictions made on the basis of the proposed structure and susceptible to experimental investigation are the following: that the normal 12-anions have the point-group symmetry T_d, and the iso-12-anions and the 9-anions the symmetry D_{3d} or D_{3h}; that the normal 12-acids have a molecular weight corresponding to one RO_4 group per complex, and the iso-12-acids and 9-acids to two; and that the constituent atoms in the complexes occupy certain positions relative to each other, such that each tungsten or molybdenum atom has a first coordination shell of six oxygen atoms none of which is part of the central RO_4 group.

THE CRYSTAL STRUCTURE OF META-IODOBENZOIC ACID[1]

BY HAROLD P. KLUG, EDWARD MACK, JR., AND F. C. BLAKE

RECEIVED APRIL 4, 1989 PUBLISHED OCTOBER 5, 1929

We have been led to an x-ray examination of the crystals of a number of benzene derivatives in connection with a study of vapor pressures and heats of vaporization. It seems worth while at this time to report the crystal structure which we have found for m-iodobenzoic acid, especially since the solution obtained seems to be unique, and very few unambiguous solutions have been reported for organic compounds crystallizing in the

---

[1] An abstract of a thesis presented by H. P. Klug in partial fulfilment of the requirements for the degree of Doctor of Philosophy at the Ohio State University in June, 1928.

monoclinic system. m-Iodobenzoic acid is a particularly interesting case because of the fact that it is so nearly orthorhombic, the angle β being **91°** 29.5'. When β is so slightly different from a right angle, it is difficult to identify the reflections from certain sets of planes, namely, the pyramids and orthodomes.

m-Iodobenzoic acid was prepared by the method of O. Grothe,[2] which consists of the hot diazotization of a strong solution of *m*-aminobenzoic acid in dilute sulfuric acid mixed with a concentrated solution of potassium iodide in excess. The yield was very poor (less than 5%). The crude product was purified by two vacuum sublimations; this gave a product with a melting point of **186.6–186.8".** Crystals grown from ether were well-formed, flat needles, showing the (0 0 1) face.

Groth[3] gives the following data on the crystal: a : b : c = 1.3450 : **1 : 5.6247;** $\beta = 91° 29.5'$; m. p. 185°; sp. gr. **2.171.**

Preparation of X-Ray Photographs and Their Analysis for Data.— Data for the analysis of this crystal were obtained by means of the powder, Laue and oscillated crystal methods. Photographs were taken **and** the usual measurements and calculations made.

In the powder method sodium chloride was used as a comparison standard. The m-iodobenzoic acid was powdered to pass through a 200-mesh sieve and the glass capillary tube was oscillated through an angle of **15"** during exposure to the molybdenum K_α doublet from a water-cooled Coolidge tube. The exposure was for twenty-six hours at 35 kilovolts with a current of **18** milliamperes. Distances on the film could be measured to within 0.002 cm. Blake's[4] correction constant, **3** cot 8 d θ, for powder films was used in all the calculations. Using the crystallographer's orientation and notation, Wyckoff's quadratic[5] form of the equation for the monoclinic unit becomes, when squared and solved for $\sin^2$ 8

$$\sin^2\theta = \frac{\lambda^2}{b_0^2}\left\{\frac{h^2}{4a^2\sin^2\beta} + \frac{l^2}{4c^2\sin^2\beta} \pm \frac{hl\cos\beta}{2ac\sin^2\beta} + \frac{k^2}{4}\right\}$$

If we designate the bracketed term by L, then

$$L = \frac{\sin^2\theta\, b_0^2}{\lambda^2}$$

The thirteen lines measurable on the powder photographs could all be accounted for only on the assumption of a 4-molecule cell.

The agreement between the observed and calculated values of L is excellent.

Laue photographs were taken perpendicular to the (0 0 1) face and at small angles to the perpendicular, with the general radiation from a tung-

[a] The calculated values of L are purely theoretical values obtained by substituting the crystallographic data in the bracketed term of the above equation. The observed values of L are obtained from the values of θ from measurements of the powder photographs.

sten target at 54–55 kilovolts, 14 milliamperes and for two and one-fifth hours. The crystal to film distance was 5 cm. for all photographs.

The oscillated crystal photographs were taken with the K_α doublet from a molybdenum target at 55 kilovolts, 19 milliamperes, for twenty-four to twenty-six hours. In addition to the usual method of calculating angle θ for each reflection, the indices of the planes reflecting were checked by means of Bernal[6] diagrams. The analysis shows unequivocally that the cell contains four molecules. The large number of reflections gives the data necessary for space-group determination.

Correction of the Axial Ratio.—On some of the oscillated crystal photographs where the reflections were unusually sharp and distinct, and therefore capable of quite accurate measurement, the agreement between the two values of L was not what it should have been. This might have been due to a slight inaccuracy in the axial ratio. Since there could be no doubt about the correctness of the various orders of (0 0 1) found on one of the films, and also of the various reflections of (0 1 l) in the first layer line above and below, it was decided to use them as a basis for correcting the axial ratio. The new axial ratio, then, assuming that β is correct as given, is

$$a : b : c = 1.3252 : 1 : 5.5824$$

The size of unit cell is

$$a_0 = 6.206,\ b_0 = 4.683,\ c_0 = 26.14\ \text{Å}.$$

All of the data for the oscillated crystal and powder photographs were recalculated on the basis of this new axial ratio; the agreement between the theoretical and observed values was remarkably good for all except a few lines out of several hundred.

Absorption in the Crystal and a New Use of Filters in Laue Photograph Technique.—The critical absorption limit for the strongly absorbing iodine falls at 0.37 Å. It might be expected that the iodine would absorb

---

[6] Bernal, *Proc. Roy. Soc. London*, **113A**, 117 (1927).

most or all of the wave lengths below its critical absorption limit. Then the calculated values of $n\lambda$ for the Laue photographs would show no values below 0.37 Å. for the correct cell, Inspection of the data showed this to be the case for a four molecule cell.

Some method was then needed to determine whether the assumption that the iodine absorbed all wave lengths below 0.37 Å. was justified. The critical absorption limit for tin lies just above that for iodine, being at 0.42 Å. If a filter of tin of sufficient thickness to cut out all wave lengths below its critical absorption limit were used, a Laue photograph might be taken without the absorption of the iodine being a factor. Since the lower wave length limit would be known accurately, there would be no doubt as to the true size of the unit cell. The thickness of pure tin foil necessary to absorb nine-tenths of the radiation in those wave lengths below 0.37 Å. was calculated with the Wyckoff[7] and Compton[8] modifications of the absorption equation. In the former case the calculated thickness was 0.0082 cm., in the latter 0.0087 cm. The filter actually used was 0.0085 cm. in thickness. It was assumed that if the absorptive power of the iodine approached the value it was supposed to have, it would absorb the other tenth of the radiation below 0.37 Å.

To check the efficiency of this filter, reflection photographs from the (10 0) face of rock salt were taken, with and without the filter. The salt crystal was oscillated through an angle of 40° during the exposure. The α_1, β_1, β_2, β_3, β_4, γ_1, γ_2 and γ_3 lines of the L spectrum of tungsten appeared on the photograph taken without the filter. These lines were used for calibration of the camera. The tube was working under the same voltage and current as during the taking of the Laue photographs. The photograph without the filter showed the low wave length limit to be at 0.31 Å. instead of 0.25 Å. This probably indicates a peak in the transformer curve. The silver absorption edge was found at 0.47 Å., the bromine edge at 0.91 Å. and the weaker second-order silver edge at 0.96 Å. The photograph taken with the filter showed a very faint radiation up to the absorption edge for tin at 0.41 Å. The second-order tin absorption edge was found to correspond with 0.83 Å.

Inspection of the photograph taken without the filter confirmed the assumption that the iodine atoms might completely absorb the radiation below 0.37 Å., for the radiation is comparatively weak below this. A Laue photograph was taken using the filter. It was analyzed in the same manner as the others, and proved that the unit cell contained four molecules, there being no values of $n\lambda$ below 0.42 Å.

Wyckoff[9] discusses the use of filters to obtain a more desirable distribu-

tion of wave lengths for Laue photographs, and concludes that their use is not desirable. Their use in the manner just described, however, seems a valuable addition to Laue photograph technique.

Determination of the Space-Group.—Inspection of the data showed that all types of planes were present except $(h\ 0\ l)$ when $(h + l)$ is odd. Since these are the only abnormalities, the basic lattice is the simple Γ_m lattice of Bravais and not Γ'_m. Astbury and Yardley[10] have tabulated the data for the examination of the 230 space-groups by x-rays. In the monoclinic sphenoidal class there are only two space-groups, C_2^1 and C_2^2, based on the Γ_m lattice. The first of these has no abnormal spacings and the latter only (0 1 0) halved. The class, therefore, cannot be sphenoidal, as given by Groth. The molecules of m-iodobenzoic acid are most certainly asymmetric, and there are four of them in the unit cell. Thus the class cannot be domatic. This leaves the two space-groups C_{2h}^4 and C_{2h}^5 in the prismatic class as the only possibilities. These two groups are the same except that the symmetry axis is a screw axis in C_{2h}^5 and therefore (0 1 0) is also halved in this space-group. Examination of the powder photograph showed that (0 1 0), which should have fallen between (1 0 3) and (0 0 6), was missing. Therefore, (0 1 0) is halved and the space-group is C_{2h}^5. C_s^2 does not have (0 1 0) halved, and this is further proof that the class cannot be domatic.

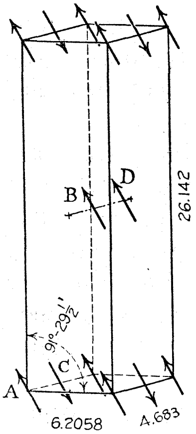

Fig. 1.

Determination of Parameters.—The space-group C_{2h}^5 contains a plane of symmetry and a screw axis of symmetry. This means that if one of the molecules is placed at the corners of the lattice, the second molecule is obtained from it by reflection in a plane perpendicular to the b axis, plus possible translations parallel to the a and c axes. The other two molecules are obtained by rotating these two through 180°, plus a translation along the b axis.

The coordinates of the equivalent points of the four molecules in the unit cell, relative to the crystallographic axes, are (0 0 0), $(^1/_2\ v\ ^1/_2)$, $(u\ ^1/_2\ w)$, $(u + {^1/_2},\ v + {^1/_2},\ w + {^1/_2})$. These are equivalent to the positions given by Wyckoff,[11] for in his notation the b and c axes have been interchanged. Also the *a* and *c* axes in the monoclinic system are interchangeable.

The determination of the variable parameters u, v and w can be accomplished with a fair degree of accuracy from the data on the oscillated crystal photographs. The presence on one of the photographs of extremely strong reflections for (10 1), (10 3), (10 5), (10 7), (10 9), (10 11), and for

---

[10] Astbury and Yardley, *Phil. Trans. Roy. Soc. London*, **224A**, 221–257 (1924).

[11] Wyckoff, "The Analytical Expression of the Results of the Theory of Space-Groups," Carnegie Institute Publication No. 318, Washington, 1922, p. 151.

the corresponding planes where l is negative, make it extremely probable that u and w are equal to 0. The coördinates then become: (0 0 0), ($^1/_2\ v\ ^1/_2$), (0 $^1/_2$ 0), ($^1/_2\ v + ^1/_2\ ^1/_2$).

The positions of the molecules within the cell are shown in Fig. 1. The B molecule is obtained from the A molecule by reflection and translations parallel to the *a* and c axes. The C and D molecules are obtained from A and B, respectively, by rotation through 180° and a translation along the b axis.

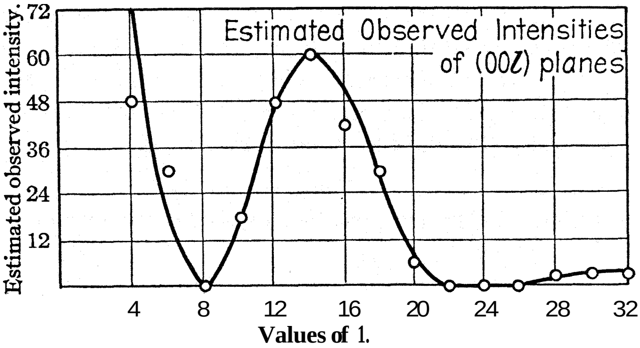

Fig. 2.—Estimated observed intensities of (0 0 l) planes.

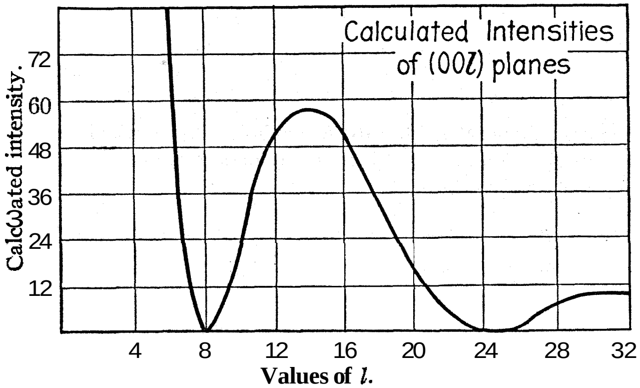

Fig. 3.—Calculated intensity of (0 0 l) planes.

The test of the correctness of these positions is whether the theoretically calculated values of the intensities of reflection check the actual intensities on the photographs. Wyckoff[12] gives the following expression for the intensity of x-ray reflection

$$I \propto \left(\frac{d_{hkl}}{n}\right)^{2.35} \left\{ [\Sigma \overline{N}_s \cos 2\pi n\ (hx_s + ky_s + lz_s)]^2 + [\sum_s \overline{N}_s \sin 2\pi n\ (hx_s + ky_s + lz_s)]^2 \right\}$$

It would be hopeless to attempt to compare in this manner the intensities for each of the several hundred reflections appearing on the films, but it

[12] Wyckoff, ref. 5, p. 107.

may be done for a few important sets of planes. In Fig. 2 is shown a graph of the estimated intensities of the various orders of (0 0 1) plane from one of the oscillated crystal photographs. It will be seen that the curve shows a minimum point at (0 0 8) and a maximum at (0 0 14). This would indicate that there must be another molecule or a periodicity along the *c* direction at a distance of approximately $^1/_{14}$ to $^1/_{16}$. The structure factors, $(A2 + B^2)$, for the even-order (0 0 1) planes were calculated, and from these the theoretical intensities were determined. It was assumed in these calculations that the molecule, as a whole, reflected from its center of gravity. Also the factor $\overline{N}_s$ was dropped since it is a constant throughout the calculations. The theoretical curve of the intensities is given in Fig. 3. The assumption has been made that this *z* parameter is $^1/_{16}$. The agreement between the two curves is good. The data for these curves are given in Table II.

TABLE II

INTENSITY DATA FOR (0 0 *l*) PLANES FROM OSCILLATED CRYSTAL PHOTOGRAPH NUMBER 3

Plane	Estimated obs. intens.	Calculated intensity	Plane	Estimated obs. intens.	Calculated intensity
0 0 2	[a]	5758	0 0 1 8	30	33
0 0 4	48	661	0 0 2 0	6	15
0 0 6	30	75	0 0 2 2	0	4
0 0 8	0	0	0 0 2 4	0	0
0 0 1 0	18	23	0 0 2 6	0	2
0 0 1 2	48	51	0 0 2 8	3	7
0 0 1 4	60	59	0 0 3 0	3	10
0 0 1 6	42	51	0 0 3 2	3	10

[a] 0 0 2 is missing from the film because of a hole in the back of the camera where the undeviated beam passed out. 0 0 4 is probably underestimated in intensity on account of blackening near undeviated beam.

Thus a periodicity along the *c* axis equal to approximately $^1/_{16}$ of its length is reasonably certain. W. H. Bragg[13] has recently been able to explain the observed intensities of the reflections from the various planes of naphthalene, on the basis of a periodicity within the molecule. An examination of a model of the molecule of *m*-iodobenzoic acid reveals some interesting things in this respect. The model, embodying the "puckered" benzene ring, may be approximately represented (to scale) by the drawing in Fig. 4. The center of gravity of the ring and the rest of the molecule is approximately at M. Since their weights are so nearly the same (I = 127) and the rest of the ring = 121, the center of gravity of the whole molecule will be approximately at P on the line joining the centers of gravity of the two parts. If it is assumed that the carboxyl group is disposed approximately as shown in Fig. 4, and that the distance between the centers of the carbon and iodine atoms is approximately 1.54/2 + 2.788/2 Å.,[14] and that

---

[13] W. H. Bragg, *Z. Krist.,* 66, 22 (1927).

[14] Harris, Mack and Blake, THIS JOURNAL, 50,1595 (1928).

the molecule is located with respect to the c-axis as shown, then the projected distance along the *c* axis between P and M or between P and I is very nearly 1.65 Å., which is about $^1/_{16}$ of the length of the cell. The general pattern of the reflections occurring is probably set up by the molecule as a whole, and may be thought of as originating from the center of gravity, P. The points M and I would also set up reflections which will be in phase with each other but will be completely out of phase with those from P for (0 0 8). Since their sum is equivalent to the reflection from P, (0 0 8) will he missing. In the neighborhood of (0 0 16) they will be in phase with P and make these reflections unusually strong. Thus the intensities for the (0 0 *l*) planes may be readily explained.

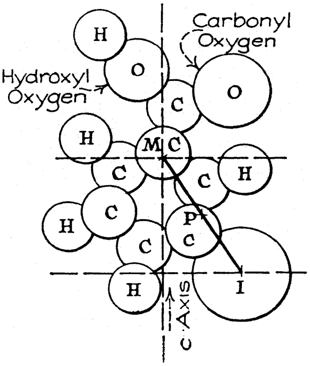

Fig. 4.

To determine the value of the parameter v along the b axis the (0 1 1) and (0 $\bar{1}$ *l*) reflections on film Number 3 were taken. Examination of the film shows that in general those reflections are weaker where *l* is even. This would indicate that the value of v must be nearly $^1/_2$. The structure factors for this set of planes were calculated and the intensities determined. The periodicity along the *c* axis had to be taken into account here, too, and with respect to this set of planes it is approximately $^1/_{12}$. Table III gives the observed and calculated intensities of this set of planes. It will be seen that the observed intensities agree only roughly with the calculated intensities. This is because the C molecule falls half way along the b axis. It is not equivalent to the A and B molecules in its effect on the x-ray beam. If it were equivalent the first order of (0 1 1) would be missing completely, whereas it is present but greatly reduced in intensity. (0 1 2) has its intensity increased considerably because of the C molecule. (0 1 3) is reduced in intensity for the same reason as (0 1 1). Beyond this the effect of the C molecule is still noticeable but not quite so great. We are not able to take it into account quantitatively in the determination of the theoretical

TABLE III

INTENSITY DATA FOR (0 1 *l*) PLANES FROM OSCILLATED CRYSTAL PHOTOGRAPH NUMBER 3

Plane	Estimated obs. intens.	Calculated intensity	Plane	Estimated obs. intens.	Calculated intensity
0 1 1	6	482	0 1 8	8	4
0 1 2	16	37	0 1 9	10	60
0 1 3	12	197	0 1 10	4	8

0 1 5	15	17	0 1 12	4	8
0 1 6	0	0	0 1 13	6	57
0 1 7	12	12	0 1 14	4	4

intensities. The best value for the parameter v is approximately $^4/_{10}$. The data on these planes are given in Table III.

Model **of the Unit** Cell.—A model was made by constructing molecules to scale from wooden balls as shown in Fig. 4. These were then placed at the positions of the four lattice points. The junctions along the *a* direction are across hydrogen atoms. The large number of orders of (0 0 1) planes reflecting indicates a concentration of the atoms in the (0 0 1) planes. The model shows this, and also explains the very complete cleavage parallel to this plane. The other cleavage (1 0 1) is likely from the model.

Summary

m-Iodobenzoic acid belongs to the monoclinic prismatic class instead of monoclinic sphenoidal. Its axial ratio is $a : b : c = 1.3252 : 1 : 5.5824$; $\beta = 91° 29.5'$. The unit cell contains four molecules and has the following dimensions: $a_0 = 6.206$ Å.; $b_0 = 4.683$ Å.; $c_0 = 26.14$ Å. The space-group is C_{2h}^5. The molecules are located within the cell at the positions (0 0 0), ($^1/_2$ v $^1/_2$), (u $^1/_2$ w), ($u + {^1/_2}$, $v + {^1/_2}$, $w + {^1/_2}$), where u and w are approximately equal to 0, and v equals very nearly $^4/_{10}$. Model molecules, built up of wooden balls, embodying the "puckered" benzene ring fit into the cell defined above very well. The model accounts for the cleavage of the crystal.

An addition to Laue photograph technique through the use of filters has been described.

THE MEASUREMENT OF THE HYDROGEN-ION CONCENTRATION IN UNBUFFERED SOLUTIONS. I. THE ADSORBENT PROPERTIES OF PLATINIZED PLATINUM

BY I. M. KOLTHOFF AND TOHRU KAMEDA

RECEIVED APRIL 25, 1929 PUBLISHED OCTOBER 5, 1929

It is a well-known fact that the measurement of the hydrogen-ion concentration in a solution with an extremely small buffer capacity is a very hard problem. If a platinized electrode is used, it takes a long time before the potential is constant and it is hardly possible to find reproducible results; moreover, it is doubtful whether the final reading of the electromotive force corresponds to the PH of the original solution. It was our intention to make a careful study of the hydrolysis of solutions of pure zinc salts and we used a platinized platinum spiral for the measurement of the *P*H.[1] However, we met with many difficulties; the e.m.f. measured always corresponded to *a* higher hydrogen-ion concentration than was

---

[1] For electrode cell, *cf.* I. M. Kolthoff and W. Bosch, *Rec. trav. chim.*, 46, 430 (1927).

expected from the results of other methods. Moreover, in many cases we were able to show in a colorimetric way that the solution taken from the electrode cell after the treatment with hydrogen had a more acid reaction than the original liquid. Recently a similar phenomenon has been described by H. G. Denham and N. A. Morris,[2] who found that solutions of zinc sulfate and cadmium sulfate after treatment in the hydrogen electrode became more acid. They attribute this to a reduction of the bivalent metal ions to the monovalent state, $Zn^{++} + H \rightleftarrows Zn^{+} + H^{+}$. This interpretation seems very improbable. In our experiments we observed that the solution from the electrode cell after treatment with hydrogen had no reducing properties whatsoever, which shows evidently that the original metal ions had not been reduced. There was more reason to ascribe the facts observed to the adsorbent properties of the platinized platinum, the more so since A. Frumkin and A. Donde[3] in a preliminary paper showed that platinum black can adsorb alkali from a neutral salt solution in a hydrogen atmosphere. It was shown by these authors that this hydrolytic adsorption is dependent upon the kind of gas with which the platinum black was saturated. In working with 0.2 N sodium sulfate solution they found that in a hydrogen atmosphere the platinum black adsorbed alkali to a considerable extent and the solution became strongly acid. After washing the platinum with conductivity water in a hydrogen current until the reaction did not change further, they treated the same platinum black with the salt solution or water, respectively, in an oxygen atmosphere instead of hydrogen. Under these conditions alkali was liberated and its amount was approximately equivalent to the amount of acid originally found in the hydrogen atmosphere; though, as a rule, somewhat less alkali was given off than corresponded to acid which had been formed. The most probable explanation of the phenomena is that in a hydrogen atmosphere a double layer is formed around the platinum particles, the metal being negative and the layer of hydrogen ions at the liquid side forming the positive part. Cations from the solution may displace part of the hydrogen ions in the double layer, which results in an adsorption of the cation, whereas an equivalent amount of hydrogen ions goes into the solution. If the hydrogen is removed the electrode is discharged, and the ions in the double layer are transformed into molecular hydrogen which escapes and the adsorbed cations into the corresponding metal. If oxygen is passed through, the metal is oxidized to its oxide, which gives the hydroxide with water. Now it may be expected that an oxygen electrode will show just the reverse behavior of a hydrogen electrode. However, Frumkin and Donde were not able to show that a sodium sulfate solution in contact with platinum black becomes alkaline on passing

---

[2] H. G. Denham and N. A. Morris, *Trans. Faraday Soc.*, **26**, 510 (1928).

[3] A. Frumkin and A. Donde, *Ber.*, **60**, 1816 (1927).

through oxygen; as a matter of fact, they always found a slightly acid reaction. It should be remembered, however, that platinum black or a platinized platinum electrode in oxygen does not behave like an ideal hydroxyl-ion electrode, because part of the platinum may be oxidized to some oxide. In this light it is worth while to mention the recent important investigations of S. W. Pennycuick,[4] who was able to prove that in the preparation of a platinum sol according to the spark method of Bredig a little of a strong acid is formed, hexahydroxyplatinic acid, $H_2Pt(OH)_6$, which is responsible for the stability of the sol. In the discussion of our results we will come back to this point.

In our preliminary experiments we tried to reproduce Frumkin and Donde's results by working with platinum black. The latter was prepared by reduction of pure chloroplatinic acid with ammonium formate; the metal was washed for several weeks with conductivity water until the conductivity of the water after the washing had not changed. The black metal powder was very heavy, and it was almost impossible to stir it up from the bottom of the cell when a strong current of hydrogen gas was passed through. Moreover, fine particles showed a tendency to coagulate in the hydrogen current; probably due to the small surface of the metal we failed in reproducing Frumkin and Donde's results, although two different preparations of platinum black have been used. Therefore we changed the experimental conditions and took a long, thin foil of platinum, 3.5 cm. long and 2.5 cm. wide, wound in a cylindrical shape. It was mounted in a pyrex glass cell. The arrangement is shown in Fig. 1.

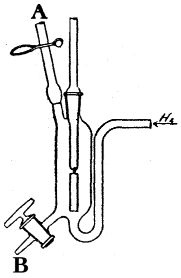

Fig. 1.

After passing the hydrogen through for a certain time, the liquid could be withdrawn from the cell in a hydrogen atmosphere by opening the glass stopcock B and closing the glass tube A. By careful electrolysis in a chloroplatinic acid-bath (without lead, of course) the platinum cylinder was coated with a black layer of platinum, then washed out with conductivity water in air and finally in hydrogen until the reaction of the water remained unchanged. The first experiments with such an electrode gave results in qualitative agreement with those of Frumkin and Donde. However, in continued investigations, a hydrolytic adsorption was no longer observed. Therefore we platinized again and washed out with sodium bicarbonate in order to remove acid which might be adsqrbed by the electrode. Thereupon the washing with water was started in the way described above but no hydrolytic adsorption was found. A third electrolysis in the chloroplatinic acid-bath was made and the electrode washed out with water in a hydrogen current until the reaction did not change further. This electrode gave continuously reproducible results, even quantitatively, and showed the adsorption phenomena quite distinctly. We do not know how to explain the first irregular behavior; we may mention here that Frumkin[5] often observed the same kind of irregularities. The hydrogen and oxygen used in these experiments were taken from a tank and purified by washing through several wash-bottles (permanganate, alkaline pyrogallol, sulfuric acid, four flasks with water, two empty wash-bottles, finally through the salt solution and then through the electrode cell). At first the hydrogen washed through perrnanganate was passed over an electrically heated copper wire; later it appeared that alkaline pyrogallol could be used as well. In the case of oxygen purification, the alkaline pyrogallol was omitted.

[5] Private communication from Professor Frumkin.

The neutral salts used were C. P. products and were recrystallized a few times from water and tested for the absence of traces of acid or alkaline impurities.

In all the experiments conductivity water ($K_{25} = 1 \times 10^{-6}$) was used as a solvent. The qualitative experiments with solutions of sodium chloride, potassium chloride, potassium sulfate and calcium chloride showed that they became more or less acid to methyl orange when hydrogen was passed through the electrode vessel. The solutions were then withdrawn from the cell in a hydrogen atmosphere; the vessel was filled up with water or with the original salt solution, whereupon oxygen was passed through. An alkaline reaction to thymol blue and in most cases to thymolphthalein was noticed.

Before making the next experiment, the cell and electrode were washed out with water in oxygen until the reaction did not change any more. It is peculiar that after prolonged washing in oxygen the water in the electrode cell always became very slightly acid (PH 5.4 to 5.6 to methyl red sodium salt), whereas the conductivity water after washing with the same gas in a pyrex flask in the absence of platinum had a PH of about 6.8 (brom thymol blue sodium salt). Probably a trace of the hexahydroxyplatinic acid is formed in oxygen. The washing in hydrogen was followed by further washing in oxygen. In order to be sure that sulfates and salts of divalent metals (zinc) were not reduced by the hydrogen electrode, 5 cc. of the solution was transferred from the cell in a hydrogen atmosphere into 0.1 cc. of 0.001 *N* permanganate. By comparison with a blank in water we found that *no reduction of sulfates or zinc* ions had taken place. In the quantitative experiments it appeared that equilibrium in hydrogen was attained within ten minutes. The same holds for the oxygen treatment. If the latter gas is passed through for a longer time, another phenomenon may take place which we will discuss later.

As a rule 25 cc. of the salt solution to be examined was placed in the electrode cell; hydrogen was then bubbled through from ten to fifteen minutes, whereupon the solution was withdrawn into a ppex flask and titrated with 0.01 *N* sodium hydroxide, using 0.1 cc. of 0.03% methyl red sodium salt as an indicator. A blank titration was performed under the same conditions with 25 cc. of the original salt solution, washed by hydrogen. After removing the solution from the cell, the latter was filled with water in the hydrogen atmosphere, withdrawn after ten minutes and titrated. This procedure was repeated until the reaction of the wash water did not change any more. Then we continued the washing in oxygen; the water became alkaline and was titrated with 0.01 N hydrochloric acid, using methyl red sodium salt as an indicator. The procedure was repeated until the reaction of the water did not change further, whereupon the electrode finally was washed out in hydrogen again. In Table I are given only the titration figures of the first solution withdrawn from the electrode and the sum of the figures for the different wash waters.

TABLE I

0.1 *N* POTASSIUM CHLORIDE

In hydrogen	0.01 *N* NaOH, cc.	In oxygen	0.01 *N* HCl, cc.
Solution taken from cell......	0.30	First wash water............	0.32
Wash water (4 washings).....	.04	Wash water	.01
	0.34		0.33

A duplicate experiment gave in hydrogen 0.33 cc. of 0.01 *N* sodium hydroxide; in oxygen, 0.30 cc. of 0.01 *N* hydrochloric acid. There is almost a complete recovery of the base adsorbed in the hydrogen atmosphere when oxygen is passed through.

Zinc Sulfate.—More elaborate experiments were made with solutions of zinc sulfate. The salt was purified by six recrystallizations from water and dried in a desiccator over deliquescent sodium bromide at a temperature below 25°. In this way a salt with seven molecules of crystal water was obtained. After the third recrystallization, solutions of the same concentration showed the same PH.

Solutions of zinc sulfate of different strengths showed after treatment in the hydrogen electrode a much stronger acid reaction than the original ones. The usual washing in hydrogen was continued in oxygen. In the latter the reaction became only slightly alkaline, the PH being about 7 to 7.5. Even after fifteen washings the reaction was still slightly alkaline and the wash water contained a trace of dissolved zinc, as was shown by a slight opalescence on the addition of ferrocyanide. In the oxygen atmosphere the adsorbed zinc is transformed into the slightly soluble zinc oxide; it would require a long time before the latter could be washed out quantitatively. Therefore, in order to remove the adsorbed zinc, the cell was filled with 0.1 *N* hydrochloric acid and oxygen passed through from thirty to forty minutes. The acid solution contained a considerable amount of zinc; in further washing with water, no zinc was given off.

In the quantitative experiments we treated the zinc sulfate solution first in hydrogen and then withdrew the solution and titrated the free acid with m e red sodium salt as an indicator, using the original salt solution as a liquid for comparison. It was interesting to know whether an equivalent amount of zinc had disappeared from the solution. Therefore, in those cases in which we worked with 0.01 *M* zinc sulfate solution, the zinc content was determined by the oxin (o-hydroxyquinoline) method before and after the adsorption. When stronger zinc sulfate solutions were used, the difference before and after adsorption was so small that the analytical error would make the result rather uncertain. Therefore, after the zinc sulfate–hydrogen treatment, the electrode and cell were washed in hydrogen with water until the reaction remained unchanged; then we added 0.1 N hydrochloric acid, passed oxygen through and determined the amount of zinc in solution—which is equal to the amount adsorbed in a direct way by the oxin method.

TABLE III

RESULTS OF EXPERIMENTS

0.01 *M* zinc sulfate

	0.01 *N* NaOH, cc.	Adsorbed, %
In hydrogen	1.16	2.3
Adsorbed zinc	1.18	2.36

0.05 M zinc sulfate

In hydrogen: 3.03 + 0.45 (6 washings) = 3.48 cc. of 0.01 N NaOH or 0.0348 milliequiv. of H^+ liberated.
Adsorbed zinc, 0.0340 milliequiv. of Zn^{++} adsorbed

Repeated experiments gave the following results

0.0350 milliequiv. of H^+ liberated and 0.039 milliequiv. of Zn^{++} adsorbed
0.034 milliequiv. of H^+ liberated and 0.037 milliequiv. of Zn^{++} adsorbed

From these experiments we learn that the results are well reproducible, that the amount of acid formed is equivalent to the amount of zinc adsorbed by the electrode and, finally, that the adsorption of zinc ions is much larger than that of cations in alkali or earth alkali salts (compare previous tables).

Ammonium Chloride.—The behavior of ammonium chloride solution was quite different from that of the other salts. It is to be expected that the platinized electrode in a hydrogen atmosphere will adsorb ammonia. In working with 1 N, 0.1 N and 0.005 N ammonium chloride solutions, respectively, we found that in hydrogen the reaction became very slightly more acid (colorimetric measurements of P_H), the difference in acidity from the original solutions being so small that it could not be titrated (for 25 cc. of solution it was less than 0.05 cc. of 0.01 N NaOH). If the electrode was treated thereafter in an oxygen atmosphere with water after washing out, a tiny trace of alkali (ammonia) was given off.

By treating the ammonium chloride solutions in an oxygen atmosphere in the electrode cell the results were still more peculiar. The solutions became distinctly acid, more acid being formed the longer the oxygen was passed over the electrode. By passing the oxygen current coming from the electrode cell over 10 cc. of 0.004 N hydrochloric acid, we could prove in a qualitative and quantitative way that no ammonia was removed due to hydrolysis. Neither was it possible to detect in the solution after the oxygen treatment any oxidation products such as nitrate or nitrite. The only plausible explanation of the peculiar behavior was that the platinum black in the oxygen atmosphere is slowly oxidized to the hexa-aquoplatinic acid, which is very slightly soluble and remains for the main part on the electrode. This acid reacts with the ammonium ions in the solution by forming an insoluble ammonium salt

$$H_2Pt(OH)_6 + 2NH_4^+ \longrightarrow (NH_4)_2Pt(OH)_6 + 2H^+$$

The solution becomes acid and ammonium ions are removed from it. If this explanation gives a correct picture of what is happening, we may expect that after washing out with water in an oxygen atmosphere the water will become alkaline if the washing is continued in hydrogen, because the platinic acid will be reduced

$$(NH_4)_2Pt(OH)_6 + 2H_2 \longrightarrow Pt + 6H_2O + 2NH_3$$

Actually we found that the first washing with hydrogen gave an acid reaction; thereupon if the cell was filled with water again, the reaction became strongly alkaline; by means of Nessler's reagent it was very simple to detect the presence of considerable amounts of ammonia. It appears strange that the first washing in a hydrogen atmosphere gives an acid reaction. This is explained by the fact that strong acids are adsorbed by platinized platinum in an oxygen atmosphere and not in hydrogen (see later). The acid adsorbed in the oxygen treatment is rapidly displaced from the electrode by the first washing in the hydrogen atmosphere. Thereupon the reduction of the ammonium salt of the aquoplatinic acid takes place and the reaction changes to alkaline. Some of the practical results are reported in Table IV.

TABLE IV

RESULTS OF EXPERIMENTS

NH_4Cl, normality (25 cc.)		0.1	0.1	0.1	0.005	0.005
Oxygen passed for, hours		1/6	12	17	1/6	3.5
NaOH[a] for solution, cc.		0.25	1.10	1.13	0.17	0.53
NaOH[a] for washings, cc.		(4) .17	(8) 0.29	(5) 0.40	(6) 0.14	(4) 0.22
Washed in hydrogen	NaOH[a] cc., 1st.	.12	.14	.09	.04	.04
	HCl,[a] cc., 2d.	.12	.24	.32	.02	.03
	HCl[a] for more washings, cc.	(3) .12	(3) .12	(4) .16	(3) .01	(3) .03

[a] NaOH and HCl, 0.01 N.

The amount of base recovered in the hydrogen current is always much less than the amount of acid formed in oxygen. It may be that the adsorbed ammonia is not completely removed by washing out in hydrogen.

	Later (3).	No change	(3) .02 HCl[a]

[a] NaOH and HCl, 0.01 N.

We also made some experiments with the salt of an organic cation, trimethylammonium chloride. Qualitatively it behaved more or less in the same way as ammonium chloride, the only difference being that after treatment in oxygen and washing with the same gas, much more acid was liberated later in hydrogen than in the case of ammonium chloride.

Experiments similar to those described for ammonium chloride were made with 0.1 N potassium chloride. After passing oxygen through for twenty-five hours, the solution was very slightly acid and took 0.03 cc. of 0.01 *N* sodium hydroxide. The wash water (five times) took 0.06 cc. 0.01 N sodium hydroxide. Then the washing was continued in hydrogen. The first wash water was distinctly acid and took 0.06 cc. of 0.01 N sodium hydroxide; the second wash water, 0.12 cc. With four more washings the reaction did not change further. Thereupon we turned back to the washing in oxygen. The first wash water was distinctly alkaline, and took 0.05 cc. of 0.01 N hydrochloric acid and the second wash water, 0.02 cc.; by further washing the reaction remained unchanged,

These results, which are reproducible from a qualitative point of view, show that the behavior of the salt solution in oxygen is fairly complicated. After passing oxygen through for twenty-five hours, the reaction is distinctly acid, due to the formation of hexa-aquoplatinic acid. Moreover, it seems that a trace of free acid is hydrolytically adsorbed from the salt solution and that a trace of potassium is adsorbed by the platinic acid. The adsorbed acid is not given off in an oxygen atmosphere but is easily removed in hydrogen (see next section).

Therefore, the first washings with hydrogen were distinctly acid. Moreover, the hydrogen reduces the aquoplatinic acid and its potassium salt; in the latter case potassium hydroxide is formed. However, as we shall see later, a trace of adsorbed hydroxide cannot be removed in a hydrogen atmosphere but is given off in oxygen. Therefore, in the final washing in oxygen we found a slightly alkaline reaction.

On account of the complex nature of the phenomena described, it is evident that they are of no significance from a quantitative point of view.

Adsorption of Hydrochloric Acid by Platinized Platinum.—After the electrode had been carefully washed out with water in hydrogen, oxygen and hydrogen, the adsorption of hydrochloric acid was studied in a hydrogen atmosphere.

We worked with 0.01 N, 0.002 *N*, 0.001 N and 0.0005 N hydrochloric acid, respectively; the results showed that there *was not even a trace of acid adsorption in a hydrogen atmosphere.* Similar experiments were performed in an oxygen current. The oxygen was passed through for ten minutes; a longer treatment had no effect on the results. The titrations were made with 0.01 *N* sodium hydroxide using a micro buret for the more dilute solutions and methyl red as indicator. The original solutions of the acid were treated for ten minutes with oxygen in the absence of platinum black and titrated in the same way. The difference between the two titration figures gave the amount of acid adsorbed by the platinized platinum in the oxygen atmosphere. In order to be certain that there was an equivalent adsorption of the hydrogen and chlorine ions, the concentration of the latter was determined before and after the adsorption in a gravimetric way. The results agreed very closely with those obtained by the volumetric determination of the hydrogen ions. Therefore, from our experiments, we may conclude that there is *an equivalent adsorption of hydrogen and chloride ions from hydrochloric acid solution by platinized platinum in an oxygen atmosphere.* The results are summarized in the following table. In all cases 35 cc. of the acid solution was used for each experiment. The first line gives the original concentration of the acid, the second the concentration after the adsorption, the third the number of micromoles adsorbed and the fourth the decrease of the concentration of the acid due to the adsorption expressed in per cent.

TABLE VI

ADSORPTION OF HYDROCHLORIC ACID BY PLATINIZED PLATINUM IN OXYGEN

Init. concn., N	Final concn., N	Micromoles of HCl adsorbed	Adsorption, %
0.00978	0.00946	10.2	3.2
	.00951	9.5	2.7
	.00950	9.7	2.8
.00490	.00468	7.7	4.4
.00092	.00081	3.9	12
.00050	.00039	3.7	22

The curve in Fig. 2 gives a graphical representation of the change of the adsorption with the final concentration in the solution. The absolute amount of adsorbed acid increases with increasing final concentration, whereas, relatively, the adsorption decreases at higher concentrations. Therefore, the adsorption isotherm has the normal appearance. A longer treatment in oxygen did not affect the results.

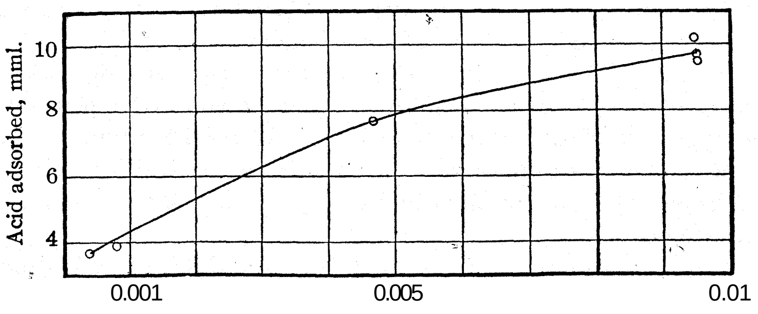

Fig. 2.—Adsorption of hydrochloric acid by platinized platinum in oxygen.

Adsorption of Sodium Hydroxide by Platinized Platinum.—As we have seen before, platinized platinum adsorbs the base from a neutral salt solution in a hydrogen atmosphere. Therefore, we may expect a much larger effect if dilute solutions of sodium hydroxide are in contact with platinized platinum in a hydrogen atmosphere. This is actually the case, though the amount adsorbed reaches a maximum at a fairly low alkali concentration; if the latter is increased, the amount adsorbed drops again. Thirty-five cc. of the solution was introduced into the cell and then hydrogen passed through for ten minutes (a longer treatment in this gas did not change the results). The solution was withdrawn in the hydrogen atmosphere and 25 cc. was titrated. The cell was washed with water in hydrogen until the reaction remained unchanged. Thereafter the washing was continued in oxygen; the wash water always was distinctly alkaline and in most cases the alkalinity was determined quantitatively. This phenomenon shows that it is impossible to remove all of the adsorbed base from the electrode in a hydrogen current. After the washing in oxygen, it was repeated again in hydrogen. In several cases we started with 20 cc. of the sodium hydroxide solution instead of with 35 cc. and analyzed later a 10-cc. portion. In the latter case only half of the electrode was covered by the solution. The titrations were made at boiling temperature with phenol red as an indicator. The original solutions have been analyzed under similar conditions. From the difference between the titration figures the amount of base adsorbed could be computed. All the results were reproducible and are summarized in Table VII.

TABLE VII

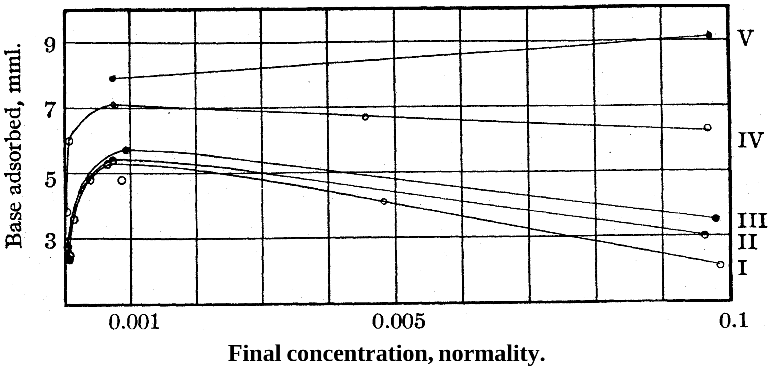
ADSORPTION OF SODIUM HYDROXIDE BY PLATINIZED PLATINUM IN HYDROGEN

Init. concn., *N*	Vol. of base taken, cc.	Final concn., *N*	Adsorbed, micromoles
0.00992	35	0.00986	2.1
.00978	20	.00963	3.0
.0049	35	.00482	4.1
.0010	35	.00086	4.8
.0010	20	.00072	5.4
.0008	35	.00066	5.3
.0005	35	.00037	4.8
.0002	35	.00011	3.6
		.00012	3.4
,00012	35	.00005	2.5
.00017	20	.00002	2.7

In Fig. 3 the results are combined in a graph; the ordinate gives the number of micromoles adsorbed and the abscissa the final concentration in the solution. It is quite evident that there is a maximum in the adsorption at a final concentration of approximately 0.0007 N sodium hydroxide. It should be remembered that a very small analytical error in the titration of the stronger solutions causes a large deviation in the amount adsorbed. Still, we believe that the general shape of the curve is right, because the values have been reproduced several times.

The shape of the curve looks similar to that representing the change of the electrokinetic potential of a platinum sol at different alkalinities. It seems to us, however, that there is no connection between the adsorption of the sodium hydroxide by platinized platinum in hydrogen and the electrokinetic potential, and it is hard at the present time to explain the maximum.

It was thought that the adsorption of the sodium ions might be increased if a sodium salt such as sodium chloride was added to the sodium hydroxide solution. This, indeed, was the case; the force required to remove the sodium ions from the solution in the presence of an excess of sodium salt is smaller than when they are absent. Under these conditions we have, moreover, the advantage that the adsorption of the hydroxide at different concentrations takes place at about the same sodium-ion concentration in the solution.



I, NaOH (35 cc.); II, NaOH (20 cc.); III, NaOH in 0.1 N NaCl; IV, NaOH in 1.0 N NaCl; V, NaOH in 3.0 N NaCl.

Fig. 3.—Adsorption of sodium hydroxide by platinized platinum in hydrogen.

The analytical procedure was the same as that described for the solutions of sodium hydroxide alone. In all cases we started with 35 cc. of solution. The results are summarized in Table VIII and graphically in Fig. 3; Curve III represents the adsorption from 0.1 N sodium chloride Curve IV from 1 *N* sodium chloride and Curve V from 3 N sodium chloride.

At larger concentrations of sodium chloride there is a decided increase in the adsorption of sodium hydroxide. Moreover, the maximum in the adsorption, which had been found at about 0.0007 N hydroxide in the absence of salt, disappears when enough sodium chloride is present.

Adsorption of Sodium Hydroxide by Platinized Platinum in Oxygen.—If a sodium hydroxide solution is in contact with platinized platinum in an oxygen atmosphere, an apparent adsorption of the base takes place.

TABLE VIII

ADSORPTION OF SODIUM HYDROXIDE IN THE PRESENCE OF SODIUM CHLORIDE BY PLATINIZED PLATINUM IN A HYDROGEN ATMOSPHERE

Concn. of NaCl, *N*	Init. concn. of base, *N*	Final concn. of base, *N*	Micromoles adsorbed
0.1	0.0099	0.0098	3.5
.1	.00097	.00080	5.7
.1	.00011	.0000	2.4
1	.0099	.0097	6.3
1	.00475	.00456	6.7
1	.00095	.00075	7.1
1	.00022	.00005	6.0
1	.00013	.00001	3.8
3	.00998	.00972	9.1
3	.00097	.00074	7.9

However, this is not a true adsorption, the amount of base which disappears from the solution increases the longer the oxygen is passed through. Some figures are shown in Table IX.

TABLE IX

APPARENT ADSORPTION OF SODIUM HYDROXIDE BY PLATINIZED PLATINUM IN OXYGEN

Concn. of base, *N*	0.01	0.001	0.001	0.001	0.0001
Passage of oxygen, hours	$^1/_6$	$^1/_6$	3.5	24	$^1/_6$
Mml. of base removed from soln.	2.8	1.8	3.2	4.4	0.36

This abnormal behavior can be explained by a reaction between the platinum black and the oxygen. The strong hexa-aquoplatinic acid is formed, which neutralizes part of the sodium hydroxide in the solution. The longer the oxygen is passed through, the more of the platinic acid is formed and the more base is neutralized. That this interpretation is right could be proved in the following way: 0.001 N sodium hydroxide was treated for twenty-four hours with oxygen in the presence of the platinized platinum. The solution was withdrawn and the vessel washed out twice with water in an oxygen atmosphere. The last wash water was practically neutral. Then water was added again and hydrogen passed through, whereupon the reaction did not change; at least the wash water required less than 0.02 cc. of 0.01 N hydrochloric acid with methyl red as an indicator. After two washings in hydrogen we turned back to oxygen. The first wash water was distinctly alkaline and took 0.11 cc. of 0.01 N hydrochloric acid; the second portion, 0.03 cc. .Continued alternate washings in oxygen and hydrogen did not change the reaction of the water. The phenomena described are well reproducible from a qualitative point of view. The sodium salt of the hexahydroxyplatinic acid which was formed in the oxygen atmosphere and adsorbed by the platinized platinum is reduced to metallic platinum and sodium hydroxide in a hydrogen gas current but, as we have seen, the platinized platinum adsorbs a trace of base in a hydrogen atmosphere very strongly. In order to liberate the base formed, oxygen has to be passed through again. It is hard to say whether the formation of the hexahydroxyplatinic acid is the only factor responsible for the disappearance of the hydroxide from the solution. It is still possible that part of the hydroxide is removed by some kind of an adsorption process.

Summary

1. The irregularities observed in the measurement of PH of unbuffered solutions with the hydrogen electrode, using platinized platinum as an electrode, are probably due to adsorption phenomena.

2. Frumkin and Donde's experiments with neutral salts in contact with platinum black were repeated with a platinized electrode. It was confirmed that platinized platinum in a hydrogen atmosphere adsorbs the cation from a neutral salt solution and an equivalent amount of free acid is found in the solution.

3. Hydrochloric acid is not adsorbed by platinized platinum in a hydrogen atmosphere, whereas a small but distinct adsorption takes place in oxygen.

4. Sodium hydroxide is strongly adsorbed by platinized platinum in a hydrogen atmosphere; a maximum occurs at a final concentration of about 0.0007 N. Sodium chloride increases the adsorption, whereas in the presence of large amounts of this salt the maximum disappears.

5. Sodium hydroxide is apparently adsorbed by platinized platinum in an oxygen atmosphere. This, however, is not true adsorption, but probably a neutralization of sodium hydroxide by the hexahydroxyplatinic acid which is formed by the action of oxygen on the platinized platinum.

6. On the same basis the abnormal behavior of ammonium chloride solutions in contact with platinized platinum in an oxygen atmosphere has been explained.

A STUDY OF THE SILVER CHLORIDE ELECTRODE

BY WALTER R. CARMODY

RECEIVED APRIL 25, 1929 PUBLISHED OCTOBER 5, 1929

Although the silver chloride electrode in various forms has been used for a good many years as a reference electrode, authors have reached no agreement as to the best method of preparing this electrode. Various investigators using different methods of preparation and manipulation have obtained different results and to a certain degree the potential of the silver chloride electrode still remains in doubt, the separate electrodes varying from 0.1 mv. to as much as 1.0 mv. It was the writer's object to study the factors which cause these relatively large differences in potential in an effort to produce an electrode that would be reproducible and constant within 0.01 mv.

The silver chloride electrode has been prepared most often by electrolytically depositing silver upon platinum gauze from a cyanide solution. After being washed for a day in water the electrode is covered with a layer of silver chloride by electrolysis as the anode in dilute hydrochloric acid solution.[1] Electrodes prepared according to the directions of MacInnes and Parker have been used by several investigators,[2] and have been discarded by others[3] as being not reproducible or constant in potential. The writer selected this form of electrode for study to determine whether a constant and reproducible silver chloride electrode could be produced by this method of preparation.

Factors that Influence the Potential of the **Electrode.**—The factors involved in the preparation and use of the silver chloride electrode that influence the potential are: (1) cyanide ion absorbed in the silver-plated electrode, (2) light, (3) time and (4) concentration of chloride solution. The writer has investigated these factors in the desire to determine acceptable methods of preparation and of use of the silver chloride electrode.

The directions of MacInnes and Parker[1b] produce electrodes of "reddish-brown color the shade of which was the same whether the electrolysis was carried out in the light or in complete darkness." Noyes and Ellis[4] prepared silver chloride electrodes that were, they state, "not appreciably affected" by the action of daylight. Several years ago the writer noted

that the odor of cyanide remained with the silvered electrodes after a period of five or six days of washing,[5] and that the shade of the color of electrodes that had been washed for two weeks did vary according as the deposition of the silver chloride was made in darkness or in daylight. Güntelberg[6] protected his electrodes from contact with light but does not mention the effect, light had upon them.

The writer prepared his silver chloride electrodes in complete darkness and protected them from exposure to light while they were being used. Results from the experimental work outlined below show that an electrolytically deposited silver–silver chloride electrode, reproducible and constant to within **0.01** mv., can be prepared if precautions are taken to protect the electrode during its preparation and use from being affected by those factors which change its potential. Both the absorption of cyanide in the silvered electrode and the exposure of the silver chloride electrode to daylight have been found to alter the potential of the electrode appreciably in the positive direction. The effect of cyanide absorption may be eliminated by washing the silvered electrode over a period of two weeks. The absorption, which determines the time of washing necessary, may be decreased by depositing the silver in an H-cell from a solution of $KAg(CN)_2$ that has been purified by careful recrystallization. The effect of daylight is eliminated by working in a dark room or by the light from an incandescent lamp, or by covering the cell with opaque cloth.

The writer has had occasion to use about fifty of these silver chloride electrodes prepared according to the directions given later in this paper. They have been found to be quite as reproducible and constant as the platinized platinum–hydrogen electrode.

Experimental

To test the effect of the time of washing of the silvered electrodes, several series of electrodes were prepared according to the directions of MacInnes and Parker[1b] in which the time of washing was varied from one to twenty days. The color and potential of the resulting electrode gradually changed until about the fourteenth day of washing, after which the silver chloride electrode produced was pure white and constant in potential. Electrodes chloridized after twenty-four hours of washing, were red-brown in color and, although checking very well within each series, were usually about **0.2** mv. positive to the white silver chloride electrodes. An attempt was made to lessen materially the time required for washing by boiling the electrodes for several hours in water and in dilute hydrochloric acid. These methods did not lessen the time appreciably.

[6] Güntelberg, *Z. physik. Chem.*, **123**, 199 (1926).

The darkening of the electrodes which had not been sufficiently washed is due evidently to the reduction of the silver chloride by the traces of cyanide that are absorbed during electrolysis. In order to decrease the possibility of this absorption of the cyanide ion, the electro-deposition of the silver was carried on in an H-cell in which the two compartments were connected by a long tube, an arrangement designed to prevent hydrocyanic acid, formed at the anode, from diffusing into the cathode chamber. Also, the time of electrolysis was shortened from twenty-four to eight hours with a corresponding increase in current from three to eight milliamperes per electrode. To further insure a low concentration of the cyanide ion, the potassium silver cyanide used in the electrolysis was precipitated from a solution free from excess potassium cyanide and recrystallized twice from distilled water. The silvered electrode carried no odor of cyanide after being washed. After being washed for two days and then coated with silver chloride it was light pink in color and reproducible and constant within 0.02 mv. When the period of washing was extended to five days the resulting electrode was white and repfoducible to well within 0.01 mv.

Several series of white electrodes were prepared and subjected to the action of daylight and the light from an incandescent lamp. All became brown in color, the shade increasing with the time of exposure, and becoming positive to the control electrodes. The results are shown in Table I.

TABLE I

RESULTS OF EXPERIMENTS

Kind of light	Diffused daylight	Direct sunlight	Incandescent lamp
Time of exposure	1 minute	1 minute	12 hours
Average change, mv.	0.05	0.2	0.01

As would be expected, daylight has a much greater effect upon the potential and color than has the light from the incandescent lamp.

To determine the effect of the concentration of the electrolytic solution, two groups of silver chloride electrodes were prepared, one group in 0.1 M hydrochloric acid and the other group in 0.01 M acid. When placed in 0.1 *M* hydrochloric acid they all acquired the same potential within an hour. This demonstrates the practicability of using silver chloride electrodes in solutions of different concentration from that in which the electrodes are made. The precaution of chloridizing the silvered electrodes in a solution of the same concentration as that in which the electrode is to be used seems to be unnecessary.

The effect of time on the electrodes noted by Scatchard'' and Nonhebel and Hartley[7] was not noted. Several electrodes that had stood in distilled water for a month as well as several that had been in constant use

---

[7] Nonhebel and Hartley, *Phil.* Mag., (6) *50*, 729 (1925).

in lead chloride solutions showed no difference in potential when being compared with electrodes freshly prepared. The change in potential noted by former investigators is evidently due to the action of light on the electrodes and not to any simple aging effect.

Directions for Preparing Electrodes

1. Clean platinum gauze electrodes by boiling in concentrated nitric acid for a few minutes.
2. Electrolyze as cathodes in an H-cell from a solution of potassium silver cyanide that has been prepared free from excess potassium cyanide and purified by recrystallization. The electrolysis is carried on for eight hours, *a* current of eight milliamperes per electrode being used.
3. Wash in running water for five days.
4. Electrolyze as anodes in dilute hydrochloric acid for one hour. A current density of **3** milliamperes per electrode is employed.
5. Keep in distilled water and protect from contact with direct or diffused-sunlight.

The writer is pleased to acknowledge his indebtedness to the chemistry department of Stanford University for apparatus and materials and for the privileges of their laboratory, at which the experimental work described in this paper was completed.

Summary

A study of the factors that affect the potential of the silver chloride electrode has been made.

Directions are given for its preparation and care while being used.

Results show that the electrolytically deposited silver–silver chloride electrode when carefully prepared and used is quite as reproducible and constant as the hydrogen electrode.

STUDIES IN THE MEASUREMENT OF ELECTROMOTIVE FORCE IN DILUTE AQUEOUS SOLUTIONS. I. A STUDY OF THE LEAD ELECTRODE

BY WALTER R. CARMODY

RECEIVED APRIL 25, 1929 PUBLISHED OCTOBER 5, 1929

The only method of determining electrode potentials and activity coefficients from electromotive-force measurements depends upon some form of an extrapolation to infinite dilution of the experimental values obtained. This method was first outlined by Lewis and Randall.[1] Experience has shown that the curve does not flatten into a straight line necessary for extrapolation until concentrations well below **0.01** *M* are attained. Therefore, measurements on solutions of low concentration are important for the accurate determination of electrode potentials and activity coefficients.

As a general rule investigators have been unable to check one another when dealing with solutions of high dilution. A recent summary by Randall and Young[2] of the electromotive force measurements involving the silver chloride electrode illustrates the varied results obtained in dilute solutions by different investigators. The value of the normal potential of the silver chloride electrode obtained by several investigators varies from 0.2221 to 0.2234, although their measurements agree very well in the concentrated solutions.

The difficulties of electromotive force measurements in dilute solutions depend upon the relatively high percentage effect of small factors which may be negligible in the more concentrated solutions. Such slight changes in concentration may be caused by a reaction of the solution with electrodes or containing vessel or by absorption of the solution by the container or electrodes. The usual method to avoid large percentage variations due to these slight changes in concentration has been to use a cell of large proportions, containing a liter or more of solution.[3] Such cells require long periods of time, sometimes several days, to reach equilibrium. It has been the writer's experience that checks on solutions below 0.005 M are very difficult if not impossible to obtain when the large cell is used, even when the same solution and the same electrodes are used in two separate measurements.

Method and Apparatus.—The use of a small cell of 20-cc. capacity (shown in Fig. 1) designed to be emptied and refilled without the electrodes being disturbed has been

found to yield reproducible results on solutions well below 0.001 *M*. The method of operation is as follows.

The cell, with electrodes in position, and reservoir are filled with the solution and seasoned by standing for several hours, when the solution is drawn off and the reservoir filled with a new supply. The cell is washed with this new solution from the reservoir at frequent intervals for a period of an hour or more, the time depending upon the concentration of the solution used.

After the final filling, the solution is stirred with a stream of nitrogen for a half hour. The cell is then allowed to attain equilibrium without further change of solution or stirring. After the cell has reached equilibrium and the electromotive force has been measured, a second measurement can be made readily by filling the cell with a new supply of solution from the reservoir and repeating the operation.

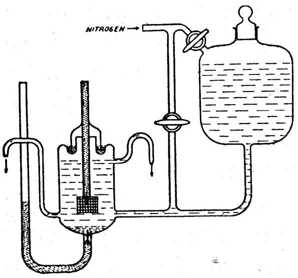

Fig. 1.

This method is designed to eliminate the effect of slight variations by using a sufficiently large volume of solution and at the same time it takes advantage of the short time necessary for the small cell to attain equilibrium. The cells described in the second half of this paper usually came to equilibrium within two hours after the nitrogen was turned off and the e.m.f. remained constant for several hours. As for the volume of the solution the writer has found it difficult to obtain checks when less than 0.001 mole of the electrolyte has been used in making up the solution. When working with concentrations approximately 0.0002 N, five liters of solution were prepared, two liters of which were passed through the cell before constant and reproducible voltages were obtained.

In the second part of this paper this method has been applied to the study of the lead electrode. A similar application of the method to the study of the silver chloride electrode in dilute solutions is planned.

The Lead Electrode

No accurate determination of the normal potential of the lead electrode has been made. Several measurements have been made that involve the potential of the lead electrode, but, since the activity coefficients of the lead salts used in these measurements are uncertain, no exact calculation of the normal potential can be made from them. Measurements of Getman,[4] Henderson and Stegeman[6] and Lewis and Brighton[6] were made on cells containing liquid junction potentials and salts of uncertain activity coefficients. Lewis and Randall[7] have roughly calculated the activity coefficient of lead chloride from the measurements of Brönsted[8] on the cell Pb, $PbCl_2$, AgCl, Ag, in which "Jahn" type silver chloride electrodes were used, by extrapolating to infinite dilution the values obtained from three measurements. Applying the activity coefficient for the saturated solution of lead chloride thus obtained to the measure-

ment of Gerke[9] on the cell Pb. $PbCl_2(s)$, $KCl + PbCl_2$, HgCl, Hg, $E = 0.5357$, they obtain the value Pb, Pb^{++}, $E_0 = 0.122$.

This value can be considered as approximate only, since it depends upon an extrapolation to infinite dilution of measurements made in relatively concentrated solutions.

Gerke also compared the potential of the two-phase saturated lead amalgam electrode with that of electrolyzed crystals and with stick lead, obtaining 0.00580 and 0.00567, respectively.

Results from the experimental work outlined below indicate that 0.0058 is a better value than 0.0057 for the potential of the lead amalgam electrode against the lead electrode. The normal electrode potential of lead is shown to be 0.1263, a value 0.0043 higher than that accepted at the present time.

Experimental

I. Electrodes and Materials

1. The silver chloride electrodes were prepared according to the method outlined by Carmody,[10] and were protected at all times from exposure to sunlight. They were prepared in groups of four, the electrodes in each group checking always within 0.02 mv.

2. The lead amalgam electrodes were prepared by heating mercury with freshly scraped stick lead (J. T. Baker's C. P.) in an atmosphere of nitrogen to form approximately a 5% solution. This was cooled to 80° and the liquid phase allowed to run into the cell through a capillary tube. The amalgam electrode so formed presented a liquid surface that was found to give more reproducible results than an amalgam that is rich in the solid phase. Repeated experiments showed it to be reproducible well within 0.01 millivolt.

3. The mercury used in the lead amalgam electrodes was purified by distilling three times in a current of air under reduced pressure as recommended by Hulett.[11]

4. Conductivity water used in preparing all solutions was the product of a laboratory still made according to the specifications given by Bengough, Stewart and Lee.[12]

5. Lead chloride (J. T. Baker's C. P.) was recrystallized three times from hot water.

6. Nitrogen for stirring cells and removing oxygen from solutions was purified by being passed in order through potassium permanganate, alkaline cuprous chloride, alkaline pyrogallol, water and finally through a solution of the same concentration as used in the cell.

II. Potential of Lead Amalgam Electrode

The Cell: Pb (Stick), $PbCl_2$, Pb(Hg).—A small cell of 20-rc. capacity was used. The freshly scraped stick electrode and the amalgam electrode were put in position in the nitrogen-filled cell. Oxygen-free lead chloride solution was allowed to run into the cell from an attached reservoir, the solution stirred with a stream of nitrogen for ten minutes and the cell then sealed. Usually the cell came to equilibrium in less than ten minutes and the potential remained constant for about two hours. After this

---

[9] Gerke, THIS JOURNAL, 44, 1684 (1922).

[10] W. R. Carmody, *ibid.*, **51**, 2901 (1929).

[11] Hulett, Phys. *Rev.*, **33**, 307 (1911).

[12] Bengough, Stewart and Lee, J. *Chem. Soc.*, **131, 2156** (1927).

time a gray coating formed on the surface of the lead stick and the potential slowly lowered without again reaching a constant value.

Five different sticks (carefully selected to be free from physical defects) were used. The results, shown in Table I, are more comparable with Gerke's results from electrolyzed lead crystals than his results from lead sticks. It would appear therefore that 0.0058 is a better value for the potential than 0.0057 obtained as an average by Gerke.

TABLE I

E.M.F. VALUES OF ELECTRODES

Electrode	1	2	3	4	5	Av.
E.m.f.	0.00580	0.00585	0.00586	0.00586	0.00582	0.00584

III. The Cell: Pb(Hg), $PbCl_2$, AgCl, Ag

The electrode vessel is shown in Fig. 1. The methods of operation have already been described. Equilibrium was obtained usually within two hours after the nitrogen had been shut off. No measurement on dilutions below 0.01 M was considered until it had been checked to within 0.1 millivolt by a second reading on the same solution. Results appear in Col. 2 of Table II.

The electromotive force of the cell is given by the equation:

$$E = E_0' - \frac{0.05915}{2} \log 4\,(m\lambda)^3 \qquad (1)$$

where E_0' is the normal potential of the cell. Following the method outlined by Randall,[13] this may be transformed into the equation

$$\log \lambda - \frac{E_0'}{0.08873} = - \left[\rule{2em}{0.4pt} + 0.2007 + \log m\right] \qquad (2)$$

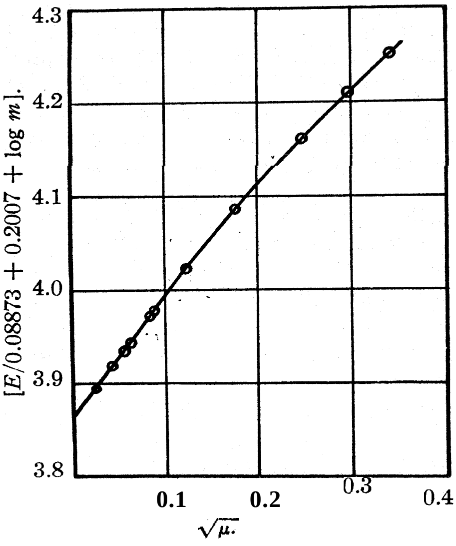

Fig. 2.

In Fig. 2 the quantity in the parenthesis is plotted against the square root of the ionic strength. By extrapolation to infinite dilution the following result is obtained: $E_0' = 0.3426$ v. Taking the potential of the silver chloride electrode to be 0.2221,[2] and the lead–lead amalgam potential to be 0.0058, the result obtained is

$$\text{Pb}, \text{Pb}^{++}, E_0 = 0.1263$$

Using this value in Equation 2, the activity coefficients of lead chloride have been calculated. They appear in Col. 3 of Table II.

.002620	.5639	.771			

[a] The effect of the solubility of the silver chloride electrode and the hydrolysis of the lead chloride have been considered. The effects are negligible except in the most dilute solution, where they are small, approximately equal and of opposite sign.

The activity coefficient of lead chloride in saturated solution **(0.03905** *M*) is found to be **0.408.** Applying this result and the value of the potential of the calomel electrode obtained by Randall and Young[2] to the measurement of Gerke,[9] we obtain Pb, Pb^{++}, $E_0 = $ **0.1264.** This checks well with the value **0.1263** obtained by extrapolation to infinite dilution.

The writer is pleased to acknowledge his indebtedness to the Chemistry Department of Stanford University for apparatus and materials and for the privileges of their laboratory, in which the experimental work described in this paper was completed.

Summary

1. A new method of electromotive-force measurement in dilute solutions is described.
2. Electromotive-force measurements have been made on the cell Pb(Hg), $PbCl_2$, AgCl, Ag.
3. From the results of these measurements the normal electrode potential of lead and the activity coefficients of lead chloride have been calculated.

SYSTEMS FORMED BY CERTAIN TETRAHALIDES

BY P. A. BOND AND W. R. STEPHENS

RECEIVED MAY 2, 1929 PUBLISHED OCTOBER 5, 1929

Work in this Laboratory on solubilities in non-aqueous inorganic solvents has extended over several years and has included a large number of inorganic compounds. Such solvents as sulfur monochloride, liquid nitrogen tetroxide, thionyl chloride, liquid hydrogen fluoride and liquid sulfur dioxide have been investigated.[1] The work with anhydrous liquid sulfur dioxide has shown that in general the metal iodides and thiocyanates are soluble to a small degree, while the chlorides and bromides are less soluble. Bond and Beach[2] investigated the solubility of stannic chloride, stannic bromide, carbon tetrachloride and titanium tetrachloride in anhydrous liquid sulfur dioxide, and have found that these compounds form binary liquid systems at low temperatures with this solvent. They determined the nature of the systems formed by the first three of these compounds but their work with titanium tetrachloride was not completed. The present work had for its purpose the completion of the system formed by titanium tetrachloride and anhydrous liquid sulfur dioxide and the extension of the investigation to include the behavior of silicon tetrachloride and zirconium tetrachloride with this solvent.

The method employed was first used by Alexjew.[3] It consists in sealing a known quantity of solvent and solute in a small glass tube, rotating it in a bath with regulated variable temperature and noting the temperature at which the two phases become one. By doing this for a series of compositions the solubility curve may be constructed. This method offers the advantage that subsequent analyses of the saturated solutions are not necessary and the determinations are not confined to temperatures below the boiling point of sulfur dioxide. Inasmuch as solubility is practically independent of the pressure over a variation of a few atmospheres, this method is the most practical one for highly volatile solvents.

Experimental Part

The tetrachlorides of titanium, silicon and zirconium show a very great affinity for water. When exposed to moist air titanium and silicon tetrachlorides form dense white fumes, while zirconium tetrachloride gives off quantities of hydrogen chloride gas. This made it necessary to exclude as nearly as possible all moisture from the apparatus and to prevent the exposure of the compounds to the air. Another difficulty arose from the

---

[1] Various unpublished theses, this Laboratory.

[2] Bond and Beach, THIS JOURNAL, 48, 348 (1926).

[3] Alexjew, *Wied.* Ann., 28, 395 (1886).

fact that titanium and silicon tetrachlorides are liquids and have considerable vapor pressures at room temperatures, which complicated transference of them to the various parts of the apparatus.

Because zirconium tetrachloride is a solid, and otherwise different from titanium and silicon tetrachlorides, it was necessary to use a different procedure for investigating it. The discussion of the experimental work with zirconium tetrachloride will, then, be taken up in the part devoted to the study of this compound.

Materials and **Procedure.**—The suifur dioxide used was the ordinary laboratory grade contained in small iron cylinders. It was purified by passing it through a train of wash bottles containing concentrated sulfuric acid and through sodium bisulfite solution. The gas was dried by passing it through calcium chloride and phosphorus pentoxide, the system consisting of tubes about one inch in diameter with a total length of thirty feet. The dried gas was condensed in a spiral condenser cooled by an ice–salt mixture and received in a special Dewar flask. This flask was so constructed as to permit withdrawal of the liquid sulfur dioxide directly from the bottom through a small outlet tube. The flask was closed with a rubber stopper. This carried a mercury seal to which the condenser was connected, another mercury seal used for the glass rod which was ground into the outlet at the bottom as a glass stopper and a third tube to permit the sulfur dioxide gas to escape. In charging the specimen tubes with liquid sulfur dioxide the rod was slightly raised and the liquid allowed to flow directly into the tubes. The total weight of mixture used varied from **2.5** to **3** g. for each determination.

Procedure.—The apparatus and the procedure in filling the tubes were the same as those described by Bond and Beach.[2] This consisted in distilling the purified material as needed into a special receiving head and admitting it to the tubes by means of a rotating flask which permitted the transference in a dry atmosphere. The tubes were attached to the outlets of the filling flask by means of cleansed rubber tubing and were connected in such a way that the tetrachloride had no contact with the rubber. After the desired amount of the tetrachloride had been admitted to the tubes, they were cooled in a freezing-bath of ice and salt before detaching them. The cooling lowered the vapor pressure of the tetrachloride and thus reduced the chance for hydrolysis, and also made it possible to seal the tubes below the boiling point of the sulfur dioxide and at atmospheric pressure. This was necessary to prevent drawing moist air into the tube when it was subsequently cooled and opened to admit the liquid sulfur dioxide. Each tube with its contents, together with the part sealed off, was weighed and from this the weight of the tetrachloride was determined. The tube was then cooled to a temperature below the boiling point of sulfur dioxide, opened by breaking off the top of the stem and the liquid sulfur dioxide admitted from the special Dewar flask. It was then sealed off as close to the liquid as possible and the mixture together with all parts of the tube weighed again. This gave the weight of the sulfur dioxide and hence the composition of the mixture.

This procedure in charging the specimen tubes provided for a minimum exposure to the air and the vaporization of the sulfur dioxide prevented to a very large degree the diffusion of water vapor into the tubes while sealing them. However, in case a trace of moisture got into the tube, its presence was shown by the ready formation of a cloudiness in the solution. Any tube showing such a condition was discarded. On account of the low temperature, and also due to the presence of sulfur dioxide gas in the tube, no measurable quantity of the tetrachloride was lost as vapor in that portion of the tube broken off.

Deterinination of Solution Temperatures.—The determination of the temperatures at which the mixtures of the various concentrations became completely miscible offered no particular difficulty for those which had solution points in the region of the binary liquid system. The solubility points in the solid–liquid region were more difficult to obtain on account of the increased viscosity of the liquids at the low temperatures and the slow rate at which the systems approached the saturation equilibrium. For those mixtures having solution temperatures above 0°, the determinations were carried out in a water-bath, the temperature of which was varied by adding small quantities of crushed ice. The temperature could be easily controlled in this manner, and any slight variation in it could be effected at will. For those mixtures having solution points at temperatures below 0° the bath consisted of acetone cooled with solid carbon dioxide and contained in a tall, unsilvered, wide-mouthed Dewar flask. The temperature in this bath could likewise easily be controlled by the rate of adding the carbon dioxide snow. As the presence of water and oil in the carbon dioxide made it undesirable for cooling at temperatures below about −50°, a eutectic mixture of acetone and chloroform **(23%** of chloroform by weight) cooled with liquid air was used instead. This latter bath remained clear and proved to be far more satisfactory for use at the lower temperatures.

In the determination of solution points the temperature was lowered until the solution showed a slight opalescence and then more slowly cooled to the point where it separated into two phases. At this point the cooling of the bath was stopped and the temperature was allowed to rise at the rate of about 1° per minute. The reading taken for the solution point in all cases was that at which the system just became homogeneous, while the temperature of the bath was slowly rising. With such a slow rate of temperature increase, together with rapid agitation of the specimen tubes, this change was sharp and the solution temperature could be read to within 0.1°.

In the region of the solid–liquid system, the solution was rapidly and sufficiently supercooled to produce crystallization whiie it was vigorously agitated. This gave fine crystals of nearly uniform size, which made the subsequent rate of solution quite uniform. The temperature of the bath was allowed to rise very slowly while the solid redissolved. Just before the last fragment of solid disappeared, the change of temperature was reversed by adding a small quantity of the cooling agent and the point at which there was any perceptible increase in the solid phase was noted. The temperature was again allowed to rise at the rate of **1** to **2**° per hour until the last fragment of crystal became almost invisible, and the temperature change was again reversed slowly to the reappearance of crystals. **A** difference between the two temperatures of **1** to **2**" for the first trials could be reduced in most cases to a difference of **0.3** to 0.4" for the last trials. The average from these latter readings was chosen as the solution temperature with a probable error of ±0.2°. In all of this work low-temperature pentane thermometers were used. These were checked against a low-temperature thermometer certified by the Bureau of Standards. In those cases where the stem could not be entirely submerged, a correction was applied and no large error could have resulted from this source.

Titanium Tetrachloride

Purification.—The starting material was an impure grade of titanium tetrachloride, colored red by ferric chloride, and containing vanadium chloride and possibly other chlorides. **A** product having a lemon-yellow color was easily obtained by fractional distillation. The yellow color was due to vanadium chloride, which has a boiling point very close to that of titanium tetrachloride, thus making further purification by"fractionation undesirable on account of the great amount of time involved. V. Merz,[4] and also M. Billy,[5] have used sodium amalgam for purifying it, and O. F. von der Pfordten[6] distilled it from sodium to remove the vanadium chloride.

---

[4] Merz, *J. prakt. Chem.*, [1] *99*, **157** (1866).

[5] Billy, *Ann. chim. phys.*, [9] *16*, 5 **(1921).**

Won der Pfordten, *Ann.*, **234,257** (1886).

In this work a special fractionation apparatus combining the essential features of the apparatus described by Peters and Baker[7] and improved by Loveless[8] was used. The fractionation column was about 30 inches long and surrounded by a silvered jacket which had been evacuated. The impure beginning material was fractionally distilled from this apparatus eight times. This was equivalent to a much larger number of fractionations from the ordinary type of column. It gave a lemon-yellow product which was allowed to stand over mercury for several days and was finally distilled from mercury. The yellow color still persisted and further purification was effected by repeated distillation from metallic sodium. The sodium was carefully freed from films of oil and other carbon compounds and cut into fine shavings. It was very essential to have the sodium as free as possible from these compounds, for whenever such were present it was observed that miniature explosions, producing sparks in the flask, took place when the temperature was raised to the boiling point of the titanium tetrachloride. The liquid was digested with the sodium at an elevated temperature for about one hour before each distillation. The number of such treatments for each portion taken varied somewhat, depending on the surface of the sodium exposed and the time of digestion. In most cases as many as six or eight distillations were sufficient, the last two or three being applied after the liquid had become colorless. This gave a colorless, highly refractive product. It boiled sharply at 136.1° (752 mm. pressure), and its freezing point was −24.4°. Other observers record the following boiling points: 136.0° by Stahler,[9] 136.5° (761 mm.) by Biltz and Meinecke,[10] and 136.0° by Bond and Beach.[2] The melting point recorded by Biltz and Meinecke was −23° and that recorded by Haase was −25°.[11]

Solution Points.—The specimen tubes were filled and the solution temperatures determined as already described. The results of these determinations of the solubility points for titanium tetrachloride in liquid

sulfur dioxide are contained in Table I and shown graphically in the diagram of Fig. 1. The separation of the solution into two liquid phases was sharp and the temperature at which the change took place was easily read. Opalescence near the critical solution point was slight and did not obscure the change at this temperature. In the region of the solid–liquid system the determination of the true solution points was more difficult on account of the slowness with which equilibrium developed. At concentrations below 7% and above 94.5% of titanium tetrachloride a metastable two-phase system was indicated, but it was possible to follow the binary liquid curve in this region only for a very short distance. These metastable points were obtained by slowly and carefully cooling the mixtures. In this way the solution separated into two distinct liquid phases without freezing. In every case the metastable liquid phases disappeared with rise in temperature at the same point at which the solid phase melted when frozen.

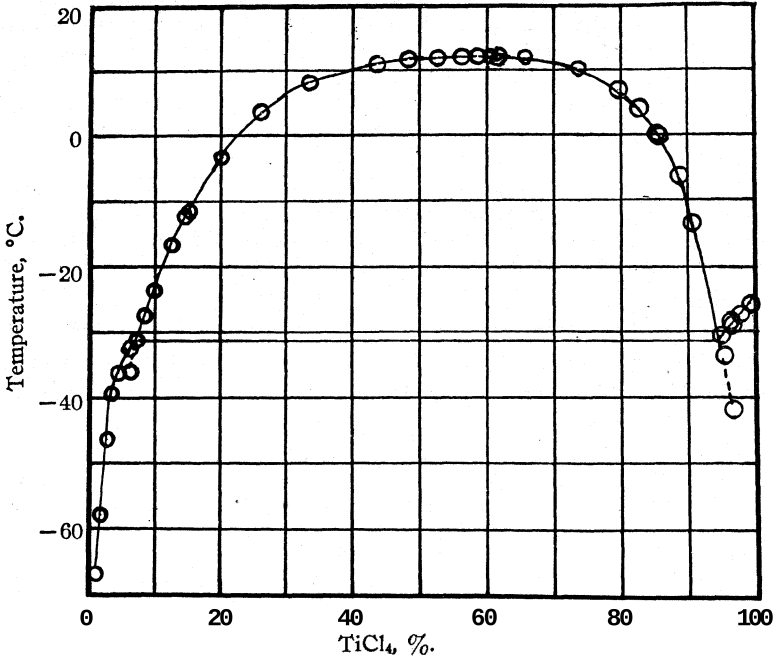

Fig. 1.—Miscibility of titanium tetrachloride with liquid sulfur dioxide.

Silicon Tetrachloride

A refined product which was colorless and appeared to be pure was taken for the starting material. It was allowed to stand over mercury for several days and finally distilled twice from mercury. It was then fractionally distilled four times, using the special fractionation apparatus already mentioned. The separation of the silicon compounds of higher order and boiling point was apparently complete by this process. The product was further distilled twice before using, the first and last portions being rejected each time. This gave a product of highest purity which boiled sharply at 56.8° (751-mm. pressure) and which had a freezing point of −69.7°. Other observers gave the following boiling points: 56.9° (760 mm.) by Becker and Meyer,[12] 56.8° (760 mm.) by Stock, Somiesky and Wintgen.[13] Latimer[14] recorded −70° for the melting point, and Stock, Somiesky, and Wintgen record −68.9°.

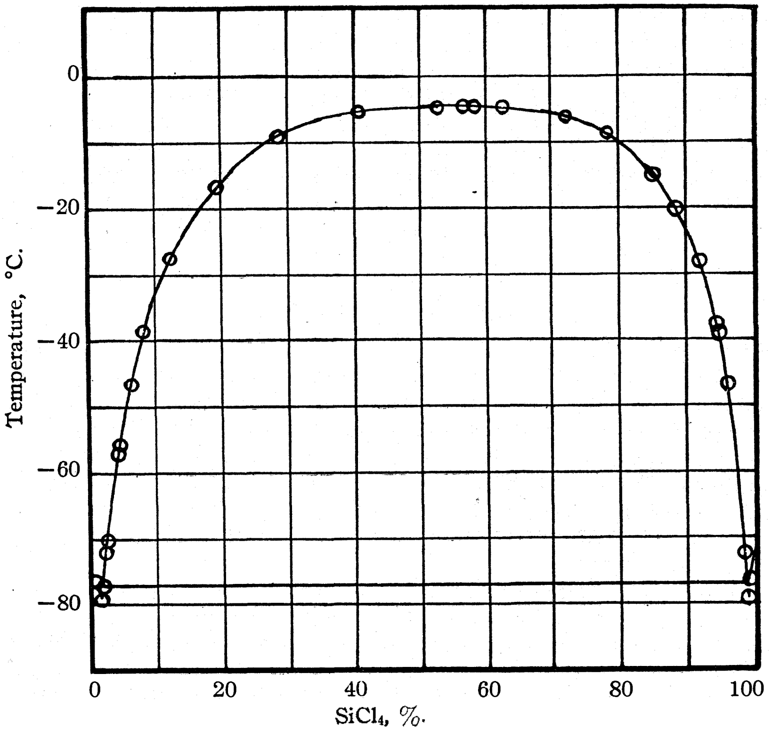

Fig. 2.—Miscibility of silicon tetrachloride with liquid sulfur dioxide.

The solution temperatures were determined in the same general way as for titanium tetrachloride. The results of these determinations are given in Table II and the accompanying diagram, Fig. 2. In the region of the binary liquid system the changes were sharp and without noticeable opalescence. In the region of the solid–liquid system the determinations were more difficult to make. The melting points were not sharp and the

Zirconium Tetrachloride

Purification of Materials.—A quantity of purified zirconium oxychloride was taken as the starting material. It was recrystallized twenty times from hydrochloric acid and fractionally recrystallized six times from distilled water. A solution of this product gave no indication of iron with potassium thiocyanate. To remove silica it was evaporated to dryness on a steam-bath, redissolved and filtered. This was repeated and the product finally recrystallized from hydrochloric acid. This purified product was dried and strongly ignited to drive off excess hydrogen chloride and water. The product after ignition was chiefly the oxide, ZrO_2, which was used as the source material for zirconium tetrachloride.

The carbon tetrachloride was purified by allowing it to stand over calcium chloride and then over solid sodium hydroxide. It was washed with concentrated sulfuric acid and allowed to stand over phosphorus pentoxide, from which it was distilled and fractionated twice before using.

Preparation of Zirconium Tetrachloride.—The method of preparation of zirconium tetrachloride was that used by Venable and Bell.[15] This method consisted in passing a stream of dry chlorine saturated with carbon-tetrachloride vapor over zirconium dioxide heated to about 450°. The process was carried out in an apparatus essentially the same as that used by these workers. The reaction was quantitative and required only a few hours for the preparation of 10 to 15 g. There always appeared in the first product formed a small quantity of a light brown substance, presumably ferric chloride, which could be driven along before the zirconium tetrachloride by carefully controlling the temperature. To free the product from this substance, all carbon tetrachloride vapor was swept out of the apparatus with dry chlorine and the product resublimed back and forth in the apparatus several times. The zirconium tetrachloride crystallized in clear colorless needles some of which were an inch in length. This purified product was distributed among the several small bulbs and after all of the chlorine had been

---

[15] Venable and Bell, THIS JOURNAL, 39, 1598 (1917).

swept out with dry air they were sealed off. The product was analyzed for chlorine volumetrically by titrating the neutral solution with standard silver nitrate, using potassium chromate as the indicator. The results by this method showed a purity of 99.9% of $ZrCl_4$. It was analyzed for its zirconium content, using the method of Lundell and Knowles,[16] which consisted in precipitating the zirconium as the phosphate in a 20% sulfuric acid solution, igniting the precipitate to the pyrophosphate and weighing as such. Results by this method showed the equivalent of 99.8% of $ZrCl_4$.

Preliminary Test for Solubility and for a **Binary** System.—The fact that zirconium tetrachloride has a high affinity for water made it necessary to transfer it to the apparatus in a dry atmosphere. For this purpose a special air-tight transference box was prepared with a glass door in the top and one side consisting of a rubber diaphragm into which rubber gloves were fixed. The rubber diaphragm permitted a fairly free use of the hands in the manipulation. This box could be filled with dry air and all transferences of zirconium tetrachloride were made in it.

A mixture of zirconium tetrachloride and liquid sulfur dioxide was sealed in a small h-shaped glass tube. The saturated solution was decanted into the side arm and sealed off. This mixture was examined at temperatures up to the critical temperature of sulfur dioxide with no indication of a binary system being formed. Evaporation of the sulfur dioxide from the tube left an appreciable residue, which showed zirconium tetrachloride to be slightly soluble in liquid sulfur dioxide.

Determination of $ZrCl_4 \cdot SO_2$.—A boiling effect was observed when the sulfur dioxide and zirconium tetrachloride were mixed, which indicated liberation of heat and the probability of chemical reaction. Further investigation showed that a solvate was formed. To establish its composition, mixtures of zirconium tetrachloride and sulfur dioxide were prepared in h-tubes as before and the decanted solutions sealed off in the side tubes in the usual manner. These tubes were placed in a freezing mixture of ice and salt and a very small opening melted in the top. The open end of the tube was then connected to a T-tube through which a current of dry air was passed. The sulfur dioxide was allowed to evaporate very slowly and at temperatures never greater than $-10°$. The time required for this evaporation was about six hours. In this way the zirconium tetrachloride was allowed to separate out very slowly and any compound formed with the sulfur dioxide would involve all of the tetrachloride. When the sulfur dioxide had evaporated, the tube was alternately evacuated and filled with dry air, disconnected from the T-tube, closed with a rubber cap, wiped dry and immediately weighed It was connected to the T-tube again and immersed in boiling water for a few minutes to drive off the sulfur dioxide of solvation. The tube was allowed to cool with dry air passing over the opening, again evacuated and filled with dry air several times, removed, dried and weighed. The loss in weight represented the weight of sulfur dioxide held by the zirconium tetrachloride. The tube was opened and the residue washed out. The parts of the empty tube were washed, dried and weighed, and from this the weight of the zirconium tetrachloride was obtained. Several analyses were made which showed the residues to be only zirconium tetrachloride. The ratio of the molecular quantities of zirconium tetrachloride and sulfur dioxide calculated from these results corresponded to the formula $ZrCl_4 \cdot SO_2$. The results of these determinations are shown in Table III. This compound crystallized in water-clear plates which appeared to be quite stable at temperatures around 0° and below. It decomposed slowly at room temperature and rapidly at elevated temperatures, reverting to a white powder.

Solubility of Zirconium Tetrachloride.—There being no existing methods for the determination of solubilities in highly volatile solvents which do not require the application of corrections that are more or less uncertain, a direct method was developed

---

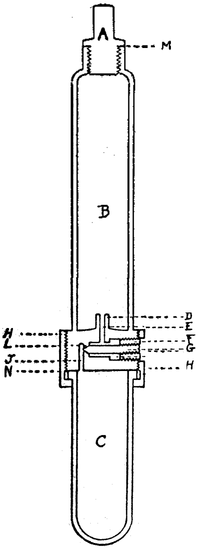
which is an adaptation from one previously used in this Laboratory.[17] A bomb made of monel metal was used (Fig. 3). The walls of this bomb are 1.5 mm. thick, the outside diameter of the main part is 2 cm. and the total length about 18 cm. Its weight assembled is about 210 g. It consists of two separate chambers, B and C, which are held together by the hexagonal nut H when assembled. In the lower part of B there is a needle valve arrangement which consists of the needle G, held in position by the collar F into which it screws. The needle is seated against the shoulder L, as shown, closing the outlet J. From the bottom of chamber B there is a narrow projection D 0.5 cm. long through which is a small opening to the needle-valve compartment. In order to withstand the pressure developed and at the same time to permit the manipulation of the needle, the needle valve was packed by winding rubber threads on the stem of the needle to fit into the space K. These threads when wound on G were held in place by two small washers which are not shown. The rubber was tested for the action of the solvent and of the solution on it by sealing pieces in both the solvent and in the solution, letting stand overnight, opening and examining the rubber for any change in weight or strength. No effect could be detected. Tests made to ascertain the effect of solvent or of solution on the metal of the bomb showed that if moisture was rigorously excluded no action took place.



Pig. 3.

Determination of Solubility.—The needle G was seated by grinding with 600-mesh carborundum against the shoulder L (Fig. 3). Into the opening in D was inserted a small bit of cotton to serve as a filter, and the parts were assembled as shown, using gaskets of lead foil at M and N.

The chambers B and C were washed and thoroughly dried by alternately evacuating and filling with dry air. The needle G was closed tight to shut off chamber C, and a quantity of zirconium tetrachloride transferred to B. The bomb was cooled and the liquid sulfur dioxide admitted in the usual way. The mixture was agitated in a constant temperature bath for twelve to fourteen hours. At the end of this time agitation was stopped and the bomb allowed to stand in a slightly inclined position for about an hour to permit the residue to settle to one side of D. A portion of the saturated solution in B was collected in C by loosening the needle G, and allowing it to filter into the valve chamber and to flow into C. The needle was very slightly loosened at first to prevent supercooling of the solution in the valve chamber, and any zirconium tetrachloride precipitated by the evaporation of the sulfur dioxide was deposited beyond the valve seat and subsequently swept into C by the liquid which followed.

When the sample had been thus collected, the needle was again tightened and the

---

[17] Stowe, Doctor's "Thesis," this Laboratory, 1927.

bomb removed from the bath. In this way a sample of the saturated solution was collected from beneath the surface of the liquid in B. The vapor in C is therefore a part of the sample and no correction for its presence is necessary. Throughout this process the bomb was kept in a stoppered glass jacket tube to protect it from contact with the bath liquid. In the manipulation of the needle valve the bomb was raised from the bath for only a few seconds at a time.'

The excess sulfur dioxide was allowed to vaporize from B, which was then washed out with absolute alcohol and dried with ether. The bomb containing the sample was weighed. The needle G was slightly loosened and the sulfur dioxide in C allowed to vaporize in a desiccator having a current of dry air flowing through it. After the sulfur dioxide had evaporated, the bomb was alternately evacuated and filled with dry air to remove all sulfur dioxide gas from C, and was weighed to ascertain the amount of sulfur dioxide.

The bomb was disconnected and the residue in C washed out and analyzed for zirconium according to the method of Lundell and Knowles[16] already mentioned. From the previous weights and the result of the analysis of the residue, the composition of the solution was calculated. The solubility was found to be a straight-line function of the temperature; the results of determinations from 0 to 20° are given in Table IV.

Discussion

The miscibility of liquids is closely connected with the polarity of their molecules. The dielectric constant gives direct evidence of polarity inasmuch as it indicates the intensity of the electrical moment in the molecule due to electron displacement. The value of this constant for titanium tetrachloride is 2.73,[18] that for silicon tetrachloride is 2.4,[19] and that for sulfur dioxide 16.2.[20] These values show titanium and silicon tetrachlorides to be alike in polarity. The greater value for sulfur dioxide could account for the partial miscibility of the tetrachlorides with it at low temperatures. Comparing the polarities of these substances on the basis of the Ramsey and Shields constant, the value of which for silicon tetrachloride is 2.20, and that given by Stowe[21] for sulfur dioxide is 2.134, we find like polarities for sulfur dioxide and silicon tetrachloride. Sufficient data were not available for calculating this value for titanium tetrachloride. To compare the polarities of these compounds further, the entropy of vaporization was calculated by applying Hildebrand's modification of Trouton's rule[22] to the value of vapor pressure at various temperatures

[18] Matthews, J. *Phys. Chem.*, **9, 641 (1905).**

[22] Hidebrand, *ibid.*, **37,970 (1915).**

as given in the "International Critical Tables" for sulfur dioxide, and to those given by Wintgen[23] for silicon tetrachloride. This gave for sulfur dioxide the value 25.6, and for silicon tetrachloride **27.9.** Hildebrand has shown the value of this constant to be **27.4** for non-polar substances in general. The values for these compounds are in sufficient agreement with that for non-polar substances in general to indicate again their non-polarity.

Hildebrand[24] has shown that the relative internal pressures of various solvents may be estimated from the solubility data of a common solute by plotting the common logarithm of the mole fraction of the solute against the reciprocal of the absolute temperature and comparing these with a like curve for the ideal solution of the solute. The displacement of these curves from that of the ideal is a measure of their internal pressure differences, and from such a plot it is possible to arrange the solvents in a relative internal pressure series. A plot of the solubilities of liquid sulfur dioxide as the solute in the various tetrahalides as solvents was made in order to compare the relative internal pressure of these compounds. The ideal solubility curve for liquid sulfur dioxide was constructed on the basis of its heat of vaporization and boiling point. The boiling point was taken as −10° and the value of A H was that given in the Landolt and Börnstein "Tabellen" as **6157** cal. per mole. These curves are shown in Fig. 4, where the curves for carbon and stannic tetrachlorides and stannic bromide are plotted for comparison from the data given by Bond and Beach.[2] Now Stowe[21] has calculated the internal pressure of sulfur dioxide from the relation $\gamma/V^{1/3}$ to be **6.33** at 20°, where γ is the surface tension

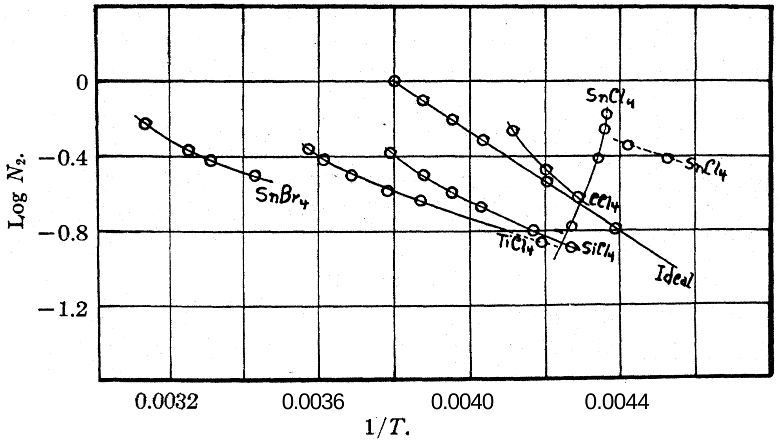

Fig. 4.—Solubility relations of sulfur dioxide.

[23] Wintgen, *Ber.*, 52, 724 (1919).

[24] Hildebrand, ref. 19, p. 113.

and V the molal volume, and has placed liquid sulfur dioxide between chloroform and benzene in the Hildebrand solubility series.[25] Mortimer[26] pointed out that the ratio of the slope of the experimental curve to that of the ideal for any solute is a measure of the relative internal pressure of the solute and solvent. Applying this method to the curves for titanium and silicon tetrachlorides as solvents we find values which indicate titanium tetrachloride not only to belong above sulfur dioxide but also above silicon tetrachloride in the Hildebrand series. In view of this relation we would expect the miscibility of sulfur dioxide to be less in titanium tetrachloride than in silicon tetrachloride for a given temperature. The experimental results are in accord with this view.

In general this investigation has shown that the systems formed by liquid sulfur dioxide with titanium and silicon tetrachlorides accord with the principles of the various factors usually considered in the problem of solubility. The results of these measurements agree in a satisfactory way with the physical properties of the compounds, such as melting points, boiling points and dielectric constants. The critical mixing temperatures are in harmony with the various melting points and the relative positions of the elements in the periodic arrangement.

The solubility of zirconium tetrachloride in liquid sulfur dioxide was examined in the region of temperature where the compound $ZrCl_4 \cdot SO_2$ is fairly stable. The noticeable heat effect, also the formation of a solvate, when zirconium tetrachloride is mixed with sulfur dioxide would indicate a large negative deviation from Raoult's law. No data are available from which its polarity and internal pressure may be measured according to the criteria usually applied. On the basis of theory we would .expect it to have an internal pressure close to that of liquid sulfur dioxide and would also expect that its apparent higher polarity would be largely induced as a result of polar bonds within the molecule. This is in accord with the general increase of basic properties of the elements from the top toward the bottom of the periodic groups. In general the solubility relations of zirconium tetrachloride in liquid sulfur dioxide are in accord with the principles governing solubility where there is a large difference of polarity.

Summary

1. The solubility relations of titanium and silicon tetrachlorides with liquid sulfur dioxide have been determined over the entire range of compositions.

2. The solubility relations are in accord with theory as to polarity, internal pressure, melting points, etc.

[25] Hildebrand, ref. 19, p. 111.

[26] Mortimer, THIS JOURNAL, 45, 633 (1923).

3. A direct method for the determination of solubilities in highly volatile solvents has been utilized.

4. The solubility of zirconium tetrachloride in liquid-sulfur dioxide from 0 to 20° has been determined and the solvate $ZrCl_4 \cdot SO_2$ has been established.

THE REACTIONS OF ETHYLENE, HYDROGEN AND THE SATURATED HYDROCARBONS UNDER THE INFLUENCE OF EXCITED MERCURY[1]

BY HUGH S. TAYLOR AND DOUGLAS G. HILL[2]

RECEIVED MAY 4, 1929 PUBLISHED OCTOBER 5, 1929

The photosensitized combination of hydrogen and ethylene has been the subject of a number of investigations.[3] The results have been in such disagreement that it seemed worth while to reopen the subject in the hope of discovering the mechanism of what would *a priori* be considered one of the simplest of hydrocarbon reactions. This hoped-for simplicity has not been found, and no final statement as to mechanism may be ventured, but it is believed that the facts to be presented afford an empirical explanation of the variations previously found. It may also be possible, we believe, to correlate them with experiments in which the same gases, although activated by other means, react to give very similar products. We may cite, for example, the reactions of ethylene[4] in the presence of hydrogen under the influence of alpha particles. Correlation should alsa be possible with other reactions due to hydrogen atoms, which Franck and Cario[5] have shown are produced under the experimental conditions employed.

Experimental Details

Apparatus.—The apparatus used in these studies consisted of a quartz reaction vessel which surrounded the arc concentrically, thus securing as great an intensity of illumination as possible, together with a constant-volume manometer to follow the pressure changes. A gas buret and a storage reservoir were also attached through

---

a three-way stopcock, and connection to the pump and to the gas analysis apparatus was made through a stopcock at the other end of the reaction vessel. Temperature control was provided by a copper water-bath in which the reaction vessel was immersed and which could be cooled by a stream of water previously brought to the desired temperature, or heated by a burner placed beneath it. A few drops of mercury were always present in the vessel, as well as in the storage reservoir, so that the gas might be saturated with mercury vapor at the temperature of the experiment.

The source of illumination was a mercury arc of the type described by Taylor,[6] constructed of pyrex glass, with a quartz section where it passed through the vessel to permit emission of the desired ultraviolet light. The base of the arc was cooled in a water-bath to 30°. This cooling is essential in order to keep the excess mercury vapor in the arc itself from absorbing the **2536.7** Å. light before it reaches the reaction vessel. An arc of this type also emits light of wave length 1869 Å., but the transmission of the quartz for this wave length is quite poor and but little could have reached the reaction system. This is indicated too by the fact that the rates were only slightly different at the end of many hundred hours of running the arc, when the quartz was quite brown. It is known that to secure transmission of 1863 Å. the quartz must be new and unusually clear. The arc was connected through a large-bore stopcock at the top to a mercury vapor pump which was kept in operation during almost all runs. It was not practicable to exhaust and seal off the arc, though this would have provided more constant conditions of intensity.

The current for the arc was supplied by a D. C. generator giving **125** volts, and resistances so adjusted that it burned at 8 amperes. The potential drop across the arc itself was about 50 volts, but due to large fluctuations in the local line voltage supplying the motor-generator, the watt load of the lamp could not be kept constant. On this account, only indirect comparison of the rates found in different experiments is possible.

The reaction vessel was exhausted by a Cenco Hyvac Oil pump capable of maintaining a vacuum of 0.001 mm. of mercury. This pressure was not attained in practice, for liquid polymers accumulated in the vessel which must have had a vapor pressure much higher than the lower limit of the pump. These would be without effect on the reaction. Air, however, was not present in the system, for unpublished experiments of Taylor and Marshall, and of Mr. A. A. Vernon in this Laboratory have shown that small quantities of oxygen added to such a reacting system cause a very large increase in rate until the oxygen is used up, when the rate drops to normal. Such an irregularity was not observed at any time in these experiments.

Preparation of Gases.—Hydrogen was taken from a cylinder, purified from oxygen by passage over hot platinized asbestos and dried by condensing the water in a trap cooled with carbon dioxide snow.

Ethylene was taken from a cylinder and dried in the same way. Analysis of the gas showed it to be better than 99% pure, with the impurity apparently higher unsaturates, which would be largely removed by the freezing mixture.

Ethane was made by catalytic combination of hydrogen and ethylene, purified as above, over nickel at room temperature. This was always accomplished in the presence of excess hydrogen, the amount being subsequently determined by analysis of the resulting mixture. For pure ethane, the hydrogen was pumped off from solid ethane at liquid air temperature, the ethane then being distilled in *vacuo* until no further gas was evolved. In most cases more hydrogen was added to the ethane as prepared to make the desired mixture for experiment.

Propane and butane were taken from cylinders and found to be upward of 98% pure. Since the impurities were other saturated hydrocarbons, they were **used** as they

---

[6] Taylor, THIS JOURNAL, 48,2840 (1926).

came from the cylinders, and the whole was considered as a hydrocarbon of the average composition found by analysis.

Gas Analysis.—The gases were analyzed in a Williams gas analysis apparatus over water. Acetylene was absorbed in ammoniacal silver nitrate, saturated with ammonium nitrate to diminish the ammonia vapor pressure. Ethylene was estimated with bromine water, after which the excess bromine vapor was removed by passing the gas through a pipet which contained a strong solution of sodium thiosulfate dissolved in 33% potassium hydroxide solution. Hydrogen was determined by combustion over copper oxide at 300°, and the saturated hydrocarbons were identified by repeating the combustion on the residual gas at 500°, absorbing the carbon dioxide in potassium hydroxide solution. All the possible constituents likely to be present could be identified, though the hydrocarbons could only be given an average composition.

Experimental Results

General Considerations.—It has been observed by all the investigators who have studied the photosensitized reaction of hydrogen and ethylene that the pressure drops on illumination of mixtures containing excess hydrogen until that pressure is reached, which would be calculated, assuming that ethane was the sole product of reaction. Bates and Taylor seem to have been the first to observe that mixtures in which ethylene was the constituent present in excess must react in some other way, for the pressure drop did not stop at the theoretical point but continued at approximately the same rate. They did not follow the reaction to completion, or they would have found that the pressure change finally ceased at the pressure of the original hydrogen in this case also. This has proved to be a quite general phenomenon. In all of the mixtures of the two gases which we have used the pressure has always fallen on illumination until it reached approximately that of the hydrogen originally present, and has then remained practically constant. This change in rate is extremely sharp, dropping from 5 or 10 mm. per minute to one or two mm. per hour.

The pressure measurements alone, however, really afford no certain indication as to what the hydrocarbon may be. In a mixture of equal parts of the two gases at the start, combination to form any saturated gaseous hydrocarbon would, after the ethylene had all reacted, leave the final pressure just one-half of the initial.

Other considerations also showed that there must be other reactions taking place than the formation of ethane. For one thing, ethylene alone reacts with excited mercury, -giving first an increase and subsequently a decrease in pressure, which continues at a constant rate, but so slowly that it has never been followed to the end-point. Even with the very high light intensities used in these experiments, it would have required a number of days of illumination to bring the reaction to an end. There must therefore be at least two distinct reactions.

That there were still other possibilities was shown by the appearance of a liquid oily substance in the reaction vessel. This had been noted by previous investigators in the case in which the initial ethylene concentration was high, but our investigations show that it is formed in all cases, though most rapidly under the conditions mentioned.

Experimental Procedure I

A. The Temperature Coefficient.—In order to control the reaction as regards temperature, it was arranged to use a very rapid stream of water of the desired temperature, which should flow into the water-bath between the reaction vessel and the arc and be removed at the outside edge of the jacket. Even with as fast a stream as possible, the heat from the arc raised the temperature several degrees shortly after starting. It was necessary then to allow the arc to run with the reaction vessel evacuated until temperature equilibrium was reached, and then admit the gas as rapidly as possible from the gas buret. The pressure could be read one-half minute after the admission, and extrapolated back to the true initial pressure with sufficient accuracy. The water stream was unnecessary with runs at a temperature of 100°, where a burner beneath the vessel kept the water boiling or nearly so.

As an indication of the presence of a temperature coefficient, two experiments are given in which the temperature was varied during the course of the run, so that no other variables were introduced.

TABLE I

RESULTS OF EXPERIMENTS

	I C_2H_4, 203 mm.; H_2, 203 mm.		II C_2H_4, 395 mm.; H_2, 0 mm.

$-\Delta p/\Delta T$, mm./min.	1.5	10.8	0.12	0.15	0.40	0.15

Discussion.—The absolute magnitudes of these temperature coefficients are not of sufficient accuracy to be of use in theoretical calculations, which will be based on later measurements, but the actuality of the temperature sensitivity is evident, and also the fact that the reaction of ethylene alone has but a very small dependence on temperature. We may therefore say that some reaction involving hydrogen is largely dependent on temperature, or is a thermal reaction, while the rate-determining process with ethylene alone is a purely photochemical one and depends on the quantity of light absorbed. This fact must be deducible from whatever mechanism is proposed.

B. Experiments with Partial Gas Analysis.—The analysis system used for the following experiments permitted the determination of the composition of the saturated hydrocarbons by combustion over copper oxide. The temperature of burning was slightly under 500°, at which point all hydrocarbons except methane burn readily. By determining the carbon dioxide formed by the combustion, the complexity of the hydrocarbons was measured and the unburned residue was considered to be methane. The results are given in Table II. The figures give pressure of the gas in mm. of mercury. Time is in minutes.

Discussion.—It will be observed that when ethylene alone is allowed to react with excited mercury, acetylene is formed. Bates and Taylor showed that both acetylene and hydrogen could be identified among the products of decomposition in the absence of initial hydrogen. Von Wartenburg and Schulze have also found acetylene but under quite different conditions, and their results will be considered later. In these experiments definite indication of acetylene was not found except in the case of ethylene alone, and the subsequent experiments show that it should only appear in mixtures initially richer in ethylene than those of Table II.

The last two columns give the amounts of carbon and hydrogen, calculated as C_2 and H_2 which have disappeared from the gas phase. This loss should be the liquid which is formed, and it will be noted that in all cases twice as much hydrogen as carbon has gone to this product.

C. The Liquid Polymer.—The liquid which is deposited in the reaction vessel during the runs is a thick, viscous oil, and difficult to remove from the vessel in quantities large enough to work with. Since the quantity formed from one hundred cubic centimeters of ethylene, which was about the average amount present during an experiment, would be very small, the oil was allowed to accumulate in a small trap over a large number of runs, and drained off by breaking a capillary *tip* when desired. By this means, of course, only the least volatile fraction was removed, for the components of low boiling point were pumped off in the course of evacuation.

Lind[7] has obtained liquid and in some cases solid substances from the

[7] Lind, Bardwell and Perry, THIS JOURNAL, **48,** 1556 (1926); Lind and Bardwell, *ibid.,* **48,** 2335 (1926); Lind and Glockler, Trans. Am. *Electrochem. Soc.,* 52, (preprint), No. 6, September, 1927.

bombardment of ethylene and of various saturated hydrocarbons by alpha particles and has examined in detail the properties of such a liquid when produced by subjecting ethane to the silent electrical discharge. It is of interest that the polymer we have obtained by yet a third method from ethylene, and as will be shown presently from saturated hydrocarbons, agrees so closely in its properties with the substance described by Lind and Glockler. They have shown that the oil is of constant composition, close to $(CH_2)_x$ but of variable molecular weight. We have reason to believe that the oil from the photosensitized reaction is similarly constituted, since its physical properties are quite variable, but its composition as calculated from a carbon–hydrogen balance sheet is the same.

The substance, then, is a viscous, colorless, or slightly yellow oil, with an odor very reminiscent of a terpene. The mean molecular weight of a sample determined by the freezing-point depression in benzene solution was 230.

Finally, as a confirmation of the calculated composition, a sample was analyzed by combustion; 0.0308 g. of oil gave on burning 0.0393 g. of water and 0.0929 g. of carbon dioxide. A few droplets of mercury unavoidably present in the oil are responsible for the failure of the weights to correspond exactly with that of the oil. However, the calculated composition from these figures is $(C_1H_{2.07})$, which is considered satisfactory confirmation of the supposed formula.

D. The Reaction Rate.—The rate of the pressure drop seemed *so* great, as compared with all previous photochemical reactions, that experiments were conducted to compare it with a better known reaction. Taylor and Marshall[3b] showed that the pressure decrease was more rapid than that in the hydrogen-oxygen combination. Marshall[8] has subsequently investigated the latter reaction in more detail, and finds it a chain reaction, in which at least six molecules must react for each quantum of **2536.7 Å.** light absorbed. Table III gives a comparison of several experiments in the first three of which the hydrogen pressure was the same, and the other gas was respectively excess ethylene, an equivalent amount of oxygen, namely, half as much as the hydrogen, and, third, one with this same amount of ethylene. The fourth experiment contains different amounts of the gases, but in the same proportions as the first, and serves to show that the rate is fairly reproducible. All of these experiments were performed on the same day and with as nearly identical conditions as possible.

The discussion of these results will be reserved until later, for they will have more bearing on the mechanism ultimately to be proposed than in the present place.

E. Secondary Reactions.—With the same procedure as before, the possibility of secondary reactions until now unrecognized was investigated.

Several experiments were made in which a sample of the gases after illumination was removed and analyzed, and the remainder, of known composition, was re-illuminated for a further period. Analysis at the end of this time would show the later course of the reaction after the main pressure drop. The results of three typical experiments are presented in Table IV.

Discussion.—It is evident that very considerable reaction has occurred during the second period, for the hydrocarbons have changed both in amount and composition, while more polymer has been deposited. The remarkable fact is that the total pressure in the system has remained unchanged, or practically so, during the second stage.

Experimental Procedure II

It was necessary, therefore, to investigate these secondary reactions in a more complete manner. A number of experiments were performed on various hydrocarbons with and without hydrogen, under the same conditions of temperature and illumination as with ethylene and hydrogen.

In these experiments, the method of analysis was modified to avoid the error which was likely to result from an assumption that methane could be quantitatively separated from the other saturated gases by preferential combustion. There was no assurance that the separation was complete, and the wide variations in the relative proportions of methane and other hydrocarbons shown in Table III were an indication that methane was being burned to an undetermined extent along with the other gases.

Therefore, from this point onward in the research, the copper oxide tube was kept at a dull red heat when burning hydrocarbons, and their composition was found as an average of the entire gas. This procedure also eliminated the errors which may so readily appear in an analysis when a substance is determined solely by difference. The results of a number of runs on the hydrocarbons are given in Table V.

Discussion.—The general trend is clear, though the constancy of the results is not very satisfactory. **All** the saturated hydrocarbons with the exception of methane are decomposed either by excited mercury or by hydrogen atoms, giving as final products methane, polymer and hydrogen. The small amount of reaction which the last experiment on methane and hydrogen would seem to show is ascribed to reaction of the polymer in the vessel with the hydrogen atoms. It seems quite likely that such hydrogen atoms as strike this liquid cause reaction and vaporization of small quantities of hydrocarbon. Work by Tolloczko[9] and by Bonhoeffer[10] confirms the hypothesis that methane is stable to excited mercury and to hydrogen atoms, respectively. The reason for this is not known, for from the linkage energies as commonly given, methane should react as readily as the others.

In general, then, the higher hydrocarbons react more readily than the lower. Hydrogen seems to have an inhibiting action when it is present in large quantities. Any mechanism proposed will have to take account of this fact.

Experimental Procedure 111.—In order to find which of the various reactions have ethylene as a basic material, and which depend on saturated hydrocarbons, analyses were made at different times during the reaction of hydrogen and ethylene. Mixtures of the same composition were illuminated until a predetermined pressure was reached, and then analyzed. A sufficient number of repetitions of this process gave the course of reaction until all ethylene had disappeared. A few experiments in which longer illumination was used gave the course of reaction after pressure changes had ceased. Due to the variations in intensity already mentioned, the stage of reaction could not be estimated from the time. Therefore, arbitrarily, the percentage of ethylene used was taken as a standard of reference, and the percentage figures in the table apply to that. In this way comparisons between various gas mixtures were possible. These experiments are summarized in Table VI.

Discussion.—It appears at once that the primary reaction of ethylene and hydrogen is the formation of saturated hydrocarbons, but not, in most circumstances, ethane. The composition of this saturated product depends on the concentration of the original mixture and is independent of the pressures used in our experiments. It is also practically independent of temperature. It may be that there is a temperature dependence which requires greater accuracy of analysis than was possible. Such a relation might be expected on the basis of the dependence of the reaction rate on temperature, which is very clearly shown.

The polymerization is a secondary reaction, and all, or at least practically all, polymer must go through the intermediate stage of saturated hydrocarbon. This is subsequently decomposed and deposits polymer, changing in composition at the same time, until nothing but methane and hydrogen is left in the gas phase.

The rate of reaction depends both on temperature and on composition of the gas. The temperature coefficient is very much greater for an initial mixture richer in hydrogen, so that this temperature dependence involves some reaction with hydrogen. All these restrictions must be satisfied by the proposed mechanism.

Mechanism of the Reactions

Taylor and Bates[3e] have proposed a mechanism for the reaction between ethylene and excited mercury which seems to be in accord with the results presented here. Their scheme of reaction between ethylene and hydrogen atoms, which reaction seems to be the more important in many cases, requires revision. The actual processes must be quite complex, so that a qualitative explanation is all that may be given. The following, then, is offered as one, possibly of many conceivable mechanisms, which will explain the observations. The reactions will be tabulated here and discussed in detail subsequently.

$$\mathrm{C_2H_4 + Hg' \longrightarrow C_2H_2 + H_2 + Hg} \qquad (1)$$

$$\mathrm{C_2H_2 + Hg' \longrightarrow Cuprene}$$

$$\mathrm{C_2H_2 + H \longrightarrow Liquid\ polymer}$$

$$\mathrm{H_2 + Hg' \longrightarrow 2H + Hg + 12{,}000\ cal.} \qquad (2)$$

$$\mathrm{H + C_2H_4 + Hz \longrightarrow C_2H_6 + H + 5000\ cal.} \qquad (3a)$$

$$\mathrm{H + C_2H_4 + C_2H_4 \longrightarrow C_2H_5 + C_2H_4 + 15{,}000\ cal.} \qquad (3b)$$

$$\mathrm{C_2H_5 + C_2H_4 + Hz \longrightarrow C_4H_{10} + H + 5000\ cal.} \qquad (4a)$$

$$\mathrm{C_2H_5 + C_2H_4 + C_2H_4 \longrightarrow C_4H_9 + C_2H_4 + 15{,}000\ cal.} \qquad (4b)$$

$$\mathrm{C_2H_5 + C_4H_9 \longrightarrow C_4H_8 + C_2H_6 + 55{,}000\ cal.} \qquad (5)$$

$$\mathrm{C_2H_6 + H \longrightarrow CH3 + CH_4 + 20{,}000\ cal.} \qquad (6)$$

$$\mathrm{C_4H_{10} + H \longrightarrow C_3H_7 + CH4 + 20{,}000\ cal.}$$

$$\mathrm{C_4H_{10} + Hg' \longrightarrow C_3H_7 + CH3 + Hg + 52{,}000\ cal.} \qquad (7)$$

$$\mathrm{C_2H_5 + C_2H_6 \longrightarrow C_4H_9 + H_2 - 10{,}000\ cal.} \qquad (8)$$

$$\mathrm{C_2H_5 + Hz \longrightarrow C_2H_6 + H - 10{,}000\ cal.} \qquad (9)$$

The reactions under (1) have been discussed by Taylor and Bates[3"] and Reaction 2 has been well established by the work of Franck and Cario,[5] so that neither need be treated here.

It is to reactions of the types indicated in (3) that we ascribe the principal course of reaction. Modern ideas, arising originally from quantum considerations, have shown that direct addition of two molecules to form one in the gas phase is an extremely improbable occurrence. For that reason we cannot assume that a hydrogen atom can add directly to an ethylene molecule to form a free ethyl radical. Such an addition can take place, however, if a third body is present at the collision, or, which amounts to the same thing, if a third molecule collides with the reactants during the short time during which an unstable pseudo-molecule might exist. If the third body is an ethylene molecule, as in (3b), it seems unlikely that anything other than the stabilization of a free ethyl radical would result. If the third body is hydrogen, however, a reaction to form ethane with liberation of a hydrogen atom is possible. This may, of course, take place in two steps, an ethyl radical being formed first, which subsequently reacts with another hydrogen as in Reaction 9, but the great rapidity of the reaction in the case where ethane is the sole product makes a mechanism of as few steps as possible the more preferable. It will be noted that (3a) has the character of a chain reaction, in that the hydrogen atom is capable of forming a large number of ethane molecules. The comparative rate measurements in Table III indicate that a chain is formed, since the rate is much faster than that of an established chain reaction.

Presumably the temperature coefficient is also to be ascribed to Reaction 3a, since the ethane is formed by this process. The results show that the temperature coefficient is greatest in the gas mixture which is transformed almost quantitatively to ethane. By inserting the temperature coefficient in this case in the Arrhenius equation, we can calculate that it corresponds to an activation energy of about 10,000 calories. In spite of this agreement, it is probably unjustifiable at the present time to connect this with the endothermic Reaction 9 and attempt to maintain the multi-stage reaction so indicated.

The reactions included in (4) are assumed to be typical of the early stages of the reaction, where ethylene is present in considerable quantities. It is possible to invent reactions which are possible energetically, almost at will. All that is necessary is that higher saturated hydrocarbons and higher radicals should result, as in (4a and 4b).

Reaction 5 is of a different type, and is the method by which the unsaturated polymer must be formed. Just what hydrocarbons are the products is unknown, and it is not improbable that Reaction 5 should form amylene and methane instead of butylene and ethane. Work of Mr. W. H. Jones in this Laboratory (to be published shortly) confirms the mechanism advanced here in so far that free radicals react to form unsaturated and saturated hydrocarbons, and that in the presence of hydrogen and ethylene, products similar to those of Reaction 4 occur.

The saturated hydrocarbons which are formed by a process such as (4a) or (5) have been shown in Table V to be decomposed both by hydrogen atoms and by excited mercury atoms. Since radicals must be formed by such reactions, we have postulated in Reactions 6 and 7 that methane or methyl and a residue are formed at once. The fact that methane is not attacked under the conditions of the reaction, but, on the contrary, is formed as a stable product in increasing quantities as exposure is continued, speaks for this hypothesis. These radicals will, as a rule, no longer react as in (4), owing to the low concentration of ethylene at the stage in the reaction where the saturated hydrocarbons are largely attacked. They will be limited primarily to Reaction 5, forming low concentrations of unsaturates which will be rapidly built up to high molecular weights as in (4b), and finally condense as liquid polymer by a repetition of (5). One would predict from this scheme that polymer, which implies high unsaturates, would be formed more rapidly after the primary ethylene was used up, for in this case the sole reaction of the hydrogen or the excited mercury is the production of the necessary radicals. This hypothesis is wholly confirmed, for Table VI shows that polymer appears late in the reaction in those cases in which reactions of the type of (3a) would predominate.

Reactions 8 and 9 are endothermic, but of small enough heat value so that their occurrence is of moderate frequency. In fact it is not unreasonable to expect that reactions of this type which can be calculated to occur on about one collision in a million will be quite appreciable, since the other possibility involves two radicals, which must be of very small concentration. Granted these reactions, then, we can explain the retarding effect on the decomposition of saturated hydrocarbons which large amounts of hydrogen appear to have.

Discussion of Other Results

The mechanism which is proposed can be shown to accord with the experimental results of other investigators.

Olson and Meyers[3] analyzed the gases resulting from the photosensitized reaction of hydrogen and ethylene by positive ray methods and found methane, propane and butane in the gas phase as well as the ethane that was expected. No mention is made of polymer formation in connection with these analyses, though they observed its formation in their earlier work.

We are not able to understand, however, the statement of these authors that ethane does not react when bombarded by excited mercury atoms. That there is no material pressure change is in accord with our findings, but the positive ray analysis should have shown a number of other hydrocarbons present and also hydrogen. This latter might have escaped notice on account of its small mass. The work of Tolloczko[9] confirms that reported here in that ethane is and methane is not attacked by excited mercury.

Bonhoeffer and Harteck[10] have recently published a paper in which they present spectroscopic evidence to show that ethylene, ethane and other hydrocarbons, except methane, are attacked by hydrogen atoms and stripped of their own hydrogen until very simple residues remain. They pulled atomic hydrogen from a discharge tube into the gas, and observed in the resulting luminescence the bands which are assigned to the C–C and the C–H radicals. We may suggest that the fact of spectral emission does not require the presence of more than a very minute quantity of the excited substance. In their experiments only slight quantities could be present, for it requires a number of collisions with hydrogen atoms to produce the radicals under any mechanism, and the nature of the method requires low pressures, where such multiple collisions will be rare.

Their results are explicable under our mechanism. It should be impossible to split an ethylene molecule into two CH_2 radicals on collision with a hydrogen atom. Fracturing a double bond demands about 125,000 calories, which the hydrogen atom cannot supply. If the primary process is that postulated here, the reaction would involve primary formation of ethane, and decomposition of that, which according to our mechanism would give both methyl and ethyl radicals. These may then lose hydrogen further, and will do so the more readily under their conditions, since the concentration of hydrogen atoms is so much greater.

Von Wartenburg and Schulze[11] have analyzed the products of reaction conducted by Bonhoeffer and Harteck's method, and find results quite compatible with our own. The saturated hydrocarbon is practically pure ethane, as it should be with the large excess of hydrogen present. In the decomposition of ethane they find but slight change in the gas. It would be but slight under their conditions and would probably have escaped notice, for the analysis depended on freezing the effluent gases. Methane and hydrogen would have passed through the liquid-air trap even if formed.

Conclusion

1. The reaction between hydrogen and ethylene under the influence of excited mercury atoms has been investigated with varying conditions of pressure, concentration and temperature. The concentration is the only factor which has any effect on the course of the reaction.

2. The reaction proceeds the more quantitatively to form saturated hydrocarbon the greater is the concentration of hydrogen. The particular hydrocarbon formed is also dependent on the composition of the original mixture illuminated. High hydrogen concentration favors mainly ethane formation.

3. These saturated hydrocarbons are subsequently decomposed both by excited mercury atoms and by atomic hydrogen, and yield methane as the stable product in the gas phase. At the same time a liquid polymer of composition C_xH_{2x} is deposited on the walls. Methane is unattacked by either excited mercury or by atomic hydrogen.

REDUCTION REACTIONS WITH CALCIUM HYDRIDE. I. RAPID DETERMINATION OF SULFUR IN INSOLUBLE SULFATES[1]

BY WILLIAM E. CALDWELL WITH FRANCIS C. KRAUSKOPF

RECEIVED MAY 6, 1929 PUBLISHED OCTOBER 5, 1929

Almost all quantitative methods of determining sulfur in either organic or inorganic matter have as their method of procedure the oxidation of the sulfur to sulfate and subsequent precipitation with barium chloride. With reductive reactions of calcium carbide and calcium hydride in mind it was thought of interest to see whether the sulfur in various compounds, both organic and inorganic, could be quantitatively converted to calcium sulfide by ignition with these substances. If the sulfur were quantitatively changed to calcium sulfide, it could be estimated by acidifying the soluble sulfide solution, followed by iodimetric titration.

The hardest test to which this reasoning could be put was to attempt quantitative reduction of sulfates to sulfides. The amount of soluble sulfide formed was then to be determined with standard iodine solution. The present paper will report results of such experiments.

Sulfur in a steel has long been determined by heating a sample of steel filings with hydrochloric acid in a closed system, dissolving the evolved hydrogen sulfide from the sulfide in the steel in either ammoniacal cadmium chloride or caustic soda solution. The absorbing solution is then diluted with water, acidified with hydrochloric acid and titrated with iodine, using starch as indicator. Soluble sulfides such as calcium sulfide and sodium sulfide may also be determined by iodine titration.

A few investigators have studied reductions of sulfur compounds to sulfides in a quantitative way. Luigi Losana[2] has attempted to reduce sulfur to sulfide by ignition with a mixture of sodium bicarbonate and iron powder. The ignited mass was placed in an evolution flask and treated with acid much as in the determination of sulfur in steel. The method is said to be of general application for inorganic sulfur compounds.

Other metals and mixtures of metals and salts have been tried in effecting conversion of oxy-compounds of sulfur to sulfides. H. Bahr and W. van

der Heide[3] used a mixture of barium peroxide and powdered aluminum. B. N. Tiutiunnikov[4] mixed in a heavy infusible glass tube magnesium powder, strips of magnesium ribbon and a sulfur containing substance. Some unpublished work involving sodium fusions with sulfur compounds has been carried on by a colleague.

Experimental

Sulfate Reductions with Calcium Carbide.—Calcium carbide is a more easily obtained and a cheaper compound than calcium hydride. Calcium carbide decomposes upon being heated, yielding metallic calcium and carbon, both in themselves reductive. It was desired to see how complete a reduction of sulfate could be had with powdered carbide. Ebler and co-workers[5] used mixtures of calcium hydride and calcium carbide in partially reducing sulfates in recovering radium from a sulfate mixture; 60–65% reduction is reported on spontaneous fusion.

Commercial calcium carbide is found to contain considerable sulfur, probably due to gypsum occurring with the carbonate from which the carbide is made. A purer, specially prepared carbide was obtained which analyzed 0.034% sulfur. Thus a weighed amount of carbide must be used in the fusions and a correction must be applied to all sulfur determinations. If a carbide free from sulfur were obtainable, it would eliminate a weighing and a correction.

Seven-tenths gram of the carbide was ground to 60-mesh and thoroughly mixed with 0.5 g. of potassium sulfate in a 25-cc. iron crucible. This crucible was heated over a Méker burner and the resultant fusion mass placed in an Erlenmeyer evolution flask for hydrogen sulfide evolution. The evolved hydrogen sulfide was collected in ammoniacal cadmium chloride solution, which was then acidified and titrated for sulfur content with iodine. As water and acid were added to the fusion mass in the evolution flask, acetylene was formed therefrom by action on undecomposed carbide, thus yielding a reducing atmosphere, insuring that no sulfide would be oxidized by the air in the apparatus. Results are given in Table I.

[5] Ebler and others, Ber., 46, 2264 (1913).

Quantitative reduction was not obtained. It was attempted to increase the yield of reduced sulfur by mixing sodium carbonate with the calcium carbide, thinking to hold back any escaping sulfur dioxide. When this was done but 60% of the sulfur was reduced to sulfide.

Calcium hydride should have the following advantages over calcium carbide: first, it is more easily obtained free from sulfur; second, evolution of hydrogen sulfide is more readily carried on from hydride residues than from carbide fusion residues, as some free carbon remaining from calcium carbide fusions tends to hold back hydrogen sulfide (it was later found that evolution from calcium hydride fusions residues was unnecessary, acidification of the water solution of the fusion residue, followed by titration, being all that is needed); third, hydrides remaining in the fusion mixture decompose with water to give off hydrogen while carbides with water yield undesirable, odorous acetylene. The hydride might give more complete reduction on fusion with sulfates.

Sulfate Reductions with Calcium Hydride.—Calcium hydride may be obtained from various chemical distributors. It is a light gray solid which may be readily ground in a mortar. All of the calcium hydride used in this work was powdered by means of a small disk grinder and passed through a 60-mesh screen. The grinding must not be too rapid or the heat of friction may cause ignition of the calcium hydride.

Samples of the hydride were tested for sulfur and no trace was detected. The calcium hydride does, however, contain calcium chloride and calcium oxide. The calcium chloride probably comes from the preparation of metallic calcium from which the hydride is made. The calcium oxide is the result of the reaction of the hydride and moisture. In the procedures used neither of these impurities hinder reductive action on sulfates.

Calcium hydride acts on water thus:

$CaH_2 + 2HOH = Ca(OH)_2$	$+ 2H_2$
42 grams	4 grams or 44,800 cc.
1 gram	1,067 cc.

One gram of calcium hydride should evolve 1067 cc. of hydrogen at standard conditions. The purity of the hydride was determined by measuring the hydrogen evolved from a weighed amount. An average of runs indicated that the hydride yielded 803.4 cc. of hydrogen at standard conditions. It is readily seen that we were not dealing with pure calcium hydride but a mixture of calcium hydride, calcium oxide, calcium chloride and probably some sub-hydride of calcium.

A sample of calcium hydride was made in this Laboratory by passing hydrogen over rasped calcium, heating in a pyrex tube to about 500° in a small electric furnace. This product was a light gray, easily ground solid, comparable to that obtained on the market. It also yielded much less than the theoretical amount of hydrogen on treatment with water.

As moisture was kept from the product and since very little chloride is present, the deficiency in amount of evolved hydrogen is probably due to a sub-hydride of calcium.

Fusions for sulfur estimation were made upon purified sulfates of potassium, barium, strontium, calcium and lead. The comparisons of these results with the theoretical are listed in later tables. Carefully standardized 0.1 *N* iodine and sodium thiosulfate solutions were used in titrations.

Of the various methods of procedure that were tried for running sulfur determinations on sulfates, starting by ignition with calcium hydride, the following outlined process gave the best results.

One-half or 0.25 g. sample of the crushed sulfate were mixed in a 25-cc. iron crucible with about 7 g. of powdered calcium hydride. This amount of hydride about half fills the crucible. Mixing is accomplished with a spatula; about thirty turns of the spatula are deemed sufficient. A surface layer of hydride is placed above this mixture to the depth of one-eighth inch.

A cover is placed on the crucible and the whole quickly heated over the full blast of a Méker burner and then allowed to stand in the full flame for ten to fifteen minutes. After cooling, the cover is removed, and if heating has not been too high, the residue is easily jarred from the crucible as one solid lump, which can then be broken up and transferred from a piece of paper into an Erlenmeyer flask of 500-cc. capacity.

Above the Erlenmeyer flask is placed a short reflux condenser, the upper end of which is closed by a two-holed rubber stopper. Through one hole of the stopper is inserted a 100-cc. dropping funnel. A bent glass tube for the escape of evolved hydrogen passes through the other. Water is slowly dropped upon the fusion residue until the excess hydride is broken up, much hydrogen being evolved the while. More water is added and a milk-like solution of calcium hydroxide and calcium sulfide is obtained. This is transferred to a liter beaker, diluted to 400–500 cc. and acidified with 100 cc. of concd. hydrochloric acid, allowing the heavier acid to run down the side of the beaker and not stirring. Stirring of the solution at this point means a loss of considerable hydrogen sulfide.

The beakers are allowed to stand for a few minutes and the solid matter therein dissolves in the acid. A clear solution will not always result but the turbidity will not interfere with the very pronounced starch–iodine end-point. The solution is now titrated with iodine, stirring gently at first, with starch solution as indicator. One cubic centimeter of the 0.1 N iodine is equivalent to 0.0016 g. of sulfur.

On the delicacy of this end-point it has been found the accuracy of the method depends. The end-point is not all that is to be desired as a little excess iodine is needed to yield a starch–iodine color to the whole solution. If the samples taken are too large, an overabundance of colloidal sulfur is formed which occludes some iodine and tends to lower results. It is well to add a slight excess of iodine and titrate back with standard sodium thiosulfate. With a little practice the end-point can be judged to less than one-half of a cubic centimeter, which is less than 0.0008 g. of sulfur. This would correspond to 0.15% sulfur in a 0.5-g. sample and is then the accuracy of the method. Results of analysis of potassium sulfate are given in Table II.

Samples 1–4, inclusive, are seen to give close approximations to the true sulfur content of the sulfate. These samples were treated as has been outlined.

Samples 5 and 6 were run as the others except that vigorous stirring

TABLE II

0.25 G. OF POTASSIUM SULFATE REDUCED TO CALCIUM SULFIDE WITH CALCIUM HYDRIDE

Sample K_2SO_4 = 18.37% sulfur

Sample	Iodine titer, cc.	Sulfur equiv., g.	Sulfur, %	Sample	Iodine titer, cc.	Sulfur equiv., g.	Sulfur, %

4	29.0	.0464	18.56	8	18.0	.0288	11.52

was carried on when acidifying the solution of the fusion residue. During this stirring the odor of hydrogen sulfide was noticed coming from the liquid and the iodine titer is quite low.

Samples 7 and 8 show the result of insufficient heating. It is not enough merely to heat until after a potassium flare is seen. The whole crucible must be heated to redness and kept in the full flame for several minutes. Fusion samples that were properly heated at redness for several minutes were tested for undecomposed sulfate and gave a negative test. The reduction is therefore quantitative. Any partial decomposition resulting in sulfite formation would not change results as the sulfite uses up iodine to the same extent as soluble sulfide. Little or no sulfite remains, however, as hydrogen sulfide may be evolved from fusion residues equivalent to all of the sulfur present. Results of analyses of barium, strontium and calcium sulfate are given in Tables III, IV and V.

0.25 G. OF CALCIUM SULFATE REDUCED TO SULFIDE WITH CALCIUM HYDRIDE ($CaSO_4$, 23.55% OF SULFUR)

Sample	1	2	3 (0.3 g.)
Iodine titer, cc.	37.0	37.0	44.0
Sulfur equiv., g.	0.0592	0.0592	0.0704
Sulfur, %	23.68	23.68	23.46

Runs were attempted fusing 0.25 g. of lead sulfate with calcium hydride and treating as in the case of the other sulfates. The following reactions undoubtedly occur.

$$PbSO_4 + 4CaH_2 = PbS + 4CaO + 4H_2$$
$$CaH_2 \leftrightarrows Ca + 2H$$
$$Ca + PbS = CaS + Pb$$

This free lead is only slowly acted upon by the hydrochloric acid which is added prior to iodine titration. As a consequence iodine end-points are fading and results are high. An attempt was made to evolve hydrogen sulfide from the fusion residue as in determining sulfur in steel. The metallic lead as it dissolved, however, formed insoluble lead sulfide and thus held back some sulfur.

The method as outlined, then, is only applicable to non-volatile sulfur compounds free from metals which form acid-insoluble sulfides. Work is being carried on making calcium hydride fusions with volatile sulfur compounds in bombs.

Discussion of Results.—Probable chemical equations for the action of calcium hydride on any sulfate are as follows

$$MSO_4 + 2CaH_2 = MS + 2CaO + 2H_2O$$
$$MSO_4 + 4CaH_2 = MS + 4CaO + 4H_2$$

Since calcium hydride decomposes to some extent around 700°, it was thought that secondary reactions might occur

$$CaH_2 \leftrightarrows Ca + 2H$$
$$MS + Ca = CaS + M$$

Experiment verifies these last reactions even to the replacement of sodium and potassium by calcium. When potassium sulfate and calcium hydride ignitions were being made a potassium flare was noticed. When fusions of sodium thiosulfate and calcium hydride were made a sodium flare resulted. On examining the cover of the crucible after these latter fusions it was noticed that some sodium metal had condensed on the cooler cover, forming small globules.

It is evident from the tables that the method gives a quantitative estimation of sulfur in alkali and alkaline earth sulfates.

Insoluble alkaline sulfates are commonly determined for sulfur content by initial fusion with sodium carbonate to decompose the sulfate, followed by extraction of the sodium sulfate formed, ultimate precipitation of barium sulfate, and necessary filtering, drying, igniting, weighing and calculating. By the method herewith outlined sulfur may be estimated in insoluble sulfate samples within forty minutes.

Calcium hydride may be readily obtained and is easily powdered. It is a rather expensive chemical at present in that there is little demand for it in quantity. The cost of 7 g. of the hydride, or enough for one fusion, is about thirty-five cents. The saving of time and labor is the main merit of the method.

Summary

1. Calcium carbide has been studied as a reductant for sulfates. It is not as effective as calcium hydride.

2. Calcium hydride presents itself as a reagent for the quantitative reduction of alkaline earth and alkali sulfates to sulfides. From such fusion residues sulfur may be determined by iodine titration.

3. An example is given of replacement of potassium and sodium by calcium.

THE POTATO AS AN INDEX OF IODINE DISTRIBUTION[1]

BY ROE E. REMINGTON, F. BARTOW CULP AND HARRY VON KOLNITZ

RECEIVED MAY 6, 1929 PUBLISHED OCTOBER 5, 1929

The theory that endemic thyroid enlargement is caused primarily by lack of iodine has been quite generally accepted by American scientists, so that studies on the occurrence of iodine in human environment are of considerable interest. McClendon and Williams[2] have shown that there is a correlation between shortage of iodine in surface water supplies and the incidence of goiter.

Numerous analyses by these and other workers have established that places in the United States where the water contains more than two parts per billion of iodine are few, and more than five parts per billion exceedingly rare. Von Fellenberg[3] concluded, as the result of an extended metabolism trial on himself, that the daily iodine requirement for a man is 14 micrograms, which is a great deal less than the amount (300 to 400 milligrams per year) recommended by Kimball[4] for goiter prophylaxis in the United States. Even if inorganic compounds of iodine are efficiently utilized in the body, water alone cannot supply the requirement in more than a very restricted area. Hence McClendon[5] turned his attention to vegetable foods, and was able to show that foods from Maine and Connecticut contain more iodine than do those from Minnesota or Oregon.

The senior author of this paper[6] has called attention to the relatively large amounts of iodine present in root and leafy vegetables from South Carolina, analytical data for which are now presented in Table I, and

McClendon[7] has published analyses of vegetables from California. Mitchell[8] has also examined a number of samples of South Carolina vegetables and feeds, and finds a tendency to higher iodine content in that part of the state which is more distant from the coast and nearer the Blue Ridge of the Appalachian Mountains. He reported marked differences in the results on samples of the same product from the same general locality, which differences have been found by us to amount to two or three hundred per cent. At first we were inclined to attribute the lack of uniformity to errors in laboratory technique, but extended experimentation has convinced us that the differences actually exist in the crops as grown. So far we have no suggested explanation, although soil type, stage of maturity of the crop at harvest, fertilizer and soil treatment, and rainfall all deserve consideration.

The salt spray theory of iodine distribution seems to have gained general acceptance, but the Atlantic Ocean contains only 23 parts per billion of iodine, and five or six parts per billion in the water of streams cannot come solely from spray unless the waters contain a like proportion of the other salts of the sea, which they do not. Mitchell[8] found six parts in the water of the Broad River at a point 150 miles from the coast, but the Broad River is not brackish. Lunde[9] believes that in the cooling of the earth iodine was distributed throughout all phases, and hence is now found in rocks, soils, and in the air and sea, but has been leached out of the soils of some areas. Von Fellenberg[10] found several hundred parts per billion in igneous rocks.

[10] Th. von Fellenberg, *Biochem. Z.*, 152, 132 (1924).

Examination of a large number of samples has heretofore been difficult owing to the intricate and laborious technique of the oxygen combustion method of McClendon, which has been the most reliable method in use up to the present time. It has been found in this Laboratory, however,? that if the organic matter were destroyed by simple ignition in a porcelain dish at a temperature which did not exceed 450°, 95% of the iodine in sodium iodide added to potatoes could be recovered, and we have since obtained as good or better recovery when 0.1 g. of dried thyroid is added to 100 g. of dried potatoes; hence we conclude that organic as well as inorganic iodine is retained by the ash of vegetables when ignited at this temperature. The method is so simple that a good technician can now make six to eight determinations per day if laboratory facilities are adequate.

In order to compare the iodine content of foods in maritime and non-maritime regions, it seemed desirable to choose a crop which is universally grown, largely used as food, and can be readily obtained and transported without spoilage. Cereal grains are not suitable because their iodine content is very low, regardless of where grown. Since we have found that Irish potatoes from South Carolina contain as much iodine as any other root crops which we have examined, the potato was chosen as the basis of our survey. Samples in South Carolina were collected by county agricultural agents; those from other states were furnished us through the courtesy of the directors of the several agricultural experiment stations.

On receipt the samples were washed, cut into small cubes without peeling, dried first for twenty-four hours or more by a current of air at room temperature blown upward through the screen wire bottoms of trays in which the samples were placed, and finally for twenty-four hours in an oven at 80°, after which they were ground and bottled. The moisture content of the dried samples ranged from 1 to 3%. The loss in drying varied in different samples between 75 and 80%. Results are given in Table II.

The Idaho samples were all produced on wind-borne silt loam soils of volcanic origin, fertilized with liberal quantities of stable compost but no commercial fertilizer. Mixed commercial fertilizers are extensively used in Michigan, Maine and South Carolina, but not in Minnesota nor North Dakota.

With regard to South Carolina, while 72 is probably not a sufficient number of samples on which to base an accurate study, it has seemed worth while to analyze the data, first with reference to distance from the sea and second with regard to soil types. If we draw lines across the map of the state at intervals of fifty miles from the coast, and average the samples within each belt, we obtain the values in Table III. There is a regular progressive increase in iodine content as we go from the coast toward the mountains.

TABLE II

IODINE CONTENT OP POTATOES PROM DIFFERENT REGIONS

With regard to soil types, the state is roughly bisected by the "fall line," which marks a prehistoric coast (Fig. 1). Below the fall line the soils are predominantly sand or sandy loam, and have come up out of the sea in comparatively recent geologic time. Above the fall line the predominating type is a red clay loam, brought down by erosion from the granite rocks of the Appalachian system. The differentiation is not sharp, and some areas of clay have been washed clear down into the lower pine belt. It is rational to expect that the remains of marine plants and animals which are incorporated in the soils below the fall line will have an effect on the iodine content of crops raised thereon. It will be noted, however, that the samples from the Piedmont (Table IV) (above the fall line) are richer in iodine than those from any of the lower areas, not excepting the coast itself. In fact, were it not for the sand hill section and the narrow coastal belt, the order would be the same as that of the previous table. The soil of the sand hills is particularly barren, and presents an agricultural problem of its own, while we can believe that the higher values along the coast (as compared with the lower pine) are due to the immediate effect of the

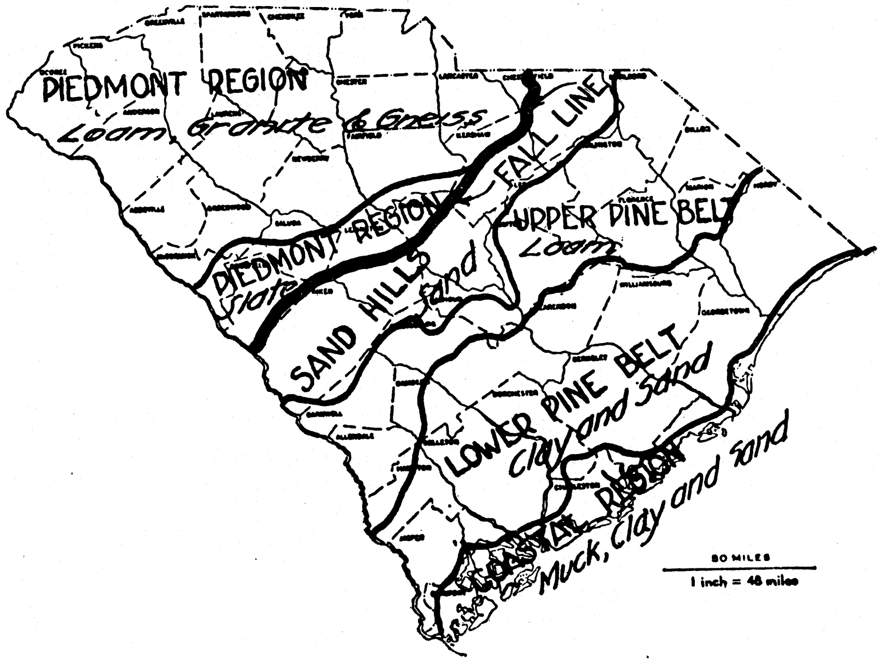

Fig. 1.—General topographic and soil areas of South Carolina.

TABLE IV

IODINE CONTENT OF POTATOES IN RELATION TO SOIL AREAS

Parts per billion, dry basis

Soil area	Number of samples	Iodine content, av.
Coastal Region	7	198
Lower Pine Belt	18	164
Upper Pine Belt	12	234
Sand Hills	7	191
Piedmont	28	249

sea, in that marsh grass is used as feed for live stock and for fertilizer, seaweed is blown ashore and finds its way into the soil, and the possible effect of sea spray. It is a matter of common agricultural knowledge that the clay soils of the Piedmont not only hold water better, but also retain mineral salts, so that only one-fourth to one-half as much fertilizer is used to make a crop as is required in the sandy soils of the low country.

Commercial fertilizers have probably been used for a longer time, and more abundantly in South Carolina than in any of the interior states. Chilean nitrate may carry as high as 0.02% of iodine[11] but the amounts reported for other usual fertilizer materials are not higher than have been found in many soils. As previously noted, fertilizers were used in producing all the samples from Michigan, where lower amounts of iodine were found. We believe that the main source of iodine in South Carolina vegetation lies in the disintegration of the granitic rocks of the Blue Ridge, and that this has been supplemented by the liberal use of commercial fertilizers over a period of years. This supply of iodine is being conserved by the return of vegetable matter and animal wastes to the soil.

Summary

Analyses of 72 samples of Irish potatoes from different parts of South Carolina, as well as of samples from Maine, Michigan, Minnesota, North Dakota and Idaho, are presented and discussed in relation to various factors which have been supposed to influence the iodine content of plants. Average values are: South Carolina 211, Maine 195, Idaho 110, Michigan 94, Minnesota SG.

Large variations are found in samples from the same area and identical soil type, the variations, however, not being confined to South Carolina. Average values increase progressively from the sea to the Appalachian Mountains, but the relative amount of clay in the soil increases in the same manner. It is suggested that the principal source of the iodine is from the disintegration of granite rocks, supplemented by the use of commercial fertilizers. The immediate influence of the sea is not seen beyond a very narrow belt along the coast.

INTENSIVELY DRIED CARBON TETRACHLORIDE

BY SAM LENHER

RECEIVED JUNE 1, 1929 PUBLISHED OCTOBER 5, 1929

Recently, in an extension of his work on intensively dried liquids, H. B. Baker[1] has reported vapor density measurements on eight liquids dried for from two to fifteen years which indicate an increase in molecular weight on drying.

Last year boiling-point determinations were carried out on benzene and carbon tetrachloride which showed no change in boiling point on prolonged drying.[2] The present paper describes some further measurements on intensively dried carbon tetrachloride.

Carbon tetrachloride was prepared in exactly the way described previously.[2] It was sealed up, as before, in specially prepared, capillary-free, hard glass tubes together with redistilled phosphorus pentoxide. The tube, which had an external diameter of 18 mm. with 2-mm. walls, was heated to softening before the introduction of the phosphorus pentoxide. The redistilled pentoxide was introduced into the dry tube by plunging a dry glass tube into the pentoxide and forcing it into the drying tube with a glass rod. This operation prevented the pentoxide from coming into contact with atmospheric moisture except possibly at the ends of the tube. The tube was sealed up on June 19, 1924. Care was taken to thicken the glass where the tube was sealed off. The tube was allowed to stand at room temperature.

This tube was opened on May 15, 1929; the drying time was five years. The boiling point of the dry carbon tetrachloride was measured in a platinum wire boiling-point apparatus[3] under conditions where there was less than 0.03' of superheating. The boiling point of the carbon tetrachloride, measured three minutes after the drying tube was opened, was 76.8° at 762.2 mm. No difference in temperature could be observed between the boiling liquid and the vapor 1–2 cm. above the liquid. The thermometer used had been compared with Bureau of Standards thermometer No. 35388.

The boiling point was then determined using the procedure adopted by Baker for his boiling-point measurements. The carbon tetrachloride from this boiling-point determination was placed with the same thermometer in a straight tube of 2-cm. diameter and heated in a Nujol-bath. The carbon tetrachloride did not begin to boil until the thermometer in the liquid registered 90°. Boiling was then not violent, but was quiet and regular and gave no indication of superheating other than the reading on the thermome-

[3] Mathews, *Trans. Am Electrochem. Soc*, 19, 81 (1911).

ter. The carbon tetrachloride was not entirely free of dust particles and of tiny bits of phosphorus pentoxide. This experiment shows clearly the difficulty of avoiding superheating when a boiling point is measured in this way.

The molecular weight of the intensively dried carbon tetrachloride was measured by the method of Victor Meyer. The familiar form of the Victor Meyer apparatus was used,[4] the only innovation being that mercury was used in the gas buret. The intensively dried carbon tetrachloride was introduced directly into small bulblets from the dry tube by dipping the open capillary end of the warmed bulblets into the liquid and allowing them to cool. The bulblets were weighed and the vapor density of the carbon tetrachloride was measured in the apparatus which had been previously evacuated for four hours at the boiling point of aniline. The measurements were carried out at the boiling point of aniline. The six measurements were made over a period of an hour and a half after the opening of the drying tube. The molecular weight of intensively dried carbon tetrachloride in six experiments was found to be 160.1, 149.9, 153.8, 152.1, 154.5, 154.9; the molecular weight of ordinary carbon tetrachloride is 153.8.

The phosphorus pentoxide in the drying tube was treated with water in a calorimeter to determine how much unused pentoxide remained after five years' contact with carbon tetrachloride. When the tube was opened the pentoxide was in a finely divided state, giving no sign of formation of phosphoric acid. This test showed that **3.5** g. of phosphorus pentoxide was still present when the tube was opened. This figure is at least 30% too low, because of the difficulty of transferring the pentoxide to the calorimeter without heat loss.

The criticism cannot be made that the drying time was insufficient to effect intensive drying for the writer's carbon tetrachloride which showed a normal boiling point and normal molecular weight by the vapor density method was dried for five years, while Baker[1] reports a molecular weight of 191 for carbon tetrachloride dried for three years and a molecular weight of 201 for the same substance dried for five years.

The writer[5] has been able to observe some of the phenomena described by Baker[1] for dried liquids and liquids subjected to electrical potential with ordinary liquids under as nearly as possible the same experimental conditions. These experiments which will be described elsewhere[6] will show that superheating is an important factor in Baker's experiments.

It may be remarked that Briscoe, Peel and Robinson[7] have recently measured with great care the density and surface tension of benzene dried

for eighteen months and have found no change which would justify an assumption of a change in degree of association on drying.

Summary

Carbon tetrachloride which has been in contact with pure phosphorus pentoxide in a sealed tube for five years at room temperature shows no change in boiling point or molecular weight, by the Victor Meyer vapor density method, which can be attributed to intensive drying and consequent change in degree of association.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF HARVARD UNIVERSITY]

THE VISCOSITY OF AQUEOUS SOLUTIONS OF STRONG ELECTROLYTES WITH SPECIAL REFERENCE TO BARIUM CHLORIDE

BY GRINNELL JONES AND MALCOLM DOLE

RECEIVED JUNE 12, 1929 PUBLISHED OCTOBER 5, 1929

Introduction

A number of related properties of barium chloride solutions have been determined with a high precision over a considerable range of concentration in the hope that a study of the data in the light of modern theories of solutions might reveal new relationships between the properties and new laws for the variation of the properties with the concentration. The first paper[1] of this series records the results of measurements of transference numbers by both the analytical- and electromotive-force methods which resulted in the discovery of a new and exact relationship between the transference number and the concentration. This, the second paper of the series, records measurements at 25° of the viscosity of barium chloride solutions relative to that of water, over the range 0.005 to 1.0 molal. This investigation has resulted in the discovery of a new exact relationship between the fluidity and the concentration. A later paper will give data on the conductivity of the same solutions.

Historical **Review.**—Poiseuille,[2] the great pioneer in research on viscosity, found that some salts increase the viscosity of water whereas others decrease the viscosity. Sprung[3] appears to have been the first to measure solutions of barium chloride and found that it increased the vis-

---

[1] Grinnell Jones and Malcolm Dole, THIS JOURNAL, 51, 1073 (1929). We regret that in this paper we implied that Washburn found it necessary to filter his solutions during his work on transference numbers [THIS JOURNAL, 31, 322 (1909)]. This implication is, however, misleading as Washburn actually avoided the filtration of his solutions.

[2] Poiseuille, Ann. *chim. phys.*, [3] *21*, 76 (1847).

[3] Sprung, Ann. *Physik*, 159, *1* (1876).

cosity of water. Arrhenius[4] made some viscosity measurements on solutions. He found that the change in viscosity caused by the addition of a salt was roughly proportional to the concentration at low concentrations but increased more rapidly than the concentration at moderate concentrations (1 normal). He proposed a new formula for the relationship between viscosity and concentration, namely, $\eta = A^c$, where η is the relative viscosity compared to that of water at the same temperature and A is a constant for any given salt and temperature. This equation has been tested by Reyher,[5] by Wagner[6] and by others and found to hold within a few tenths of 1 per cent. between $^1/_8$ and $^1/_2$ normal and within about 1% up to 1 normal.

Sutherland[7] suggests that the depolymerization of triple water molecules by the dissolved salt causes diminution in viscosity.

The next outstanding investigator on this subject was Grüneisen,[8] who made a careful and critical study of the experimental technique with the Ostwald form of viscometer and then made measurements, which are probably more precise than any previously made, on aqueous solutions of sixteen salts and of sucrose over a wide range of concentration. Grüneisen made measurements with more dilute solutions than his predecessors and thereby discovered that the viscosity–concentration curves, instead of becoming more nearly straight at the dilute end, exhibit a negative curvature. This behavior is not in accord with Arrhenius' equation which must, therefore, be regarded as invalid, even as a limiting law for low concentrations. Grüneisen found that both the salts which increase the viscosity and those which decrease the viscosity show a negative curvature of the viscosity–concentration curves at low concentrations. The viscosity-concentration curves for salts which increase the viscosity are so nearly straight lines that the deviations would not be readily apparent on the scale which could be printed on this page, but the deviations are clearly systematic and greater than the experimental error. For a salt which increases the viscosity of water, the curve starts at $\eta = 1.0000$ when $c = 0$ with a positive but diminishing slope, giving a negative curvature, then straightens out, passes through a point of inflection at moderate concentrations (about 0.3 molal), and then the curvature becomes slightly positive. These changes in the curve are more apparent if, following a suggestion of Grüneisen, we plot $(\eta - 1)/c$ against c (or some root of c for the sake of spreading out the points at the lower concentrations). $(\eta - 1)/c$ is strictly the slope of the chord connecting a point on the $\eta - c$ curve with the origin, but it is approximately the same as the slope of the $\eta - c$ curve at the same point.

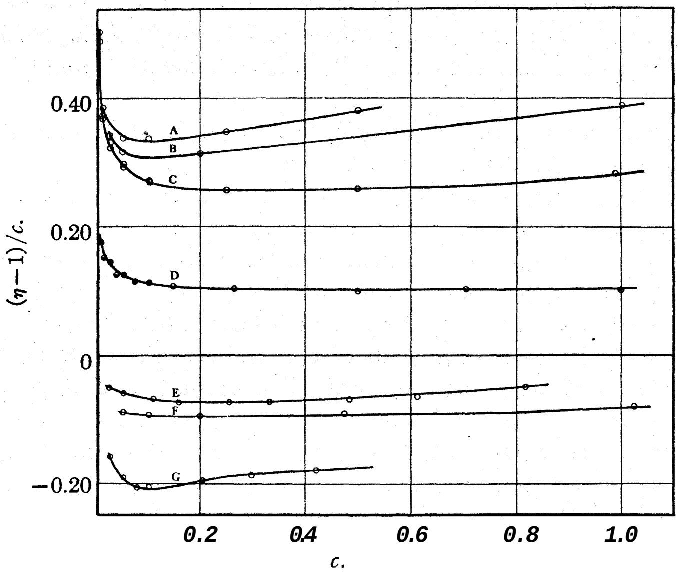
[7] W. Sutherland, *Phil.* Mag., [5] **50**, 481 (1900).

[8] E. Grüneisen, *Wiss. Abh. Phys. Techn. Reichsanstalt*, **4**, 151, 237 (1905).

If the relationship between the viscosity and concentration were a linear one, $(\eta - 1)/c$ would be a constant and its plot would be a straight line parallel with the c axis. Figure 1 gives such curves for several salts (magnesium sulfate (A), lithium iodate (B), potassium iodide (F) from data by Grüneisen; lithium nitrate (D) from data by Grüneisen and by Applebey; cesium nitrate at 25° (E) and at 0° (G) from data by Merton; and the data on barium chloride (C) reported below in this paper). As will be seen, the values of $(\eta - 1)/c$ decrease rapidly with increase of concentration at low concentrations, pass through a minimum and then slowly rise. A downward slope in this curve corresponds to a negative curvature in the $\eta - c$ curve. Grüneisen's paper gives similar curves for many other salts. Grüneisen proposed the equation



Curve A, $MgSO_4$ at 18° after Grüneisen; *B*, $LiIO_3$ at 18° after Grüneisen; C, $BaCl_2$ at 25°, Jones and Dole; D, $LiNO_3$ at 18° ◒ Applebey, ● Grüneisen; E, $CsNO_3$ at 25° after Merton; F, KI at 18° after Grüneisen; G, $CsNO_3$ at 0° after Merton.

Fig. 1.—$(\eta-1)/c$ against c.

$$\eta = 1 + Aic + B(1 - i)c + Cc^2$$

where i is the degree of dissociation as computed from the conductivity and A, B and C are constants for any given salt and temperature. *A* is supposed to represent the effect of the friction of the ions on the water, B that of the un-ionized molecules on the water and C that of the ions and molecules on each other. Grüneisen was able to select values for the empirical constants to make the equation fit his data, although negative values of A and B had to be selected in many cases, However, his equation is not a useful interpolation formula permitting the computation of the viscosity at any concentration owing to the presence of the parameter i, which is itself a function of the concentration. Grüneisen pointed out that the smaller the electrical mobility of an ion the greater is its influence in increasing the viscosity of solutions.

Schneider[9] has made measurements similar to Grüneisen's with many other salts, although with less precision, and obtained similar results, showing that Grüneisen's observation of negative curvature of the viscosity–concentration curves at low concentrations is a general one. He made no advance in the interpretation of the phenomena.

Among the many investigators of the viscosity of solutions the next who deserves mention in this brief review is Applebey,[10] who made careful measurements at 25, 18 and 0° on solutions of lithium nitrate, a salt which increases the viscosity of water. Applebey's work extended over a wide range of concentration, including solutions even more dilute ($c = 0.00724$) than those studied by Grüneisen. His results show that the negative curvature becomes more pronounced at very low concentrations (see Fig. 1, Curve D) and that the curvature in this region is much greater than would be predicted by Grüneisen's equation. He also showed that the negative curvature becomes greater as the temperature is lowered. Applebey made the suggestion that when a salt is dissolved in water there are two different effects on the viscosity: (1) a depolymerization of triple water molecules, $(H_2O)_3$, to form single molecules, which tends to diminish the viscosity; (2) an increase in viscosity due to the presence of the ions of the salt and the un-ionized molecules of the salt. It is assumed that the friction depends primarily on the size of the ion or molecule. In the case of salts composed of ions which are not greatly hydrated, such as the Cs^+, Rb^+, K^+, NH_4^+, I^-, Br^- or NO_3^- ions, the increase due to the friction of the ions on the water is less than the diminution of the viscosity due to depolymerization of the water, giving a net decrease in viscosity or a negative slope of the viscosity-concentration curve. Most ions, however, are sufficiently hydrated so that the increase in viscosity due to their presence more than offsets the decrease due to depolymerization, giving a net increase in viscosity with concentration. Applebey attempted to derive an equation connecting viscosity and concentration but the equation which he obtained contains the degree of dissociation of the salt computed from the conductivity, the association factor of water, and the hydration numbers of the ions (the number of molecules of water attached to each ion to form the hydrated ion). However, the exact form of the function connecting any of these variables with the concentration is unknown, and, therefore,

---

[10] M. P. Applebey, *J. Chem. Soc.*, 93, 2000 (1910).

Applebey's equation does not give even by implication the exact functional relationship connecting viscosity and concentration. In order to make his equation give any negative curvature at low concentrations, it was necessary for him to assume that the ions have a greater friction against the water than the un-ionized salt, which is hardly in accord with his assumptions that the volume of the particles is the important factor in the viscosity, or else that the ions are less effective than undissociated salt molecules in depolymerizing the water. But even with these assumptions, his equation cannot predict the rapid change in slope which actually occurs and, of course, the modern view that solutions of strong electrolytes are completely dissociated makes the attempt to account for the negative curvature in this manner entirely illusory. Applebey used his equation as a means of computing hydration numbers of the ions and obtained results for lithium nitrate which he regarded as plausible, but for cesium nitrate he obtained negative hydration numbers which are obviously absurd. Curve D in Fig. 1 shows the good agreement between Grüneisen's and Applebey's data on lithium nitrate at 18° and also the sharp curvature at low concentrations.

The viscosity-concentration curves for salts which diminish the viscosity of water are more complicated than for salts which increase the viscosity. The behavior at extreme dilutions has never been adequately investigated, but at the lowest concentrations for which data are available the curve has a slight negative curvature. These curves then pass through a point of inflection at moderate concentrations (about 0.1 to 0.2 molal), and have a positive curvature at all higher concentrations. The viscosity passes through a minimum in the neighborhood of one molal and has a positive slope at higher concentrations and at very high concentrations may again become greater than that of water.

The work of Merton[11] on cesium nitrate appears to be the most accurate and extensive study of a salt which diminishes the viscosity of water. His work confirms the observation of Applebey on lithium nitrate that at low temperatures negative slopes and negative curvatures are more pronounced than at higher temperatures. Merton made no theoretical advances. His data on cesium nitrate are shown in Fig. 1, Curves E and G.

The various hypotheses which have been suggested to account for "negative viscosity" are discussed at considerable length by Rabinovich.[12] He concludes that depolymerization of water molecules must be responsible for "negative viscosity."

It is apparent that although the general shape of the viscosity-concentration curves has been established, the phenomena at extreme dilutions have not been adequately investigated, and no one has yet found an exact general equation connecting viscosity and concentration.

Measurements of the viscosity of barium chloride solutions have been carried out by Sprung[3] at 18°, by Arrhenius[4] at 17.6°, by Wagner[6] at 25°, by Schneider[9] at 18° and by Herz[13] at 25°. Although the earlier work makes it clear that barium chloride increases the viscosity of water, the available data on this salt are lacking in precision and do not cover the lower range of concentration.

Experimental Part

The viscometer was of the Ostwald type made of quartz in accordance with the recommendations of Washburn and Williams,[14] except that a small bulb was blown between the lower mark on the upper reservoir and the capillary as suggested by Chadwell.[15] The capillary was 17.0 cm. long and its effective average radius was 0.026 cm. All measurements were made at 25°. The thermostat showed an extreme variation during the experiments of only 0.003°. The viscometer was permanently mounted in a stiff brass frame which was designed so that it could be attached to a rigid frame in a definite position inside the thermostat; but in spite of our efforts to ensure stability and reproducibility in the mounting, a major operation on the building produced an unavoidable disturbance in the mounting of the viscometer. During the first part of the work one end of the building (the Jefferson Physical Laboratory) was supported on jacks while repairs were being made on the foundations. During this period the time of flow of water in our viscometer was 342.54 seconds (see Table I). Then during the period beginning on August 30 and completed on September 2, the jacks were lowered, permitting one end of the building to move onto its new foundations. Following this event we found that the water value of our viscometer had changed to 342.33 seconds, or 0.21 second faster (see Table I). The data are therefore divided into two series, the first series including all measurements before September 2, which are computed with 342.54 as the water value, and the second series all made after this date which are computed with 342.33 seconds as the water value. The concentrations are expressed in gram molecules of barium chloride per liter. All of the data for a given concentration are grouped together in the table to facilitate comparison and averaging. In comparing the time of flow of an experiment in the first series with one in the second, proper allowance must be made for the change in the water value.

We found it advisable to fill the viscometer with sulfuric-chromic acid cleaning mixture and allow it to stand overnight at frequent intervals to ensure proper drainage. In order to avoid dust particles, everything that went into the viscometer—the water, the solutions, the cleaning mixtures and wash waters and the air used to dry the instrument between experiments—was passed through a sintered Jena glass filter. After this precaution was adopted only one experiment out of 39 had to be rejected on account of dust particles, which shows that this filtration was very helpful.

The so-called kinetic energy correction has been applied in accordance with the method recommended by Bingham,[16] but since there is some question as to the magnitude of this correction[17] we give our results both with and without the correction and have designed our viscometer so as to make the correction small. In our experiments this

correction has its maximum value of 0.14% with the molar solutions and falls off with dilution to 0.013% with 0.1 molar solution.

Measurement of Time of Flow.—The standard clock of the Jefferson Physical Laboratory, which has been proved by many tests to be sufficiently constant for our purpose, was used as our time standard. This clock has an attachment which gives a momentary electric impulse once every second. By means of a relay and induction coil the electric impulses from the clock produced a spark between two platinum points every second. This spark burned a hole in moving paper tape (stock market ticker tape) which passed at a constant velocity through the spark gap. The moment of passage of the meniscus past the marks was recorded on the same tape by touching a tapping key which also produced a spark. The motor which drove the paper tape was designed as a constant speed motor and a constant speed governor of the centrifugal type was added. The velocity of the tape was adjustable by means of the governor and in the final experiments was always within the limits of 9 to 12 cm. per second. Careful test indicated that this device recorded the moment of touching the tapping key within 0.01 second. There is, however, a psychological lag of unknown and variable amount between the observation of the passage of the meniscus past the mark and the tapping of the key with the finger. If this lag were equal at the beginning and the end of the time interval being measured, it would make no error. Therefore, the shape of the

viscometer at and immediately above the upper and lower marks was made as nearly identical as possible by an expert glass blower and care was taken to ensure that both marks were equally well illuminated in order that the two events being timed should be as nearly as possible identical. Much practice is also helpful in attaining precision, just as it is in many other endeavors which depend upon exact coördination of eye and hand. During the first series, the time of flow with water was measured 57 times on six different days with six independent fillings of the viscometer, giving an average of 342.54 seconds. The extreme variation between the highest and lowest of the 57 measurements was 0.26 second. The average was probably correct within 0.03 second or 0.01%. (The probable error of the mean when computed by Bessell's formula is 0.005 second.) During the second series with nine different fillings with water and 27 measurements, the average was 342.33 seconds and the extreme variation was 0.15 second. For the reasons explained above these averages are not comparable.

The experimental data on water are recorded in Table I and the solutions in Table II. The viscometer was cleaned, dried and refilled with water or barium chloride for each experiment. From 2 to 14 runs were made on

each filling and the time of each is recorded in Table I to show the concordance of the data. The average time only is recorded for the solutions to save space.

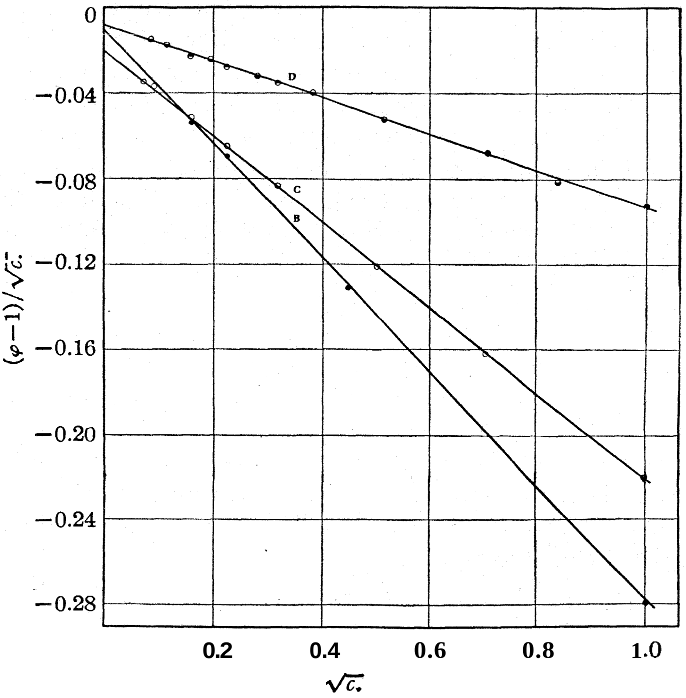
Analysis and Interpretation of our Data on Barium Chloride.—The data recorded in Table II were then brought to round concentrations by applying very slight corrections and then averaged, except in the case of the two higher concentrations where the concentrations actually used were so far from the round concentrations that any attempt to correct them was thought to be inadvisable at this stage of the interpretation of the data. The viscosities thus obtained are shown in Col. 2 of Table III. Then we plotted the viscosity against the concentration and obtained a curve which is approximately straight but with a negative curvature at the dilute end, a point of inflection at a concentration of about 0.4 molal, and a slight positive curvature at the upper end. These deviations from linearity are apparent from Col. 3 of Table III, which gives the values of $(\eta - 1)/c$, which would be a constant if the line were straight. These values are plotted in Fig. 1, Curve C. We next tested the Arrhenius equation, $\eta = A^c$, or $\log \eta = c \log A$. If this equation holds, $(\log \eta)/c$ should be a constant, but it is evident from Col. 4 that $(\log \eta)/c$ is by no means a constant, especially at low concentrations, so that the Arrhenius equation must be rejected. Bingham[18] has pointed out that in the case of mixtures of organic liquids the relationships are simpler if the computation or curves, instead of being based on viscosity, are based on its reciprocal—the fluidity. This suggested that we try the fluidity in the case of aqueous solutions of electrolytes. Column 5 gives the fluidity, φ, at each concentration and Col. 6 the value of $(\varphi - 1)/c$. As will be seen, these values are by no means constant, showing that the fluidity is not a linear function of the concentration. Although the fluidity–concentration curve has a positive curvature at the dilute end (corresponding to the negative curvature of the viscosity–concentration curve) it has no point of inflection and no double curvature (up to 1 molal at least), and therefore evidently has a simpler form than the viscosity-concentration curve.

It was evident from our study of our data reinforced by data on other salts by Grüneisen, Applebey, and Merton that, although the principal effect of dissolved salts on viscosity or fluidity is proportional to the concentration, there must be some effect which is of relatively greater importance in dilute solutions and which is responsible for the curvature found in the dilute end of the viscosity–concentration and of the fluidity–concentration curves. Furthermore, this effect always tends to increase the viscosity regardless of whether the sum of all of the effects of adding the salt is an increase or decrease of the viscosity. The interionic attraction theory of

---

[18] Bingham, "Fluidity and Plasticity," McGraw-Hill Book Company, Inc., New York, 1922, Part II, Chapter I.

electrolytes gives a clue to the nature of this effect. According to this theory the ions tend to build and maintain a space lattice structure in the solution and any influence tending to disturb this space lattice arrangement whether by heat motion of the solvent molecules, the electrostatic force of charged electrodes in the solution, or any relative motion of parts of the liquid, will be opposed by the interionic forces. The forces which tend to maintain a space lattice structure of the ions, therefore, tend to stiffen the solution or increase its viscosity.[19] The effect of the interionic forces in opposing the motion of ions in an electric field has been shown by Debye and Hiickel to be proportional to the square root of the concentration in very dilute solutions. It therefore occurred to us to try introducing a term proportional to the square root of the concentration into the equation for the fluidity, giving an equation of the form



Curve D, $LiNo_3$ at 18°, ○ Applebey, ● Griineisen; C, $BaCl_2$ at 25°, Jones and Dole; B, $LiIO_3$ at 18°, Griineisen.

Fig. 2.—$(\varphi-1)/\sqrt{c}$ against $\sqrt{c}$.

$$\varphi = 1 + A\sqrt{c} + Bc$$

Since the interionic forces mentioned above tend to stiffen the solution or decrease its fluidity, it is to be expected that A will have a negative value

---

[19] W. Sutherland, *Phil. Mag.*, [6] 14, 1 (1907), suggests that interionic attraction should increase the viscosity.

for all strong electrolytes and the value 0 for non-electrolytes. Whether B will be positive or negative for any particular salt can only be determined at present by a study of the experimental data. Thus B will be positive for salts like potassium iodide or cesium nitrate which increase the fluidity and negative for salts which, like barium chloride, diminish the fluidity. This equation may readily be transformed to the form $(\varphi - 1)/\sqrt{c} = A + B\sqrt{c}$. Therefore, the simplest way to test the validity of this equation is to plot $(\varphi - 1)/\sqrt{c}$ against $\sqrt{c}$ and see if a straight line is obtained which does not pass through the origin. This was done with our data on barium chloride and gave a good straight line through the entire range from **0.005** to **1.0** molal. This curve (C) is reproduced on a much reduced scale in Fig. 2. It will be noticed that the intercept on the $(\varphi - 1)/\sqrt{c}$ axis, which gives the value of A, is negative, as was predicted, and that the slope, which gives the value of B, is also negative in this case. The numerical values of A and B were then determined with greater precision than is possible by plotting by the method of least squares, giving

$$\varphi = 1 - 0.02013\sqrt{c} - 0.20087\sim$$

The values of the fluidity as computed by this equation are shown in Col. 7 of Table III and the deviations between the computed and observed values in Col. 8. The greatest deviation is only **0.032%** and the average deviation only 0.013% and there is no systematic trend. It may be concluded, therefore, that this equation is valid for barium chloride solutions at 25° within the limit of accuracy of the experiments over the entire range up to 1 molal. Table IV gives the values of φ and η at round concentrations computed from this equation.

Analysis and Interpretation of Other Data.—Most of the data in the literature are not well suited to test the generality of our new relationship because measurements on very dilute solutions are lacking. Most authors have apparently assumed that at low concentrations the curves become linear. The best available data for this purpose known to us are those of Grüneisen and of Applebey on lithium nitrate at 18° which cover the range from 0.00724 to 4.363 moles per liter. These data were first used to prepare a plot of $(\varphi - 1)/\sqrt{c}$ against $\sqrt{c}$ and gave a good straight line up to 1 molal, which is reproduced in Curve D of Fig. 2, giving negative values of A and B, as was expected. Then the equation of this line was determined by the method of least squares. (In this computation the data for Applebey's 0.7034 molal solution were omitted because the plotting indicated a serious error in this value.) The result was

$$\varphi = 1 - 0.00818\sqrt{c} - 0.08458c$$

The fundamental data and the derived values are shown in Table V. The conclusion that Arrhenius' equation is invalid is reinforced by a consideration of Col. 4. As will be seen by inspection of Col. 8, the values of the fluidity computed by our formula agree with the experimental results within 0.022% for all solutions measured up to 1 molal except for Applebey's 0.7034 molal solution, which is apparently in error experimentally. These data on lithium nitrate confirm in all respects the conclusions which we have drawn from our own data on barium chloride.

Grüneisen's data on lithium iodate have been used to prepare Curve B in Fig. 2. Lithium iodate solutions have an exceptionally high viscosity, but in spite of the magnitude of the effect, the equation

$$\varphi = 1 - 0.01076\sqrt{c} - 0.2689{\sim}$$

is in accord with the data up to 1 molal with a maximum deviation of only 0.03%. The equation, however, fails completely at 3 molal.

We have plotted the data on a number of other salts which increase the viscosity of water but forego to adduce other examples since in all other cases known to us the measurements lack precision or there are not sufficient measurements on solutions of low concentration to permit a sharp test of the validity of our general equation. The evidence of other cases studied, however, so far as it goes, supports the validity of our equation.

We next turn to salts which may decrease the viscosity of water within certain ranges of concentration and temperature. Such salts are sometimes said to exhibit a "negative viscosity" but this is not accurate phraseology since there is no such thing as a negative viscosity. Here the phenomena are more complicated than for salts which increase the viscosity. The data which are most suitable for testing our equation are the measurements of Merton[11] on cesium nitrate. Merton has made accurate measurements at 0° covering the range 0.025 to 0.42 molal, at 10° covering the range 0.029 to 0.7, at 18° covering the range 0.023 to 0.8, and at 25° covering the range 0.023 to 0.8. The values of $(\varphi - 1)/\sqrt{c}$ were plotted against $\sqrt{c}$. The resulting plots, which are omitted to save space, appear to be straight lines at the dilute end (below 0.2) but deviations are evident at higher concentrations; whereas for the salts which increase the viscosity, the straight lines were obtained up to 1 molal in the cases studied.

It is evident from these curves that the value of A is always negative, as is expected from our theoretical interpretation of the phenomena. Then by the method of least squares the coefficients were determined, giving at 18°

$$\varphi = 1 - 0.01029\sqrt{c} + 0.12456{\sim}$$

and at 0°

$$\varphi = 1 - 0.01488\sqrt{c} + 0.2587{\sim}$$

These data furnish further evidence as to the invalidity of Arrhenius' formula. There are several inferences which may be drawn tentatively from the variation of the constants with the temperature although we must be cautious because the available data do not extend to solutions as dilute as is desirable for the evaluation of the constant A. However, there are indications that the numerical value of A is greater at low temperatures than at high temperatures. Since A depends upon the stiffening effect of the space lattice, it is to be expected that this effect will be greater at low temperatures because the space lattice is less disturbed by heat vibration. This effect apparently exceeds the opposite effect of the change in dielectric constant with temperature. It is also to be observed that the value of B is greater at low temperatures, which is in harmony with Applebey's suggestion that the increase in fluidity is due to depolymerization of triple water molecules. There are more triple molecules present at low temperatures and therefore more available to be depolymerized.

Grüneisen's data on potassium iodide and potassium nitrate at 18° have been computed and plotted and found to fit an equation of the same form with a negative value of A up to 0.2 molar.

If our hypothesis that the negative curvature at the lower end of the viscosity–concentration curves is due to a stiffening effect of the ionic space lattice is correct, there should be no such negative curvature manifested in solutions of non-electrolytes. Accurate measurements of the viscosity of such solutions at very low concentrations are very scarce in the literature. The best examples known to us are the data of Grüneisen on sucrose and of Washburn and Williams[20] on raffinose at three temperatures. Grüneisen's measurements extend down to 0.01 molal and according to Grüneisen may be accurately represented by the equation

$$\eta = 1 + 0.8816c + 0.7970c^2$$

and thus show no evidence of negative curvature at low concentrations or of any influence which is proportional to the square root of the concentration. The measurements of Washburn and Williams on raffinose extend down to 0.038 molal and also give no indication of a negative curvature at the dilute end of the viscosity-concentration curves. Further corroboration is given by the measurements of Chadwell[21] on aqueous solutions of methyl acetate, ethyl acetate and diethyl ether, which, although not extending to as great dilution as would be desirable to test this question, nevertheless show no indication of a negative curvature at the dilute end of the viscosity–concentration curves.

It may be predicted from our equation that at very low concentrations the viscosity of solutions of all strong electrolytes will be greater than that of water, including salts which at moderate concentrations show diminished viscosity. So far as we are aware, the only published measurement which shows that even those salts which cause diminished viscosity at moderate concentration will give an increase in viscosity at extreme dilutions is by Schneider,[9] who reports a relative viscosity of 1.0008 for 0.05 N potassium chlorate, and viscosity of less than 1 for solutions of 0.1 to 0.5 N potassium chlorate. We expect to test this prediction experimentally in the near future.

Grateful acknowledgment is made to Professor Theodore Lyman, Director of the Jefferson Physical Laboratory, for permission to work in that Laboratory and for making available to us its standard clock. We also wish to express our appreciation for a grant from the Milton Fund of Harvard University for the expenses of this research.

Summary

1. Measurements have been made on the viscosity of solutions of barium chloride at 25° covering the range 0.005 to 1.0 molal.

2. The fluidity (reciprocal of the viscosity) of these solutions can be computed within the limit of error of the data from the equation

$$\varphi = 1 - 0.02013\sqrt{c} - 0.20087c$$

3. It is shown that an equation of the form $\varphi = 1 + A\sqrt{c} + Bc$ can be made to fit the data by proper choice of the values of A and B in the case of many other salts for which precise data are available extending to low concentrations.

4. The value of A is negative for all strong electrolytes for which accurate data are available. This term probably represents the stiffening effect on the solution of the electric forces between the ions which tend to maintain a space lattice structure. The value of A is zero for non-electrolytes.

5. The value of B may be either positive or negative. Most salts resemble barium chloride in causing an increase in viscosity or a decrease in fluidity at all concentrations giving a negative value to B. In such cases the equation is apparently valid up to about 1 molal.

6. Some salts cause an increase in the fluidity or a decrease in the viscosity over a wide range of concentration, so that the value of B in our equation is positive. In such cases the equation is apparently valid up to nearly 0.2 molal.

THE DETERMINATION OF ALUMINUM IN PLANTS. II. ALUMINUM IN PLANT MATERIALS[1]

BY O. B. WINTER AND O. D. BIRD

RECEIVED JUNE 12, 1929 PUBLISHED OCTOBER 5, 1929

The biological significance of the use of aluminum in food materials, water purification, cooking utensils, etc., has been a live problem during the last one or two decades. Because of this, the aluminum content of plants has been considered of importance, even though the amount present may be small.

Langworthy and Austin,[2] Gonnerman,[3] Bertrand[4] and more recently

Myers and Voegtlin,[5] Gray,[6] McCollum, Rask and Becker,[7] and others have made quantitative determinations of aluminum in plant materials. All of these analysts, with the exception of McCollum, Rask and Becker, found aluminum present in these materials. The differences in the results obtained by these analysts, however, indicate that there is considerable variation in the aluminum content of some of the materials analyzed or that some of the materials were contaminated more than others. Because of these variations and because of the present interest in the aluminum content of foods, a number of plants and plant materials were analyzed for this element by the colorimetric method[8] described in an earlier article. The work herein presented gives the method used for preparing the samples for analysis and also the results of aluminum determinations.

Experimental Part

Preparation of the Material.—Since the real problem at hand was to determine the amount of aluminum in the materials as they are used for food, the samples were prepared in practically the same way as in the ordinary preparation for table use. The impurities were removed when possible by carefully washing the materials with water and a brush. When the impurities were not readily removed by this method, as in the case of some roots, the contaminated spots were scraped with a knife and then washed. All fresh materials were dried at approximately 35°. The moisture was determined. The dry materials were ground so as to pass a 20-mesh sieve and stored in stoppered bottles.

Preparation of the Sample.—From 1 to 30 g. of material (depending on the amount of aluminum present) was placed in a platinum dish in an electric muffle, the temperature was raised to just below redness and allowed to remain overnight. Any unburned carbon at this point was ignored, since it could be ignited later. The ash was digested with hydrochloric acid, centrifuged, the supernatant liquid decanted and the residue washed once with about 5 cc. of water by means of the centrifuge and decantation. Since it was found that the aluminum in the ash was not always entirely dissolved by hydrochloric acid, the residue was washed into a platinum crucible by means of a fine jet of water, the water evaporated, the residue ignited if necessary, fused with 0.5 g. each of sodium and potassium carbonates, taken up with hydrochloric acid and added to the original solution.[9]

Determination of Aluminum.—After adding a few drops of nitric acid and boiling to oxidize the iron and removing the silica by dehydration, the solution was transferred to a centrifuge tube of about 25-cc. capacity with marks at 15.20 and 25 cc. The iron

[9] The wet method (digesting the sample with sulfuric and perchloric acids) used by Myers and co-workers was tried. The method proved entirely satisfactory when only a comparatively small sample was used, *e. g.*, 1 g. However, since the blank on the reagents was appreciable, in cases where only a small amount of aluminum was present, it was found much more satisfactory to ash a larger sample, carry it through to where the iron is separated and then take an aliquot of the solution.

and aluminum were precipitated and the iron was separated by the method of Myers. Mull and Morrison[10] (practically all of the materials analyzed contained sufficient iron to carry down the aluminum but did not contain phosphoric acid enough to insure complete precipitation of the iron and aluminum as phosphates; hence no iron but about 0.10 g. of ammonium hydrogen phosphate was added to each sample). The solution was made up to a volume of 25 cc. An aliquot was transferred to a 50-cc. volumetric flask, a small piece of litmus paper was added, then water to make a volume of about 20 cc., and finally hydrochloric acid until the litmus paper just turned red. The aluminum was determined by the colorimetric method previously mentioned.

The Blank.—Among the reagents used for making aluminum determinations, sodium hydroxide, sodium carbonate and potassium carbonate contain aluminum. Ordinary C. P. sodium hydroxide is not suitable for this work, but samples specially prepared from metallic sodium were obtained which contained very little of the element. The carbonates contained only a very small amount. In every case, however, it was found necessary to run a blank on all the reagents used and make a correction.

Comparison of Methods.—In order to check the method herein used for making aluminum determinations, the combined iron and aluminum were determined in each of three plant materials by the method described by Patten and Winter.[11] The iron was also determined colorimetrically by the method described in the same paper and the aluminum by the method herein referred to. The results of this work are found in Table I.

TABLE I

COMPARISON OF METHODS

Sample	$FePO_4 + AlPO_4$, %	Fe, %	Al, %	Calcd. to $FePO_4 + AlPO_4$, %
1	1.530	0.250	0.141	1.514
2	0.800	.104	.098	0.737
3	.860	.126	.107	.860

The data in Table I indicate that the method herein described gives fairly accurate results.

The Recovery of Aluminum Added to Materials.—In order to show whether or not the aluminum added to materials can be determined, different quantities of aluminum chloride solution were added to four samples of red beets. The samples were ashed and the aluminum was determined. The results are shown in Table II.

TABLE II

RECOVERY OF ALUMINUM

Material	Sample	S. + 0.01 mg. Al	S. + 0.02 mg. Al	S. + 0.03 mg. Al
Al found, mg.	0.0038	0.0130	0.0230	0.0325

These results indicate that added aluminum can be accurately determined.

Table III gives a list of plant materials on which aluminum determinations were made. Tap water and a few animal products used for food are

materials analyzed in quantities ranging from 2.0 p.p.m. in wheat flour to 325.0 p.p.m. in peanut shells. It should be noted here that in all cases where the aluminum content ran unusually high (peanut shells, lettuce, carrot tops, beet tops, etc.) the sample was of such material that the adhering impurities could not be completely removed.

Since in the analyses made of the materials in Table III no special precautions were taken to remove the outer surfaces which undoubtedly were contaminated, samples of four different materials were cleaned and pared so as to remove all of the exterior portions. These were carefully dried, ground in an iron mortar and analyzed for aluminum. The results of these analyses and four blanks which were run at the same time are shown in Table IV.

TABLE IV

ALUMINUM IN FOUR SPECIALLY PREPARED MATERIALS

Material	Sample, g.	Aluminum Mg.	Aluminum P.p.m. corr. for blank
Apples	1.00	0.0145	5.2
Red beets	2.50	.0240	5.9
Potatoes	2.50	.0197	4.2

Blanks		0.0090 0.0098	
		0.0083 0.0102	
	Av.	.0093	

The results in Table IV show that aluminum was found present in each of the materials analyzed or that some other element was present which reacted like aluminum with the dye. Since all elements known to interfere with this reaction had been removed, we conclude that aluminum was a constituent of these materials.

Summary and Conclusions

1. A method is given for the preparation of plant materials for making colorimetric aluminum determinations.
2. The results of determinations of aluminum in 76 samples of materials are presented.
3. Aluminum was found present in all of the samples examined.
4. Four samples which were carefully prepared by removing the external surfaces so as to avoid contamination were analyzed and aluminum was found present in each of them.

EAST LANSING, MICHIGAN

[CONTRIBUTION FROM THE RESEARCH LABORATORIES OF THE STANDARD OIL DEVELOPMENT COMPANY]

A NEW PETROLEUM BY-PRODUCT: OCTANESULTONE

BY E. L. BALDESCHWIELER AND H. A. CASSAR

RECEIVED OCTOBER 27, 1928 PUBLISHED OCTOBER 6, 1929

In the process for the manufacture of the higher secondary and tertiary alcohols such as isopropyl, secondary butyl, amyl and hexyl alcohols, etc., as used in the alcohol plant of the Bayway Refinery of the Standard Oil Company of New Jersey, the permanent gases from the stills are scrubbed first through a strong solution of sulfuric acid. The unsaturated compounds such as olefins are thus extracted by the acid. The latter is then diluted with water and hydrolysis takes place with the separation on the surface of a dark liquid of a very disagreeable odor and of high sulfur content. The latter is then drawn off and on cooling and standing deposits a black material. From this substance a new compound has been separated by extraction with hot benzol and precipitation with gasoline, whereupon a large crop of crystals was obtained which were found to consist of a single compound of the empirical formula $C_8H_{16}SO_3$ melting at 129.[1]

Structural **Formula.**—The structural formula  $C_5H_{11}\overset{O}{C}HCH_2CH_2\text{—}SO_2$ was assigned to this compound from the data and deductions given below,

The empirical formula is $C_8H_{16}SO_3$, and molecular weight determinations show the compound to be monomolecular.

The compound does not form salts with dilute alkalies in the cold and reacts neutral to indicators; therefore it does not contain a free acid group.

The compound reacts acid on boiling with water; therefore it must contain an acid group bound up with an hydroxyl group, since the compound does not contain nitrogen.

The compound gives no bromine number and so does not contain an unprotected double bond; it cannot be brominated in a boiling solution of acetic acid and sodium acetate, and therefore can scarcely contain an aromatic nucleus.

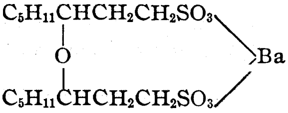
The compound is not attacked by boiling acetyl chloride and hence can scarcely contain any free hydroxyl groups.

The compound on heating with dilute sulfuric acid under pressure and also on distillation over caustic potash liberates sulfur dioxide and yields a number of isomeric octanes and octenes boiling mainly around 110 to 116°; this splitting off of sulfur dioxide is characteristic of sulfonic acids.

On refluxing the compound with barium hydroxide a barium salt is obtained, the analysis of which agrees with the formula

---

[1] The compound was isolated by E. L. Baldeschwieler, who first purified it and determined its empirical formula and physical constants; the chemical properties and structure were worked out by H. A. Cassar.



This formula represents the anhydride of the barium salt of an hydroxyoctanesulfonic acid. All attempts to prepare the hydrated compound failed; the silver salt was prepared by double decomposition from the barium salt and the potassium salt from the original compound by means of potassium hydroxide. These salts were found to be anhydrides, too, and were prepared to determine whether the double valency of the barium atom might have had any effect in promoting closure of the ring with elimination of the elements of water; this effect was not observed to take place.

In a further search for the hydrated salt hydrolysis with mild alkalies was tried, but sodium carbonate yields the same salt, and barium carbonate yields a crystalline salt which is also anhydrous and a sirup, both of which derivatives were proved to be different from the salt by barium hydroxide.

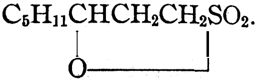
The simplest member of the oxysulfonic acids is oxyethanesulfonic acid (isathionic acid), $HOCH_2CH_2SO_3H$, and when the barium salt of this acid is heated to 190 it loses the elements of water and changes into di-isathionic acid (di-ethyl ether β,β'-disulfonic acid).[2] It is not surprising, therefore, that when dealing with a higher member of this series containing eight carbon atoms the anhydrides should be the compound obtained, as the stability of organic compounds diminishes with increase in the length of the carbon chain, and anhydrides are generally more stable than hydrates.

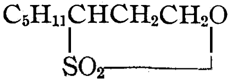
When the barium salt by barium hydroxide or the sirup by barium carbonate are treated with dilute mineral acids and refluxed, the original compound separates out.

This hydrolysis by means of dilute alkalies and reformation by means of acids is characteristic of carboxylic and sulfonic acid lactones; the great solubility of the alkaline salts incidentally excludes carboxylic acids altogether.

All that remains now is to determine whether the amyl grouping in the compound is a straight or a branched chain and to characterize it. Unfortunately this point is still obscure. The main difficulty is the lack of intermediate compounds such as amyl- and hexyl halides and olefins of known constitution and well-defined methods for identifying them in small quantities, which makes the remaining part of the problem almost hopeless of solution at the present time.

Since we are dealing with a sulfonic acid lactone with an octane group in it, and since all sulfonic acid lactones so far prepared in the aromatic series are γ-lactones, we must have a compound of the structure $C_5H_{11}\underset{\llcorner O}{C}HCH_2CH_2\underset{\lrcorner}{SO_2}$. The structure $C_5H_{11}\underset{\llcorner SO_2}{C}HCH_2CH_2\underset{\lrcorner}{O}$ is highly im-





---

[2] Carl, *Ber.*, 14, 65 (1881).

probable since primary alcohols are known not to form sulfonic lactones (see below) and also all alcohols made from olefins and sulfuric acid are secondary or tertiary. This compound we propose to call octane-sultone to fall in line with the present accepted nomenclature in the aromatic series.

Naphthsultone,  , discovered by C. Mensching, examined by G. Schultz[3] and further investigated by H. Erdmann,[4] who invented the name sultone for this class of compound, contains three carbon atoms in the lactone group and is, therefore, a γ-sulfonic lactone. Ortho-phenol sulfonic acid, which could only give a β-sulfonic lactone, does not form a ring compound at all, but o-benzyl alcohol sulfonic acid forms a γ-sulfonic lactone called benzyl-sultone by the discoverers, W. Marckwald and H. H. Frahne.[5] All this leads one to expect the present sultone to be gamma; $CH_2OHCH_2CH_2SO_3H$ was also prepared by the latter co-workers and no lactone could be prepared from it, probably because the hydroxyl group is a primary alcohol.

TABLE I

SOLUBILITIES

	Octane-sultone	Benzyl-sultone	Naphthsultone
Cold water	Slight	Slight	?
Hot water	Medium	Medium	?
Cold alcohol	Slight	Slight	Slight
Hot alcohol	Very	Very	?
Chloroform, hot and cold	Very	Very	Very
Hot benzol	Very	Very	Very
Ligroin	Very slight	Very slight	?

Both octane-sultone and naphthsultone give flat transparent glassy crystals on slowly evaporating their benzol solutions, and all three can be sublimed; octane-sultone and benzyl-sultone are volatile in steam and naphthsultone distils unchanged.

All three sultones are dissolved by hot but not cold strong alkali, and the free acids of naphthsultone and benzyl-sultone are stable and are only changed back into the sultones by such drastic treatment as sublimation or phosphorus pentachloride, while octane-sultone changes from the free acid into the sultone by standing in warm dilute acid solutions overnight. Naphthsultone is not dissolved by alkali carbonates while octane-sultone is. As can be seen from the above comparison, the general properties of the three sultones are very similar.

Halogenation.—Octane-sultone cannot be brominated, but its alkaline salts, of which there are three varieties, absorb bromine very rapidly in

---

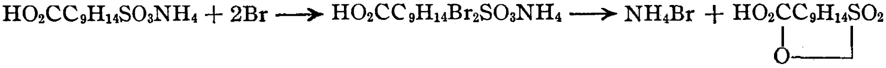
[4] Erdmann, Ann., 247,344 (1888).

[5] Marckwald and Frahne, *Ber.*, 31,1898 (1898).

alkaline solution with reformation of the sultone ring. This is scarcely odd, since Géza Braun, for instance, found that the lactone of hydroxyisocrotonic acid had maximum ability to absorb bromine only immediately after saponification.[6] Also, when ammonium hydrogen sulfocampholenecarboxylate is treated with bromine in aqueous solution, a white precipitate of the brominated sultone is thrown down.[7]



$$HO_2CC_9H_{14}SO_3NH_4 + 2Br \longrightarrow HO_2CC_9H_{14}Br_2SO_3NH_4 \longrightarrow NH_4Br + HO_2CC_9H_{14}SO_2$$

Type A salt, obtained by hydrolysis of the sultone with barium or calcium hydroxide, with sodium or potassium hydroxide and with sodium or potassium carbonate, absorbs two atoms of halogen in aqueous solution, yielding a monohalogen derivative with immediate reformation of the sultone ring. The position of the halogen atom is unknown but it is probably adjacent to the sulfonic group. On refluxing these halogenated octanesultones with strong alkali, they hydrolyze to easily crystallizable salts of oxyhalogenoctanesulfonic acids; the halogen atom is not hydrolyzed off, even on fusion with caustic soda. All attempts to reduce the halogen atom failed; a zinc–copper couple is sufficiently alkaline to yield the zinc salt of the oxyhalogenoctanesulfonicacid. The free acid was prepared from the barium salt through the lead salt followed by hydrogen sulfide and was found to be extremely soluble in water and not to show any tendency to reform the sultone. It is probable that the halogen atom is next to the sulfonic group, the sulfonic group hindering the hydrolysis and reduction of the halogen group, and the halogen group hindering the ring-closing tendency of the sulfonic group.

Type B salt, obtained by hydrolyzing the sultone with barium carbonate, is a sirup, and absorbs halogens like those of Type A, yielding monohalogen derivatives with immediate reformation of the sultone ring. These halogenated sultones of Type B are isomeric with those of Type A, but either strong or mild alkali splits off the halogen atom as halogen acid and at the same time hydrolyzes the sultone ring to give a salt that cannot be crystallized. On treating this sirup with warm dilute mineral acids the unsaturated sultone is obtained that crystallizes from dilute alcohol in beautiful white needles.

Here too the double bond and hence the original halogen atom must be in close juxtaposition with the sulfonic group, probably in the β-position with respect to it as the unsaturated sultone, which does not absorb bromine in the ring form, absorbs one atom of halogen by displacement in the form of its alkaline salts to give an unsaturated halogenated octane-sultone; here too the sultone ring is reformed at the instant of halogenation.

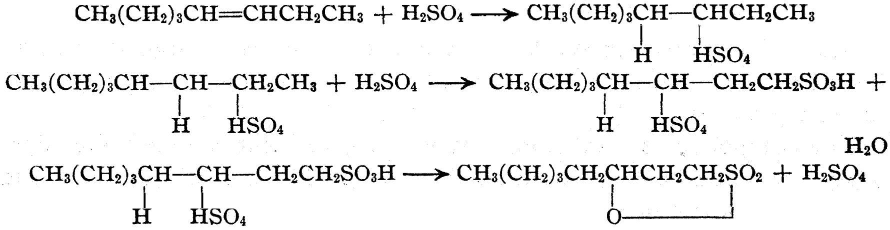
[7] Harvey and Lapworth, J. Chem. *Soc.*, **83**, 1102 (1903).

Enough is already known about unsaturated sulfonic acids in the aliphatic series to make this reaction seem plausible; for ethylene sulfonic acid absorbs bromine by substitution and not by addition.[8]

Type C salt, obtained by hydrolyzing the sultone with excess barium or calcium carbonate, is easily crystallized; it is completely isomeric with salts of Type A, being also the salt of an anhydride; treating this salt with warm dilute mineral acids does not give back the original sultone as with Types A and B but the sulfonic group is split off and an olefin boiling at i13 to 115° is obtained. Also, on halogenation the sulfonic group is split off and a mixture of octane mono and di-halides is the result. On treating salts of Type C with free iodine in warm aqueous solution alkyl iodides are obtained which decompose readily on steam distillation to olefins, which indicates that these alkyl halides are secondary or tertiary derivatives, since primary iodides as a rule can be steam distilled.

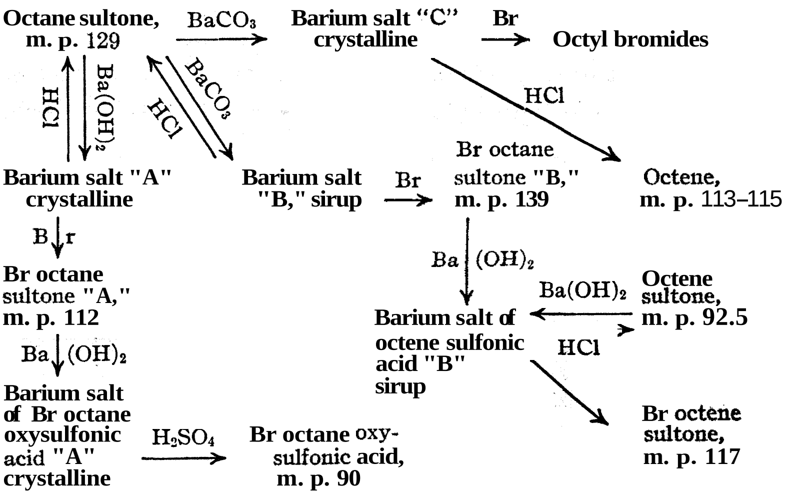
Octane-sultone, unlike carboxylate lactones, is not attacked by phosphorus pentachloride or acetyl chloride; the alkaline salts Types A and B are decomposed by the former and changed back by the latter into the original sultone.



$$CH_3(CH_2)_3CH{=}CHCH_2CH_3 + H_2SO_4 \longrightarrow CH_3(CH_2)_3\underset{H}{CH}{-}\underset{HSO_4}{CH}CH_2CH_3$$

$$CH_3(CH_2)_3\underset{H}{CH}{-}\underset{HSO_4}{CH}{-}CH_2CH_3 + H_2SO_4 \longrightarrow CH_3(CH_2)_3\underset{H}{CH}{-}\underset{HSO_4}{CH}{-}CH_2CH_2SO_3H + H_2O$$

$$CH_3(CH_2)_3\underset{H}{CH}{-}\underset{HSO_4}{CH}{-}CH_2CH_2SO_3H \longrightarrow CH_3(CH_2)_3CH_2\underset{O\text{———}}{CH}CH_2CH_2\underset{\text{—}|}{SO_2} + H_2SO_4$$



REACTIONS OF OCTANE-SULTONE

---

[8] E. P. Kohler, *Am. Chem. J.*, 20, 680 (1898).

The formation of this octane-sultone in the alcohol plant is still rather obscure; ordinary ethyl alcohol is known to react with fuming sulfuric acid by the well-known carbyl sulfate reaction to yield an hydroxyethylsulfonic acid and a similar reaction might occur here. Another explanation is given in the preceding series of reactions.

Experimental

Extraction and Purification of the Octane-sultone.—The crude material is grayish black and so finely divided as to appear amorphous. It was pulverized in a mortar with repeated additions of cold gasoline until all odor of the original mother liquor was removed as well as any adhering oil, that is, until the last gasoline wash became colorless. The residue was then extracted with boiling 90% benzol and filtered. A fine crop of crystals was produced by adding three volumes of gasoline to the benzol solution. The precipitation under these conditions is practically complete after standing overnight. The excess solvent was drained from the crystals, the latter were redissolved in benzol and again precipitated with three times the volume of gasoline. The gasoline used was normal benzine, a specially treated and steam distilled product which was free from heavy oils and unsaturated compounds. The process was repeated, the resulting crystals were dried for two days at 85°, pulverized and dried again overnight at 85°.

Anal. Calcd. for $C_8H_{16}SO_3$: C, 49.97; H, 8.33; S, 16.75; O, 24.95. Found: C, 49.70; H, 8.64; S, 16.73; O (by difference), 24.93; N, none; ash, none.

The molecular weight was determined by the freezing-point method using benzol as solvent and was found to be 188 as compared with the theoretical molecular weight, 192.

The compound is very stable; it has a very faint camphor-like odor, especially when heated. It melts sharply at 129° and sublimes without decomposition when melted in small quantities. When melted in large quantities, partial decomposition takes place with evolution of sulfur dioxide and a black tarry mass is left behind. It distils very readily with steam and can also be purified by crystallization from hot water, from which it comes out in long prismatic needles belonging to the monoclinic system. It can also be purified by evaporation of the benzol solution.

TABLE II

SOLUBILITY IN VARIOUS SOLVENTS

Solvent	Temp., °C.	Wt. %	Solvent	Temp., °C.	Wt. %
Water	100	1.55	Methyl alcohol	20	13.15
Water	20	0.025	Abs. ethyl alc.	20	4.98
Ethyl ether	20	4.84	Ethyl alc. 95%	20	5.21
Benzene, 90%	20	25.88	Isopropyl alc.	20	4.37
Chloroform	20	55.57	Normal benzine (above)	20	0.22
Acetone	20	52.43			

Specific gravity at 20°, 1.2973.

The yield from the original material as obtained from the refinery was as follows

Adhering oils	62.35%	soluble in benzol
$C_8H_{16}SO_3$	19.45%	
Residue	18.20%	insoluble in benzol
Total	100.00%	

The above insoluble residue, which was of a light gray color, was pulverized, dried at 60° and found to have the following composition

Analysis of residue insoluble in benzol

Ferrous sulfate	82.08%	
Sodium sulfate	1.40%	
Free sulfuric acid	0.26%	
Water of crystallization	13.16%	(by difference)
Silica	0.35%	
Basic ferrous sulfate	2.75%	(water insoluble)
Total	100.00%	

It is thought possible that the presence of such a large quantity of ferrous sulfate might help the formation of the sultone by maintaining reducing conditions in the solution.

Barium Salt Type "A" of Octane-sultone.—Fifty grams of octane-sultone is refluxed for four hours with 30 g. of barium hydroxide in 500 cc. of water in a 2-liter flask to avoid foaming over; the sultone goes completely into solution, the hot liquid is filtered to remove traces of insoluble matter, diluted with twice its volume of water to facilitate precipitation of the barium carbonate and saturated with carbon dioxide. The barium carbonate is filtered off and the liquid is carefully evaporated to dryness on the water-bath. It is purified for analysis by dissolving it in a mixture of absolute alcohol and ether, filtering and blowing air over the solution until crystals appear, when it is left in the ice box for an hour to finish the crystallization. The third or fourth recrystallization gives fine white needles. The salt can be crystallized from water but on drying it decomposes partially and the barium content is high. The silver salt is prepared by double decomposition of the barium salt with silver sulfate suspended in water, and is purified by crystallization from acetone. The potassium salt is prepared from octane-sultone and potassium hydroxide and is purified by dissolving in a mixture of absolute alcohol and benzol, adding gasoline and evaporating by blowing a current of air over the solution.

Anal. Calcd. for $C_{16}H_{32}O_7S_2Ba$: Ba, 25.50. Found: Ba, 25.58, 25.61, 25.57, 25.50. Calcd. for $C_{16}H_{32}O_7S_2Ag_2$: Ag, 34.97. Found: Ag, 35.22. Calcd. for $C_{16}H_{32}O_7S_2K_2$: K, 1633. Found: K, 16.46.

Octane-sultone from Barium Salt Type "A."—Twenty grams of octane-sultone is refluxed for four hours with 10 g. of barium hydroxide and 100 cc. of water, the filtered solution is treated with enough sulfuric acid in the cold to precipitate all of the barium, then with enough concentrated sulfuric acid to make up a 5% solution and refluxed for an hour. The octane-sultone comes out as an oil that solidifies on cooling; yield of crude product, 10 g. The crude material is purified by recrystallization from alcohol and melted at 129°; a mixture of this substance and some of the original octane-sultone melted at 129°, too.

Bromo-octane-sultone Type "A*"—Twenty-five grams of octane-sultone is refluxed with 200 cc. of a 15% solution of potassium hydroxide for twenty hours, or until all of the sultone is dissolved. To the cooled solution bromine is carefully added until the contents turn red, excess bromine is removed by acidifying and adding sodium sulfite, and the whole is cooled in ice until the pasty precipitate has turned brittle so that it can be collected on a Büchner funnel; yield of crude material, 34 g. against 35.3 g. theoretical. The compound is purified by crystallization from alcohol, from which solvent it comes out in fine white needles; m. p. 112°.

Anal. Calcd. for $C_8H_{15}BrSO_3$: C, 35.50; H, 5.57; S, 11.81; Br, 29.44. Found: C, 35.32; H, 5.67; S, 12.40; Br, 29.10.

The chlorine derivative was made in the same way, chlorine gas being bubbled into the solution until a test sample did not decolorize bromine water; m. p. 122.5".

Anal. Calcd. for $C_8H_{15}ClSO_3$: C, 42.46; H, 6.66; S, 14.12; Cl, 15.62. Found: C, 42.86; H, 6.86; S, 13.99; Cl, 15.68.

From 0.1 to 0.3 g. of the purified barium salt of the octane-sultone Type "A" was dissolved in water and titrated with $N/10$ bromine in glacial acetic acid. The end-point is so sharp that a back-titration is not required, the first appearance of a faint yellow color persisting for a few minutes being taken as the end-point. The atoms of bromine required per molecule of $C_{16}H_{32}S_2O_7Ba$ were in one case 3.98 and in another case 3.96. This indicates that the reactiop proceeds thus

$$C_{16}H_{32}S_2O_7Ba + 2\ Br_2 \longrightarrow 2C_8H_{15}BrSO_3 + BaBr_2 + H_2O$$

The same bromine derivative was made from solutions prepared by hydrolyzing octane-sultone with barium hydroxide, with sodium hydroxide or with sodium or potassium carbonate in 20% concentration.

Hydrolysis of the Bromo-octane-sultone Type "A."—Fifty grams of bromo-octane-sultone Type "A" was refluxed with one liter of water, to which was added 1.5 moles of barium hydroxide, for two hours or until the bromine derivative went into solution; the liquid was filtered hot and allowed to cool, when a crop of the barium salt crystallized out and was purified by crystallization from alcohol. The potassium salt was prepared in the same way. They are both anhydrous.

Anal. Calcd. for $C_{10}H_{30}Br_2S_2O_7Ba$: Ba, 19.73. Found: Ba, 19.77, 19.85, 19.72. Calcd. for $C_{16}H_{30}Br_2S_2O_7K_2$: K, 12.27. Found: K, 11.64.

Preparation of Free Bromo-octane-oxysulfonic Acid.—The barium salt of the sulfonic acid was changed into the free acid by dissolving it in water, in which it is quite soluble, adding a slight excess of sulfuric acid to precipitate all the barium, boiling the filtrate with lead carbonate to remove excess sulfuric acid, filtering, precipitating the lead with hydrogen sulfide, refiltering and carefully concentrating on the water-bath to a sirup, which crystallizes in a few days. This solid is then dried by pressing onto porous plates and is purified by crystallizing several times from benzol; m. p. 90°. The presence of slight traces of mineral acids in the solution gives the compound a purple color.

Barium Salt Type "B" of Octane-sultone.—Twenty-five grams of octane sultone was refluxed for twelve to sixteen hours with 14 g. of barium carbonate and 50 cc. of water, the hot liquid is filtered to remove traces of insoluble matter, and cooled. Should any of the barium salt crystallize out it is removed, as the crystallizable salt is Type "C;" the filtrate can be concentrated down to a sirup but will not crystallize out.

Bromo-octane-sultone Type "B."—The sirupy barium salt Type "B" is diluted with water and to the cooled solution bromine is added until the upper layer turns red, excess bromine is removed by acidifying and adding sodium sulfite and the whole is cooled in ice until the pasty precipitate has turned brittle so that it can be collected on a Buchner funnel. A certain amount of a brominated oil will always be formed and run through the Buchner funnel into the receiver; this comes from the barium salt Type "C" which is always present to a certain extent. The precipitate is purified by crystallization from alcohol, from which solvent it comes out in fine white needles; m. p. 139°. The chlorine derivative is made in the same way; m. p. 118.5°.

Anal. Calcd. for $C_8H_{15}BrSO_3$: C, 35.50; H, 5.57; S, 11.81; Br, 29.44. Found: C, 35.65; H, 5.80; S, 12.30; Br, 29.49; 29.32, 30.00.

Anal. Calcd. for $C_8H_{15}ClSO_3$: C, 42.46; H, 6.66. Found: C, 42.79; H, 6.90.

Hydrolysis of Chloro-octane-sultone Type "B" and Subsequent Closing of Sultone Ring to Form Octene-sultone.—Ten grams of octane chloro-sultone Type "B" is refluxed with 15 g. of barium hydroxide in 80 cc. of water for an hour, the solution is cooled, a slight excess of sulfuric acid is added and the barium sulfate filtered off. Ten cc. of concentrated sulfuric acid is then added to the filtrate, which should amount to about 200 cc., and the acid solution is refluxed for an hour to close the sultone ring. The sultone comes out as an oil which solidifies on cooling; it is collected on a Buchner funnel and dried at 60°; yield, 7.3 g. of crude substance or 86% of the theoretical. The crude is purified by repeated crystallization from dilute alcohol, from which it comes out in beautiful white needles over an inch long; m. p. 92.5".

Anal. Calcd. for $C_8H_{14}SO_3$: C, 50.59; H, 7.40; S, 16.79. Found: C, 50.67; H, 7.59; S, 17.26.

The barium salt of this unsaturated sultone is a sirup; hydrolysis of the chlorosultone lactone Type "B" in acid solution causes decomposition.

Preparation of Bromo-octene-suitone.—About ten to twenty grams of the sodium salt of octene sultone in aqueous alkaline solution is treated with bromine until a permanent yellow color is obtained. The precipitate is crystallized from alcohol; m. p. 117°.

Anal. Calcd. for $C_8H_{13}BrSO_3$: C, 35.77; H, 4.87; S, 11.97; Br, 29.66. Found: C, 35.93; H, 5.13; S, 12.55; Br, 29.96.

Calcium Salt Type "C" of Octane-sultone.—Twenty-five grams of octane-sultone is refluxed with nine grams of calcium carbonate and 400 cc. of water overnight, the solution is filtered hot and concentrated. The calcium salt comes out in white pearly plates; yield, first crop, 9.8 *g.*; second crop, 9 g.; third crop, 7.5 g.

The barium salt was made in the same manner, using a larger excess of barium carbonate; the yield is not as good.

Anal. Calcd. for $C_{16}H_{32}O_7S_2Ba$: Ba, 25.50. Found: Ba, 25.21, 25.35.

Octyl Bromides.—On treating the above salts in alkaline solution with bromine a heavy oil is deposited that on distillation under vacuum gives a lighter fraction lighter than water and a heavier fraction heavier than water. Purification was not successful.

Octene.—Two hundred and fifty grams of the calcium salt of octane-sultone Type "C" was dissolved in 1000 cc. of water, a slight excess of sulfuric acid added to precipitate all the calcium and the mixture was steam distilled. An octene came over and was carefully fractionated twice; yield of crude olefin, 130 g. (61%). 96% of this olefin distils between 113 and 115°, the remainder between 110 and 113°. Repeated distillation does not effect a further separation. The olefin does not give a solid nitrosochloride.

Anal. Bromine absorbed: 171, 169 g. per 112 g. of olefin, as against 160 g. required for C_8H_{16}.

Acknowledgment.—The writers wish to express their appreciation and thanks to M. G. Gardella for his carbon and hydrogen determinations and to C. C. Callis for the molecular weight determination.

Summary

1. A compound of empirical formula $C_8H_{16}SO_3$ has been obtained from one of the by-products of the manufacture of alcohols at the Bayway Re-

finery of the Standard Oil Co. (N. J.) and separated as crystals of a high degree of purity.

2. The compound is undoubtedly an octane-sultone, since its behavior is strictly analogous to that of sultones in the aromatic and camphene series.

3. On refluxing with alkalies various alkaline salts are obtained whose different chemical properties are explained by a shifting of the double bond generated from the hydroxyl group.

4. Attempts are now being made to synthesize sultones in the aliphatic series.

5. The compound is interesting to the petroleum technologist as it is volatile in steam; hence aliphatic sultones may be partly responsible for the sulfur content of refined gasolines.

REACTIONS OF VINYL CHLORIDE AND BENZENE IN THE PRESENCE OF ALUMINUM CHLORIDE

BY JAMES M. DAVIDSON WITH ALEXANDER LOWY

RECEIVED JANUARY 23, 1929 PUBLISHED OCTOBER 5, 1929

The purpose of this investigation has been to study the reactions of vinyl chloride and benzene in the presence of aluminum chloride, under variable conditions, in order to determine the course of the reactions and to study the products formed. These reactions seemed important since vinyl chloride has recently been prepared in large quantities.

Boeseken and Bastet[1] found that vinyl chloride and benzene condensed in the presence of a catalyst made from aluminum and mercuric chloride, and produced chiefly unsymmetrical diphenylethane and a small quantity of 9,10-dimethyldihydro-anthracene. Vinyl bromide and benzene were found to react in the presence of aluminum chloride by Angelbis and Anschütz,[2] and Anschütz,[3] and yielded the identical products described by Boeseken and Bastet. Hanriot and Guilbert[4] obtained products believed to have been β-bromo-ethylbenzene and *p*-di-(β-bromo-ethyl)-benzene in the same reaction.

From the nature of the Friedel–Crafts reaction, styrene would be expected as an intermediate in the reaction under consideration. Schramm[6] obtained unsymmetrical diphenylethane from the reaction between styrene, benzene and aluminum chloride, but Boeseken and

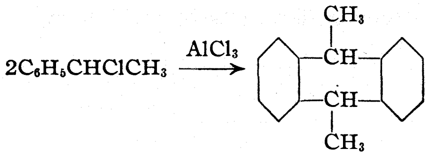
[5] *J. Schramm, Ber.,* 26,1709 (1893).

Bastet described polymerization of styrene under these conditions. The present investigation showed that styrene did polymerize in the presence of benzene and aluminum chloride, and could not have been an intermediate in the reaction between vinyl chloride, benzene and aluminum chloride. Unsymmetrical diphenylethane and an anthracene-type resin were the main products isolated and under special conditions 9,10-dimethyldihydro-anthracene was also obtained. In previous work no mention has been made of this resin.

The following schematic outline substantiated the reactions given by Boeseken and Bastet, in which they used the Al–$HgCl_2$ catalyst

$$C_6H_6 + CH_2 = CHCl \xrightarrow{AlCl_3} C_6H_5CHClCH_3 \xrightarrow[C_6H_6]{AlCl_3} (C_6H_5)_2CHCH_3$$



The reactions, as carried out at 0–5°, tended to produce only traces of 9,10-dimethyldihydro-anthracene and relatively large amounts of unsymmetrical diphenylethane and resinous substances. Both of the latter substances were found to decrease if the temperature was maintained at 60–70°, and appreciable amounts of 9,10-dimethyldihydro-anthracene were formed. Similar results were obtained when 0.1 g. of iodine, originally used to prevent the polymerization of styrene, was present.

Experimental

Considerable preliminary experimental work was done to study the rate of addition of vinyl chloride, the temperature effects, and the variation of addition of components to the reaction mixture.

Description of a Typical Experiment.—Fifty grams of anhydrous aluminum chloride and 300 cc. of benzene (thiophene free, dried over sodium) were agitated in a one-liter three-necked flask, provided with an upright condenser, thermometer, gas inlet tube and a stirrer run at 1000–1400 r.p.m., until the aluminum chloride was in a finely divided state. Vinyl chloride gas, supplied in small cylinders by the Carbide and Carbon Chemicals Corporation, was passed into the flask, kept at 0–5°, at such a rate that only a few bubbles of gas escaped from an alkali trap connected to the condenser. No evolution of hydrogen chloride was observed until after an initial period of fifteen to twenty minutes. After 90 g. of gas had been added, all of the hydrogen chloride apparently had been evolved.

The reaction mixture was poured into ice, acidified with hydrochloric acid and, after the heavy black layer had completely disappeared, the fluorescent brown top layer was separated, washed with water and steam distilled. The distillate, consisting chiefly of unreacted benzene, was dried and fractionated. Besides benzene, some ethylbenzene was obtained in the fraction boiling at 130–135°. In no case was a styrene fraction (140–145°) obtained.

The residue from the steam distillation was a very viscous, fluorescent, greenish oil. This was distilled under reduced pressure in a 500-cc. Claisen flask. Water was removed first at 50-mm. pressure, after which unsymmetrical diphenylethane distilled at 130–140° under 12-mm. pressure. The latter was a nearly colorless oil, but possessed a strong violet fluorescence. On redistillation most of the fraction boiled at 134–136° (12 mm.). Above 140° the pressure was reduced to 0.5 mm., and traces of 9,10-dimethyldihydro-anthracene sublimed from 180–200". The residue was poured into a beaker and solidified on cooling to a dark green resin having a reddish fluorescence when in solution.

Occasionally the residue from the steam distillation crystallized on standing. In this event the solid was filtered and crystallized from alcohol. It was identified as 9,10-dimethyldihydro-anthracene, and possessed the following characteristics: yellow platelets, melting at 179–181°, purplish fluorescence in solution. The oily filtrate was distilled as described above.

The following table outlines the purpose, details and results obtained in experiments performed under variable conditions.

TABLE OF RESULTS

Purpose of expt.	Reagents		Temp., °C.	Time, hrs.	Products			
	$AlCl_3$, g.	Vinyl chloride, g.			A, g.	B, g.	C, g.	D, cc.
Variation of reagents	2	90	0–5	2	4	10	tr.	50
	50	90	0–5	2	3	46	tr.	40
	133.5 (1 mole)	90	0–5	2	4	35	tr.	60

			then 60–70	2	15	17	tr.	20

[a] A, Ethylbenzene; B, unsymmetrical diphenylethane; C, 9,10-dimethyldihydro-anthracene; D, resin. 300 cc. of benzene was used in each of the above experiments.

Discussion of Results

A maximum quantity of unsymmetrical diphenylethane was obtained with 50 g. of aluminum chloride. Very small amounts of aluminum chloride gave smaller yields of all the products, while larger amounts of this reagent tended to diminish the yield of unsymmetrical diphenylethane. Holding the aluminum chloride constant and diminishing the amount of vinyl chloride added reduced the quantities of products formed, as expected. Larger amounts of vinyl chloride could not be absorbed by the reaction mixture.

When the reacting compounds were heated from the start, a relatively large amount of 9,10-dimethyldihydro-anthracene was obtained. This could not have been a product at the lower temperature, since heating of the cold reaction product did not cause the formation of this compound.

The amounts of resin and unsymmetrical diphenylethane were decreased in the first instance, but the amount of resin increased at the expense of the unsymmetrical diphenylethane after the reaction products formed in the cold had been heated. This seemed to indicate that the resin was formed by the action of aluminum chloride upon unsymmetrical diphenylethane.

The presence of a trace of iodine was sufficient to accelerate the reaction, for hydrogen chloride was evolved immediately, At the same time there was a relatively large amount of 9,10-dimethyldihydro-anthracene formed and the amounts of resin and unsymmetrical diphenylethane were reduced.

Mercury caused the reduction of α-phenylchloro-ethane, probably formed as an intermediate, to ethylbenzene. The amounts of resin and unsymmetrical diphenylethane were also reduced. The reducing power of mercury accounted for the formation of large quantities of ethylbenzene and polyethylated benzenes obtained during a preliminary experiment, when a mercury-seal stirrer was used.

Effect of Carbon Disulfide.—Carbon disulfide was used as a solvent or diluent in one experiment. Sulfur-containing oils, formed probably by the condensation of vinyl chloride and carbon disulfide, were obtained, but they were not related to the products of the normal reaction.

Study of the Resin.—The resin, which was a brittle, dark green solid possessing a reddish fluorescence in solution, melted at 50–65°. It was soluble in benzene, acetone and glacial acetic acid, slightly soluble in alcohol, but insoluble in water, acids or alkalies. It contained no halogen and therefore was not a vinyl chloride-type resin.

On heating the resin formed a dark green, fluorescent liquid which was very viscous. Although heated to 300°, no *traces* of 9,10-dimethyldihydro-anthracene were observed. Instead of sublimation, there was a noticeable decomposition. When heated to 220° under 0.5-mm. pressure, small amounts of 9,10-dimethyldihydro-anthracene were obtained. Continued heating caused decomposition.

A benzene solution of styrene, when treated with aluminum chloride under the normal experimental conditions, yielded a resin different from those obtained with vinyl chloride, since styrene was obtained by heating it.

Oxidation of a solution of the resin in glacial acetic acid and benzene with chromium trioxide produced anthraquinone, indicating an anthracene-type resin. No crystalline picrate could be obtained from the resin and the exact identity of the hydrocarbon constituent of the resin could not be learned.

Summary

1. The reaction of vinyl chloride and benzene in the presence of aluminum chloride took place with the formation of unsymmetrical diphenylethane, 9,10-dimethyldihydro-anthracene and an anthracene-type resin. No styrene or metastyrene was formed. a-Phenylchloro-ethane has been considered as the most probable intermediate.

2. Increased amounts of aluminum chloride at low temperatures decreased the amounts of unsymmetrical diphenylethane.

3. The amounts of 9,10-dimethyldihydro-anthracene were increased by using a higher temperature, or by the presence of iodine.

4. Mercury caused the formation of ethylbenzene and considerably reduced the amount of resin formed.

5. Certain physical and chemical properties of the resin have been studied.

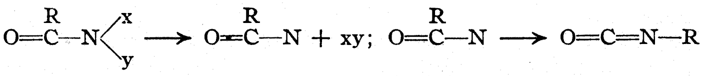
THE BECKMANN REARRANGEMENT IN THE PRESENCE OF FREE RADICALS

BY EVERETT S. WALLIS[1]

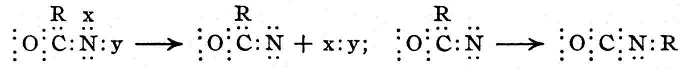
RECEIVED FEBRUARY 23, 1929 PUBLISHED OCTOBER 5, 1929

Of the several theories that have been advanced to explain the rearrangement of hydroxamic acids, halogen amides, acyl azides and other similar classes of compounds, the most successful has been the interpretation by Stieglitz.[2] Assuming the intermediate formation of a univalent nitrogen derivative, he proposed that all rearrangements of this character take place as follows



$$O{=}\overset{R}{C}{-}N\left\langle\begin{matrix}x\\y\end{matrix}\right. \longrightarrow O{=}\overset{R}{C}{-}N + xy;\quad O{=}\overset{R}{C}{-}N \longrightarrow O{=}C{=}N{-}R$$

Jones and Hurd,[3] suggesting an interpretation of the mechanism of these rearrangements based upon the modern conception of chemical bonds and electrons, formulated the rearrangement thus



$$\vdots O \vdots \overset{R}{C} : \overset{x}{\ddot{N}} : y \longrightarrow \vdots O \vdots \overset{R}{C} : \ddot{N} + x : y;\quad \vdots O \vdots \overset{R}{C} : \ddot{N} \longrightarrow \vdots O \vdots C \vdots \ddot{N} : R$$

Their interpretation, which excluded the oximes, assumed that the radical, R, in its wandering from the carbon atom to the nitrogen atom existed momentarily as a free radical, and that the relative ease of rearrangement of such types of compounds depended upon the tendency of the radical, R, in the univalent nitrogen derivative to exist as a free radical. This hypothesis was tested by studying the rearrangement of monophenyl-, diphenyl- and triphenylacethydroxamic acids and their derivatives.

Hurd[4] also found further evidence in support of this hypothesis in his study of certain derivatives of N-diphenylhydroxyurea, $(C_6H_5)_2N$-CO-NHOH.

---

[1] Some of the preliminary experiments in this investigation, including the preparation of materials, etc., were carried out with the help of Mr. Howard W. Gilbert, a graduate assistant in the department.

[4] Hurd, *ibid.*, 45, 1472 (1923).

Continuing these investigations Jones and Wallis[5] studied the nature of the products formed by the rearrangement of certain acid azides and hydroxamic acids in which the group, R, is an optically active radical. d-Benzylmethylacetazide, $C_7H_7(CH_3)HCCON_3$, was found to give on rearrangement an optically active isocyanate, $C_7H_7(CH_3)HCNCO$, which could be converted into an optically active amine hydrochloride, and by treatment with aniline into an optically active monosubstituted urea. These experiments, together with certain other facts taken from a survey of the properties of optically active compounds described in the literature, led them to suggest that it was very probable that in the rearrangement of d-benzylmethylacetazide the optically active radical, R, if existing as a free radical, did so in such *a* way as to maintain a configuration required to produce an optically active rearrangement product; that is, it was, as originally supposed by Jones,[6] a positive radical which is of the nature of a carbonium ion, and that in its wandering from the carbon atom to the nitrogen atom it leaves behind the electron which it shared with the carbon atom.

The Rearrangement of Benzylmethylacetazide in the Presence of a Free Radical.—I have continued these investigations in order to determine the products formed by rearrangement when the rearrangement is carried out in the presence of a free radical; for I believed that such a determination would give further evidence in support of the hypothesis just outlined.

It has been known for some time that triphenylmethyl, because of its preeminent tendency to make addition compounds, is a good reagent for the detection of free radicals. Wieland,[7] for instance, used it in his study of tetraphenylhydrazine, and the assumption that the dehydrophenols[8] contain monovalent oxygen, and that the tetrazanes[9] are dissociable to form triarylhydrazils is based upon the fact that both classes of compounds readily combine with triphenylmethyl. It therefore seemed possible that this same interesting and very reactive compound might be used to advantage in a further study of those classes of compounds that undergo the Beckmann rearrangement. For this investigation benzylmethylacetazide was chosen as a compound typical of this group of substances. It was allowed to rearrange in the absence of air in a benzene solution of triphenylmethyl and the products of the rearrangement were determined. With no triphenylmethyl present the rearrangement has been formulated[6] as follows

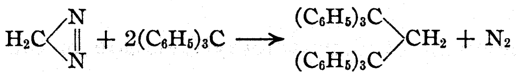
$$\underset{\text{CO N}_3}{\overset{C_7H_7}{\text{H—C—CH}_3}} \longrightarrow \underset{\text{CO N}<}{\overset{C_7H_7}{\text{H—C—CH}_3}} + N_2 \longrightarrow \underset{\text{N=C=O}}{\overset{C_7H_7}{\text{H—C—CH}_3}}$$

However, a little reflection will show that when triphenylmethyl is present two different rearrangement products are possible. (1) If the radical, R, in the univalent nitrogen derivative, in its wandering from the carbon atom to the nitrogen atom exists momentarily as a true free radical, that is, does not leave behind on the carbon atom its electron and so become a positive ion, the formation of two different isocyanates is possible. The radical triphenylmethyl, can then compete with the radical, R, for the univalent nitrogen residue, and the quantity of triphenylmethyl isocyanate, $(C_6H_5)_3CNCO$, so formed would depend on well-known physical-chemical principles. An illustration of such a phenomenon is found in the reaction of diazomethane and triphenylmethyl. Investigations[10] have shown that these two substances react according to the equation



Here, apparently, the free radical, triphenylmethyl, when in the proper concentration, is so successful in its competition with the methylene radical for union with another methylene radical that no ethylene seems to be formed in the reaction.

(2) However, if the radical, R, in its wandering from the carbon atom to the nitrogen atom, leaves behind its electron and becomes a positive ion as suggested by Jones and Wallis,[5] the chances of the formation of any triphenylmethyl isocyanate would be very slight. In fact the radical, R, would then be of an entirely different nature than the free radical, triphenylmethyl, and only the one isocyanate, $C_7H_7(CH_3)HCNCO$, would be expected.

The author's experiments on the rearrangement of benzylmethylacetazide in the presence of triphenylmethyl seem to give further evidence which tends to exclude the first possibility, and to show that the latter view of the rearrangement is the more probable. When a benzene solution of benzylmethylacetazide was added to a benzene solution of triphenylmethyl, and the rearrangement allowed to take place in the absence of air, a quantitative determination of the amount of oxygen absorbed by the free radical remaining after the rearrangement indicates that none of it took part in the reaction, and an analysis of the products of the rearrangement shows that only one isocyanate, $C_7H_7(CH_3)HC\text{-}NCO$, is formed in appreciable amounts.

Experimental Part

Materials.—The benzylmethylacetazide used in these investigations was prepared by the action of sodium azide on benzylmethylacetyl chloride dissolved in ether according to a method previously described.[5] The purity of the azide was determined by measuring quantitatively the amount of nitrogen evolved when the compound undergoes rearrangement. The solid triphenylmethyl used in these experiments was prepared and its purity determined according to the method of Gomberg.[11] The benzene used was of the purified variety that is commonly employed in investigations involving the use of free radicals.

Procedure.—A three-holed round-bottomed flask immersed in a thermostat was connected by means of glass tubing containing stopcocks to three azotometers[12] filled with benzene. After the air had been completely removed from the apparatus a known volume of benzene was run into the flask by means of a dropping funnel and a weighed portion of solid triphenylmethyl was introduced. When solution had taken place a weighed amount of benzylmethylacetazide dissolved in a small amount of benzene was added. The stopcocks in the azotometers were opened and the rearrangement was allowed to take place at a constant temperature. The volume of nitrogen evolved was measured and corrected to standard conditions of temperature and pressure. After the rearrangement was completed all stopcocks were closed and the azotometers were disconnected and filled with dry oxygen. After being again connected to the reaction flask, the stopcocks were opened and the oxygen was allowed to diffuse into the reaction chamber and be absorbed by the triphenylmethyl remaining in the solution. The flask was shaken vigorously from time to time and the volume of oxygen absorbed was measured and corrected to standard conditions of temperature and pressure. Several experiments were carried out varying the temperature at which the rearrangements took place and the concentrations of the benzylmethylacetazide and triphenylmethyl. In all cases the volume of oxygen absorbed after the rearrangement corresponded very closely to the theoretical amount of absorption expected if no triphenylmethyl had taken part in the reaction. The results are given in Table I.

TABLE I[a]

[a] The vapor pressures of benzene used in these calculations were taken from tables published in Landolt and Bornstein. In Expt. 5 about two moles of triphenylmethyl were used for 1 mole of azide.

Analysis of the Products of Rearrangement.—An analysis was carried out of the products of rearrangement in Expt. 5. The benzene was partially removed by evaporation at room temperature in a vacuum desiccator. The triphenylmethyl peroxide,

---

[11] Gomberg and Cone, *Ber.*, 37, 2034, **3638 (1904).**

[12] Three azotometers were necessary since in some of the experiments the amount of azide used gave more than 100 cc. of nitrogen on rearrangement.

formed by the action of the oxygen on the triphenylmethyl, was collected on a filter and washed with a small amount of benzene: 2.38 g. of dry product was obtained, melting point, 183'. One recrystallization from carbon disulfide gave a product melting at 185°. The recorded melting point of pure triphenylmethyl peroxide is 185–186°; yield of peroxide, 78%. The filtrate was analyzed for any isocyanates that might be present. Dry ammonia gas was passed through the solution and in a few minutes a white precipitate of the urea was obtained. This was collected on a filter, after 25 cc. of ligroin had been added to decrease its solubility in the benzene solution; 1.00 g. of dry product was obtained, melting point 146°. One recrystallization from alcohol and water gave a solid melting at 149'; yield assuming but the one isocyanate to have been formed, 97%.

The filtrate from the urea was concentrated and some oily products were obtained. Attempts to isolate any compounds of known constitution that might be expected to be formed failed. In all probability these oily products are produced by the decomposition of the triphenylmethyl peroxide. As has been already stated in the literature, although the absorption of oxygen by triphenylmethyl is nearly quantitative, the amount of triphenylmethyl peroxide obtained from a known weight of triphenylmethyl is not quantitative; other substances of unknown constitution are produced.

Summary

The Beckmann rearrangement of an acylazide in the presence of a free radical has been studied, and the products of the rearrangement have been determined. Benzylmethylacetazide was allowed to rearrange in the absence of air in a benzene solution of triphenylmethyl. Evidence is submitted in this paper to show that only one isocyanate, benzylmethylisocyanate, is formed. A discussion of this fact with reference to certain theories on the Beckmann rearrangement is given.

A CLEAVAGE OF AZO DYES BY MEANS OF SULFITES*

BY KARL H. ENGEL

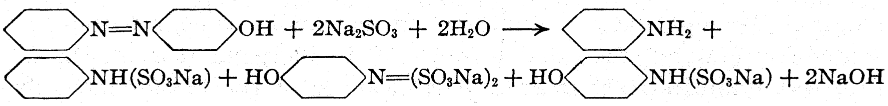
RECEIVED FEBRUARY 26, 1929 PUBLISHED OCTOBER 5, 1929

Cleavage of azo dyes through the action of sulfurous acid or of acid sulfites has frequently been observed heretofore but, apparently, has not been investigated in detail. A few experiments of the writer, the interaction of 4-hydroxyazobenzene and sodium bisulfite, for example, indicated that a cleavage of the dye was apt to be complicated by various secondary changes, the rearrangement of primary reaction products sometimes, the formation of resinous by-products and a reduction of some of the azo nitrogen to ammonia. In short, such a reaction looked rather unpromising.

---

* The material here presented has been submitted as a thesis in partial fulfilment of the requirements for the degree of Doctor of Philosophy at the Pennsylvania State College.

A number of years ago, however, the author made the observation that neutral alkali or ammonium sulfites react with azo dyes, in an exact ratio of two moles of sulfite to one mole of dye, resulting in a clear-cut fission of the dye between the two nitrogen atoms of the azo group. The reaction does not parallel the reduction by means of hydrosulfite, which, as is well known, leads to the formation of two primary amines. The sulfite cleavage, it is true, also yields a certain amount of primary amine. It differs in that the reacting sulfite tends to combine with the nitrogen atom attached to the secondary dye component, to a smaller extent with the nitrogen of the primary component. 4-Hydroxyazobenzene, for example, yields the following primary cleavage products



The formation of N-sulfonic acids points to certain similarities with the sulfite reduction of aromatic nitro and nitroso compounds. As expected, the resulting N-sulfonic acids, according to their specific nature, may either hydrolyze or rearrange, in the presence of mineral acids.

Some forty monoazo dyes were treated with ammonium, sodium or potassium sulfite, the dyes comprising hydroxy- and amino-azobenzene derivatives as well as dyes which contained hydroxy- or aminonaphthalene derivatives as secondary components. Most of these were found to react according to the scheme above. In a few cases, 2,4-dihydroxyazobenzene, for example, only two cleavage products were obtained: the original primary amine (aniline) and the N-disulfonic acid of the secondary component, of aminoresorcinol. A totally unsulfonated nitrogen of the secondary component was not observed, except in one instance: dimethylaminoazobenzene yielded a trace of dimethyldiaminobenzene.

A detailed investigation of the cleavage of 4-hydroxyazobenzenb and of 4'-hydroxyazobenzene-4-sulfonic acid is the subject of the following pages.

Earlier References.—An interesting cleavage of an azo compound was observed by Schmitt and Bennewitz,[1] who found that aqueous suspensions of 2,2'-dichloro-azobenzene reacted readily with sulfurous acid or sodium bisulfite, yielding a difficultly soluble 1-amino-4-phenol-6-sulfonic acid. A. Spiegel,[2] on heating azobenzene in an alcoholic solution of ammonium bisulfite, obtained a white crystalline reaction product which corresponded to the composition $C_{12}H_{11}N_2SO_3H$. It yielded benzidine sulfate in dilute mineral acid, and was therefore taken to be a monosulfaminic acid of benzidine, $H_2NC_6H_4C_6H_4NHSO_3H$. Bucherer and Sonnenberg[3] heated azobenzene in an aqueous solution of ammonium

[1] Schmitt and Bennewitz, *J. prakt. Chem.*, [2] 8, 7 (1874).

[2] A. Spiegel, *Ber.*, 18, 148 (1885).

[3] H. Th. Bucherer and Sonnenberg, *J. prakt. Chem.*, 81, 33 (1910).

sulfite at 110° and obtained a nearly quantitative yield of the ammonium salt of an N-sulfonic acid of hydrazobenzene, which, like Spiegel's reduction product, yielded benzidine sulfate on addition of mineral acid.

The Cleavage Reaction.—The experimental procedure, briefly, consisted of heating accurately weighed samples of pure dye and measured volumes of sulfite solution in closed containers, generally at 90 to 95°, until the dye was dissolved and decolorized. Primary amines such as aniline could then be separated by extraction or distillation. The N-sulfonic acids, on account of their extreme solubility and their sensitive character, could not be isolated. They rearranged with great ease, as free acids, forming primary amines or sulfonic acids of primary aromatic amines. To supplement the information that might be gained from such secondary products, the reaction course of the inorganic reagent, the sulfite, was quantitatively traced. The cleavage of the unsulfonated dye may be considered representative.

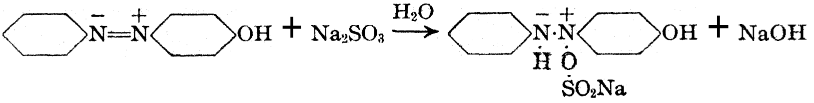
It was found that one mole of 4-hydroxyazobenzene yielded 0.78 mole of free aniline and 0.22 mole of an N-sulfonic acid of aniline, whereas the secondary dye component yielded 0.78 mole of N-disulfonic acid of 1-amino-4-phenol and 0.22 mole of N-monosulfonic acid of 1-amino-4-phenol. On addition of mineral acid to the cleavage products, the N-sulfonic acid of aniline hydrolyzed to give aniline. All of the primary dye component could therefore be recovered in its original form. The secondary dye component, upon rearrangement, yielded 0.54 mole of the insoluble 1-amino-4-phenol-5-sulfonic acid, and 0.46 mole of 1-amino-4-phenol-sulfonic ester, $H_2NC_6H_4OSO_3H$, a compound surprisingly resistant to hydrolytic action of mineral acids and so extremely soluble that it could not be isolated as such, in pure form. In all, two moles of diazotizable amines were ultimately obtained, through cleavage and rearrangements, from one mole of azo dye.

It appeared most likely that a cleavage of an azo group should proceed in two distinct steps, *i. e.*, that formation of N-sulfonic acids of hydrazo bodies should precede a final cleavage. Such intermediate stages, however, have not been observed, so far.

The most interesting feature of the reaction, from a theoretical viewpoint, appeared to be the distribution of the two sulfite molecules between two nitrogen atoms of the azo group. It was observed, in every dye examined, that the two sulfite molecules showed a pronounced tendency to combine with the nitrogen atom attached to the secondary dye component. The nitrogen of the primary component tended to combine with hydrogen. A conclusion that the two nitrogen atoms were marked by rather definitely fixed functional differences suggested itself. Plainly the nitrogen of the secondary component must have functioned very much like the nitrogen of a nitro or nitroso group toward the sulfite, as a positive atom; the nitrogen of the primary dye component, presumably, as a negative atom.[4]

Observation of a number of N-sulfonic acids showed differences, frequently very pronounced, in the character of N-mono- and N-disulfonic acid derivatives of the same amine, particularly in regard to orientation of sulfonic acid groups during rearrangement. Observations of this kind suggested that deeper-lying constitutional differences existed between the N-mono- and N-disulfonic acids in question and it was concluded that only the former were amine derivatives, or "sulfaminic" acids, of a type formula $RNHSO_3Na$; that the N-disulfonic acids, on the other hand, were derivatives of a positive nitrogen, presumably conforming to the type $RN(OSO_2Na)_2$. These various considerations led to the following view regarding the mechanism of the cleavage reaction.

It appeared most likely that an addition product of sulfite molecule and azo group should first be formed, the negative nitrogen joining a sodium atom (or its equivalent hydrogen), the positive nitrogen joining an oxygen of the sulfite molecule and that a reshifting of valency forces should result in a hydrazo derivative



If such a compound suffered no further intramolecular rearrangement, the second sulfite molecule might add and combine in the same manner *as* the first, forming the final cleavage products, aniline and the N-disulfonic acid, $HOC_6H_4N(OSO_2Na)_2$. Yield figures indicated that 78% of the dye could have reacted in this way. The remaining 22% formed N-monosulfonic acids of aniline and of aminophenol. Possibly such products might have been formed following an intramolecular shift of the hydrazo-N-sulfonic acid. The N-disulfonic acid of the experiment might be considered as a sulfurous ester of an hypothetical ortho-nitrous acid derivative, $HOC_6H_4N(OH)_2$. The N-monosulfonic acids, presumably, were true sulfaminic acids, $C_6H_5NHSO_3Na$ and $HOC_6H_4NHSO_3Na$.

The tentatively suggested explanation of the cleavage reaction will be substantiated, it is believed, by further experiments in this field. The reaction may have a practical value as a convenient tool in the synthesis of dye intermediates.

Experimental

Preparation of Materials.—The dyes required were prepared by coupling diazobenzene, or 1-diazobenzene-4-sulfonic acid, respectively, with pure phenol in solutions

---

[4] It might be of interest in this connection to recount the origin of the two atoms, the negative one being derived from an aromatic amine, *i. e.*, a substituted ammonia· the positive one from nitrous acid.

containing sodium acetate and acetic acid.[5] 4-Hydroxyazobenzene was repeatedly recrystallized from ethyl alcohol. The pure dye melted at 156.5°, corr.

Anal. Calcd. for $C_{12}H_{10}ON_2$: N, 14.14. Found: N, 14.06.

The sodium salt of the sulfonated dye was recrystallized from water until free from the chlorides originally present.

Anal. Calcd. for $C_{12}H_9O_4N_2SNa$: N, 9.32; S, 10.67; Na, 7.67. Pound: N, 9.29; S, 10.62; Na, 7.63.

A stock solution of ammonium sulfite, approximately 5 N, was prepared from pure ammonia solution and liquid sulfur dioxide. The solution was guarded against air oxidation by keeping the storage bottle filled to capacity with benzene. Slight traces of sulfate were determined and properly discounted later on.

Cleavage of **4-Hydroxyazobenzene.**—19.8200 g. of dye (1/10 mole), and 320 cc. of ammonium sulfite solution, equivalent to 490.3 cc. of a normal solution of sulfurous acid and to 496.7 cc. of a normal solution of ammonia, were placed in nitrogen-filled pressure bottles (to prevent oxidation and loss of volatile substances). Experiments were made in triplicate. The bottles, tightly closed in a reclining position, were heated in a constant-temperature oven at 90 to 93°. The suspended dye, slightly soluble, gradually disappeared. After seventy-two hours, the solution assumed a pale yellowish coloration which did not change on further heating. After seventy-eight hours of continuous heating, the bottle contents were diluted to 500 cc., accurately. Portions of these solutions were used in subsequent analytical determinations.

Removal **of Aniline.**—Aniline formed during cleavage was quantitatively removed from solution by six extractions with 50-cc. portions of benzene. It required 78.8, 78.2 and 77.4 cc. of 1 *N* nitrite solution for diazotization, corresponding to an average yield of 0.78 mole per mole of dye. No trace of 1-amino-4-phenol could be detected in the benzene extract, nor upon complete evaporation of the original solution and extraction of the residue with organic solvents.

After removal of the aniline, a small part of the primary and all of the secondary component of the dye remained in solution. It showed a pronounced bluish fluorescence. A few drops diluted to about 10 cc. showed a beautiful sky blue coloration with ferric chloride in the presence of a little acetic acid. The coloration changed to claret after about thirty minutes.

Attempts were made to isolate the N-sulfonic acids as barium salts. Crystallization, however, did not begin until the solution had been evaporated to a very small volume. The addition of alcohol to more dilute solutions caused a precipitate that was not of uniform composition. These products, dry or in solution, were extraordinarily sensitive to air oxidation, in the absence of protecting traces of sulfite, short exposure causing immediate darkening and an overpowering odor suggestive of isocyanides.

Ammonia, determined in 25-cc. portions, corresponded to 496.4 cc. of 1 N solution, against 496.7 cc. present before cleavage. No ammonia, therefore, could have been generated through reduction of the azo nitrogen.

Aromatic **Amines.**—One hundred-cc. portions, freed from sulfite by addition of barium chloride, required, after addition of concd. hydrochloric acid, 24.2 and 24.4 cc. of 1 *N* nitrite solution for diazotization, potassium iodide–starch indicator giving sharp end-points. One tenth mole of dye, therefore, yielded amines corresponding to 121.5 cc. of 1 N nitrite solution, or 0.121 mole, in addition to the previously isolated 0.078 mole of aniline; one mole of dye yielded a total of 1.99 mole of diazotizable amines

---

[5] The reaction was slower under these conditions but yielded cleaner products than the customary coupling in the presence of alkali.

through cleavage and upon addition of acid, cleavage of the azo group had been complete and quantitative. The diazotized solution contained diazobenzene hydrochloride (which could be separated by preferential coupling with 2-naphthol) and sulfonic acids of 1-amino-4-diazobenzene.

Sulfite Consumed.—Excess of hydrochloric acid was added to 50-cc. portions of original solution and the liberated sulfur dioxide distilled into standardized iodine solution: 9.00, 9.10 and 9.17 cc. of a normal solution being reduced, an average of 9.07 cc., corresponding to 90.7 cc. of normal sulfite solution in the original. Since 490.3 cc. was present before cleavage, the difference, 399.6 cc. of a normal solution (0.5 M) was consumed in reacting with one-tenth mole of dye. Quite accurately, two moles of sulfite reacted with one mole of dye.

Sulfate Formed During Cleavage.—Addition of mineral acids to the solution of cleavage products would have caused formation of sulfuric acid through hydrolysis of N-sulfonic acids. The sulfate formed during cleavage was therefore isolated from the ammoniacal solution as barium sulfate: 0.0280 g, of barium sulfate was found in 25-cc. portions of solution, which corresponded to 0.56 g. for the original solution, or to 4.8 cc. of normal sulfite solution that had been oxidized to sulfate during cleavage. Of the 399.6 cc. of sulfite solution, all but 1.2% remained in combination with cleavage products of the dye.

Distribution of Combined Sulfite between the Two Dye Components.—Conclusions could now be drawn regarding the probable composition of the reaction products; 0.78 equivalents of the primary component had been isolated, as free aniline. Two molar equivalents of sulfite (minus 1.2%), therefore, remained in combination with one full equivalent of 1-amino-4-phenol, and 0.22 equivalent of aniline. The solution contained N-mono- as well as N-disulfonic acids. Free 1-amino-4-phenol could not be detected. All of the secondary component was combined with at least one molecule of sulfite. If a single dye molecule combined with two molecules of sulfite, free aniline being formed as a result, both sulfite molecules must have attached themselves to the nitrogen atom of the secondary component. Conversely, since no free aminophenol had been formed, no N-disulfonic acid of the primary component could have been formed either. Disregarding the small amount of sulfate formation, one mole of dye should have yielded, approximately, 0.22 mole of an N-sulfonic acid of aniline, 0.22 mole (or slightly more) of N-monosulfonic acid of 1-amino-4-phenol and 0.78 mole (or slightly less) of an N-disulfonic acid of 1-amino-4-phenol.

Intramolecular Rearrangement and Hydrolysis of the N-Sulfonic Acids.—Two 50-cc. portions, boiled with an excess of hydrochloric acid to expel sulfur dioxide (residues from determinations of excess sulfite), were combined; an insoluble precipitate formed on cooling was isolated and dried over concd. sulfuric acid; a 100-cc. portion yielded 2.055 and 2.029 g., 0.1 mole of dye gave an average of 10.21 g. of substance. It showed the same characteristics, crystal habit, solubility, etc.. as the 1-amino-4-phenol-5-sulfonic acid.[6]

Anal. Calcd. for $C_6H_7O_4NS$: N, 7.40; S, 16.93; acidity, 1.0000 g. equiv. to 5.29 cc. of 1 N NaOH. Found: N, 7.39; S, 16.86; acidity, 1.0000 g. equiv. to 5.30 cc. of 1 N NaOH (phenolphthalein). The yield, 10.21 g., corresponded to 0.54 mole of I-amino-4-phenol-5-sulfonic acid per mole of dye.

Aniline, Originating through Hydrolysis of Its N-Sulfonic Acid.—The filtrate and wash liquor of the insoluble aminophenolsulfonic acid contained aniline, originating through decomposition of its free N-sulfonic acid. Two residual filtrates from the last-mentioned determination were combined, representing thus a 200-cc. portion of the original. The solution, after neutralization with sodium hydroxide, was evaporated

---

[6] Post, *Ann.*, 205, 46 (1880).

to a smaller volume in a distilling flask. The aniline entrained was absorbed in dilute sulfuric acid and diazotized, 7.2 cc. of 1 N nitrite solution being required, corresponding to 18.0 cc., or to 0.018 mole of aniline per tenth mole of dye. 0.078 mole of anilime had been accounted for as a primary cleavage product; 0.096 mole, or 96%, of the primary dye component, therefore, was ultimately recovered as unchanged aniline.

Soluble 1-Amino-4-phenol-sulfonic Acid.—The distillation residue, free from traces of aniline or of aniline sulfonic acids, contained an aminophenol derivative of extraordinary solubility. By determining the amount of sulfuric acid formed through hydrolysis of N-sulfonic acids, it could be shown that the soluble product was a monosulfonated derivative of 1-amino-4-phenol. Its solution, again acidified with an excess of hydrochloric acid, required 17.8 cc. of 1 N nitrite solution for diazotization, corresponding to a total yield of 0.45 mole per mole of dye. The yield of this product, together with a yield of 0.54 mole of 1-amino-4-phenol-5-sulfonic acid, accounted for practically all of the secondary component of the dye. The diazonium compound of the soluble product showed similar characteristics as the 1-diazo-4-hydroxybenzene-5-sulfonic acid. It coupled with active azo components such as 1-naphthylamine, m-phenylenediamine, resorcinol, et~. Dyed upon untreated wool these dyes yielded shades which differed from those of corresponding azo derivatives of 1-amino-4-phenol-5-sulfonic acids by a noticeably greater tendency toward absorption in regions of longer wave lengths. Thus the dye containing 1-amino-8-hydroxynaphthalene-3,6-disulfonic ("H") acid as secondary component, gave clear bluish violet shades; the corresponding aminophenol-5-sulfonic acid derivative carmine red shades.

The dye containing 1-naphthylamine as secondary component was insoluble in the form of its free acid. It could be quantitatively isolated and was freed from impurities such as salts by thorough washing.

Anal. Calcd. for $C_{16}H_{13}O_4N_3S$: N, 12.25; S, 9.32. Found: N, 12.18; S, 9.34.

Identification of the Soluble Aminophenol Sulfonic Acid.—Since the product differed decidedly from the 1-amino-4-phenol-5-sulfonic acid, it was at first surmised that it was identical with the only other isomeric, nuclear, sulfonic acid, the 6-sulfonic acid. For comparison, the latter compound was prepared by two different methods.[7] The products thus obtained, identical with each other, were decidedly soluble in hot water but very little so at room temperature. They yielded azo dyes which were more soluble than corresponding dyes of the 5-sulfonic acid. The isomeric dyes did not differ visibly in color reactions or dyeing shades. The two sets differed perceptibly, however, from corresponding azo derivatives of the unknown substance. The possibility that the sulfonic acid group occupied the 2-, 3-, 5- or 6-position of the 1-amino-4-phenol nucleus was therefore excluded; it could exist only in combination with either the amino or the hydroxyl group. The formation of sulfonated, and distinctive azo derivatives excluded the first of these possibilities, leaving as the only remaining alternative conclusion that the product in question was a sulfonic ester of 1-amino-4-phenol, $H_2NC_6H_4OSO_3H$, a compound which apparently has not been observed previously, and which should also occur among the end-products of the sulfite reduction of nitro and nitrosophenol. The stability of this product in the presence of mineral acids seemed surprising in view of the comparative instability of the unsubstituted phenolsulfonic acid.[8] The compound hydrolyzed, apparently completely, when heated with about 5 *N* hydrochloric acid, at 90 to 93°, for eighty hours. The nuclear sulfonic acids of 1-amino-4-phenol proved perfectly stable under parallel conditions. Attempts to isolate the soluble compound as a potassium, barium or lead salt proved fruitless.

[8] Baumann, *Ber.*, 9, 1715 (1876); 11, 1907 (1878).

Boiling of its solution with alkalies, even with lead monoxide, caused destruction or displacement of the aromatic amino group.

The conditions under which hydrolysis and rearrangement of N-sulfonic acids proceeded were so chosen as to produce stable end-products in the most rapid manner (at 100° and a few minutes of boiling). Under slightly milder conditions hydrolysis proceeded more slowly. Portions of the original solution were heated to 90° and hydrochloric acid was added. On cooling the difficultly soluble 1-amino-4-phenol-5-sulfonic acid crystallized out and was isolated. Determination of sulfuric acid in solution yielded notably smaller amounts than were found previously, indicating the presence of disulfonic acids of aminophenol. On diazotization at 0° and subsequent coupling with azo components, derivatives of the aminophenol-sulfonic ester were obtained. Presumably, then, the disulfonic acid present before diazotization still possessed a sulfonic acid group attached to the nitrogen atom. The reaction (as well as yield figures) indicated that part of the N-disulfonic acid rearranged to form 1-amino-4-phenol-5-sulfonicacid, part of it to form the aminophenol-sulfonicester described above.

Cleavage of 4-Hydroxyazobenzene at Higher Temperatures.—Cleavage of the dye proceeded more rapidly at higher temperatures. The reagents, in the same proportions as before, were heated at 130 to 135°, in a small steel autoclave. Cleavage was complete after fifteen hours. Determination of molar ratio of reagents of primarily formed aniline gave practically the same results as were found in preceding experiments. A greater amount of sulfate, from 12 to 15% of the sulfite consumed, was formed. Since no trace of free aminophenol could be found, the formation of sulfate did not coincide with formation of greater amounts of totally unsulfonated products, but must have occurred at the expense of the N-*di*sulfonic acid yield. Hydrolysis and rearrangement, under the influence of acids, gave the same final reaction products as before. The yield of 1-amino-4-phenol-5-sulfonic acid was smaller; that of the aminophenol-sulfonic ester, however, correspondingly larger.

Sodium and Potassium Sulfite as Reagents.—Interaction between sodium or potassium sulfite and 4-hydroxyazobenzene was exceedingly slow below 100°, but went to completion in reasonable time at higher temperatures, requiring, for example, fifty hours of heating at 145 to 150". The reaction proceeded as with ammonium sulfite. As before, higher temperatures caused an increase in sulfate formation.

Cleavage of 4-Hydroxyazobenzene-4-sulfonic Acid, Na-Salt.—30.1270 g. of dye, exactly 0.1 mole, and 320 cc. of ammonium sulfite solution, equivalent to 490.3 cc. of 1 N solution, were heated under the same condition as described before, at 90 to 93°. Cleavage in this case was complete after eighteen hours. The decolorized solution was made up to volume and analyzed as previously described: 401.4 cc. of 0.5 M ammonium sulfite was consumed; 2.007 moles of sulfite reacted with one mole of dye. Ammonium sulfate formed during cleavage was equivalent to 0.6843 g. of barium sulfate, or to 5.6 cc. of normal sulfite solution, 1.4% of the sulfite consumed. An aliquot portion was freed of sulfite, acidified and diazotized with 1 N nitrite solution. A total of aromatic amines corresponding to 199.7 cc. of nitrite solution was found present, or practically the theoretically possible limit.

The addition of sodium chloride to the solution of cleavage products caused precipitation of sodium sulfanilate, which was identified by its crystal form. An exact quantitative estimation of primarily formed sulfanilate could not be made. Undoubtedly by far the greater part of the primary dye component was regenerated in its original form, as a result of cleavage.

An excess of hydrochloric acid was added to a portion of the original solution at 90 to 95°. The final useful products were sulfanilic acid (quantitative regeneration of the primary dye component), 1-amino-4-phenol-5-sulfonic acid (0.54 mole per mole of dye) and the extremely soluble 1-amino-4-phenol-sulfonic ester (0.46 mole per mole of dye). The yield ratio of the latter two products was identically the same as obtained in the cleavage of the unsulfonated dye.

Cleavage of 4-Hydroxyazobenzene-4-sulfonic Acid at 140 to 145°.—The sodium salt of the dye and sodium sulfite solution of approximately 0.75 M concentration were heated in a steel autoclave at 140 to 145°. At the end of twenty hours cleavage was found complete. Analytical determinations yielded very nearly the same results: 3.6% of the consumed sulfite was changed to sulfate, a little more than was formed at the lower temperature.

Summary

1. A new type reaction of monoazo dyes has been observed. They combine with two moles of a neutral sulfite, in solution, suffering cleavage into a primary amine and the salts of N-sulfonic and N-disulfonic acids.

2. 4-Hydroxyazobenzene yielded approximately 0.78 mole of aniline, 0.22 mole of an N-sulfonic acid of aniline, 0.78 mole of an N-disulfonic and 0.22 mole of an N-monosulfonic acid of 1-amino-4-phenol and no trace of unsulfonated aminophenol.

3. 4'-Hydroxyazobenzene-4-sulfonic acid reacted similarly, sulfanilate being formed as a result of cleavage.

4. Hydrolysis and rearrangement of free N-sulfonic acids resulted in complete recovery of the primary dye component in its original form; the secondary component yielded 1-amino-4-phenol-5-sulfonic acid and an extremely soluble, stable 1-amino-4-phenol-sulfonic ester, a compound not previously reported.

5. An explanation of the cleavage reaction has been suggested, founded on an assumption of functional differences between the two nitrogen atoms of the azo group.

STUDIES ON THE POLYMETHYLBENZENES. I. A STUDY OF THE JACOBSEN REACTION WITH PENTAMETHYLBENZENE, AND THE PREPARATION OF PREHNITENE[1]

BY LEE IRVIN SMITH AND ALBERT R. LUX

RECEIVED MARCH 2, 1929 PUBLISHED OCTOBER 5, 1929

I. Introduction and Historical

In 1887 Oscar Jacobsen[2] discovered that pentamethylbenzene when treated with concd. sulfuric acid undergoes a rather curious reaction in which a methyl group migrates from one molecule to another, leading to hexamethylbenzene and a tetramethylbenzene, prehnitene (1,2,3,4-),

---

[2] Jacobsen, *Ber.,* 20, 896 (1887).

which appears in the form of its sulfonic acid. This reaction is expressed by Jacobsen as follows

$$2C_6H(CH_3)_5 + H_2SO_4 \longrightarrow C_6(CH_3)_6 + C_6H(CH_3)_4SO_3H + H_2O$$

Jacobsen extended this reaction to other alkylated benzenes and found that it also took place with durene,[3] giving pentamethylbenzene and two trimethylbenzene-sulfonic acids, and with penta-ethylbenzene,[4] which gives hexa-ethylbenzene and the sulfonic acid of 1,2,3,4-tetra-ethylbenzene. Jacobsen also found that analogous reactions occurred when some of the halogenated benzenes were treated with concd. sulfuric acid, only in these cases it is the halogen which migrates instead of the alkyl group. Thus monobromodurene[6] gives dibromodurene and durene, the latter, of course, reacting at once to give higher and lower methylated benzenes.

The hexa-substituted benzenes obtained in these reactions are apparently end products and are stable toward sulfuric acid, even after several months' contact. In the case of the methylated benzenes, the reaction appears to be limited to the tetra- and pentamethylbenzenes, for the trimethylbenzenes are simply sulfonated by concd. sulfuric acid without any rearrangement; but in the case of the halogenated benzenes, even monobromobenzene will rearrange when treated with sulfuric acid, giving dibromobenzene and (presumably) benzene,[5] dibromobenzene giving tetra- and hexabromobenzene, and tribromobenzene giving hexabromobenzene. Similar migrations of halogens have been noted in the case of iodobenzene, o- and p-iodotoluene and o- and *p*-iodophenol.[6]

It has long been known that anhydrous aluminum salts will cause alkyl groups to migrate, not only into different positions in the same molecule but also from one molecule to another, but sulfuric acid is not frequently a reagent which causes migrations of this sort to take place. For this reason we were interested in *a* study of the Jacobsen reaction and we selected pentamethylbenzene as the object of our first study for two reasons: first, pentamethylbenzene when it undergoes the reaction gives fewer products than any other methylated benzene and, second, the tetramethylbenzene obtained in this way from pentamethylbenzene is prehnitene (1,2,3,4-), a very rare hydrocarbon, and we hoped to discover the conditions which would enable us to use the Jacobsen reaction with pentamethylbenzene as a method for making prehnitene in quantity. The work reported in this paper represents the preliminary investigation of a problem which has for its object: (1) verification of the facts as stated by Jacobsen, (2) determination of the limits of the Jacobsen reaction, and any special conditions which influence the reaction, (3) determina-

tion of the mechanism of the reaction and (4) determination of the conditions under which the reaction can be run with pentamethylbenzene to give a good yield of prehnitene.

II. Method of Procedure and Discussion of Results

The procedure, from the initial materials to the final products, may be divided into four steps: (a) the Jacobsen reaction proper, (b) isolation of the products, (c) separation and purification of the products and (d) conversion of the prehnitene-sulfonic acid into prehnitene, together with the purification of the crude hydrocarbon. Each step in this procedure was examined, varying conditions as much as possible and determining the effects of these variations upon the yields of the products.

(a) The Jacobsen Reaction Proper.—The three variables studied in this step were the amount of sulfuric acid, the time and the temperature. The last two of these depend upon each other, for the same results are obtained by heating for a short time as are obtained by standing at room temperature for a longer time. In order, therefore, to standardize the procedure, we ran all of our experiments at room temperature, merely varying the time of standing. From the data in the table it is apparent that twenty-four hours is a sufficient time and that no improvement in the yield of products results on longer standing. The amount of sulfuric acid is also of little consequence as far as the final products are concerned, provided enough is used to react according to Jacobsen's equation, but it is more convenient to use more than this amount in order to get a thorough contact between the acid and the solid hydrocarbon.

(b) Precipitation of the **Sulfonic** Acid from the Sulfuric Acid Solution.—This is accomplished by adding ice to the solution; the variables in this step are the amount of ice added and the rate at which it is added, since this controls the temperature. The amount of ice used--enough to dilute the original acid to 50% by volume—was decided on the basis of the different yields of sulfonic acid obtained by using different amounts of ice. In order to avoid charring and the formation of tars, this ice must be added slowly and the mixture cooled in a bath of ice and salt.

(c) Separation and Purification of the Products.—The precipitate which forms when the sulfuric acid is diluted consists of hexamethylbenzene, prehnitene-sulfonic acid and tars. The separation of this mixture into its constituents is fairly easy, and is given in the experimental part.

(d) Conversion of Sodium Prehnitene-sulfonate into Prehnitene and Purification **of** the Hydrocarbon.—The hydrolysis of sulfonic acids to hydrocarbons in the presence of mineral acids has been studied by a number of investigators, but the most systematic investigation appears to be that of Armstrong and Miller,[7] who found that the reaction depends

---

[7] Armstrong and Miller, *J. Chem. Soc.*, **45**, **148** (**1884**).

primarily upon the temperature and that any mineral acid can be used, provided means are available for obtaining high enough temperatures. These temperatures are all rather critical for given sulfonic acids, and are, in general, in the range of 120–200°—too high for hydrochloric acid unless autoclave conditions are employed. For this reason we chose sulfuric acid as the mineral acid, for any temperature up to the boiling point of sulfuric acid may be obtained by varying the concentration of the acid. Preliminary experiments showed, however, that the sulfonic acid of prehnitene (and also of other highly methylated hydrocarbons) is not only hydrolyzed by hot sulfuric acid but that other decompositions occur, leading to large amounts of tars from which no hydrocarbon can be obtained, and that the formation of these tars is largely a function of the time the sulfonic acid remains in contact with the hot sulfuric acid. Consequently, the only feasible method of hydrolysis appeared to be a "flash" system, in which the sulfonic acid was dropped slowly into hot sulfuric acid and the hydrocarbon distilled out immediately. Such a flash system gave beautiful results when applied to the hydrolysis of durene-sulfonic acid, yielding almost the quantitative amounts of durene; but prehnitene-sulfonic acid is exceedingly sensitive to the hot sulfuric acid and it requires very careful manipulation to get a good yield of hydrocarbon in this way. It was finally discovered, however, that if instead of the sulfonic acid, a water solution or paste of the sodium salt were used, good results could be obtained. The procedure finally developed consisted in passing superheated steam through sulfuric acid, holding the temperature of the acid at 145 to 150° by means of an outside bath, and then running in slowly a paste of the sodium salt of the sulfonic acid at such a rate that the temperature did not fall below 140 or rise above 155°. In this way the yield of hydrocarbon from the sodium sulfonate often runs as high as 90% and the average of a large number of runs is well over 80%. The temperature of hydrolysis is quite critical; below 140° the reaction is very slow, while above 160° there is much decomposition with charring and evolution of sulfur dioxide.

Experimental Part

The Jacobsen Reaction.—One typical run will be described in detail and others are summarized in the table. One-half mole (74 g.) of pentamethylbenzene (m. p. 52° or higher) is heated to 65° and to the resulting oil is added, with vigorous stirring, 200 cc. of concd. sulfuric acid which is at room temperature. By this procedure the hydrocarbon is cooled below its melting point and crystallizes in a finely divided form. This is essential, for if lumps of solid form they are quickly coated over with sulfonic acid or other material and the interior is protected completely against the sulfuric acid. After adding all of the acid, the resulting mush of white crystals and reddish liquid is placed in a cooling bath until it reaches room temperature, after which it is allowed to stand.

After standing for the requisite length of time, the mixture is cooled to 0° in a bath of ice and salt and 165 to 200 g. of cracked ice added in three portions, with vigorous stirring, making certain that the ice and water touch all parts of the mixture. This can be told by the disappearance of the dark reddish-brown color wherever the water touches the solid. After all of the ice has been added, the mixture is cooled to 0° and then filtered with suction through a cloth filter, pressing as dry as possible. The filtrate contains no appreciable amount of organic material and is discarded. The filter cake is leached out thoroughly with about 700 cc. of cold water and the resulting suspension is filtered. The precipitate is light brown and is hexamethylbenzene and by-products, while the red filtrate consists of a water solution of prehnitene-sulfonic acid also containing sulfuric acid.

The filtrate is worked up by converting the acids into the calcium salts by adding powdered calcium carbonate in small portions until there is no further effervescence. The precipitate of calcium sulfate is filtered off, washed thoroughly and discarded. The combined filtrates and washings contain the calcium salt of the sulfonic acid, which is converted into the sodium salt by adding concd. sodium carbonate solution as long as any calcium carbonate precipitates. The precipitate is filtered off, washed with water and discarded, after which the filtrate and washings are evaporated to dryness on the steam-bath, leaving the solid sodium salt of prehnitene-sulfonic acid; weight, about 40 g. or about 68% yield (assuming Jacobsen's equation to be correct). This sodium salt need not be purified before the hydrolysis to prehnitene, but for purposes of identification portions of it from several different runs were converted in the usual manner into the sulfone chloride, m. p. 73–75', and the sulfonamide, m. p. 187°.[8]

Purification of the Hexamethylbenzene.—The light brown precipitate of crude hexamethylbenzene weighs about 50 g. and melts gradually from 140 to 160°. It was purified by distillation under reduced pressure, 30 g. of distillate passing over at 170° under 80 mm. or 162' under 55 mm., and solidifying in the receiver to a white solid which, after recrystallizing once from a mixture of chloroform and alcohol, melts at 162'. A mixed melting point with a specimen of hexamethylbenzene, m. p. 162°, showed no depression. The yield, based on Jacobsen's equation, is 74%. The tarry residue remaining in the distilling flask weighed 20 g.

Conversion of the Sodium Prehnitene-sulfonate into Prehnitene, (a) Using Concd. Hydrochloric Acid.—About 10 g. of the sodium salt (or the sulfonic acid itself) was dissolved in 100 cc. of concd. hydrochloric acid. The solution was heated to the boiling point and steam passed through it for two hours. The distillate contained no oil, while the residue in the distilling flask was red and tarry. In another experiment 9 g. of the sulfonic acid was refluxed with 100 cc. of concd. hydrochloric acid for two hours and then distilled with steam. No trace of oil distilled over and the residue was very tarry.

(b) Distillation of the Sodium Salt with Ammonium Chloride.—Ten grams of dry sodium sulfonate was ground in a mortar with 50 g. of ammonium chloride, the mixture placed in a distilling flask and heated until the glass began to soften. In this case 1.5 g. of colorless oil distilled over, a yield of only 30%.

(c) Using Sulfuric Acid.—Preliminary experiments were carried out on the hydrolysis of durene-sulfonic acid to durene, as we could obtain this sulfonic acid in quantity from durene. These experiments indicated that it was necessary to heat, for very little durene is formed in the cold when the sulfonic acid is shaken with concd. sulfuric acid, contrary to the statement of Jacobsen.[3] By using 50% sulfuric acid and regulating the temperature very carefully, we finally found the conditions which would give a nearly quantitative yield of durene from the sulfonic acid, but when these condi-

---

[8] Jacobsen, Ber., 19,1214 (1886); Kelbe and Pathe, *ibid.*, 19, 1552 (1886), however, give the m. p. of the amide as 177°.

tions were applied to prehnitene-sulfonic acid, only a 50% yield of hydrocarbon resulted. Moreover, if the temperature was increased, the yield diminished, and large amounts of tarry material resulted. After many experiments a procedure was developed which gave excellent results and which consists essentially of a "flash" hydrolysis and distillation with superheated steam. The flask in which the hydrolysis was conducted was an ordinary distilling flask of 500-cc. capacity, with two tubulatures in the bulb, one for carrying a thermometer, and the other for carrying a separatory funnel. The steam was superheated by means of a small superheater of copper tubing placed in the line. A typical experiment is described: the flask is charged with **100** cc. of water and immersed in an oil-bath at about **200'.** Then, with superheated steam passing through, concd. sulfuric acid is added through the dropping funnel until the temperature of the diluted acid in the flask reaches 150–160°. At this point a saturated water solution of **40** g. of the sodium prehnitene-sulfonate (or a thin paste of the solid and water) is run in at such a rate that the temperature of the acid mixture remains between **140** and **150'.** The hydrolysis takes place rapidly and the hydrocarbon is distilled out immediately by the current of steam. The oil distilling over is a very pale yellow and weighs **20** g. (88% yield based on the weight of the sodium sulfonate). On redistillation over 90% of the oil passes over within a range of 0.5°; b. p. **97** to 98° at **24–25 mm.**, and the distillate shows a freezing point of **−7.4".** (The freezing point of carefully purified prehnitene is −6.4°.)

Representative runs are shown in the table. The final run represents an experiment on a large amount of pentamethylbenzene to see whether or not the data obtained from small runs were applicable to larger quantities; the results show that prehnitene can be made in quantity by this method. It is, in fact, the only method for obtaining this hydrocarbon in any quantity, starting with materials which are themselves easily available.

TABLE I

SUMMARY OF THE RESULTS OF THE JACOBSEN REACTION WITH PENTAMETHYLBENZENE

The Mechanism of the Jacobsen Reaction.—In this preliminary study most of the work was directed toward establishing the best conditions for carrying out the Jacobsen reaction in order that it might be used as a method for making prehnitene, and no extensive study of the mechanism of the reaction was made. In connection with another phase of this work, however, a sample of pentamethylbenzene-sulfonic acid was prepared and was placed in a desiccator over sulfuric acid for final drying. At the end of a week it was noticed that the acid had darkened quite a bit, and as the time went on, the color deepened. The sulfuric acid in the desiccator also darkened in color and sulfur dioxide was evolved, but this came from the sulfuric acid and not from the sulfonic acid above it. At the end of eight weeks both the sulfonic acid and the sulfuric acid were dark brown. The sulfonic acid (10 g.) was removed and worked up exactly according to the procedure used in carrying out the Jacobsen reaction. There resulted a brownish solid, insoluble in water or alkali, and an aqueous solution containing sulfonic acids.

The solid was sublimed, giving a white sublimate, m. p. 75 to 101°, which could not be purified because of the small amount. This m. p. is above that of pentamethylbenzene (52°) but below that of hexamethylbenzene (164°). However, some of the solid was mixed with pure hexamethylbenzene and the resulting mixture melted at 122–140°. Hence the solid is probably impure hexamethylbenzene and the impurity is most likely pentamethylbenzene resulting from hydrolysis of the sulfonic acid.

The sulfonic acids contained in the aqueous solution were converted into the sodium salts in the usual way and evaporated almost to dryness. A pasty mass of yellowish solid resulted; when this was hydrolyzed with sulfuric acid, there resulted 1.5 g. of oil in the distillate.

This experiment indicates that the first step in the Jacobsen reaction is a sulfonation and that it is the sulfonic acid, not the hydrocarbon, which rearranges, for the reaction will take place with the sulfonic acid alone in the absence of direct contact with sulfuric acid. Further study of this phase of the problem is in progress and will be reported later.

Summary and Conclusions

1. The rearrangement known as the Jacobsen reaction takes place essentially in the manner reported by Jacobsen, although there are considerable amounts of tarry by-products and Jacobsen's equation does not represent all that happens.
2. The optimum conditions for this reaction with pentamethylbenzene have been determined and when properly handled the reaction can be used as a method for making the rare hydrocarbon prehnitene (1,2,3,4-tetramethylbenzene) in quantity and with a yield of about 65% based on the pentamethylbenzene used. The yield of hexamethylbenzene is over 70%, while somewhat less than one-third of the original pentamethylbenzene is lost, principally as tars.
3. The hydrolysis of prehnitene-sulfonic acid to prehnitene has been studied in detail and a method is described which gives high yields of the hydrocarbon.
4. One experiment is reported which has a bearing upon the mechanism of the Jacobsen reaction.

STUDIES ON THE POLYMETHYLBENZENES. II. THE MELTING POINTS OF THE TETRAMETHYLBENZENES, AND OF PENTA- AND HEXAMETHYLBENZENE, AND THE FREEZING POINT DIAGRAM OF MIXTURES OF DURENE AND XSODURENE

BY LEE IRVIN SMITH WITH F. H. MACDOUGALL

RECEIVED MARCH 2, 1929 PUBLISHED OCTOBER 5, 1929

The easiest method for preparing the polymethylbenzenes is by the direct methylation of commercial xylene[1] but at present the only pure polymethylbenzenes which can be isolated from the reaction mixture are durene, pentamethylbenzene and hexamethylbenzene. This is because alkylation, using the Friedel-Crafts reaction, yields all possible isomers, and while it is possible to separate by distillation the different steps in the alkylation, it is not possible to separate the isomers of the same step by this method. Durene (1,2,4,5-tetramethylbenzene) can, however, be made in this way because it has a relatively high melting point (80°) and can be frozen out of a mixture of its isomers containing relatively large proportions of it.

The yield of tetramethylbenzenes obtained by methylating xylene usually amounts to about 35% based on the xylene used, and contains about 4045% of durene. When this is frozen out, the filtrate contains all of the isodurene (1,2,3,5-) and prehnitene (1,2,3,4-), and this mixture is saturated, of course, with durene at the temperature of crystallization. This filtrate is at present useless as a source for isodurene and prehnitene because there is no known method by means of which the three tetramethylbenzenes can be separated from one another. The problem of this separation is now under investigation in this Laboratory, and the work reported in this paper deals with the preparation and (or) purification of each of the three tetramethylbenzenes, pentamethylbenzene and hexamethylbenzene, and a determination of their melting points and the freezing-point diagram for the system durene–isodurene, together with some thermodynamic considerations based upon these experimental data.

Preparation and Purification of Materials

1. Durene. Preparation[1] and Purification.—Eight hundred grams of crude durene was recrystallized four times by dissolving it in an equal weight of hot 95% ethyl alcohol, then cooling to 0°, filtering and washing with a little cold alcohol. After four recrystallizations, the durene weighed 500 g. This was then recrystallized once from 300 g. of thiophene-free benzene, yielding 430 g. The melting point of the durene (determined in the ordinary way, using a capillary tube and not correcting) rose slowly after each recrystallization until the fourth and fifth recrystallizations, which gave products having practically the same melting points (79.3–79.9° for the fourth, and

---

[1] Smith and Dobrovolny, THIS JOURNAL, 48, 1413 (1926).

79.3–79.7° for the fifth). The sample to be used for accurate determinations was then placed in a vacuum desiccator over phosphorus pentoxide for two or three days.

2. Pentamethylbenzene. Preparation[1] and Purification.—Five hundred and fifty grams of crude pentamethylbenzene, m. p. 49–51°, was recrystallized four times from its own weight of 95% ethyl alcohol, followed by one recrystallization from 60% of its weight of thiophene-free benzene. The melting point rose progressively and was 51.5–53.0° for the fourth recrystallization and 52.2–53.1° for the fifth. The yield was only 127 g., as pentamethylbenzene is very soluble in benzene. The final sample was placed in a vacum desiccator over phosphorus pentoxide for a few days.

3. Hexamethylbenzene. Preparation[1] and Purification.—Three hundred and fifteen grams of hexamethylbenzene, m. p. 157–161°, was recrystallized from 400 g. of chloroform. The first and second crops were combined, as they showed practically the same melting point; yield, 270 g.; m. p. 162–164°. This product was then recrystallized three times by dissolving it in twice its weight of boiling chloroform, adding its own weight of hot 95% ethyl alcohol and cooling; yield at this point, 200 g. This product was then recrystallized once from its own weight of thiophene-free benzene; yield, 147 g.; m. p. 164.3–164.8°. The final sample was placed in a vacuum desiccator over phosphorus pentoxide for a few days.

4. **Isodurene, 1,2,3,5-Tetramethylbenzene.**—This compound has been previously made from bromomesitylene, methyl iodide and sodium,[2] but the yields are very poor. In addition to this method of synthesis, Jacobsen[3] reports a synthesis from mesitylene, methyl chloride and aluminum chloride, while Claus and Foecking[4] report a synthesis from mesitylene, methyl iodide and aluminum chloride; in view of the effect of aluminum chloride on aromatic hydrocarbons, it is very doubtful if these last two syntheses yielded pure isodurene.[6]

The method of preparation used in this work is new and it gives a good yield of product which is easily purified, as the crude product contains no isomeric substances. The synthesis starts with pure mesitylene and involves the reactions

$$C_6H_3(CH_3)_3\text{-}(1,3,5) + Br_2 \longrightarrow C_6H_2Br(CH_3)_3 + HBr$$
$$C_6H_2Br(CH_3)_3 + Mg \longrightarrow C_6H_2(CH_3)_3MgBr$$
$$C_6H_2(CH_3)_3MgBr + (CH_3)_2SO_4 \longrightarrow C_6H_2(CH_3)_4\text{-}(1,2,3,5) + (CH_3)(MgBr)SO_4\ (?)$$

Bromination of Mesitylene.—Six hundred and thirty-six grams (5.3 moles) of pure mesitylene (b. p. 58.3–58.5° at 15 mm.) is dissolved in 600–700 g. of carbon tetrachloride and the solution placed in a 3-liter flask provided with a reflux condenser, motor-driven stirrer and a dropping funnel, The flask is placed in a cooling bath, the stirrer is started and the mesitylene is brominated by running into it a solution of 900 g. of bromine in 900 g. of carbon tetrachloride (about 5% excess of bromine). The bromination requires about three hours but the rate at which the bromine is added is limited only by the efficiency of the condenser, as the reaction itself is quite rapid. Direct sunlight should not be allowed to strike the flask, as this increases side-chain bromination, although it is not possible to prevent some of this even in very dim daylight. After the bromination is completed, the reaction mixture is allowed to stand for an hour or so at room temperature. It will then have a light yellow or orange color. It is washed with water and then with alkali, after which the solvent is removed by distillation through a good

column. The oil remaining in the distilling flask is dark and fumes when heated, and to remove side-chain halogen compounds it is boiled for an hour or two with a solution of 50 g. of sodium in a liter of 95% ethyl alcohol and then allowed to stand overnight. Unless this treatment with sodium ethylate is carried out, it is impossible to get a product which will not evolve hydrogen bromide on standing or on distillation.

The alkaline solution is diluted with much water, bringing the oily layer to the top by adding ether. The ethereal solution is washed thoroughly with water, separated, dried over calcium chloride and the ether then distilled off. The remaining oil is fractionated in *vacuo* using a good column. If enough sodium ethylate has been used in the purification, the product will not give any trace of precipitate with alcoholic silver nitrate on standing for twenty-four hours, if it is to be used in a Grignard reaction, it should meet this silver nitrate test. It is a colorless oil, b. p. 105–107° at 16–17 mm., 102.5–103.5° at 14 mm., m. p. -1 to $+1$°; yield, 800–900 g. (76 to 85%).

Grignard Reaction.—The apparatus consists of a 3-liter flask with 3 openings carrying a motor-driven stirrer, a dropping funnel and a reflux condenser, and provided with suitable calcium chloride guard tubes. In the flask are placed 48 g. of fine magnesium turnings,[6] 100 g. of bromomesitylene and 150 g. of ether, and the reaction is then started using the catalyst recommended by Gilman.[7] After the reaction has started. the stirrer is turned on and a solution of 298 g. of bromomesitylene in 600 g. of ether (total bromomesitylene. 398 g. = 2 moles) is added through the dropping funnel at such a rate that a brisk refluring continues. After all of the halogen compound has been added, the reaction mixture is refluxed on the steam-bath until practically all of the magnesium is dissolved. The flask is then cooled and a solution of 600 g. of dimethyl sulfate (freshly distilled in *vacuo*) in 400 g. of ether is run in through the dropping funnel with *vigorous* stirring until the amount of precipitated solid renders stirring useless. The reaction is quite vigorous and as the solid magnesium compounds separate out there is violent bumping. After adding all of the dimethyl sulfate (two to three hours), the reaction mixture is allowed to stand overnight and is then decomposed by adding excess dilute hydrochloric acid. The layers are separated and the ether layer is washed with water two or three times until the magnesium salts are removed, after which the excess dimethyl sulfate is destroyed by adding strong sodium ethylate *carefully* and boiling for an hour. The alcohol is then washed out with water, the ether solution dried over calcium chloride and the ether boiled off. The orange oil remaining is heated on the steam-bath for three to four hours with 25–30 g. of sodium shavings, after which it is filtered and then fractionated in *vacuo* using an efficient column.

The products of two such runs, when combined and fractionated, gave the following: I, b. p. up to 85° at 18 mm., 120 g.; II, b. p. 85–87° at 18 mm., 323 g.; III, b. p. above 87° at 18 mm. 10 g. (residue in the distilling flask). Fraction II is isodurene, with an almost constant boiling point of 86.5° at 18 mm. and a freezing point of -24.2 ± 0.1°. The yield is slightly over 60%. Fraction I consists of regenerated mesitylene, which may be brominated and used again. If the yield of isodurene is based upon the mesitylene used up in the reaction instead of the mesityleue taken, it runs about 80%.

Although the isodurene made in this way is quite pure, for purposes of determining physical constants it was refractionated through a long (4-foot) jacketed column,[8] separating the middle half, which was then refractionated, again separating the middle

half. This gave one quarter of the original material having a constant boiling point of 84.6–84.7° at 17 mm.

5. **Prehnitene, 1,2,3,4-Tetramethylbenzene.**—This was prepared from pentamethylbenzene through the Jacobsen reaction, according to the directions given in the paper by Smith and Lux. Purification: 492 g. of crude prehnitene was washed twice with concd. aqueous sodium hydroxide, then once with water, dried over calcium chloride and fractionated through a 4-foot jacketed Peters column. The prehnitene fraction which resulted weighed 393 g. and had a constant boiling point of 97–98" at 24–25 mm. This was refractionated and the middle half collected (b. p. 97.2–97.6° at 24.5 to 24.8 mm., freezing point −6.9°, weight 186 g.). This product was again fractionated, collecting a middle portion of 132 g., b. p. 96.9 to 97.9' at 24 mm., freezing point −6.8'. As the recorded melting point of prehnitene is higher than this figure,[9] it was decided to attempt a further purification by converting prehnitene into the monobromo compound, purifying this by crystallization, and then regenerating the prehnitene through the Grignard reaction. One hundred and forty-five grams of prehnitene b. p. 98.9–99.0° at 26 mm., was brominated in chloroform, using the same procedure and proportions of materials as were given previously for the bromination of mesitylene. The product was washed with sodium ethylate and purified also according to the procedure used in the case of bromomesitylene. The yield of bromoprehnitene was 180 g. or 77%; b. p. 166–167° at 50 mm.; m. p. +24°. This material, recrystallized twice from its own weight of petroleum ether gave 110 g., m. p. 26.2–26.4°. Although the recorded m. p. of bromoprehnitene is +30°,[10] no further purification was attempted because the crystallization is accompanied by relatively large losses; 80 g. of this material was converted into the Grignard reagent using the procedure already outlined in the case of bromomesitylene. The Grignard reaction with bromoprehnitene does not run as smoothly, however, as it does with bromomesitylene, for after decomposing with acid the yield of prehnitene was only 28 g. (61%). This was boiled with sodium ethylate for two hours; the alcohol then was washed out, the oil heated with metallic sodium for two hours and then allowed to stand overnight, after which it was filtered and distilled. There resulted 23 g. of colorless, highly refractive oil, b. p. 66.5–66.8° at 4 mm., freezing point −6.9'. It is doubtful whether any effective purification is obtained as a result of this long process, for the freezing point of −6.9' is practically the same as that of the product obtained by three fractional distillations of the crude prehnitene from the Jacobsen reaction (−6.8'). In order, however, to be certain of the purity of the prehnitene, it was purified by converting it into the picrate[11] as follows: 69 g. of picric acid (0.3 mole) and 42 g. of prehnitene (slightly more than 0.3 mole; b. p. of the sample used, 100.0–100.5° at 27.5 mm., freezing point −7.7°) were mixed together in a beaker and heated on the steam-bath until most of the solid had dissolved. Then 200 cc. of hot 95% ethyl alcohol was added, everything brought into solution and the mixture cooled to 0°. The picrate crystallizes beautifully in the form of bright yellow stout needles, and after one recrystallization from its own weight of ethyl alcohol melts at 89.5 to 90.5'. The melting point depends somewhat upon the rate at which the bath is heated and also upon the length of time that the picrate is exposed to the air, for it slowly loses prehnitene, and as this happens the color fades and the melting point rises until, after standing for about a week, it reaches the melting point and color of picric acid. This undoubtedly explains the higher melting points given for the picrate by Töhl (92–95°) and by Schultz and Würth (92–96°). The yield of recrystallized picrate was 52 g., or about 50%, though the

---

[9] Jacobsen, *Ber.*, 19, 1213 (18963; gives −4°; Töhl, *ibid.*, 21, 905 (1888), gives −5°.

[11] Töhl, *ibid.*, 21, 905 (1888); Schultz and Worth, *Chem. Centr.*, 76, [1] 1443 (1905).

yield may be improved by using less alcohol in the preparation, as the second crop of crystals is as pure as the first. The picrate was decomposed by dropping it into an excess of concd. sodium hydroxide and steam distilling, when it gave practically the quantitative yield of prehnitene. The prehnitene is washed with alkali and then with water, dried and distilled. From 52 g. of pure picrate there resulted 17 g. of prehnitene and this, on distillation, gave 12 g. boiling at 75.0–75.5° (corr.) at 6.5 mm., and freezing at −6.4° (corr.).

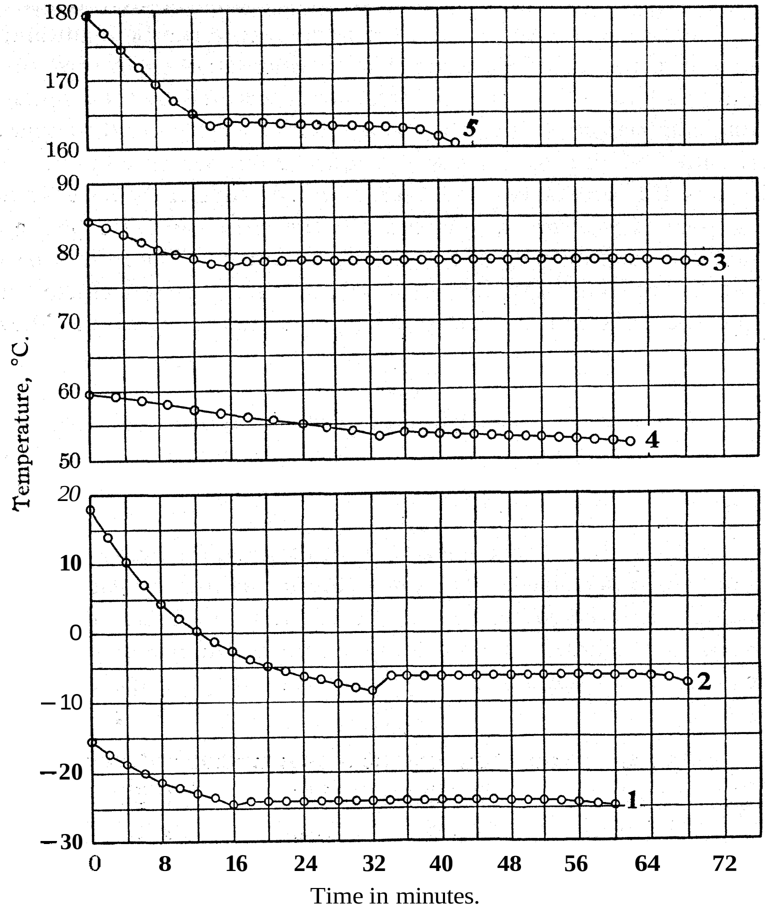

Fig. 1.—Cooling curves, freezing points of the polymethylbenzenes. **1**, Isodurene (1,2,3,5-); **2**, prehnitene (1,2,3,4-); 3, durene (1,2,4,5-); **4**, pentamethylbenzene; **5**, hexamethylbenzene.

Determination of Freezing Points.—The apparatus consisted essentially of the ordinary Beckmann Type for determining freezing points. The liquids used in the bath were water up to 100° and cottonseed oil for temperatures above 100°. For temperatures below that of the room, water and ice were used, while for temperatures below zero various freezing mixtures of ice and salt, ice and calcium chloride, or ice and hydrochloric acid were used. In a few cases carbon dioxide snow was used as the cooling agent, the temperature being limited by using as a bath a liquid freezing a few degrees below the freezing point of the sample. This procedure, however, is rather troublesome and does not have much advantage over a direct cooling bath of a freezing mixture, for with a little practice these freezing mixtures can be adjusted to almost any desired temperature and if a large enough bath is used, the temperature can be maintained for an hour without much difficulty. The thermometers used were all certified and in all cases the temperatures were corrected to total immersion. In taking the freezing points, the cooling curves were plotted, temperature against time, keeping the bath well below the temperature of the sample; in all cases the substances had been purified sufficiently so that at the freezing point there was a "plateau" in the curve and the temperature remained constant until all of the sample solidified. The results are given in Table I, together with the estimated accuracy, based chiefly on the length of the "plateau" in the freezing point curves, which are shown in Fig. 1.

TABLE I

CORRECTED FREEZING POINTS OF PURE POLYMETHYLBENZENES

Durene	79.28 ± 0.05°	**Pentamethylbenzene**	54.0 ± 0.1°
Isodurene	−24.0 ± 0.1°	**Hexamethylbenzene**	164.8 ± 0.1°
Prehnitene	− 6.40 ± 0.05°		

In much the same way the freezing point diagram for the system durene–isodurene was determined. The procedure in making up the sample was to start with a weighed amount of one of the pure constituents and add to it weighed amounts of the other, determining the freezing point of the mixture between each addition. There was always some supercooling,

but no attempt was made to correct for the amount of material separating out and the freezing point of the mixture was taken as the highest point to which the thermometer rose after crystals once appeared. The data are given in Tables II and III, and are shown graphically in Fig. 2.

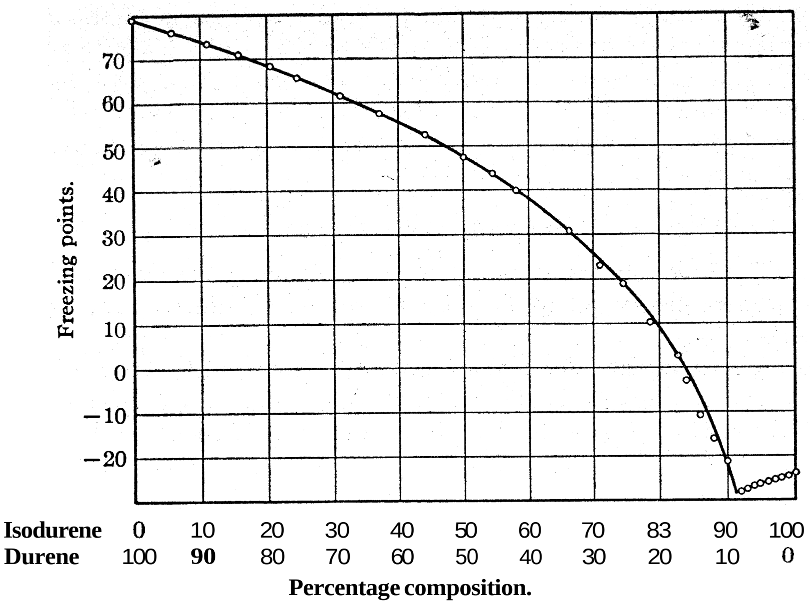

Fig. 2.—Freezing point diagram for the system durene-isodurene.

Discussion of the Results

A. Durene.—Assuming that durene and isodurene form an ideal liquid solution, at least over a certain range of concentrations, we obtain for the equilibrium constant, K_x (expressed in terms of mole fractions), the expression $K_x = x$ for the reaction

$$\text{Durene (solid)} \rightleftarrows \text{Solution of Durene}$$

where x is the mole fraction of durene in the solution. Hence we may write

$$\frac{d \log_e x}{dT} = \frac{L_f}{RT^2} \text{ or } \frac{d \log_e x}{d(1/T)} = -\frac{L_f}{R}$$

where L_f is the molar latent heat of fusion of durene. Making the substitution, $u = 1000\ (1/T - 1/T_0)$, where T_0 is freezing point of pure durene, and changing to ordinary logarithms, we obtain

$$L_f \text{ (in calories)} = -4574 \frac{d \log_{10} x}{du}$$

Over the range from 100% to about 66% of durene, it is found that the following equation represents satisfactorily the experimental data

$$-\log_{10} x = bu + cu^2$$

By the method of least squares, we find $b = 1.098$ and $c = 0.0993$. Hence

$$L_f = 4574\,(b + 2cu) = 5022 - 9.08 \times 10^5(1/T - 1/T_0)$$

For the temperature $T_0 = 352.38$, we find $L_f = 5022$ cal.

B. Isodurene.—The data for the freezing points cover the range from 100 to 92% isodurene with a maximum depression of the freezing point of only four degrees. An analysis of the results leads to the conclusion that liquid isodurene has a higher heat capacity than solid isodurene, but the accuracy of the measurements is not sufficient to enable us to make a more exact statement. The molar latent heat of fusion of isodurene turns out to be about 2550 calories.

Summary and Conclusions

1. The freezing points of all of the polymethylbenzenes containing four or more methyl groups have been determined, using carefully purified materials.
2. A new method for making isodurene in quantity is given.
3. The freezing point diagram for the system durene–isodurene has been studied, and from these data the latent heats of fusion have been calculated.

1,6-ADDITION OF HYDROGEN TO UNSATURATED 1,4-DIKETONES

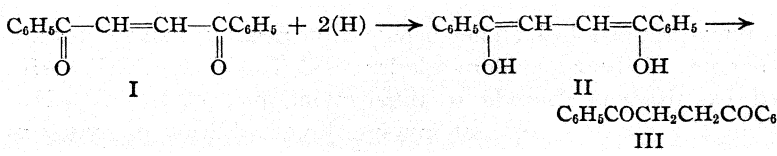
BY ROBERT E. LUTZ

RECEIVED MARCH 27, 1929 PUBLISHED OCTOBER 5, 1929

It is well known that conjugated systems of two or more multiple unions ending in oxygen are reduced with remarkable ease as compared with simple isolated ethylenic or carbonyl double linkages.[1] Typical examples are to be found in the conjugated systems of 1,2-diketones such as benzil, unsaturated 1,4-dicarbonyl and dinitro compounds such as fumaric and o-phthalic acids, unsaturated 1,4-diketones and ketonic acids, quinones, vat dyes and o-dinitrobenzenes; and doubly unsaturated 1,6-dicarbonyl and dinitro compounds such as muconic and p-phthalic acids and *p*-dinitrobenzene. The reductions of these compounds are generally interpreted as 1,4-, 1,6- or 1,8-addition of hydrogen to the terminal oxygen atoms to give dienols which, if the reductions are irreversible, immediately rearrange into stable forms or undergo some other secondary reaction such as the loss of water. Dibenzoylethylene (I), for example, is assumed to undergo the following changes in the course of reduction to dibenzoylethane (III).

---

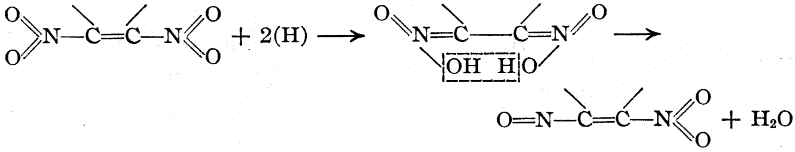
[1] Thiele, *Ann.*, 306, 87 (1899); 308, 333 (1899).



$$\underset{\mathrm{I}}{\mathrm{C_6H_5\underset{\underset{O}{\|}}{C}\!-\!CH\!=\!CH\!-\!\underset{\underset{O}{\|}}{C}C_6H_5}} + 2(\mathrm{H}) \longrightarrow \underset{\mathrm{II}}{\mathrm{C_6H_5\underset{\underset{OH}{|}}{C}\!=\!CH\!-\!CH\!=\!\underset{\underset{OH}{|}}{C}C_6H_5}} \longrightarrow \underset{\mathrm{III}}{\mathrm{C_6H_5COCH_2CH_2COC_6H_5}} \qquad (1)$$

Physico-chemical studies on the strictly reversible reduction of quinones show that electrons and hydrogen add to the terminal oxygen atoms to give as the final product a stable dienol, the corresponding hydroquinone.[2] The irreversible reductions of open chain 1,4-dicarbonyl compounds obviously cannot be directly studied by these physico-chemical methods, but they have been formulated and classified on a moderately exact basis in terms of the reduction potentials of a series of soluble reducing agents.[3] The evidence accumulated in these studies, particularly as concerns the unsaturated 1,4-diketones, is entirely consistent with and best interpreted in terms of a theory of conjugate reduction,[4] but this evidence, although convincing, can hardly be looked upon as conclusive.

The primary formation of the dienols postulated in irreversible reduction has been indirectly demonstrated in a few cases. In the reduction of benzil under special conditions Thiele[5] was able to isolate derivatives of the hypothetical intermediate stilbenediol. In the reduction of *o*- and *p*-dinitrobenzenes to nitronitrosobenzenes, Meisenheimer[6] isolated derivatives of the hypothetical di-aci-nitro-dihydrobenzenes and thus showed convincingly that reduction begins with 1,6- and 1,8-addition of hydrogen to the terminal oxygen atoms of the conjugated systems.



(2)

It was the object of this study of the reduction of certain unsaturated 1,4-diketones to obtain, also, more definite and positive evidence of the actual formation of the intermediate dienols that are postulated by the theory.

---

[2] Conant, Kahn, Fieser and Kurtz, Jr., This Journal, 44, 1382 (1922).

[3] Conant and Lutz, ibid., 45, 1047 (1923); 46, 1254 (1924); Conant and Pratt, *ibid.*, 48, 1036 (1926).

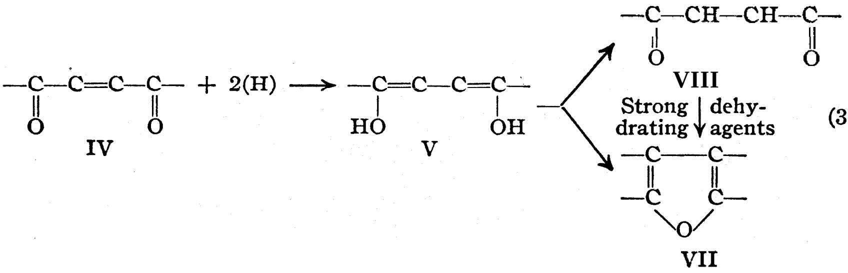
[4] The term "conjugated" is adequately defined as alternate, multiple and single unions, but so far as I am aware no general term has been applied to 1,4-, 1,6- and 1,8-additions which are peculiar to these systems. I shall therefore use the term "conjugate addition" and define it as addition to the ends of a conjugated system as distinct from simple addition to an individual multiple union either of that system or isolated. Conjugate reduction, then, is equivalent to conjugate addition of hydrogen.

[5] Thiele, Ann., 306, 142 (1899).

[6] Meisenheimer, *Ber.*, 36, 4147 (1903); Meisenheimer and Patzig, *ibid.*, 39, 2526 (1906).

Certain unsaturated 1,4-diketones behave in a peculiar manner toward reducing agents. Dibenzoyl-chloro-ethylene,[7] $C_6H_5COCH{=}CClCOC_6H_5$, is reduced by titanous chloride to dibenzoylethane, $C_6H_5COCH_2CH_2COC_6H_5$, but the reaction does not involve direct addition of hydrogen to the ethylenic double bond, as is shown by the fact that dibenzoyl-chloroethane, $C_6H_5COCH_2CHClCOC_6H_5$, is not reduced under these conditions and therefore is not an intermediate product. The chlorine must have been eliminated from some intermediate such as the dienol postulated by the theory of conjugate reduction.

It has been observed that the unsaturated 1,4-diketones, dibenzoylstyrene,[8] benzoyl-(trimethylacetyl)-styrene,[9] and dibenzoylmethoxyethylene,[7] are reduced under certain conditions to the corresponding triphenyl-, diphenyl-(*tert.*-butyl)- and diphenylmethoxyfurans; and that dibenzoylstilbene is reduced by zinc and acetic acid to a mixture of dibenzoyldiphenylethane and tetraphenylfuran.[10] These isolated reactions have not been adequately studied. The formation of the furans, however, suggests that the mechanism of the reaction involves the formation, just as in Equation 1, of an intermediate dienol (V) which can undergo one or both of two possible transformations, dehydration to the furan (VII), and rearrangement into the stable saturated 1,4-diketone (VIII).



(3)

No evidence has been obtained in the experiments cited to show that the saturated 1,4-diketone (VIII) is not directly formed in the reduction, and that it would not itself be dehydrated to the furan under the experimental conditions. Dehydration to the furan is a characteristic reaction of saturated 1,4-diketones of this type, and is usually interpreted as enolization followed by the loss of water from the intermediate dienol[11] (second

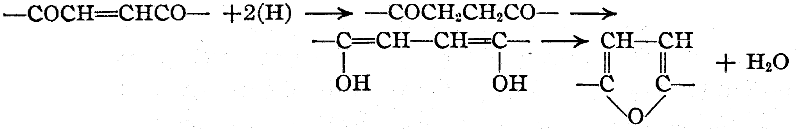
[9] Japp and Maitland, *ibid.*, 85, 1496 (1904).

[10] Zenin, Z. *Chem.*, 3, 313 (1876); *Jahresber. Fort. Thier-Chem.*, 409 (1875); Dorn, Ann., 153, 358 (1870); Magnanini and Angeli, *Ber.*, 22, 853 (1889).

[11] Smith, Ann., 289, 310 (1896); Knorr and Rabe, *Ber.*, 33, 3501 (1900); Borsche and Fels, *ibid.*, 34, 3877 (1906).

and third steps, Equation 4). This transformation can be brought about by a powerful catalytic and dehydrating agent such as sulfuric acid, or the hydriodic acid actually used in two of the reductions cited.[8,9] The general reaction, therefore, might be written not only as in Equation 3, but also as in Equation 4, where the assumed primary reduction product, the saturated 1,4-diketone, may be stable or may be partly or completely dehydrated to the furan under the conditions of the experiment.



(4)

Obviously it is important to know whether or not the saturated 1,4-diketones are stable under these various reducing conditions. If they are unstable and readily converted into the furans (as they would be with hydriodic acid as the reducing agent), then the formation of furans during reduction can have no bearing, either one way or the other, on the problem of mechanism, because reduction direct to the saturated 1,4-diketone (Equation 4) is thereby admitted as possible, and yet the possibility of the primary formation of a dienol (Equation 3) is by no means excluded. On the other hand, if reduction to the furans can be accomplished by reagents which have no dehydrating action upon the saturated 1,4-diketones, then the possibility of hydrogen adding directly to the ethylene double bond would be definitely excluded and the theory of conjugate reduction would be greatly strengthened.

In this research varied conditions have been found under which reduction of six unsaturated 1,4-diketones (Table I) takes place to give largely or exclusively the corresponding furan. In these six cases the corresponding saturated 1,4-diketones have been prepared and have been subjected to identical reducing conditions. In every case very little or no furan was formed and in most cases the saturated 1,4-diketones were largely or wholly recovered unchanged. Therefore, in these six cases, and by analogy in other related compounds, the saturated 1,4-diketones cannot be the primary intermediates in reduction (Equation 4), and the possibility of hydrogen adding directly to the ethylenic double bond is thereby definitely excluded. It would be difficult indeed to explain this formation of the

TABLE I

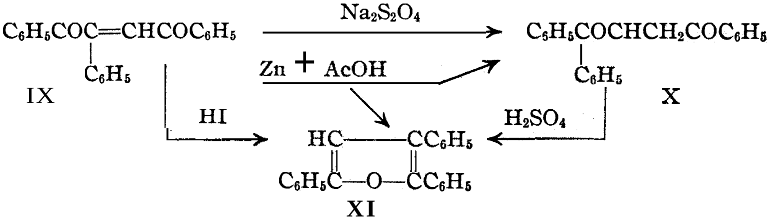
COMPOUNDS AND FORMULAS

1,2-Dibenzoylstyrene	$C_6H_5COC(C_6H_5)=CHCOC_6H_5$
1,2-Dibenzoylmethoxy-ethylene	$C_6H_5COCH=C(OCH_3)COC_6H_5$
1,2-Di-(4-chlorobenzoyl)-methoxy-ethylene	$ClC_6H_4COCH=C(OCH_3)COC_6H_4Cl$
1,2-Di-(4-bromobenzoyl)-methoxy-ethylene	$BrC_6H_4COCH=C(OCH_3)COC_6H_4Br$
1,2-Dibenzoylphenoxy-ethylene	$C_6H_5COCH=C(OC_6H_5)COC_6H_5$
1,2-Dibenzoyl-(4-methylphenoxy)-ethylene	$C_6H_5COCH=C(OC_6H_4CH_3)COC_6H_5$

furans on any other hypothesis than that the dienol, already predicted by the theory, was actually formed as an intermediate product (Equation **3**). Thus the theory of 1,6-addition of hydrogen to systems of this type seems to be strikingly confirmed.

Discussion of Results

Dibenzoylstyrene (IX) is reduced by zinc and acetic acid to a mixture of dibenzoylphenylethane (X) and triphenylfuran (XI), but under these conditions dibenzoylphenylethane, once formed, is stable and can be nearly quantitatively recovered unchanged in a test case. A much more powerful dehydrating agent (sulfuric acid) will convert it into the furan.[12]



IX X XI

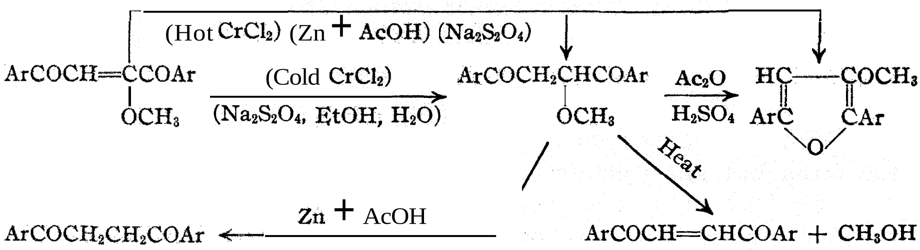
On varying conditions and temperature the relative yields of ethane and furan are greatly altered. Zinc added to a boiling acetic acid solution of dibenzoylstyrene gave the furan in the larger amount; heating a mixture to boiling (reduction nearly complete before actually boiling) gave a larger proportion of the ethane; heating a similar mixture diluted with alcohol, or heating in alcohol with sodium hydrosulfite, yielded only traces of the furan; heating with sodium hydrosulfite in an alcohol–water mixture gave a practically quantitative yield of ethane, no furan being isolated. Thus the yield of furan depends on conditions and solvent, the two extremes being boiling acetic acid, which favors dehydration, and the alcohol–water mixture, which does not. These results are consistent with Equation **3** and the obvious prediction of the theory, namely, that the relative yields of ethane and furan are determined by the velocities of the two competing reactions, ketonization and dehydration of the intermediate dienol, and that these reaction velocities, particularly that of dehydration, are in turn dependent on temperature and solvent.

The methoxy derivatives of dibenzoyl-, di-(chlorobenzoyl)- and di-(bromobenzoyl)-ethylenes, $ArCOCH{=}C(OCH_3)COAr$ (Ar=aryl), were reduced with zinc and acetic acid to the corresponding methoxyfurans. In many of the experiments the corresponding methoxy-ethanes, $ArCOCH_2$-$CH(OCH_3)COAr$, were also obtained in appreciable yields; in other cases, although probably formed in small amounts, they were not isolated in a crystalline form.[13]

---

[12] Smith, J. Chem. *Soc.*, 57, 643 (1890).

[13] The methoxy-ethanes of this series are low-melting solids which crystallize ex-



The methoxy-ethanes, prepared by other methods, were subjected to reducing conditions identical with those under which the unsaturated compounds were converted partly or largely into the corresponding furans. They were not always completely stable. Nevertheless, a variety of reducing conditions were found under which the unsaturated 1,4-diketones gave the furans, yet under which the corresponding methoxy-ethanes were not appreciably dehydrated. In a few cases traces of the furan were isolated, produced by the dehydrating action of the solvent, acetic acid, on the saturated 1,4-diketones; but the yields were in no case significant. In the tests upon dibenzoyl-methoxy-ethane no attempt was made to recover the unchanged material because of the experimental difficulty involved,[13] but no appreciable conversion to the furan was observed (the furan is easily crystallized and significant amounts would have been found). In all of the other cases studied the bulk of the methoxy-ethanes was recovered unchanged and identified.

In many of the test experiments, particularly those carried out in acetic acid, small but definite amounts of the corresponding dibenzoylethanes, $ArCOCH_2CH_2COAr$, were produced by elimination of the methoxyl group. In one case a similar elimination of an aroxyl group was observed. The demethoxylated products were not obtained during reductions of the unsaturated 1,4-diketones where the furan was the sole or the main product. In qualitative tests it seemed that the methoxy-ethanes in the boiling solvents did not sufficiently decompose into the corresponding dibenzoylethylenes to account for the formation of the demethoxylated ethanes by reduction of this decomposition product. It would appear, then, that the methoxyl groups are directly reduced from the saturated methoxy 1,4-diketones.

The structures of the various products are shown by the transformations indicated above. The methoxy-ethanes in every case decompose on heating into the corresponding dibenzoylethylene and methyl alcohol,

---

ceedingly slowly, particularly when they are obtained as oils and in a crude state. These properties explain why dibenzoylmethoxy-ethane was not obtained crystalline in an earlier investigation (ref. 7). In general these oils will stand for weeks before solidifying. Once well started crystallization occurs in from a few hours to several days or a week.

a reaction analogous to the easy elimination of water from β-hydroxy acids, and parallel with the decomposition of α-methoxy-β-(5-bromo-2,4-methoxybenzoyl)-propionic acid and its ester.[14] Two of the methoxy-ethanes are dehydrated by means of acetic anhydride and sulfuric acid to the corresponding furans. Dibenzoyl-methoxy-ethane does not yield the furan but undergoes some transformation not yet understood.

On the basis of the theory of conjugate reduction the factor governing whether or not reduction will occur is the potential of the reducing agent,[3] but the relative yields of furan and ethane should be independent of the nature and potential of the reducing agent,[15] except for specific catalysis of either of the two competing reactions, ketonization and dehydration. It is difficult to predict the extent of this possible catalytic effect, but it is probably concerned mainly with the hydrogen-ion concentration rather than with any specific effect of the reducing agent itself. However, I think it may be said that if the nature of the solvent and the temperature are not greatly altered (even if the hydrogen-ion concentration varies somewhat) different reducing agents should give results of the same order. Thus if sodium hydrosulfite reduced an ethylene to the furan, then in the same solvent and at the same temperature reduction by means of chromous chloride, and even by zinc and acetic acid (assuming its reducing action to depend on potential), ought to give comparable yields of the furan.

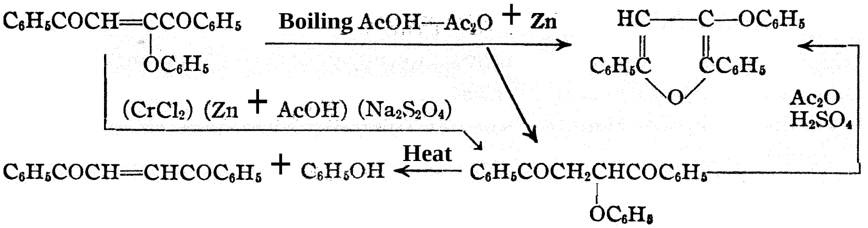
Experiments in boiling 95% ethyl alcohol on two methoxyethylenes show that chromous chloride, sodium hydrosulfite and zinc and acetic acid give in each case considerable and comparable yields of the furan. With chromous chloride the yield of furan was rather low, but as a certain amount of water was present in the reagent the discrepancy in relative yields is not significant. The experiments are thus in qualitative agreement with prediction and are consistent with the view that the second step in Equation 3 is independent of the nature of the reducing agent,[15] but is dependent on the nature of the solvent and its effectiveness in promoting dehydration. I hope to investigate this problem further.

The aroxy-dibenzoylethylenes, $C_6H_5COCH{=}C(OAr)COC_6H_5$, are easily reduced but usually only to the corresponding dibenzoyl-aroxy-ethanes. Reduction by zinc in boiling acetic acid and acetic anhydride, however, gives simultaneously the aroxy-ethanes and the furans; under these conditions the aroxy-ethanes are perfectly stable. Dibenzoyl-phenoxy-ethane decomposes into dibenzoylethylene and phenol on heating and can be readily converted by acetic anhydride and sulfuric acid into the furan.

---

[14] Rice, THIS JOURNAL, 50, 229 (1928).

[15] I refer to the ordinary reducing agents as distinct from "hydrogenating" agents such as platinum and hydrogen, the action of which certainly cannot be expressed in terms of reduction potential [Conant and Cutter, *ibid.*, 44, 2651 (1922)]. Investigation of the catalytic hydrogenation of the unsaturated 1,4-diketones is now under way in this Laboratory.



The simple and aryl substituted dibenzoylethylenes, in marked contrast to those in which an ethylene hydrogen is replaced by methoxyl, aroxyl or phenyl, do not give furans on reduction under the conditions studied. Ethylenic substituents may be arranged in the following order of increasing tendency toward furan formation during reduction; hydrogen, halogen and 3-methylphenoxyl (no tendency), 4-methylphenoxyl, phenoxyl, phenyl and methoxyl. When, however, one benzoyl in dibenzoylstyrene is replaced with trimethylacetyl, no furan formation at all is observed under comparable conditions. Little significance can be attached to this series at present since distinction is not made between the two entirely different effects on the rate of ketonization and on the ease of dehydration.

It might be argued that these reductions of unsaturated 1,4-diketones are really 1,4-additions (they cannot be 1,2-additions). The large amount of information at hand (refs. 1–5) and the results of this investigation are not consistent with such a hypothesis; the theory of 1,6-addition is far more reasonable and involves fewer assumptions than 1,4-addition, particularly as concerns transformations of the intermediate products, affinity of oxygen for hydrogen and the mechanism of the reducing action of the reagents. Furthermore, dimolecular reduction products, though frequently obtained in the reduction of α,β-unsaturated ketones,[16] have never been reported in the extensive studies on unsaturated 1,4-diketones. In this investigation, however, a dimolecular product (m. p. 161°) was obtained in one case, namely, the reduction of dibenzoylethylene with zinc and acetic acid. A study of this reaction is being made and will be reported in detail in a later paper.

Conclusion

The conclusions of this investigation are based on the experimental observations that certain unsaturated 1,4-diketones are reduced under definite conditions to furans, that the saturated 1,4-diketones are not the primary intermediate products and that the saturated 1,4-diketones and the furans are independent end products of the reduction. These experimental results coincide exactly with the obvious prediction of the theory of conjugate reduction, namely, that the dienol (the hypothetical

---

[16] Harries, *Ann.*, *296*, 285 (1897); see, also, Conant and Cutter, THIS JOURNAL, **48**, 1016 (1926).

intermediate both in reduction of unsaturated 1,4-diketones and in dehydration of saturated 1,4-diketones) can either rearrange or pass into the furan by the loss of water. Furthermore, these results can be explained reasonably only by assuming the intermediate formation of this dienol in the process of reduction. Therefore, although the dienol has not been and probably cannot be isolated and studied directly, the evidence so far accumulated points clearly toward its existence momentarily as the primary intermediate reduction product, and thus affords confirmation of the theory of 1,6- or conjugate addition of hydrogen to the unsaturated 1,4-diketones and related substances.

Certain of the preliminary experiments on dibenzoylstyrene were carried out by Mr. William B. Brown at New York University, as a part of Senior Research under the Department of Chemistry.

Experimental Part

Preparation of Methoxy Unsaturated **1,4-Diketones.**—The methoxy unsaturated 1,4-diketones were prepared by methods outlined in earlier investigations.[7,17] The following preparation of the di-(chlorobenzoyl)-methoxy-ethylene (new) illustrates the general procedure employed.

dl-**1,2-Di-(4**-chlorobenzoyl)-1,2-**dibromo**-ethane, $ClC_6H_4COCHBrCHBrCO-C_6H_4Cl$.—Seventy g. of di-(chlorobenzoyl)-ethylene (trans) was dissolved in hot chloroform and treated with a chloroform solution of 37 g. of bromine. The temperature was maintained at about 60° by the heat of reaction. On cooling 49 g. of nearly pure *meso*-dibromide[7] separated, and on evaporation of the solvent 49.5 g. of nearly pure dl-isomer was obtained. The total yield of dibromides was 92%. The dl-isomer (new) was recrystallized from alcohol and was more soluble than the *meso;* m. p. 124.5".

Anal. Calcd. for $C_{16}H_{10}O_2Cl_2Br_2$: Cl, Br, **49.53.** Found: Cl, Br, 49.78.

When bromine was added to 50 g. of the ethylene in glacial acetic acid, 55 g. of the *meso*-dibromide crystallized from the mixture and 18 g. of the dl-isomer was isolated from the filtrate (total yield, 95%).

These results correspond with those previously reported on other dihalides of dibenzoylethylene;[17] nearly equal yields of the two isomers were obtained using chloroform as the solvent at elevated temperature, but the product was largely *meso* when acetic acid was used. That the configurations are as I have assumed is evident by analogy to the mode of preparation and properties of the dihalides of dibenwylethylene the configurations of which are known.[18]

1,2-Di-(4-chlorobenzoyl)-methoxy-ethylene, $ClC_6H_4COCH{=}C(OCH_3)COC_6H_4Cl$.—Di-(chlorobenzoyl)-dibromo-ethane was treated in the usual way[7] with two equivalents of sodium methylate. The colorless product was recrystallized from alcohol; m. p. 130°; soluble in hot alcohol and in cold chloroform, benzene and acetone; insoluble in cold alcohol and petroleum ether.

Anal. Calcd. for $C_{17}H_{12}O_3Cl_2$: Cl, 21.23. Found: Cl, 21.30.

Preparation of Dibenzoyl-aroxy-ethylenes

Dibenzoylphenoxy-ethylene.—The method of preparation formerly used[7] involved the action of sodium phenolate in ether on dibenzoyldibromo-ethane. The procedure

---

[17] Lutz, This Journal, 48, 2905 (1926).

[18] Lutz, *ibid.*, 49, 1106 (1927).

was altered. The sodium was first dissolved in absolute ethyl alcohol, treated with an excess of phenol and added to a suspension of dibenzoyldibromo-ethane in absolute ethyl alcohol. The method gave fair results and was rapid. Using m-cresol a mixture of two stereoisomers was obtained, analogous to the two di-(2,4,6-trimethylbenzoyl)-methoxy-ethylenes.[17] One new compound was prepared by this method, dibenzoyl-(3-methoxyphenoxy)-ethylene.

In a typical experiment 20 g. of phenol was added to a solution of 5 g. of sodium in 200 cc. of absolute ethyl alcohol. This solution was added to a suspension of 40 g. of dibenzoyldibromo-ethane in 160 cc. of absolute alcohol. The mixture was boiled for a few minutes and diluted with water. The gummy precipitate was crystallized from alcohol and gave 21 g. of nearly pure dibenzoylphenoxy-ethylene (63%).

A 62% yield of dibenzoyl-(4-methylphenoxy)-ethylene was obtained by this method using *p*-cresol instead of phenol.

1,2-Dibenzoyl-(3-methoxyphenoxy)-ethylene, $C_6H_5COCH{=}C(OC_6H_4OCH_3\text{-}m)\text{-}COC_6H_5$.—By the above method, using resorcinol monomethyl ether instead of phenol, a small yield (about 10%) of colorless crystals was separated from an oil and recrystallized from alcohol; m. p. 110°.

Anal. Calcd. for $C_{23}H_{18}O_4$: C, 77.08; H, 5.06. Found: C, 76.79; H, 4.93.

1,2-Dibenzoyl-(3-methylphenoxy)-ethylene (Low-Melting Isomer), $C_6H_5COCH{=}C(OC_6H_4CH_3\text{-}m)COC_6H_5$.—*m*-Cresol was substituted for phenol in the above reaction. The product obtained was partially separated by fractional crystallization from alcohol into the known dibenzoyl-(3-methylphenoxy)-ethylene (m. p. 103°),[7] and a stereoisomer. The latter, purified by repeated recrystallization from alcohol, was obtained as nearly colorless needles which melted at 95° to a pale yellow liquid. When crystallized slowly the high-melting isomer (103°) gave bunches of flat, thin, long, radiating, colorless needles. The low-melting isomer (95°) gave long thick prisms which had a very pale yellowish luster. The latter probably corresponds in configuration to the yellow isomer of di-(2,4,6-trimethylbenzoyl)-methoxyethylene.

Anal. Calcd. for $C_{23}H_{18}O_3$: C, 80.69; H, 5.30. Found: C, 80.70; H, 5.32.

Reduction of both isomers by means of (a) chromous chloride, (b) zinc and acetic acid and (c) sodium hydrosulfite gave nearly quantitative yields of the known dibenzoyl-(3-methylphenoxy)-ethane.[7] Zinc and acetic acid reductions failed to give appreciable amounts of a furan; in one case, however, a trace of dibenzoylethane was isolated.

Preparation of Reduction Products

1,2-Dibenzoylmethoxy-ethane, $C_6H_5COCH_2CH(OCH_3)COC_6H_5$.—A mixture of 2 g. of dibenzoylmethoxy-ethylene, 5 g. of sodium hydrosulfite, 20 cc. of alcohol and 12 cc. of water, was boiled for forty minutes and diluted with water. The precipitated oil was dissolved in methyl alcohol and cooled; 0.04 g. of diphenylmethoxyfuran separated. The filtrate was diluted with water and the precipitated oil was separated and allowed to stand for several weeks. It finally crystallized and 1.5 g. of crude product (m. p. 41–43°) was obtained. It was quite soluble in most organic solvents but was insoluble in petroleum ether. The product tends to precipitate as an oil which crystallizes exceedingly slowly. Recrystallization was accomplished by dissolving the substance in ethyl bromide, cooling and diluting the solution with petroleum ether until very slightly turbid. The mixture was then seeded and allowed to stand in an ice-bath for four to six hours, during which time more petroleum ether was added. Colorless crystals formed slowly and after two such operations melted at 48.5–49°.

Anal. Calcd. for $C_{17}H_{16}O_3$: C, 77.25; H, 6.11. Found: C, 76.64; H, 6.08.

In a second experiment the time of heating was cut down to ten minutes; 1 g.

of furan was obtained from 10 g. of the ethylene. Since long heating does not appreciably affect the yield of furan, it follows that dibenzoylmethoxy-ethane, once formed, is stable and not appreciably dehydrated to the furan under these conditions.

Acetic anhydride and concd. sulfuric acid failed to dehydrate the ethane to the furan, but gave instead oils and a colorless solid which will be investigated further.

Decomposition of Dibenzoylmethoxy-ethane.—One-tenth gram **of dibenzoyl**methoxyethane was heated to 210–215° for twenty minutes. The molten mass turned yellow and decomposed with the evolution of a droplet of methyl alcohol which was collected and identified by conversion into the methyl ester of 3,5-dinitrobenzoic acid. The residue was crystallized from alcohol and gave 0.45 g. of dibenzoylethylene (identified by mixed melting point).

A small sample of dibenzoylmethoxy-ethane was boiled for a few minutes in an acetic acidanhydride mixture. The solution remained colorless and no evidence of decomposition was observed.

2,5-Di-(4-chlorophenyl)-methoxyfuran, $ClC_6H_4C{=}CH{-}C(OCH_3){=}C(C\ H_4Cl)O$.—A mixture of 14 cc. of glacial acetic acid, 1 cc. of acetic anhydride, 6 g. of zinc dust and 2 g. of di-(chlorobenzoyl)-methoxy-ethylene was brought to a boil, filtered and poured into water. The product was crystallized from alcohol; yield, 1.1 g.; m. p. 114°.

Anal. Calcd. for $C_{17}H_{12}O_2Cl_2$: Cl, 22.14. Found: Cl, 22.22.

1,2-Di-(4-chlorobenzoyl)methoxy-ethane, $ClC_6H_4COCH_2CH(OCH_3)COC_6H_4Cl$.—A mixture of 6 g. of di-(chlorobenzoyl)-methoxy-ethylene, 25 g. of sodium hydrosulfite, 120 cc. of alcohol and 30 cc. of water was boiled under a reflux condenser for twenty minutes, cooled and diluted with water. The resulting oil, after standing for several weeks, was induced to crystallize. It was purified by dissolving in enough warm methyl alcohol to prevent immediate precipitation as an oil on cooling to room temperature. It was then seeded and allowed to stand for one to two days to crystallize. The yield of nearly pure material (m. p. 58–59°) was 5.7 g. It was soluble in hot ligroin, petroleum ether and alcohol but insoluble cold, and soluble in cold acetic acid, benzene, chloroform and ether. It formed colorless granular crystals, m. p. 61.5°.

Anal. Calcd. for $C_{17}H_{14}O_3Cl_2$: C, 61.45; H, 4.25; Cl, 21.35. Found: C, 61.47; H, 4.14; Cl, 21.04.

A small sample was converted by the action of acetic anhydride containing a trace of sulfuric acid into di-(chlorophenyl)-methoxy-furan, which was identified by mixed melting points. The yield was low.

Decomposition of Di-(chlorobenzoyl)-methoxy-ethane.—Two-tenth gram **of di-**(chlorobenzoyl)-methoxy-ethane was heated for ten minutes at 200° in a suitable apparatus. Decomposition took place. A droplet of distillate was obtained and identified as methyl alcohol by conversion into the methyl ester of 3,5-dinitrobenzoic acid. The dark orange residue was crystallized from acetone and gave 0.05 g. of yellow crystals which were identified by mixed melting points as di-(chlorobenzoyl)-ethylene.

In a qualitative experiment a sample of di-(chlorobenzoyl)-methoxyethane dissolved in an acetic acid–anhydride mixture to give a colorless solution which remained colorless on boiling. Failure to develop a yellow color indicated that no decomposition into dibenzoylethylene occurred.

2,5-Di-(4-bromophenyl)-methoxy-furan, $BrC_6H_4C{=}CH{-}C(OCH_3){=}C(C_6H_4Br)O$.—A mixture of 1 g. of di-(bromobenzoyl)-methoxy-ethylene, 2 g. of zinc dust and 15 cc. of glacial acetic acid was brought to a boil. filtered and diluted with water. The product (0.82 g.) was recrystallized several times from alcohol and obtained as a mat of colorless needles melting at 113°

Anal. Calcd. for $C_{17}H_{12}O_2Br_2$: C, 50.01; H, 2.97; Br, 39.17. Found: C, 49.83; H, 3.01; Br, 39.45.

1,2-Di-(4-bromobenzoyl)-methoxy-ethane, $BrC_6H_4COCH_2CH(OCH_3)COC_6H_4Br$.—A mixture of 6 g. of di-(bromobenzoyl)-methoxy-ethylene, 120 cc. of alcohol, 30 cc. of water and 25 g. of sodium hydrosulfite was boiled for twenty minutes. On dilution with water an oil was obtained which was induced to crystallize after standing for several weeks. It was purified by dissolving in warm methyl alcohol, cooling, seeding and allowing to stand for twenty-four hours; yield, 4.5 g. The recrystallized product was colorless, melted at 72° and was soluble in benzene, acetone, ether and hot alcohol, and slightly soluble in cold alcohol.

Anal. Calcd. for $C_{17}H_{14}O_3Br_2$: C, 47.91; H, 3.32. Found: C, 47.93; H, 3.37.

Decomposition of **Di-(bromobenzoyl)-methoxy-ethane.**—Fifteen hundredths of a gram of di-(bromobenzoyl)-methoxy-ethane was heated to 210–220° for ten minutes. Decomposition took place and a droplet of methyl alcohol distilled and was identified as the methyl ester of 3,5-dinitrobenzoic acid. The yellow residue was dissolved in hot chloroform and 0.05 g. of yellow crystals was obtained and identified as di-(bromobenzoyl)-ethylene.

1,2-Dibenzoylphenoxy-ethane, $C_6H_5COCH_2CH(OC_6H_5)COC_6H_5$.—Reductions of 0.5 g. of dibenzoylphenoxy-ethylene by (a) chromous chloride and (b) sodium hydrosulfite gave, respectively, 0.47 g. and 0.49 g. of nearly pure dibenzoylphenoxy-ethane. The product was purified for analysis by recrystallizations from alcohol (m. p. 120°). Reduction of 1.65 g. of **dibenzoylphenoxy-ethylene** with zinc and acetic acid gave 0.9 g. of the ethane.

Anal. Calcd. for $C_{22}H_{18}O_3$: C, 79.99; H, 5.49. Found: C, 80.10; H, 5.77.

2,5-Diphenyl-3-phenoxyfuran, $C_6H_5\overline{C{=}CH{-}C(OC_6H_5){=}C(C_6H_5)O}$.—One gram of dibenzoylphenoxy-ethane was treated with acetic anhydride containing a drop of concd. sulfuric acid. Immediate reaction occurred accompanied by color formation. The mixture was decomposed in water and the product (0.9 g.) recrystallized several times from alcohol; m. p. 91°.

Anal. Calcd. for $C_{22}H_{16}O_2$: C, 84.57; H, 5.17. Found: C, 84.74; H, 5.12.

Decomposition of **Dibenzoylphenoxy-ethane.—A** sample of dibenzoylphenoxy-ethane was heated to 270°. A droplet of phenol distilled and was identified by its odor and conversion into tribromophenol. A good yield of dibenzoylethylene was obtained by recrystallizing the dark colored residue.

1,2-Dibenzoyl-(4-methylphenoxy)-ethane, $C_6H_5COCH_2CH(OC_6H_4CH_3)COC_6H_5$.—Dibenzoyl-(4-methylphenoxy)-ethylene was reduced by (a) sodium hydrosulfite and (b) zinc and acetic acid, to give in each case nearly theoretical yields of dibenzoyl-(4-methylphenoxy)-ethane, which was obtained after repeated crystallization from alcohol as colorless crystals melting at 108.5°.

Anal. Calcd. for $C_{23}H_{20}O_3$: C, 80.18; H, 5.85. Found: C, 80.28; H, 5.84.

2,5-Diphenyl-3-(4-methylphenoxy)-furan, $C_6H_5\overline{C{=}CHC(OC_6H_4CH_3\text{-}p){=}C(C_6H_5)O}$.—One gram of dibenzoyl-(4-methylphenoxy)-ethane was dissolved in acetic anhydride containing a trace of concd. sulfuric acid. The mixture was decomposed with water and the product crystallized from alcohol; yield, 0.7 g.; m. p. (pure) 113°.

Anal. Calcd. for $C_{23}H_{18}O_2$: C, 84.60; H, 5.56. Found: C, 84.18; H, 5.59.

A Study of the Formation of Furans During Reduction of Unsaturated 1,4-Diketones

Methods of Reduction and Isolation of Products.—Three reducing

agents, sodium hydrosulfite, chromous chloride and zinc and acetic acid were used under different conditions in this research.

[a] The symbol "A" indicates heating the solution to boiling or heating at the boiling point (unless another temperature is specified).

[b] "Recov." = starting material recovered unchanged.

[c] When the amount of reducing agent is not specified a considerable excess was used. Reagents were added in the order named.

[d] "Ethane" refers to the saturated 1,4-diketones from which the niethoxyl or aroxyl group has been eliminated.

[e] The dibenzoylmethoxyethanes were often obtained as oils and in these cases no attempt was made to crystallize them. When dissolved in methyl alcohol and cooled, no crystalline products were isolated (other than those specified). Even small amounts of the furans crystallized from mixtures under these conditions. These residual oils are therefore assumed to consist largely of dibenzoylmethoxyethane.

[f] If the furan is not mentioned it was not found among the products.

[g] A sample of this ethane was prepared by reduction of the dl- and *meso*-di-(bromobenzoyl)-dibromo-ethanes by means of zinc and acetic acid, both isomers yielding the same di-(bromobenzoyl)-ethane (known), Hale and Thorpe, THIS JOURNAL, 35, 272 (1913).

[h] The crude diphenylphenoxyfuran was freed from the last traces of the less soluble dibenzoylphenoxyethane by dissolving in hot alcohol and allowing to cool quietly to room temperature. The furan separated first and was filtered off rapidly; the ethane, remaining up to this point in supersaturated solution, immediately crystallized from the filtrate.

[i] The separation of the 4-methylphenoxy derivatives was facilitated by the following procedure. A hot alcohol solution of the mixture was allowed to cool quietly to room temperature and was seeded with the ethane. Bunches of radiating hair-like needles spread rapidly through the solution, and were quickly filtered off. The furan, remaining up to this point in supersaturated solution, rapidly crystallized from the filtrate and was obtained nearly pure.

The reductions with sodium hydrosulfite were carried out in alcohol as the solvent, but varying amounts of water were added in order to increase the solubility of the reducing agent and to decrease the dehydrating action of the solvent. The procedure was the same in every case. The substance being reduced was placed in a mixture of alcohol and water, sodium hydrosulfite was added and the mixture was boiled under a reflux condenser. The products were isolated by diluting the mixture with water, allowing the gummy precipitate to settle out (usually overnight) and then fractionally crystallizing the residue in order to isolate the components; products in every case were identified finally by mixed melting points with known materials. The yields in Table II refer to nearly pure products actually separated out, and which melted within a few degrees of the theoretical.

Reductions with zinc and acetic acid were carried out by heating a mixture of the substance and the reducing agent under the conditions selected, followed by rapid suction filtration while hot to remove the zinc. The filtrate was diluted with water and allowed to stand (usually overnight) until the gummy precipitate settled. The residue was separated by fractional crystallization (usually from alcohol) into its components, which were identified in every case by mixed melting point methods.

Chromous chloride reductions were carried out in alcohol as the solvent. The reagent was prepared by treating 50 g. of chromic chloride with 350 cc. of alcohol, 50 g. of zinc and 100 cc. of concd. hydrochloric acid. It was preserved under an atmosphere of hydrogen in a suitable apparatus.

Reductions were carried out in closed vessels protected by an atmosphere of carbon dioxide. In a few experiments the reducing agent was introduced through the side arm of the reaction flask into a rapidly boiling solution of the substance to be reduced, the chromous chloride being protected from the air by the vapor of the solvent. The products were isolated by diluting with water, fractionally crystallizing the gummy precipitate from some solvent (usually methyl or ethyl alcohol) and identifying the products in the usual way by means of mixed melting points.

The Action of Reducing Agents on Saturated 1,4-Diketones.—Samples of the saturated 1,4-diketones were tested with the reducing agents under conditions identical with those under which the reductions of the unsaturated 1,4-diketones were carried out. Although smaller amounts of materials were used, the same proportions were maintained. In these experiments the oxidized form of the reducing agent was added in order to make sure that conditions were identical with those actually involved during a reduction. Thus sodium bisulfite was added in tests with sodium hydrosulfite as the reducing agent, zinc acetate in zinc and acetic acid reductions and chromic chloride (by rapid oxidation of the chromous chloride through contact with the air) in tests with chromous chloride. The products were isolated and identified in the usual way.

The results of reductions of the six unsaturated 1,4-diketones and the effects of the reducing agents on the saturated 1,4-diketones are given in Table II.

Reduction of 1-Benzoyl-2-trimethylacetylstyrene.—Benzoyltrimethylacetylstyrene was reduced nearly quantitatively under various conditions with zinc, acetic acid and acetic anhydride to the known benzoyl-(trimethylacetyl)-phenylethane (desylpinacoline).[19] This product was found to be unstable when heated with hydriodic acid (sp. gr. 1.96).

Elimination of Methoxyl and Aroxyl Groups by Reduction.—In a number of experiments small amounts of unsubstituted saturated 1,4-

diketones were obtained, resulting from the elimination of the methoxyl or aroxyl group through the action of the reducing agents. The loss of methoxyl or aroxyl occurs only in experiments in which the methoxy- or aroxyethanes, $ArCOCH_2CH(OCH_3)COAr$, are the starting materials or are the principal products in the reactions concerned. Apparently these substances do not decompose (splitting out alcohol or phenol) under the most drastic conditions involved during a reduction, namely, boiling in an acetic acid–anhydride mixture. The reaction, therefore, must involve direct reduction. In Table III are listed the methoxy- and aroxyethanes reduced in this manner.

Summary

1. A variety of reducing conditions are described under which six different substituted unsaturated 1,4-diketones are converted into the corresponding furans, and under which conditions the corresponding saturated 1,4-diketones are stable.

2. The bearing of these facts on the theory of 1,6-addition of hydrogen to unsaturated 1,4-dicarbonyl compounds is discussed and the conclusion is drawn that the dienol postulated by the theory is actually formed as the primary intermediate in reduction and accounts for the formation of the furans.

3. The diaryl-methoxy- and aroxy-substituted 1,4-diketones are easily dehydrated to the corresponding furans and decompose on heating into the corresponding dibenzoylethylene and alcohol or phenol.

4. The methoxyl groups in certain cases are eliminated by reduction from the methoxy-saturated 1,4-diketones.

5. New aroxy- and methoxydibenzoylethylenes are described.

ISOMERS OF 2-PENTENE. I. PENTENE-2 FROM 3-BROMOPENTANE AND FROM 3-PENTANOL[1]

BY MARY L. SHERRILL, BELLE OTTO AND LUCY W. PICKETT

RECEIVED MARCH 29, 1929 PUBLISHED OCTOBER 5, 1929

The present study is one of a series involved in an investigation of the preparation and properties of the isomeric 2-pentenes.[2] Wurtz[3] was the first to report the preparation of 2-pentene and the reaction of this with

---

[1] Presented in abstract before the Organic Division, at the Swampscott Meeting of the American Chemical Society, September, 1928.

[2] The work originated in the request of Professor Morris Kharasch (September, 1926) that Professor Carr make, in this Laboratory, absorption spectra measurements of a 2-pentene obtained from 3-bromopentane and of an isomeric form of this 2-pentene which Professor Kharasch had obtained by heating 2-pentene in xylene.

[3] Wurtz, *Ann.*, 125, 114 (1863).

hydrogen bromide. Wagner and Saytzeff[4] prepared the 2-pentene from 3-iodopentane and reported an addition of hydrogen iodide to the pentene to form 2-iodopentane. Brochet[5] also reported the formation of 2-iodopentane by this addition reaction. Van Risseghem[6] prepared 2-pentene by the dehydration of 3-pentanol with *p*-toluenesulfonic acid. In the study of the reactions of the double bond Brunel[7] and Cuy[8] used the work of Wagner and Saytzeff to support their theories. Cuy interpreted the addition reactions in support of the theory of alternate polarity in carbon chains. Lucas and collaborators[9] in a series of investigations presented experimental evidence at variance with this theory and advanced in its place the theory of electronic displacement. According to the alternate polarity theory, addition of hydrogen bromide to 2-pentene should give largely 2-bromopentane, but according to the theory of electronic displacement as interpreted by Lucas, the chief product should be 3-bromopentane. In view of the fact that the accuracy of the older work seemed in doubt, Lucas and Moyse[9b] prepared 3-bromopentane and from this the 2-pentene was obtained by the action of alcoholic potash. The 2-pentene was distilled directly into xylene and from the dried xylene solution 2-pentene (boiling between 35 and 37°) was distilled into glacial acetic acid containing hydrogen bromide. The bromide obtained had a refractive index of n_D^{20} 1.4437 and was 78% 3-bromopentane and 22% 2-bromopentane. This percentage was determined entirely by the index of refraction, since Lucas had shown that the refractive index of a mixture of 3-bromopentane and of 2-bromopentane was a linear function of the composition. Lucas considered the electron displacement theory confirmed by these data. Kharasch[10] has determined the relative electronegativity of certain organic radicals and found that the methyl group is more electronegative than the ethyl group. This is in accord with Lucas' ideas but Kharasch disagrees with Lucas as to the resultant condition of the carbons at the double bonds. Lucas and Moyse[9b] state that "methyl exerts a stronger pull on electrons than ethyl does, as shown by the relative ionization constants of organic acids and bases, and therefore 2-pentene, where a methyl and an ethyl radical are situated on opposite sides of the double bond, should have the electrons of this bond closer to the methyl. Therefore when hydrogen bromide adds, the bromine should go largely to the

middle carbon atom." According to the Kharasch theory the substitution of an electronegative atom or radical for a hydrogen in the methyl group decreases the electronegativity of the group, and since the methyl group is more electronegative than the ethyl group, the carbon atom in the ethylenic linkage which carries the methyl group will be *less* electronegative than that which has the ethyl group. As a consequence the pair of electrons should be displaced toward the carbon atom to which the ethyl group is attached and when hydrogen bromide is added to 2-pentene the product should be 2-bromopentane and not 3-bromopentane as would follow from the hypothesis of Lucas.

As a corollary of this theory of the partial polarity of the ethylene bond, Kharasch[11] predicted the existence of electronic isomers in cases where the radicals attached to the two carbon atoms of the double bond differ very slightly in electronegativity, as is the case in 2-pentene. In one isomer the second pair of electrons would be displaced toward the carbon atom to which the ethyl group is attached and in the other isomer toward the carbon atom carrying the methyl group, but the latter isomer should be the less stable. In the preparation of 2-pentene from *3-bromopentane* it was reasonable to expect the formation of the less stable isomer since the carbon atom to which the bromine is attached would have its electronegativity decreased and the electrons would be displaced in such a way that with the splitting off of hydrobromic acid in the formation of the pentene the second pair of electrons of the double bond would be displaced toward the methyl group. This form of 2-pentene should add hydrogen bromide to give 3-bromopentane. Kharasch further postulated the possibility of transforming this form of 2-pentene into the more stable form which should add hydrogen bromide to form 2-bromopentane.

In order to confirm this theory, Kharasch repeated the work of Lucas and, under similar conditions, obtained results identical with those of Lucas. Kharasch found, however, that whereas this 2-pentene, made from 3-bromopentane, in glacial acetic acid added hydrogen bromide to form 78% of 3-bromopentane and 22% of 2-bromopentane, in a non-polar solvent such as carbon tetrachloride or petroleum ether or by direct addition of hydrogen bromide without a solvent, the 2-pentene gave 97–100% of 3-bromopentane. Kharasch then heated a solution of 2-pentene in xylene in a sealed glass tube at 90–100° for varying lengths of time and found that the 2-pentene was gradually transformed into an isomeric form of 2-pentene which gave addition products with hydrogen bromide varying from 63% of 3-bromo- and 37% of 2-bromopentane to 16% of 3-bromo- and 84% of 2-bromopentane depending on the length of time

---

[11] Private communication, September, 1926; paper presented at Organic Symposium, Columbus, Ohio, December, 1927. Since the preparation of this article a full discussion of Kharasch's theory has been published in *Chemical Reviews*, 5, 571 (1928).

it had been heated. The percentage composition was determined by the index of refraction of the bromide obtained. This work of Kharasch gave evidence of the two electromers which he had believed theoretically possible. To obtain additional data Professor Kharasch asked Professor Carr to make absorption spectra measurements of these compounds. The preparation, the purification of the 2-pentene and its transformation into the isomeric form were undertaken in this Laboratory, the products to be used for absorption measurements. The addition products and the physical properties of the 2-pentene have been studied. The work of Kharasch has been duplicated and additional data have been obtained.

In view of the fact that for absorption measurements it is highly important to have materials of a high degree of purity, it seemed essential to have the measurements made on each of the pure isomers rather than on possible mixtures. This involved the consideration of methods of separation. In addition to the electronic isomers considered by Kharasch, there is also the possibility, in 2-pentene, of *cis-trans* isomerism. In the present work this possibility has been kept constantly in mind. Van Risseghem[6] attempted the separation of the *cis-trans* isomers of 2-pentene. She prepared the 2-pentene by the dehydrating action of *p*-toluenesulfonic acid on diethylcarbinol at 135–140°. Repeated fractionation through a Young column gave no evidence of separation and since attempts to isomerize also failed she concluded that only one form was stable or that there was an equilibrium mixture of the two. In spite of these results it was considered advisable to use the method so successfully used by Van de Walle[12] in the separation of *cis-trans* isomers of the halogen ethylenes, that is, the fractionation of azeotropic mixtures of the pentenes with absolute alcohol. In the separation of *cis-trans* isomers the alcohol has seemed to have a stabilizing effect and by its use isomers have been separated which had not been separated by any other method. The method has proved highly satisfactory for the purification of the pentenes.

Experimental

Preparation of 3-Pentanol (Diethylcarbinol).—3-Pentanol was prepared by a Grignard synthesis from ethylmagnesium bromide and ethyl formate. A detailed description of the method is given by Lucas and Moyse[9b] and their work was repeated in this Laboratory. The ethyl formate, prepared from ethyl alcohol (6 moles), concentrated sulfuric acid (6.8 moles) and sodium formate (6 moles) was obtained in 90% yield (b. p. 54.2 ± 0.1°). The final distillation of the 3-pentanol gave a product (70% yield) which boiled at 114.8–115.2° and had a refractive index, n^{20}_{D} 1.4078. Lucas and Moyse[9b] give the boiling point as 117–119° (corr.) at 745 mm. The values given by other investigators[13] correspond more closely to that obtained in this Laboratory.

[13] Timmermans, *ibid.*, 27, 334 (1913), gives 115.35 ± 0.10" at 760 mm.; Willcox

In addition to the 3-pentanol prepared in this Laboratory, pentanol-3 (synthetic) was obtained from R. E. Marker. This material (b. p. 114–116.8° corr., and n_D^{20} 1.4078) was used in some comparison runs. Commercial 3-pentanol (Sharples Solvents Corporation) was fractionated several times through a 50-cm. Crismer column and gave fractions 114–115.8°, n_D^{20} 1.4078, and 115.8–116.2°, n_D^{20} 1.4079. This material was used only in trying some variations of method and not for any of the conclusive experiments.

Preparation of **3-Bromopentane.**—This compound was formed by treating the carbinol according to the method given by Kharasch.[14] The carbinol was placed in a round-bottomed flask and cooled to −10°. It was then saturated with hydrogen bromide which was obtained by the action of bromine on red phosphorus and water, passed through U-tubes containing moist red phosphorus and one tube containing anhydrous sodium sulfate. After saturation the flask containing the carbinol was closed with a stopper to which a toy rubber balloon was attached and was heated in a water-bath up to 60° and kept at that temperature until the collapse of the balloon indicated complete absorption of the hydrogen bromide. This saturation process was repeated several times until no more gas was absorbed. The product was separated from the hydrobromic acid–water layer, washed four times with ice water, twice with ice-cold concentrated sulfuric acid, once with ice water, twice with a cold saturated solution of sodium carbonate and once with ice water. It was then dried over potassium carbonate and distilled from a flask with fractionating neck. The 3-bromopentane was obtained in 84–85% yields and had the following properties: boiling point, 118.2–118.5" at 760 mm.; n_D^{20} 1.4443 (Abbé), 1.44431 (Zeiss dipping); d_4^{20} 1.2170. Repetition of the above procedure in many runs gave identical results. The process was slow and in an effort to hasten the process variations in the above procedure were tried which brought out the interesting fact that unless great care was taken in the preparation of the bromopentane the product was not pure 3-bromopentane but a mixture of 3-bromopentane and 2-bromopentane (b. p. 117.5–118.5° at 745 mm., n_D^{20} 1.4415).[9c,3] The variations in treatment of the carbinol were the use of gaseous hydrogen bromide under pressure,[9b] the action of phosphorus tribromide in the cold and gently warmed

and Brunel, THIS JOURNAL, 38, 1838 (1916), give 114.8–115.2° at 760 mm.; Brunel, *ibid.*, 45, 1337 (1923), gives 115.4" at 754 mm., n_D^{25} 1.4077; Norris and Cortese, *ibid.*, 49, 2644 (1927), give 115.8–116° and n_D^{25} 1.4079.

[14] Kharasch, private communication, 1926.

to 60° and the action of 48% hydrobromic acid refluxed for several hours. Table I shows the variations in the product obtained.

Not only does the variation in boiling point and refractive index give evidence of the presence of 2-bromopentane in these products, but the absorption spectra of 2-pentene obtained from these give more conclusive evidence of this.[15] The results obtained in C indicated the probable course of the transformation. In that case a considerable amount of 2-pentene distilled over. The hydrocarbon is therefore evidently formed by the more vigorous method and after being formed under these conditions of higher temperature or pressure adds to form 2-bromopentane in varying amounts. This may be considered as some evidence in favor of the fact that this 2-pentene is the more stable form of 2-pentene.

Preparation of 2-Pentene

A. From 3-Bromopentane by the Action of Alcoholic Potash.—Bromopentane-3 (n^{20}_D 1.4443, 229 g.) was dropped slowly into a solution of potassium hydroxide (261 g.) in absolute methyl alcohol (500 cc.) heated on an oil-bath kept at 110–115°. The vapors were passed through a reflux condenser kept at 40°, then through a cold downward condenser and the distillate was collected in absolute methyl alcohol protected from the moisture of the air and kept cold with ice and salt. When ethyl alcohol was used as the collecting solvent it was then used for the alcoholic potash and the temperature of the bath was 125–127°. The distillate was fractionated through a Crismer column (50 cm. or 1.5 m. in various runs) surrounded by an air jacket and the azeotropic mixture which was distilled was collected in a flask surrounded by ice and salt. The 2-pentene was separated from the alcoholic solution by repeated washings with ice water; then it was dried over calcium chloride. The yield of 2-pentene was 89–92%. Whenever pure 3-bromopentane (n^{20}_D 1.4443) was used the distillation of the azeotropic mixture was practically constant throughout, and the 2-pentene isolated was pure. When, however, the 3-bromopentane used contained some 2-bromopentane, the distillation was not constant, and the hydrocarbon isolated had different physical properties. This variation is shown in Table II.

TABLE II

RESULTS OF EXPERIMENTS

				2-Pentene	
		n^{20}_D		B. p. at 760 mm., °C.	n^{20}_D
1	3-Bromopentane	1.44431		36.30 ± 0.05	1.37963
2	3-Bromopentane	1.4437	after 2d fractionation		1.37935
			after 3d fractionation		1.37945
3	3-Bromopentane	1.4432			1.37930
4	3-Bromopentane	1.4427			1.37923
5	3-Bromopentane	1.4417			1.3791

The rate of fractionation of azeotropic mixtures of the pure 2-pentene and of a mixture done simultaneously is shown in Fig. 1, Curve I, representing the fractionation of 2-pentene from (1) above, and II representing the fractionation of 2-pentene from (4) above.

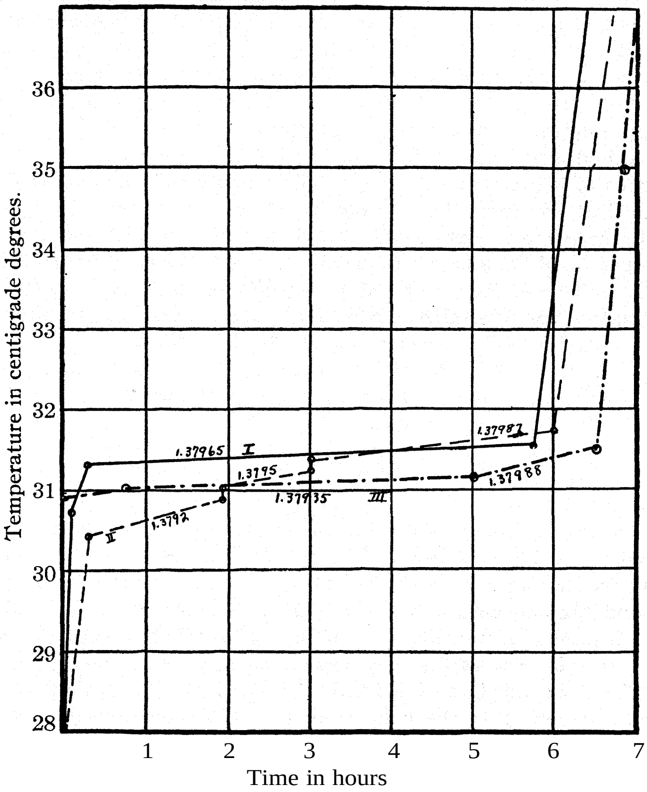
B. From 3-Pentanol by the Action of 60% Sulfuric Acid.—The method is that reported by Norris,[16] in which commercial 2-pentanol was treated with sulfuric acid.

---

[15] Carr, THIS JOURNAL, 51, 3041 (1929).

[16] (a) Norris and Reuter, *ibid.*, 49, 2630 (1927); (b) Norris and Joubert, *ibid.*, 49, 885 (1927), had dehydrated 3-pentanol with phosphorus pentoxide.

A 60% solution of sulfuric acid (containing 105 g. of concentrated acid) was placed in a flask provided with a drop funnel and connected with a long condenser, and 3-pentanol (43 g.) was slowly added from the funnel. The flask was cooled in ice and shaken gently during the addition of the alcohol. The mixture was then heated slowly on a water-bath and finally on a boiling water-bath as long as the hydrocarbon distilled. The distillate was collected in a bottle surrounded by ice and salt. It was washed with 5% sodium hydroxide and dried over calcium chloride; yields, 73-90%. The crude pentene had a refractive index of 1.3820–1.3823 at 20". Refractionated as an azeotropic mixture with methyl alcohol the following fractions were obtained.



——, I, 2-Pentene from 3-bromopentane, n^{20}_{D} 1.44431 (762 mm.); – –, II, 2-pentene from 3-bromopentane, n^{20}_{D} 1.4427 (762 mm.); — - —, III, 2-pentene from 3-pentanol, n^{20}_{D} 1.4078 (755 mm.).

Fig. 1.—Fractionation of azeotropic mixtures of 2-pentane in methyl alcohol.

	B. p. at 760 mm.., °C.	Time	Wt. of 2-pentene, g.	n^{20}_{D}
I	31.1–31.2	45 min.	6.7	1.3793
II	31.2–31.3	4 hours	11.7	1.3794
III	31.3–31.7	1.5 hours	12.9	1.37988

Fractions I and II, from absorption spectra measurements, were identical and when mixed gave a refractive index of 1.37935 at 20°. The lower index and lower boiling azeotropic mixture would indicate a small amount of the isomeric 2-pentene. Fraction III contained a large amount of more absorptive material, the higher index being due to this. This may be polymeric material and it is present in much greater quantities in 2-pentene made by this method than in that from the alcoholic potash method. The alcoholic solution after fractionation was washed with water and gave a large amount of a residue of high index, much larger than any ever obtained by the other method.

In addition to the method given for the preparation of 2-pentene, the dehydration of the 3-pentanol by *p*-toluenesulfonic acid was tried. The product obtained, however, contained an impurity which was very absorptive in the ultraviolet and therefore made the method of no value for the purposes of this problem.

Properties of 2-Pentene.—The azeotropic mixture with methyl alcohol boiled at 31.40 ± 0.05' at 760 mm. Fifty grams of the mixture gave 47 g. of the 2-pentene (87%). The azeotropic mixture with ethyl alcohol boiled at 34.7 ± 0.05". The physical properties of the 2-pentene were obtained as follows and comparative literature data are also given. Boiling point, 36.40 ± 0.05°, 760 mm.; d_4^{20} 0.6503; n_D^{20} 1.37965 (Zeiss dipping); Van Risseghem,[6] b. p. 36.40°, 760 mm.; d_4^{11} 0.6595; n_D^{11} 1.3857; $d_4^{17.2}$ 0.6535; $n_D^{17.2}$ 1.3817. Auwers,[17] b. p. 36–37°; d_4^{20} 0.653; n_D^{20} 1.3812. Lucas and Moyse,[9b] b. p. 35–36°. Norris and Joubert,[16b] from synthetic 3-pentanol, b. p. 36–37.5°. Norris and Reuter,[16a] from 2-pentanol (commercial), b. p. 36.39 ± 0.04°, 760 mm.; d_4^{20} 0.65054; n_D^{20} 1.38081.

Addition Reactions of 2-Pentene.—Since Lucas and Moyse[9b] used the addition reaction of hydrogen bromide to 2-pentene as conclusive proof of their theory and since the directive addition of an unsymmetrical substance as hydrogen bromide should in the case of electronic isomers give different products, it was necessary to study the addition under varying conditions. The possible addition products formed by the action of hydrogen bromide on 2-pentene are 3-bromopentane (b. p. 118.2–118.5°, n_D^{20} 1.4443) and 2-bromopentane (b. p. 117.5–118.5°, n_D^{20} 1.4416). Lucas and co-workers[g]" have shown that the refractive index of mixtures of the two bromides is a linear function of the composition. The addition of bromine to 2-pentene should give 2,3-dibromopentane. The dibromide formed had b. p. 178–179°, n_D^{33} 1.5010, n_D^{20} 1.5074, n_D^{15} 1.5102. Wagner and Saytzeff[4] gave the boiling point as 178° uncorrected. Van Risseghem[6] gives the boiling point as 60.5–61° at 14 mm.; n_D^{17} 1.50926; n_D^{11} 1.5119. Norris and Reuter[16a] prepared the dibromide by addition of bromine to 2-pentene (36.3–36.4°) made from 2-pentanol and obtained a dibromide which boiled with slight decomposition at 180.2–180.8" at 754 mm. and had a refractive index, n_D^{20} 1.5098; n_D^{10} 1.5149. These values are higher than other recorded values ("International Critical Tables," b. p. 175°, n_D^{15} 1.5094) and higher than those obtained in this Laboratory (given previously). The fact that the Ppentene used by Norris and Reuter may have had some 1-pentene in it may account for the higher values. The 1,2-dibromide boils at 184° corr. at 760 mm. and 68° at 12 mm. and the refractive index is n_D^{21} 1.5088 according to Kirrmann.[18]

Reaction of 2-Pentene with Hydrogen Bromide.—The 2-pentene, either pure or in a solvent, was placed in a flask surrounded by ice and salt mixture and saturated with gaseous hydrogen bromide. The hydrogen bromide was prepared as given above, in the preparation of 3-bromopentane, but an additional tube containing naphthalene (to remove traces of bromine) was added to the drying train. The saturation was repeated two or three times, then the bromopentane was washed in the usual way with

---

ice water, ice-cold sulfuric acid, with water, sodium carbonate Qnd water. The dried products were distilled in fractionating flasks and the refractive indices taken. When the addition reaction was carried out in a non-polar solvent such as carbon tetrachlaride or with the 2-pentene without a solvent, the product was almost pure 3-bromopentane. When the solvent was a polar one, as glacial acetic acid, the product was 78% 3-bromopentane and 22% 2-bromopentane, as found by Lucas and Moyse.[9b] When the 2-pentene was prepared from a mixture of 2- and 3-bromopentanes the quantity of 2-bromopentane obtained by addition of hydrogen bromide was considerably greater. It was found also that if the addition of hydrogen bromide was not made very carefully at low temperatures (−10°), a larger proportion of 2-bromopentane was formed. The 2-pentene made from mixtures of 3-bromopentane and 2-bromopentane might also contain some 1-pentene and the resultant bromopentane might then contain some 1-bromopentane (n_D^{20} 1.4444, I. C. T.). Representative data are given in Table III.

Reaction of 2-Pentene with Bromine.—The 2-pentene, dissolved either in glacial acetic acid or carbon tetrachloride, was cooled in ice and salt and *a* solution of bromine in the corresponding solvent was added drop by drop until a permanent yellow color remained. The amount absorbed was in every case practically the theoretical quantity. The dibromide was washed and dried in the same way as the monobromide. Whenever pure 2-pentene was used, there was only one product, the 2,3-dibromide, formed as indicated by the distillation temperature and the refractive index. In some cases where the 2-pentene used had been made from a mixture of 3-bromopentane and 2-bromopentane and therefore might possibly have had a small amount of 1-pentene present, there was a small amount of higher-boiling dibromide, probably the 1,2-dibromide. Some representative data are given in Table III.

Transformation of 2-Pentene into an Isomeric Form.—Kharasch[14] had found that the 2-pentene prepared from 3-bromopentane when heated in xylene gave an isomeric form. In the work in this Laboratory it was found that heat alone did not produce this change but that light was necessary. Since, too, the presence of even a minute trace of xylene was detrimental to absorption spectra measurements, the use of this solvent was avoided and the 2-pentene, without any solvent, was exposed to sunlight and ultraviolet light.

(1) Some of the 2-pentene (n_D^{20} 1.37965) was sealed in a glass tube and heated in a water jacket at 70–SO° at intervals for a total of sixty-five hours and was then left in the laboratory under a skylight for thirteen weeks, thus exposed to the available sunlight. At the end of this time, the tube was opened and the material investigated. The refractive index was taken, the absorption spectra were measured and addition compounds with hydrogen bromide and with bromine were prepared. The data are given in Table IV.

(2) Some 2-pentene (n_D^{20} 1.37945) from the third fractionation of 2-pentene from bromopentane (n_D^{20} 1.4437) was placed in a small quartz flask fitted with a reflux condenser; the flask and condenser were kept cold with solid carbon dioxide and the flask was placed about 10–12 cm. away from an Hanovia quartz mercury vapor lamp. The material was exposed to the ultraviolet light for a total of four hours and thirty minutes. Absorption spectra measurements were made after one hour and fifty minutes, after three hours and forty minutes and after four hours and thirty minutes. The physical properties were determined and the addition reactions of this transformed 2-pentene were studied. The data are given in Table IV.

(3) Some 2-pentene (n_D^{20} 1.37930) which had been prepared from 3-bromopentane (n_D^{20} 1.4432) containing a little 2-bromopentane as an impurity, was placed in a quartz flask with a reflux condenser, cooled with solid carbon dioxide and exposed to ultraviolet light for eight hours and thirty minutes. The data obtained from the transformed material are given in Table IV. Some of the transformed material was fractionated with methyl alcohol and three fractions were obtained. The boiling point of each of these mixtures was lower than the boiling point of the azeotropic mixture of the original untransformed material, indicative of a transformation to the lower-boiling form.

		Azeotropic mixture, b. p. at 760 mm., °C.	Refractive index of the pentene, n_D^{20}
Original material		31.3 –31.4	1.37930
Material after transformation	(1)	30.5 –30.9	1.3793
	(2)	30.95–31.15	1.3792
	(3)	31.15–31.25	1.3795

The bromide formed from the third fraction had a somewhat higher index and higher boiling point than the bromide made from the unfractionated sample of the transformed material, showing that the two isomers were partially separated.

The following points are worthy of note: (1) the azeotropic mixture of the transformed material has a lower boiling point and a wider range than the original; this seems indicative of a mixture. (2) The transformed pentene boils over a wider range than the untransformed. (3) The refractive indices of the transformed material are lower than those of the original except in the case of long exposure to ultraviolet light, and

TABLE IV

			Transformation product		
		Untransformed 2-pentene	(1) Sunlight	(2) Ultraviolet 4.5 hrs.	(3) Ultraviolet 8.5 hrs.
1	B. p. of azeotropic mixt. with MeOH	31.35 ± 0.05°	.....	.....	30.50–31.25°
2	B. p. of 2-pentene	36.30 ± 0.05°	.....	.....	36.4 ± 0.20°
3	n^{20}_D	1.37965	1.37934	1.37937	1.37956
4	d^{20}_4	0.6503	......	0.6500	.....
5	n^{20}_D of monobromide	1.4437 (78% 3-bromo, 22% 2-bromo)	1.4420 (15% 3-bromo, 85% 2-bromo)	1.4423	1.4421 (av.)
6	n^{20}_D of dibromide	1.5074	1.5074	.....	.....

the increase here may be due to the formation of polymeric material or decomposition products. There is evidence of this in the absorption measurements. (4) The monobromide from the transformed material is largely 2-bromopentane rather than 3-bromopentane, as in the case of the untransformed 2-pentene. (5) The dibromide formed from the light-transformed pentene is identical with that from the original pentene, indicating that there has been no shift in the double bond. There was a possibility of a racemic mixture or a *meso* form if isomers were *cis-trans*, but no evidence of two kinds has been obtained.

Summary

1. Pentene-2 has been prepared from 3-bromopentane and from 3-pentanol. This has been purified by fractionation of constant-boiling mixtures with methyl and with ethyl alcohol. The physical properties of this 2-pentene have been determined. This pentene adds hydrogen bromide in a non-polar solvent such as carbon tetrachloride to give 98–99% of 3-bromopentane. In glacial acetic acid it adds hydrogen bromide to give 78% of 3-bromopentane and 22% of 2-bromopentane. Addition of bromine to this 2-pentene gives 2,3-dibromopentane.

2. Sunlight and ultraviolet light transform this 2-pentene into an isomeric form which has slightly different physical properties. The transformed 2-pentene adds hydrogen bromide to form 15% of 3-bromopentane and 85% of 2-bromopentane. With bromine it forms the same dibromopentane, 2,3-dibromo-, as the original 2-pentene.

3. The 3-bromopentane can be prepared pure only by great care in the hydrobromination of the 3-pentanol. Strong reagents like phosphorus tribromide or higher temperatures and pressures give mixtures of 3-bromopentane and 2-bromopentane.

ISOMERS OF 2-PENTENE. II. PENTENE-2 FROM 2-BROMOPENTANE AND FROM 2-PENTANOL[1]

BY MARY L. SHERRILL, CATHERINE BALDWIN AND DOROTHEA HAAS

RECEIVED MARCH 29, 1929 PUBLISHED OCTOBER 5, 1929

The transformation of 2-pentene prepared from 3-bromopentane by the action of ultraviolet light or by diffused light into an isomeric form differing slightly in physical properties and radically in the addition product formed by hydrogen bromide was indicative of electronic isomerism.[2] If these were electronic isomers then it ought to be possible to use as initial material 2-bromopentane in which the strongly electronegative bromine atom was attached to the second carbon atom (C-2) making it less electronegative than the adjacent carbon (C-3) and to obtain a 2-pentene in which the carbon atom (C-3) of the double bond adjacent to the ethyl group would be more electronegative than the carbon atom (C-2) adjacent to the methyl group. This 2-pentene should be the stable form and should be identical with the product obtained by the action of light on the 2-pentene obtained from 3-bromopentane. Lucas, Simpson and Carter[3] had prepared 2-pentene from 2-bromopentane but made no effort to separate it from the 1-pentene formed at the same time nor to compare it in physical properties with the 2-pentene from 3-bromopentane. The addition of hydrogen bromide to the mixture of 1-pentene and 2-pentene was carried out and the product obtained was fractionated but in view of the fact that the refractive indices of 1-bromopentane (n_D^{20} 1.4444, "I. C. T.") and of 3-bromopentane (n_D^{20} 1.44431) are so nearly identical and the boiling points of 2-bromopentane (117.5–118°) and of 3-bromopentane (118.2–118.5°) are so close together, the inferences made from the data are not conclusive.

The chief difficulty in the preparation of 2-pentene from 2-bromopentane or 2-pentanol lay in the fact that the removal of hydrogen bromide or the dehydration of 2-pentanol gave as products both 2-pentene and 1-pentene and a complete separation of these was necessary. Lucas, Simpson and Carter[3] estimated that from 2-bromopentane approximately 71% of 2-pentene and 29% of 1-pentene was obtained. Norris and Reuter[4] prepared 2-pentene by the dehydration of secondary amyl alcohol manufactured from petroleum and obtained a 90% yield of the hydrocarbon boiling between 36.5 and 40°. The amount of 1-pentene was not estimated. The data found in the literature with regard to 1-pentene are contradictory.

Brochet[5] in the fractionation of boghead gas obtained a product, designated 1-pentene, with a boiling point 39–40°. Norris and Joubert[6] prepared 1-pentene from ethylmagnesium bromide and allyl bromide. The product obtained after rather rigorous treatment to remove the halide and the diethyl ether boiled at 39–41'. Some diallyl, boiling at 59–61", was also obtained. Kirrmann[7] had prepared 1-pentene by a similar synthesis but the Grignard reagent was added to the allyl bromide to diminish polymerization and the solvent used was dipropyl ether, which being of much higher boiling point did not have to be removed by vigorous treatment with concentrated hydrochloric acid as in the Norris method. The boiling point of 1-pentene is given by Kirrmann as 30.5–31" at 767 mm. Bourguel[8] has prepared 1-pentene by the hydrogenation of a true acetylene pentine ($CH_3CH_2CH_2C{\equiv}CH$). The boiling point of 1-pentene as given by Bourguel is 32.5" at 760 mm. Bourguel found, in a series of hydrocarbons, that the hydrocarbon with the double bond between the first and second carbon atoms boiled lower than the one with the double bond between the second and third carbon atoms.

The results in the present work depended upon the separation of 1-pentene from 2-pentene and it was believed to be possible by the fractionation of an azeotropic alcohol mixture as used in the purification of the 2-pentene prepared from 3-bromopentane and 3-pentanol.[2] This method has been used with very satisfactory results. 2-Pentene, practically free from 1-pentene, has been obtained and its properties are different from those of the 2-pentene prepared from 3-bromopentane and 3-pentanol but are almost identical with those of the 2-pentene which had been transformed by light.

Experimental

Preparation of **2-Pentanol (Methyl-*n*-propylcarbinol).**—Secondary amyl alcohol was prepared according to the method of Wood and Scarf by the action of *n*-propylmagnesium bromide on acetaldehyde.

Propyl Bromide.—Normal propyl bromide (Eastman Kodak Co.) was purified by washing with concentrated sulfuric acid (ice cold) and with sodium hydroxide (2 M) until neutral, was dried and distilled, the fraction boiling at 71–71.2° being used.

Grignard Synthesis—The Grignard reagent was prepared in the usual way, 75 g. of magnesium (3.1 moles) and 394 g. (3 moles) of n-propyl bromide being used. The reaction mixture was stirred for two hours after all of the propyl bromide had been added. Then the required amount of acetaldehyde was passed into the reaction mixture, which was kept cold in an ice and salt mixture and was stirred continuously. The acetaldehyde was distilled from a flask provided with a reflux condenser; the water through the condenser was kept at 40°. From the condenser a tube led to a

combustion tube containing calcium chloride and a tube from this led to the bottom of a side-arm test-tube. The test-tube was connected with a three-way stopcock, one arm of which was attached to a tube leading into the Grignard reaction flask. The aldehyde was heated on a water-bath (30–35°) and dried by passing over calcium chloride. In the beginning the test-tube was chilled so that enough aldehyde was condensed to a liquid, then the rate at which the gas bubbled through this served as a gage for the speed of addition of aldehyde to the reaction flask. After the addition of the aldehyde the reaction mixture was stirred for twelve hours. Then part of the excess ether and the excess aldehyde was distilled from the reaction mixture and the mixture decomposed with ice and ammonium chloride. The 2-pentanol was extracted with ether. The water layer was steam distilled and the distillate also extracted with ether. From the ether extracts 2-pentanol was obtained, boiling at 118.5–119.5° at 760 mm. and having a refractive index n^{20}_{D} 1.4060. The literature data for the methyl-n-propylcarbinol are as follows. Brunel[10] gives the boiling point as 119.275° at 754 mm. and index n^{25}_{D} 1.4043; Norris and Cortese[11] give the boiling point as 119.16–119.26' at 760 mm. and n^{25}_{D} 1.4048. "International Critical Tables" gives secondary amyl alcohol as b. p. 119.5°, 760 mm., and n^{20}_{D} 1.4072 and for d-secondary amyl, b. p. 118° and index n^{20}_{D} 1.4053. The yields of the carbinol were poor, due in part to the formation of hydrocarbons in the reaction and in part to acetal formation. Commercial 2-pentanol (Sharples Solvents Corporation) was fractionally distilled several times through Crismer columns and some very constant boiling fractions, b. p. 118–118.5°, $n^{20°}_{D}$ 1.4073, were obtained. This material was used in some comparison runs.

Preparation **of 2-Bromopentane.—The** 2-pentanol was hydrobrominated by the method given for the preparation of 3-bromopentane,[2] by the saturation of the 2-pentanol with hydrogen bromide at —10' and then by warming the mixture to 60° under atmospheric pressure. The product was purified as in the case of the 3-bromopentane, dried and distilled. The boiling point was 117–118° at 760 mm. and the refractive index was n^{20}_{D} 1.4412. Lucas, Simpson and Carter[3] give the refractive index as n^{20}_{D} 1.4416. In cases where the hydrobromination was carried out under increased

pressure the value obtained in this Laboratory was also n_D^{20} 1.4416. It should be noted that the 2-bromopentane is much more easily obtained as a rather pure compound than is the 3-bromopentane. Table I gives representative data.

Preparation of 2-Pentene

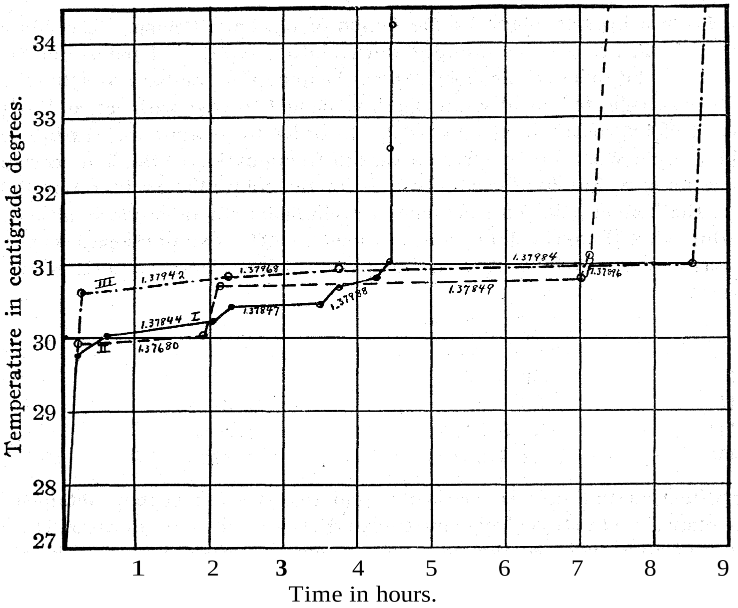
A. From 2-Bromopentane by the Action of Alcoholic Potash.—The 2-bromopentane (n_D^{20} 1.4412, 229 g.) was dropped slowly into a solution of potassium hydroxide (261 g.) in absolute methyl alcohol (500 cc.) heated on an oil-bath at 110–115°. The 2-pentene was collected in absolute methyl alcohol, cooled with ice and salt. The crude yield of hydrocarbon was 85–90%. In order to separate any 1-pentene which might be present with the 2-pentene a careful fractionation of the hydrocarbon as an azeotropic mixture was necessary. In view of the contradictory literature data with regard to the boiling point of 1-pentene, a preliminary fractionation in absolute ethyl alcohol through a Hempel column was first made. After two fractionations the hydrocarbon was washed free from alcohol, dried with calcium chloride and refractive indices were taken.

	B. p. of azeotropic mixture with ethyl alcohol at 760 mm., °C.	n_D^{20} of the hydrocarbon	% of total yield
I	32.8–33.1	1.3769	20
II	33.1–33.5	1.3773	21
III	33.5–33.8	1.3780	55
IV	33.8–34	1.3790	2

This fractionation differed markedly from that of the 2-pentene obtained from 3-bromopentane.[2] The ethyl alcohol mixture in that case boiled constantly at 34.7 ± 0.05° and the refractive index of the 2-pentene obtained was n_D^{20} 1.3796. The results of this fractionation indicate the presence of at least two hydrocarbons, one (I) lower boiling occurring in the smaller amount. The main fraction (III) is higher boiling, and II is probably a mixture of I and III. The fact that nothing was obtained higher than 34° would indicate that the 2-pentene (III) is not identical with the 2-peutene obtained from 3-bromopentane. In the continuation of the work the purification of the 2-pentene was made by the repeated fractionation of methyl alcohol mixtures through Crismer columns (50 cm. and 1.5 m. in length). After the third fractionation the separation of 2-pentene from 1-pentene seemed practically complete. Curves I and II in Fig. 1 are typical of various runs and show the difference in the results of a first and third fractionation and also the relative rates of distillation. Practically all of the 1-pentene distilled off in the azeotropic mixture boiling below 30°. It is of interest to compare the values of the hydrocarbons obtained by methyl alcohol fractionation with those given above for ethyl alcohol fractionation.

	B. p. of azeotropic mixture with methyl alcohol at 760 mm., °C.	n_D^{20} of the hydrocarbon	% of the total yield
I	29.9 –30.1	1.37680	15
II	30.75–30.95	1.37849	80
III	30.95–31.2	1.37896	5

B. From 2-Pentanol by the Action of 60% Sulfuric Acid.—The method of Norris and Reuter[4] was employed. The yield from 200 g. of 2-pentanol, fraction boiling at 118–118.5°, n_D^{20} 1.4073 (obtained from material from the Sharples Solvents Corporation), was 146 g. or 92% of the theoretical amount. The crude 2-pentene, washed with sodium hydroxide and dried, was fractionated in methyl alcohol (Curve III, Fig. 1) and the physical constants of the pentene were measured. All of the values, boiling points of azeotropic mixture and of the pure hydrocarbon, the density and the refractive indices were higher than those of the 2-pentene from 2-bromopentane. This was believed to be due to some polymeric material, as found in the case of the preparation of the 2-pentene from 3-pentanol by this method. From the residual alcoholic solution, after fractionation, a rather large amount of material of high index was obtained.



——, I, 2-Pentene from 2-bromopentane, n_D^{20} 1.4416 (753 mm.); – – –, II, 3d fractionation of 2-pentene from 2-bromopentane, n_D^{20} 1.44123 (755 mm.); — · —, III, 2-pentene from 2-pentanol, n_D^{20} 1.4073 (750 mm.).

Fig. 1.—Fractionation of azeotropic mixtures of 2-pentene in methyl alcohol.

Properties of 2-Pentene.—The azeotropic mixture with ethyl alcohol boiled at 33.7 ± 0.2" at 760 mm. The methyl alcohol mixture boiled at 30.85 ± 0.05" at 760 mm. The physical properties of the best 2-pentene prepared from 2-bromopentane considered practically free from 1-pentene are given below with those for the 2-pentene prepared from 3-bromopentane and the 2-pentene formed by the action of light on the latter.

	B. p. (760 mm.), °C.	d_4^{20}	n_D^{20}
2-Pentene from 2-bromopentane	35.85 ± 0.05	0.6481	1.37849
2-Pentene from 3-bromopentane	36.40 ± 0.05	.6503	1.37965
Same 2-pentene after action of light	36.4 ± 0.2	.6500	1.3793

The properties of the 2-pentene prepared from 2-pentanol by sulfuric acid are as follows, with the data given by Norris and Reuter[4] for comparison. This Laboratory data: b. p. 36.15 ± 0.2° at 760 mm ; d_4^{20} 0.6506; n_D^{20} 1.37968; Norris and Reuter data, b. p. 36.39 ± 0.04° at 760 mm.; d_4^{20} 0.65054; n_D^{20} 1.3808. It is also of interest to compare the boiling points of the azeotropic mixtures with methyl alcohol and the refractive indices of other samples of 2-pentene which were not so completely freed from the low-boiling 1-pentene.

B. p. of azeotropic mixt. (760 mm.)	30.85 ± 0.05°	30.5 ± 0.2°	30.3 ± 0.05°
n^{20}_D of the 2-pentene	1.37849	1.37826	1.37803

Addition Reactions of 2-Pentene.—The possible products of the 2-pentene prepared from 2-bromopentane with hydrogen bromide are 3-bromopentane (n^{20}_D 1.4443) and 2-bromopentane (n^{20}_D 1.4416). In addition, if 1-pentene is present there is also the possibility of 1-bromopentane (n^{20}_D 1.4444). The 2-bromopentane has a lower refractive index, as well as a lower boiling point, than either of the other two. In the case of the addition compounds formed by bromine and 2-pentene there should be only one, the 2,3-dibromopentane; if there is 1-pentene present, however, it would be possible to have some 1,2-dibromopentane. The addition compounds and their boiling points and indices are listed below.

-Bromopentane	3-	2-	1-	2.3-Di-	1,2-Di-
n^{20}_D	1.44431	1.4416	1.4444	1.5074	1.5088 (21°)
B. p., °C.	118.5	117.5	127.9	178	184

Reaction of 2-Pentene with Hydrogen Bromide.—The 2-pentene (prepared from 2-bromopentane), either pure or in a solvent, was placed in a flask surrounded by an ice and salt mixture and saturated with hydrogen bromide. The bromide was washed once with ice water, twice with ice-cold concentrated sulfuric acid, once with ice water, twice with sodium carbonate solution, once with water, dried with calcium chloride and distilled. Typical results are given in Table II. The main product formed by the hydrobromination of 2-pentene is 2-bromopentane nearly 100% pure. In glacial acetic acid the product is about 80–85% 2-bromopentane, but the presence of some 3-bromopentane is indicated by the higher refractive index of the higher-boiling fractions. In the cases where there was the possibility of some 1-pentene being present, the higher boiling point and higher index of the product may be due to the presence of some 1-bromopentane. In some of the addition reactions of hydrogen bromide to this 2-pentene the temperature was not maintained as low as advisable and the results therefore are not as reliable as those made with the isomeric-2-pentene. It is of interest here to note that Norris[4] found that the chief product formed by the addition of hydrogen chloride to 2-pentene was 2-chloropentane.

Reaction of 2-Pentene with Bromine.—The 2-pentene (prepared from 2-bromopentane) dissolved in either carbon tetrachloride or in glacial acetic acid was cooled in an ice and salt mixture and treated with a solution of bromine in the corresponding solvent as long as the bromine was absorbed. The dibromopentane was washed as in the case of the monobromopentane, dried and distilled. Typical results are given in Table II. In the case of the 2-pentene which from its index of refraction was free from 1-pentene, the dibromopentane seemed to be pure 2,3-dibromopentane; in samples which were believed to contain some 1-pentene there was more or less of a product with a higher boiling point and higher index than the 2,3-dibromopentane, indicating some 1,2-dibromopentane.

Effect of Ultraviolet Light.—Some 2-pentane (from 2-pentanol) was irradiated by ultraviolet light for eight and one-half hours under identical conditions with those used for the 2-pentene prepared from 3-bromopentane.[2] There was a slight increase in the refractive index of the pentene, due in part, perhaps, to polymerization. The monobromopentane formed from the pentene before and after exposure seemed the same, that is, about 93% of 2-bromopentane.

	Exposure to light

n_D^{20} of addn. prod. with HBr	1.4418	1.4418

Summary

1. Pentene-2 has been prepared from 2-bromopentane and from 2-pentanol. The pentene has been obtained practically free from 1-pentene by the fractionation of constant-boiling mixtures with methyl alcohol. The 1-pentene is separated in the lower-boiling fractions. The 2-pentene obtained from 2-pentanol by the action of sulfuric acid contains some higher-boiling product which can probably be removed by repeated fractionation of alcoholic mixtures, for a large amount of it remains in the alcoholic residue.

2. The physical properties of the 2-pentene obtained from 2-bromopentane have been determined and have been found to differ slightly from those of the 2-pentene prepared from 3-bromopentane, the former having a slightly lower boiling point, refraction index and density.

3. This 2-pentene (without solvent) adds hydrogen bromide to form 93–95% 2-bromopentane. In a polar solvent such as glacial acetic acid the 2-pentene adds hydrogen bromide to form 85% of 2-bromopentane. It adds bromine to form 2,3-dibromopentane.

4. The action of ultraviolet light on the 2-pentene obtained from 3-bromopentane tends to alter its properties in the direction of those of the isomeric 2-pentene obtained from 2-bromopentane, while the latter isomer remains practically unchanged by ultraviolet light.

5. The differences in physical properties between the two 2-pentenes are such as might be expected in the case of *cis-trans* isomers. The fact,

however, that each isomer has been prepared in a directed manner from a compound of definite and different polarity and that each adds a polar compound in a directed manner corresponding to the method of preparation for each seems to indicate that the two isomers are electronic rather than geometrical. Moreover, the fact that the 2-pentene prepared from 3-bromopentane is transformed into a more stable form is in accord with this theory.

ISOMERS OF 2-PENTANE. III. THE ULTRAVIOLET ABSORPTION SPECTRA OF THE ISOMERIC 2-PENTENES[1]

BY EMMA P. CARR

RECEIVED MARCH 29, 1929 PUBLISHED OCTOBER 5, 1929

A study of the ultraviolet absorption spectra of the isomeric 2-pentenes prepared by M. I,. Sherrill and co-workers of this Laboratory[2] has been of particular interest in its relation to the electro-isomerism of these compounds and has given further experimental evidence in support of Kharasch's theory of the partial polarity of the ethylene bond.[3] The effect of unsaturation on all of the optical properties of a compound is well known but this effect is particularly marked in the ultraviolet absorption spectra. For example, a 3-cm. length of optically pure hexane transmits to X = 2000 Å. or even further, while the limit of transmission for the same length of pentene is in the region of X = 2600–2800 Å. A quantitative study of the influence of the ethylene group on the infra-red and ultraviolet absorption has been made by Henri,[4] and he shows that, in general, the simple ethylenic compounds have two bands in the ultraviolet, one of very small intensity in the region 2600–2300 Å. and another very intense band in the extreme ultraviolet, X = 2000–1800 Å. These conclusions were based on the investigation of several olefin acids and of allyl alcohol, the *exact* position of the bands due to the double bond being dependent upon the other groups in the molecules. The results of recent spectrographic study of substances in liquid, solution or vapor phase point to the conclusion that ultraviolet absorption is closely related to electronic motion within the molecule and on this basis one would expect that slight differences in the electronic condition of the molecule might be detected by light absorption methods.

The determination of the absorption curves for the isomeric 2-pentenes offered a promising point of attack in the study of electro-isomerism and this investigation was undertaken at the suggestion of Dr. M. S. Kharasch. Since traces of impurities have such a profound effect upon the absorption spectra, the problem resolved itself into the preparation of these isomers in a high degree of purity and it has been only by the constant comparison and checking of absorption measurements with the physical and chemical properties as determined by Sherrill and collaborators[2] that it has been possible to obtain what seems to be confirmatory evidence of the correctness of Kharasch's theory of the electro-isomerism of the 2-pentenes.

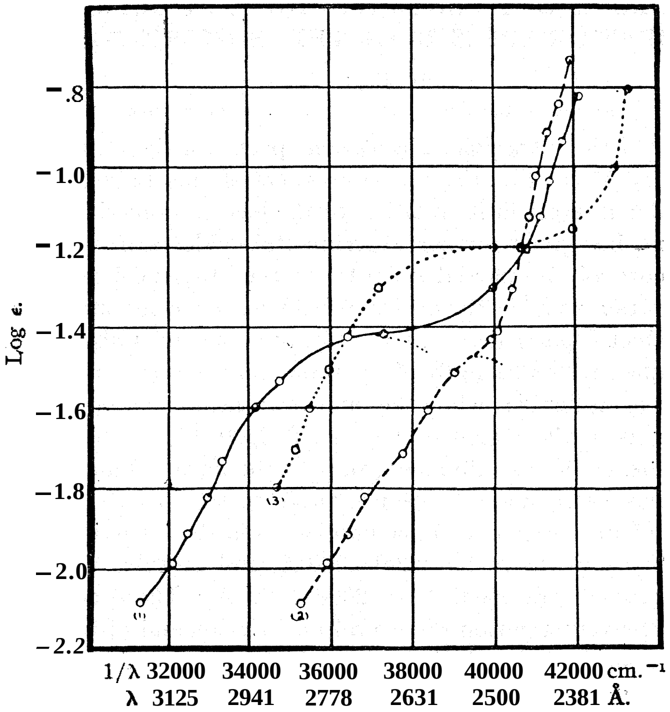

Fig. 1.—(1) ——, 2-Pentene prepared from 2-bromopentane, n_D^{20} 1.37849; (2) – – –, 2-pentene prepared from 3-bromopentane, n_D^{20} 1.37945; (3) ...., trimethylethylene according to Lüthy [*Z.* physik. *Chem.*, 107,285 (1923)].

Our results show that the absorption curve for the 2-pentene prepared from 3-bromopentane differs markedly from that of the 2-pentene obtained from 2-bromopentane (Fig. 1). The absorption curves of these two isomers are so characteristic that they have given a most delicate method of identifying these isomers as well as of differentiating them from 1-pentene and the polymeric forms of 2-pentene which may be present as impurities. The absorption spectrum of trimethylethylene has been measured by Lüthy[5] and that part of the curve in the region in which the 2-pentenes were examined has been reproduced in Fig. 1. A marked "step-out" in the general absorption of a substance indicates an absorption band of such small persistence that the complete band is not evident and such a step-out is shown by all of the pentenes in the region λ 2700–2500 Å.

The curves for the stable 2-pentene (Curve 1, Fig. 1) and trimethylethylene (Curve 2, Fig. 1) are almost exactly similar in form and differ only in the position of the band and to a slight degree in intensity,[6] whereas the curve for the isomeric 2-pentene prepared from 3-bromopentane is very different. The broad step-out has disappeared entirely and there is only the slightest tendency toward an absorption band. In the longer wave lengths this isomer transmits farther; in the shorter wave lengths slightly less. The differences are striking and of great interest in connection with the possibility of the electro-isomerism of the 2-pentenes. The shallow absorption band in this region is characteristic of all ethylenic compounds and if this absorption band is related to the second pair of electrons, the so-called labile pair, in the double bond it would be in this band that one would expect differences in the absorption of electronic isomers to be most evident and there should be little or no difference in the second band in the far ultraviolet. In this connection it is of interest to note that in seven pairs of *cis-trans* isomers which ham been examined by quantitative methods[7] the two forms have very similar absorption curves but the *trans* form is somewhat more absorptive and this difference becomes *much more marked* the shorter the wave length. It would seem, therefore, that with geometrical isomerism it is the intense band in the far ultraviolet which differs with the two isomers while in electro-isomerism it is the band of low intensity in the near ultraviolet which shows the marked differences. Although experimental data are too meager to justify far-reaching conclusions, these results certainly suggest the possibility that the absorption band in the far ultraviolet is related to the characteristic frequency of the stable pair of electrons in the double bond and these electrons are primarily concerned in *cis-trans* isomerism, while the second pair of electrons, being much more labile, produce the shallow band of much lower frequency and, according to the theory of Kharasch, it is the relative position of this pair of electrons which determines electronic isomerism.[3]

[5] Lüthy, Z. *physik.* Chem., **107,** *285* **(1923).**

[6] Repetition of the work on trimethylethylene in this Laboratory corroborates Lüthy's measurements as to the position of the band but shows the step-out at log $\epsilon = -1.4$ instead of -1.2.

[7] Errera and Henri, *Compt. rend.,* **181, 548 (1925).**

The absorption curves for different preparations of 2-pentene prepared from 3-bromopentane by the action of alcoholic potassium hydroxide and from 3-pentanol by the action of 60% sulfuric acid are given in Fig. 2. The solid line curve gives results for three completely independent preparations of 2-pentene made from different samples of synthetic 3-bromopentane. The broken line curves show the absorption of 2-pentene prepared from synthetic 3-bromopentane which, from its index of refraction, contained some 2-bromopentane. Where the index of refraction shows a mixture of 2- and 3-bromopentane the absorption curve of the pentene prepared from the mixture indicates at once that the product is a mixture of the two isomeric 2-pentenes, (Curves 2 and 2′, Fig. 2) and calculations of the relative amounts of the two isomers on the basis of the extinction coefficient as a linear function of the concentration, give very satisfactory agreement with those calculated from the index of refraction of the mixture. The fact that these results are in agreement also with those obtained from the addition of hydrogen bromide to the pentene

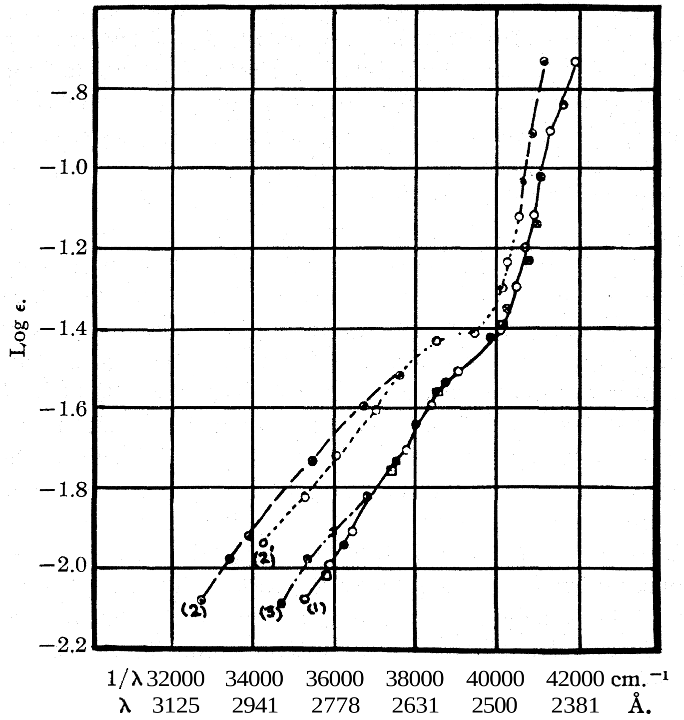

Fig. 2.—Different preparations of 2-pentene. (1) From 3-bromopentane, ○, n_D^{20} 1.37945; ● n_D^{20} 1.37965; □ n_D^{20} 1.37965. (2) From 3-bromopentane, ⊙ n_D^{20} 1.37923; ○ . . ., n_D^{20} 1.37909. (3) From 3-pentanol (synthetic), ⊗, n_D^{20} 1.37935.

and analysis of the mixture of bromopentanes has established confidence in the accuracy of our conclusions. In all preparations of 2-pentene which were made directly from the alcohol there is a small amount of a more absorptive material which is evidenced by a slightly increased absorption in the longer wave lengths. Inasmuch as sulfuric acid increases the polymerization of the olefins and the higher-boiling fractions contain a greatly increased amount of this more absorptive material and have a correspondingly higher index of refraction, the increased absorption is no doubt due to the presence of polymeric forms of the pentene. The delicacy of the spectrographic method of examination is shown in Fig. 3, where a difference in boiling point of three-tenths of a degree in the azeotropic mixtures gives an enormous difference in absorption, although the increase in index of refraction is comparatively slight. No such striking increase in the absorption of the higher fractions of 2-pentene obtained from the bromopentanes was found since the tendency to polymerize is very much less when prepared by alcoholic potash than by the action of sulfuric acid.

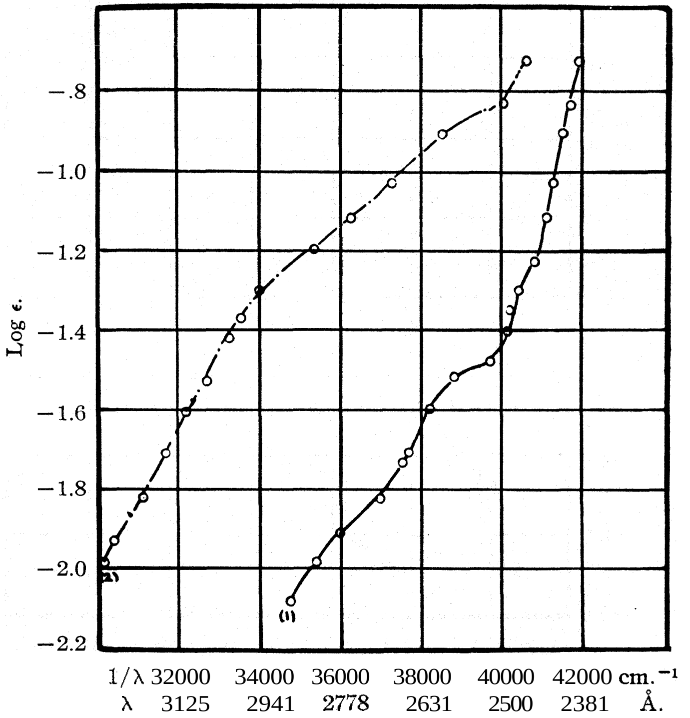

Fig. 3.—Fraction of 2-pentene from 3-pentanol. (1) Azeotropic mixt. with CH_3OH, b. p. 30.9–31.1°; C_5H_{10} n_D^{20} 1.37935. (2) Azeotropic mixt. with CH_3OH, b. p. 31.1–31.5°; C_5H_{10} n_D^{20} 1.37988.

In the preparation of the 2-pentene from 2-bromopentane and 2-pentanol, small amounts of 1-pentane are formed and by means of absorption spectra measurements it was possible to follow the separation of these isomers. Figure 4 shows the absorption curves of the different fractions in the distillation of a methyl alcohol solution of 2-pentene prepared from 2-bromopentane. Results from bromination and hydrobromination data[2b] showed that the low-boiling fraction contained the 1-pentene, and the absorption curve for the fraction (Curve 1) shows greater transmission than either of the 2-pentenes.[8]

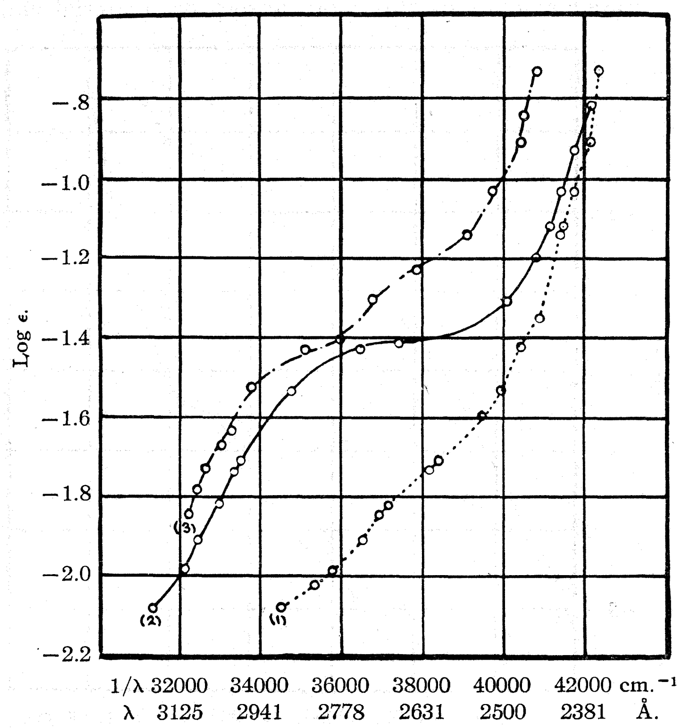

Fig. 4.—Fractionation of 2-pentene prepared from 2-bromopentane. (1) Azeotropic mixt. with CH_3OH, b. p. 29.9–30.1°; C_5H_{10}, n_D^{20} 1.37680. The effect of diffused light on the absorption spectrum of the 2-pentene prepared from 3-bromopentane is shown in Fig. 5. The solid line (Curve

---

[8] A recent preparation in this Laboratory of 1-pentene confirms the low boiling point and index of refraction, but the 1-pentene contains traces of allyl bromide from which it was prepared. This impurity increases the absorption tremendously but even so the preparation transmits further than either of the 2-pentenes, thus confirming our conclusion that the low-boiling fraction is 1-pentene.

1) gives the absorption of the original material and the broken line (Curve 2) that of the same material after standing in a sealed glass tube and exposed to the diffused sunlight of the laboratory for three months. In comparison with the absorption curve of the 2-pentene from 2-bromopentane (Curve 3), which according to Kharasch should be the stable form, this light-transformed material shows the presence of a more absorptive

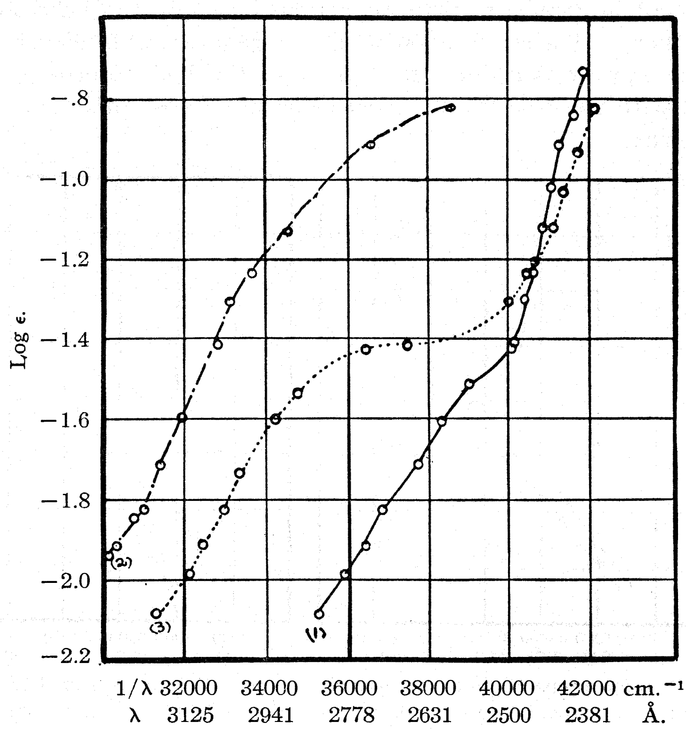

Fig. 5.—(1) ——, 2-Pentene prepared from 3-bromopentane, n^{20}_{D} 137965; (2) —·—, 2-pentene after 3 months in sunlight and diffused light, n^{20}_{D} 1.37934; (3)......., 2-pentene prepared from 2-bromopentane, n^{20}_{D} 1.37849.

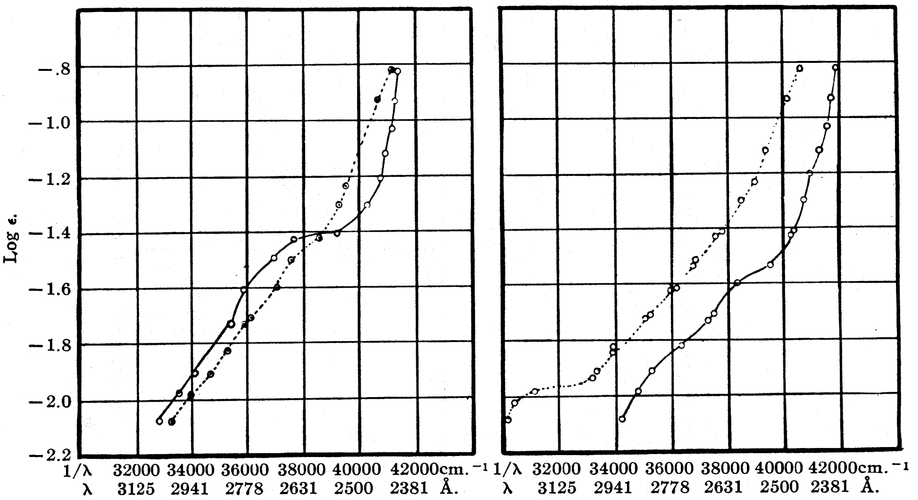
material of higher index of refraction. The most probable conclusion, and one which is in accord with results of hydrobrominating this substance, is that this curve represents a mixture of the isomeric 2-pentene together with a small amount of the very absorptive polymer.

The study of the absorption curves of the two isomeric pentenes before and after exposure to ultraviolet light from the mercury arc for eight and a half hours shows an opposite effect of light on the two isomers (Fig. 6). The 2-pentene prepared from 2-pentanol shows much greater stability and the absorption is shifted only very slightly toward the ultraviolet, whereas the absorption of the 2-pentene from 3-bromopentane is shifted toward the visible and a new band in the region of λ = 3125 Å. indicates a decomposition with the formation of a new substance.

The study of the progressive action of light on these isomers is being continued in this Laboratory and the results so far obtained give strong support to our conclusion that the two isomers are electromers. Their relative stabilities are in accord with the postulates of Kharasch's theory and are not in agreement with predictions based on the behavior of *cis-trans* isomers. The usual action of light on geometrical isomers is to transform the more absorptive trans-form into the less absorptive *cis-form,* whereas with the isomeric 2-pentenes the more absorptive isomer is the stable form.

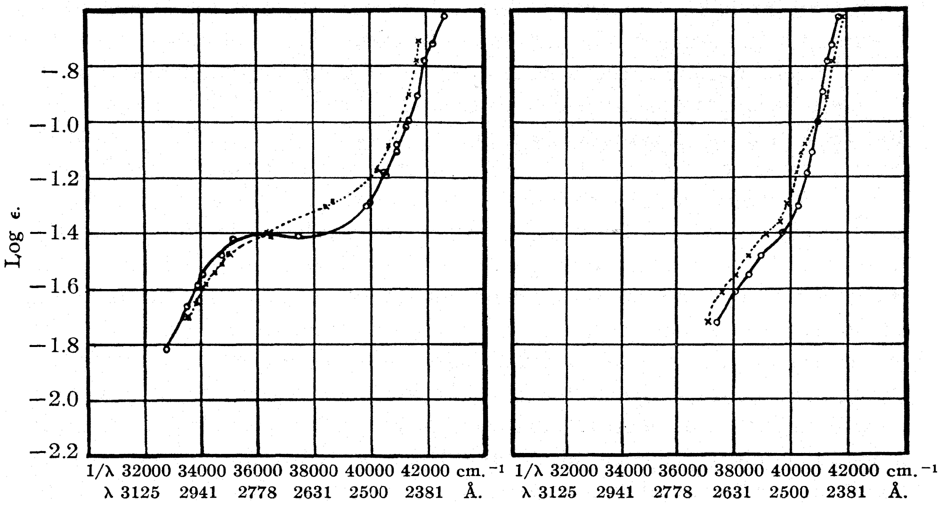


——, 2-Pentene prepared from 2-pentanol, n_D^{20} 1.37968; - - - -, 2-pentene after exposure to ultraviolet light for 8.5 hours, n_D^{20} 1.37989.

——, 2-Pentene from 3-bromopentane, n_D^{20} 1.37930; - - - -, 2-pentene after exposure to ultraviolet light for 8.5 hours, n_D^{20} 1.37956.

Fig. 6.—Action of ultraviolet light on the 2-pentenes.

Inasmuch as the relative amounts of 3-bromopentane and 2-bromopentane obtained by hydrogen bromide addition to the 2-pentenes are dependent upon the solvent used, it is of interest to compare the absorption spectra of each of the 2-pentenes when photographed in a non-polar solvent such as hexane and in a polar solvent, glacial acetic acid. V. Henri and his collaborators, in a long series of investigations of the ultraviolet absorption spectra of organic substances in vapor phase and in various solvents, have shown that the absorption curve in hexane solution most closely resembles that in the vapor phase and have regarded the absorption curve in hexane as the "normal" spectrum. Our results show a very slight shift in intensity between the curves of the pure liquid pentene and its hexane solution, due no doubt to the difficulty in determining the exact concentration of the solution of the very volatile 2-pentene. In order to study the absorption spectrum in the region of the "step-out" it was necessary to use very concentrated solutions, as the intensity of this band is too small to measure in dilute solution. Solutions of each isomer in hexane and in glacial acetic acid were made up in the ratio of three volumes of pentene to one volume of solvent and the molar concentration was calculated from the density determinations. The absorption curves for these solutions are given in Fig. 7. With each isomer the curve for the hexane solution coincides practically with that obtained from the examination of the liquid pentene, but in glacial acetic acid the curve for the 2-pentene which had been prepared from 2-bromopentane is shifted slightly toward that of the isomeric 2-pentene and that of the second isomer prepared from 3-bromopentane is shifted toward the curve for the first isomer. These results in acetic acid solution are surprising in that they involve, in the curve for one isomer, a shift of absorption toward the ultraviolet end of the spectrum in the longer wave lengths and toward the visible in the shorter wave lengths. With the other isomer the shift in absorption is exactly opposite and these results are in complete agreement with predictions based on hydrogen bromide addition to the two isomers.[2] When hydrogen bromide gas is added to the 2-pentene prepared from 2-bromopentane either without any solvent or in a non-polar



2-Pentene prepared from 2-bromopentane; ——, 2-pentene dissolved in hexane; ......, 2-pentene dissolved in glacial acetic acid.

Fig. 7.

solvent the product is 98–100% 2-bromopentane; with the other isomer the product is 98–100% 3-bromopentane.

The absorption curves in hexane give no evidence of any change in electronic condition brought about by the solvent and on this basis, if the isomers are electronic, addition of hydrogen bromide in a non-polar solvent would give 100% 2-bromopentane or 100% 3-bromopentane, as the case might be. Further, if the isomers are electronic a polar solvent such as glacial acetic acid would give a different electrical environment with a consequent effect on the relative position of the pair of labile electrons and therefore of the polarity of the double bond. In the addition of hydrogen bromide this electronic shift would be indicated by a change in the relative amounts of 2-bromo- and 3-bromopentane obtained; addition of hydrogen bromide to the 2-pentene obtained from 3-bromopentane when the pentene is dissolved in glacial acetic acid gives 78% of 3-bromopentane and 28% of 2-bromopentane; addition to the other isomer of 2-pentene in glacial acetic acid gives 85% of 2-bromopentane and 15% of 3-bromopentane. In ultraviolet absorption the effect of the polar solvent should be most evident in the region of the spectrum where the absorption is directly related to the characteristic frequency of the pair of labile electrons. Our spectrographic results so far all point to the conclusion that the band at λ2500–2700 Å. is due to the electronic motion of the second or labile pair of electrons in the double bond and it is exactly here that the pronounced changes in the absorption curves of the acetic acid solutions are shown.

Although no one piece of evidence is completely conclusive in itself in establishing the electro-isomerism of the 2-pentenes, the complete agreement of results based on methods of preparation, directive addition of hydrogen bromide and ultraviolet absorption spectra make such a conclusion the most reasonable interpretation. The differences in physical properties of the two isomers, although slight, certainly indicate two distinct substances. Kharasch and Darkis[3] have pointed out that there are no experimental data which would justify the assumption that cis-*trans* isomers add an unsymmetrical reagent in a different manner and base their conclusions on the electro-isomerism of the 2-pentenes before and after exposure to light on the change in the directive addition of hydrogen bromide. Independent confirmation of their theory is obtained in the preparation by Sherrill and collaborators in this Laboratory of two isomeric 2-pentenes from either 3-bromopentane or 3-pentanol and from 2-bromopentane. Since these preparations were from substances which differed primarily in their electronic structure due to the difference in position of the electronegative bromine atom, or hydroxyl group, it is reasonable to expect that the pentenes formed would differ in electronic structure, but there is no reason to predict or expect a different spatial configuration as in geometrical isomerism.

In the spectrographic study of geometrical isomers the *trans* form, which is the less stable in light, is more absorptive than the cis form. In the 2-pentenes the isomer which is less stable in light is the less absorptive. *Cis-trans* isomers show their marked differences in absorption in the far ultraviolet; the 2-pentenes show their marked differences in the near ultraviolet. In the study of the 2-pentenes there has been no experimental result which is not readily explained on the basis of electronic isomerism, whereas a number of results cannot be reconciled with the previously established behavior of geometrical isomers.

Experimental

The absorption spectra measurements were made by means of a Hilger quartz spectrograph (E2) using an iron spark as a source of light. The sparking apparatus consisted of a 0.25 kilowatt transformer and condenser of approximately 0.03 m. f. capacity as recommended by Hilger for spectrum work. The rectangular iron electrodes, cross-section 2 mm. by 3 mm., were carried in a holder with vertical and horizontal adjustment and the width of the spark-gap was kept at 2 mm. Measurements of the absorption were made in small Baly absorption tubes of clear fused quartz with optically worked ends fused to the tube and with ground quartz connections such that the length of absorbing liquid could be adjusted without the use of the ordinary rubber connections. This avoidance of rubber and also of cement for fastening the quartz plates to the tube was of great advantage in maintaining the purity of the liquids under examination. The length of the absorbing medium was varied from 70 mm. to 4 mm. Lumière and Jougla photographic plates were used throughout the investigation. The extinction coefficients were determined by the photographic method of comparison spectra developed by Henri.[9]

The intensity of the incident light was varied by varying the time of exposure and a uniform time of ten seconds was adopted for photographing the spectrum of the solvent. Between each two spectra of the solution exposed for forty seconds and sixty seconds, respectively, was photographed the spectrum of the solvent through the same thickness, for ten seconds. The duration of the exposure was carefully timed and for the times which were used the validity of Schwarzschild's law has been accurately established

$$\frac{I_0}{I} = \left(\frac{t}{t_0}\right)^n$$

where I_0 is the intensity of the incident light; I, the intensity of the transmitted light; t_0 is the time of exposure through the solvent of a given thickness; t, the exposure time through the solution of the same thickness, and n, a constant dependent on the photographic plates used. The

---

[9] Ref. 4, p. 5.

value of this constant was checked in this Laboratory by comparison with the absorption curve of potassium chromate in 0.05 N potassium hydroxide.[10] Extinction coefficients for this curve were determined both by photoelectric and different photographic methods and the close agreement of our results checked not only the value of the constant for the photographic plates but gave a very satisfactory check on the accuracy of our experimental procedure.

A Leitz binocular was used for determining the points of equal density between the spectra of solution and solvent of the same thickness and the wave lengths were identified from the known wave lengths of the iron spark. By combining Schwarzchild's law with the Bunsen-Roscoe law, which defines the extinction coefficient, $\epsilon = 1/cd \log I_0/I$, and substituting the value of $n = 0.9$, the extinction coefficients can be calculated from the experimental data by the following formula

$$\epsilon = \frac{0.9}{\text{cd}} \log \frac{t}{t_0}$$

where c is the concentration in moles per liter, d is the thickness in cm., t is the exposure time for solution, and t_0 for solvent.

Where the absorption spectrum of the pure liquid pentene was photographed, the molar concentration was calculated from the density and as a comparison spectrum the spark through the same thickness of optically pure hexane was used rather than the spark alone, since the density of hexane (0.660) is close to that of the pentene (0.650). In determining the effect of solvent on the absorption spectra of the 2-pentene, very concentrated solutions were used for two reasons: first, such concentrated solutions are necessary in order to obtain the region in which the band of low intensity is found; second, glacial acetic acid is itself quite absorptive and solutions containing too large proportions of the acid would not transmit sufficiently far to study the region in which this shallow band appears. Two cc. of solvent was added to 6 cc. of pentene and the molar concentration was calculated from the density. A solution of 2 cc. of glacial acetic acid in 6 cc. of hexane was used for the comparison spectrum with the acetic acid solutions of the 2-pentenes.

The optical purity of the solvent in spectrographic work is of the greatest importance and methods of purification of organic solvents have been worked out in Henri's laboratory.[11] One liter of hexane from petroleum (b. p. 65-70°) was shaken for twelve hours with 150 cc. of fuming sulfuric acid (10%), the hexane was decanted and this process was repeated twice with fresh amounts of fuming sulfuric acid. It was then shaken for twelve hours with 150 cc. of concentrated sulfuric acid (sp. gr. 1.84), washed twice with distilled water and shaken for another twelve hours each with (1) 150 cc. of 10% sodium carbonate solution, (2) 150 cc. of a mixture containing 100 cc. of normal potassium permanganate and 50 cc. of 10% sodium carbonate and (3) 150 cc. of a mixture containing 50 cc. of 10% sulfuric acid and 100 cc. of normal potassium permanganate. The hexane was then decanted, washed several times with water,

dried over sodium wire and distilled with a fractionating column. The hexane thus prepared transmitted the copper line λ 2105 Å., which is the limit of transmission of this type of spectrograph. The glacial acetic acid was purified by repeated recrystallization of the c. p. glacial acetic acid obtained from the General Chemical Company. The 2-pentenes were thoroughly dried over fused calcium chloride before spectrographic examination.

Summary

The ultraviolet absorption spectra of the 2-pentene prepared from 3-bromopentane or 3-pentanol and of the 2-pentene from 2-bromopentane or 2-pentanol show marked differences, particularly in the region of the shallow absorption band in the near ultraviolet. The absorption curves of the two isomers are so characteristic that they have given an excellent method of identifying these isomers as well as of differentiating them from 1-pentene and the polymeric forms of 2-pentene which may be present as impurities.

The effect of a polar solvent, glacial acetic acid, as compared with the non-polar solvent, hexane, on the absorption spectra of the two isomeric 2-pentenes shows that the acetic acid in each case shifts the absorption slightly toward that of the other isomer, while in hexane solution each curve is almost identical with that for the corresponding pure liquid pentene. These results are in accord with the addition reactions of the isomeric pentenes in the two solvents and indicate the existence of electronic isomers. In a non-polar solvent each isomer retains its identity; in a polar solvent there is an electronic shift with the consequent formation of some of the other isomer.

Absorption spectra measurements of the 2-pentene from 3-bromopentane before and after prolonged exposure to diffused light show a shift in the absorption corresponding to a transformation into the isomeric 2-pentene, together with the formation of some more absorptive polymer. When exposed to the ultraviolet light from the mercury arc for eight to nine hours, the absorption spectrum of 2-pentene obtained from 3-bromopentane or 3-pentanol shows a decided shift of the absorption toward the visible, while the isomeric 2-pentene from 2-bromopentane or 2-pentanol under identical conditions is quite stable and shows only a very slight shift of absorption in the opposite direction, that is, toward the absorption curve of the isomeric 2-pentene.

The results of the spectrographic examinations of the isomeric 2-pentenes are in accord with the interpretation of electronic isomerism as proposed by Kharasch, but are not in agreement with the previously established behavior of geometrical isomers.

STUDIES ON PYRETHRUM FLOWERS. I. THE QUANTITATIVE DETERMINATION OF THE ACTIVE PRINCIPLES

BY C. B. GNADINGER AND C. S. CORL

RECEIVED APRIL 26, 1929 PUBLISHED OCTOBER 5, 1929

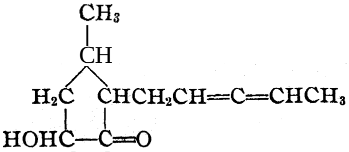
Although the insecticidal properties of *Pyrethrum* flowers have been known for more than a century, no satisfactory method has existed for the determination of the toxic principles. During the last five years the use of *Pyrethrum* has grown enormously, because of the development of new types of liquid insecticides, and the need for a method for evaluating the flowers has increased correspondingly. Of the methods in use prior to 1927,[1] only the physiological tests on insects give results that indicate the comparative value of different samples. These tests are difficult to conduct under constant conditions and are, at best, inaccurate. The chemical methods, involving the determination of ash constituents, ether-extract, nitrogen, etc., afford no idea of the amount of toxic principles present.

Staudinger and Harder[2] have published a method that is an adaptation of the process originally used by Staudinger and Ruzicka,[3] for the isolation of the active principles of *Pyrethrum*. This method is long, tedious and difficult to conduct quantitatively, requiring 500 g. of sample for a single determination.

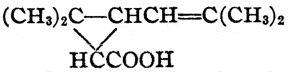
The purpose of this paper is to describe an accurate and comparatively rapid chemical method for determining the percentage of active principles in *Pyrethrum* flowers.

Experimental Part

Preparation of the Pure Active Principles.—In 1916 Staudinger and Ruzicka[4] isolated the toxic principles of *Pyrethrum* and definitely established their composition and structure. The two toxic substances, which they named pyrethrin I and pyrethrin II, were shown to be esters of the ketone-alcohol pyrethrolon with two acids, chrysanthemum monocarboxylic acid and chrysanthemum dicarboxylic acid methyl ester. Since these compounds will be referred to frequently throughout this paper, their structural formulas, as determined by Staudinger and Ruzicka, are given herewith



Pyrethrolon



$(CH_3)_2C{-}CHCH{=}C(CH_3)_2$, $HCCOOH$

Chrysanthemum monocarboxylic acid

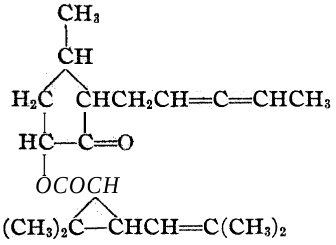
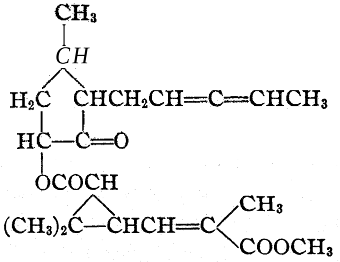
Chrysanthemum dicarboxylic acid methyl ester



Pyrethrin I



Pyrethrin II

By using a modification of the method of Staudinger and Ruzicka, quantities of nearly pure pyrethrin I and pyrethrin II were prepared from the best quality of Japanese *Pyrethrum (Chrysanthemum cinerariaefolium* Bocc.). For this purpose 680 kg. of the flowers was ground to 30-mesh and extracted with 3800 liters of acetone. The acetone was removed by distillation *in vacuo,* and there remained 90 kg. of oleo-resin of *Pyrethrum.* This material was worked up in small portions because of the difficulty of handling the large volumes of solvents required in the process. For example, the last portion was treated in the following manner: 6.5 kg. of the oleo-resin (corresponding to 49.1 kg. of flowers) was dissolved in 10 liters of acetone and mixed with 15 liters of low-boiling petroleum ether. A large amount of gummy material separated and it was washed with 8 liters of ether and then with 8 liters of benzene. The insoluble residue, which weighed 3120 g., contained only 2.96 g. of pyrethrins and was discarded. The mixture of solvents, containing the main portion of pyrethrins, was distilled *in vacuo* to 4 liters and was poured into 16 liters of petroleum ether. A further separation of green, semi-solid material occurred; it weighed 1680 g., contained 77.76 g. of pyrethrins and was discarded. The petroleum ether solution was distilled *in vacuo* and the residue was poured into 4 liters of methanol. The fatty material that separated was washed four times with 1-liter portions of methanol. The methanol-insoluble fat weighed 640 g. and contained 5.60 g. of pyrethrins. The methanol solution was chilled at −7° until no further precipitation took place and the fatty precipitate weighing 90 g. was filtered off; it contained 9.74 g. of pyrethrins. The methanol solution was distilled *in vacuo* to a volume of 2500 cc. and sufficient water was added to make the alcohol content 88%. The solution was chilled overnight and the fatty material that separated was washed three times with 1-liter portions of 90% methanol. This insoluble fat weighed 260 g. and contained 13.31 g. of pyrethrins. All of the fatty residues were discarded. The methanol solution was distilled *in vacuo* and the residue was dissolved in petroleum ether. The petroleum ether solution was filtered from the 149 g. of insoluble material that contained only a trace of pyrethrins and was distilled in *vacuo.* The oily residue from the petroleum ether distillation weighed 548 g. and contained 304 g. of pyrethrins. In addition to the 304 g. of pyrethrins recovered in impure condition, 109 g. was lost in the process. Thus the total pyrethrin content of the 49.1 kg. of flowers was 413 g., or 0.84%. Subsequently, analysis of the same lot of flowers showed a pyrethrin content of 0.87%.

The oil containing 55.5% of pyrethrins was further purified by treatment with sodium carbonate solution and basic lead acetate. The pyrethrins were then converted into their semicarbazones by the method described by Staudinger and Ruzicka;[5] 288

---

[5] *Cf.* ref. 4, p. 190.

g. of the oil yielded 220 g. of the impure, mixed semicarbazones of pyrethrin I and pyrethrin II.

The semicarbazone of pyrethrin I was separated in nearly pure condition (m. p. 117–119°) by repeated crystallization of the crude mixture from benzene and alcohol. The pure semicarbazone of pyrethrin II could not be isolated, but after fifty-one crystallizations from benzene, alcohol and mixtures of benzene and petroleum ether, a semicarbazone was obtained that melted at 56–59°. Both semicarbazones crystallized from benzene in white needles. A large amount of mixed pyrethrin semicarbazones melting at 70–90° was also obtained.

By heating the semicarbazones with oxalic acid solution,[6] they were converted into the corresponding pyrethrins. The crude pyrethrins were extracted from the oxalic acid solution with petroleum ether and washed free from acids with 1% sodium hydroxide solution. Further purification was effected by washing with 3% chromic acid solution and 3% potassium permanganate solution, which did not attack the pyrethrins appreciably. The petroleum ether was then removed *in vacuo* and the residue was dissolved in alcohol, whereby a small amount of insoluble matter was precipitated. The alcohol solution was filtered and distilled in *vacuo*, the residue was dissolved in petroleum ether and the solution was filtered and distilled in *vacuo* at a maximum temperature of 55° until constant weight was attained. Ten grams of semicarbazone of pyrethrin I (m. p. 117–119°) yielded 3.53 g. of pure pyrethrin I; 10 g. of semicarbazone of pyrethrin II (m. p. 56–59°) yielded 2.76 g. of nearly pure pyrethrin II.

Anal. Calcd. for $C_{21}H_{30}O_3$ (pyrethrin I): *C*, 76.31; H, 9.16. Found: C, 75.95, 76.36; H, 9.32, 9.06. Calcd. for $C_{22}H_{30}O_5$ (pyrethrin II): C, 70.54; H, 8.08. Found: C, 72.71; H, 8.18.

In the course of this work it was noticed that when a drop of solution containing the pyrethrins was applied to the tongue, a very marked numbing effect was produced. Eventually it was proved that the sensation was caused by pyrethrin I and pyrethrin II. The numbing or tingling sensation was much the same as that produced by rubbing the tongue with aconite root. With pyrethrins the numbness developed five or ten minutes after placing on the tongue, and the effect persisted for one to three hours.

Toxicity of the Pyrethrins to Insects.—The insecticidal activity of the isolated pyrethrins was determined by experiments on cockroaches (*Blatta germanica*). One of us had observed that an acetone or alcohol

[6] Cf. ref. 4, p. 194.

solution of pyrethrins, when diluted with water, forms a stable colloidal suspension of great insecticidal power.' Por the experiments with cockroaches the pyrethrins were dissolved in alcohol and then diluted with water to the desired strength. The amount of alcohol in the solution applied to the cockroaches was less than 0.5%. The dilute solutions were freshly prepared before each experiment and the pyrethrins remained uniformly distributed without settling or floating. The results of the experiments are given in Table I.

Pyrethrin I was slightly more active than pyrethrin II, as Staudinger and Ruzicka have noted. The pure pyrethrins were extremely toxic to cockroaches.

Reducing Action of the Pyrethrins on Alkaline Copper Solution.—Staudinger and Ruzicka have mentioned that pyrethrolon reduces alkaline copper solution. It was found that pyrethrin I and pyrethrin II have the same property and the idea of using the reaction for determining the pyrethrins at once suggested itself. The copper reducing power of the pyrethrins was found to be considerably less than that of dextrose and the other reducing sugars, and for this reason the gravimetric sugar methods could not be applied satisfactorily. Of the other sugar methods, the colorimetric method of Folin,[8] for determining dextrose in blood, seemed to be the most promising. In this method a measured amount of specially treated blood is heated with an alkaline copper solution, in a tube designed to prevent oxidation of the precipitated cuprous oxide. A tube containing a known amount of dextrose is treated in precisely the same manner. When the heating is finished, the Folin phosphomolybdate reagent is added to the tubes and a deep blue color is developed by the action of the cuprous oxide on the phosphomolybdate solution. The intensities of the colors are compared and the amount of dextrose in the blood is calculated in the usual way.

In a long series of experiments this method was adapted to the determination of pure pyrethrins in alcoholic solution. A special size of Folin sugar tube was used because oxidation of the reduced copper took place rapidly when test-tubes were used as suggested by Benedict.[9] Several modifications of Folin's reagent were tried and a large number of alkaline copper solutions were investigated. The effects of varying the temperature and time of the reaction were noted. More than 700 experiments were made before the best procedure for conducting the test was determined.

Comparisons of the colors produced by known amounts of the pyrethrins with those obtained from known amounts of dextrose, indicated that dextrose could be used as a standard, as in the Folin method. The ratio of the pyrethrin used to the copper reduced was not a constant. A number

[9] Benedict, *ibid.*, 64, 207–213 (1925).

of comparisons were made between different quantities of pyrethrins and a constant amount of dextrose; the results of these experiments were plotted. The curves were not linear functions, but more nearly conformed to the parabolic equation used by Allihn[10] in his work on dextrose. In Table II the amounts of dextrose equivalent in copper reducing power to different quantities of pyrethrin I and pyrethrin II are given. These ratios were obtained by comparing the color produced by 2 mg. of dextrose with the colors yielded by the different weights of pyrethrins; the method by which these comparisons were made will be described later.

TABLE II

COMPARISON OF COPPER REDUCING POWER OF DEXTROSE AND PYRETHRINS

Weights having equivalent copper reducing power									
Pyrethrin I, mg.	Dextrose, mg.				Av., mg.	Pyrethrin II, mg.	Dextrose mg.		Av., mg.
5.0	0.735	0.767	0.787	0.797	0.772	..	...	...	...
7.5	1.166	1.175	1.228	1.246	1.204	7.5	0.973	1.003	0.988
12.5	2.020	2.036	2.046	2.061	2.041	12.5	1.636	1.642	1.639
15.0	2.222	2.222	2.253	2.292	2.247	15.0	1.956	1.980	1.968
17.5	2.469	2.500	2.500		2.489	17.5	2.253	2.272	2.263
20.0	2.730	2.826	2.836		2.797	20.0	2.402	2.539	2.471

By substituting the values in Table II in the equation $y = a + bx + cx^2$, (where y = mg. of dextrose, x = mg. of pyrethrin, and a, b and c are constants) and applying the method of least squares, two equations were obtained

Eq. I (for pyrethrin I): $y = -0.2536 + 0.2237x - 0.00365x^2$
Eq. II (for pyrethrin II): $y = -0.0101 + 0.1437x - 0.0009x^2$

From these equations the dextrose equivalent to the quantities of pyrethrins in Table II was calculated; the observed and calculated values are compared in Table III, where the ratio of the reducing power of pyrethrin I to that of pyrethrin II also appears.

TABLE III

[a] Calculated from dextrose equivalent to given weight of pyrethrin I and pyrethrin II; theoretical ratio, 1.133 (374/330).

---

[10] Allihn, *J. prakt. Chem.*, **22,** 46 (1880).

It was expected that the amounts of dextrose equivalent to a given weight of the two pyrethrins would be inversely proportional to the molecular weights of the pyrethrins. This is shown to be approximately the case in Table III. Direct colorimetric comparisons were made between equal weights of pyrethrin I and pyrethrin II. The colorimeter readings were almost directly proportional to the molecular weights of the pyrethrins; the ratio of the pyrethrin II readings to the pyrethrin I readings was 1.152, compared with the theoretical ratio 1.133.

By substituting different values for y in Equation I, the weights of pyrethrin I equivalent to amounts of dextrose from 0.750 to 2.875 mg. were calculated. These calculations were made at intervals of 0.125 mg. of dextrose and other values were interpolated at intervals of 0.025 mg. In this way Col. II of Table IV was formed.

[a] Third column calculated for a mixture of equal parts of pyrethrin I and II.

Staudinger and Ruzicka found that the active material, in the flowers they used, consisted of about 40% of pyrethrin I and 60% of pyrethrin II. The proportion of the two pyrethrins in the flowers probably varies.[2] It was assumed that the pyrethrins occur in equal amounts, and from the values for pyrethrin I, in Table IV, the corresponding values for a 1:1 mixture of pyrethrin I and II were calculated, using the average molecular weight *352* and multiplying the figures for pyrethrin I by the factor 1.06666 (third column, Table IV).

The semicarbazones of the pyrethrins had little or no copper reducing action. The by-products of the semicarbazone conversion, with oxalic acid, were carefully examined for copper reducing compounds; none was found that resisted the purification with sodium hydroxide, chromic acid and permanganate.

The pyrethrins were altered by prolonged beating at 90°; they became insoluble in petroleum ether and lost their activity but the copper reducing power was increased slightly. Saponification of pyrethrin I with alcoholic sodium hydroxide solution lowered the copper reducing power.

The semicarbazone of pyrethrolon was prepared from the mixed semicarbazones of pyrethrin I and II by saponification at 0°, with a methanol solution of sodium hydroxide.[11] The pyrethrolon semicarbazone melted at 203°; it was converted into the ketone-alcohol by prolonged shaking with benzene and potassium bisulfate solution.

The copper reducing power of pyrethrolon was slightly less than that of pyrethrin I. Pyrethrolon was dissolved in petroleum ether and washed with 3% potassium permanganate solution; 98.5% of the pyrethrolon was oxidized and removed from the petroleum ether. The residue from the evaporation of the petroleum ether solution had very little copper reducing action.

Application of the Copper Reduction Method to Pyrethrum Flowers.—Having found that the amount of pure pyrethrins in alcoholic solution could be determined accurately, it remained to apply the method to pyrethrum flowers and to eliminate, by appropriate means, any other copper reducing material that might be present.

Preliminary tests with petroleum ether extracts yielded percentages of pyrethrins of about the magnitude expected. Washing the petroleum ether extracts with 1% sodium hydroxide or with concentrated sodium bisulfite solution did not remove any material that reduced alkaline copper solution.

Staudinger and Ruzicka found that the pyrethrins in petroleum ether solution were not oxidized by chromic acid solution. Washing the petroleum ether extracts of *Pyrethrum* flowers with chromic acid solution did not decrease the amount of copper reducing material. No petroleum ether

---

[11] Staudinger and Ruzicka, *cf.* ref. 4, pp. 196 and 216.

soluble compounds that reduced copper could be found, excepting the pyrethrins.

The residues from the purification of the semicarbazones of the pyrethrins were carefully examined for petroleum ether soluble copper reducing compounds but none was found.

No other compounds that formed semicarbazones could be isolated from the petroleum ether extract excepting the pyrethrins; this agrees with the findings of Staudinger and Ruzicka.

Application of the method to daisy flowers (*Chrysanthemum leucanthemum)* showed no pyrethrins present and tests on *Pyrethrum* stems yielded mere traces of pyrethrins. Finally, the pyrethrins were isolated from 2500 g. of *Pyrethrum* flowers and weighed as semicarbazones. The same flowers were analyzed by the copper reduction method; the gravimetric method yielded 0.66% of pyrethrins; the copper reduction method, 0.88%. In view of the unavoidable losses in separating the semicarbazones, the agreement is good.

It is believed, therefore, that the following method determines only the toxic principles in *Pyrethrum* flowers.

Method for the Evaluation of Pyrethrum Flowers

Reagents. (a) Petroleum ether, 90–99% distilling between 20 and 40"; maximum boiling point, 60°.

(b) Aldehyde-Free **Alcohol.**[12]—Allow 95% alcohol, containing 5 g. of *m*-phenylenediamine hydrochloride per liter, to stand for twenty-four hours with frequent shaking. Boil under a reflux condenser for at least eight hours, allow to stand overnight and distil, rejecting the first 10 and the last 5% of distillate. Store in a dark place in well-filled bottles.

(c) Basic Lead Acetate Solution.—Dissolve 20 g. of Horne's basic lead acetate in sufficient recently boiled water to make 1 liter.

(d) Alkaline Copper Solution.—Dissolve 2.5 g. of purest copper sulfate, $CuSO_4.5H_2O$, in about 100 cc. of water, warming gently; cool when dissolved. Dissolve 5 g. of highest purity sodium potassium tartrate and 7.5 g. of purest sodium hydroxide separately in about 100 cc. of cold water. Transfer the solutions to a 500-cc. volumetric flask, mix and dilute to the mark. This solution should not be used after it is three days old.

(e) **Folin's Reagent.**[13]—Dissolve 150 g. of sodium molybdate, $Na_2MoO_4{\cdot}2H_2O$, in 300 cc. of water. Filter through a 15-cm. quantitative filter paper into a 1-liter flask and wash with 75 cc. of water. Add 0.1 to 0.2 cc. of bromine and shake until the bromine is dissolved. Let stand for one hour, then add with shaking 225 cc. of 85% phosphoric acid. Add 150 cc. of sulfuric acid (1 vol. of concentrated acid mixed with 3 vols. of water and cooled). Remove the liberated bromine by means of a moderately rapid current of air; the aëration requires about half an hour. Finally add 75 cc. of 99% acetic acid, mix and dilute to a volume of 1 liter.

(f) Standard Dextrose Solution.—Dissolve exactly 1 g. of pure anhydrous dextrose

---

[12] "Methods of Analysis," Association of Official Agricultural Chemists, Washington, D. C., **1925,** 2d. ed., p. 353.

[13] Folin, *J. Biol. Chem.*, **67,** 357–370 (1926).

in water and transfer to a 200-cc. volumetric flask. Add 40 cc. of aldehyde-freealcohol, mix and dilute to 200 cc. with water. Transfer 10 cc. of this solution to a 250-cc. volumetric flask by means of a pipet, add 210 cc. of aldehyde-free alcohol and dilute to 250 cc. with water. Ten cc. of this dilute solution contains 2 mg. of dextrose. The strong solution is stable for months; the dilute solution should be made fresh each week.

Apparatus. (a) Constant-temperature water bath, set at 78°, corrected, and controlled within ±0.2°.

(b) **Colorimeter** of Duboscq or Klett type, with artificial illuminator.

(c) Folin sugar **tubes,**[14] blown to contain 15.5 cc. to base of constriction. When heated to 78° the surface of the liquid must fall between points **A** and B, Fig. 1. The internal diameter of the constricted portion should be the same for all tubes in a set.

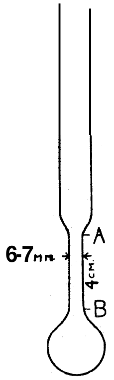

Fig. 1.—Modified Folin tube. Bulb contains 15.5 cc. to Point B.

Determination.—Extract 20 g. of ground *Pyrethrum* flowers (about 30-mesh) for five hours with petroleum ether in a Soxhlet extractor. Cool the petroleum ether solution to about 20" and let stand for at least half an hour. Filter through a quantitative filter paper into a 400-cc. beaker, add a few grains of ignited sand and evaporate at a temperature not exceeding 75°. As soon as the last traces of petroleum ether are driven off, transfer the residue with five or six portions of boiling 95% aldehyde-free alcohol to a 100-cc. volumetric flask (previously marked at the 80-cc. point), using sufficient boiling alcohol to make the volume 80–85 cc. To the hot solution add from a pipet 15 cc. of basic lead acetate solution and make to the mark with hot alcohol. Shake vigorously, cool at once to 20° and again make to the mark with alcohol. Filter and to the filtrate add about 1 g. of anhydrous sodium carbonate. Let stand for ten to fifteen minutes, shaking frequently, and filter. Immediately pipet 10 cc. of the clear filtrate into a Folin tube and add, also from a pipet, 6 cc. of alkaline copper solution. Mix thoroughly, keeping the solution in the bulb of the tube. Measure 10 cc. of standard dextrose solution (2 mg. of dextrose) with a pipet into *a* second tube and add 6 cc. of copper solution. Place the tubes upright in the constant-temperature bath, set at 78° corrected, and heat for exactly forty-five minutes. Remove from the bath and place in water at 20° for three minutes. Add 10 cc. of Folin's reagent from a pipet and let stand for three minutes; then stopper the tubes, mix thoroughly, transfer to 100 cc. volumetric flasks and make to the mark with water. Filter through a Gooch crucible fitted with a heavy asbestos pad, using gentle suction. Do not use filter paper. The dextrose solution need not be filtered. Compare the solutions at once in the colorimeter and from the readings calculate the dextrose equivalent to the unknown solution in the usual way. Reference to Col. **3** of Table IV will give the amount of pyrethrins, in milligrams, equivalent to the dextrose found in the unknown solution, or milligrams of pyrethrins in the 2 g. aliquot of flowers taken.

Discussion of Method

Blank determinations were run several times each day, or with nearly every set of tests. No difficulty was experienced in obtaining blanks equivalent to 0.05 mg. of dextrose, and for this reason no correction for the blank was made in calculating Table IV. Reagents that yield a blank equivalent to more than 0.10 mg. of dextrose should be rejected. High blanks may be due to impurities in any of the reagents, but the sodium potassium tartrate,

---

[14] Folin, J. *Biol. Chem.*, ***41,*** 372 (1920).

sodium molybdate and aldehyde-free alcohol especially should be carefully tested. If the blank is between 0.05 and 0.10 mg. of dextrose, when compared with the standard dextrose solution, the error due to the blank is negligible.

The petroleum ether extract should not be heated longer than necessary to drive off the solvent. Generally only five or ten minutes' heating above 60° will be required if the petroleum ether meets the specifications given. High-boiling petroleum ether should not be used.

The proportion of alcohol and water in the contents of the Folin tubes is carefully adjusted; if more alcohol is used the copper salts will be precipitated; if the percentage of water is increased the pyrethrins will be thrown out of solution. In either case incorrect results will be obtained. The Folin tubes should be dried before using and the measurements should be made with pipets. Smaller aliquots than 10 cc. can be used for a determination, but sufficient aldehyde-free alcohol (80.5%) must be added to the tube to make the total volume of the pyrethrin solution 10 cc. Larger aliquots than 10 cc. cannot be used.

It is essential that the bath be maintained at 78° corrected, ±0.2°, and a stirrer should be provided to insure even temperature and circulation around the tubes, which should be immersed to a depth of 8 to 10 cm. Variations in time of heating or in temperature will yield results that are not comparable with Table IV. After removing the tubes from the bath they should be treated as nearly alike as possible; therefore it is inadvisable to run more than 3 or 4 tubes at a time.

In making the color comparisons the standard dextrose is set at 20 mm. The unknown will then read between 14 and 50 mm., for quantities between 23 and 5 mg. of pyrethrins. If the reading is less than 12 mm., the entire amount of copper may have been reduced, and the determination should be repeated using a smaller aliquot. It is also desirable, if the reading is more than 40 mm., to run a duplicate determination using 40 g. of flowers instead of 20.

The pyrethrins, in petroleum ether solution, can be washed with dilute sodium hydroxide solution, concentrated sodium bisulfite solution and 3% chromic acid solution without appreciable loss. These methods of purification were not necessary for the analysis of the flowers, but may be used in the examination of *Pyrethrum* sprays.

The dextrose used as standard in this work was of the highest purity obtainable and was dried for thirty days over sulfuric acid. All volumetric glassware, weights and thermometers used were Bureau of Standards certified. Colorimeter readings were made with artificial light and a blue glass screen.

Percentage of Toxic Principles in Pyrethrum Flowers.—The foregoing method was applied to *Pyrethrum* flowers and stems and to daisy flowers. The analyses are shown in Table V.

TABLE V

DETERMINATION OF PYRETHRIN CONTENT OF FLOWERS AND STEMS

No.	Description of sample	Pyrethrins %	No.	Description of sample	Pyrethrins, %
7	Pyrethrum flowers, 1928 crop	0.40	2	Pyrethrum flowers, 1926 crop	0.87
6	Pyrethrum flowers, 1927 crop	.43	20	Pyrethrum flowers, 1928 crop	.94
13	Pyrethrum flowers, 1925 crop	.44	19	Pyrethrum flowers, 1928 crop	1.10
21	Pyrethrum flowers, 1925 crop	.45	17	Pyrethrum flowers, 1928 crop	1.17
16	Pyrethrum flowers, 1925 crop	.47	18	Pyrethrum flowers, 1928 crop	1.20
14	Pyrethrum flowers, 1925 crop	.53	1	Pyrethrum flowers, 1928 crop	1.21
4	Pyrethrum flowers, 1927 crop	.56	8	Dalmatian stems, 6 years old	0.00
11	Pyrethrum flowers, 1925 crop	.57	9	Spanish stems, 1927 crop	.04
5	Pyrethrum flowers	.59	15	Dalmatian stems	.04
3	Pyrethrum flowers, 1928 crop	.80	22	Daisy flowers, 3 years old	.00

The pyrethrin content varied, in the samples examined, from 0.40 to 1.21%; duplicate determinations agreed within 0.03% or less. The range of the pyrethrin content found is greater than reported by Staudinger and Harder (0.4 to 0.6%); Staudinger and Ruzicka found only 0.3% of pyrethrins in the flowers they examined.

Further work is in progress to determine the comparative value of the different varieties and grades of *Pyrethrum,* and to determine the distribution of the active principles in the different parts of the flower. The method is also being adapted to the examination of oleo-resin of *Pyrethrum* and to the analysis of *Pyrethrum* insecticidal sprays for household and garden use.

Summary

1. Pyrethrin I and II have been isolated from Japanese *Pyrethrum* flowers, and their action on alkaline copper solution has been investigated. The copper reducing power of the pyrethrins has been compared with that of dextrose.
2. A method has been described for determining the percentage of active principles in *Pyrethrum* flowers.
3. The percentage of pyrethrins ranged from 0.40 to 1.21%, in the sixteen samples of *Pyrethrum* flowers examined.
4. *Pyrethrum* stems contain about one-tenth the amount of pyrethrins found in the poorest flowers.
5. Daisy flowers contain no pyrethrins.
6. The active principles of Japanese *Pyrethrum* are the same as those of Dalmatian *Pyrethrum* flowers.
7. The toxicity of the pyrethrins to cockroaches has been determined.

A SERIES ARRANGEMENT OF ORGANIC GROUPS. I. AS DETERMINED BY THE HALOGENATION OF MIXED STANNANES

By Ralph H. Bullard

Received May 14, 1929 Published October 5, 1929

When a tetra-alkyl- or arylstannane is treated with two atoms of halogen one of the organic groups is replaced by halogen. The reaction is represented by the equation $R_4Sn + X_2 = R_3SnX + RX$. When a mixed alkyl- or alkylarylstannane such as R_3SnR' is halogenated, two reactions are possible

$$R_3SnR' + X_2 = R_3SnX + R'X \quad (1)$$
$$R_3SnR' + X_2 = R_2R'SnX + RX \quad (2)$$

It is a remarkable fact that in general only one of these reactions occurs. We may consider, therefore, that the velocity of one reaction is enormously greater than that of the other, or that the affinities of the groups are such that only one reaction occurs. In any case, the groups can be arranged in a series corresponding with the order of their removal by means of halogen.

Grüttner and Krause[1] from their investigations of mixed alkylplumbanes formulated a rule stating that, on bromination, the lightest group splits off first. Later, on working with mixed alkylstannanes, these authors state[2] that, without exception, the same rule applies to the alkylstannanes.

Frankland[3] and also Morganoff[4] state that, on iodination of dimethyldiethylstannane, $(CH_3)_2(C_2H_5)_2Sn$, the methyl group is removed before the ethyl. Pope and Peachey[5] found that on iodinating trimethylethylstannane, $(CH_3)_3C_2H_5Sn$, and dimethylethylpropylstannane, $(CH_3)_2(C_2H_5)(C_3H_7)Sn$, the methyl group is in each case removed first. Cahours,[6] however, reports that an ethyl group is removed on iodinating trimethylethylstannane. Bullard and Vingee[7] found that trimethylethylstannane, on bromination, yields dimethylethylstannyl bromide, $(CH_3)_2(C_2H_5)SnBr$, with the removal of a methyl group. This does not agree with the observations of Cahours but is in accord with those of Frankland, Morganoff and Pope and Peachey.

Ladenburg[8] found that iodination of triethylphenylstannane, $(C_2H_5)_3(C_6H_5)Sn$, yields iodobenzene and triethylstannyl iodide, $(C_2H_5)_3SnI$, while

Krause and Schmitz[9] showed that the phenyl group is removed before ethyl with such reagents as silver nitrate or mercuric chloride. Bullard and Robinson[10] found that on bromination of trimethylphenylstannane, $(CH_3)_3(C_6H_5)Sn$, the phenyl group is removed.

It has been shown by Kipping and Smith[11] that the benzyl group is removed before ethyl by iodine, sulfuric acid or chlorosulfuric acid. Kraus and Bullard[12] showed that the benzyl group is removed on brominating trimethylbenzylstannane, $(CH_3)_3(C_6H_5CH_2)Sn$.

In the experimental part of this paper it is shown that the phenyl group is removed before the benzyl group.

From the above it is seen that the series of groups arranged in the order of decreasing ease of removal from tin by free halogen is as follows: phenyl, benzyl, methyl, ethyl, propyl.

In a later paper the author hopes to present the'order of substitution for mixed stannanes of the type $R_2SnR'_2$ when treated with halogen acids.

Experimental Part

Preparation of Triphenylbenzylstannane, $(C_6H_5)_3(C_6H_5CH_2)Sn$.—Triphenylstannyl iodide was dissolved in liquid ammonia and converted into the sodium salt by adding two atoms of sodium per mole of iodide. The theoretical amount of benzyl chloride was then added. A white precipitate was formed. The reaction took place according to the equation $NaSn(C_6H_5)_3 + C_6H_5CH_2Cl = (C_6H_5)_3(C_6H_5CH_2)Sn + NaCl$. The ammonia was allowed to evaporate and water was added to dissolve the sodium chloride. The residual white powder was dried and crystallized from petroleum ether; yield, practically quantitative. The substance melted at 90–91°.

Anal. Subs., 0.2579, 0.2584: SnO_2, 0.0873, 0.0880. Calcd. for $(C_6H_5)_3(C_6H_5CH_2)$-Sn: Sn, 26.94. Found: Sn, 26.66, 26.82.

Mol. wt. Subs., 0.3095, 0.4317: C_6H_6, 19.25, 19.25; *At,* 0.189, 0.267. Calcd. for $(C_6H_5)_3(C_6H_5CH_2)Sn$: mol. wt., 440.7. Found: mol. wt., 435.7, 426.8.

Bromination of Triphenylbenzylstannane.—The stannane was brominated by adding to its benzene solution cooled in ice water a carbon tetrachloride solution of four atoms of bromine per mole of stannane. Bromination took place instantly. The benzene and carbon tetrachloride were removed by distillation from a steam-bath under atmospheric pressure. The pressure was then reduced and a liquid was obtained which boiled under atmospheric pressure at 154° uncorr. This indicated the presence of bromobanzene. The residual liquid did not distil at 100° under a pressure of three millimeters. On cooling it solidified and was crystallized from petroleum ether. Large colorless prisms melting at 74–75' were obtained. This further indicated that phenyl groups had been removed with the formation of phenylbenzylstannyl dibromide because diphenylstannyl dibromide melts at 36–38'.

Anal. Subs., 0.1024, 0.1581: SnO_2, 0.0408, 0.0536. Calcd. for $(C_6H_5)(C_6H_5CH_2)$-$SnBr_2$: Sn, 26.59. Found: Sn, 26.69, 26.70. Subs., 0.1669, 0.2503: AgBr, 0.1391, 0.2099. Calcd. for $(C_6H_5)(C_6H_5CH_2)SnBr_2$: Br, 35.79. Found: Br, 35.47, 35.69.

---

Hence the bromination of triphenylbenzylstannane results in the removal of phenyl groups, the reaction proceeding according to the equation $(C_6H_5)_3$-$(C_6H_5CH_2)Sn + 2Br_2 = (C_6H_5)(C_6H_5CH_2)SnBr_2 + 2C_6H_5Br$.

The author wishes to acknowledge his indebtedness to the Warren Fund of the American Academy of Arts and Sciences for a grant which assisted in defraying the expenses of the present investigation.

Summary

1. It has been shown that on bromination of triphenylbenzylstannane the phenyl groups are first removed.

2. The series arrangement of some organic groups based on the relative ease of removal from tin by halogen is: phenyl, benzyl, methyl, ethyl, propyl.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF BROWN UNIVERSITY]

THE CONSTITUTION OF TRIPHENYLSILICANE AND ITS REACTION WITH SODIUM IN LIQUID AMMONIA[1]

BY HARRY H. REYNOLDS,[2] LUCIUS A. BIGELOW AND CHARLES A. KRAUS

RECEIVED MAY 18, 1929 PUBLISHED OCTOBER 5, 1929

The present study was undertaken as a part of a broader investigation now in progress in this Laboratory, which deals with certain of the fundamental properties of the element silicon in its organic combinations. In attacking this problem it was necessary to form organic silicon derivatives of the general type R_3SiNa to be used as reagents. Since the corresponding halides R_3SiX are completely ammonolyzed by liquid ammonia, it was attempted to prepare the desired compound by the action of sodium on triphenylsilicane in the same solvent. The corresponding reaction of sodium with triphenylstannane takes place readily and quantitatively. When, however, this simple reaction was attempted in the case of the silicane, unexpected results were obtained and it was found necessary to carry out a detailed study, the results of which are described in the present paper.

Ladenburg[3] reports the preparation of triphenylsilicane, melting at 200–203°, by the action of sodium and a little benzene upon triphenyl silicon bromide. On the face of it, this reaction seems a little improbable, especially in view of the fact that the corresponding triphenylstannane, and triphenylgermane, recently prepared, have been found to melt at

---

[1] This paper is constructed from a portion of the Dissertation presented by Harry H. Reynolds to the Faculty of the Graduate School of Brown University, in June, 1928, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Rice Fellow, 1925–1926; Metcalf Fellow, 1926–1927.

[3] Ladenburg *Ber.*, 40, 2278 (1907).

about 25°[4] and 47°,[5] respectively. Our work has shown that the earlier results of Ladenburg are in error, and that the compound of the formula $(C_6H_5)_3SiH$ melts at 36°.[6]

The silicane, which is a white crystalline solid, was first synthesized by Nelson,[7] who treated silicochloroform with phenylmagnesium bromide. The reaction takes place according to the equation $SiHCl_3 + 3C_6H_5MgBr \longrightarrow SiH(C_6H_5)_3 + 3MgBrCl$. He analyzed the silicane for silicon but did not examine it further. The present writers have confirmed the synthesis and fully established the constitution of the compound in the following manner. (1) The molecular weight of the material was determined and found to correspond to the formula requirements; (2) the substance was quantitatively brominated and one mole of hydrogen bromide was evolved for each mole of the silicane used, and (3) the triphenyl silicon bromide formed in (2) yielded, upon hydrolysis, an approximately quantitative amount of pure, known triphenylsilicol, $(C_6H_5)_3SiOH$.

When triphenylsilicane is treated with sodium in liquid ammonia solution, a very simple reaction might be expected to take place, namely, $(C_6H_5)_3SiH + Na \longrightarrow (C_6H_5)_3SiNa + {}^1/_2 H_2$, which calls for the utilization of 1 gram atom of sodium and the evolution of $^1/_2$ mole of hydrogen per mole of the silicane employed. Actually, however, only $^2/_3$ gram-atom of sodium was consumed and 1.9 atoms of hydrogen were evolved in the reaction. Furthermore, since a distinct end-point was reached, the excess of hydrogen could not have come from any interaction between the sodium and the ammonia. If the above reaction occurred, the addition of ammonium bromide to the solution should regenerate the original material, according to the equation $(C_6H_5)_3SiNa + NH_4Br \longrightarrow (C_6H_5)_3SiH + NaBr + NH_3$. Actually, the product obtained under these conditions, upon evaporation of the liquid ammonia, consisted of a white crystalline solid melting at 175° and a thick sirup which was not further investigated. About two-thirds of the original silicon was recovered as crystalline solid. The addition of reagents other than ammonium bromide, such as ethyl or phenyl bromide or oxygen, yielded, in every case, the same crystalline product.

[4] L. S. Foster, "Thesis," Clark University, **1923.**

[5] Kraus and Foster, THIS JOURNAL, **49,** 465 (1927).

[6] Since the above was written an article has appeared by Kipping and Murray, *J. Chem. Soc.*, **131, 360** (1929), in which they have prepared a substance believed to be triphenylsilicane, as a by-product in the destructive distillation of octaphenylcyclosilicotetrane under reduced pressure. They describe it as an oil which did not solidify at 0°. Analyses, molecular weight determination and hydrogen equivalent, corresponding closely to the values required by the formula $(C_6H_5)_3SiH$ are given, as well as certain reactions tending to confirm the constitution of the product. It seems certain that these investigators had in hand a somewhat impure sample of the silicane, as it failed to solidify at 0°.

[7] Walter K. Nelson, unpublished work, **1927.**

The substance melting at 175° is very stable, not being affected by the air or even by boiling dilute sodium hydroxide. It is rather difficultly soluble in alcohol and crystallizes well from this solvent. When analyzed for silicon it gave figures closely corresponding to the values required for triphenylsilicon or hexaphenylsilico-ethane, while molecular weight determinations yielded values closely approximating those required by the formula $[(C_6H_5)_3Si]_2$ or hexaphenylsilico-ethane. However, this latter compound has previously been synthesized and melts at 354°.[8] We have prepared a sample of this silico-ethane by the method described in the literature and have shown that our substance is structurally different, inasmuch as no transition from one into the other occurred when they were melted together.

The material melting at 175° was brominated in carbon tetrachloride in an effort to throw light upon its constitution. One-half of the silicon appeared as triphenyl silicon bromide, while all the rest of the bromine employed went to form bromobenzene. A very small quantity of di-triphenyl silicon oxide was also isolated. The remainder of the material produced in the bromination consisted of pasty by-products which were not further examined. No definite conclusions could be drawn from these experiments.

At this point it was discovered that the substance melting at 175° could be hydrolyzed readily by means of hydrochloric acid, and that the inorganic product of hydrolysis was ammonium chloride. Inasmuch as our material was quantitatively stable toward boiling alkali, and since all compounds containing a silicon–nitrogen linkage, with which we were familiar, hydrolyzed even in moist air, this observation was entirely unexpected. However, it was established that the material contained 2.6% of nitrogen, which corresponds closely to that required by di-triphenylsilicon-imine, $[(C_6H_5)_3Si]_2NH$. The analytical results above described correspond, within the normal limits of error, to the values required by this formula, while the amount of hydrogen evolved in the preparation, as well as the phenomena observed in the bromination, may also be accounted for. Finally, the product of hydrolysis of the imine, other than ammonium chloride, which should be triphenylsilicol, has been identified as such.

A somewhat similar reaction has been observed in this Laboratory by Eatough,[9] who treated triphenylsilicane with lithium dissolved in ethyl amine. In this case, also, $^2/_3$ gram-atom of the metal reacted with 1 mole of the silicane and 1 mole of hydrogen was evolved, but the products were not further investigated. The mechanism of these reactions is as yet obscure, though undoubtedly complex.

---

[8] Schlenk, Renning and Racky, *Ber.*, 44, 1178 (1911).

[9] Harry Eatough, unpublished work, 1928.

Altogether, the structure of the substance melting **at** 175" seems definitely established as di-triphenylsilicon-imine, notwithstanding its extraordinary stability in alkaline solution, not frequently observed in compounds of this type.

Experimental

Triphenylsilicane.—This compound was prepared according to the method of Nelson[7] as follows. A Grignard reagent was prepared in the usual manner from 185 g. of bromobenzene, 28.6 g. of magnesium and 400 cc. of anhydrous ether. This solution (4.5 molar equivalents) was cooled to 0° and 36.2 g. of silicochloroform dissolved in 200 cc. of anhydrous ether was slowly added to it. After standing at room temperature for two hours the mixture was boiled for twenty hours. The resulting crystalline mass was cooled to 0°, acidified with dilute sulfuric acid, extracted with ether and the solvent distilled. The residue was fractionated twice at 2 mm. and the final product collected from 152–167°. It condensed as a colorless oil which on cooling solidified to a white solid; yield, 52 g. or 73% of the theoretical. Upon recrystallization from 95% alcohol, under 21°, white plates were formed melting at 36–37°. At higher temperatures the compound separated as an oil.

Anal. (Nelson) Subs., 0.3716, 0.3580, 0.4880: SiO_2, 0.0852, 0.0830, 0.1131. Calcd. for $C_{18}H_{16}Si$: Si, 10.78. Found: Si, 10.71, 10.83, 10.83.

Mol. wt. Subs., 0.1941, 0.1930, 0.1941: Benzene, 21.79, 21.77, 21.77; AT, 0.177°, 0.173°, 0.179°. Calcd. for $C_{18}H_{16}Si$: 260. Found: 252, 256, 249.

Bromination of Triphenylsilicane in Carbon Tetrachloride Solution.—In this experiment an all glass apparatus was used, arranged in such a manner that a current of nitrogen could be passed through the reacting mixture and the gases produced (N_2, HBr and CCl_4 vapor) conducted through a reflux condenser and then an absorption train. This consisted of a trap containing metallic mercury to absorb free bromine, a U-tube immersed in liquid ammonia to condense any carbon tetrachloride vapor and finally a series of bulbs partly filled with 10% sodium hydroxide solution to absorb all the hydrobromic acid evolved. One mole of triphenylsilicane was placed in this apparatus and 1 mole of bromine dissolved in carbon tetrachloride added through a side tube. The mixture was allowed to stand for some time to complete the reaction and the carbon tetrachloride was then frozen by means of a liquid ammonia bath to liberate the dissolved hydrobromic acid. A current of dry nitrogen was now passed through the solidified mass to carry all the hydrobromic acid into the absorption train. In the course of an hour the mixture was allowed to warm up and was finally boiled to expel the last traces of hydrobromic acid. The sodium hydroxide solution was carefully washed out of the bulbs, acidified with nitric acid and the bromine precipitated as silver bromide in the usual manner.

Anal. Subs., 1.000: Br, 0.614; AgBr, 0.724. Mols HBr/mole subs.: 1.00.

Upon hydrolysis of the brominated product formed in the reaction by boiling with dilute sodium hydroxide solution, a 93% yield of practically pure triphenylsilicol (m. p. 148–151°) was obtained.

Reaction between Triphenylsilicane and Sodium in Liquid Ammonia.—To a suspension of triphenylsilicane in anhydrous ammonia there was added, in small portions, one mole of metallic sodium. As the metal was added, a moderately vigorous reaction occurred, accompanied by the appearance of a deep red color and the copious evolution of an inflammable gas, later identified as hydrogen. As the reaction progressed the silicane gradually dissolved and a colorless crystalline product separated. When approximately two-thirds of the sodium had been added, the evolution of gas ceased and a permanent blue color, due to **an** excess of the metal, was imparted to the solution. Further additions of sodium produced no further apparent change. Ammonium bromide was then added, in small portions, to the mixture. The blue color was first discharged and the red color gradually faded, with the momentary formation of a white curdy precipitate. The color finally disappeared entirely, and from then on until one mole of ammonium bromide had been added, a white curdy precipitate continued to be formed. When the reaction was complete, the liquid ammonia was allowed to evaporate and the reaction mixture was extracted with carbon tetrachloride. The solvent was removed by distillation and a white solid mass remained which, upon recrystallization from 95% alcohol, yielded a white crystalline product melting at 170–175°. Approximately two-thirds of the product consisted of this substance and the remainder, recovered by evaporating the alcoholic mother liquor, was a thick sirup, from which no single substance could be isolated. Further crystallization of the solid from alcohol yielded long white needles melting at 175°.

It was especially noteworthy, in the above reaction, that the addition of ethyl bromide, phenyl bromide or oxygen, instead of ammonium bromide, yielded in every case the same crystalline product, m. p. 175°. This indicated that the substance was formed directly by the action of the sodium with the triphenylsilicane, and not later upon the addition of ammonium bromide.

Anal. Subs., 0.3008, 0.3002, 0.3901: SiO_2, 0.0683, 0.0692, 0.0896. Subs., 0.3808, 0.5101: 16.58, 14.39 cc. of 0.1008 N NaOH; 20.04, 20.18 cc. of 0.1199 N HCl; blank, 0.23 cc. of HCI. Calcd. for $C_{36}H_{31}Si_2N$: Si, 10.61; N, 2.62. Found: Si, 10.66, 10.82, 10.78; N, 2.59, 2.58.

Mol. wt. Subs., 0.3866, 0.3807: benzene, 21.78, 21.78; AT, 0.174°, 0.167°. Calcd. for $C_{36}H_{31}Si_2N$: 534. Found: 510,524.

The analysis for silicon was carried out by treating the sample in a pyrex test-tube with fuming sulfuric acid and then with successive portions of fuming nitric acid until decomposition was complete. The acids were evaporated and the residue of silicon dioxide was ignited and weighed.

The analysis for nitrogen was conducted in the following manner. The sample was boiled for half an hour with 6 N hydrochloric acid, the mixture filtered and the residue washed free from chlorides. The filtrate was evaporated to a small volume, poured into a Kjeldahl apparatus, made alkaline and the ammonia collected in the usual manner in standard hydrochloric acid. The residue from the filtration, on crystallization from petroleum ether, melted at 151–152°. A known sample of triphenylsilicol, $(C_6H_5)_3SiOH$, and a mixture of the two each melted at the same point.

Quantitative Determination of the Gas Evolved in the Reaction between **Triphenylsilicane** and Sodium in Liquid Ammonia.—The treatment of the silicane with the sodium was carried out in an apparatus arranged in such a manner that all of the gas evolved might be collected over water, to dissolve most of the ammonia. The gas was then drawn very slowly through a drying tube containing phosphorus pentoxide into an evacuated bulb of known weight and volume. A manometer was attached to the system and the volume of the drying tube and connecting tubes was known. The molecular weight of the gas was calculated from the weight, pressure and temperature of the gas in the density bulb, together with the known volume of the bulb. The total volume of the gas at N.T.Y. was determined in a similar manner from its pressure, temperature and the known volume of the entire containing system. The molecular weight obtained indicated that the gas must be hydrogen, and a correction to the total volume of hydrogen was calculated, upon the assumption that the only impurity in it was ammonia. The results of this experiment are indicated below.

Mol. *wt.* Gas in bulb, 0.0115, 0.0156 g.; P, 200, 212 mm.; *T*, 25°, 27"; vol. of

bulb, 351.4 cc. Calcd. for H_2: 2.0. Found: 3.1, 3.9. ***Total vol. of gas.*** **Subs., 1.086, 1.029; Na, 0.096, 0.091; P, 200, 212 mm.; T, 25°, 27°; vol. of system, 391 cc.; vol. of pure H at N.T.P., corr. for NH_3 content, 87.0, 86.4 cc. Gram atoms of H_2 per mole of $(C_6H_5)_3SiH$, 1.8, 1.9.**

Summary

1. The constitution of triphenylsilicane, melting at 36°, has been established.
2. The reaction between triphenylsilicane and sodium in liquid ammonia has been studied. The chief product of the reaction was found to be di-triphenylsilicon-imine, $[(C_6H_5)_3Si]_2NH$.

MONOBROMOGUAIACOL CARBONATE. ESTIMATION OF GUAIACOL CARBONATE

BY LEWIS H. CHERNOFF

RECEIVED MAY 1, 1929 PUBLISHED OCTOBER 5, 1929

As far as the writer is aware there are only two published methods for the estimation of guaiacol carbonate. One method[1] depends on the solubility of the carbonate in ether and its use is therefore limited to mixtures which do not contain other ether-soluble substances. In the other[2] the substance is saponified with alcoholic potassium hydroxide, acidified and after the addition of sodium chloride the volume of guaiacol is read.

The method herein described is more specific and depends on the conversion of guaiacol carbonate into a bromine derivative insoluble in 50% methyl alcohol.

When bromine is added to a solution of guaiacol carbonate in methyl alcohol, large needle-like crystals begin to separate out almost immediately. The compound is reasonably pure and after recrystallization from hot 95% ethyl alcohol melts sharply to an oil at 178°. It is easily soluble in chloroform, ether, benzene and hot methyl and ethyl alcohols, but less easily soluble in the cold alcohols. In water and petroleum ether it is insoluble.

A bromine determination by the Pringsheim method[3] slightly modified indicates the compound to be a monobromo guaiacol carbonate. This is apparently a new compound, as it does not seem to be described in the literature.

[3] Scott, "Standard Methods of Analysis," D. Van Nostrand Co., Inc., New York, 1917, 2d ed., revised, p. 122; *Chem. News*, 91, 215, 2372 (1905). The mixture of substance with sodium peroxide was heated slowly in a nickel crucible until melted. The contents was then allowed to cool and the whole plunged into water.

Anal. Subs., 0.2 g.: AgBr, 0.1763. Calcd. for $(BrC_6H_3OCH_3)_2O_2CO$: Br, 37.07. Found: Br, 37.50.

Method

To 0.1–0.5 g. of guaiacol carbonate in a 100-cc. Erlenmeyer flask add 10–20 cc. of methyl alcohol. Heat on the steam-bath until all of the substance is dissolved. Remove from the bath while hot, add about 1 cc. of bromine and let stand for ten minutes, shaking occasionally to promote crystallization. Add an equal volume of water and allow to stand for ten minutes longer. Filter through asbestos in a weighed Gooch crucible, wash with 50% methyl alcohol, dry for about an hour at the temperature of boiling water and weigh. Multiply the weight of the bromine derivative by the conversion factor 0.6343 to obtain the weight of guaiacol carbonate.

The bromine derivative is somewhat soluble in methyl alcohol and the addition of water is necessary to precipitate it completely. The following table shows the results obtained with pure guaiacol carbonate.

TABLE I

RESULTS WITH PURE GUAIACOL CARBONATE

Subs., g.	Bromine deriv., g.	Equiv. guaiacol carbonate, g.	Error, %
0.5	0.7788	0.4939	1.2
.1	.1567	.0994	0.6
.1	.1575	.0999	.1
.01	.0158	.0100	.0

When only one-fourth volume of water is added, the error becomes slightly larger, as is shown in Table II.

TABLE II

ERROR WITH LESS WATER

Subs, g.	Bromine deriv., g.	Equiv. guaiacol carbonate, g.	Error, %
0.5	0.7586	0.4812	3.8
.1	.1533	.0972	2.8
.1	.1557	.0988	1.2

Mixtures

In mixtures with the usual excipients such as starch, sugar and the gums acacia and tragacanth, a preliminary separation by the use of proper solvents may be made. Chloroform, in which the carbonate is easily soluble, is useful.

Mix 0.5 to 0.1 g. of powdered material with 10 cc. of chloroform, heat to boiling and filter through a small paper into an evaporating dish. Wash thoroughly with chloroform and evaporate the solution on the steam-bath. Dissolve the residue in hot methyl alcohol and brominate as above.

The results shown in Table III were obtained on three different mixtures whose compositions were unknown to the writer at the time of analysis. Later their compositions were given for comparison,

TABLE III

RESULTS ON UNKNOWN MIXTURES

Mixture	Composition, %	Guaiacol carbonate found, %
1	Guaiacol carbonate, 31.5; sucrose, 0.5; starch, 68.0	29.38, 30.64
2	Guaiacol carbonate, 51.5; sucrose, 9.5; acacia, 1.0; starch, 38.0	49.16, 49.76
3	Guaiacol carbonate, 63.7; tragacanth, 0.3; starch, 36.0	63.5, 63.89

A sample of commercial 5-grain guaiacol carbonate tablets was prepared by pulverizing twenty tablets, the average weight of each being 0.3865 g. or 5.96 grains. Three-tenths gram samples were analyzed according to the method for mixtures, with the check results 75.53 and 75.56%. The average content, therefore, was 4.50 grains instead of the declared 5 grains.

Summary

A new method for the estimation of guaiacol carbonate, depending on the conversion of guaiacol carbonate into a monobromo derivative, and a new compound, monobromo guaiacol carbonate, are described.

Acknowledgement is made to L. E. Warren of the Food, Drug and Insecticide Administration for submitting the problem and furnishing the "unknowns."

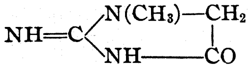
NEW DERIVATIVES OF CREATININE AND DIKETOPIPERAZINE[1,2]

BY L. R. RICHARDSON AND CLAUDE E. WELCH WITH S. CALVERT

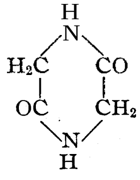
RECEIVED MAY 25, 1929 PUBLISHED OCTOBER 5, 1929

Creatinine, since it is excreted by the animal body, and diketopiperazine, because recent research has indicated that it is an integral part of the protein molecule, are both of great physiological importance. Extensive investigations of the physiological nature of creatinine have been completed but the known chemical reactions of both compounds are comparatively few in number.

A consideration of the formulas of these substances shows that both contain methylene groups



Creatinine



Diketopiperazine (keto form)

---

[1] An abstract of the theses submitted by L. R. Richardson and Claude E. Welch in partial fulfilment of the requirements for the degree of Master of Arts in Chemistry at the University of Missouri.

[2] Revised paper; original manuscript received August 6, 1928.

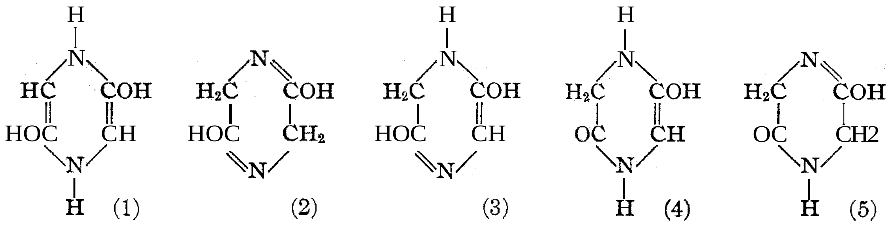
Methylene groups, if sufficiently affected by one or more negative groups such as the carbonyl group, tend to react with aldehydes,[3] substituted amidines and at times with an anilide such as benzylidene aniline. It seemed not unreasonable that similar condensations might be expected with creatinine and diketopiperazine.

Efforts to condense diphenylformamidine with creatinine were successful. We have not yet, however, succeeded in determining the precise formula of the product obtained. This work is being continued.

It was found that aldehydes condense very easily with creatinine upon fusion. Several aromatic aldehydes were condensed in this manner. The derivative that was prepared with benzaldehyde was prepared by Greenwald from creatine[4] and, during the course of these experiments, by Nicolet and Campbell[5] from the dihydrochloride of 5-benzalcreatinine. We have prepared this compound by two different methods: by fusing creatinine with benzaldehyde and with benzylidene aniline. Creatinine was condensed with vanillin and m-nitrobenzaldehydein the same manner.

Diketopiperazine, however, fails to condense with aromatic aldehydes on fusion. It seems that the only suitable method of effecting condensation is an application of the Perkin synthesis first applied to diketopiperazine by Sasaki:[6] several hours' heating of a mixture of the parent compounds in the presence of sodium acetate and acetic anhydride. 3,6-Derivatives of diketopiperazine are prepared in this manner without acetylation of the imino nitrogen. However, as such, the reaction is not general; aliphatic aldehydes do not form simple 3,6-derivatives and, though it is generally applicable to the aromatic series, o-hydroxy-substituted aldehydes give poor yields. By this reaction condensations of vanillin, cinnamaldehyde, piperonal, salicylaldehyde, tolualdehyde and o-chlorobenzaldehyde with glycine anhydride were effected. Diketopiperazine failed to condense with benzylidene aniline on fusion. Likewise, all attempts to condense diketopiperazine with substituted amidines have been unsuccessful.

Diketopiperazine exists, theoretically, in five enol forms



Enol forms Half-enol forms

---

[3] Bamberger and Berle, *Ann.*, **273**, 269 ff. (1880); F. Henrich, *Ber.*, **32**, 673 (1899).

[4] Greenwald, This Journal, **47**, 1443 (1925).

[5] Nicolet and Campbell, *ibid.*, **50**, 1115 (1928).

[6] Sasaki, *Ber.*, **54**, 163–171 (1921).

The proof of the presence of the hydroxyl groups in enol-diketopiperazine is based mainly upon color tests such as a positive xanthoproteic and a negative picric acid reaction. Definite confirmation of their presence is furnished by the fact that two molecules of a-naphthyl isocyanate condense easily with one of the diketopiperazine.

It is probable that not more than one or two of the various enol forms exists in more than a negligible amount in the equilibrium mixture. Evidence of the structure of the ordinary form of enol-diketopiperazine may be obtained from the chemical conduct of the a-naphthyl isocyanate derivative.

Since two molecules of the isocyanate react with one of diketopiperazine it seems that the more stable form must contain two hydroxyl groups. It is necessary, then, to decide among forms (1), (2) and (3). When the isocyanate derivative is formed it is evident that an equilibrium mixture of the keto and enol forms is no longer present but that a derivative of one or more of these forms will be produced. Since the reactions of these forms with aldehydes will differ because of their structure, an attempt was made to determine the predominant enol form by condensation with *m*-nitrobenzaldehyde.

If the ordinary enol form is (1), the compound should not condense with aldehydes, for no methylene groups are present; (2) should condense with two aldehyde groups while (3) should react with only one.

On condensation the product showed a nitrogen content of 14.73%. The unexpected fact is that this compound is, according to the analysis, virtually identical with that obtained from the condensation of glycine anhydride and m-nitrobenzaldehyde. Such a derivative has a nitrogen content of 14.73%. If the enol form had been (2), the condensed product would have contained 11.70% nitrogen, and if it had been (3), 13.21%.

The most probable explanation seems to be that during the course of the reaction the isocyanate derivative first hydrolyzed, forming enol-diketopiperazine, which reverted to the more stable keto form and then condensed with the aldehyde. It is to be expected that (2) would condense with the aldehyde without hydrolysis; on the other hand, before (1) could react with an aldehyde, it would necessarily have to hydrolyze. The analysis showed that nearly complete hydrolysis had taken place. This indicates that (1) is the ordinary form of diketopiperazine.

To confirm this statement another condensation was made with tolualdehyde. The condensation product formed from tolualdehyde and glycine anhydride has a nitrogen content of 8.81%. If the conclusion drawn from the preceding analysis is correct, the product resulting from the reaction of the a-naphthyl isocyanate derivative of diketopiperazine with tolualdehyde should agree quite closely with this figure. The compound formed contained 8.92% of nitrogen. The decomposition point of this product also checked closely with that of 3,6-*bis*-tolual-2,5-diketopiperazine. Hence the probability of the carbon–carbon double bond is supported by this reaction.

Other reports on methylene condensations which have been in progress in this Laboratory will appear at an early date.

Experimental Part

1. Creatinine

5-Benzalcreatinine.—The method employed in the preparation of this compound is typical of the derivatives of creatinine which were made. Five grams of creatinine and an excess of benzaldehyde were thoroughly mixed and then heated at 150° in a flask attached to an air reflux. The creatinine dissolved in about forty-five minutes, giving a reddish-yellow solution which formed a yellow solid on cooling. Flaky, golden-yellow crystals were obtained by recrystallization from boiling alcohol. The compound was difficultly soluble in boiling alcohol and water, and slightly soluble in ether, benzene and chloroform; m. p. 244°, uncorrected.

Anal. Calcd. for $C_{11}H_{11}ON_3$: N, 20.89. Found: N, 20.76, 20.64.

Fusion of benzylidene aniline and creatinine (equivalent quantities) for an hour at 150° produced the same compound. Aniline was liberated, as was shown by the bleaching powder test.

5-*m*-Nitrobenzalcreatinine.—Five g. of creatinine and an equivalent quantity of m-nitrobenzaldehyde were fused for three hours at 150°, and then for two hours more at 180". The product was purified by extracting first with alcohol and then with water. It is very slightly soluble in each. A 70% yield of the yellow powder was obtained; it decomposes at 288°, uncorrected.

Anal. Calcd. for $C_{11}H_{10}O_3N_4$: N, 22.76; C, 53.75; H, 4.1. Found: N, 22.63; C, 53.85; H, 4.19.

5-(*m*-Methoxy-*p*-hydroxybenzal)-creatinine.—Half an hour's fusion of equivalent quantities of vanillin and creatinine gave a 75% yield of the condensation product. It was purified by extracting first with alcohol and then with water. It was very slightly soluble in each of these solvents and slightly soluble in ether, chloroform and benzene; it melts with decomposition at 267°, uncorrected.

Anal. Calcd. for $C_{12}H_{13}O_3N_3$: N, 17.0; C, 58.3; H, 5.30. Found: N, 16.78; C, 58.04; 58.06; H, 5.43, 5.55.

II. Diketopiperazine

Preparation of Glycyl-glycine Anhydride.—Diketopiperazine was prepared according to the method of Emil Fischer[7] from glycine ethyl ester hydrochloride.

3,6-Bis-(*m*-methoxy-*p*-acetoxybenzal)-2,5-diketopiperazine.—The method employed in the preparation of this derivative is typical of the 3,6-derivatives which were prepared. One and four-tenths grams of glycine anhydride, 4.5 g. of vanillin, 4 g. of sodium acetate and 8 g. of acetic anhydride were thoroughly mixed and heated at 120–130° for eight hours. During this period the liquid solidified into a brown mass of crystals. After cooling the product was washed several times with hot water and then extracted for a short time with alcohol. The bright yellow crystals were recrystallized from boiling acetic acid and, for analysis, dried for three hours at 130°.

A list of the six aldehyde derivatives is given in Table I. They were prepared in a similar manner. All of this series of compounds are soluble

---

[7] Fischer, *Ber.,* 39, 2930 (1906).

in boiling acetic acid, but they are insoluble in water, alcohol, ether, benzene and chloroform.

TABLE I

DATA ON ALDEHYDE DERIVATIVES

3,6-Bis-( )-2,5-diketopiperazine	Formula	Diketopiperazine condensed with	Nitrogen, % Calcd.	Found		Brown at °C.	Dec., °C.

Tolual	$C_{20}H_{18}O_2N_2$	Tolualdehyde	8.81	8.69	8.80	305	320
o-Chlorobenzal	$C_{18}H_{12}O_2N_2Cl_2$	*o*-Chlorobenzaldehyde	7.80	7.82		330	340

α-Naphthyl Isocyanate Derivative of Diketopiperazine.—One gram of thoroughly dried glycine anhydride was finely powdered and covered with 8 g. (excess) of α-naphthyl isocyanate. The mixture was heated in the sulfuric acid bath to 175'. At this temperature it rapidly turned into a white solid. After fifteen minutes it was cooled. The compound was insoluble in ligroin, ether, water, benzene and chloroform; it was very slightly soluble in boiling acetic acid. To remove the excess isocyanate the mass was extracted with ligroin for three hours; two hours' extraction with water removed any unchanged glycine anhydride. The fine white crystals were dried for three hours at 130°. They melt with decomposition at 232°.

Anal. Calcd. for $C_{26}H_{20}O_4N_4$: N, 12.39. Found: N, 12.15, 12.18.

Condensation of the Isocyanate Derivative with *m*-Nitrobenzaldehyde.—Three grams of the isocyanate derivative, 10 g. of m-nitrobenzaldehyde, 8 g. of sodium acetate and 20 g. of acetic anhydride were heated at 125°. After eight hours the product was cooled, digested with warm water and boiling alcohol, recrystallized from boiling acetic acid and dried for three hours at 130'.

Anal. Calcd. for $C_{18}H_{12}O_6N_4$: N, 14.73. Found: N, 14.38.

Condensation of the Isocyanate Derivative with *m*-Tolualdehyde.—Five grams of the isocyanate derivative, 2 g. of tolualdehyde, 2 g. of sodium acetate and 4 g. of acetic anhydride formed the condensation product on heating for several hours at 125°. It was digested with water and alcohol and recrystallized from boiling acetic acid; yellow crystals, decomposing at 320°.

Anal. Calcd. for $C_{20}H_{18}O_2N_2$: N, 8.81. Found: N, 8.92.

Summary

1. A method of preparation of condensation products of creatinine with aldehydes and benzylidene aniline has been described.

2. Six new derivatives of diketopiperazine with aldehydes have been prepared.

3. The presence of hydroxyl groups in the enol form of diketopiperazine has been confirmed by the formation of the a-naphthyl isocyanate derivative.

4. The a-naphthyl isocyanate derivative condenses with aldehydes only after hydrolysis. It, therefore, appears that the ordinary enol form of diketopiperazine has double bonds between carbon atoms.

PARA-CYMENE STUDIES. XII. 2-PARA-CYMYL-4-SEMICARBAZIDE AND CERTAIN DERIVATIVES

BY ALVIN S. WHEELER AND J. G. PARK[1]

RECEIVED MAY 27, 1929 PUBLISHED OCTOBER 5, 1929

This paper presents a continuation of studies of semicarbazides as ketone reagents[2] In view of the fact that cymene is a fair priced product, its derivatives are more available than formerly. Ketone reagents such as hydroxylamine, phenylhydrazine and semicarbazide differ in their properties from strongly basic to neutral. This series is extended in the acid direction by using phenylsemicarbazide with its negative phenyl group and finally the substituted phenylsemicarbazides containing bromine or the nitro group. It is desirable to have such a variety for detecting and characterizing ketones since no one is applicable to all cases.

2-p-Cymyl-4-semicarbazide, not known hitherto, was prepared by known methods. 2-Amino-p-cymene was converted into p-cymylurea, a compound first mentioned by Kremers and Demonbreun,[3] who made only a very brief note about it and gave no analysis. We believe their product was impure since our product melts six degrees higher. Three methods of preparation were tested. The first was Davis and Blanchard's method[4] of preparing phenylurea. An aqueous solution of aminocymene hydrochloride and urea was heated. This was unsatisfactory on account of the simultaneous production of di-p-cymylurea, a compound not hitherto described. The second method was that of Kelbe and Warth,[5] who prepared *m*-cymylurea. The hydrochloride of aminocymene was heated with potassium cyanate. No dicymylurea was produced but the yield was poor. The method adopted was to heat an acetic acid solution of aminocymene with potassium cyanate. In a similar way Walther and Wlodkowski[6] made o-tolylurea. The yield was better and the product readily purified.

The urea was converted into the cymylsemicarbazide on heating with hydrazine hydrate as Curtius and Burkhardt[7] made phenylsemicarbazide.

Cymylsemicarbazide readily condenses with ketones, forming semicarbazones which are very stable. It was noted that the purely aliphatic and mixed aliphatic-aromatic ketones condensed with great readiness, whereas the purely aromatic ketones as well as camphor and carvone required the presence of some acetic acid and one or more hours of heating.

Experimental

Di-*p*-cymylurea, $(C_{10}H_{13}NH)_2CO$.—(a) A solution of 6 g. of urea and 18.5 g. of aminocymene hydrochloride in 75 cc. of water was boiled until bumping due to separated crystals became violent. The crystals were filtered off and proved to be dicymylurea. They were quite bulky and the weight was extremely small. The filtrate was cooled and the crystals which separated consisted of a mixture of dicymylurea and probably cymylurea. The solution was boiled again until bumping occurred and the process completed as above. The products proved to be the same so the method was given up.

(b) Baeyer's method[8] of preparing phenylurea was found to be much better. Two moles of aminocymene were heated wifh one mole of urea at 150–170° until the evolution of ammonia greatly slackened. This required about three hours. On cooling the mixture solidified. The product was extracted with ligroin and hot dilute hydrochloric acid to remove any unchanged aminocymene and urea. Coloring matter was removed with charcoal. The product crystallized from alcohol in bulky microscopic needles, melting at 240° to a dark brown viscous liquid. It is soluble in chloroform and slightly soluble in ether, benzene and carbon tetrachloride; 1.2 g. of urea gave 1.4 g. of the pure diurea.

Anal. Calcd. for $C_{21}H_{28}ON_2$: N, 8.64. Found: N, 8.79.

***p*-Cymylurea,** $C_6H_3(CH_3)(C_3H_7)NHCONH_2$.—To 74.5 g. of aminocymene dissolved in 200 cc. of warm glacial acetic acid was slowly added with stirring 48 g. of powdered potassium cyanate. After heating nearly to boiling the mixture was poured into a liter of cold water; yield, 84.7 g. The product was recrystallized by dissolving in glacial acetic acid and reprecipitating with water. It was finally recrystallized from 40% alcohol; yield of pure product, 55 g. Cymylurea is soluble in chloroform, moderately soluble in ether and slightly soluble in carbon tetrachloride. It dissolves in warm benzene but on cooling separates as a gelatinous mass. *p*-Cymylurea may also be prepared by the action of potassium cyanate on aminocymene hydrochloride, but the yield is lower.

Anal. Calcd. for $C_{11}H_{16}ON_2$: N, 14.58. Found: N, 14.47.

2-*p*-Cymyl-4-semicarbazide, $C_6H_3(CH_3)(C_3H_7)NHCONHNH_2$.—38.5 g. of cymylurea and 60 g. (2.5 equivalents) of 42% hydrazine hydrate were dissolved in 200 cc. of 95% alcohol and the mixture boiled for thirty hours under a reflux condenser, though not continuously. The solution was filtered hot to remove some black particles and concentrated to one-half of its original volume. A small amount of a yellow oil separated. In order to bring about crystallization some water was added, the mixture was cooled with ice water and vigorously stirred. A mass of yellowish crystals formed weighing 33.5 g. and melting at 96–105°. A saturated ice-cold ether solution was made and treated with a stream of hydrogen chloride. The salt was filtered off, redissolved in warm water and sufficient potassium hydroxide added to precipitate the free base; yield, 25.7 g.

[7] Curtius and Burkhardt, *J. prakt. Chem., 58,* 205 (1898).

[8] Baeyer, *Ann. Chem. Pharm., 131,* 251 (1864).

The carbazide crystallizes from warm dilute alcohol in colorless microscopic prisms, melting at 112°. It is soluble in benzene, ether, chloroform and warm carbon tetrachloride.

Anal. Calcd. for $C_{11}H_{17}ON_3$: N, 20.28. Found: N, 19.77.

The hydrochloride forms colorless microscopic needles from water, melting at 166–168° with decomposition. The melting point varies somewhat with the rate of heating.

Anal. Calcd. for $C_{11}H_{17}ON_3 \cdot HCl$: HCl, 14.97. Found: HCl, 14.86.

Semicarbazones.—The semicarbazones were prepared by dissolving one mole of cymylsemicarbazide in alcohol (1 g. per 10 cc. of alcohol) and adding two moles of the ketone. Unless otherwise stated crystallization of the carbazone began at once. The mixture was heated for ten minutes on the steam-bath and cooled for complete crystallization. The product was recrystallized from alcohol or benzene as found best. All thermometer readings were made with a set of Wheeler Standard Thermometers, each instrument having a small 50-degree scale for complete immersion.

TABLE I

SEMICARBAZONES

	Ketone	Crystal form	Solvent	M p., °C., (corr.)	Liquid
1	Acetone	Fluffy needles	Alcohol	182	Colorless
2	Methylethyl	Rect. plates	Alcohol	182–183	Colorless
3	*a*,γ-Dichloro-acetone	Prisms	Benzene	173	Decomposes
4	Mesityl oxide	Fluffy needles	Alcohol	163	Colorless
5	Acetoacetic ester	Fluffy needles	50% alc.	133.5	Colorless
6	Cyclohexanone	Fluffy needles	Alc.–Bz	192.5	Yellow
7	Camphor	Micro needles	Alc.–Bz	217	Yellow
8	Carvone	Micro prisms	70% alc.	97	Yellow
9	Benzophenone	Fluffy needles	Alcohol	150	Colorless
10	Acetophenone	Fluffy needles	Benzene	212	Colorless
11	Benzoin	Fluffy needles	Alcohol	172	Yellow

1. Soluble in chloroform, benzene, slightly soluble in ether; yield, 90% of weight of semicarbazide. 3. Alcohol for reaction medium not satisfactory. Benzene used. 5. Soluble in chloroform, ether and benzene. 6. Slightly soluble in hot alcohol and in ether. 7. One cc. of glacial acetic acid added to the reaction mixture before heating; mixture heated for two hours. 8. One cc. of acetic acid required and one hour of heating. In order to isolate the product water was added dropwise as long as it dissolved. On cooling a viscous oily product separated. This crystallized on a porous plate after two days. 9. One cc. of glacial acetic acid was added and heating for two and one-half hours was necessary. The crude product was gummy but became crystalline on a porous plate. In recrystallizing from alcohol seeding was a great aid. 10. The product weighed 20% more than the weight of the semicarbazide used. 11. Acetic acid needed and an hour and a half of heating.

Summary

1. Di-*p*-cymylurea is obtained in small amount by the action of urea upon aminocymene hydrochloride in aqueous solution. The best method is to heat aminocymene and urea together at 150–170°.

2. *p*-Cymylurea is best prepared by the action of potassium cyanate upon aminocymene in glacial acetic acid solution.

3. 2-p-Cymyl-4-semicarbazide is best made by the action of hydrazine hydrate on p-cymylurea.

4. p-Cymylsemicarbazide yields semicarbazones with the following ketones: acetone, methyl ethyl ketone, a,y-dichloro-acetone, mesityl oxide, acetoacetic ester, cyclohexanone, camphor, carvone, benzophenone, acetophenone and benzoin. The products are very stable. The reactions are immediate except those with camphor, carvone and the purely aromatic ketones. These require some acetic acid and a period of heating.

THE INDUCED CHLORINATION OF ETHYLENE DICHLORIDE. THE EFFECT OF OXYGEN UPON THE REACTION BETWEEN ETHYLENE AND CHLORINE

BY T. D. STEWART AND DONALD M. SMITH

RECEIVED MAY 27, 1929 PUBLISHED OCTOBER 5, 1929

Gaseous chlorine and gaseous ethylene react to form ethylene dichloride. The reaction takes place upon the surface of the containing vessel.[1,2]

$$C_2H_4 + Cl_2 \longrightarrow C_2H_4Cl_2 \qquad (1)$$

The reaction rate may be expressed by the equation

$$-\frac{d(C_2H_4)}{dt} = K_a' (C_2H_4)(Cl_2)$$

in which the bracketed formulas represent partial pressures of the respective gases. The specific reaction rate varies with the nature of the

catalytic surface,[3] but under given conditions is constant over wide variations in the pressures of the reactants. The experiments upon which these conclusions are based were carried out in the presence of air and in glass vessels whose surfaces were only superficially dried. Water is known to be a catalyst for the addition reaction.[2,4]

Stewart and Fowler[1] made their experiments at such concentrations that ethylene dichloride did not separate as a liquid. Norrish[2] worked at higher pressures, but states that the specific reaction rate, under the conditions mentioned above, was unaltered by the separation of the liquid. In the total absence of water or other catalyst the reaction does not take place,[3,4] and there is some evidence[1] that the reaction is autocatalytic.

The present paper concerns experiments carried out with thoroughly pure dry reactants and in glass vessels which were evacuated at a pressure of 1 X 10^{-6} mm. of mercury and at a temperature of 500° to remove all traces of water and oxygen from the walls.

Under these conditions there is an inhibition period and the reaction, when once started, is autocatalytic, with a marked increase in reaction rate accompanying the deposition of liquid. Besides the addition reaction, substitution occurs, and the facts suggest that the latter reaction is induced by the former. The effect of oxygen is to decrease the induced reaction, presumably by dissipating the energy of the exothermic addition reaction.

Experimental Method

Description of Apparatus and Preparation of Materials.—Figure 1 shows diagrammatically the reaction system. The apparatus was constructed of pyrex glass. The reaction vessel A was of three hundred cubic centimeters' capacity. All the connecting lines were of 2 mm. inside diameter except that leading from Stopcock 4 into A, which was 1 mm. inside diameter.

A and E and the attached capillaries (to within a few centimeters of the stopcocks) could be baked out at any temperature up to 550° by means of an electric oven. While baking was in progress, the stopcocks were kept cool by a blast of air. After the baking was completed the oven was replaced by an oil thermostat. This was controlled by hand to one tenth of a degree, the oil being pumped around the bulb at a constant rate.

The ethylene was made by dropping ethylene dibromide on zinc. It was washed with 95% alcohol, then passed over calcium chloride and phosphorus pentoxide and liquefied in a liquid air trap. A middle fraction of the liquid ethylene was distilled slowly at low pressure into the ethylene supply system, which was composed of several small traps containing small amounts of phosphorus pentoxide so that the ethylene was continually in contact with the drying agent. Between experiments the ethylene was kept frozen in one of the traps by means of a liquid-air bath. Before each experiment the ethylene system was evacuated for half an hour to an hour to the vapor pressure of solid ethylene.

The chlorine used was taken from a tank of liquid chlorine, passed over calcium chloride and liquefied in a trap with liquid air. The first fourth of the chlorine was

---

[4] Brooks and Humphrey, *J. Ind. Eng. Chem.*, **9**, 750 (1917).

distilled away; the next half of the original was distilled slowly into the supply system at low pressure and sealed off for use in the experiments; it was then handled in a manner similar to that described for the ethylene. Analysis showed that the chlorine contained one and eight-tenths mole per cent. of hydrogen chloride as an impurity. As it subsequently appeared that hydrogen chloride had no important effect on the reactions studied, it was not thought worth while to attempt the removal of the hydrogen chloride.

Other substances were introduced to the reaction bulb through Stopcocks 9, 8 and 5. In the case of vapors they were first liquefied in G and subjected to high vacuum before introduction to A. The course of the reaction was followed at constant volume by means of a double manometer system. One leg of a constant level mercury manometer was connected by a 2-mm. capillary tube to the reaction bulb through Stopcocks 1 and 4. During a reaction the two sides of the mercury column of this manometer were maintained at constant level by adjusting the pressure on a second mercury manometer. The probable error in readings in the rapid reactions was not greater than 1 mm., and the readings for the slow reactions were accurate to 0.5 mm. The ratio of volumes of reaction flask and manometer system was approximately 100:3.

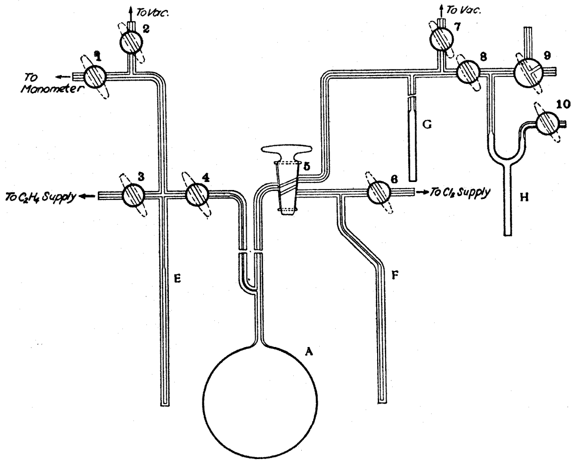

Fig. 1.

Experimental Procedure.—After baking at high temperature under vacuum for several hours, the furnace was removed and replaced by the oil-bath. All light was excluded from A and connections by black coverings. The substance (oxygen, ethylene dichloride, etc.), whose effect was being studied was then introduced through Stopcocks 9, 8 and 5; 5 was then closed and 1 and 4 were opened to determine the pressure of the substance in A. Stopcock 4 was then closed and the manometer system swept out with ethylene, through 3 and 1. Ethylene pressure in E was next built up greater than the pressure in A and 4 opened, the pressure being then increased until the total pressure in the system was equal to the pressure of the substance in A plus the desired pressure of ethylene in A; 4 was then closed and the pressure in the manometer system built up further with ethylene to a few centimeters greater than the expected initial total pressure in A after the introduction of chlorine; 3 was then closed. The desired amount of chlorine from the supply system was liquefied in F at approximately $-30°$. All lights in the room were turned out except the small ruby bulbs on the manometers; 5 was turned to connect F and A and a water-bath placed on F. As soon as the chlorine was evaporated into A, 5 was closed and 4 opened, and the initial total pressure in A noted. Less than a minute elapsed from the time of starting to admit chlorine to **A** to the time of making the first reading. In general an accurate determination of the total initial pressure was obtained; in those cases where the initial reaction rate was rapid, a satisfactory extrapolation to zero time could be made. At the start of the reaction the partial pressure of each substance in the reaction bulb was accurately known. The manometer system contained pure ethylene equal to the total pressure in A and as the reaction progressed some of this expanded into A in amount proportional to the pressure drop. Since the relative volumes of the manometer system and A were known, a correction could be applied for this effect in making rate calculations. Moreover, since this expansion was from the manometer system into the reaction bulb, it served to prevent any substance from leaving the reaction vessel.

The Determination of End-Products.—At the end of the reaction the condensable gases and vapors were frozen out in G or H with liquid air. Any non-condensable gases present were removed through 10. When the pressure in A dropped to zero, 5 was closed and the vapor evacuated through 8 and 9 and through a bubbler containing water. In those experiments where there was an excess of chlorine, potassium iodide was included in the bubbler contents. The iodine was titrated with 0.1 *N* sodium thiosulfate solution and any hydrogen chloride present was determined by titrating with standard sodium hydroxide solution. Ethylene dichloride did not hydrolyze in the time allowed and the amount of hydrogen chloride present did not interfere with the thiosulfate titration. The amounts of the residual gases were expressed in terms of their respective partial pressures.

In most cases there was excess of ethylene at the end of the reaction. The amount of hydrogen chloride formed was a measure of the amount of substitution reaction and. since the initial chlorine was accurately known, it was possible to calculate the amount of addition reaction and hence the amount of ethylene used up. Knowing the amounts of addition product (ethylene dichloride) and substitution product (trichloro-ethane), the volume of the reaction vessel, and assuming Raoult's Law, it was possible to calculate the vapor pressure of the liquid.

The sum of the final hydrogen chloride pressure, the final vapor pressure and the final ethylene or chlorine must be equal to the final pressure observed for the experiment. This was found to be true within a millimeter of mercury pressure in every case.

Experimental Results

When ethylene and chlorine were allowed to react in a darkened glass flask from whose surface all volatile substances had been removed by means of prolonged evacuation at 500°, the following observations were made. There was a short inhibition period. followed by an autocatalytic reaction. The reaction rate became relatively high as soon as the reaction products separated as liquids upon the walls. A high proportion of the reacting chlorine was used up to produce hydrogen chloride, according to the reactions

$$C_2H_4 + Cl_2 \longrightarrow C_2H_4Cl_2 \qquad (I)$$

$$C_2H_4Cl_2 + Cl_2 \longrightarrow C_2H_3Cl_3 + HCl \qquad (II)$$

Reaction II was not independent of Reaction I. Oxygen gas decreased the total reaction rate and tended to eliminate Reaction II.

The Inhibition Period.—In Fig. 2 the pressure of the reacting system is plotted against the time for several typical experiments carried out in the same vessel. Experiment 4–1 was performed before the reaction flask was evacuated at high temperatures and therefore the form of the plot corresponds closely to those of similar plots previously reported.[1] Succeeding experiments gave erratic results, but in each of them there was marked autocatalysis and indication of a true inhibition period. About twenty experiments were carried out before it was felt that the surface conditions were reproducible, the chief difficulty being complete evacuation of the walls.[5]

In no case, in the absence of oxygen, could the reaction be inhibited for more than a few minutes. The plot of Expt. 5–8 (Fig. 2) shows the effect of 3.1 cm. of mercury pressure of oxygen, in which an inhibition period of fifty-five minutes was observed. It is believed that this inability to prolong the inhibition period indefinitely was due to the autocatalytic feature of the reaction. It started in some unbaked portion of the capillary connections and gradually extended to the reaction flask.[6]

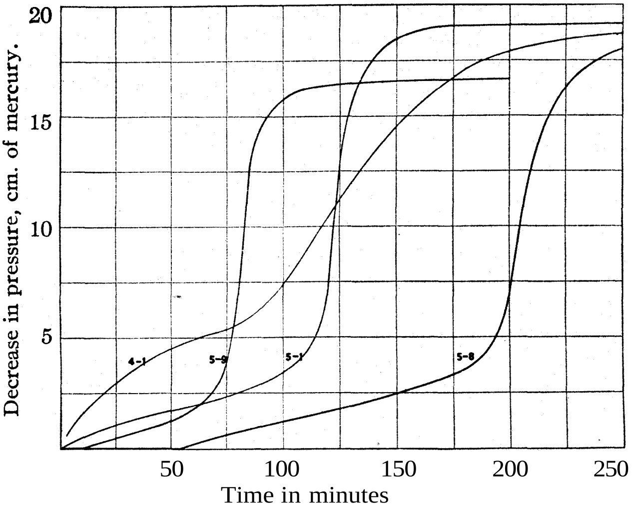

Fig 2.—The effect of surface evacuation and of oxygen upon the catalysis of the reaction between ethylene and chlorine gases. Conditions: Curve 4–1, evacuated at room temperature; Curves 5–1, 5–9, prolonged evacuation at 500°; Curve 5–8, dry oxygen gas introduced after evacuation.

[5] After each experiment the system was evacuated at 100° for an hour; then the temperature was raised to 500° and dry oxygen admitted to burn off any film of carbonaceous matter. The evacuation was then carried to 1×10^{-6} mm. of mercury pressure for several hours before the succeeding experiment. In the earlier experiments there was evidence of incomplete evacuation, since in spite of a very good vacuum before admitting the reactants, some gas which was non-condensable in liquid air appeared after the reaction was over. Eventually this no longer happened.

[6] Nitrogen gas as well as oxygen served to prolong the inhibition period by slowing diffusion in the capillaries. Faulty manipulation of the manometer, causing convection currents in the capillaries, hastened the apparent start of the reaction.

It is important to note that the evacuated surface was not a catalyst for the reaction.

The Substitution Reaction.—As the evacuation of the walls progressed an increasing amount of hydrogen chloride appeared among the reaction products. Under given initial concentrations of reactants, however, this appeared to reach a maximum when about thirty-five to forty mole per cent. of the initial chlorine was used up in the substitution reaction. An attempt was made to increase this amount in two ways, first by introducing ethylene dichloride vapor or liquid as an initial constituent, second, by using a large excess of chlorine over ethylene. The results are presented in Table I, in which the experiment number gives the order in which the experiments were performed although, for the sake of clarity, they are grouped in a different order. The influences of some other factors are also indicated.

A maximum of one-half the reacting chlorine was used in Reaction II, even when excess chlorine remained in contact with the reaction products for a period several times as long as the half period of the reaction itself. This maximum was approached closely only when the vapor phase was initially nearly saturated with ethylene dichloride (6.1 cm. of mercury pressure). Hence in the absence of such vapor, that is, in the initial stages of an experiment such as Expt. 5–7, the reaction was probably largely addition. On the other hand, some substitution took place before the actual separation of liquid. This was shown by a comparison of such plots as appear in Pig. 2, with respect to the magnitude of the observed pressure change at which the reaction became very rapid. When the hydrogen chloride content was high (Expts. 5–7, 5–9) this point corresponded to about three centimeters of mercury, but when it was low (Expts. 4–1, 5–3, 6–1) the pressure change was about five centimeters before the rapid reaction set in. Since the vapor pressures of the ethylene dichloride and trichloro-ethane are, respectively, 6.1 cm. and 1.6 cm. at 20.0°, and since the appearance of a rapid reaction corresponds in time with the separation of liquid, then the compound of low vapor pressure started to form before the gas phase became saturated with ethylene dichloride.

Similarly, Expts. 6–6 and 6–8 suggest that the mere presence of the liquid phase does not ensure the maximum substitution reaction if the ethylene concentration is high and the chlorine concentration low. Experiment ***5–2*** indicates that if both are low in concentration the substitution reaction is inhibited. However, Expt. 6–4, toward its end, duplicated the concentration condition of Expt. 5–2, but with liquid present, and yielded nearly the maximum substitution. There is no doubt that liquid ethylene chloride facilitates the substitution (Reactions I and 11), and that low concentrations of reactants favor addition only.

The presence of trichloro-ethane apparently decreased the chance of the substitution reaction (Expts. 6–11 and 6–9).

Oxygen gas definitely tends to decrease the amount of Reaction II but does not entirely eliminate it on an evacuated surface. It also causes Reaction I to go more slowly, although this effect will be made the subject of a separate paper. A small amount of oxygen is almost as effective as a large amount. Attempts were made to reproduce the original glass surface by exposing it to moist air at 100° for several hours, cooling the system and then evacuating at room temperature. In every instance the freshly adsorbed gas was quickly removed, giving rise to the characteristic substitution reaction. On the other hand, the original surface was difficult to evacuate.

Nitrogen gas and water vapor had no apparent effect upon the induced substitution reaction.

Other investigators[4] report the formation of trichloro-ethane as a side reaction during the addition of ethylene to chlorine. That it was the sole product of substitution in this case is made probable by the facts mentioned above. Further, the total reaction products from several experiments were collected in Bulb G (Fig. 1) by condensation in liquid air and then allowed to evaporate. After the ethylene and hydrogen chloride had volatilized, the remaining liquid was condensed in E (Fig. 1) and its vapor pressure measured at 20.0°. The liquid was then allowed to distil slowly into A and the vapor pressure of the residue measured from time to time. The vapor pressure slowly dropped from 5.8 cm. of mercury to 1.5 cm., at which point about 7% of the original liquid remained, and finally to 1.2 cm. when 2% of the liquid remained. Since the higher chlorinated ethanes have still lower vapor pressures, it is apparent that they were not present in appreciable quantities.[7]

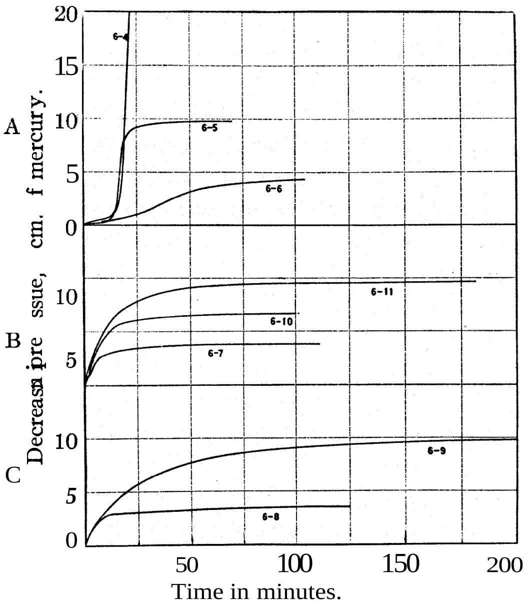

Fig. 3.—Catalysis of the reaction between ethylene and chlorine gases by (A) ethylene dichloride vapor, (B) trichloro-ethane vapor, (C) the mixed liquids.

The Catalyst.—The existence of an inhibition period in the presence of an evacuated surface, with or without oxygen gas, and in the presence of hydrogen chloride, indicated that none of these or any combination of them was a catalyst. Experiments were therefore made with the other products of the reaction, ethylene dichloride and trichloro-ethane, present at the start of the reaction. The results are presented graphically in Fig. 3. In Expts. 6–4, 6–5 and 6–6 ethylene dichloride vapor was used as a possible catalyst (see Table I). In Expts. 6–7, 6–10 and 6–11 pure trichloro-ethane vapor was present at the beginning of the reaction; in Expts. 6–8 and 6–9 the mixed liquids were present.

In each case using the ethylene dichloride vapor, the initial reaction

[7] It was found impossible to separate fully the liquid reaction products by such distillations because of the small amount available. The above measurements indicated the futility of an analysis of the mixture. The total liquid formed and collected could be measured in volume from the known dimensions of the bomb G. It always corresponded within experimental error (5%) to the volume of liquid to be expected from the reactants and hence the carbonaceous film left upon the glass constituted but a minute fraction of the total products.

rate was very low, suggesting in fact a short inhibition period.[8] The autocatalytic part of these reactions could be due either to an approach to saturation of the vapor, with eventual separation of liquid, or to the production of trichloro-ethane, or both. The absence of any suggestion of an inhibition period in those experiments in which trichloro-ethane vapor was initially present indicates definitely that this compound was a catalyst. The above-mentioned curves represent the experimental observations and take no account of the larger pressure changes to be expected, for a given amount of ethylene reacted, after the saturation of the gas phase with vapor. In every case liquid started to separate some time before the maximum reaction rate was reached. This showed that a relatively large amount of liquid was necessary to produce the optimum catalytic conditions, perhaps because it first separated in droplets rather than as a coherent surface film.

In the absence of oxygen, either liquid, or a mixture of them, is a powerful catalyst, but in the presence of oxygen, or upon an unbaked surface, the separation of liquid is not accompanied by a large increase in specific reaction rate (Expts. 4–1 and 5–8, Fig. 2 and Ref. 2).

It may be concluded that upon an evacuated surface the trichloro-ethane vapor is a more powerful catalyst than is the ethylene dichloride vapor; that upon an evacuated surface in the presence of oxygen the addition reaction is catalyzed by the vapors, but less effectively than in its absence; and that upon an unevacuated surface neither vapor is an effective catalyst. The liquids are each effective catalysts but apparently less effective in the presence of oxygen. The order of their catalytic activity in the absence of oxygen is undetermined, but in the presence of oxygen ethylene dichloride is somewhat the better catalyst.[9]

Discussion of Results

The Induced Substitution Reaction.—Since ethylene dichloride is not ordinarily chlorinated under the conditions of time and temperature of the experiments described above, the formation of the trichloro-ethane is brought about as a result of the addition reaction. The course of the reaction and the role of the oxygen may be represented as follows. The starred formulas represent either molecules of sufficiently high energy content to react, as compared to the unstarred molecules of average energy content, or complex compounds with the catalyst. The equilibria indicated by the arrows are arbitrary assumptions.

---

[8] The initial abnormal pressure drop in Expts. 6–6 and 6–7 was possibly due to experimental difficulty. It occurred also in Expt. 5–1 (Fig. 2). If it be significant, it would suggest a rapid reaction involving a small amount of adsorbed ethylene.

[9] The experimental data upon which this conclusion is based are not included in this paper; the difference in the catalytic activity is small (40%), hence it may be presumed that any mixture of the two liquids insures constant catalytic activity.

$$\begin{array}{llll} C_2H_4^* + Cl_2^* & \longrightarrow & C_2H_4Cl_2^* \xrightarrow{Cl_2} C_2H_3Cl_3 + HCl + \text{Heat} \\ \ \ \updownarrows \qquad \ \ \downuparrows & & \\ C_2H_4 \qquad Cl_2 & & C_2H_4Cl_2^* \xrightarrow[\text{Wall}]{O_2} C_2H_4Cl_2 + \text{Heat} \\ & & \\ & & C_2H_4Cl_2^* \xrightarrow{C_2H_3Cl_3} C_2H_4Cl_2 + \text{Heat} \end{array}$$

In the absence of the addition reaction ethylene dichloride molecules do not become activated sufficiently for chlorination.[10]

The fact that the presence of liquid ethylene dichloride, at least in the form of a film, increases the chance of the substitution, suggests the transfer of the activation energy to other molecules of the same kind. In effect the liquid dilutes the various deactivators and prolongs the life of the activated form, but this view requires the assumption of relatively slow dissipation of the activation energy among ethylene dichloride molecules as compared to a thermal equilibrium rapidly established in the presence of oxygen or of trichloro-ethane.[11,12]

In view of the facts regarding the catalysis of the reaction it appears likely that the molecular species represented by the symbols $C_2H_4^*$ and Cl_2^* are in reality complex aggregates of ethylene and chlorine with ethylene dichloride or trichloro-ethane. These aggregates may be within the liquid film or adsorbed upon the glass surface. That the latter concept is important is suggested by the fact that a trace of adsorbed gas within the walls during the early experiments reduced the amount of the substitution reaction, and was itself displaced and appeared in the gas phase at the conclusion of the reaction. These effects could have occurred only if the reaction involved the glass surface. On the other hand, if this were the only reaction area, the separation of liquid should introduce a diffusion factor and decrease the rate of the reaction. Since the presence of a liquid film increased the reaction rate it must be assumed either that there is a rapid homogeneous reaction within the film, or that the liquid surface is a better catalyst or that some other influence increases the reaction rate. These factors will be considered in detail in a separate communication. It is sufficient to note now that when the glass surface with adsorbed water is itself a catalyst (Expt. 4-1, Fig. 2) not only is the amount of substitution reaction diminished but also the catalytic effect of the condensing vapor is lessened. When the surface is not a catalyst, due to evacuation of water from it, oxygen gas reduces both the amount of substitution and the reaction rate, even in the presence of

---

[10] The chlorine used in the substitution may or not require independent activation. Another alternative assumption would utilize the energy of reaction to activate the chlorine to a degree sufficient for the substitution of an unactivated ethylene dichloride molecule.

[12] N. A. Milas, *Proc. Nat. Acad. Sci.*, 14, 844 (1928), presents a case of induced polymerization of styrene and refers to other results of a similar character.

the liquid. It seems probable (1) that the glass surface functions as an adsorbing medium for any catalyst; (2) that the reaction is normally initiated on this surface; *(3)* that the energy liberated by the reaction may be transmitted to a liquid film if the glass is slow to adsorb it; (4) that this energy may induce the substitution reaction; *(5)* that in the absence of light and water[13] the normal liquid phase reaction is very slow; (6) that in the absence of deactivators a liquid-phase addition reaction may be induced by the glass surface reaction; (7) that oxygen is neither a catalyst nor an inhibitor for the addition reaction, but serves very effectively in maintaining equilibrium in the thermal distribution among the molecules, thus preventing induced or chain reactions.[14]

The Specific Reaction Rate.—By assuming that after the separation of the reaction products as liquids the catalytic conditions were constant, the rates of the reaction under different conditions may be compared. The law governing the rate may be expressed

$$-\frac{d(C_2H_4)}{dt} = K'' (C_2H_4)(Cl_2) \qquad (1)$$

In order to evaluate the concentrations of the reactants at any instant from their initial concentrations and from the measured change in pressure, the amount of the substitution reaction taking place and the vapor pressure of the deposited liquid must be known.

Consider first the case that the reaction is simple addition. If a and b are the initial pressures of ethylene and chlorine, respectively, and x the amount, expressed in pressure, of ethylene that has reacted, then

$$\frac{dx}{dt} = K_a'' (a - x)(b - x) \qquad (2)$$

Since the rate-determining step of the substitution reaction is this same reaction, but for each ethylene molecule reacting two chlorine molecules are used up, then for a reaction in which the maximum of substitution occurs the expression becomes

$$\frac{dx}{dt} = K_s'' (a - x)(b - 2x) \qquad (3)$$

The numerical values of K_a'' and K_s'' should be identical under given catalytic conditions. In this paper it is intended to establish only that the above expressions are true within certain limits, namely, in the presence of oxygen to insure Reaction I (addition) as the main reaction and in the presence of excess chlorine (but no oxygen) to insure the maximum of substitution (Reactions I and II). Under these conditions the specific

---

[13] H. S. Davis, THIS JOURNAL, 50, 2769 (1928).

[14] The fact that the reaction takes place only upon the surface (or liquid film) would minimize the importance of radiation as a means of transfer of energy from one molecule to another. Moreover, the reaction as studied in this paper was very susceptible to light from electric globes, which brought about a gas-phase reaction. This effect is under investigation.

reaction rates are the lowest obtained for an evacuated surface. Under other conditions the reaction was faster and the specific reaction rates were not constant during the period of constant catalytic conditions.[15]

Tables II and III present the data as calculated from the experimental observations (see section on Experimental Procedure). In Expt. 6–1 (Table II) the values of K_a'' are not calculated from the beginning because of the separation of liquid during the reaction, with attendant change in the catalytic surface. Also it was impossible to interpret the observed change in pressure in the presence of partial substitution; hence it was assumed that all of this substitution occurred in the early stages of the reaction while the chlorine concentration was high. Similarly in Expt. 6–9 (Table III) the small amount of simple addition was presumed to occur after the chlorine concentration became low.

The agreement of the two specific reaction rates with each other is very good in consideration of the assumption regarding equal catalytic activity

in the two cases. The trend of the constants is quite characteristic. In experiments made under other conditions the trend involved from five to ten times this minimum rate, but in such cases the specific reaction rate constant decreased toward the end of the reaction and approached the same value.

Attempts were made to show that the reaction rate was independent of the concentration of the one or other reactant, but without success.

Diffusion in either the gas phase or liquid film is not an important factor in determining the rate; calculations show that for the fastest reactions about 10^5 molecules strike the surface for each one that reacts.

Summary

Under certain circumstances gaseous ethylene and gaseous chlorine react quantitatively to form ethylene dichloride. Under other circumstances they form only 1,2,2-trichloro-ethane and hydrogen chloride. The specific reaction rates for the two reactions are the same. The

substitution reaction is induced by the addition reaction, the heat of formation of ethylene dichloride being utilized to promote the formation of trichloro-ethane.

In the absence of water and light the reactions are autocatalytic.

Oxygen inhibits the utilization of the reaction energy to promote substitution. Nitrogen and water have little effect in this respect. Oxygen and excess chlorine reduce the specific reaction rate to the same minimum value. It is suggested that besides the induced substitution reaction there is also an induced addition reaction.

[COMMUNICATION NO. 389 FROM THE KODAK RESEARCH LABORATORIES]

THE FRACTIONAL PRECIPITATION OF CELLULOSE ACETATE AND SOME PROPERTIES OF THE FRACTIONS

BY J. G. MCNALLY AND A. P. GODBOUT

RECEIVED MAY 27, 1929 PUBLISHED OCTOBER 5, 1929

Introduction

It is well known that cellulose acetates may be prepared that have widely different physical properties but identical chemical compositions. These differences are commonly ascribed to some difference in state of aggregation or molecular weight of the cellulosic micelles. Several synthetic organophilic colloids—polyvinyl acetate,[1] polyindene,[2] polycinnamalfluorene[3] and polystyrene[2]—have been shown to be mixtures of polymers representing a rather wide range of polymerization of the monomer; it also has been shown that the physical properties of these colloids are intimately connected with the range of sizes of the molecular aggregates present.

The easiest method yet found for fractionating such mixtures is a precipitation process which makes use of the fact that the more highly polymerized components are the first to precipitate from a solution when a precipitating liquid is added. It has been found possible to adapt this method to the case of cellulose acetate and show that a representative material is a mixture of acetates having widely different characteristics.

Materials.—All the experiments reported here were made on a single sample of cellulose acetate prepared by subjecting a dope acetylated triacetate to acid hydrolysis until the product was soluble in acetone. The acetyl number determined by the Eberstadt[4] method was 44.50.

Methods of Fractionation.—Two procedures were used to separate

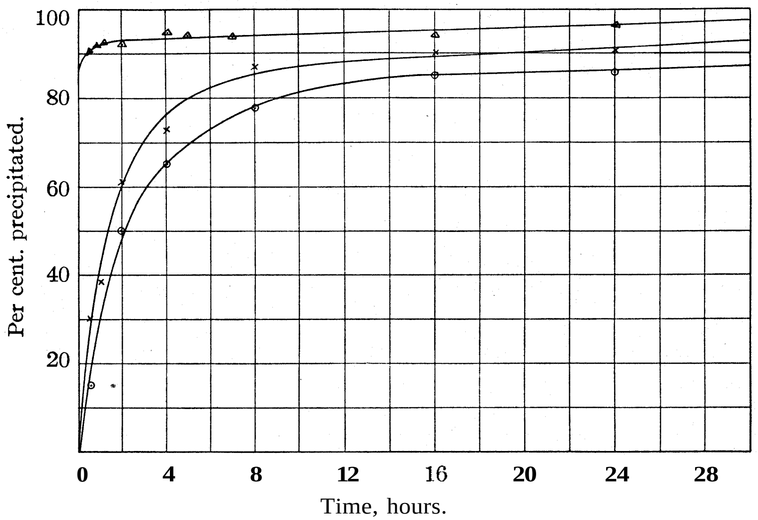
the cellulose acetate into fractions. In Method A a 10% solution of the acetate in acetone was made and either water or a mixture of three parts of water and one of acetone added in insufficient amount to completely precipitate the acetate. It is essential that the formation of large clots of precipitate be avoided if a true fractional precipitation is to be effected. In our experiments the precipitation was carried out in a 250-cc. centrifuge bottle fitted with a rubber stopper provided with holes for the shaft of *a* Cenco stirrer and the tip of a buret. The solution to be fractionated was placed in the bottle and water added slowly through the buret, rapid stirring being maintained during the operation. Near the latter end of the precipitation, it is advantageous to substitute a **3**:1 mixture of water and acetone as the coagulating liquid. The precipitated acetate was separated by centrifuging and more precipitant added to the liquid. In this manner a series of fractions was obtained that differed in their solubility in acetone–water mixture.



⊙, **34%** water; ×, 36% water; △, **45%** water.

Fig. 1.

On attempting to repeat quantitatively the fractionation outlined above, it was found that the amount of acetate that could be separated on centrifuging under standard conditions depended very much on how long the solution was allowed to stand after the precipitant had been added.

Fig. 1 shows the percentage of acetate separated by centrifuging partially precipitated solutions that had been allowed to stand for different periods of time after the addition of 34, 36 and 45% of water to a 10% solution of the acetate in acetone. A convenient method of fractionation consists, then, in adding a suitable amount of water to the acetone solution of cellulose acetate and collecting the precipitates that form after various lengths of time. This will be called Method B. By controlling the length of time the solution stands before centrifuging, Method A could he quantitatively repeated. Fig. 2 shows the percentage of cellulose acetate precipitated by various water concentrations after standing for thirty minutes. The water concentration is given as percentage by volume of the total amount of liquid.

Changes in the Properties of Cellulose Acetate Caused by Precipitation, Drying and Re-solution.—De Mosenthal[5] found that the viscosity of cellulose nitrate was *decreased* by repeated precipitation and re-solution while McBain[6] states that cellulose nitrate recovered from solution either by evaporation or precipitation is more insoluble and gives solutions of *higher* viscosity than the original material. No similar experiments appear to be on record for cellulose acetate, but if any difference in the properties of fractions collected by either Method A or B is to be attributed to the heterogeneity of the original material, it should first be shown that the treatment involved in the precipitation process does not appreciably alter the characteristics of the acetate. To obtain data on this point, 500 g. of a 10% acetate solution in acetone were precipitated by thoroughly mixing with 2 liters of distilled water. The precipitate was dried to a constant weight at 105° and a 5-g. sample set aside. The remainder was redissolved and the procedure repeated until all of the acetate was used up. In Table I the acetyl numbers and viscosities of 4% acetone solutions are given. Sample A was precipitated once, B twice, etc. Viscosity measurements were made at 25° with an Ostwald viscometer. The samples did not give sharp melting points but they all showed the same behavior on heating, softening at 255–260° and decomposing at 260–265°.

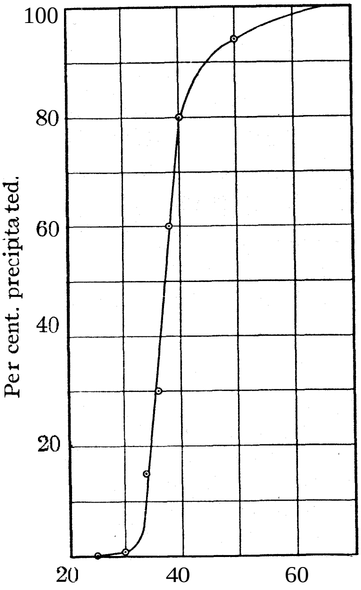


Fig. 2.

These experiments indicate that not much change is produced by repeatedly precipitating cellulose acetate. An increase in viscosity of **13%** showed after nine precipitations. It will be noted from the table that a small part of the acetate was lost during each precipitation. This portion

I	5	4.6	92.0	7.72	40.45

remained suspended in the water as a finely divided suspensoid and the increase in viscosity may be reasonably attributed to the loss of this probably less highly polymerized fraction rather than to any change in the remaining fraction. It will be noted that in Fraction F, where this suspended material was collected by filtration, only a very slight increase in viscosity was noted over the preceding sample.

Melting Points, Acetyl Numbers and Viscosities of the Fractions.—Typical results obtained by both methods of fractionation will now be given.

Method A.—Seventy grams of cellulose acetate was dissolved in 630 g. of acetone and 250 cc. of water and 250 cc. of 3:1 water–acetone mixture was added. The precipitate collected was labeled Fraction A. One hundred and twenty-five cc. of the 3:1 mixture was added to the filtrate and Fraction B separated. Fraction C was obtained on the addition of 120 cc. of water to the filtrate from B. On distilling off the acetone from the filtrate from C, Fraction D was obtained.

Fraction A contained the bulk of the precipitate. About 80% of this material was dissolved in 500 cc. of acetone, and 153 cc. of water and 180 cc. of 3:1 mixture were added to give Fraction A-1. This filtrate was mixed with 25 cc. of 3:1 mixture and Fraction A-2 precipitated. The addition of 170 cc. of 3:1 mixture to this filtrate gave A-3, and A-4 appeared on distilling off the acetone from the filtrate from A-3.

Fraction A-1 was then refractionated as follows. The precipitate was dissolved in 300 cc. of acetone and 110 cc. of water added. The resulting precipitate was marked A-1-a. The addition of 25 cc. of water and 100 cc. of 3:1 mixture precipitated A-1-b; 150 cc. of water added to this filtrate gave A-1-c. A-1-d was obtained by distilling the acetone from the filtrate of A-1-c.

The melting points, acetyl numbers and viscosities of these fractions are given in Table II, with their weights and the composition of the liquid from which they precipitated.

Method B.—Thirty-six per cent. of water was added to a 10% solution of cellulose acetate in acetone and the precipitate separated after the mixture had been standing for thirty minutes at room temperature. The filtrate was then set aside and allowed to stand for four hours, when it was again centrifuged and a fraction obtained. Two other fractions were obtained in like manner and the data for all of them are given in Table III.

Specific Rotation.[7]—The optical rotary powers of Fractions A, B, C and D were determined by using the green mercury line (546 mμ) in a 20-cm. tube. The solvent was a mixture of 85 parts of chloroform and 15 of alcohol by volume. At a concentration of 1% the observed α for each of the fractions was —0.34" and $[\alpha]_{546}^{20} = -17°$.

The data in the two preceding tables make it clear that the original sample of cellulose acetate was a mixture of a large number of components with widely different physical constants. The acetyl numbers of all of the fractions remained sensibly constant, indicating that an explanation of the difference in properties is not to be found in a difference in the degree of acetylation of the components. This conclusion receives further support in the constancy of the specific rotation. The changes in melting point, viscosity and solubility of fractions of the same chemical constitution all point to the conclusion that the original cellulose acetate contains a series of micelles differing either in the number of elementary glucose anhydride units they contain or in the manner in which they are joined together to form the micelle. In this respect cellulose acetate resembles the synthetic organophilic colloids already mentioned.

Solubility of Cellulose Acetate Fractions in Organic Liquids.—Cellulose acetate fractions that were separated by a procedure that made use of

---

[7] We are indebted to Mr. Murray of the Organic Research Laboratory for these measurements of optical rotation.

their different solubilities in acetone–water mixtures might well be expected to show different solubility relationships in other solvents. Such was found to be the case. The fractions used in these solubility tests were prepared by Method B. The concentration of water was 36%. Fraction A was collected after standing for twenty minutes and contained 29.7% of the original acetate; B, three hours, 17.85%; C, twenty hours, 28.5%. D was obtained by adding a large volume of water to the filtrate of C and amounted to 19.3% of the original.

Solubility was estimated by placing about 0.1 g. of the sample in a test-tube and adding 20 cc. of the liquid in question. The test-tube was stoppered and placed on a tumbling machine for twenty-four hours. The appearance of the samples was noted at frequent intervals during this time and final notations were made three days later.

The data obtained in these tests are compiled in Table IV, these observations representing the final condition of the acetate.

					Tetrachloro-ethylene	1	2	2	2

[a] The meanings of the symbols are as follows: 0, insoluble, that is, no apparent change; 1, slightly swollen; 2, highly swollen—almost solated; 3, turbid solution; 4, blue opalescent solution; 5, clear solution.

It appears on examination of the above data that the fractions of cellulose acetate that precipitate first from an acetone–water mixture are more insoluble in solvents in general than are those which precipitate later. It will be remembered that the observations recorded in the table were made after the cellulose acetate had been in contact with the solvent for three days and, therefore, indicate an equilibrium state of affairs with no description of the rate at which this equilibrium was reached. In every case where all the fractions ultimately dissolved, the rate of solution was invariably in the order D:C:B:A. Thus, with methyl acetate, the D fraction dissolved in eight minutes, C in twenty minutes, B in one hour and **A** in three hours.

All the fractions show a greater tendency to swell and dissolve in the lower member of an homologous series. If the most prominent atomic grouping in the cellulose acetate molecule is taken, as $\mathrm{H{-}\overset{|}{\underset{|}{C}}{-}O{-}CO{-}CH_3}$, it may be said in a broad sense that cellulose acetate tends to swell and dissolve in those liquids that resemble it most closely in chemical structure. This is in general agreement with the views of Sheppard[8] and Whitby.[9]

Summary

1. A sample of a commercial acetone-soluble cellulose acetate has been fractionally precipitated. The fractions have the same chemical composition but different physical properties; this has been attributed to a difference in the state of aggregation of the glucose anhydride units in the micelles.
2. The solubility of cellulose acetate in organic liquids has been shown to be a function of its state of aggregation as well as its acetyl content.

THE REDUCTION POTENTIALS OF VARIOUS PHENANTHRENEQUINONES

BY LOUIS FREDERICK FIESER

RECEIVED MAY 31, 1929 PUBLISHED OCTOBER 5, 1929

The problem of correlating the structures of the quinones with their reduction potentials divides itself naturally into two distinct parts: a comparison of the potentials of the parent quinones which are derived from the various aromatic hydrocarbons and heterocycles, and a study of the manner in which substituent groups influence the oxidizing power of a given substance. The results of the present electrochemical study of a number of quinones of the phenanthrene series thus fall into two groups and each of these may be considered in the light of one or the other of the two aspects of the general problem.

1. Isophenanthrenequinones.—While all of the homonuclear quinones of benzene, naphthalene and anthracene have been investigated by the electrochemical method, and while rational interpretations have been found for the values of the reduction potentials of these substances, only one of the four possible homonuclear phenanthrenequinones, the 9,10-derivative, has been studied and no adequate account of the potential of this compound has been given. With the object of completing the data for this series, and with the hope that an explanation of the potential of 9,10-phenanthrenequinone might be suggested by a knowledge of the values for the isomeric quinones, 1,2-, 1,4 and 3,4-phenanthrenequinone and a few of their substitution products have been prepared[1] and the normal reduction potentials have been determined by standard methods.

The results are summarized in Table I. The normal potential, E_0, was determined by the electrometric titration of a solution of either the oxidant or the reductant, as indicated by the nature of the titrating reagent. This potential is equal to the e.m.f. of the cell Pt | Solvent, Oxidant, Reductant || Solvent, H_2 | Pt, at the point of half-reduction or half-oxidation. Under ΔE_1 and ΔE_2 are given the average differences between E_0 and the potential at 20% and at 80% reduction or oxidation. The theoretical value is 17.8 mv. The two unsubstituted ortho-quinones, Nos. 1 and 3, are destroyed by an acidic solution too rapidly to permit the preparation and titration of a solution of the oxidant, but the reductant could be titrated so rapidly that the decomposition of the quinone involved an error which was estimated to be less than 3 mv.

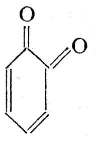
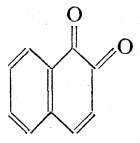
[1] (a) Fieser, THIS JOURNAL, 51, 940 (1929); (b) 51, 1896 (1929); (c) 51, 1935 (1929); (d) 51, 2460 (1929); (e) 51, 2471 (1929).

Examination of the table will show that the relationships between the ortho- and para-isophenanthrenequinones and between the substituted and unsubstituted members of the series are much the same as those found with the corresponding naphtho- and anthraquinones, though there are some deviations for which it is not easy to account. Thus the'two ortho quinones, Nos. 1 and 3, differ considerably in potential, though their sulfonated derivatives, Nos. 2 and 4, are quite similar. From the fact that 3,4-phenanthrenequinone differs in potential from its sulfonate and from 1,4-phenanthrenequinone by normal increments, while the corresponding differences for 1,2-phenanthrenequinone are smaller than would be anticipated, it may be argued that it is 1,2-phenanthrenequinone which exhibits a somewhat abnormal character.

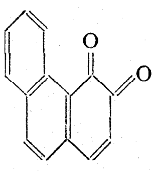
With this minor irregularity, the isophenanthrenequinones form a distinct group, and it is important to establish the exact relationship between this and other series of quinones. A comparison of the normal reduction potentials of the ortho quinones I-V will show that there is little similarity between the two phenanthrene derivatives III and IV or between the isophenanthrenequinone, III, and the isoanthraquinone, V. The difference between 3,4- and 9,10-phenanthrenequinone is not surprising in view of the fact that the former has a terminal quinonoid nucleus while in the latter the quinone grouping is flanked by benzene rings. That 1,2-anthraquinone has a peculiarly low potential has been attributed[4] to a unique structure of anthracene, and the present results furnish no indication that this interpretation should be altered.



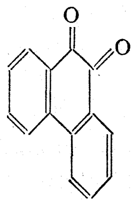
$E_0 = 0.783$[2]
I



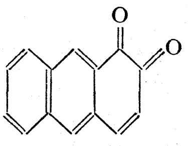
$E_0 = 0.579$[2]
II



$E_0 = 0.615$
III



$E_0 = 0.458$[3]
IV



$E_0 = 0.490$[4]
V

It will be observed that the potential of 3,4-phenanthrenequinone is of the same order of magnitude as that of β-naphthoquinone, and this suggests that the isophenanthrenequinones should be considered in comparison with the corresponding naphthoquinones. Such a comparison,' given in Table II, indicates that the isophenanthrenequinones are higher in potential than the naphthoquinones by a fairly regular increment. The chief structural difference between the two series, or between the quinones II

Average difference, 48 mv.					

[a] The two figures give the differences observed in solvents **A** and B, respectively.

[b] The first figure refers to the 2-derivative, the second to the 3-substituted isomer.

and III, is that in the tricyclic compounds a naphthylene, rather than a phenylene, group is attached to the quinonoid nucleus. The presence of the phenylene group is responsible for a decrease in the reduction potential of o-benzoquinone amounting to 204 mv. (compare I and 11), an effect which has been attributed to the stabilization of the benzoquinone by the incorporation of one of the otherwise reactive quinonoid ethylene linkages in an aromatic ring.[2] In the same way 3,4-phenanthrenequinone may be regarded as o-benzoquinone with a fused-on naphthylene group, and this group may be said to produce a decrease in the potential of 168 mv. (compare I and III). That the effect is less than for the phenylene group is entirely consistent with the fact that naphthalene is a more reactive hydrocarbon, that it is less ‹'aromatic," than benzene.

That a reasonable interpretation of the potentials of the isophenanthrenequinones is thus found in comparing these compounds with the naphtho- and benzoquinones, is of assistance in seeking an explanation of the potential of 9,10-phenanthrenequinone. The value is abnormally high, that is, it is 83 mv. higher than one would be led to expect from the relationship between quinones I and II. This means either that 9,10-phenanthrenequinone possesses an added reactivity or that its hydroquinone is abnormally inert. Since 1,2-, 1,4- and 3,4-dihydroxyphenanthrene appear to be quite normal, it is highly probable that this is also true of the 9,10-derivative and hence that an account of the observed deviation is to be sought in the structure of 9,10-phenanthrenequinone.

Two explanations of the peculiarly great oxidizing power of 9,10-phenanthrenequinone suggest themselves. The molecule appears to be in a condition of some strain and it is possible that this strain is the result of a configuration in which the two benzene rings are coplanar but not co-axial, the nuclei being spread apart by the carbonyl groups on one side of the diphenyl linkage. It is also possible, and perhaps somewhat more probable, that the two benzene rings are co-axial but not coplanar, that is, that, owing to the normal spatial requirements of the carbonyl groups, the diphenyl skeleton suffers a distortion or twisting which produces a strain within the molecule. It may be possible to distinguish between these two hypotheses, for according to the latter suggestion a monosubstituted phenanthrenequinone should have an asymmetrical configuration.

2. **Substituted 9,10-Phenanthrenequinones.**—Table III summarizes the results of a study of a number of compounds of the type indicated.

The quinones which have been described by other investigators were prepared according to the methods indicated in the references and purified until they corresponded in properties to the best samples known. The electrometric titration curve often reveals the presence of an impurity, and in one case, that of 4-hydroxyphenanthrenequinone, the sample appeared to be somewhat contaminated and the results may be somewhat in error for this reason.

An explanation must be given of the considerations which determined the choice of solvent and the method of measurement employed. The most convenient means of determining the reduction potential of a quinone in an acidic solution consists in the electrometric titration of the oxidant with titanous chloride, but this reagent often forms complex compounds

[19] Phenanthrene-3-carboxylic acid (ref. 18) was converted by the action of methyl iodide on the silver salt into the methyl ester: colorless plates, m. p. 97°. Calcd. for $C_{16}H_{12}O_2$: C, 81.33; H, 5.12. Found: C, 81.00; H, 5.10. This was oxidized at 70° in the usual manner and the quinone was crystallized from glacial acetic acid, giving orange-yellow needles, m. p. 212°. Calcd. for $C_{16}H_{10}O_4$: C, 72.17; H, 3.79. Found: C, 71.86; H, 3.94.

[20] A solution of phenylmagnesium bromide was slowly added to a stirred and well-cooled solution of 3-phenanthroyl chloride (distilled and crystallized from ligroin, m. p. 118°) in benzene. The benzoyl-3-phenanthrene which resulted was not obtained in a pure condition, for the reaction product was an oil which failed to solidify. Oxidation of this oil with chromic acid in glacial acetic acid solution yielded an orange oil from which 3-benzoylphenanthrenequinone was obtained easily by crystallization from glacial acetic acid. The quinone forms golden-yellow plates melting at 205–206°. The substance is not easily burned. Analyses in a copper oxide tube, even with the use of the Dennstedt contact star, gave low values for carbon. The difficulty was overcome completely by the use of a combustion tube packed with small lumps of fused lead chromate, and by heating the tube to a full red glow. Calcd. for $C_{21}H_{14}O_3$: C, 80.75; H, 3.87. Found: C, 80.59; H, 4.04. This procedure, which was suggested by an observation of Bamberger and Hooker, *Ann.,* **229,** 118 (1885), has been of great service in the analysis of certain other substances which could not be burned completely either by the platinum star method or with the use of cuprous chloride according to Haas, *J. Chem. Soc.,* **89,** 570 (1906).

[21] Dimroth and Roos, *Ann.,* **456,** 177 (1927). The author wishes to thank Professor Dimroth for kindly furnishing him with a sample of this substance.

with substances having ortho hydroxyl groups or with o-hydroxyquinones. For this reason it seemed expedient in many cases to prepare a solution of the reductant by catalytic hydrogenation and to titrate with an organic oxidizing agent such as benzoquinone. It was found that nitrophenanthrenequinones can be reduced to the hydroquinones by titanous chloride in acid solution without reduction of the nitro group; a sharp inflection of the titration curve occurred at a point corresponding to just two equivalents of reducing agent. There were indications that the nitrohydroquinones slowly undergo a disproportionation after the end-point has been reached, but this does not affect the results of the titration.

The solvent most generally employed was a 50% alcoholic hydrochloric acid solution containing lithium chloride to increase the sensitivity of the readings; in some cases a higher concentration of alcohol was required to bring the quinone into solution. It has appeared to the author advisable to compare the potentials of the various quinones under conditions which permit of no dissociation of moderately acidic or basic groups of either the oxidant or the reductant. For this reason, in studying the aminophenanthrenequinones, a solvent ("C") was selected which is probably about neutral and in which the amino group doubtless is undissociated. In one case (No. 28) results in an acidic solution are also included, though they are of little value for the purpose of relating potential and structure.

In the case of the acetoxy-, the di- and triacetoxyphenanthrenequinones, a number of which were studied, it was found that a group in the 1-position interfered with the attainment of electrode equilibrium and the results were not satisfactory. Hydroxyl and sulfonate groups in this position exhibited no such influence, but with 1-methylphenanthrenequinone a constant potential was reached only very slowly.

Considerable information is available from previous work concerning the effect of substituents in a quinonoid nucleus on the potential of a quinone, but little is known regarding substitutions at points more distant from the quinone grouping except that the effect is considerably less. The phenanthrenequinones afford a particularly favorable series in which to study such substitutions because the number of possible isomers is great and because the potential of the parent quinone is subject to considerable change as the result of substitution. Thus the potential range of the quinones here studied is from 0.281 to 0.590 v.

The most striking and novel feature of the results given in Table III is the pronounced influence of the position of a substituent on the potential. A hydroxyl group in the 1-position causes a decided drop in the potential of phenanthrenequinone, the effect is negligible in the 2-substituted isomer, a considerable lowering is produced by substitution in the 3-position and 4-hydroxyphenanthrenequinone has the same potential as the parent compound. This seems rather surprising until it is considered that the 1- and

3-positions are ortho and para, respectively, to one of the quinonoid carbonyl groups, while the 2- and 4- are meta positions. It is not odd that the effect of the hydroxyl group in the ortho and para positions, or in the two meta positions, is about the same. This regularity is not confined to the hydroxyl group or, indeed, to groups which cause a lowering in the potential. Table IV shows that a para amino group lowers the potential considerably more than does a meta-(2) group or a meta-(4) group. A para nitro group produces a greater increase in the potential than does a nitro group in either of the meta positions.

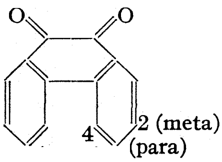

TABLE IV

THE INFLUENCE OF THE POSITION OF THE SUBSTITUENT

Effect in millivolts on the potential of substituting a group in the positions

Substituent	Ortho-Para 1	Ortho-Para 3	Meta 2	Meta 4
OH	**−50**	−53	− 1	0
NH2	. .	−98	−17	−28
NO_2	. .	+91	+69	+57
SO_3H	+21	+30	+24	. .

In the case of the sulfonic acid group the influence on the potential is so slight that the effect of the position of the substituent may well be masked. There is sufficient evidence to warrant the generalization that the effect on the potential of a substituent in the ortho (1) and para (3) positions is about the same, and that it is greater than the effect of a group in either meta position (2 or 4). This conclusion harmonizes well with the known facts concerning the directive influence of substituents in the benzene ring.

The next point of interest is to compare the effects produced by the different kinds of substituent groups. In view of the above generalization, the most favorable series for such a study is that of the 1- or 3-substituted phenanthrenequinones, and one is justified in comparing a 1-derivative with a 3-derivative. This has been done in constructing Table V, though the results for both positions are included wherever available. The figures represent the differences in the potentials of the substituted and unsubstituted quinones in the same solvent. In a few instances two such comparisons are possible for a single substituent.

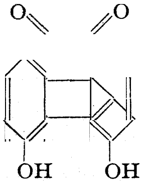
COC_6H_5	+59	SO_3H	+23, 30	CH_3	−64
$COOCH_3$	+58	$OCOCH_3$	+ 9	NH_2	−98

From the results given in the table it will be seen that all of the unsaturated substituent groups cause an increase in the potential of phenanthrenequinone. The nitro group is the most effective, the sulfonic acid group is the least so and the cyano, ketone and carboxylate groups occupy intermediate positions. Methoxyl, hydroxyl, methyl and amino groups all lower the potential of the parent quinone. The effect of an hydroxyl group is eliminated, and to a slight extent reversed, by acetylation. In general, an ortho-para directing group lowers the potential and a meta directing group causes an increase, though the bromine atom constitutes an exception to this rule, for the substitution of hydrogen by bromine results in an appreciable increase in the potential. Aside from this exception, and aside from the fact that the effect of a methyl group appears to be surprisingly pronounced, the order here indicated for the various substituents is much the same as that found by other methods of comparison. The exact theoretical significance of the present results is not yet completely clear, for there are certain complicating aspects of the whole question of the effect of substituent groups on the potential. Thus, for example, it is not easy to decide whether the substituent alters the nature of the oxidant, of the reductant or of both components of the reversible system. Experiments designed to settle this and other points are now in progress and a more thorough consideration of the above comparison of groups will be reserved until this work is completed.

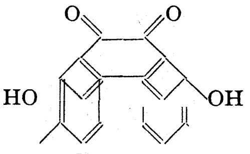
The potentials of the polysubstituted phenanthrenequinones would present a perplexing problem if one had no knowledge of the difference between the ortho-para and the meta types of substitution. Thus 3,6-dihydroxyphenanthrenequinone, VI, and the 2,7-isomer, VII, differ in potential by 104 mv., but this difference is understandable when it is observed that in one case each hydroxyl group is para to a quinonoid carbonyl group while in the other compound both hydroxyls are in meta positions. Furthermore, the difference in potential between 3,6-dihydroxyphenanthrenequinone and 3(or 6)-hydroxyphenanthrenequinone is nearly the same as that between the mono-substituted derivative and phenanthrenequinone. In other words, the effect of the second substituent is approximately equal to that of the first. In order to determine whether this is generally true, a comparison is given in Table VI of the observed total effect of two or

.VI



$E_0 = 0.344$

VII



$E_0 = 0.448$

more substituents with the effect calculated on the assumption that the influence of each group is the same as in a mono-substitution product.

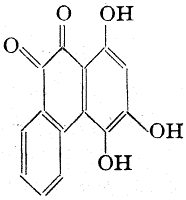
TABLE VI

THE EFFECT OF POLY-SUBSTITUTION

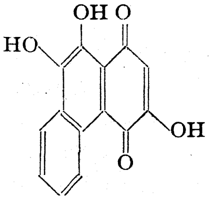
Substituents	Positions of substituents	Effect of substituents on the potential, mv. Found	Calcd.	Diff.
1,2-$(OH)_2$	*o, m*	−78	−51	−17
1,4-$(OH)_2$	*o, m*	−79	−50	−19
3,4-$(OH)_2$	*p, m*	−73	−53	−20
2,6-$(OH)_2$	*m, p*	−57	−53	−4
2,7-$(OH)_2$	*m, m*	−23	−2	−21
3,6-$(OH)_2$	*p, p*	−127	−106	−21
3,6-$(OCH_3)_2$	*p, p*	−84	−74	−10
2,5-$(NO_2)_2$	*m, m*	+98	+126	−27
2,7-$(NO_2)_2$	*m, m*	+119	+138	−19
1,2,4-$(OH)_3$	*o, m, m*	−118	−51	−68
1,3,4-$(OH)_3$	*o, p, m*	−177	−103	−74

It will be observed that with the disubstituted phenanthrenequinones the calculated value is in every case slightly more positive than the value found. The difference is remarkably constant, the average being 18 mv., and this is true regardless of whether the substituents raise or lower the potential and of whether they are situated in the same or in different rings. It appears that the effect of a second substituent is greater by about 18 mv. than that of the first; if the potential is increased (or decreased) by a single substitution, it is increased (or decreased) to a slightly greater extent by a second such substitution, regardless of the positions. From the results with the two tri-substituted quinones it may be concluded that the potential lowering produced by three hydroxyls is greater than that expected from the known effect of each separate group by about 72 mv. The influence of a substituent thus becomes progressively greater as substitution proceeds.

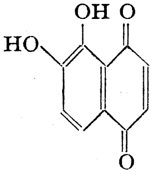
One further question of interest in connection with the present results is that of the possible tautomerism of certain of the hydroxyphenanthrenequinones. It is conceivable, for example, that 1,3,4-trihydroxyphenanthrenequinone, VIII, as the result of a tautomeric change, exists largely in



VIII



IX



X

the form of the para quinone, IX. There is some chemical evidence in support of Structure VIII,[1c] and it is of interest to inquire if this conclusion is in accord with such electrochemical evidence as is available, The reduction potential of the quinone is 0.281 v., a value which appears to be consistent with Structure VIII, though it does not necessarily confirm this structure. One can arrive at a prediction concerning the potential of a quinone having the structure of IX by considering that it is derived from 5,6-dihydroxy-1,4-naphthoquinone, X, by the attachment of a phenylene and an hydroxyl group. Thus: potential of IX = 0.427 v. (5,6-dihydroxy-1,4-naphthoquinone) + [0.396 v. (3-hydroxy-1,4-phenanthrenequinone) − 0.356 v. (3-hydroxy-1,4-naphthoquinone)] − [0.523 v. (1,4-phenanthrenequinone) − 0.396 v. (3-hydroxy-1,4-phenanthrenequinone)] = 0.340 v. This calculation gives a result which is much higher than the potential found for the compound. According to the theory that an hydroxyquinone should exist in that tautomeric form having the lowest possible reduction potential,[22] this means that the quinone in question does not have the structure of IX, a conclusion which is consistent with the other evidence. Similar reasoning supports the 9,10-phenanthrenequinone structure for all of the hydroxy quinones studied.

Summary

The normal reduction potentials at 25° of 43 phenanthrenequinones have been determined and an analysis of the data has led to the following conclusions: (1) an isophenanthrenequinone, such as 1,4-phenanthrenequinone, has a somewhat higher potential than the corresponding naphthoquinone; the difference results from the substituting of a naphthylene group for the less reactive phenylene group. (2) The abnormally high potential of 9,10-phenanthrenequinone is due to a strain resulting from some peculiar spatial arrangement of the molecule. (3) Among the substituted 9,10-phenanthrenequinones, a group has the same effect on the potential when it is ortho or para to a quinonoid carbonyl group and the effect is much greater than when the substituent occupies either of the meta positions. A second substituent has a somewhat greater influence than the first. The potential is increased by the substitution of nitro, cyano, ketone, carboxyl, bromo and sulfonate groups; it is decreased by amino, alkyl, hydroxyl and methoxyl groups.

THE PREPARATION OF TRIPHENYL LEAD CHLORIDE AND DIPHENYL LEAD DICHLORIDE

BY HENRY GILMAN AND JACK D. ROBINSON

RECEIVED JUNE 1, 1929 PUBLISHED OCTOBER 5, 1929

Introduction

In connection with studies on organolead compounds a need was felt for a satisfactory method for the preparation of triaryl lead chlorides and diaryl lead dichlorides. We selected the chlorides in preference to the other halides for three reasons: first, the chlorides are more stable than the bromides and iodides; second, they are less expensive than the other halides, assuming that all of them can be prepared in approximately equal yields; and, third, there is no essential difference in reactivity between the several halides in our particular studies.

Triphenyl lead halide, $(C_6H_5)_3PbX$, and diphenyl lead dihalide, $(C_6H_5)_2PbX_2$, have generally been prepared from tetraphenyl lead, $(C_6H_5)_4Pb$, which is obtainable in satisfactory yield from the reaction between lead chloride and phenylmagnesium bromide.[1] Triphenyl lead bromide has been prepared in excellent yields by Grüttner[2] from tetraphenyl lead and the bromine addition compound of pyridine, at low temperatures obtained with solid carbon dioxide. Objections to this method are the expense of pyridine and the inconvenience of using solid carbon dioxide. Krause and Reissaus[3] prepared triphenyl lead iodide by adding a dilute solution of iodine to triphenyl lead. Krause and Pohland[4] prepared triphenyl lead fluoride by double decomposition of potassium fluoride with triphenyl lead bromide, and Krause and Schlottig[5] prepared triphenyl lead chloride by treating phenylmagnesium bromide with a slight excess of lead chloride. They also observed that triphenyl lead chloride could be obtained in 75% yield by heating tetraphenyl lead with four equivalents of ammonium chloride at 170–180° for twelve hours. This method, however, only gives satisfactory yields with small quantities of compound and is valueless with mixed aryl lead chlorides because of their thermal instability. The method most generally used has been that of Grüttner.[2]

The first diphenyl lead dihalide was prepared by Polis,[6] who obtained diphenyl lead di-iodide from a chloroform solution of tetraphenyl lead and iodine. Later[7] he prepared the corresponding bromide and chloride

in like manner using bromine and chlorine. Werner and Pfeiffer[8] incidentally obtained some diphenyl lead dichloride in searching for an addition compound of tetraphenyl lead and hydrogen chloride. Goddard, Ashley and Evans[9] obtained the dichloride from a reaction between tetraphenyl lead and a miscellany of inorganic chlorides. The method most generally used has been that of Polis.[6,7]

The methods described at this time involve the following reactions

$$(C_6H_5)_4Pb + HCl \longrightarrow (C_6H_5)_3PbCl + C_6H_6 \qquad (I)$$

$$(C_6H_5)_3PbCl + HCl \longrightarrow (C_6H_5)_2PbCl_2 + C_6H_6 \qquad (II)$$

These reactions are in agreement with Werner and Pfeiffer's[8] observations that hydrogen chloride reacts with tetraphenyl lead in a dry chloroform solution. Polis,[6] on the other hand, reported that concentrated hydrochloric acid does not react with tetraphenyl lead until heated in a tube at 230°, and then lead chloride results.

In our preparation of triphenyl lead chloride, the hydrogen chloride was bubbled into a warm chloroform solution of tetraphenyl lead until crystals of diphenyl lead dichloride formed. The formation of this insoluble dichloride is an excellent end-point, and the yields are distinctly satisfactory (about 75%). The diphenyl lead dichloride was prepared in practically quantitative yields by merely saturating a benzene solution of tetraphenyl lead with hydrogen chloride.

The high yields of the monochloride and of the dichloride make it possible to prepare the corresponding other halides in either of two ways. First, the following metathetical reactions can be used

$$R_3PbX + NaX' \longrightarrow R_3PbX' + NaX \qquad (III)$$

$$R_2PbX_2 + 2NaX' \longrightarrow R_2PbX_2' + 2NaX \qquad (IV)$$

These reactions are readily carried out in dilute alcoholic solutions.[2,4,10] A second indirect method, and the one which is generally recommended, involves the following reactions[11]

$$R_3PbX + NaOH \longrightarrow R_3PbOH + NaX \qquad (V)$$

$$R_3PbOH + HX' \longrightarrow R_3PbX' + H_2O \qquad (VI)$$

The unusual smoothness of the reactions described at this time has recommended them not only for synthetic purposes (for the preparation of aryl lead halides in general) but also for studies in progress on the relative electronegativities of organic radicals.

[11] It is probable that the bromides can be prepared in equally good yields after the methods described here for the preparation of the chlorides, that is, from tetraphenyl lead and hydrogen bromide. The hydrogen chloride method also gives excellent yields of the tin mono- and dichlorides. Also, alkyl lead mono- and dichlorides can be prepared in the same high yields as the corresponding aryl halides.

Experimental Part

The following directions are typical of a series of experiments carried out by us.

Triphenyl Lead Chloride.—20.2 g. (0.04 mole) of tetraphenyl lead is dissolved in 300 cc. of boiling chloroform and hydrogen chloride is then bubbled through the solution, which is kept near its boiling point (or it may be refluxed gently) by the application of heat. After about fifteen minutes (depending on the rate of flow of gas) a precipitate of shiny plates of diphenyl lead dichloride starts to form and the stream of gas is quickly shut off. This precipitate resembles greatly a precipitate of mercurous chloride, and is not to be confused with a flocculent precipitate that may form if the tetraphenyl lead is impure or if the gas is introduced very rapidly. The flocculent precipitate need not be removed if it forms, inasmuch as the precipitate of diphenyl lead dichloride is very readily recognized even in the presence of the flocks. After the entry of hydrogen chloride has been terminated, the solution is boiled to complete the reaction with any dissolved hydrogen chloride and the solution is then filtered. The quantity of diphenyl lead dichloride obtained by this filtration is 1.5–2.0%.

The chloroform is removed from the clear solution by distillation from a water-bath. The residue when extracted with two 200-cc. portions of hot alcohol leaves the unaltered tetraphenyl lead (about 20%). The alcohol extract yields the pure triphenyl lead chloride (about 75% yield). Approximately the same ratio of products was obtained from a run starting with 56.7 g. (0.11 mole) of tetraphenyl lead.

Diphenyl Lead Dichloride.—An excess of hydrogen chloride is run into a solution of 51.5 g. (0.1 mole) of tetraphenyl lead in 500 cc. of benzene warmed to about 50°. The flask may be open or closed, but one advantage of a closed system is that it gives an indication of the stage of the reaction from the rate at which the gas is being absorbed. The end of the reaction is not readily determined inasmuch as the hydrogen chloride is very slowly absorbed even when the reaction appears to be completed. A better way is to filter the shiny plates of diphenyl lead dichloride when the reaction appears to be at an end and then pass more hydrogen chloride into the hot filtrate.[12] If there is no additional precipitate the reaction is done. Only a very small quantity of lead chloride forms even after prolonged treatment with hydrogen chloride.[12] The yield is 42.2 g. or 98.5%.

Summary

Triphenyl lead chloride and diphenyl lead dichloride may be prepared in high yields by the action of hydrogen chloride on tetraphenyl lead.

AMES, IOWA

---

[12] The mixture should be filtered hot in order to avoid precipitation of any unaltered tetraphenyl lead. Tetraphenyl lead and triphenyl lead chloride are readily soluble in hot benzene.

STUDIES ON REACTIONS RELATING TO CARBOHYDRATES AND POLYSACCHARIDES. XXIII. SYNTHESIS AND PROPERTIES OF HYDROXY ALKYLIDENE GLYCOLS AND GLYCEROLS

BY HAROLD HIBBERT AND MYRON S. WHELEN[1]

RECEIVED JUNE 7, 1929 PUBLISHED OCTOBER 5, 1929

Investigations dealing with a study of cyclic acetal formation during recent years have dealt almost exclusively with cyclic acetals prepared from saturated derivatives. The tendency of unsaturated aldehydes toward cyclic acetal formation has been but little investigated. The study of this type of cyclic acetal apparently has been rendered difficult by the fact that unsaturated aldehydes, in general, condense only with difficulty with polyhydric alcohols under the experimental conditions usually employed. The use of acid catalysts is disadvantageous, due in many cases to polymerization of the aldehyde. The difficulty appears to lie in the securing of the optimum hydrogen-ion concentration, and failure to undergo condensation may be due to this, coupled with low reaction velocity between the aldehyde and polyhydroxy derivative.

The possibility that the lignin complex, as it occurs in wood, may contain an unsaturated aldehyde grouping,[2] which may be combined with a carbohydrate complex in the form of a cyclic acetal or half acetal, pointed to the necessity for obtaining further information regarding the interaction of unsaturated aldehydes with polyhydric compounds.

Also of added interest is the close connection, as indicated in a previous communication,[3] between cellulose considered as an anhydroglucose (A) and 1,2-dihydroxypropylidene-glycerol-1,2 (2-dihydroxy-ethyl-1,3-dioxolane-4-carbinol) (B), *e.* g.

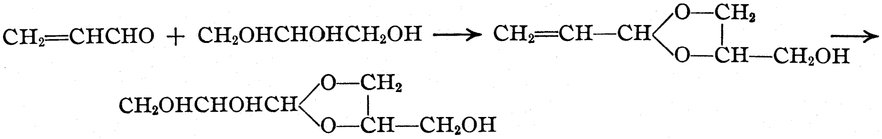
[3] Hibbert and Whelen, THIS JOURNAL, 51, 620 (1929).

For these reasons it seemed of interest to prepare the cyclic acetals involving condensation of acrolein with glycol and glycerol, namely, acrylidene glycol and glycerol, and to use these as initial materials from which, by oxidation, the corresponding dihydroxy derivatives could be obtained



(B)

in order to ascertain how far such structures exhibit a tendency toward polymerization or association.

Investigations on unsaturated cyclic acetal formation have been very limited. Lochert,[4] in an attempt to prepare α-hydroxy-*iso*-amylidene glycol,  (C), by the saponification of α-bromo-*iso*-amylidene glycol, secured a very small amount of what he believed to be the desired compound, (C), but as was to be expected the bulk of the reaction product was the unsaturated cyclic acetal, β-methylcrotonylidene glycol, [2 - (β - methylpropene - 2) - 1,3 - dioxolane], . No investigation of the chemical properties of the unsaturated acetal was made and the presence of α-hydroxy-*iso*-amylidene glycol was not definitely established.

Peacock[6] was the first to prepare cinnamylidene glycerol, and its preparation, properties, etc., have been studied more fully by the present authors.[3]

More recently several unsaturated aldehydes have been condensed with glycol by Hibbert and co-workers[6] to give unsaturated cyclic acetals.

As far as can be ascertained the literature contains no reference to the condensation of acrolein with glycol, and the authors' experiments to bring about such a condensation were unsuccessful. It was, however, possible to prepare the desired acrylidene glycol by indirect synthesis.

The condensation of acrolein and glycerol was first carried out by Nef,[7] who in a study of the dehydration of glycerol isolated a material which he considered to be acrylidene glycerol, though he did not make a detailed investigation of it nor did he establish its identity.

In the present investigation it is shown that the product obtained on heating acrolein with glycerol, without a catalyst, under low pressure, is

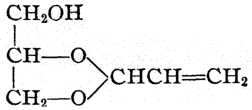
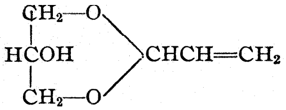
[7] Nef, Ann., 335, 224 (1904).

an acrylidene glycerol which is identical with the material isolated by Nef. This author pointed out that his material could be either of two products (D or E)



(D)

or



(E)

The present investigation shows that the condensation apparently gives rise to only the five-membered acetal (D). From the point of view of Michael's partition principle the second isomer is probably formed but either in quantity too small to be isolated, or, if in larger amount, it possibly undergoes spontaneous polymerization and remains in the thick, viscous, undistillable residue which is always left in large quantity.

It will be readily observed that with acrylidene glycol only one ring system is possible, namely,  $CH_2{=}CHCH\langle\begin{matrix}O{-}CH_2\\ |\\ O{-}CH_2\end{matrix}$. This product was obtained by indirect synthesis as shown in the experimental part.

These products, acrylidene glycol and glycerol (after determination of the structure of the latter), were then used as convenient starting materials for the preparation of the corresponding dihydroxy derivatives, this being accomplished by oxidation with potassium permanganate at a low temperature.

Of the two dihydroxy acetals thus obtained, the former represents the first cyclic acetal of glycerol to be synthesized containing hydroxyl groups in the alkylidene side chain. It will be observed that they represent the condensation of a simple sugar with a polyhydric alcohol.[8]

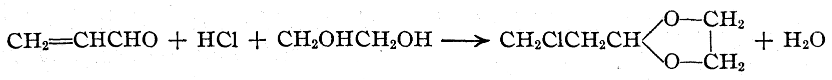
The direct condensation of acrolein and ethylene glycol to form acrylidene glycol (2-allyl-1,3-dioxolane) does not take place readily enough to form the basis of a practical method of preparation. The use of catalysts such as anhydrous copper or sodium sulfate, and variation of the experimental conditions, did not appreciably aid the reaction. Catalysts with an acid reaction were precluded due to their action in bringing about a polymerization of the acrolein. Accordingly, the method used was one of indirect synthesis and was an application of that used by Wohl,[9] as modified by Witzemann,[10] for the preparation of open-chain acetals. This slightly modified procedure consisted in dropping acrolein into a solution of hydrogen chloride in ethylene glycol at a temperature of 0 to +5°, the following change taking place.

---

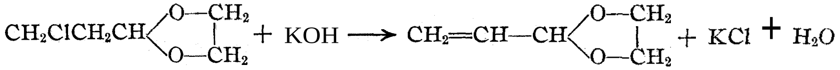
[8] Hydrolysis of this compound should readily yield glyceric aldehyde as one product, although this phase of the subject was not investigated.

[9] Wohl, *Ber.*, **31,** 1797, 2394 (1898); **33,** 3095 (1930).

[10] Witzemann, THIS JOURNAL, **36,** 1766, 1908 (1914).



The reaction mixture was poured into water, the oily layer separated, taken up in ether, dried and fractionated under reduced pressure. The β-chloropropylidene glycol (2-β-chloro-ethyl-1,3-dioxolane) so obtained was heated with dry, powdered potassium hydroxide in order to convert it into acrylidene glycol



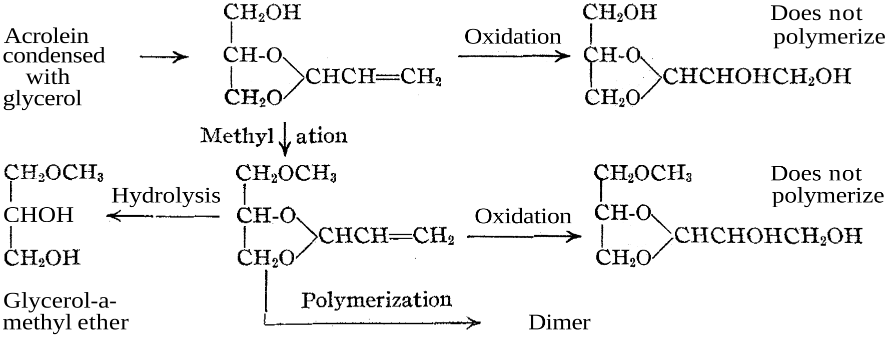
The conversion of acrylidene glycol to 1,2-dihydroxypropylidene glycol (2-dihydroxy-ethyl-l,3-dioxolane) was accomplished by oxidizing with potassium permanganate at a low temperature, removal of the precipitated manganese dioxide, concentration of the slightly alkaline aqueous solution and distillation under low pressure.

Dihydroxypropylidene glycol, as isolated, is a clear liquid with a viscosity approximating to that of ethylene glycol. It burns vigorously when ignited, giving a non-luminous flame. It is quite stable on distillation under reduced pressure and shows no tendency to polymerize under prolonged heating with, or without, non-acid catalysts,

Acrylidene glycerol was prepared by the direct condensation of acrolein and glycerol without a catalyst. The only product isolated from the reaction mixture was shown to possess the five-membered cyclic structure (D) by the usual methylation and hydrolysis technique. No product indicating the presence of the isomeric six-membered acetal could be found. There was always, however, a very large quantity of a thick, viscous, dark brown oil left in the reaction flask, which probably consisted of unchanged glycerol, polyglycerols, polymerized acrolein and possibly a polymerized six-membered cyclic acetal of acrolein and glycerol. No method could be found permitting of the isolation of the individual components.

1,2-Acrylidene-glycerol (2-allyl-1,3-dioxolane-4-carbinol), prepared as above, is a clear liquid of relatively low viscosity, possessing a distinct and somewhat strong odor. It has a marked tendency to hydrolyze, with evolution of acrolein, in dilute aqueous acid solution, especially when warmed. It is monomolecular and shows no tendency toward polymerization. On the other hand, its methyl ether (1,2-acrylidene-glycerol-1′-methyl ether) was found to be a mobile liquid of somewhat pleasant odor, monomolecular when first prepared, but changing after standing for several months into a very viscous product, the composition of which corresponded approximately to that of a dimer. It is possible that this change is due to association, or it may be the result of aggregation involving the migration of a hydrogen atom from one part of the molecule to the double linkage, with subsequent ring closure and polymerization. An interesting comparison is to be found in the fact that acrylic acid ($CH_2=CHCOOH$) shows little or no tendency to polymerize, while with ethyl acrylate ($CH_2=CH—COOC_2H_5$) this tendency is very pronounced.

Both 1,2-acrylidene-glycerol-α-methyl ether and 1,2-acrylidene-glycerol were subjected to oxidation by aqueous permanganate to convert them into the corresponding dihydroxy compounds; thus prepared these were very viscous, high-boiling liquids. They were monomolecular and showed no tendency toward polymerization either under the influence of heat or non-acid catalysts. Distillation of the 1,2-acrylidene-glycerol, however, always left a considerable quantity of a caramel-like, dark brown residue, the nature of which could not be determined. The course of these reactions may be shown as follows



Experimental

Preparation of 8-Chloropropylidene Glycol (2-(β-Chloro-ethyl)-1,3-dioxolane).—Eighty grams of acrolein was allowed to drop slowly, with vigorous stirring, into a solution of 40 g. of hydrogen chloride dissolved in 120 g. of ethylene glycol. The temperature was carefully maintained by means of a freezing mixture at 0 to +4°. If this precaution was not taken the heat of reaction was such that much of the acrolein was polymerized. The reaction mixture was allowed to stand for two hours at room temperature and then poured into a liter of cold water. The β-chloropropylidene glycol separated as an oily layer. It was removed in a separatory funnel, taken up in ether, dried over anhydrous sodium sulfate and fractionated under reduced pressure, yielding 70 g. of a clear, colorless liquid, b. p. 70–72° (18 mm.). A small residue (which was probably polymerized acrolein or β-chloropropionaldehyde) remained in the distillation flask.

β-chloropropylidene glycol on standing gradually turns dark brown in color. When warmed with dilute aqueous acid, a very obnoxious odor, even more offensive than that of acrolein, is evolved, which in all probability is β-chloropropionaldehyde produced by the hydrolysis of the acetal.

Preparation of Acrylidene Glycol (2-Allyl-1,3-dioxolane).—The preparation of acrylidene glycol involved the removal of hydrogen chloride from β-chloropropylidene glycol. Dry powdered potassium hydroxide was used for this purpose.

To six times the theoretical quantity of very finely-powdered potassium hydroxide (124 g.), placed in a round-bottomed copper flask fitted with a short distilling column and condenser, was added 50 g. of β-chloropropylidene glycol. A marked rise in temperature occurred and the mixture was then slowly heated over a free flame until distillation took place. A clear liquid, b. p. 115–119°, was obtained, which on redistillation yielded usually about 20 g. of acrylidene glycol, b. p. 115–116°. Yields from various 50-g. lots averaged approximately 50%.

Excess potassium hydroxide was used in these preparations to absorb the water formed in the reaction. If the latter is allowed to remain uncombined, some of the β-chloropropylidene-glycol undergoes hydrolysis to β-chloropropionaldehyde. A small amount of this compound escapes polymerization by the hot alkali (probably being formed in the vapors above the alkali) and passes over with the distillate giving it an extremely lachrymatory odor, even more pronounced than that of acrolein. Whenever this was formed the yield of acrylidene glycol was always somewhat lower. Acrolein odors were also sometimes present.

If the reaction is carried out in glass flasks great care must be taken to avoid accidents liable to result from the leaking of hot alkali from a cracked flask. For this reason it was found more satisfactory to use a copper vessel.

Acrylidene glycol is a clear, colorless, very mobile and volatile liquid possessing a somewhat strong, sweetish, slightly unpleasant odor. When hydrolyzed by warming with dilute acid, acrolein is readily evolved.

Anal. Calcd. for $C_5H_8O_2$: C, 60.00; H, 8.00. Found: C, 59.28; H, 7.84.

Preparation of **1,2-Dihydroxypropylidene-glycol (2-Dihydroxyethyl-1,3-dioxolane).**—The oxidation of acrylidene glycol to 1,2-dihydroxypropylidene glycol was accomplished by allowing a nearly saturated solution of potassium permanganate to drop into a suspension of acrylidene glycol in water.

Eight hundred and twenty cc. of an aqueous solution containing 42.1 g. of potassium permanganate was added to 40 g. of acrylidene glycol suspended in 400 cc. of water and contained in a three-necked liter flask, the addition being made at the rate of approximately 20 cc. per minute, the mixture being cooled by an ice-bath and vigorously agitated by a mechanical stirrer. The initial temperature was about 9°. After commencement of the reaction the temperature was allowed to fall and then maintained below 5° throughout the addition. The reaction mixture was kept in an ice-bath for two hours, then heated to 90° in a water-bath, the manganese dioxide separated by filtration and the water removed from the aqueous, slightly alkaline filtrate by distillation under reduced pressure at 28° until the volume was approximately 50 cc. The residual liquid was filtered and fractionated; yield, 22 g. (41%) of a viscous, clear, colorless liquid; b. p. 136–138 (5 mm.); n_D^{17} 1.4695.

Anal. Calcd. for $C_5H_{10}O_4$: C, 44.77; H, 7.46. Found: C, 44.38; H, 7.17. Mol. wt. (ethylene bromide). Calcd.: 134. Found: 140.

It is to be noted that the above distillation was carried out using the alkaline solution formed in the oxidation in order to avoid hydrolysis of the acetal.

Preparation of **1,2-Acrylidene-glycerol (2-Allyl-1,3-dioxolane-4-carbinol).**—One hundred and twelve grams (2 moles) of acrolein and 184 g. (2 moles) of glycerol were placed in a pressure bottle and heated for several weeks under pressure at a temperature of 50–60°. Placing the bottle on a warm radiator was found to be satisfactory. On first mixing, the two substances were immiscible, but after heating for several days a homogeneous solution resulted. Various experiments were carried out and it was found that the longer the heating was continued, the better was the yield. The reaction mixture was then distilled under reduced pressure. Usually very little unchanged acrolein remained and the distillate boiling under 165" (10 mm.) was collected separately. A very large quantity of a thick, viscous, undistillable liquid remained which probably contained unchanged glycerol, polyglycerols and various polymerized products. The distillate on fractionation gave a clear oil, b. p. 204–215°; (98–105°, 10 mm.); n_D^{17} 1.4638. It was further refractionated into two fractions, (1) b. p. 204–208°, and (2) b. p. 208–

215°. Both of these reacted as strongly unsaturated substances toward bromine and potassium permanganate, and on warming with dilute acid evolved acrolein very readily. The odor of the fractions when first prepared was marked but not unpleasant; on standing, the odor of acrolein was noticeable due to slight hydrolysis. Yields from a number of experiments averaged between 10 and 15%.

Anal. (Fraction b. p. 98–105°, 10 mm.). Calcd. for $C_6H_{10}O_3$: C, 55.44; H, 7.67. Found: C, 55.40; H, 7.87. Mol. wt. (ethylene bromide). Calcd.: 130. Found: 132.

Determination of Structure.—Both of the above fractions (1) and (2) yielded the same acrylidene-gylcerol-α-methyl ether, the wide range in boiling point possibly being due to the presence of cis and *trans* isomers.

The usual methylation–hydrolysis method was employed and it was found that the acrylidene glycerol as isolated above consisted only of the five-membered acetal. The six-membered acetal either was not formed in sufficient quantity for isolation or it was polymerized and remained in the residue from the reaction.

Methylation of 1,2-Acrylidene-glycerol.—Fifty grams of acrylidene glycerol, b. p. 98–102° (10 mm.), was methylated in the usual manner, using 200 g. of methyl iodide and 120 g. of silver oxide. The reaction mixture was extracted with ether, dried with anhydrous sodium sulfate, and fractionated under reduced pressure; 38 g. of acrylidene-glycerol-a-methyl ether, b. p. 70° (13 mm.), (174–178°, 760 mm.), n_{D}^{17} 1.4408, was obtained. Nine and six-tenths grams of 1,2-acrylidene glycerol, b p. 204–207°, was also recovered.

Acrylidene-glycerol-a-methyl ether is a mobile liquid, monomolecular when first isolated, and possessing a somewhat pleasant, ethereal odor. However, after standing for several months it became very viscous in character and a molecular weight determination showed it had been almost completely converted into a dimer. No hydrolysis had taken place during this period.

Methylation of the other fraction of acrylidene-glycerol, b. p. 208–215°, gave only acrylidene-glycerol-a-methyl ether, b. p. 174–178".

The identity of the material in question was proved by (a) the formation of glycerol-a-methyl ether on hydrolysis, and (b) its conversion into 1,2-dihydroxypropylidene-glycerol-1'-methyl ether on oxidation.

Mol. *wt.* of freshly prepared acrylidene-glycerol-a-methylether in ethylene bromide, calcd.: 144. Found: 145. Mol. *wt.* of above compound after standing (ethylene bromide). Found: 273.

Hydrolysis of Acrylidene-glycerol-α-methyl Ether.—Seven grams of acrylidene-glycerol-a-methyl ether (b. p. 174–178°) was hydrolyzed by boiling under a reflux condenser for seventy minutes with 25 cc. of 75% aqueous ethyl alcohol containing 0.5% hydrochloric acid. Acrolein was evolved vigorously and was removed by applying gentle suction to the top of the condenser. The reaction mixture was neutralized with lead carbonate, filtered, concentrated and the residue distilled under reduced pressure, yielding only glycerol-a-methyl ether, b. p. 110–112° (13 mm.), n_{D}^{17} 1.4465, and thus serving to identify the structure of the original product as the five-membered acrylidene glycerol, (D).

Preparation of 1,2-Dihydroxypropylidene-glycerol-1'-methyl Ether.—The simplest and most dependable mode of synthesis appeared to lie in the oxidation of acrylidene-glycerol-a-methyl ether to the corresponding dihydroxy compound. By protecting the a-hydroxyl group by a prior methylation, it was thought that any secondary oxidation might be avoided. Moreover, this would yield a new type of cyclic acetal ether.

Thirty grams of acrylidene-glycerol-a-methyl ether was suspended in 300 cc. of water and oxidized in the usual manner with 560 cc. of an aqueous solution containing 29.5 g. of potassium permanganate. The water was removed from the filtered, slightly alkaline solution by distillation under reduced pressure. The residual oil on fractionation and refractionation yielded 9.4 g. of a heavy, slightly yellowish liquid, b. p. 146° (1–2 mm.), n_D^{17} 1.4680. Analysis showed it to be 1,2-dihydroxypropylidene-glycerol-1'-methyl ether.

Anal. Calcd. for $C_7H_{14}O_5$: C, 46.54; H, 7.92. Found: C, 46.56; H, 7.98. Mol. wt. (ethylene bromide). Calcd.: 178. Found: 197.

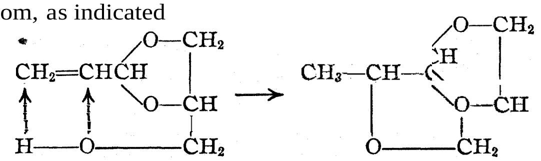
The product shows no tendency to polymerize either on heating or under the influence of non-acid catalysts such as alkalies, aluminum alkylates, etc.

Synthesis of **1,2-Dihydroxypropylidene-glycerol (1,2) (1,2-Dihydroxy-ethyl-1,3-dioxolane-4-carbinol)**.—Twenty-five and five-tenths grams of 1,2-acrylidene-glycerol (b. p. 204–207°) was dissolved in 250 cc. of water and oxidized with a solution containing 20.7 g. of potassium permanganate in 365 cc. of water under the same conditions that were employed in the preceding experiment. The reaction product after filtration, but without neutralizing, was concentrated under reduced pressure. The residual oil on fractionation yielded 3 fractions—(1) 8 g. of a clear oil, b. p. 54° (2 mm.); (2) a small quantity of unchanged acrylidene-glycerol, b. p. 70° (2 mm.); and (3) 28 cc. of a very viscous, slightly yellow-colored liquid, b. p. 200–204° (6 mm.), n_D^{17} 1.4888, proved by analysis to be 1,2-dihydroxypropylidene-glycerol (1,2-) and which could be redistilled unchanged. A large, undistillable, tarry, caramel-like residue remained.

The identity of Fraction I, b. p. 54° (2 mm.), was not determined. It behaved as a saturated substance toward potassium permanganate and bromine and also reacted with metallic sodium. On warming with dilute acid an aldehyde was evolved, the identity of which was not determined.

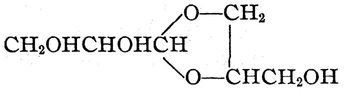
Anal. of Fraction (3). Calcd. for $C_6H_{10}O_3$: C, 55.44; H, 7.67. Mol. wt., 130. Found: C, 55.40; H, 8.00. Mol. wt. (ethylene bromide), 124.

It is possible that the product represents a bicyclic acetal formed by the wandering of a hydrogen atom, as indicated



The product is at present under investigation. If this mechanism should prove correct, the reaction would form an interesting example of the wandering of a hydrogen atom to a vinyl radical in an *alkaline* medium.

1,2-Dihydroxypropylidene-glycerol (1,2),



$$CH_2OHCHOHCH\begin{cases}O-CH_2\\O-CHCH_2OH\end{cases}$$

—1,2-Dihydroxypropylidene-glycerol-1,2 is monomolecular, and as far as could be determined, shows no tendency to polymerize on heating with, or without, non-acid catalysts. During its preparation a large quantity of residue remained and it was thought that a better yield could be obtained by carrying out the distillation at a very low pressure. However, distillation at 0.15 mm. (using a Hyvac and mercury vapor pump) gave no better results, the reaction product yielding only 2 g. of dihydroxypropylidene-glycerol (1,2), b. p. 146" (0.15 mm.). A considerable amount of a caramel-like substance again remained but it was impossible to determine whether this represented a polymerization or a decomposition product.

Anal. of 1,2-Dihydroxypropylidene-glycerol (1,2). Calcd. for $C_6H_{12}O_5$: C, 44.77; H, 7.46; mol. wt. 163. Found: C, 44.38; H, 7.17; mol. wt. (acetone), 156.

Attempts to Bring about Polymerization.—1,2-Dihydroxypropylidene-glycerol

(1,2) was heated for several weeks at 110° with non-acid catalysts such as potassium hydroxide, and sodium and aluminum ethylates, but no tendency to polymerize was observed. Likewise, heating for long periods at 110° without a catalyst, or exposure to sunlight in a quartz glass tube, had no effect.

The close relationship of 1,2-dihydroxypropylidene-glycerol (1,2) to the cellulose nucleus was previously pointed out,[3] and it would seem that polymerization does not take place unless ring closure has been previously effected.

Summary

1. Two new unsaturated cyclic acetals, namely, acrylidene-glycol and acrylidene-glycerol have been prepared. Their physical properties and chemical behavior have been investigated.
2. It is shown that the reaction product from the condensation of acrolein and glycerol yields a five-membered acrylidene glycerol. The greater part of the reaction product is left as a thick, viscous residue. No indication was observed of the presence of the corresponding six-membered acetal, although it is possible that it may be formed and at once undergo spontaneous polymerization.
3. The corresponding acrylidene-glycerol methyl'ether was prepared. It undergoes polymerization to a dimolecular form on standing.
4. The dihydroxypropylidene cyclic acetals of glycol and glycerol were prepared and their properties studied. They are apparently the first cyclic acetals of glycol and glycerol that have been prepared containing hydroxyl groups in the alkylidene radical.
5. Dihydroxypropylidene glycol and glycerol as well as dihydroxy-propylidene-glycerol-a-methyl ether show no tendency to polymerize, a fact of some interest in connection with their relationship to cellulose and other polysaccharides.

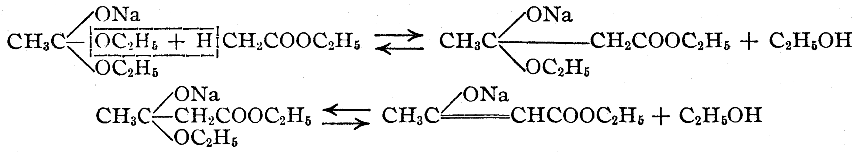
SOME OBSERVATIONS ON THE ACETOACETIC ESTER CONDENSATION

BY S. M. McELVAIN

RECEIVED JUNE 7, 1929 PUBLISHED OCTOBER 5, 1929

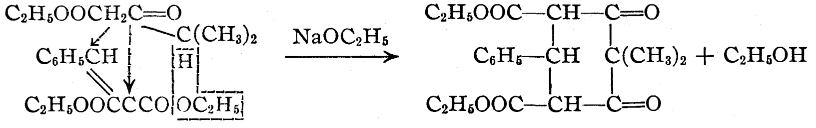
The well-known mechanism for the course of the acetoacetic ester condensation proposed by Claisen[1] was questioned by Dieckmann[2] on the basis of his work on the splitting of alkyl acetoacetic esters by alcohol and sodium ethoxide. Dieckmann preferred to represent the condensation as a reversible reaction that took place in two phases



$$CH_3\overset{ONa}{\underset{OC_2H_5}{C}}-\boxed{OC_2H_5 + H}CH_2COOC_2H_5 \rightleftarrows CH_3\overset{ONa}{\underset{OC_2H_5}{C}}-CH_2COOC_2H_5 + C_2H_5OH$$

$$CH_3\overset{ONa}{\underset{OC_2H_5}{C}}-CH_2COOC_2H_5 \rightleftarrows CH_3\overset{ONa}{C}=CHCOOC_2H_5 + C_2H_5OH$$

According to this explanation it is necessary to have only one hydrogen atom on the a-carbon atom of the ester that condenses with the ortho derivative in order to bring about the first phase of the condensation. The reason for the apparent failure of an ester of the type, $R_2CHCOOC_2H_5$, to undergo the acetoacetic ester condensation is due, according to Dieckmann, to the ease with which the condensation product is split, *i. e.*, the relative completeness of the reversal of the first phase of the above reaction. In support of this mechanism Dieckmann and Kron[3] reported the condensation of ethyl *iso*butyryl acetate and benzalmalonic ester by means of sodium in absolute alcohol to 2,2-dimethyl-5-phenyl-4,6-dicarbethoxycyclohexandedione-1,3



The enolic acidity of the condensation product resulting from the simultaneous formation of two β-ketonic ester groupings prevented the reversal of the acetoacetic ester condensation.

In 1922 Scheibler and Ziegner[4] proposed a new mechanism, which resembled that of Dieckmann's to the extent that it indicated that esters of the type $R_2CHCOOC_2H_5$ should undergo the condensation. This new proposal, however, met with considerable criticism[5] and was recently

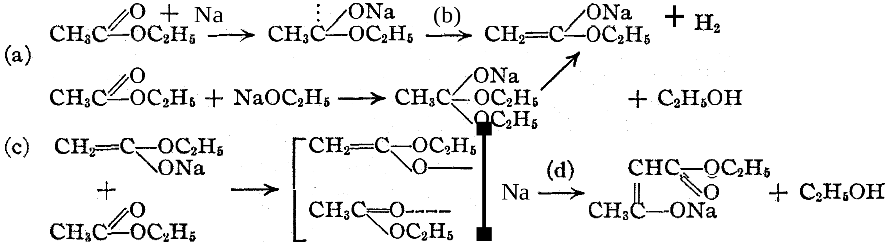
abandoned by Scheibler and Marhenkel[6] in favor of a rather complicated formulation which assumes four phases in the condensation: (a) the formation of a metal ketyl (when a metal such as sodium is used) or an addition product (when a metallic alkoxide is used) on the ester carbonyl group; (b) the change of the compound formed in (a) into an enolate; *(c)* reaction of the enolate with a molecule of the keto form of the ester with the formation of a molecular compound; (d) the formation of a condensation product from the molecular compound formed in (c) by splitting out alcohol. To illustrate with ethyl acetate, sodium and sodium ethoxide

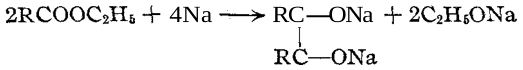


This mechanism resembles Claisen's original proposal to the extent that for complete condensation two hydrogen atoms are required on the α-carbon atom of the ester molecule that reacts with the keto form. Scheibler and Marhenkel state that when sodium ethoxide is the condensing agent, it is the alcohol split out when the enolate is formed (b) that prevents the continuation of the reaction; in other words, the ester enolate is a necessary intermediate and the reversible phase of the acetoacetic ester condensation is

$$CH_3C(=O)OC_2H_5 + NaOC_2H_5 \rightleftharpoons CH_2{=}C(OC_2H_5)ONa + C_2H_5OH$$

They state further that an ester of the type $R_2CHCOOC_2H_5$ will proceed in the above transformations through phase (c) but cannot go through phase (d) for obvious structural reasons. This conclusion is based on their observation that such an ester forms with sodium ethoxide **a** ketene acetal.

In the application of the acetoacetic ester condensation to ethyl acetate and its higher homologs, the choice between sodium and sodium ethoxide as condensing agents is an important consideration. It has been shown[7] that such esters in ether solution react with sodium at 0° to form sodium derivatives of acyloins



$$2RCOOC_2H_5 + 4Na \longrightarrow \begin{array}{l} RC{-}ONa \\ \;| \\ RC{-}ONa \end{array} + 2C_2H_5ONa$$

This reaction is quite distinct from the acetoacetic ester condensation and in no way involves the hydrogens of the a-carbon atom of the ester

[7] Bouveault and co-workers, Bull. *soc. chim.*, 35, 629 (1906), and preceding papers.

because it will proceed when R is tertiary butyl. Work now in progress in this Laboratory and which will be the subject of a future communication indicates that this competing reaction takes place at higher temperatures than 0° and that the acyloin type may be the major if not the sole product of the reaction between esters of this type and sodium.

In order to avoid this complication sodium ethoxide was used as a condensing agent in the work reported here. It seemed that the difficulty of the reversal of the condensation (which Dieckmann[2] has shown to be more serious with alkyl acetoacetic esters than with the unsubstituted ester) could be overcome by the removal of the alcohol by distillation as it was formed in the reaction. This principle has been applied[8] to the large scale production of acetoacetic ester from ethyl acetate using sodium, potassium or magnesium as condensing agents.

In the procedure that was used in the present work the ester was allowed to react with sodium ethoxide, the reaction mixture periodically distilled and the distillate replaced with pure ester. The amount of alcohol formed in the reaction was determined from the refractive indices of the distillates and when it was indicated that no more alcohol was being formed, the β-keto-ester was isolated from the reaction mixture.

Ethyl acetate, ethyl propionate, ethyl butyrate and ethyl *iso*butyrate were treated in this manner. Since a large excess of ester was necessarily taken, the yield calculations were based on the amount of sodium ethoxide used, according to the equation

$$2RCH_2COOC_2H_5 + NaOC_2H_5 = RCH_2C(ONa)CRCOOC_2H_5 + 2C_2H_5OH$$

The yields of β-keto-esters and of alcohol obtained from these various esters, using 0.5 mole (34 g.) of sodium ethoxide as the condensing agent are summarized in Table I.

TABLE I

YIELDS OF β-KETO-ESTERS

Ester used	Condensation product	Keto-ester isolated Mole	% of theoretical	Alcohol in distillate Mole	% of theoretical
Ethyl acetate	Ethyl acetoacetate	0.340	68	0.83	**83**
Ethyl propionate	Ethyl a-propionylpropionate	.405	81	0.97	97
Ethyl butyrate	Ethyl a-butyrylbutyrate	.380	76	1.03	103
Ethyl isobutyrate	....		0	0.03"	6[a]

[a] In this case the theoretical yield of alcohol would be 0.5 mole instead of 1 mole as is the case with the other esters under consideration.

While under ideal conditions the percentage yield of alcohol should be the same as that of the β-keto-ester in each case, the discrepancy between the two that is shown in the above table is not particularly great when manipulative losses during the isolation of the keto-ester, effect of traces of water on the yield of alcohol ($1H_2O$ produces $2C_2H_5OH$), possible im-

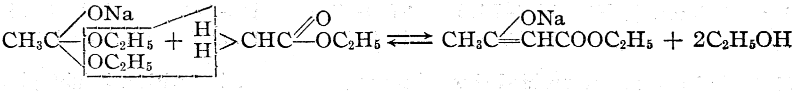
purities in the sodium ethoxide, and the method of analysis for alcohol in the distillates are considered, The results show that the reversal of the condensation can be prevented by such a procedure, since Higley[9] has found that the equilibrium point in the acetoacetic ester condensation represents about 36% of the keto-ester and the work of Dieckmann[2] indicates that a still smaller percentage of keto-ester would be present at the equilibrium point of alkyl-substituted acetoacetic esters.

The results obtained with ethyl isobutyrate are of some interest in connection with the mechanisms that have been proposed for the condensation. It is seen that no keto-ester and an insignificant amount of alcohol are formed in the reaction of this ester with sodium ethoxide. If Dieckmann's proposal were correct, it is difficult to see why this ester under the conditions of the experiment should not condense to form the sodium ethoxide addition compound of ethyl isobutyryl-isobutyrate, $(CH_3)_2C(ONa)(OC_2H_5)C(CH_3)_2COOC_2H_5$, with the simultaneous appearance of alcohol in the distillate, for this keto-ester is known[10] to be sufficiently stable to isolate. Both Claisen's original proposal and Scheibler's later suggestion as to the mechanism of the reaction are in accord with the fact that none of the β-keto-ester is formed from ethyl isobutyrate, but Scheibler's postulate that an intermediate enolate is an essential step in the course of the reaction is not in agreement with the fact that no alcohol is found in the distillate.

It seems on the basis of these results that the original mechanism for the acetoacetic ester condensation proposed by Claisen, supplemented by the reversible feature



$$CH_3C\begin{matrix}\diagup ONa \\ - OC_2H_5 \\ \diagdown OC_2H_5\end{matrix} + \begin{matrix}H \\ H\end{matrix}>CHC\begin{matrix}\diagup\!\!\diagup O \\ - OC_2H_5\end{matrix} \rightleftharpoons CH_3C\overset{ONa}{=}CHCOOC_2H_5 + 2C_2H_5OH$$

is the most acceptable of those that have been considered. It may be suggested that the results presented here do not prove conclusively the correctness of the Claisen mechanism, but rather that they support it to the extent that they do not show it to be incorrect. The behavior of ethyl isobutyrate does show, however, that the mechanisms proposed by Dieckmann and by Scheibler and Marhenkel for the reaction of sodium ethoxide and esters of the type of ethyl acetate are questionable.

Since Scheibler and Marhenkel postulate the same enolate (b) and molecular compound (c) as necessary precursors for both the acetoacetic ester condensation and ketene acetal formation it appears that their mechanism for the formation of the latter type is also in error. The ketene acetal from ethyl isobutyrate has been prepared[11] by the action

---

[9] Higley, *Am. Chem.* J., *37, 299* (1907).

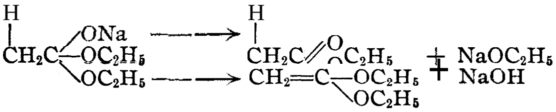
[10] Salkind, *Chem. Centr.,* II, *315 (1906).*

[11] Scheibler and Friese, *Ann., 445, 149 (1926).*

of sodium ethoxide on this ester, but it has been pointed out above that these two reactants do not enter into the reversible reaction

$$(CH_3)_2CHC\overset{\diagup O}{—}OC_2H_5 + NaOC_2H_5 \rightleftharpoons (CH_3)_2C{=}C\overset{\diagup ONa}{—}OC_2H_5 + C_2H_5OH$$

which is essential to the Scheibler and Marhenkel mechanism. For this reason it seems that a different explanation for the formation of ketene acetals is needed. In this connection it may be suggested that it would not be unreasonable to assume that Claisen's ester–sodium ethoxide addition product might undergo decomposition in two ways, (a) into the original ester and sodium ethoxide and (b) into a ketene acetal and sodium hydroxide, e. g.



Experimental

Materials Used.—–Each of the esters, ethyl acetate, ethyl propionate, ethyl butyrate and ethyl isobutyrate, that was used was purified in the following manner. The ester was shaken in a separatory funnel with an equal volume of 2% potassium carbonate solution and then with an equal volume of water. The ester layer was separated and allowed to stand for three days over anhydrous potassium carbonate, after which it was filtered and distilled. The distillate was treated with 2% of its weight of phosphorus pentoxide and after standing for twenty-four hours it was distilled from the phosphorus pentoxide. The distillate was then fractionally distilled The boiling points and refractive indices of the esters used in the experiments described below were:

Ethyl ester	Acetate	Propionate	Butyrate	Isobutyrate
B. p. (735 mm.), °C.	76.4–76.5	97.5–98.4	119–121	108.5–109.5
n_D^{25}	1.36899	1.38053	1.38883	1.38404

The ethyl acetate so purified showed no apparent reaction with a bright piece of sodium after six hours. The ethyl propionate showed a slight reaction after about one hour. The ethyl butyrate and ethyl isobutyrate reacted completely with sodium (acyloin formation) within a few minutes. In no case, however, was there any evidence of evolution of hydrogen. Although it has been pointed out[12] that the distillation of ethyl acetate from phosphorus pentoxide caused a slight amount of decomposition, as indicated by a change in density of the ester, it was felt that the decomposition induced by this treatment was not sufficient to have any marked effect on the results of this work.

The sodium ethoxide that was used was prepared by dissolving freshly cut sodium in absolute alcohol (distilled from sodium) and, while the final hydrogen was being evolved from the reaction, removing the excess alcohol by distillation. The resultant sodium ethoxide was then heated in an oil-bath to 150° at 20 mm. for four hours.

Determination of Alcohol in the Ester Distillates.—Mixtures of varying percentages of the different esters and absolute alcohol were made up, their refractive indices taken, and these values plotted against the percentage composition. The points thus determined did not fall on the line joining the refractive index of the pure ester and that of pure alcohol (n_D^{25} 1.35774) but formed a smooth curve, quite dose to this line, of the

---

[12] Wade and Merriman, *J. Chem. Soc.*, 101, 2429 (1912).

type recently reported by Adkins and Broderick[13] for mixtures of different aldehydes and alcohols. Within the range used (80–100% ester) for the analyses of the distillates the greatest difference between the refractive indices as given by the curve and the straight line amounted to only 0.0004. In spite of this small difference the curves obtained from mixtures of ester and alcohol of known composition and their corresponding refractive indices were used for the analyses. The refractive indices were determined with a Pulfrich refractometer at 25° and with an accuracy, it is believed, of 0.0001.

Reaction of the Esters with **Sodium Ethoxide.**—The standard procedure that was used for all of the esters with the exception of ethyl isobutyrate was: 280 g. of the ester and 34 g. (0.5 mole) of sodium ethoxide were placed in a 1-liter three-necked flask fitted with a reflux condenser, a mercury seal stirrer and a condenser for downward distillation. The receiver to this latter condenser was arranged to fit tightly or loosely depending on whether it was desired to send the vapors of the boiling reaction mixture into the reflux condenser or through the other condenser for distillation. All connections in the apparatus were ground-glass joints in order to prevent any contamination from stoppers. The top of the reflux condenser carried a calcium chloride tube. The contents of the flask was refluxed for four hours, with stirring, by heating in an oil-bath. After this time the excess ester was distilled off and collected in two portions (1 and 2, Table II). Then 200 g. of pure ester was added to the reaction flask and the mixture allowed to reflux for three hours. After this time the excess ester was again distilled off and collected in two portions (3 and 4, Table II). Finally 100 g. of pure ester was added to the flask and after allowing it to reflux for three hours it was distilled off and collected in one portion (5, Table II).

In the case of ethyl isobutyrate a similar procedure was followed except that after the four-hour period of refluxing of 0.5 mole of sodium ethoxide and 280 g. of the ester, the distillation was carried on slowly over a period of three hours. The distillate was

[13] Adkins and Broderick, THIS JOURNAL, 50, 499 (1928).

collected in four portions. Due to the fact that practically no alcohol appeared in the distillate and that the boiling point of the latter was identical with that of the pure ester, no fresh portions of the ester were added to the reaction flask.

A summary of the weights, refractive indices and alcohol content of the distillate portions for the different esters used is shown in Table II.

The condensation product was isolated from the residue in the reaction flask by the addition, with constant cooling and stirring, of a solution of 35 g. of glacial acetic acid in 70 cc. of water. When complete solution of the salt had taken place, the ester layer was separated and the aqueous portion extracted with two 50-cc. portions of ether. The combined ester layer and ether extract was then fractionated. In this manner there were obtained 44 g. of ethyl acetoacetate (68% of calcd.), b. p. 78–80" (16 mm.); 64 g. of ethyl a-propionylpropionate (81% of calcd.), b. p. 88–90" (12 mm.); 70 g. of ethyl α-butyrylbutyrate (76% of calcd.), b. p. 102–105° (12 mm.). All yield calculations were based on the amount of sodium ethoxide used. The two latter compounds were definitely characterized by hydrolysis to diethyl ketone and di-n-propyl ketone, the semicarbazones of which melted at 139–140° and 133–134°, respectively.[14] In the case of ethyl isobutyrate this ester was the highest boiling product that was isolated from the reaction mixture.

Ethyl a-propionylpropionate has been prepared in rather poor yields by the action of sodium on ethyl propiouate[15] Although ethyl a-butyrylbutyrate has previously been prepared,[16] it has not heretofore been prepared by a Claisen condensation of ethyl butyrate.

Summary

1. A study of the action of sodium ethoxide on ethyl acetate and certain of its higher homologs has been made and the amounts of both reaction products, β-keto-ester and alcohol, that were formed have been determined.

2. Certain of the mechanisms that have been proposed for the course of the acetoacetic ester condensation are discussed in the light of the results which have been obtained.

ALPHA-FURFURYL CHLORIDE AND ITS DERIVATIVES. II

BY W. R. KIRNER AND G. HOLMES RICHTER

RECEIVED JUNE 7, 1929 PUBLISHED OCTOBER 5, 1929

The recent preparation and isolation of α-furfuryl chloride[1] has greatly simplified the synthesis of a-furfuryl compounds and it is now possible, by using this reagent, to prepare compounds which were in many cases previously obtainable only by more or less indirect methods which usually started with furfural and involved several steps in the procedure. By the use of a-furfuryl chloride, which contains a highly reactive chlorine atom, we have prepared the following new compounds, which are listed in Table I, together with their physical constants.

TABLE I

NEW FURYL DERIVATIVES

In most of these reactions it was not considered necessary to use the pure distilled furfuryl chloride so the ethereal solution obtained directly from the reaction mixture was treated with the desired reagent. The main objection to this procedure is that it does not permit of an accurate method of determining the yield of product theoretically obtained in the various reactions. However, by assuming that the crude reaction product was formed in 70% yield (since a 63% yield of distilled product can be obtained), an approximate idea is obtained of the percentage yields in the various reactions.

The furfuryl-ethyl-barbituric acid is of special interest because of the possibility of its possessing a physiological activity analogous to that of Veronal. We are indebted to Professor A. M. Hjort of the Dartmouth Medical School for his investigation of the action of this substance in producing hypnosis. A more detailed report of the physiological action will be published elsewhere.

Experimental

α-Furfurylmalonic Ester.—This substance was first prepared by Sandelin[2] by condensing furfural with malonic acid, yielding furfuralmalonic acid which was then reduced to furfurylmalonic acid and esterified; b. p. 171–173° at 33 mm.; 265–267° at atmospheric pressure. It was described as a light yellow oil with a weak fruity odor. This ester was also prepared by Ojiyama, Hasegawa and Matsumura.[3] Only the abstract of their article was available in which no details were given but their method is obviously complicated.

We obtained this ester by the usual malonic ester condensation using thoroughly anhydrous alcohol prepared according to the method of Smith[4] In this one case distilled furfuryl chloride was used and was added in a solution of Grignard ether. The yield of distilled product was 76%; b. p. 125.5–127° at 4 mm. The product was a colorless oil with an odor resembling that of malonic ester; d_{20}^{20} 1.11196; d_4^{20} 1.10999; n_D^{20} 1.4591; M_D (calcd.) 59.433; M_D (obs.) 59.152.

Anal. Subs., 0.2033: CO_2, 0.4457; H_2O, 0.1283. Calcd. for $C_{12}H_{16}O_5$: C, 59.98; H, 6.72. Found: C, 59.79; H, 7.06.

Ethyl-α-furfurylmalonic Ester.—This is a new compound. It was made by ethylating the above furfurylmalonic ester in the usual manner using ethyl iodide. The

[3] Ojiyama, Hasegawa and Matsumura, J. *Pharm. Soc.* Japan, 533, 597 (1926); C. A., 21,2251 (1927).

[4] Smith, J. *Chem. Soc.*, 1288 (1927).

purification of the compound was found difficult due to the continued appearance of iodine during the vacuum distillation. This was finally all removed by several extractions with sodium thiosulfate solution. The boiling point was 135.5–136.5° at 5 mm.; yield, 67%. This substance was not analyzed but was used directly for the preparation of the furfuryl-ethylbarbituric acid.

α-Furfurylbarbituric Acid.—This substance was first prepared by Ojiyama, Hasegawa and Matsumura.[3] They gave the melting point as 193°. We prepared it according to the directions given by Dox and Yoder,[5] using furfurylmalonicester, urea and sodium ethylate made from special anhydrous alcohol. In the isolation of the compound it was found that it was quite sensitive to the action of mineral acids and therefore should be left in contact with them over as short a period as possible and at a low temperature. The yield was 37%; m. p. 186–187.5°.

Anal. Subs., 0.2511: N_2, 30.00 cc. at 26° and 762.3 mm. Calcd. for $C_9H_8O_4N_2$: N, 13.46. Found: N, 13.53.

Ethyl-α-furfurylbarbituric Acid.—This is a new compound and was made in precisely the same manner as the substance just described above; yield, 51%; m. p. 144.5–145°.

Anal. Subs., 0.1168: N_2, 13.15 cc. at 23.6° and 760.1 mm. Calcd. for $C_{11}H_{12}O_4N_2$: N, 11.86. Found: N, 12.41.

α-Furfurylacetoacetic Ester.—This new substance was prepared by the usual acetoacetic ester condensation using specially dehydrated alcohol, the crude furfuryl chloride being added in a solution of dry ether. The product was purified by distillation in a vacuum; b. p. 111.0–111.5° at 4 mm.; yield, 61%; d^{20}_{20} 1.10562; d^{20}_{4} 1.10366; n^{20}_{D} 1.4718; M_D (calcd.) 53.172; M_D (obs.) 53.290.

Anal. Subs., 0.1993: CO_2, 0.4556; H_2O, 0.1193. Calcd. for $C_{11}H_{14}O_4$: C, 62.83; H, 6.71. Found: C, 62.34; H, 6.70.

2-α-Furfurylacetic Acid (3-α-Furylpropanoic Acid).—Baeyer[6] and also Marckwald[7] made this acid by first carrying out a Perkin's synthesis on furfural, yielding furfurylacrylic acid, which was then reduced. They give the melting point as 50–51°. Marckwald[8] also obtained it by preparing furfurylmalonic acid, which was heated and thus made to lose carbon dioxide. Sandelin[9] prepared furfuralmalonic ester, which was converted to furylsuccinic acid; this on loss of carbon dioxide yielded the furfurylacetic acid. He gave the melting point as 58.5°.

We obtained this acid by the usual acid splitting of the acetoacetic ester using very concentrated alkali for the hydrolysis according to the conditions given by v. Euler and Ölander.[10] We obtained in this way a 75% yield of crude product which was twice recrystallized from water; m. p. 56.5–58°.

α-Furfurylacetone (1-α-Furylbutanone-3).—This substance has been made by carrying out a Claisen condensation between furfural and acetone, yielding furfuralacetone, which on reduction with sodium amalgam gives the saturated ketone.[11] We obtained the ketone as a by-product in the acid splitting of the acetoacetic ester;

yield of crude product, 12%. It was converted into the semicarbazone which melted at 140–141°. Harries gave the melting point as 143".

a-Furfuryl Nitrile.—This is a new compound. It was prepared by treating a very concentrated aqueous solution of sodium cyanide dropwise with furfuryl chloride, the mixture being heated to about 70°. When the addition was complete, the mixture was heated just to the boiling point and cooled. Two layers separated. The oily layer was removed, the aqueous solution extracted with ether and the combined layers dried over anhydrous sodium sulfate. The crude yield was 90%. It was found difficult to obtain the compound in a pure state. Four systematic vacuum fractionations were carried out, yielding a colorless liquid possessing a very sweet odor; b. p. 74–75" at 27 mm.; d_{20}^{20} 1.04813; d_4^{20} 1.04627; n_D^{20} 1.4833; M_D (calcd.) 30.571; M_D (obs) 29.236.

Anal. Subs., 0.1528: N_2, 16.82 cc. at 765.3 mm. and 25". Calcd. for C_6H_5ON: N, 13.08. Found: N, 12.57.

a-Furylacetic Acid.—This new acid was obtained by hydrolyzing the above nitrile using a 25% solution of potassium hydroxide. The hydrolysis went rapidly after heating the mixture for only four to five minutes, the oily layer disappearing; heating was continued for one hour. The alkaline solution was extracted with ether to remove unhydrolyzed impurities, then cooled to 10°, decolorized and filtered. The filtrate was treated with excess concentrated hydrochloric acid; crystallization of the acid started immediately on cooling; yield, 43%; m. p. 108.5–109.5".

Anal. Subs., 0.1813: CO_2, 0.3802; I-120, 0.0776. Calcd for $C_6H_6O_3$: C, 57 13; H, 4.80. Found: C, 57.19; H, 4.79.

α-Furfuryl Thiocyanate.—This new substance was prepared by treating furfuryl chloride with sodium thiocyanate in acetone solution, a method suggested by the work of Steinkopf, Herold and Stöhr.[12] Sodium chloride precipitated immediately and the mixture was refluxed for two and one-half hours and allowed to stand overnight. The product was isolated by filtering, adding water, extracting with ether and then drying the ethereal solution over anhydrous sodium sulfate Distillation in a vacuum yielded a colorless oil boiling at 111.5–112.5° at 27 mm.; yield, 70%; b. p. (2 mm.) 66–67'; d_{20}^{20} 1.18919; d_4^{20} 1.18709; n_D^{20} 1.5614; M_D (calcd. as RSCN) 36 083; M_D (obs.) 37.971.

Anal. Subs., 0.1998: $BaSO_4$, 0.3350. Calcd. for C_6H_5OSN: S, 23.04. Found: S. 23.03.

α-Furfuryl Mercaptan.—The only previous preparation of this compound which could be found in the literature was given in a patent issued to Staudinger and Reichstein.[13] Since only the abstract was available no details of the preparation could be learned except that furfural was converted into *bis*-furfuryl disulfide by treatment of furfural with ammonium hydrosulfide which was then reduced to the mercaptan. No physical properties of the compound were given.

The first synthesis attempted was the treatment of furfuryl chloride with sodium hydrosulfide; this was unsuccessful. The mercaptan was finally obtained by first condensing furfuryl chloride with thiourea and then hydrolyzing this product, without isolating it, to the mercaptan. After hydrolysis the mercaptan was extracted with carbon tetrachloride and dried. After removal of the solvent the product distilled very uniformly at 84° at 65 mm. It was a colorless oil with the usual penetrating mercaptan odor; yield, 33%; d_{20}^{20} 1.13386; d_4^{20} 1.13186; n_D^{20} 1.5329; M_D (calcd.) 31.489; M_D (obs.) 31.302.

Anal. Subs., 0.2045: $BaSO_4$, 0.4203. Calcd. for C_5H_6OS: S, 28.09. Found: S, 28.23.

α-**Furfuryl Ethyl Sulfide.**—The furfuryl mercaptan was converted into the previously unknown sulfide by treatment of its sodium derivative with ethyl bromide in alcoholic solution. Sodium bromide precipitated immediately and the reaction mixture was heated on a stearn-bath for one hour. On cooling the solution was decanted from the sodium bromide and after extraction of the sodium bromide with ether the solution and extract were distilled and the residue was fractionated in vacuum. The product, a colorless liquid of pungent odor, boiled at 90.5–91° at 28 mm.; yield, 80%; d_{20}^{20} 1.05144; d_4^{20} 1.04958; n_D^{20} 1.5140; M_D (calcd.) 41.005; M_D (obs.) 40.773.

Anal. Subs., 0.1983: $BaSO_4$, 0.3379. Calcd. for $C_7H_{10}OS$: S, 22.55. Found: S, 23.40.

Summary

1. By using a-furfuryl chloride as the starting material, the following new substances have been prepared: ethyl-a-furfurylmalonic ester, ethyl-a-furfurylbarbituric acid, a-furfurylacetoacetic ester, a-furfuryl nitrile, a-furylacetic acid, a-furfuryl thiocyanate and a-furfuryl ethyl sulfide.

2. The following substances, which had previously been prepared by indirect methods starting with furfural, have now been directly synthesized from a-furfuryl chloride: a-furfurylmalonic ester, a-furfurylbarbituric acid, 2-a-furfurylacetic acid, α-furfurylacetone and its semicarbazone and a-furfuryl mercaptan.

3. Ethyl-a-furfurylbarbituric acid has possibilities as an hypnotic. Its physiological activity is being studied and will be published later. It is expected that this study will yield some information concerning the effect of the a-furfuryl group upon physiological action.

PARA-CYMENE STUDIES. XIII. PARA-CYMYLHYDRAZINE-2 AND DERIVATIVES[1]

BY ALVIN S. WHEELER AND CHARLES L. THOMAS

RECEIVED JUNE 8, 1929 PUBLISHED OCTOBER 5, 1929

Phenylhydrazine is widely used in the identification of aldehydes and ketones. A limited number of its homologs have been prepared but phenylhydrazine remains the most available from the cost standpoint. The tolylhydrazines should follow and then cymylhydrazine. The latter compound seems to have been made so far in only one investigation.[2] It was not analyzed and a wide fraction, boiling at 110–120° at 1.5 mm., was taken as cymylhydrazine. The authors prepared the hydrochloride, the acetate and the hydrazones of glucose, mannose and galactose. The cymylhydra-

[1] This paper is an abstract of a thesis submitted by Charles L. Thomas in partial fulfilment of the requirements for the degree of Master of Science at the University of North Carolina in June, 1929.

[2] Kremers and Demonbreun, *J. Am.* Pharm. *Assocn.*, 12, 589 (1923).

zine was made by diazotizing 2-aminocymene with ethyl nitrite and reducing the diazo compound with stannous chloride. They found that when sodium nitrite was used a reddish brown tar was obtained. We used sodium nitrite, however, with very satisfactory results, but used sodium sulfite[3] instead of stannous chloride as reducing agent. Sometimes a tar was obtained but by boiling this with concd. hydrochloric acid it was partly converted into cymylhydrazine hydrochloride.

Not all condensation products of cymylhydrazine are stable. Kremers and Demonbreun could not isolate any product of the action of benzaldehyde or furfural. If obtained, it decomposed as soon as separated from the reaction mixture. The authors attributed these results to the steric hindrance of the *iso*propyl group. In our own work we failed to get a product with methyl ethyl ketone, acetophenone or benzaldehyde sufficiently pure for a good analysis. A peculiar reaction, as yet unexplained, was noted with carbon disulfide. Analysis gave exact figures for a ratio of two atoms of nitrogen for each atom of sulfur.

We prepared the hydrochloride, hydrobromide, sulfate and picrate of cymylhydrazine and condensations with benzophenone, salicylaldehyde and cinnamic aldehyde. The semicarbazide and thiosemicarbazide were readily made, also the *p*-nitrobenzoyl derivative. The product obtained from benzoyl chloride was amorphous and contained chlorine. No products were obtained by the action of methyl nonyl ketone, thionyl chloride, Michler's ketone and benzoylacetone.

Experimental

***p*-Cymylhydrazine-2,** $C_{10}H_{13}NHNH_2$.—Sixty cc. of 2-aminocymene (0.4 mole) was added with stirring to 88 cc. of concd. hydrochloric acid cooled by a freezing mixture; 100 g. of ice was then added and the stirring continued until a thick paste resulted. A solution of 33 g. of sodium nitrite in 75 cc. of water was added slowly, with ice also to keep the temperature around 0°. More sodium nitrite was added if complete solution did not take place. It is best to keep the temperature below 5° to prevent the formation of a green scum. The diazo solution was then poured rapidly with stirring into a freshly prepared solution of sodium sulfite, cooled to 5°. The sodium sulfite solution was prepared by dissolving 89 g. of sodium hydroxide in 600 cc. of water and passing in sulfur dioxide until the solution was slightly acid to phenolphthalein. After the diazo solution has been added to the sulfite solution it should be reddish-orange in color. The flask, which then contained 1 to 1.5 liters of solution, was heated on a hot-plate to 80–90° for one and one-half hours. The color darkened somewhat. Hydrochloric acid was then added until the odor of sulfur dioxide was distinctly noticeable. The heating was then continued for ten hours. The solution became a light yellow. After the period of ten hours a sample of about 10 cc. was removed and an equal volume of concd. hydrochloric acid added. If a reddish-brown tar separated, the heating was continued. If crystals were formed, the reaction was complete. The solution was cooled and 300 cc. of concd, hydrochloric acid added. The crystals obtained were dried

---

[3] G. H. Coleman, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1922, Vol. II, p. 71.

and weighed; 58 g. or 72.5% of the theoretical yield. The crude product usually melts about 189°. It may be purified by boiling the aqueous solution with charcoal and reprecipitating with hydrochloric acid. Slow crystallization yields long white needles melting at 198°. This salt was prepared by Kremers and Demonbreun but they gave 186-187° as the melting point. On analysis we found for HCl, 17.95; calcd., 18.18. The free base was obtained by neutralizing the salt with sodium hydroxide, extracting with ether, drying and distilling at 5 mm. The fraction boiling from 129 to 132° was used for the determination of the constants. The drops of liquid at the top of the condenser appeared colorless but those falling into the receiver already had a slight yellow color. The liquid on standing in the dark slowly deepens in color. One preparation became cherry-red in the dark and sunlight brought the yellow color back. Cymylhydrazine is odorless and dissolves as completely in 50% acetic acid as phenylhydrazine. It melts at 26.5" and boils at 129–132" at 5 mm. Its density is d_{28}^{28} 0.9863; index of refraction at 25°, 1.5551. In the solid state it takes the form of long yellow needles.

Anal. Calcd. for $C_{10}H_{16}N_2$: N, 17.07. Found: N, 16.70.

Salts

Hydrobromide, $C_{10}H_{16}N_2 \cdot HBr$.—Long white needles, melting at 174°.

Anal. Calcd. for HBr: 33.05. Found: HBr, 33.00.

Sulfate, $C_{10}H_{16}N_2 \cdot H_2SO_4$.—Sulfuric acid of 1:1 strength was used. The last traces of acid were difficult to get rid of and the color was always slightly brown; small scales, melting at 130°.

Anal. Calcd. for H_2SO_4: 37.40. Found: H_2SO_4, 37.10.

Picrate, $C_{10}H_{16}N_2 \cdot C_6H_2OH(NO_2)_3$.—To a solution of 2 g. of the hydrochloride in 25 cc. of alcohol was added 2.3 g. of picric acid dissolved in the least possible amount of water. After several days the picrate separated out in long yellow needles. These decompose suddenly at 124°.

Anal. Calcd. for $C_{16}H_{19}O_7N_5$: N, 17.80. Found: N, 17.83.

Hydrazones

Cinnamylaldehyde-*p*-cymylhydrazone-2, $C_{10}H_{13}NHN{=}CHCH{=}CHC_6H_5$.—Equimolecular amounts of cinnamylaldehyde and cymylhydrazine were mixed. A noticeable rise in temperature took place and a yellow solid separated. The yield may be increased by heating for a short time on the water-bath. The product was recrystallized from dilute alcohol as thick picric yellow needles melting at 90°. The product is quite stable, for it turns brown only after standing about two months.

Anal. Calcd. for $C_{19}H_{22}N_2$: N, 10.08. Found: N, 9.88.

Salicylaldehyde-*p*-cymylhydrazone-2, $C_{10}H_{13}NHN{=}CHC_6H_4OH$.—Equal volumes of the components were mixed and heated for an hour on the water-bath. On cooling a mass of crystals separated. They crystallized from dilute alcohol in yellow needles melting at 87°. No signs of decomposition were visible after three months.

Anal. Calcd. for $C_{17}H_{20}ON_2$: N, 10.41. Found: N, 10.28.

Benzophenone-*p*-cymylhydrazone-2, $C_{10}H_{13}NHN{=}C(C_6H_5)_2$.—This compound could not be prepared by heating the components together. It was made by dissolving 2 g. of cymylhydrazine hydrochloride and 2 g. of benzophenone in 50 cc. of alcohol, adding a little sodium acetate and heating under a reflux for six hours. Upon cooling and adding water an oil separated. On standing for several days it turned red and red needles separated. The crystals came out of dilute alcohol in needles which were slightly brown, melting at 88°. No change in color occurred in two months.

Anal. Calcd. for $C_{23}H_{24}N_2$: N, 8.54. Found: N, 8.47.

Other **Hydrazones.**—A reaction was obtained with methyl ethyl ketone, the product consisting of plates, slightly brown, melting at 57°. It is unstable and the percentage found for nitrogen was 1.2 low. Acetophenone gave a product, consisting of mustard-yellow needles, melting at 84°. This was also unstable and the percentage for nitrogen was 1.2 low. The reaction with benzaldehyde gave an oil sometimes and again crystals which were light yellow leaflets. This product begins to decompose before it is dry. The crystals are exceedingly thin and give a fine display of interference colors.

Semicarbazides

p-Cymyl-1-semicarbazide-2, $C_{10}H_{13}NHNHCONH_2$.—Three g. of urea was added to 4 cc. of cymylhydrazine. Upon heating the urea melted and formed a layer underneath the hydrazine. Heating was continued until the two layers united. Upon cooling crystals separated. These were recrystallized from dilute alcohol, filtered and washed with water and ether, giving fine snow-white plates melting at 171°.

Anal. Calcd. for $C_{11}H_{17}ON_3$: N, 20.30. Found: N, 20.20.

p-Cymyl-1-thiosemicarbazide-2, $C_{10}H_{13}NHNHCSNH_2$.—An attempt to prepare this compound by heating the hydrazine with thiourea proved a failure. It was made by dissolving 3 cc. of cymylhydrazine in 10 cc. of glacial acetic acid and adding an excess of potassium thiocyanate. The mixture was warmed until complete solution took place. It was then cooled and poured into water. The solid product was recrystallized from dilute alcohol as flat white plates melting at 184". It turns slightly brown on standing.

Anal. Calcd. for $C_{11}H_{17}SN_3$: N, 18.84; S, 14.35. Found: N, 18.26; S, 14.28

Other Reactions

p-Nitrobenzoyl-p-cymylhydrazine-2, $C_{10}H_{13}NHNHCOC_6H_4NO_2$.—An attempt was made to prepare this compound by treating a mixture of cyrnylhydrazine hydrochloride and p-nitrobenzoyl chloride with sodium hydroxide, but no product could be isolated. It was then found that cymylhydrazine and nitrobenzoyl chloride unite in benzene solution without the evolution of hydrochloric acid gas to give a light yellow crystalline compound. It contained hydrochloric acid and melted at 160°. If sodium hydroxide and dilute alcohol are added to the product, the liquid becomes deep purplish-brown. If the mixture is heated until all of the solid goes into solution and then is neutralized with acid, a precipitate is thrown down. This was recrystallized from dilute alcohol, forming long yellow needles melting at 177".

Anal. Calcd. for $C_{13}H_{19}O_3N_3$: N, 13.41. Found: N, 13.16.

Reaction with Carbon **Disulfide.**—Two volumes of the hydrazine were mixed with five volumes of carbon disulfide and heated on the water-bath for an hour. Hydrogen sulfide was evolved and a deep yellow to green precipitate formed. Upon cooling the substance turned to a transparent resin. This was covered with much petroleum ether and worked with a glass rod. The resin turned to a mass of small white crystals which melted at 177°.

Anal. Found: *N*, 18.75; S, 21.25. These results indicate two atoms of nitrogen for one of sulfur.

Summary

1. p-Cymylhydrazine-2 was prepared by diazotizing 2-arninocyrnene and reducing the product with sodium sulfite. The hydrochloride, hydrobromide, sulfate and picrate were made.

2. Cymylhydrazones of cinnamylaldehyde, salicylaldehyde and benzophenone were made. The hydrazones of methyl ethyl ketone, acetophenone and benzaldehyde were found to be unstable.
3. p-Cymyl-1-semicarbazide-2 and *p*-cymyl-1-thiosemicarbazide-2 were prepared.
4. A p-nitrobenzoyl derivative was prepared.
5. Cymylhydrazine reacts with carbon disulfide to give a product whose nature was not solved.

SEQUOYITE, A CYCLOSE FROM REDWOOD (SEQUOIA SEMPERVIRENS)

BY E. C. SHERRARD[1] AND E. F. KURTH[2]

RECEIVED JUNE 10, 1929 PUBLISHED OCTOBER 5, 1929

In a recent paper[3] we reported the isolation of a new cyclose which occurs with pinite in the cold-water extract of the heartwood of redwood. First analyses indicated that the new compound might have the empirical formula $C_8H_{16}O_7$, but later analyses upon purer and larger amounts of the material proved that it is a monomethyl ether of *i*-inosite and is isomeric with pinite, bornesite and quebrachite. The present paper describes the details of isolation, the experimental results that convinced us of its structural formula and the preparation of some of its derivatives.

Sequoyite, as we have named it, was isolated from the aqueous extract of redwood in a manner similar to that employed for pinite. The two cycloses crystallized out together upon the addition of alcohol to the thick, concentrated extract. They were separated from each other by fractional crystallization; sequoyite, being less soluble in either alcohol or water, crystallized readily from a 50% alcoholic solution, while the pinite crystallized slowly from a 70% solution.

The impure sequoyite crystals were purified by warming with a small amount of barium hydroxide, then filtering off the precipitated gums and coloring matter and acidifying the filtrate with sulfuric acid to remove the excess barium. The solution that remained after filtering off the barium sulfate was nearly colorless. The new cyclose was obtained from this solution by concentrating it to a thin sirup and then diluting it with

[2] Junior Chemist, U. S. Forest Products Laboratory, Forest Service, Madison, Wisconsin.

[3] Sherrard and Kurth, *Ind. Eng. Chem.*, **20**, 722 (1928).

alcohol. The crystals were finally obtained in the pure state after recrystallization from alcohol and water.

The yield on the basis of the weight of the oven-dried heartwood varied from traces to 0.06%.

When pure, sequoyite crystallizes from alcohol and water in small transparent prisms which melt at 234–235° (uncorr.) and sublime at temperatures above this. It has a sweet taste, is readily soluble in water, is only slightly soluble in hot alcohol and is insoluble in ether, benzene or carbon tetrachloride. It is optically inactive, does not reduce Fehling's reagent, gives no precipitate with phenylhydrazine and is not affected by dilute acids or alkalies. When heated with nitric acid it is oxidized to oxalic acid. In cold, concentrated sulfuric acid it dissolves slowly without charring. It is not affected by acetic anhydride at room temperature.

Anal. Calcd. for $C_7H_{14}O_6$: C, **43.27; H, 7.27.** Found: C, **43.11, 43.31, 43.20;** H, **7.24, 7.30, 7.28.** Calcd. for $C_6H_{11}O_5OCH_3$: OCH_3, **15.9.** Found: OCH_3, **14.87, 15.3, 16.4.** Determination of the molecular weight by cryoscopic methods gave **188** and **197.**

Sequoyite Pentacetate.—The new cyclose was acetylated by boiling 1 g. of the pure crystals with an equal weight of anhydrous sodium acetate and **15** cc. of acetic anhydride for one hour in an oil-bath. Upon adding water to the cooled reaction mixture, the pentacetate separated out. It was recrystallized from hot alcohol.

Sequoyite pentacetate is obtained from hot alcohol in small, needle-like crystals which melt at 198° (uncorr.) and sublime at temperatures above this. It is also soluble in ether and is insoluble in water.

Anal. Calcd. for $C_6H_6(O_2C_2H_3)_5OCH_3$: **C, 50.47;** H, **5.98;** CH_3CO, **53.22.** Found: **C, 50.26, 50.50; H, 5.86, 5.82;** CH_3CO, **52.62, 52.78,** 52.60.

The percentage of acetyl was determined by hydrolyzing the pentacetate with sodium hydroxide and also with barium hydroxide.

In hydrolyzing with sodium hydroxide, the acetylated compound was boiled for one-half hour with an excess of the $N/10$ alkali. It was then rapidly cooled, phenolphthalein was added and the amount of alkali required for hydrolysis was determined by titrating with standard acid.

In the barium hydroxide method the acetylated compound was boiled for two and a half hours in a reflux apparatus using a **1:1** solution of methyl alcohol and water as a solvent. The product was filtered, the filtrate was treated with carbonic anhydride in excess, was again filtered and the final filtrate was then evaporated. The residue was dissolved in water, the liquid was Ntered and the barium in the filtrate was determined as sulfate. The original sequoyite was recovered by this method and retained a melting point of **235".**

From the hydriodic acid residue remaining from the methoxyl determinations, inactive inosite was obtained. It is formed when sequoyite is heated with hydriodic acid, reacting in accordance with the following equation:

$$C_6H_6(OH)_5OCH_3 + HI = C_6H_6(OH)_6 + CH_3I$$

It was separated from the reaction mixture by evaporating off the hydriodic acid in a steam-bath, dissolving the residue in a small amount of warm water and precipitating with alcohol. When recrystallized from alcohol and water it melted at 224° (corr.). The hexacetate derivative was prepared and it melted at 215° (corr.).

When 1.0688 g. of sequoyite was heated with hydriodic acid in a small distilling flask, 0.9192 g. or 86.0% of the sequoyite was recovered as i-inosite and a sufficient amount of the methyl iodide was collected for a boiling-point determination. It boiled between 43 and 44°. A maximum yield of 93.1% of the theoretical amount of i-inosite or 89.4% of the weight of the sequoyite was obtained from a hydriodic acid residue remaining from a methoxyl determination.

A careful investigation of the chemical literature indicates that no compound with the properties here described has been previously reported. We are therefore convinced that we have isolated a new cyclose. Since methyl iodide and *i*-inosite are the only decomposition products obtained and since they are obtained in the proportion corresponding to a compound having the molecular formula $C_6H_6(OH)_5OCH_3$, sequoyite must be a monomethyl ether of inactive inosite.

Summary

1. The isolation of a new cyclose from the heartwood of redwood has been described.

2. Experimental results show that this compound is a monomethyl ether of i-inosite.

3. Upon heating with hydriodic acid, two decomposition products are obtained and have been identified as methyl iodide and i-inosite.

4. The pentacetate derivative has been prepared and described.

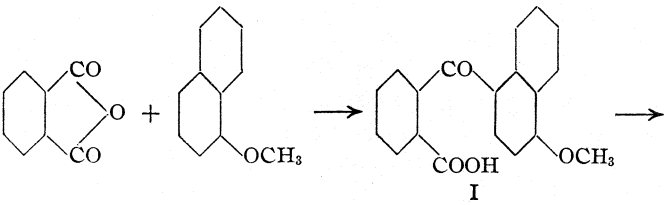
1,2-BENZ-3,4-ANTHRAQUINONE

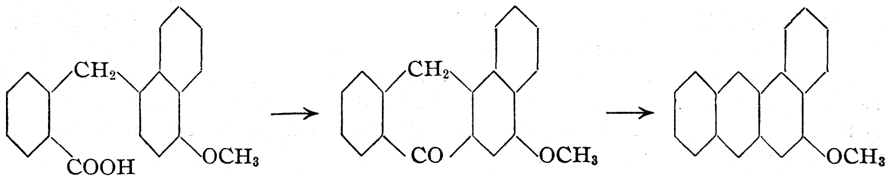
BY LOUIS F. FIESER AND EMMA M. DIETZ

RECEIVED JUNE 10, 1929 PUBLISHED OCTOBER 5, 1929

In connection with a study of the reduction potentials of some of the higher benzologues of anthraquinone and phenanthrenequinone, we became interested in securing the compound named in the title. A suitable method of preparing the quinone was found in the oxidation of 4-amino-3-hydroxy-1,2-benzanthracene, which, in turn, was obtained from 3-hydroxy-1,2-benzanthracene.

The synthesis of the methyl ether of 3-hydroxy-1,2-benzanthracene, IV, was accomplished in the following manner





II III IV

2-(4'-Methoxy-naphthoyl-1')-benzoic acid, I, has been described by Scholl, Seer and Zincke,[1] and the structure which they assumed for the acid is established by the present work. By using tetrachloro-ethane rather than nitrobenzene as the solvent in carrying out the Friedel and Crafts reaction, their method of preparation became easily applicable to quantity production. While the keto-acid, I, failed to condense easily to give an anthraquinone, the condensation of the reduction product, II, to the anthrone, III, was accomplished readily by dissolution in cold, concentrated sulfuric acid. 3-Methoxy-1,2-benz-10-anthrone, III, is a rather unstable compound and it was isolated only in the form of the acetyl derivative of the enol modification. It was reduced to 3-methoxy-1,2-benzanthracene, IV, with aluminum amalgam and ammonia in alcoholic suspension, according to the general method of Hall and Perkin.[2] Owing to side reactions, the yield was only about 55%.

On hydrolysis of the ether with a hydrobromic acid–glacial acetic acid mixture, 3-hydroxy-1,2-benzanthracene (V) was obtained. This phenol, which was characterized by the preparation of a number of derivatives, is only very sparingly soluble in alkali and it failed to couple with diazotized sulfanilic acid under a variety of conditions. An azo compound was obtained only by the use of the method which Meyer, Irschick and Schlosser developed for carrying out the coupling reaction with phenol ethers.[3] By the interaction of 3-hydroxy-1,2-benzanthracene and *p*-nitrobenzene diazonium sulfate in glacial acetic acid solution the dyestuff, VI, was produced without difficulty. Being only very sparingly soluble in organic solvents or in alkali, the dyestuff is not easily reduced by the usual methods, but a satisfactory means of preparing the amine, VII, was found in the re-

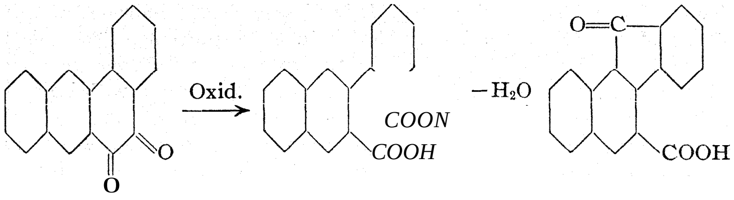
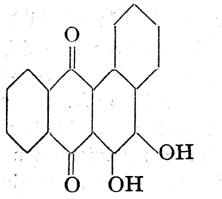
duction of the azo compound with stannous chloride in a boiling butyl alcoholic suspension.

The hydrochloride of 4-amino-3-hydroxy-1,2-benzanthracene yielded 1,2-benz-3,4-anthraquinone, VIII, on oxidation in glacial acetic acid solution. The quinone crystallizes in bright red needles and forms a bisulfite addition product. It was converted by oxidation with hydrogen peroxide in glacial acetic acid solution into a substance having the properties of a diphenic acid derivative. This acid, to which the structure of 4,5-benzodiphenyl-2,2′-dicarboxylic acid, IX, may be assigned, was condensed by the action of concentrated sulfuric acid to a yellow fluorenone-carboxylic acid which probably has the structure of X, though the structure of 2,3-benzofluorenone-5-carboxylic acid is also possible. These facts indicate that the quinone in question is of the ortho type and similar to 9,10-phenanthrenequinone, hence that it has the structure of VIII.



VIII IX X

The structure of the hydroxybenzanthracene, V, is fixed by the method of synthesis and the structure of the above ortho-quinone; but the following independent evidence also may be cited. By the reductive acetylation of 1,2-benz-3,4-anthraquinone, followed by oxidation and by hydrolysis of the oxidation product, there was obtained the dihydroxy-1,2-benz-9,10-anthraquinone, XI. The compound gives an intense coloration with Dimroth's boro-acetic anhydride reagent,[4] showing that one hydroxyl group is adjacent to a quinonoid carbonyl group. The second hydroxyl group must be ortho to the first, for the hydroxybenzanthracene couples in the ortho position, as shown by the formation of an oxazole derivative, XII, from 4-amino-3-hydroxy-1,2-benzanthracene. The dihydroxyquinone, XI, could be formed from either 3- or 4-hydroxy-1,2-benzanthracene, but the latter possibility is excluded by the fact that the monohydroxy-1,2-



XI

benz-9,10-anthraquinone (XIII), prepared by the oxidation of the acetyl derivative and the hydrolysis of the oxidation product, gives a negative result in the Dimroth test.

Experimental Part

2-(4'-Methoxynaphthoyl-1')-benzoic Acid (I).—To a solution of 78 g. of α-methoxynaphthalene and 78 g. of phthalic anhydride in 400 cc. of tetrachloro-ethane there was added 150 g. of powdered aluminum chloride in three portions. The mixture was stirred mechanically at room temperature for twelve hours and allowed to stand for an equal period of time. The dark addition product was decomposed with ice and hydrochloric acid and the solvent was removed by steam distillation. This operation was completed in a small fraction of the time required when nitrobenzene was employed as the solvent. The granular, brown residue was dissolved in the requisite quantity of hot sodium carbonate solution, the solution was treated with animal charcoal and then 50 cc. of 6 *N* sodium hydroxide solution was added. The sodium salt of the acid separated from the cooled solution in the form of colorless crystals. When washed with sodium chloride solution and dried, the product contained a small quantity of sodium chloride but it was otherwise pure and the salt was well suited for carrying out the following reaction; yield, 147 g. (91%). The acid obtained from this sodium salt melted at 196–197° (Scholl, Seer and Zincke, 193–194°).

(4-Methoxynaphthyl-1)-phenylmethane-2′-carboxylic Acid (II).—A solution of 86 g. of the sodium salt of 2-(4'-methoxynaphthoyl-1')-benzoic acid and 104 g. of sodium hydroxide in 1.5 liters of water was treated with 145 g. of zinc dust and the mixture was heated so as to maintain a lively evolution of gas for ten hours. The hot solution was filtered, the zinc was extracted with several portions of boiling water and 50 cc. of 6 N sodium hydroxide was added to the filtrate. The sodium salt often separated in an oily condition but it soon crystallized. The material was washed with sodium chloride solution, dissolved in water and converted into the free acid. Prepared by precipitation, the acid was not easily collected by filtration until it had been coagulated somewhat by heating the mixture to the boiling point. A colorless product melting at 215–219° and requiring no further purification was obtained; yield, 75 g. (91%).

The acid dissolves readily in alcohol, benzene or glacial acetic acid. It forms colorless plates melting at 217–219° (221–223°, corr.).

Anal.[5] Calcd. for $C_{19}H_{16}O_3$: C, 78.07; H, 5.52. Found: C, 78.01; H, 5.62.

3-Methoxy-1,2-benz-10-anthrone (III).—The above acid dissolves in cold, concentrated sulfuric acid to give a deep red solution and ring closure takes place without side reactions. Twenty grams of the powdered acid was stirred into 220 cc. of concentrated sulfuric acid at 20° and after forty-five minutes the solution was slowly poured into 1.2 liters of a well-stirred mixture of ice and water. This precipitated a finely divided, pale yellow product which was collected and washed with dilute ammonia solution. The anthrone is very sensitive to heat and to oxygen, particularly when in solution, and it was not purified for analysis. A glacial acetic acid solutioa rapidly turned dark green and deposited a brown, amorphous material while still well below the boiling point. The anthrone dissolves readily in alcohol or benzene, but the solutions darken rapidly; it dissolves slowly in alkali.

For purposes of identification the acetyl derivative of the anthranol form was prepared by boiling for a short time a solution of 0.7 g. of the anthrone in 3 cc. of pyridine and 5 cc. of acetic anhydride. The product, crystallized from benzene–ligroin and from alcohol, formed colorless needles melting at 194° (197' corr.).

---

[5] The Dennstedt platinum contact star was employed in carrying out all of the analyses reported.

Anal. Calcd. for $C_{21}H_{16}O_3$: C, 79.72, H, 5.10. Found: C, 79.76; H, 5.14.

3-Methoxy-1,2-benzanthracene (IV).—The reduction of the anthrone was carried out in alcoholic suspension with aluminum amalgam and ammonia, a method employed extensively by Hall and Perkin.[2] In the present case the reaction is difficult to control and the formation of by-products greatly decreases the yield. It was found advisable to work with no more than 20 g. of material at one time and to prepare the amalgam very carefully, according to the directions of Wislicenus.[6] Twenty grams of aluminum turnings was etched with 10% sodium hydroxide, washed with water, shaken for one-half minute with a 0.5% mercuric chloride solution, washed again, and the whole process was repeated, The resulting amalgam was added to 960 cc. of alcohol and the mixture was heated to obtain a lively gas evolution. The cake of moist anthrone obtained as above from 20 g. of (4-methoxynaphthyl-1)-phenylmethane-2′-carboxylic acid was broken into large pieces and introduced into the mixture. Sixty cc. of concentrated ammonia solution was then added gradually. The mixture was boiled under the reflux condenser for four hours, 30 cc. of ammonia solution and the amalgam from 10 g. of aluminum being added after the second and third hours. The light yellow solution rapidly became deep red and later pale yellow or pink, while much aluminum hydroxide separated. At the end of the reaction the liquid was decanted, treated with 250 cc. of concentrated hydrochloric acid and heated to the boiling point in order to dissolve the hydroxide, which otherwise occludes much material. An equal volume of water was added, the solution was cooled and the material which separated was collected and again digested with hydrochloric acid. The dried residue (17 g.) contained some inorganic material. It was extracted twice with benzene and the well-concentrated, dark red solution deposited 10 g. of straw-colored needles, m. p. 165–167°.

3-Methoxy-1,2-benzanthracene is very soluble in benzene or chloroform, moderately soluble in alcohol or glacial acetic acid, and the solution in the latter solvent has a violet fluorescence. The pure material forms colorless needles melting at 167–168°.

Anal. Calcd. for $C_{19}H_{14}O$: C, 88.34; H, 5.47. Found: C, 88.03; H, 5.47.

When the preparation was carried out exactly as described above, the yield was usually from 45 to 55% of the theoretical, though in two instances it rose to 65%. The results were much poorer (25%) when the mixture was stirred and when the anthrone was added in very small portions. In this instance it was possible to isolate a considerable quantity of a yellow by-product which melted at 272° and which was less soluble than 3-methoxy-1,2-benzanthracene. The yellow substance contains a higher percentage of oxygen than the original material and it is probably a dimolecular product. Traces of the substance were always present in the residue after extracting the main product with benzene.

3-Methoxy-1,2-benz-9,10-anthraquinone.—3-Methoxy-1,2-benzanthracene was oxidized in glacial acetic acid solution at 90° with chromic acid. The oxidation product, precipitated by the addition of water after one-half hour, was crystallized from methyl ethyl ketone and from benzene. It forms brown-red needles melting at 188.5°. It forms a red vat with alkaline hyposulfite solution, while the solution in concentrated sulfuric acid is intensely blue-green. The quinone is moderately soluble in benzene or glacial acetic acid and only slightly soluble in alcohol.

Anal. Calcd. for $C_{19}H_{12}O_3$: C, 79.13; H, 4.20. Found: C, 78.96; H, 4.19.

3-Hydroxy-1,2-benzanthracene (V).—The hydrolysis of 3-methoxy-1,2-benzanthracene was accomplished by the use of hydrobromic acid. Aluminum chloride had no effect in carbon disulfide solution and when heated with the solid material it caused decomposition. A hot, stirred solution of 33 g. of the ether in 1 liter of glacial acetic

---

[6] Wislicenus, *J. prakt. Chem.*, [2] **54**, 54 (1896).

acid was treated with 43 cc. of 40% hydrobromic acid and boiled for one and three-quarters hours. The color changed from yellow to dark green to red-brown and finally to a pale orange. On adding 50 cc. of water to the solution and cooling, 27.2 g. (87.5%) of nearly pure, greenish-yellow needles separated. Recrystallization from toluene removed a trace of green material and small, orange-yellow needles were obtained. The substance melts with decomposition at about 196–205° and imparts an orange color to the glass capillary. It is moderately soluble in toluene, less soluble in alcohol, and the sodium salt, which is yellow, is very sparingly soluble. The solutions darken on long heating, The material may be distilled at a reduced pressure without much decomposition if care is taken to avoid contact of the hot material with the air.

Anal. Calcd. for $C_{18}H_{12}O$: C, 88.50; H, 4.96. Found: C, 88.47; H, 4.81.

3-Acetoxy-1,2-benzanthracene.—Prepared by boiling a solution of the hydroxy compound in acetic anhydride for one hour, and crystallized from benzene and from benzene–ligroin, the acetate formed colorless needles melting at 129°.

Anal. Calcd. for $C_{20}H_{14}O_2$: C, 83 93; H, 4.93. Found: C, 83 67; H, 4.99.

3-Acetoxy-1,2-benz-9,10-anthraquinone.—The oxidation of the acetate with chromic acid in glacial acetic acid proceeded smoothly and in nearly quantitative yield when the solution was kept at a temperature of 70°. The quinone, which is moderately soluble in toluene or glacial acetic acid, formed small, yellow crystals melting at 232°.

Anal. Calcd. for $C_{20}H_{12}O_4$: C, 75.93; H, 3.83. Found: C, 76.13; H, 4.00.

3-Hydroxy-1,2-benz-9,10-anthraquinone (XIII) was prepared, but not purified for analysis, by warming the acetate with alcoholic alkali. The intensely purple solution which resulted deposited a light brown product on acidification. The quinone dissolves in concentrated sulfuric acid with an intense blue-green color; in pyridine it forms a dark orange-red solution; while the solution in boro-acetic anhydride is pale yellow. The alkali salts of the quinone dissolve with difficulty in water but give purple solutions in alcohol; the vat is orange.

4-Amino-3-hydroxy-1,2-benzanthracene (VII).—This compound was prepared in the form of the hydrochloride and analyzed as the triacetate. It was obtained from 3-hydroxy-1,2-benzanthracene by the formation and reduction of an azo dye. Attempts to couple this phenol with diazotized sulfanilic acid in aqueous or alcoholic suspension or in pyridine solution were unsuccessful, but it was found possible to prepare **4-(*p*-Nitrobenzene-azo)-3-hydroxy-1,2-benzanthracene (VI)** in the following manner. Sixteen and seven-tenths g. of p-nitro-aniline was converted into p-nitrobenzene diazonium sulfate as described by Meyer, Irschick and Schlosser[3] and dissolved in glacial acetic acid. On adding this solution to a well-stirred, cooled solution of 15 g. of 3-hydroxy-1,2-benzanthracene in 1250 cc. of glacial acetic acid, a dark red dyestuff separated immediately. On completion of the reaction the solution was diluted with water and the product was collected. The substance is insoluble in alkali and sparingly soluble in most organic solvents, It dissolves fairly readily in nitrobenzene but does not form good crystals suitable for analysis.

For the reduction of the dye it is advisable to use the moist material. The above product was suspended in 850 cc. of n-butyl alcohol containing 100 g. of stannous chloride and 200 cc. of concentrated hydrochloric acid. The mixture was stirred mechanically and heated at the boiling point for four to five hours, when all of the dye had dissolved to give a clear orange solution. On adding 150 cc. of concentrated hydrochloric acid and cooling, pale yellow crystals of the amine hydrochloride separated. A further quantity (3 g.) was obtained on concentrating the mother liquor in a vacuum; yield, 21 g. Dried at room temperature, the material contained some solvent, but only traces of tin. In solution the substance decomposes very easily in the absence of a reducing agent and an analytically pure sample was not obtained. It is sparingly soluble in water but soluble in alcohol. For purposes of characterization it was converted into the following derivatives.

Triacetate of 4-amino-3-hydroxy-1,2-benzanthracene.—This was prepared by boiling for one hour an acetic anhydride solution of equal parts of the amine hydrochloride and fused sodium acetate. The product was not homogeneous but the less soluble fraction yielded, after repeated crystallization, a substance crystallizing in colorless plates and melting constantly at 199-201° (203–205°, corr.). The compound is insoluble in acids or alkalies and dissolves readily in benzene or glacial acetic acid. It is converted by distillation into the oxazole derivative.

Anal. Calcd. for $C_{24}H_{19}O_4N$: C, 74.78; H, 4.97. Found: C, 74.27, 74.13; H, 5.13, 5.22.

Oxazole Derivative of 4-amino-3-hydroxy-1,2-benzanthracene (XII).—The crude product obtained on acetylating in the manner described above was distilled *in vacuo*. After the removal of acetic acid and anhydride, the oxazole distilled as a yellow oil which soon solidified. It is only moderately soluble in glacial acetic acid but it dissolves easily in benzene and separates in dusters of light yellow needles, m. p. 175.5".

Anal. Calcd. for $C_{20}H_{13}ON$: C, 84.78; H, 4.63. Found: C, 84.99, 85.05; H, 5.05, 5.00.

1,2-Benz-3,4-anthraquinone (VIII).—The 4-amino-3-hydroxy-1,2-benzanthracene obtained from 15 g. of 3-hydroxy-1,2-benzanthracene was largely dissolved in 670 cc. of glacial acetic acid, a solution of 5 g. of chromic anhydride was added at 100° and the temperature was held there for fifteen minutes. On adding water a dull red product was obtained. The quinone was extracted with toluene from some dark brown material, giving 8.1 g. of bright red needles. The yield from 3-hydroxy-1,2-benzanthracene was 57% of the theoretical.

The quinone is moderately soluble in toluene or glacial acetic acid, less soluble in benzene or alcohol. The solution in concentrated sulfuric acid is purple in color; in pyridine it is red-orange, The quinone dissolves slightly in hot concentrated bisulfite solution and precipitates on the addition of sodium carbonate. The pure material forms red needles melting with some decomposition at 254-255" (262–263°, corr.).

Anal. Calcd. for $C_{18}H_{10}O_2$: C, 83.70; H, 3.90. Found: C, 83.56; H, 3.79.

3,4-Diacetoxy-1,2-benzanthracene.—The quinone was reduced and acetylated by heating a mixture with equal parts of zinc dust and fused sodium acetate and with 10 parts of acetic anhydride for one-half minute, when the original dark green color was replaced by a clear orange. An equal volume of glacial acetic acid was added and the heating continued pntil all of the quinone had dissolved and the solution had lost all red color, but the heating was discontinued at the first sign of darkening. A pale yellow product was obtained on decanting into water. The substance dissolves readily in benzene and forms plates containing solvent of crystallization. From methyl alcohol, in which it is much less soluble, small, faintly pink needles were obtained. The solution in benzene has a marked blue fluorescence. The melting point is 197° (201°, corr.).

Anal. Calcd. for $C_{22}H_{16}O_4$: C, 76.72; H, 4.69. Found: C, 76.47; H, 4.69.

3,4-Diacetoxy-1,2-benz-9,10-anthraquinone.—The oxidation of the above diacetate was carried out with an equal weight of chromic anhydride in glacial acetic acid solution at 70°, the yield being nearly quantitative. The quinone crystallizes from benzene or glacial acetic acid in the form of small, yellow prisms melting at 198-199°.

Anal. Calcd. for $C_{22}H_{14}O_6$: C, 70.58; H, 3.77. Found: C, 70.75; H, 3.83.

On hydrolysis of the quinone with alcoholic alkali, **3,4-dihydroxy-1,2-benz-**

9,10-anthraquinone (XI) was obtained as a purplish black powder. The solutions of the quinone in organic solvents are red or purple. The color in concentrated sulfuric acid is an intense Prussian blue and in warm pyridine it is orange red. The alkaline solution is bluish green; the solution in acetic anhydride is pale red and in boro-acetic anhydride it is an intense chrome green. The structure of this dihydroxyquinone is a combination of those of alizarin and of 1,2-benzanthraquinone, both of which are valuable dyes; but the compound is too sparingly soluble in water to be applied to mordanted cloth and the greenish blue dyeing imparted to cotton on vatting is not fast to washing with soap.

4,5-Benzodiphenyl-2,2'-dicarboxylic Acid (IX).—This acid resulted from the oxidation of 1,2-benz-3,4-anthraquinone. A solution of 3 g. of the quinone in 300 cc. of glacial acetic acid was treated with 2 cc. of 30% hydrogen peroxide and the temperature was maintained at 90° for one hour, when the original red color had paled somewhat. After a second addition of peroxide, the solution was allowed to stand for ten hours and then it was concentrated to a small volume and diluted with water. A light brown oil separated and soon crystallized. After precipitation from a sodium carbonate solution, the material was crystallized from dilute methyl alcohol, when it formed slightly tan microcrystals melting at 246° (252°, corr.). The yield was 2.6 g.

Anal. Calcd. for $C_{18}H_{12}O_4$: C, 73.96; H, 4.14. Found: C, 74.08; H, 4.18.

1,2-Benzofluorenone-4-carboxylic Acid (X) (or 2,3-Benzofluorenone-5-carboxylic Acid).—A solution of 0.6 g. of 4,5-benzodiphenyl-2,2'-dicarboxylic acid in 50 cc. of concentrated sulfuric acid was allowed to stand for several hours; the dark green solution was then poured into water and the fine yellow precipitate was collected. The product appeared to be homogeneous. It dissolved readily in glacial acetic acid and the solutions tended to remain supersaturated. It crystallizes well from toluene, in which it is moderately soluble, forming slender, yellow needles melting at 261° (268°, corr.).

Anal. Calcd. for $C_{18}H_{10}O_3$: C, 78.83; H, 3.68. Found: C, 78.79; H, 3.90.

Summary

3-Methoxy-1,2-benzanthracene has been synthesized from phthalic anhydride and α-methoxynaphthalene and converted into 3-hydroxy-1,2-benzanthracene. The latter compound was converted, through the p-nitrobenzene-azo derivative, into the 4-amino derivative, which yielded 1,2-benz-3,4-anthraquinone on oxidation.

THE CONSTITUTION AND THE DISSOCIATION OF THE GRIGNARD REAGENT[1]

BY HENRY GILMAN AND ROBERT E. FOTHERGILL

RECEIVED JUNE 12, 1929 PUBLISHED OCTOBER 5, 1929

Introduction

It is possible to write a large number of formulas for the Grignard reagent prepared in ether. The so-called central element to which might be attached the largest number of other elements and groups can be magnesium (variously coordinated) or oxygen or a halogen. Or we might have combinations of two or more of such central atoms, and structures involving residual valences of carbon and even of hydrogen. Then there are electronic interpretations of the structure, which because of the polar characteristics of organomagnesium halides may have formal, classical bonds replaced by electrostatic forces after some representations of the structure of compounds like magnesium chloride.

If we omit the diethyl ether, which is not a ***necessary***[2] part of the molecule, it is possible to simplify matters considerably by restricting discussion arbitrarily to two formulas to which most attention has been directed recently.[3] These formulas are

$$\text{(A) } 2RMgX \text{ and } R_2Mg{\cdot}MgX_2 \text{ (B)}$$

One of several ways of deciding between these two formulas is to determine whether MgX_2 is an integral part of the Grignard reagent. Some light can be thrown on this by use of the very interesting recent studies of Gomberg and Bachmann[4] on the following equilibrium

$$MgI_2 + Mg \rightleftarrows 2MgI \qquad \text{(I)}$$

The magnesious halide formed in accordance with Reaction I can be characterized in a number of ways, particularly by its reaction with benzophenone to give benzopinacol

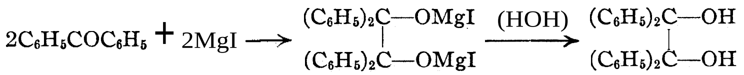
---

[1] An account of this work was read at the Spring Meeting of the American Chemical Society held at Columbus, Ohio, in April, 1929.

[2] It is possible to prepare RMgX compounds with no ether, and it is possible to remove all ether from RMgX compounds. These so-called "individual organomagnesium halides" show the general reactions of the corresponding compounds containing ether.

[3] It is out of the question, because of space limitations, to give a complete (even though uncritical) consideration of the large amount of work on the constitution of organomagnesium halides. Some leading references are Grignard, *Compt. rend.*, 130, 1322 (1900); 185, 507 (1927); Bull. *soc. chim.*, 41, 759 (1927); Jolibois, *Comfit. rend.*, 155, 353 (1912); Meisenheimer and co-workers, *Ber.*, 54, 1655 (1921); 61, 708, 720 (1928); Ivanoff, *Compt. rend.*, 185, 505 (1927); Terentieff, *Z. anorg. Chem.*, 156, 73 (1926); Kierzek, Bull. *soc. chim.*, 41, 1299 (1927); Schlenk and Schlenk, *Ber.*, 62, 923 (1929). A list of general references may be found in Footnote 3 on p. 748 of an article by Gilman, Fothergill and Parker, *Rec. trav. chim.*, 48, 748 (1929).

[4] Gomberg and Bachmann, THIS JOURNAL, 49, 236, 2584 (1927).



$$2C_6H_5COC_6H_5 + 2MgI \longrightarrow \begin{array}{l}(C_6H_5)_2C\text{—}OMgI \\ \quad | \\ (C_6H_5)_2C\text{—}OMgI\end{array} \xrightarrow{(HOH)} \begin{array}{l}(C_6H_5)_2C\text{—}OH \\ \quad | \\ (C_6H_5)_2C\text{—}OH\end{array} \qquad \text{(II)}$$

If the Grignard reagent has Formula B and if, also, the MgX_2 part of the molecule has an attachment to the rest of the molecule of a kind that will permit its reaction with magnesium to give magnesious halide (Reaction I), then on the addition to the Grignard reagent of one equivalent of magnesium and two equivalents of benzophenone, benzopinacol should result in equivalent quantities, together with a tertiary alcohol formed as follows

$$R_2Mg \text{ (or } RMgX) + (C_6H_5)_2CO \longrightarrow R(C_6H_5)_2COH \qquad \text{(III)}$$

The results reported at this time of several experiments made with typical organomagnesium halides show that the Grignard reagents are better represented by the RMgX formula. We do not mean by this that no benzopinacol was formed. Actually some benzopinacol was obtained in many of the reactions. This, of course, might have been predicted because the reaction between an RX compound and magnesium is not simple[5] and invariably leads to the formation of small (and in some cases large) quantities of MgX_2.[6] Obviously the presence of such MgX_2 compounds, formed incidentally to side reactions, would make it possible for benzopinacol to be formed in accordance with Reactions I and II. The quantity of benzopinacol formed in this way is apparently proportional to the quantity of MgX_2 formed. This was strikingly illustrated in two experiments carried out with *n*-butylmagnesium iodide. In one case the butyl iodide was added rapidly to the magnesium in ether, and in the other experiment it was added slowly. In the former case the yield of Grignard reagent is lower[6] because of the larger formation of magnesium iodide, and in agreement with this a greater quantity of benzopinacol was obtained in the experiment carried out with a more rapid addition of the butyl iodide.

Furthermore, no benzopinacol was obtained in the reactions involving organomagnesium *chlorides*.[7] This is in strict agreement with the experiments of Gomberg and Bachmann,[4] in which it was shown that magnesium chloride, very probably because of its sparing solubility, does not react with magnesium after Reaction I to give magnesious chloride (—MgCl).

---

[5] Gilman and Fothergill, THIS JOURNAL, 50, 3334 (1928). This paper discusses some side reactions in the preparation of alkylmagnesium halides. Related work is by Gilman and Kirby, *ibid.*, 51, 1571 (1929).

[6] Very recent work on the yields of some Grignard reagents, with leading references to earlier work, is to be found in papers by Gilman, Zoellner and Dickey, *ibid.*, 51, 1576, 1583 (1929).

[7] With the exception of the special cases of *tert.*-butylmagnesium and triphenylmethylmagnesium chlorides; see the latter part of the Introduction and also the Experimental Part.

From such evidence it appears that there is little or no $R_2Mg{\cdot}MgX_2$ in the Grignard reagent. This found some support in a reaction carried out between magnesium diethyl, magnesium iodide, magnesium and benzophenone in which no benzopinacol was obtained. One interpretation of this reaction is that the magnesium diethyl and magnesium iodide reacted as follows

$$(C_2H_5)_2Mg + MgI_2 \longrightarrow 2C_2H_5MgI \qquad \text{(IV)}$$

In other words, an R_2Mg compound cannot exist apparently to any appreciable extent in the presence of an MgX_2 compound, and it must have such an existence if Formula B ($R_2Mg{\cdot}MgX_2$) is correct.

However, all of the preceding discussion gives but a partial picture of things. In the first place, Gilman and Schulze[8] have presented convincing evidence for the following equilibrium with the related organoberyllium compounds

$$2RBeX \rightleftharpoons BeR_2 + BeX_2 \qquad \text{(V)}$$

Also, they called attention at that time to the probability of the same equilibrium with Grignard reagents, basing such a conclusion on the effect of heat on some Grignard reagents incidental to the preparation of ether-free crystalline organomagnesium halides.[9] Those experiments showed that Grignard reagents were converted to R_2Mg compounds on the application of heat.

$$2RMgX \longrightarrow R_2Mg + MgX_2 \qquad \text{(VI)}$$

The experiment with magnesium diethyl (previously referred to) shows that Reaction VI can also go from right to left. Since then we[10] have actually succeeded in distilling from the Grignard reagent (by a modification of the technique used by Gilman and Schulze[8] in the organoberyllium studies) the R_2Mg compound. In addition, the Experimental Part of this report contains an account of a second experiment with magnesium diethyl which may lend support to the following equilibrium

$$2RMgX \rightleftharpoons R_2Mg + MgX_2 \qquad \text{(VII)}$$

All available evidence certainly confirms an equilibrium of this type with the RMgX form as the *chief* component of most Grignard reagents.

But this is not all. Some Grignard reagents undergo dissociation in the following manner

$$RMgX \longrightarrow R{-} + {-}MgX \qquad \text{(VIII)}$$

This is strikingly illustrated in the reaction between triphenylmethylmagnesium chloride, $(C_6H_5)_3CMgCl$, *free of metallic magnesium*, and benzophenone. In strict accordance with Reaction VIII the magnesious

[10] Gilman and Brown, *Rec. tmv. chim.*, 48, (1929). In confirmation of the reaction between magnesium diethyl and magnesium iodide to give ethylmagnesium iodide, Mr. Brown has shown that magnesium diphenyl with magnesium iodide gives phenylmagnesium iodide.

chloride[11] reduces benzophenone to benzopinacol, and the free radical or its equivalent (the peroxide) is formed. The dissociation postulated in Reaction VIII finds support in related unpublished studies. First, it is possible to prepare triphenylmethylmagnesium iodide from triphenyl methyl and magnesious iodide (—MgI).[12] This is, incidentally, a new method of theoretical interest for the preparation of Grignard reagents and lends support to earlier[13] experimental studies on the intermediate formation of free radicals in the preparation of Grignard reagents. Second, the molecular weight determinations of triphenylmethylmagnesium chloride and its reactions with hydrogen, oxygen and nitrous oxide lend further support to Reaction VIII.[14]

There is then a large amount of convincing evidence for both the equilibrium[15] represented by Reaction VII and the dissociation pictured by Reaction VIII. It remains to be determined to what extent the equilibrium and to what degree the dissociation takes place with a variety of Grignard reagents. From a purely theoretical basis it would be a relatively easy matter to assume that the equilibrium and the dissociation are properties of all Grignard reagents to *some* extent. Whatever results may come from future experiments, it is possible from the results of the present studies to have, as a working basis in the interpretation of some Grignard reactions, the postulate that Grignard reagents in solution may be a mixture of $RMgX$, R_2Mg, MgX_2, R— and —MgX in a series of equilibria.

[11] This does not appear to be in harmony with the statement that magnesium chloride does not react with magnesium to give magnesious chloride, an experiment verified by us. It may be argued that if Reaction VIII is correct, then a Grignard reagent like triphenylmethylmagnesium chloride should go irreversibly to form triphenylmethyl, magnesium and magnesium chloride, inasmuch as the magnesious chloride should (in accordance with Reaction I) proceed irreversibly to give the sparingly soluble magnesium chloride. But because such a reaction (leading to the formation of triphenylmethyl, magnesium chloride and magnesium) appears not to take place, one may conclude that the respective equilibria and rates of reaction are such as to make Reaction VIII a correct expression of the state of things under our experimental conditions. In this connection attention should also be directed to Menschutkin's studies [*Z. anorg. Chem.*, **49,** 34, **207** (1906)] on the tendency of magnesium halide etherates to form metastable supersaturated solutions.

Experimental Part

The primary objective of the several experiments was to isolate the benzopinacol[16] from other reaction products. After preparing the Grignard reagent in the customary manner, another equivalent of magnesium turnings and 50 to 100 cc. of dry benzene were added. We used magnesium turnings because preliminary experiments showed that the yield of benzopinacol prepared from such turnings and iodine and benzophenone was equal to the yield of benzopinacol obtained when magnesium powder was used. Gomberg and Bachmann[4] have shown that the rate of reaction is more rapid with magnesium powder.

The calculated quantity of a benzene solution of benzophenone was added with stirring to the cooled solution of Grignard reagent and the heat of reaction was generally great enough to cause the ether–benzene solution to reflux. External heat was not applied in any of the experiments. After adding the benzophenone, the reaction mixtures were stirred or shaken vigorously for varying lengths of time. In long runs when the flask was not tightly stoppered an inert atmosphere was used.

At the conclusion of an experiment, any precipitate that formed was allowed to settle, the clear supernatant solution was decanted and to this solution was added an ether–benzene washing of the precipitate. The solution and the precipitate were hydrolyzed separately, first with water and then with dilute hydrochloric acid.[17]

The acid layers were extracted once or twice with an ether–benzene mixture, and the combined extract and ether–benzene layers were dried with anhydrous sodium sulfate, after which the solvents were removed by distillation from a water-bath followed by a current of dry air. The residues from the solution and from the precipitate were then extracted with 100 to 200 cc. of petroleum ether (40–60°), and after this treatment benzopinacol remained.[18] If the precipitate of the reaction mixture were

---

[16] Others have obtained benzopinacol from the reaction between benzophenone and the Grignard reagent. Actually it was the formation of benzopinacol from a reaction between benzophenone, magnesium and an aryl halide that led Gomberg and Bachmann[4] to a study of magnesious halides. Prior to that time, Schmidlin, *Ber.*, **39**, 4198 (1906), obtained benzopinacol from benzophenone, triphenylmethylmagnesium chloride and an excess of magnesium. Subsequently Lagrave, *Ann. chim.*, [10] 8, **363** (1927), isolated small quantities of benzopinacol from benzophenone and various Grignard reagents. He very correctly attributed the formation of the small quantities of benzopinacol to a secondary reaction between some magnesium iodide and a slight excess of magnesium.

[17] Any unused magnesium in the precipitate was removed prior to the acid hydrolysis.

[18] Benzopinacol is partly soluble in petroleum ether. This was shown in a thirteen-hour extraction of 10 *g.* of benzopinacol in a Soxhlet extractor by 150 cc. of petroleum ether. Two and four-tenths grams of benzopinacol was dissolved in this way. Accordingly, our yields of benzopinacol are, in some cases, slightly less than those actually

not washed well with the ether–benzene mixture, some of the halogen-magnesium pinacolate (dissolved in the ether–benzene mixture) would remain with the precipitate (the halogen-magnesium tertiary alcoholate) and a mixture of pinacol and tertiary alcohol, $R(C_6H_5)_2COH$, would result on hydrolysis. This small quantity of pinacol can be separated largely from the tertiary alcohol by dissolving the mixture in hot glacial acetic acid; then, on cooling, the pinacol crystallizes first.

In those experiments concerned with the dissociation of the Grignard reagent, the reagent was prepared in the usual manner and then filtered through cotton or glass wool packed in a tube.[19] The benzophenone was then added to the filtered solution of the Grignard reagent and the reaction carried out and worked up as previously described.

A general account of the results of the several experiments is given in Table I and particular details and comments are included in the footnotes accompanying it.

Magnesium Diethyl, Magnesium Iodide and Magnesium.—The magnesium diethyl was prepared by heating 38.9 g. (0.15 mole) of mercury diethyl with 7.3 g. (0.3 atom) of magnesium turnings in a sealed tube at 100–120° for thirty-six hours. The magnesium iodide solution was prepared[4] from 14.6 g. of magnesium and 38.1 g. of iodine. All transferals and operations were carried out in a special apparatus and in a stream of dry and pure hydrogen. There was little evidence of reaction when the ether solution of magnesium diethyl was added to the magnesium iodide and magnesium. After adding 109.2 g. (0.6 mole) of benzophenone in 100 cc. of benzene, stirring was continued for five hours and then the mixture was allowed to settle overnight. The pink supernatant solution yielded 1.3 g. or 1.18% of benzopinacol.

Inasmuch as a deep pink color formed near the particles of magnesium, more solvent was then added and the precipitate was stirred intermittently, for an additional twenty-five hours, during a total time of one hundred hours. The red solution was then decanted and worked up separately from the precipitate. This solution yielded 7.8 g. or 7.1% of benzopinacol. Crystallization of the products obtained from the precipitate gave 5.0 g. of benzopinacol and 20.1 g. of ethyldiphenylcarbinol. The total yield of benzopinacol, based on benzophenone, was 14.1 g. or 12.83%.[20]

In a second experiment an atmosphere of nitrogen was used and the reaction mixture was stirred for only one-half hour subsequent to addition of benzophenone, and then hydrolyzed. No benzopinacol was obtained from the yellow solution of the reaction mixture and the yield of ethyldiphenylcarbinol was 22.9 g. or 18.0%.

---

present. Also, it must be remembered that we are dealing here with mixed solvents, because the benzopinacol is being extracted not only by petroleum ether but also by any benzophenone and tertiary alcohol dissolved by the petroleum ether. The Soxhlet extractor was used only in the benzylmagnesium chloride experiment.

[19] Another way of filtering solutions from magnesium is to use a matte of sintered glass fused into a glass tube. Such a filter has been used by Gilman and Brown in their studies on magnesium dialkyls and diaryls (see ref. 10 of this paper).

[20] There are several possible explanations for the formation of benzopinacol in this long-time run. One of them involves the following reaction: $2(C_6H_5)_2(C_2H_5)\text{-}COMgI \longrightarrow ((C_6H_5)_2(C_2H_5)C\text{—}O)_2Mg + MgI_2$. The magnesium iodide thus formed would react with the magnesium present to give magnesious iodide, which in turn would reduce the benzophenone to benzopinacol.

TABLE I
REACTANTS AND PRODUCTS

	Reactants				Products				
					Benzopinacol				
Expt.	RMgX	Mole	Mg, g. atom	Benzophenone, mole	G.	%	Tertiary alcohol	G.	%
1	CH_3MgI[a]	0.2	0.2	0.4	0.04	0.057	$(C_6H_5)_2(CH_3)COH$	22.1	27.9

[a] All of the yields given in Table I are based on the quantity of benzophenone taken for each experiment. Unless otherwise stated iodine was not used as a catalyst in the preparation of the several Grignard reagents. The diphenylmethylcarbinol, $(C_6H_5)_2(CH_3)COH$, and unused benzophenone formed an oil that did not separate well by fractional crystallization from petroleum ether. It was partly for this reason that the excess of benzophenone was not used in many of the other experiments. Where such an excess was not used, the results, of course, are not of the same accuracy as in the other experiments where an excess was used. However, the differences at best are very slight in those experiments carried out with a selected Grignard reagent and with and without an excess of benzophenone (*cf.* Expts. 1 and 2, 8 and 9). Actually, from these comparative experiments (1 and 2, 8 and 9) more benzopinacol was isolated when the excess of benzophenone was not used. In this experiment the mixture was stirred for one hour prior to hydrolysis. There was no red color in the solution at the end of addition of ketone and the whitish precipitate was tinged slightly with a greenish yellow color. When about one-half of the ketone had been added there was a faint red color.

[b] In this run with methylmagnesium iodide, the solution took on a reddish color and the red precipitate which formed did not diminish appreciably after shaking for twenty minutes. As with all other solid products isolated in this study, the identity of the benzopinacol was confirmed by a mixed melting-point determination with an authentic specimen.

[c] The addition of benzophenone in **50** cc. of benzene to the ethylmagnesium chloride and magnesium caused the formation of a white precipitate. An orange color formed momentarily at the spot of addition of benzophenone but when all of the ketone had been added no color was left in the solution. The mixture was stirred for one hour prior to hydrolysis.

[d] A white precipitate formed and the solution was of a purple color. Stirring was continued for three hours after the addition of ketone and at the end of the three-hour period the solution had become a pink color. From the precipitate of the reaotion mixture there were obtained **15.1** g. or 27.4% of crude benzohydrol, $(C_6H_5)_2CHOH$, melting at **64–65'**, and **9.3** g. or 17.8% of dibenzohydryl ether, $((C_6H_5)_2CH)_2O$. In all of the experiments with n-butylmagnesium iodide, a vacuum distillation was carried out with the oil that did not crystallize from petroleum ether. The dibenzohydryl ether may owe its formation to the effect of heat on benzohydrol and benzopinacol.

[e] This experiment was like Expt. No. 4, excepting that n-butylmagnesium iodide was prepared by the *rapid* addition of butyl iodide to magnesium in ether, thus favoring the greater formation of magnesium iodide as a side-product.

Part of the benzopinacol (**5.0** g. or **9.1**%) came from the solution, and the remainder was obtained from the precipitate as **19.9** g. of a solid which melted between **66** and 160° and which proved to be a mixture of benzopinacol and benzohydrol. An attempt was made to separate this mixture by converting the benzopinacol in it to benzopinacolone hy the method of Gomberg and Bachmann,[4] which involves boiling the pinacol in glacial acetic acid for a few minutes with a trace of iodine. On cooling the acetic acid solution, there separated pure benzopinacol instead of the expected benzopinacolone. In this manner the mixtnre gave **4.5** g. of benzopinacol and **15.4** g. of benzohydrol.

[f] In this third run with *n*-butylmagnesium iodide the object was to determine whether there was any dissociation of the Grignard reagent. Accordingly, the ketone was added to a filtered solution of n-butylmagnesium iodide free of magnesium. A white precipitate formed and the solution turned brown with a trace of pink, which may have been indicative of some reduction of the benzophenone. The mixture was stirred for three hours and among the reaction products was **9.9** g. or 26.9% of benzohydrol which melted at **67–68**" and which was obtained from the precipitate portion of the reaction mixture. The tertiary alcohol from this experiment was not worked up.

[g] In a first experiment with *tert.*-butylmagnesium chloride, the Grignard reagent was prepared by the use of a bare trace of iodine as a catalyst. Because this experiment was carried out to determine whether any dissociation occurred, the Grignard solution was filtered through a funnel packed with glass wool. The solution took on a red color and the precipitate which formed did not dissolve after shaking for a few minutes. The quantity of benzopinacol formed was **0.45** g. or **0.98%.** By a vacuum distillation of the residues left after evaporation of the petroleum ether solutions of both parts of the reaction mixture, there was obtained **30.6** g. or **63.7%** of an oil distilling at 147–165° (4 mm.). This was probably *tert.*-butyldiphenylcarbinol or dehydration products. In the experiment listed as No. 7 in Table I, no iodine was used as a catalyst and the Grignard solution was filtered through a plug of cotton instead of glass wool. **A** white precipitate formed and with it a reddish colored solution which gradually changed to greenish yellow. No benzopinacol was isolated. Some benzophenone (**2.4** g.) was recovered. Nothing was done with the tertiary alcohol fraction in this experiment.

[h] In this experiment with phenylmagnesium bromide, stirring was continued for two hours after addition of the ketone. The solution containing a white precipitate was of a yellow color prior to hydrolysis. In this experiment, as in the others in which an excess of benzophenone was used, there was a residue composed of a mixture of tertiary alcohol and benzophenone which did not lend itself to ready separation by means of

fractional crystallization from petroleum ether. The quantity of benzophenone recovered was **25.4** g. or **34.87,.**

[i] stirring was continued for three hours in this run and the trace of benzopinacol isolated is very probably due to the trace of iodine used in the preparation of the phenylmagnesium bromide. The trace of benzopinacol was obtained from 1.7 g. of a solid (melting at 145–150°) which was separated from the solution part of the reaction mixture. It was obtained in a pure condition by recrystallization From a mixture of alcohol and chloroform, followed by two crystallizations from glacial acetic acid.

[j] On the first addition of benzophenone to the benzylmagnesium chloride prepared with a trace of iodine, **a** small quantity of white precipitate formed; this dissolved completely by the time all of the ketone had been added. The faint lavender colored solution was stirred for one hour and then worked up in the usual manner. The benzyldiphenylcarbinol was not very soluble in petroleum ether, so that any small quantity of benzopinacol could not be isolated by extraction with **300** cc. of petroleum ether. **A** 3.5-hour extraction with 250 cc. of petroleum ether in a Soxhlet extractor failed to separate any benzopinacol (see ref. **18). A** recrystallization of a portion of the tertiary alcohol from glacial acetic acid gave no trace of benzopinacol.

[k] The mixture was stirred for four hours and the yellowish solution present prior to hydrolysis contained a white precipitate. The quantity of benzophenone recovered was **38.5** g. or 52.9%.

[l] In this experiment the object was to determine whether benzylmagnesium bromide dissociated. On adding the benzophenone to the filtered Grignard solution, a momentary purple color formed at the spot of addition and when all of the ketone had been added the solution was of a yellow-brown color. No precipitate formed. **A** recrystallization of a part of the benzyldiphenylcarbinol from glacial acetic acid gave no benzopinacol.

[m] The triphenylmethylmagnesium chloride and bromide, respectively, used in Expts. **13** and 14 were prepared in accordance with the directions of Gilman and Zoellner, THIS JOURNAL, 51, NOV. **(1929).** When benzophenone in benzene was added to the filtered benzene solution of Grignard reagent an intense red color formed. The solution was shaken for a few minutes and then hydrolyzed. In addition to the products listed in Table I, there was obtained **4.3** g. or 55.3% of triphenylmethyl peroxide. There was an excess of benzophenone because a small quantity of it was recovered directly from the petroleum ether extract of the crude pinacol. This experiment was carried out in a nitrogen atmosphere.

[n] This experiment was like that with the triphenylmethylmagnesium chloride. The yield of triphenylmethyl peroxide was **4.5** g. or **57.9%.** Evidently there was an excess of benzophenone because a portion of the petroleum ether extract of the crude pinacol gave some benzophenone-oxime when treated in the customary manner with hydroxylamine. This experiment was carried out in a nitrogen atmosphere.

Summary

Evidence is presented for the following equilibrium, $2RMgX \rightleftarrows R_2Mg + MgX_2$, and the following dissociation, $RMgX \longrightarrow R- + -MgX$, of Grignard reagents.

N-PHENYL-BETA-AMINOPROPIONAMIDE-4-ARSONIC ACID AND RELATED COMPOUNDS

BY CLIFF S. HAMILTON AND CARTER L. SIMPSON

RECEIVED JUNE 13, 1929 PUBLISHED OCTOBER 5, 1929

The comparatively recent preparation of "tryparsamide," N-phenylglycine-amide-4-arsonic acid[1] and its growing use in trypanosomiasis and neuro-syphilis stimulated an interest in the preparation and study of other arsenicals of a similar structure which might be more efficient. Those which merited special interest were the two compounds corresponding to tryparsamide, one having an additional methylene group in the side chain and the other having a shorter side chain.

The method employed in the preparation of "tryparsamide" involved the condensation of p-arsanilic acid with chloro-acetamide and subsequent conversion into the monosodium salt. N-Phenyl-β-aminopropionamide-4-arsonic acid was prepared by refluxing a neutral solution of sodium p-arsanilate with either β-bromopropionamide or with β-iodopropionamide. The monosodium salt was obtained by dissolving the acid in a sodium hydroxide solution and filtering into absolute alcohol. Attempts to prepare 4-carbamido-phenylarsonic acid by the action of carbamyl chloride on p-arsanilic acid were unsuccessful. However, N-4-methylcarbamidophenylarsonic acid[2] was prepared by the action of methylcarbamyl chloride on p-arsanilic acid. This compound was first prepared from methyl isocyanate and p-arsanilic acid. β-iodopropionamide was also condensed with several other amino-arylarsonic acids.

It was of interest also to make a study of an unsymmetrical arseno compound, composed of a half molecule of arsphenamine, used in the treatment of primary syphilis, and a group somewhat similar to tryparsamide, of benefit in neuro-syphilis. 3-Amino-4-hydroxy-4'-propionamideamino-arsenobenzene resulted when molecular equivalents of 3-amino-4-hydroxyphenylarsonic and N-phenyl-β-aminopropionamide-4-arsonic acid were condensed, using hypophosphorous acid as the reducing agent.

A detailed study of the pharmacological action of N-phenyl-β-aminopropionamide-4-arsonic acid is now being carried out in the Department of Pharmacology, University of Wisconsin. Preliminary results indicate that it may be useful in trypanosomal infections.

Experimental Part

β-Bromopropionyl Chloride.—Twenty *g*. of β-bromopropionic acid and 10 cc. of phosphorus trichloride were heated under a reflux condenser on a water-bath for five hours. The pale straw-colored liquid was collected at 65–70° at 25–30 mm.; yield, 19.6 g.

---

[1] Jacobs and Heidelberger, THIS JOURNAL, 41, 1589 (1919).

[2] Farb. Meister, Lucius and Bruning, German Patent 213,155.

Anal. Subs., 0.2001, 0.2004. Calcd., 0.3865, 0.3871 g. of silver halide. Found: 0.3854, 0.3862.

β-Iodopropionyl Chloride.—This was obtained in 80% yields, being collected at 85–90' and 30 mm.

β-Bromopropionamide.—Sixteen g. of β-bromopropionyl chloride was admitted drop by drop with rapid stirring to a solution of 21 cc of concentrated ammonium hydroxide diluted to 35 cc. and kept at −10°. The white crystalline amide separated and after stirring the mixture for a short time it was filtered and washed with a small amount of ice water to remove ammonium chloride; yield, 11.2 g.; m. p. 110–111°. For analysis the product was recrystallized twice from hot water.

Anal. Subs., 0.4005, 0.4011: 2G.1, 26.3 cc. of 0.1 N HCl. Calcd.: X, 9.21. Found: N, 9.13, 9.17.

β-Iodopropionamide.—This compound was prepared in 80% yields by following the method of Jacobs and Heidelberger.[3]

N-Aryl-β-aminopropionamide-arsonic Acids

General Method of Preparation.—One molecular equivalent of the amino-arylarsonic acid was dissolved in the calculated amount of normal sodium hydroxide solution to form a monosodium salt; one and one-half molecular equivalents of the halopropionamide was then added and the mixture boiled under a reflux condenser for five hours. Sufficient concentrated hydrochloric acid was added to the hot solution to hold any unchanged arsanilic acid in solution. The solution deposited almost colorless crystals on cooling. The product was filtered, washed with a little cold water and purified by dissolving in 2 N sodium hydroxide solution, filtering and reprecipitating by the addition of concentrated hydrochloric acid. This purification was repeated until the product gave a negative R-salt test.

β-Bromopropionamide and β-iodopropionamide were the two halopropionamides used in the preparation of the N-aryl-β-aminopropionamide-arsonic acids. Of these the β-bromo compound was found to give the better results, the crude products being whiter and the yields just as high as when β-iodopropionamide was used.

TABLE I

N-ARYL-β-AMINOPROPIONAMIDE-ARSONIC ACIDS

N-Phenyl-β-amino-propionamide-( )-arsonic acid	Formula	Yield, %	Subs., g.	Analysis 0.0497 *N* I2, cc.	Analysis Arsenic, % Calcd.	Analysis Arsenic, % Found
-4-	$NH_2CO(CH_2)_2NHC_6H_4AsO_3H_2$	35–40	0.2060	28.52	26.04	26.00
-2-Methyl-5-	$NH_2CO(CH_2)_2NHC_6H_3(CH_3)AsO_3H_2$	15–20	.2016	26.6	24.73	24.60
-2-Methyl-4	$NH_2CO(CH_2)_2NHC_6H_3(CH_3)AsO_3H_2$	25–30	.2034	26.8	24.73	24.54

Monosodium Salt of N-Phenyl-β-aminopropionamide-4-arsonic Acid.—This was prepared by dissolving N-phenyl-β-aminopropionamide-4-arsonic acid in the calculated amount of 2 N sodium hydroxide solution to give a neutral solution and filtering in a fine stream into 10 volumes of absolute alcohol, previously cooled to 0°. The mixture was allowed to stand for several hours in a freezing bath to insure complete precipitation. The sodium salt separated in fine white needles containing approximately two moles of water of hydration. The yield was almost quantitative.

Anal. (Sample dried at 110°) Subs., 0.2245; 29.33 cc. of 0.0497 N I_2. Calcd. for $C_9H_{12}O_4N_2AsNa$: As, 24.19. Found: As, 24.20. (Sample air dried) Subs., 0.2016:

---

[3] Jacobs and Heidelberger, J. *Biol. Chem.*, *21*, 145 (1915).

23.90 cc. of 0.0497 N I_2. Calcd. for $C_9H_{12}O_4N_2AsNa2H_2O$: As, 21.68. Found: As, 21.90.

N-Phenyl-β-aminopropionic Acid-Carsonic Acid.—Five g. of N-phenyl-6-aminopropionamide-4-arsonic acid was gently boiled under a reflux condenser with 50 cc. of 2 N sodium hydroxide solution for three hours, or until ammonia ceased to be evolved. The solution deposited fake-like crystals when made acid to Congo Red paper with concentrated hydrochloric acid and cooled in a freezing mixture; yield 4.5 g. It did not melt below 250°.

Anal. Subs., 0.2019, 0.2012; 28.1, 27.9 cc. of 0.0497 N I_2. Calcd. for $C_9H_{11}O_4NAs$: As, 26.04. Found: As, 25.92, 25.83.

N-4-Methyl-carbamido-phenylarsonic Acid.—Five g. of methylcarbamyl chloride, prepared by treating methylamine hydrochloride with phosgene at 250–300°, was dissolved in 30 cc. of dry benzene and cooled to 5°. Five g. of finely powdered sodium *p*-arsanilate was then added in small portions with shaking. In order to complete the reaction the temperature of the mixture was allowed to rise slowly to 20°. The resulting product was then filtered, washed repeatedly with benzene and finally with ether. It was then triturated with water to remove the hydrochloride formed in the reaction and recrystallized from hot water; yield, 25%.

Anal. Subs., 0.2004: 29.50 cc. of 0.0497 N I_2. Calcd. for $C_8H_{11}O_4N_2As$: As, 27.37. Found: As, 27.44.

Arseno Compounds

3-Amino-4-hydroxy-4′-propionamidamino-arsenobenzene Dihydrochloride.—A mixture of 4.7 g. of 3-amino-4-hydroxyphenylarsonic acid and 5.8 g. of N-phenyl-0-aminopropionamide-4-arsonic acid was dissolved in a solution of 50 cc. of concd. hydrochloric acid and 30 cc. of water. Fifty cc. of 50% hypophosphorous acid was then added and the solution kept in a refrigerator for twenty-four hours. The yellow precipitate was filtered, washed with alcohol, then with ether and dried in a vacuum; yield, 4.2 g. The compound was soluble in water.

Anal. Subs., 0.2012, 0.2005: 32.0, 31.9 cc. of 0.0501 N I_2. Calcd. for $C_{15}H_{19}O_2N_3Cl_2As_2$: As, 30.36. Found: As, 29.88, 29.89.

In order to prepare the free base, the dihydrochloride was dissolved in water and 3-amino-4-hydroxy-4′-propionamidamino-arsenobenzene precipitated by the careful addition of a sodium hydroxide solution. The free base was also prepared as follows: one hundred g. of sodium hydrosulfite was added with stirring to a solution of 21.2 g. of magnesium chloride hexahydrate in 500 cc. of water. To this was then added 3.6 g. of 3-amino-4-hydroxyphenylarsonic acid and 4.6 g. of N-phenyl-β-aminopropionamide-4-arsonic acid, dissolved in 160 cc. of water containing 20 cc. of a saturated sodium carbonate solution. The mixture was filtered as quickly as possible and warmed at 50° for one hour. The free base separated as a yellow, insoluble powder, which was filtered, washed with water and immediately dried in a vacuum; yield, 5.5 g. It decomposed at 120–125° and contained a small amount of sulfur as an impurity.

Anal. Subs., 0.2006: 38.44 cc. of 0.0497 N I_2. Calcd. for $C_{15}H_{17}O_2N_3As_2$: As, 35.63. Found: As. 35.01.

Summary

1. N-Phenyl-P-aminopropionamide-4-arsonic acid and its sodium salt have been prepared. Preliminary pharmacological tests indicate that it may be useful in treatment of trypanosomal infections.

2. β-Bromopropionyl chloride, β-bromopropionamide, N-phenyl-β-

aminopropionamide-2-methyl-5-arsonic acid and N-phenyl-β-propionamide-2-methyl-4-arsonic acid have been described for the first time.

3. 3-Amino-4-hydroxy-4'-propionamido-arsenobenzene and its hydrochloride have been prepared.

NEW CONDITIONS FOR THE FORMATION OF GLUCOSAZONE

BY C. L. BUTLER AND LEONARD H. CRETCHER

RECEIVED JUNE 15, 1929 PUBLISHED OCTOBER 5, 1929

Hydrazine derivatives of recently described compounds in which uronic acids are conjugated with sugars[1] have not yet been studied. We desired to prepare such derivatives of the aldobionic acid isolated from gum arabic[1b] in order further to characterize it. While a number of hydrazine derivatives of glucuronic acid have been prepared, the lack of agreement in the results of various investigators in this field seems to indicate that the reaction is not a simple one.[2]

A preliminary investigation of the action of phenylhydrazine on the simpler sugars, glucose, mannose and fructose was therefore made. The chemistry of glucose phenylhydrazone[3] is complicated by the existence of at least two isomeric forms. Although we have spent a considerable amount of time attempting to prepare the pure isomers, our results indicated that these are not readily produced by any of the published methods. Since our results were not conclusive, further discussion in this paper will be confined to a description of the formation of glucosazone from glucose and fructose, and from their phenylhydrazones under conditions not ordinarily considered favorable to osazone formation, and of the behavior of mannose phenylhydrazone under similar conditions.

The precipitation of glucosazone from a cold dilute acetic acid solution of 1 equivalent of glucose and 1.5 equivalents of phenylhydrazine was observed by Jacobi.[3c] This investigator did not examine the reaction further. It was found in the present work that when glucose is treated under

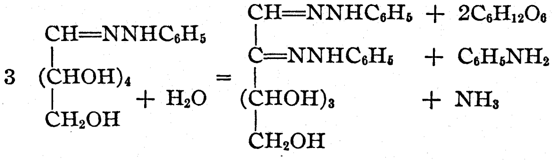
similar conditions with an equimolecular proportion of phenylhydrazine, a precipitate of glucosazone is formed after a few hours. On prolonged standing a 62.5% yield of glucosazone, based on the amount of phenylhydrazine used, was obtained. In the absence of acetic acid this reaction did not take place.[4] No other crystalline product could be isolated from the mother liquors. It was also shown that glucose phenylhydrazone itself, when allowed to stand at room temperature in dilute acetic acid, changes to glucosazone. The yield was 85% based on the equation



$$3\begin{array}{l}CH{=}NNHC_6H_5\\ |\\ (CHOH)_4\\ |\\ CH_2OH\end{array} + H_2O = \begin{array}{l}CH{=}NNHC_6H_5\\ |\\ C{=}NNHC_6H_5\\ |\\ (CHOH)_3\\ |\\ CH_2OH\end{array} \begin{array}{l}+ 2C_6H_{12}O_6\\ + C_6H_5NH_2\\ + NH_3\end{array}$$

The formation of glucosazone under these conditions probably involves an intramolecular oxidation and reduction the mechanism of which will not be discussed in the present paper. That this is also the main reaction in alcoholic solutions of glucose and phenylhydrazine containing acetic acid was shown by the isolation of a 63% yield of glucosazone on attempting to repeat the preparation[3f] of Behrend's glucose a-phenylhydrazone. It was not possible to isolate any hydrazone from the glucosazone mother liquors.

Attempts to prepare crystalline fructose phenylhydrazone were unsuccessful. The reaction product in the absence of solvent was a gummy mass which could not be crystallized. However, equimolecular proportions of fructose and phenylhydrazine in dilute acetic acid at room temperature gave a 67% yield of glucosazone. The gummy reaction product of fructose and phenylhydrazine also changed to glucosazone when treated in a similar manner.

Mannose phenylhydrazone was found to be stable under these conditions. However, when warmed in dilute acetic acid it gave rise to black resinous material which could not be purified. That mannose was liberated in this reaction was shown by the fact that the mother liquor, after removal of the resinous material by filtration, deposited mannose phenylhydrazone on treatment with phenylhydrazine.

Experimental

Attempted Preparation of Glucose Phenylhydrazone by the Method of Behrend and **Lohr.**[3f]—To a solution of 20 g. of glucose in 15 g. of glacial acetic acid and 5 cc. of water was added a solution of 15 g. of phenylhydrazine in 160 cc. of absolute alcohol. On thorough mixing a clear yellow solution was obtained. After standing for three days 10.5 g. of crude yellow crystals was filtered from the solution. On washing with acetone 7.5 g. of bright yellow crystals, melting at 206–207°, was obtained. The

---

[4] Cameron, THIS JOURNAL, 48, 2233 (1926), has noted the effect of acetic acid as a catalyst in the reaction of weak bases such as aniline with glucose. His conclusions are confirmed by the experiments herein reported.

mother liquor from these crystals was allowed to stand for two days, and deposited during this time a further quantity of crystalline material which after washing with acetone weighed 2.0 g. One additional gram of crystals was recovered from the mother liquors on concentration *in vacuo* to about 60 cc. This material was recrystallized from 70% alcohol. The purified substance, which melted at 210°, did not depress the melting point of an authentic sample of glucosazone which melted at 210°. The total yield of glucosazone was 10.5 g. or 63.2% of the theoretical based on the amount of phenylhydrazine used.

Preparation of Glucose Phenylhydrazone by the Method of **Fischer.**[3a]—The yield from 5 g. of glucose. 5 g. of phenylhydrazine and 2.5 g of water was 4.5 g or 60% of the theoretical of hydrazone melting at various temperatures between 140 and 150°. On addition of ether to the concentrated sirupy mother liquor, 1.7 g., or 22.7% of the theoretical of Skraup's phenylhydrazone[3b] melting at 111–112° was obtained. The total hydrazone yield was thus 6.2 g. or 82.7% of the theoretical.

A modification of this method was tried in the hope of obtaining the glucose α-phenylhydrazone of Behrend. To a suspension of 18 g. of glucose in 6 cc. of water and 25 cc. of absolute alcohol was added a solution of 11 g. of phenylhydrazine in 25 cc. of absolute alcohol. The resulting clear solution was allowed to stand overnight at room temperature and then for several days in the ice box. The crystalline mass was filtered and the crystals were washed with ether. The material was then precipitated several times from alcohol solution by ether. The yield was 17 g. of Skraup's phenylhydrazone melting at 110–112°, or 63% of the theoretical.

Preparation of **Mannose Phenylhydrazone.**—This compound was prepared from 3.6 g. of mannose and 2.2 g. of phenylhydrazine in the usual way. The yield was 4.8 g. (89% of the theoretical) of pure mannose phenylhydrazone melting at 200–201°.

Attempted Preparation of Fructose **Phenylhydrazone.**—The method of Laudrieu[5] applied to the production of fructose phenylhydrazone gave unsatisfactory results. The preparation was therefore attempted without solvent. To 1.8 g. of fructose was added 1.8 g. of phenylhydrazine and the mixture was stirred until uniform. It was allowed to stand at room temperature for forty-eight hours. The sticky mass was extracted with ether to remove the excess of phenylhydrazine. On drying about 1.5 g. of a soft gummy mass was obtained. It could not be crystallized.

Preparation of Glucosazone.—Glucosazone was prepared by the usual method. The substance purified by crystallization from 60% alcohol and washing with acetone melted at 210°. The melting point was not changed by recrystallization from 60% alcohol; α^{20}_{D} $-2.625''$ for $l = 2$ and $c = 2$, ten minutes after solution in a mixture of 1 part of pyridine and 1.5 parts of alcohol; $[\alpha]^{20}_{\mathrm{D}\,(\mathrm{initial})}$ $-65.6°$. The rotation became constant after twenty-five hours at $-1.44°$; $[\alpha]^{20}_{\mathrm{D}\,(\mathrm{final})}$ $-36.0°$.

The Formation of Glucosazone from Equimolecular Proportions of Glucose **and Phenylhydrazine.**—Thirty-six g. of glucose was dissolved in 200 cc. of water and to the solution was added a mixture of 50 cc. of water, 10 cc. of glacial acetic acid and 21.6 g. of phenylhydrazine. The resulting milky suspension was allowed to stand at room temperature. The following day a large amount of yellow crystalline solid had separated. The amount of solid increased on standing. After six days the material was filtered off and washed with a little water. It melted at 183° with decomposition. The crude product, when purified as described above, melted at 209–210°. Six g. of bright yellow crystals was obtained in this crop. The filtrate from the crude crystals, on standing for several weeks longer, deposited a further quantity of glucosazone which after purification weighed 7 g.

The combined mother liquors were concentrated to about 30 cc. in *vacuo* and diluted

---

[5] Landrieu, Comfit. *rend.,* 142, 182 (1906).

with an equal volume of alcohol. Water was then added until no further precipitation occurred and the mixture was filtered. The crude solid material on purification yielded two additional grams of pure osazone. The total yield was thus **15** g. of pure substance or **62.5%** of the theoretical based on the equation given in the first part of this paper. The substance did not depress the melting point of pure glucosazone prepared as described above; $[\alpha]^{20}_{\mathrm{D}\ (\text{initial})}$ $-56.3°$ for $c = 2$ and $l = 2$; $[\alpha]^{20}_{\mathrm{D}\ (\text{final})}$ $-36\ 5°$.

A control experiment in which **1.8** g. of glucose was treated with **1.1** g. of phenylhydrazine in **12.5** cc. of water in the absence of acetic acid was made. No precipitate of glucosazone was formed after standing for two days at room temperature.

Formation of Glucosazone from Glucose **Phenylhydrazone.**—One cc. of glacial acetic acid was added to a solution of **2** g. of Fischer's glucose phenylhydrazone in 10 cc. of cold water. The solution became cloudy after standing for two hours at room temperature. After standing overnight, a large amount of yellow insoluble material had separated from solution. The mixture was filtered ten days later. The yield was **0.75** g. of recrystallized glucosazone melting at 210° or 85% of the theoretical based on the equation given on page **3162.** The substance did not depress the melting point of a sample of pure glucosazone which melted at 210°.

The presence of glucose was demonstrated in the filtrate from the glucosazone precipitate by warming with a little phenylhydrazine and a few drops of acetic acid. The glucosazone which was formed was filtered off and purified in the usual way. It melted at **210°**.

A control experiment was run with **2** g. of glucose phenylhydrazone in **10** cc. of water without the addition of acetic acid. There was no glucosazone formation in this experiment.

Two grams of Skraup's phenylhydrazone was treated similarly. The yield of purified osazone melting at 210° was **0.7** g. or **80%** of the theoretical.

Formation of Glucosazone from Equimolecular Proportions of Fructose and **Phenylhydrazine.**—A suspension of **2.2** g. of phenylhydrazine in **5** cc. of water was added to a solution of **3.6** g. of fructose in **15** cc. of water and 1.5 cc. of acetic acid. The mixture became cloudy after several hours and after several days the deposition of glucosazone appeared to have ceased. The mixture was filtered and the glucosazone purified by methods which have been described. The yield was **1.6 g.** of pure glucosazone melting at **209–210°,** or **67%** of the theoretical.

Formation of Glucosazone from the Crude Reaction Product of Equimolecular Proportions of Fructose and **Phenylhydrazine.**—One g. of the sticky product was dissolved in **5** cc. of water and filtered from a trace of yellow insoluble material. Several drops of acetic acid were added and the mixture was allowed to stand for two days at room temperature. The yield of pure glucosazone melting at 210° was **0.35** g. or about **80%** of the theoretical.

Behavior of **Mannose** Phenylhydrazone in the Presence of Acetic Acid.—A mixture of **2** g. of mannose phenylhydrazone, **10** cc. of water and 1 cc. of acetic acid did not change after standing for two days at room temperature except for a slight darkening of the liquid. It was then heated for two hours on a water-bath. Some dark resinous product was formed from which nothing could be separated. That the mother liquor contained mannose was shown by the fact that on treatment with a little phenylhydrazine it gave an almost immediate precipitate of mannose phenylhydrazone which after recrystallization melted at 200–201°. It did not depress the melting point of a sample of pure mannose phenylhydrazone melting at this temperature.

Summary

1. The reaction of glucose or fructose with an equimolecular amount of phenylhydrazine in cold dilute acetic acid gives a high yield of glucosazone,

instead of glucose phenylhydrazone as might be expected. Mannose, on the other hand, yields only the hydrazone under these conditions.

2. Glucose and fructose phenylhydrazones are converted practically quantitatively to glucosazone on standing in dilute acetic acid. Mannose phenylhydrazone is unchanged by this treatment.

PHOTOCHEMICAL DECOMPOSITION OF LACTIC ACID

BY G. RICHARD BURNS

RECEIVED JUNE 15, 1929 PUBLISHED OCTOBER 5, 1929

This study of the photochemical decomposition of lactic acid is part of an investigation of the oxidation of lactic acid by oxygen in the presence of ultraviolet radiation. The investigation was undertaken as a result of a consideration of the theories of physiological chemists in regard to the oxidation of lactic acid in the body. It appeared that a study of the oxidation from a purely chemical viewpoint would be of value in connection with these theories.

Before this could be done a more thorough investigation of the decomposition of the acid, in the absence of oxygen, by ultraviolet radiation was necessary. There is a marked conflict between the results of other investigators over the decomposition of lactic acid in solution by the radiations of a quartz mercury arc. The differences found may be explained, in part, by taking into consideration the fact that some observers exposed the irradiated solution to air and some took the necessary precaution to see that no oxygen was present. Another discrepancy arose from the fact that some observers used glass containers. The wave lengths of radiation that decompose lactic acid are absorbed by glass.

Bolin[1] states that there is no decomposition of lactic acid in glass flasks. Euler's[2] investigation showed that at 70° alcohol and a gas mixture composed of 90% of carbon dioxide and 10% of hydrogen and carbon monoxide resulted. No substance was formed that reduced Pehling's solution. More recently Euler,[3] in experiments carried out both at **30** and 70°, confirms these results. He states that no reaction takes place in glass flasks. In all his experiments he finds an induction period of about two hours. This was, doubtless, the length of time necessary to produce enough carbon dioxide to saturate the solution. Euler's results were confirmed by Scharz[4] with the exception that methane was also found in small

quantities. Neuberg,[5] in criticizing Euler's results, claims that there is no decomposition in quartz flasks when exposed to the radiation from a mercury arc. This conclusion was based on the fact that no evolution of carbon dioxide was observed and that titration of the irradiated solution showed no loss of acid. The failure to obtain carbon dioxide gas could be explained on the basis of the fact that the rather low radiation intensity used would not give enough carbon dioxide to saturate the solution. The fact that the amount of lactic acid remains unchanged is based on the assumption that no other acid is formed under the conditions of his experiment. Baudisch[6] states that no alcohol, no methane and no carbon monoxide were found, but that acetaldehyde was found in large quantities. Neuberg's and Baudisch's results differ greatly from Euler's and those of the present investigator.

Apparatus

The apparatus used in this experiment although designed for the study of the oxidation of lactic acid was fairly well adapted to measuring the decomposition. Two sources of radiation were used. One was a commercial, 220-volt, Cooper-Hewitt quartz mercury arc A operated at 3.1 amperes. This lamp had been used previously for about 500 hours. It was air-cooled by a steady blast at 22°. The other was an iron arc operated at 15 amperes from a 220-volt line. The voltage on the line was held steady by adjusting resistances at the motor generator unit. The visible and ultraviolet radiation from the mercury arc did not vary over 3% in the course of a day. The reaction tube T was placed in a tin-lined thermostat B. The thermostat had a 5 cm. by 15 cm. quartz window Q in the front and a smaller one in the back. In order to remove carbon dioxide from the solution it was found necessary to shake the tube vigorously as well as to evacuate it; otherwise as much as 6 cc. of the gas would remain in the solution. For this reason the reaction tube was mounted on a slide and could be shaken over a 6-cm. stroke at 310 r.p.m. The reaction tube itself was made by the General Electric Company from ground and polished quartz plates fused together to form a square container with internal dimensions of 1.9 X 1.9 X 10.0 cm. At one end a neck 10 cm. long and 0.4 cm. in internal diameter was fused. The tube for the removal of gases was ground into the mouth of the reaction tube and extended the length of the neck. Rubber tubing was wired over the joint; 25 cm. of heavy rubber tubing led from this tube to the 2-mm. bore glass tube from the Töpler pump. The pump delivered the gas directly to the buret of the gas analysis apparatus. Radiation from the arc passed successively through the quartz window, 3.8 cm. of distilled water, the reaction vessel, 0.5 cm. of water and out the

back window. The thermopile P was one made by Coblentz of the Bureau of Standards for the Vermont Agricultural Experiment Station and was loaned by them for this work. The galvanometer was used as a zero instrument, the current from the thermopile being balanced by a certain fraction of a measured current.[7] The thermopile was standardized by a Bureau of Standards standard of radiation. 0.1302×10^{-3} cal. per $cm.^2$ per min. gave an e.m.f. of 1.55×10^{-6} volts. This standardization depends somewhat on the assumption that the thin quartz window on the thermopile reflects and absorbs the same amount of radiation from the hot carbon filament of the standard of radiation as it does from the source to be measured.

Experimental Part

Absorption Measurements.—In order to determine the wave lengths absorbed, a series of photographs of the absorption spectrum was made. These were made both with the reaction tube and with a cell the thickness of which could be varied. The results showed that very little radiation of wave lengths longer than 2500 Å. was absorbed and that practically all below that value was absorbed. As most of the radiation from this arc below 2500 Å. was concentrated in five lines between 2330 Å. and 2500 Å., the average wave length of absorbed radiation was taken as 2450 Å.[8] Absorption measurements were made by comparing the amount of radiation transmitted by the reaction tube filled with water and-with a lactic acid solution. As the sides of the tube had been slightly distorted when it was fused together, care was taken to see that it was in the same position for each measurement. The arrangement for shaking permitted this without difficulty. Absorption measurements were also made with a 23-mm. tube with quartz windows fastened on by de Khotinsky cement. In this case the radiation was first run through 6.6 cm. of water to remove most of the heat radiated from the lamp. The absorption measurements were all fairly unsatisfactory as the lamp was not steady and showed variations of about 1% over short periods of time. Values were obtained ranging from 3.7 to 4.5%. Most of the measurements were between 4.1 and 4.2%. 4.15% was used as the value. The radiation intensity was measured at the back window. The ratio between this value and that at the position of the reaction cell was determined by experiment.

Lactic Acid.—The lactic acid (Kahlbaum) was prepared by rapid distillation at 5 mm. pressure. Only the constant boiling point fraction was used. After distilling, it was diluted to approximately 1 *N* and refluxed for eight hours to hydrate all lactide.[9] The normality was found to be 1.137 (by oxidation) and 1.140 (by titration with phenolphthalein).

Quantum Yield Determinations.—In the experiments described below the temperature of the thermostat was 25.00' and the gas volumes are corrected to 0° and 760 mm. The lactic acid solution was run into the reaction tube until the bottom of the meniscus was 4.5 cm. from the bottom of the tube. It was then placed in the shaking apparatus in the thermostat, The thermostat was emptied, rinsed out with distilled water and refilled with distilled water. It was found to be important to change the water every run. The tube was evacuated, with shaking between the strokes of the Töpler pump, until no more gas could be pumped out, The shutter in front of the thermostat was then opened to the extent of 4.5 cm., exposing the solution to the quartz mercury arc. A shield was placed close to the arc so that only 4.5 cm. of the tube of the arc was exposed. At the end of the exposure the arc was turned off and the gas pumped out of the solution as described above. This gas was analyzed for carbon dioxide; then oxygen

was admitted and the mixed gases were run over a hot platinum spiral; the carbon dioxide thus formed was then determined. Typical runs are given in Table I.

TABLE I

QUANTUM YIELDS OF CARBON DIOXIDE

Duration of irradiation, hours	6	6	6
Av. radiation intensity at tube, microvolts	359.5	386.4	372.0
Surface exposed, square centimeters	8.55	8.55	8.55
Carbon dioxide produced, cc.	4.94	5.15	4.90
Decrease on ignition, cc.	0.51	0.53	0.42
Carbon dioxide produced by ignition, cc.	0.50	0.50	0.38
Moles of carbon dioxide found X 10^4	2.220	2.315	2.202
Moles of carbon dioxide calculated X 10^4	3.30	3.55	3.41
Quantum yield on carbon dioxide produced, %	67.4	65.2	64.7

Analysis of Gas.—The gases other than carbon dioxide comprised about 9% of the total volume of gas formed. These gases were investigated as follows. A 54-hour run with the reaction tube three-quarters full and exposed to the full length of the mercury arc gave 168.36 cc. of gas. This was analyzed in a special apparatus with the following results:[10] 153.10 cc. of carbon dioxide, 1.50 cc. of unsaturated compounds, 6.44 cc. of carbon monoxide, 16.99 cc. decrease on ignition with oxygen, 11.08 cc. of carbon dioxide produced by ignition. The ratio, 1.53, between the decrease on ignition and carbon dioxide produced is very close to that which would be produced by 3.67 cc. of methane and 3.67 of ethane. If this mixture of gases had been analyzed by the method customarily used in this investigation, a decrease on ignition of 23.20 cc., and the formation of 20.52 cc. of carbon dioxide would have been found. This ratio is roughly the same as that usually obtained (Table I).

When the iron arc was substituted for the mercury the results in Table II are typical of those obtained.

TABLE II

DECOMPOSITION BY IRON ARC

Carbon dioxide in two hours, cc.	1.40	1.31
Decrease on ignition, cc.	0.21	0.23
Carbon dioxide produced by ignition, cc.	.14	.13

This shows that the higher percentage of short wave lengths from the iron arc produces a different type of decomposition from that produced by the mercury arc. It shows also that the mixture of gases produced above will change in composition with increasing age of the mercury arc. For these reasons, and because the length of time necessary to produce samples of this gas was so great, the experiment was not repeated.

Determination of Ethyl Alcohol.—Ethyl alcohol was found in substantial quantities. The amount was determined by the Bourcart–Kuriloff method.[11] This consists of oxidizing the alcohol to acetic acid by potassium dichromate and sulfuric acid at 100° in a sealed tube, treating the excess dichromate with potassium iodide and sulfuric acid and titrating the iodine by freshly standardized sodium thiosulfate. The applicability of the method to the present type of analysis was as follows. A solution containing 0.020 g. of ethyl alcohol was found to be equal to 8.75 cc. of 0.200 N dichromate: calcd. 8.69 cc. This was within the error in weighing out the 2 g. of alcohol from which the alcohol

---

[10] Analyzed with the aid of Dr. Huffman of this Laboratory, who has had much experience with this type of analysis.

[11] Poznanski, THIS JOURNAL, 50, 981 (1928).

solution was prepared. It was found that oxidizable material equivalent to 0.33 cc. of 0.200 N dichromate would distil from the unirradiated lactic solution. This was due to impurities, as the second fraction distilling showed no reaction with dichromate. That all of the alcohol would distil was shown by putting 0.020 g. of alcohol into 16.2 cc. of lactic acid solution and distilling it according to the procedure below: dichromate used, 9.10 cc.; calcd. 0 33 cc. plus 8 75 cc. = 9.08 cc.

The 16.2 cc. of irradiated lactic acid solution was washed into a 100-cc. flask and 8.0 cc. of 20% sodium hydroxide added. Ten cc. was then distilled off through a short air-cooled reflux condenser in about thirty minutes. Typical determinations are given in Table III.

TABLE III

RATIO OF ALCOHOL TO CARBON DIOXIDE

Carbon dioxide produced in seven hours, cc.	20.10	21.70
0.200 N $K_2Cr_2O_7$ used, cc.	21.63	23.64
Moles of carbon dioxide produced X 10^4	9.04	9.74
Moles of alcohol found $\times 10^4$	10.65	11.67
Carbon dioxide/alcohol ratio	1:1.18	1:1.20

Test for Acetaldehyde.—Although no aldehyde could be detected after any run, either in the solution or in the gases pumped out, one quantitative test for it was made. The Schiff's reagent was prepared by Alyea and Bäckström's method.[12] A lactic acid solution was irradiated, after all air had carefully been removed, for six and one-half hours with an intensity great enough to produce 21 cc. of carbon dioxide. The apparatus was so arranged that substances distilling from the solution were condensed and held in an unirradiated trap. The liquid from the trap was then returned to the reaction tube, the tube packed in ice and left for an hour. At the end of this period it was opened, the contents made up to a volume of 25 cc. and 10 cc. of Schiff's reagent added. For purposes of comparison a 0.0006 M aldehyde solution and a blank were prepared. To 25 cc. of the former (1.5 X 10^{-5} mole of aldehyde) 10 cc. of Schiff's reagent were added. The latter consisted of 25 cc. of distilled water plus 10 cc. of Schiff's reagent. The unknown solution developed no color and when compared in a colorimeter was identical with the blank. The 0.0006 M aldehyde solution developed a strong pink color.

The amount of carbon monoxide produced in this run must have been about 0.84 cc. If some of the lactic acid had decomposed into carbon monoxide and acetaldehyde this would correspond to a production of 4.0 X 10^{-5} moles of the aldehyde. It would seem that this amount of aldehyde would give a test even though most of it were destroyed by the action of the radiation.[13]

Discussion of Results

As the decomposition of lactic acid is approximately a quantum reaction, it was not possible to use monochromatic illumination and obtain appreciable quantities of the products. The radiation absorbed comprised so small a portion of the spectrum of the mercury arc that the error from this source in determining the quantum yield was not over 2%. The fact that several wave lengths were absorbed meant that several decomposition reactions were taking place concurrently. Exactly one hundred runs were

---

[12] Alyea and Bäckström, THIS JOURNAL, 51, 97 (1929).

[13] Ellis and Wells, "The Chemical Action of Ultra-Violet Rays," 1925, p. 155.

made, and, in each, as many products were investigated as could be tested in the same experiment. Successive runs only are used as examples in this paper.

Lactic acid, $CH_3CHOHCOOH$, might break up into a carbon dioxide and alcohol. It was found that this was the main decomposition, as 90.9% of the gas given off was carbon dioxide. Vigorous shaking of the reaction tube in addition to evacuation was found to be necessary to remove all of the carbon dioxide from the solution. The neglect of these precautions accounts, in part, for the erratic results of previous investigators. The amount of carbon dioxide found corresponded to a quantum yield of about 0.65 molecule per quantum. As the amount of radiation absorbed could not be satisfactorily determined, the error from this source may be as much as 10%. The other factors necessary to determine the quantum yield were measured to a much higher degree of accuracy.

The amount of alcohol found in the solution was 19% in excess of the quantity required by the assumption that the lactic acid decomposed into equal amounts of alcohol and carbon dioxide. The reason for this discrepancy has not yet been determined. In order to avoid removing alcohol vapor the gases were not as completely removed from the solution in cases where the alcohol content was to be determined as in other instances. The amount of carbon dioxide left in solution was very much less than the amount required to account for this discrepancy. As the alcohol was determined by oxidation of the distillate from a strongly alkaline solution of the reaction mixture, there might have been present other substances which were also oxidized but, as there was no aldehyde, it is difficult to imagine an impurity that could have been present. The method of determining alcohol was accurate to 0.5%. The quantum yield based on the amount of alcohol produced is about 0.77 molecule per quantum.

It is interesting to consider the reactions that took place other than the main decomposition into alcohol and carbon dioxide. The additional substances found in the gas were: (by volume) unsaturated compound (probably ethylene), 0.89%; carbon monoxide, 3.82%; methane (calculated), 2.18%; ethane (calculated), 2.18%. If one molecule of lactic acid is decomposed into ethylene, carbon dioxide would be produced in equal amounts. This would mean that 0.98% of the carbon dioxide came from this decomposition. If methane is one of the products formed, the other might be two molecules of carbon monoxide. The carbon monoxide found was 87% of that required by this decomposition. Carbon monoxide might also be formed by a decomposition giving acetaldehyde as the other product. As a quantity of the aldehyde much less than that required by this reaction could have been detected it was assumed that this decomposition did not take place. One molecule of the acid might give ethane and hydrogen peroxide or its decomposition products. No hydrogen peroxide was found. Oxygen, in the few cases in which it was found, was accompanied by nitrogen and was assumed to have been the result of air leaking into the apparatus. Ethane might have been formed by the decomposition of two molecules of the acid, yielding ethylene glycol as the other product. No attempt was made to find this trace of ethylene glycol as the author's previous experience with this compound did not Lead to the belief that it could be detected.

Summary

1. Lactic acid in water solution is decomposed by radiations of wave lengths shorter than 2500 Å. The chief products of decomposition by radiations from a quartz mercury arc are alcohol and carbon dioxide. Carbon monoxide, saturated hydrocarbons and unsaturated hydrocarbons form about 9% of the gaseous products.

2. Aldehyde, if produced, is present in quantities less than 1% of the total decomposition products.

3. The ratio between the energy absorbed and the carbon dioxide produced corresponds to a quantum yield of approximately 0.65.

4. More ethyl alcohol is produced than is required by the assumption that lactic acid decomposes into equal amounts of alcohol and carbon dioxide.

NEW HAVEN, CONNECTICUT

NEW BOOKS

Das Buch der grossen Chemiker. (The Book of the Great Chemists.) Edited by Dr. GÜNTHER BUGGE with the cooperation of special scholars. Vol. I. From Zosimos to Schonbein. Verlag Chemie G. m. b. H., Corneliusstrasse 3, Berlin W 10, Germany, 1929. xii + 496 pp. Illustrated. 16 X 24 cm. Price, unbound, M. 21; bound, M. 24.

This is a book for the chemist's leisure. The publisher's advertisement says that biographical essays in the history of chemistry have not before been published in the German language. The various chapters have been written by scholars who are well known for their researches in the history of chemistry and generally include the latest knowledge on the subjects with which they deal. The first volume brings the account nearly up to the middle of the nineteenth century, and contains chapters on Zosimos (Ruska), Jabir (Ruska), Albertus Magnus (Strunz), Roger Bacon (Strunz), Raymund Lull (Strunz), pseudo-Geber (Ruska), Biringuccio (Johannsen), Paracelsus (Strunz), Agricola (Darmstaedter), Libavius (Darmstaedter), pseudo-Basil Valentine (Fritz), Van Helmont (Strunz), Glauber (Walden), Boyle (Farber), Stahl (Koch), Boerhaave (Speter), Goeffroy the Elder (Speter), Marggraf (Speter), Black (Speter), Cavendish (Lockemann), Priestley (Lockemann), Scheele (Lockemann), Leblanc (Bloch), Lavoisier

(Speter), Klaproth (Bugge), Berthollet (Farber), Proust (Farber), Fourcroy and Vauquelin (Bloch), Davy (Ostwald), Faraday (Ostwald), Berzelius (Soderbaum), Mitscherlich (Bugge) and Schonbein (Farber).

It is apparent that we cannot charge Dr. Bugge, as Colson charged Ladenburg, with overemphasizing the part which Germans have played in the development of chemistry. Indeed we think that another German ought to have been included—Kunckel, who discovered fulminate and phosphorus, and manufactured ruby glass, whose writings first turned Scheele toward chemistry, a man who early developed the applications of chemistry, not alchemy, to the production of *thalers*. His school is numerous in the twentieth century. And there ought certainly to have been a chapter on Lomonosov.

The illustrations are excellent, old prints, pictures of apparatus and portraits which have been chosen with care. A reproduction of an autograph recipe of Paracelsus is very convincing. The book is well bound, well indexed, and well printed in a modernistic manner with paragraphs commencing at the margin. The book can be recommended to chemists in general and to students who wish to improve their chemistry or their knowledge of literary German. Each chapter is an adventure. The book will surely have a wide circulation.

TENNEY L. DAVIS

The Corrosion of Metals. Part I. General Theory. BY PROFESSOR WILH. PALMAER, D.Sc. Ingeniorsvetenskapsakademiens Handlingar Nr 93. Svenska Bokhandelscentralen A.-B., Stockholm, Sweden, 1929. 347 pp. 101 figs. 5 plates. 16.5 × 24 cm.

This Memoir (in English) of the Royal Swedish Institute for Scientific-Industrial Research of Stockholm gives an extended account of the investigations that Professor Wilh. Palmaer and his associates have been conducting since 1920 on the corrosion of metals. Two brief preliminary summaries of these investigations have already been published, one in Sweden and one in Germany.

The author first gives a thorough discussion of earlier theories of the solution of metals in aqueous solution. The *Theory of Local Galvanic Elements* is discussed with particular thoroughness. Several experimental investigations are then presented in detail, as follows: (a) the Velocity of Solution of Aluminum in Acids; (b) the Voltage Required to Deposit Hydrogen on Graphite; (c) the Velocity of Solution of Iron in Acids; and finally (d) the Velocity of Solution of Calcium Carbonate in Acids.

The bearing of these results and of those obtained by others in similar researches on the three main theories of this phenomenon are then discussed at length, the conclusion being that the primary factor in the solution of metals in acids is the activity of local galvanic elements. Various consequences of this conclusion are then examined and certain catalytic phenomena are explained.

Part II is to deal with special researches on the solution of metals; Part III with the special theory of the corrosion of iron.

This comprehensive and exhaustive study of a scientific and practical problem of the first importance will be of great interest to the many chemists and engineers who are concerned with it.

ARTHUR B. LAMB

The Theory and Technique of Quantitative Analysis. BY MARIE FARNSWORTH, Ph.D., Instructor in Chemistry, Washington Square College, New York University. John Wiley and Sons, Inc., New York, 1928. vii + 154 pp. 34 figs. 15 X 23.5 **cm. Price, $2.50.**

This little book differs from other books on this subject in that its purpose is not to describe definite procedures but to classify and generalize the operations and to apply the theory of quantitative analysis. Most courses in this subject lay too much stress on the ability of the student to obtain results merely by following a definite set of directions and too little on a thorough discussion of the theory involved. In the laboratory the student is too often left to acquire the technique as best he can, and although it can best be taught by demonstration, this book will at least acquaint him with the tools of the analyst and his manner of working.

It is obvious that this book is mainly the work of Dr. Wendt although his name does not appear as co-author.

Chapters are devoted to the balance and its use, to reagents, laboratory ware, preparation of samples, precipitation and filtration, as well as to the various types of volumetric reactions. The nephelometer is briefly described but unfortunately nothing is said about colorimetric methods, which are more commonly used than nephelometric. Chapters on electrolytic processes and electrometric titrations complete the book.

Inasmuch as many students in quantitative analysis have not yet studied physical chemistry, a book of this type will be of great assistance. In presenting the theory as simply as possible, the author has not made much mention of the many cases to which the simple theory will not apply. For example, the solubility product principle is not as generally applicable as might seem from the chapter in which this subject is discussed, owing to the disturbing effects of hydrolysis, complex formation and presence of other salts.

Attention might be called to a few errors and omissions which can readily be corrected in a future edition. The reviewer cannot agree with the optimistic statement on page **32** that sillimanite ware "rarely breaks when dropped from the laboratory table to the floor." On page 140 it is recommended to remove platinum black from a hydrogen electrode previous to replatinizing by means of sandpaper; it is difficult to imagine anyone doing it that way. The chapter on filtration should include descriptions of sintered glass and porous porcelain filtering crucibles. On page 97 in the list of primary acidimetric standards, potassium acid phthalate is not included, although it answers every requirement and is issued by the Bureau of Standards. The use of the ball mill in grinding samples and the electric muffle for ignitions should be mentioned.

This book can be heartily recommended to all students in quantitative analysis.

H. H. WILLARD

Die anisotropen Flüssigkeiten. (Anisotropic Liquids (Liquid Crystals).) BY C. W. OSEEN, Professor at the University of Upsala. Gebrüder Borntraeger, W 35 Schöneberger Ufer 12 a, Berlin, Germany. 1929. iii + 87 pp. 5 figs. 16.5 × 25.5 cm. Price, unbound, RM. 6.80.

Here at last is the long desired monograph, the only balanced and unbiased account of the highly important yet little known field of liquid crystals. Lehmann's discovery and exploration of this truly remarkable subject earned for him much obloquy and sharp recrimination from many sides, continued throughout his lifetime. The subject is still regarded in most quarters as a somewhat doubtful scientific curiosity. It will be news to most men of science of the present time that Vorlander has prepared 2000 different substances in one or more of the liquid crystalline or anisotropic liquid states. It will be news to almost every chemist that perfectly stable material in this condition is being manufactured and sold in the form of soap solutions on the scale of thousands of tons. Every soap is capable of forming two kinds of liquid crystal, existing over a wide range of temperature and concentration.

The subject of liquid crystals has suffered from the fact that most exemplars of this state are complicated organic compounds easily decomposed by excessive heating and yet exhibiting these states only over comparatively narrow ranges of elevated temperature, usually observed only in microscopes provided with heating stages and water-cooled objectives. These liquids are doubly refracting, like crystals, and often spontaneously assume highly characteristic and hitherto totally unexplained shapes, as, for example, the double cone of an ammonium oleate droplet. The adequate elucidation of this group of states of matter, which cannot be called gaseous, liquid or crystalline, is obviously *a* problem of first class importance.

Oseen, who in his own papers has developed a highly mathematical treatment, has avoided this almost completely in his admirable review of the subject. He has brought together *a* most interesting account of the quantitative studies of various phenomena such as the dependence of electrical and other physical properties on direction in a liquid crystalline phase. It is very interesting to note that none of the English speaking countries have contributed anything worthy of mention to this subject. It has been developed exclusively by Germans, French, Dutch and Swedes. Oseen's monograph is held together by constantly referring the phenomena and measurements described to the touchstone of a comparison between the general theory of Oseen and its somewhat primitive rival, the dipole theory of Riecke (1905) adopted by Vorlander (1910) and given quantitative form by M. Born and F. Grandjean in 1916 and 1917.

JAMBS W. MCBAIN

Elements of Physical Chemistry. BY JAMES M. BELL, Head of the Department of Chemistry, University of North Carolina, and PAUL M. GROSS, Head of the Department of Chemistry, Duke University. Longmans, Green and Co., 55 Fifth Avenue, New York, 1929. xiii + 466 pp. 88 figs. 13.5 X 21 cm. Price, $3.75.

The authors describe this volume as prepared with the college student in mind who has had a course in "General Chemistry, Analytical Chemistry and Organic Chemistry, and who has had a course in General Physics and preferably in the Calculus." In the text the kinetic theory, behavior of solutions, crystal structure, equilibrium and phase rule are among those topics which are particularly emphasized. An interesting chapter on Polar Properties of Solutions is included. The derivation of equations throughout the text is very clear cut. Descriptive matter is not included in large measure, the topics of atomic structure and colloid chemistry being described rather briefly and radioactivity being omitted entirely. Each chapter is followed by ten or a dozen problems with answers at the end of the book.

The volume is also a laboratory manual, giving at the conclusion of fourteen of the chapters a laboratory experiment illustrative of the foregoing principles. No special apparatus is required for most of these experiments.

The text is well illustrated with diagrams which are particularly legible and the experiments by large clear drawings.

HENRY E. BENT

Colloid Chemistry. BY THE SVEDBERG, Professor of Physical Chemistry, University of Upsala. Second edition, revised and enlarged in collaboration with ARNE TISELIUS, Research Assistant in Physical Chemistry, University of Upsala. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc, 419 Fourth Ave., New York, 1928. 302 pp. 167 figs. 15.5 × 23.5 cm. Price, $5.50.

The special lectures on Colloids given by Professor Svedberg and the research which he organized on his visit to the University of Wisconsin during the spring and summer of 1923 not only gave an immense impetus to the study of Colloids in this country but culminated in the brilliant development of the author's experimental methods on the grand scale, providing a new and invaluable method for the investigation of some of the most obstinate problems of chemical and biological science. The prompt publication of Svedberg's lectures as an outstanding volume of the American Chemical Society's series of monographs did much to fructify the study of some of the more quantitative aspects of colloid science.

Now after five years, during which the author has become a Nobel Prizeman, we have a new and enlarged edition in which the remarkable invention of the ultracentrifuge is described and some of its many varied fields of application in general science are illustrated by actual results. The quantitative information that will come from the use of this unfortunately very costly apparatus is bound to become as distinctive and important as, for example, the study of everyday materials by X-rays. The exposition of these two methods constitutes the most important addition in the present edition, although the whole book has been thoroughly revised.

This is one of the few indispensable works of colloid science. Nevertheless, one is bound to point out that the title is somewhat of a misnomer, since there is comparatively little chemistry in the book. The strength of the treatment lies in its one-sidedness, in the full presentation of the study of colloids in relation to kinetic theory, a field in which the author has played so prominent a part.

PRECIPITATED SELENIUM DIOXIDE[1]

BY G. F. HOFFMANN AND VICTOR LENHER

RECEIVED DECEMBER 13, 1928 PUBLISHED NOVEMBER 8, 1929

Many unsuccessful attempts have been made to prepare the hypothetical trioxide of selenium analogous to the trioxides of sulfur and tellurium. Worsley and Baker[2] were the first investigators to report the preparation and properties of this compound. In brief, their method of preparation consisted of the oxidation of selenium dissolved in vacuum distilled selenium oxychloride by ozone. Following the publication of their researches, two former students of V. Lenher attempted the preparation of selenium trioxide but failed to obtain products which corresponded in selenium content to the trioxide and which responded to available oxygen tests for hexavalent selenium. Recently Julius Meyer and Anton Pawletta[3] reported their failure to obtain the trioxide by the above method and concluded that the oxidation product was selenium dioxide containing selenium monochloride as an impurity.

The following investigation was begun in 1925 and completed in January 1927, previous to the publication of Meyer and Pawletta. The data given not only establish the identity of oxidation products obtained, but prove the non-existence of selenium trioxide in products prepared according to Worsley and Baker's method.

Materials

Selenium.—Pure, resublimed selenium dioxide was dissolved in 10% hydrochloric acid and selenium subsequently precipitated by the addition of sulfur dioxide. Precipitated selenium was washed by decantation until free from acid, then boiled in distilled water, filtered and finally fused and cast in the form of sticks.

Selenium Oxychloride.—Lenher's[4] method of preparation was used. The oxychloride was fractionally distilled several times at 17 mm. pressure in a moisture-free

system (Fig. 1). Extremely dry selenium oxychloride was obtained by fractional distillation at reduced pressure from resublimed phosphorus pentoxide. The purity of the distillate was confirmed by freezing point determinations and the molybdate test for phosphate. Absorption of moisture by selenium oxychloride during transference from the still receiver was avoided by draining the distillate directly into reaction flasks through ground-glass joints.

Ozone.—Oxygen produced by the fractional distillation of liquid air was employed. Precautions to insure the absence of impurities such as hydrogen, carbon dioxide and water were taken, as shown in Fig. 2. Concentrations of ozone varying between 2 and 6% were produced in a triple cell ozonizer.

Carbon Tetrachloride.—Dry carbon tetrachloride was prepared by double distillation from phosphorus pentoxide immediately before use.

Analytical Methods

Selenium.—Selenium was determined giavimetrically according to the method of Lenher and Kao[5] It was precipitated in the presence of 15% hydrochloric acid by sulfur dioxide and hydroxylamine hydrochloride. Precipitation was allowed to take place slowly at room temperature. The supernatant liquid was decanted through a tared Gooch crucible and the precipitate remaining in the beaker was converted to gray crystalline selenium in boiling water. It was then brought on the same crucible, washed with water and alcohol, dried at 105° and weighed.

Available Oxygen.—Selenic acid and all selenates liberate free chlorine from hydrochloric acid solutions.[6] According to Worsley and Baker the product of ozone oxidation of selenium in selenium oxychloride reacts with water to give selenic acid; hence a water solution of the product should liberate chlorine from a hydrochloric acid solution.

Available oxygen was accurately determined by gently boiling a 10% hydrochloric acid solution containing a hexavalent selenium compound and conducting the liberated chlorine into a solution of potassium iodide slightly acidic with sulfuric acid. Iodine was titrated with $N/10$ sodium thiosulfate solution. The distillation of chlorine into iodide solution was aided by a slow current of carbon dioxide. This method is in common use for the determination of hexavalent selenium.

Chlorine.—Chlorine was determined in the presence of selenium by precipitation as silver chloride from solutions containing approximately 10% nitric acid and an excess of silver nitrate. The accuracy of such analyses was established hy numerous trial analyses of solutions which were prepared to contain known amounts of selenious or selenic acid, nitric acid and chloride.

Fig. 2.—Preparation of pure ozone.

Experimental Details

A reaction flask similar to that described by Worsley and Baker was used in the preparation of the first products. One modification of their apparatus was adopted. It consisted of an additional tube filled with resublimed phosphorus pentoxide inserted between the ozonizer and the reaction flask. This additional drying precaution was taken following the observation that water was formed in the ozonizer when hydrogen was not completely removed from the oxygen by reaction with hot copper oxide. The low selenium results of Worsley and Baker might be traced to this point since their ozonizer was connected directly with the reaction flask, allowing any water formed to be absorbed by the product.

The time required for a precipitate to appear on passing ozone through the selenium oxychloride solution of selenium varied between twenty and seventy hours. A white sublimate was formed on the walls of the reaction flask and gas outlet tube. Precipitates were brought on dry asbestos filters and thoroughly washed with dry carbon tetrachloride in the absence of moist air. Dry air was drawn through the washed precipi-

tates to remove the carbon tetrachloride. The use of absolute ether for washing purposes was abandoned following the observation that the color of the product was changed from white to yellow or pink when in contact with pure ether. Upon mixing the oxychloride filtrate of a product with dry carbon tetrachloride a white precipitate was formed. This precipitate resembled the original product in appearance and composition.

Analytical results of the products of ozone oxidation of selenium oxychloride solutions are summarized in Table I. For preparations I–VII, inclusive, vacuum distilled selenium oxychloride was used as the solvent medium. Due to the variable selenium content of the first products, analyses for water and chlorine were included for all subsequent products. After the presence of water in Products V, VI and VII was definitely established, it was concluded that vacuum distilled selenium oxychloride was not dry in spite of numerous fractional distillations. In an attempt to prepare dry products, an apparatus consisting of two reaction flasks connected in tandem but separated by filtering tubes was constructed. A series of products was obtained in this apparatus by using the same solvent. In Table I the third and fourth precipitates of Preparation VIII and the second and third of Preparation IX represent products prepared in such an apparatus. Although a few drops of water were added to the solution of selenium in selenium oxychloride before starting Preparation IX, Precipitate 2 was found to contain only 0.23% of water. The major portion of the water presumably was removed from the solution by the first precipitate.

Fig. 3.

It was found practically impossible to wash products entirely free from $SeOCl_2$. Several products were found to contain chloride after having been washed continuously with dry carbon tetrachloride for one week. It appeared perfectly logical to consider the chlorine in the product to be present as selenium oxychloride. It is not likely that chlorine should be present as the monochloride, as supposed by Meyer and Pawletta, because selenium monochloride is readily oxidized by ozone, as is evident from the change in color of its solutions during contact with ozone. The presence of appreciable amounts of monochloride in the solution or in the product would impart a distinct reddish color to them.

Products X, XI and XII were prepared from oxychloride fractionally distilled from phosphorus pentoxide. Product XII was prepared in a different type of reaction flask shown in Fig. 4. Manipulation was greatly simplified in that the product was precipitated, washed, dried and weighed in the same container without coming in contact with moist air.

6	48.05	42.42	1.01	99.27	100.28

The above results and the general properties of the filtrates indicate the solvent, $SeOCl_2$, to be unchanged apparently by ozone during the oxidation of the dissolved selenium. Pure dry selenium oxychloride, however, was found to react with dry ozone when the latter was passed through a porous glass plate serving as a support for the liquid (see Fig. 4). The ozone–oxygen mixture passed through the solvent as thousands of tiny bubbles, thereby exposing an enormous surface of the liquid to the powerful oxidant. The oxidation product of $SeOCl_2$ was similar in every respect to the products obtained from $Se–SeOCl_2$ solutions.

Some Properties of Precipitated Selenium Dioxide.—Exposed to the air of the laboratory this substance rapidly absorbs water until its water content approaches 14% of the total weight of the sample; then the absorption of water practically stops. Although only approximate, this result corresponds to the water content of selenious acid.

The vapor pressure of the precipitated dioxide when moistened with water was observed to be lower than that of water alone at the same temperature; therefore, it is unlikely that oxygen was evolved when the products were dissolved in water.

Molecular Weight in Selenium Oxychloride.—A freezing point constant for selenium oxychloride was determined experimentally with solutions of ignited potassium chloride and barium chloride. An average of six determinations gave a value of 26. The molecular weights of the precipitated dioxide and the sublimed dioxide were then determined and found to be approximately three times 111.2, the calculated molecular weight of selenium dioxide. Absorption of moisture by selenium oxychloride solutions during determination of freezing points was avoided.

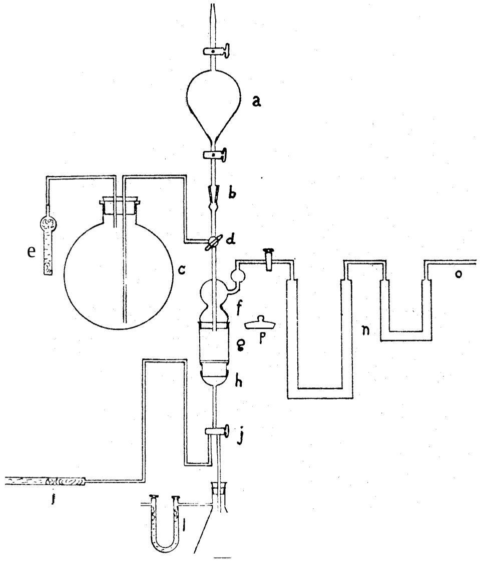
TABLE IV

RESULTS OF MOLECULAR WEIGHT DETERMINATIONS

Drop in f. p., °C.	Grams of pptd. SeO_2/1000 g. $SeOCl_2$	Mol. wt., calcd.	Drop in f. p., °C.	Grams of sublimed SeO_2/1000 g. $SeOCl_2$	Mol. wt., calcd.
0.264	3.4285	338	0.252	3.221	334
.259	3.2717	328	.239	3.078	333
.236	3.000	332	.236	2.947	325
.233	3.000	336	.227	2.886	331
.205	2.571	327	.209	2.613	325
.195	2.400	326	.184	2.347	330
.186	2.361	332	.180	2.289	331

Density of Precipitated Selenium Dioxide.—The density of precipitated selenium dioxide was determined in benzene at 20°. Two separate determinations gave 3.590 and 3.595 as the density of the product. Worsley and Baker reported 3.6 as the density of their product; therefore there can be little doubt concerning the similarity of their product and that of the authors.

A sample of precipitated selenium dioxide was exposed to moist air until a calculated amount of water was absorbed, corresponding to the water content of selenious acid. A subsequent water analysis gave 13.87% of water as compared to 13.92% of water in selenious acid. A density determination of the same hydrated oxide gave a value of 2.982 at 20°. The true density of selenious acid is d_4^{15} 3.004. Hence, within the limits of experimental error, the density of hydrated precipitated dioxide of selenium is identical with that of ordinary selenious acid.



a, Receiver of oxychloride still; b, ground-glass joint; c, 4-liter flask for washing liquid; d, 3-way stopcock; e, drying tube; f, top of Drechsel bottie; g, Jena glass crucible with waled-in sintered glass plate; h, Gooch funnel; i, oxygen ozone delivery tube; j, 3-way stopcock; 1, drying tube; m, filter flask; n, sulfuric acid traps; o, gas outlet; p, stopper for Jena glass Gooch crucible.

Fig. 4.

That the different densities of

precipitated and sublimed selenium dioxide indicate merely a difference in physical state and not in composition, is shown definitely by analyses.

"Chloroselenic Acid."—Worsley and Baker reported their selenium oxide product to absorb hydrochloric acid gas, forming chloroselenic acid, a fuming straw-colored liquid. The density of this liquid was found by them to be 2.26. The density of selenium hydroxychloride (a fuming straw-colored liquid) is 2.24 at 25°.[8]

Several samples of this substance were prepared by the authors from the precipitated selenium oxide. The resulting straw-colored liquids varied in composition and density, depending on the temperature and the time allowed for absorption. This is a characteristic property of selenium hydroxychloride. Upon plotting chlorine percentages against densities of respective samples, it was found that a straight line drawn through the plotted points passed through a point representing the density and calculated chlorine content of $SeO_2 2HCl$.

Summary

1. Attempts to prepare selenium trioxide by the method of Worsley and Baker failed.

2. The product of ozone oxidation of $Se-SeOCl_2$ solution was identified by analyses as precipitated selenium dioxide.

3. The density of precipitated selenium dioxide was found to be appreciably lower than that of the sublimed dioxide.

4. Precipitated selenium dioxide absorbs moisture rapidly to form selenious acid.

5. The molecular weights of precipitated and sublimed SeO_2 dissolved in $SeOCl_2$ were found to be identical.

6. The product of ozone oxidation of $Se-SeOCl_2$ solutions absorbs dry hydrogen chloride gas to form a fuming, straw-colored liquid similar in composition and density to selenium hydroxychloride and not chloroselenie acid.

THE REPULSION OF ATOMIC KERNELS AS A FACTOR IN ORGANIC REARRANGEMENTS

BY WENDELL M. LATIMER

RECEIVED FEBRUARY 11, 1929 PUBLISHED NOVEMBER 8, 1929

Although the repulsion of the atomic kernels is an obvious factor[1] in the stability of molecules, its importance in organic chemistry does not seem to be fully appreciated. In the recent monograph on Molecular Rearrangements by Porter,[2] there are so many examples of the influence of the inter-kernel repulsions, that it appears desirable to formulate a statement which will be of assistance in interpreting these complex organic reactions.

The energy of the molecule is, of course, the sum of the energies of the repulsions and attractions of the electrons and atomic kernels and at present it is quite impossible to evaluate all these energies. Indeed, our one bit of quantitative information is the energy of repulsion of the atomic kernels. In this case, since these kernels are small in comparison to the interatomic distances, the energy of repulsion between two kernels of charges e and e', separated by a distance, d, is $E = ee'/d$. The interatomic distances are capable of determination from crystal structure data and as the kernel is, by definition, the atom minus the valence electrons, its charge is equal to the number of valence electrons possessed by the neutral atom.

The magnitude of this repulsive energy is very great, for example, that between carbon and nitrogen in aniline is over two million calories. In a stable molecule this repulsion is overcome by the mutual attractions of the kernels for the electrons or electron pairs of the two atoms, but it seems obvious that if any arrangement of the molecule is possible in which this repulsion force may be greatly decreased and at the same time satisfy equally well the electron affinities of all the atoms, such a rearrangement might take place. For example, in the change of methylaniline into p-toluidine, N—C and C—H bonds are changed to N—H and C—C bonds. In the resulting molecule the atoms all possess the same number of electrons which they had before the rearrangement but the energy of repulsion has been decreased by approximately 400,000 cal. The free energy of the change is very much less than this, so there must also be a decrease in the energy of the bonding electrons. Although the latter cannot be calculated, it seems probable that it should always be less than the decrease in the repulsion energy.

In order to test this assumption, a survey has been made of all the re-

---

[2] Porter, "Molecular Rearrangements," The Chemical Catalog Co., Inc., New York, 1928.

arrangements listed by Porter and the reactions are classified according to the bonds broken and formed. The values used in calculating the increase or decrease of the repulsion energies are summarized in Table I. These energies are based upon interatomic distances determined by x-ray diffraction data and molecular moments from band spectra data. It is to be expected that each type of bond should be only approximately constant in various compounds and in general variations of 10 and 15% in the interatomic distances are found. The values for the interatomic distances which have been employed are taken from summaries by Pauling,[3] Huggins[4] and Birge.[5]

The various types of rearrangements and their repulsion energies are summarized in Table I. In the following discussion the numbers refer to the types as listed in Table II.

TABLE I

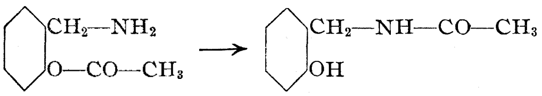
REPULSION ENERGIES OF ATOMIC KERNELS IN VARIOUS BONDS[a]

Bond	Dist. bet. atomic centers, Å.	Repulsion energy, kilocal.	Bond	Dist. bet. atomic centers, Å.	Repulsion energy, kilocal.
C—H	1.20	550	N—N	1.40	2950
C—C	1.52	1700	N=N	1.21	3400
C=C	1.47	1750	N—O	1.35	3650
C—N	1.46	2250	N=O	1.20	4100
C=N	1.20	2750	N—S	1.65	3000
C—0	1.41	2800	N—Cl	1.64	3500
C=O	1.29	3050	N—Br	1.79	3200
C—S	1.71	2300	O—H	1.05	940
C—Cl	1.70	2700	O—O	1.30	4550
C—Br	1.85	2500	O=S	1.56	3800
N—H	1.15	715	0—Cl	1.52	4550

[a] Instead of these values, as a rough approximation, applicable in most cases, the interatomic distances may be assumed constant and the energies expressed in terms of the product of the kernel charges. For example, in the N—C and C—H rearrangement to N—H and C—C given above (5 × 4) + (4 X 1) = 24 and (5 X 1) + (4 × 4) = 21. This decrease of 3 units corresponds to about 400 kilocal. in this example.

Rearrangements Taking Place with a Decrease in Repulsion Energy.—(1) The example of methylaniline has been given above. Other rearrangements of this type are methylenedi-p-tolylimide to diaminoditolymethane, ethylphthalimidoacetate to a derivative of oxycarbostyril, diacylanilides to acylamino ketones and N-acetylpyrrole to b-acetylpyrrole.

(2) There are a number of reactions similar to the following



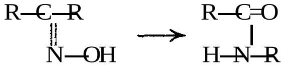
Pauling, Z. *Krist.*, 67, 377 (1928).

Huggins, *Phys. Rev.*, 28, 1086 (1926).

[5] Birge, "International Critical Tables," Vol. V, 1929, p. 409.

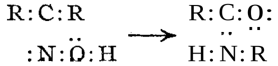
Other examples are: the ethyl ester of formanilide to ethylphenylformamide and the rearrangement of the triazoles.

(3) Many examples of the Beckmann rearrangement



$$\begin{array}{c} R-C-R \\ \| \\ N-OH \end{array} \longrightarrow \begin{array}{c} R-C=O \\ | \\ H-N-R \end{array}$$

It seems probable that these double bonds between carbon and the more electronegative atoms are not to be interpreted as two electron pairs, but rather as carbon with a coördination number of three, as in carbonate. However, the interatomic distances are less in the double bond and there is doubtless considerable distortion of the octet of the nitrogen and oxygen. The electron formula then would be



$$\begin{array}{c} R:C:R \\ :N:\ddot{O}:H \end{array} \longrightarrow \begin{array}{c} R:C:\underset{\cdot\cdot}{O}: \\ H:\overset{\cdot\cdot}{N}:R \end{array}$$

This interpretation is important in the generalization which we wish to draw later. Another example is the conversion of fluorenone oxime to phenanthridone.

TABLE II

CHANGE IN INTER-KERNEL REPULSION ENERGIES IN VARIOUS MOLECULAR REARRANGEMENTS

	Bonds rearranged	Energies in kilocal.

(19)	(C—C + —N) to (C—N= + C=)	+ 550
(20)	(N—C + =0) to (—N= + O—C)	+ 450

(4) The rearrangements of amine sulfoxides.

(5) Thioncarbamates to thiol derivatives.

(6) A great many examples of which the rearrangement of the allyl ethers is typical.

(7) The rearrangement of acyl halogen aminobenzene.

(8) The conversion of ethyl isocyanide to propionitrile.

(9) Several cases in the sulfonic acids and amides of sulfonic acids.

(10) The rearrangement of brominated benzenediazonium chloride.

(11) The benzidine type of rearrangement.

(12) Numerous cases of the nitroso-amines and hydrazines.

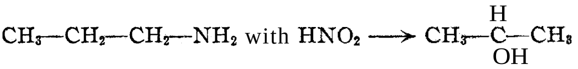
(13) One example is β-phenylhydroxylamine to p-aminophenol. Other examples are the rearrangements of the amine oxides and the conversion of quinoline by alkyl halides to carbinol bases.

(14) This change appears to be an intermediate step in some of the pinacol rearrangements. Although the definite formation of the intermediate ethylene oxide may not always occur in these reactions, the free bonds on the oxygen and carbon which result from the splitting off of water are potentially equivalent to the oxide formation. Other rearrangements essentially the same are benzil to benzilic acid and benzoin to diphenylacetic acid.

(15) The change of methyl thiocyanate to methyl isothiocyanate, R—S—C—N $\longrightarrow$ R—N=C=S. Although in the older bond theories of organic chemistry this change might be interpreted as involving a shift in the number of electrons on each atom, the probable electron formulas do not indicate that such is the case, that is, the structure is similar to that of carbon dioxide

$$R:\ddot{S}:C:\ddot{N}: \longrightarrow :\underset{\cdot\cdot}{\ddot{S}}:C:\underset{\cdot\cdot}{\ddot{N}}:R$$

Reactions Involving no Change in Repulsive Energy.—(16) There are a number of examples of shifts of carbon to carbon bonds. These often take place during reactions, that is, when the molecule is in a highly activated state, as in the following



$$CH_3—CH_2—CH_2—NH_2 \text{ with } HNO_2 \longrightarrow CH_3—\underset{OH}{\overset{H}{C}}—CH_3$$

As might be expected if the two possible forms have nearly the same energy the product is a mixture of the two forms. In some examples, however, symmetry and steric effects also doubtless play a part in determining the more stable form. Carbon to carbon shifts also occur in unsaturated compounds, the rearrangement giving forms which decrease the electrical moment of the molecule. An example of such a change is found in the reduction of methyl *tert.*-butyl ketone to tetramethylethylene.

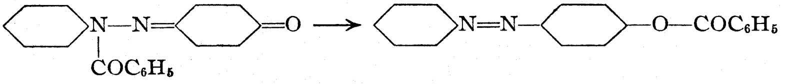
(17) One of the simpler examples is the change of (NHR)(NR—NH$_2$)C=O to (NHR)(NH—NHR)C=O. Although this reaction involves no change in the kernel repulsions in the various bonds, it might be pointed out that the repulsion of the R group for all of the neighboring atoms appears to be decreased by this rearrangement,

(18) There are several examples of the shift of a halogen from one carbon to another.

Rearrangements Involving an Increase in the Repulsion Energy.—(19) Porter[6] considers that the best theory of the Hofmann and Curtius rearrangements is the formation of an intermediate compound containing an unsaturated nitrogen which then rearrange with the transfer of a carbon radical to the nitrogen. For example, R—CO—NHBr ⟶ R—CO—N ⟶ R—N=C=O, or **in** electron formulas, $R:\underset{:N:}{\underset{..}{\overset{..}{C}}}:\underset{..}{\overset{..}{O}}: \longrightarrow R:\underset{..}{\overset{..}{N}}:C:\underset{..}{\overset{..}{O}}:$. If this mechanism is correct the change involves an increase in the repulsion energies but it also involves a change in the number of electrons on the nitrogen, that is, it takes place because the more electronegative nitrogen will gain electrons at the expense of the carbon. However, there is a possibility that the first step is the interchange of the R and Br and in this case there is first a decrease in the repulsion energy.

In addition to the many examples of the Hofmann rearrangement, certain benzene-azo-acetyldibenzoylmethane changes may be considered as involving a transfer of electrons from carbon to nitrogen.

(20) The rearrangement of the quinonehydrazones



takes place with an increase in the repulsion energy of the kernels. Although the shift appears to involve complicated electron rearrangements, the evidence regarding the electron structures of benzene and quinone does not permit a complete interpretation.

The keto-enol tautomerism of the acetoacetic acid esters seems at first sight to be a case of increasing repulsion energies, since a hydrogen may shift from carbon to oxygen, O=C—C—H to H—O—C=C. However, the sum of the repulsion energies, including the double bonds, as calculated from Table I, for the two forms gives only a small positive value and at ordinary temperatures the equilibrium favors the ketone as predicted. Moreover, the rearrangement must involve some redistribution of electrons in the formation of the double bond between the carbons,

Conclusions and Summary

The results of this detailed study of the various types of organic rearrangements show: (1) the great majority of these changes take place with a decrease in the inter-kernel repulsion energy. (2) A few occur with no change in repulsion energy. These often result from a state of high activation of the molecule and the product is a mixture of the two forms. **(3)** Rearrangements with an increase in repulsion energy are rare

---

[6] Porter, ref. 2, p. 16.

and invariably accompanied by complex redistributions of electrons in the molecule.

These observations are entirely in accord with the following premise: *if there are a number of possible arrangements of the atoms in a molecule which have the same number of electrons per atom and which satisfy equally well the tendencies of the more electronegative elements to complete their octets of electrons, that form will be the most stable which gives a minimum of repulsion between the atomic kernels.*[7]

THE MECHANISM OF HOMOGENEOUS GAS REACTIONS. II. THE ABSORPTION SPECTRUM OF NITROGEN PENTOXIDE AND ITS METHOD OF DECOMPOSITION

BY H. C. UREY, L. H. DAWSEY AND F. O. RICE

RECEIVED MARCH 8, 1929 PUBLISHED NOVEMBER 8, 1929

The thermal and photochemical dissociation of nitrogen pentoxide has been the subject of a number of important investigations during the past few years. Daniels and Johnston[1] showed that the thermal dissociation followed a unimolecular law and that the temperature coefficient of the velocity constant gave a mean value for the energy of activation calculated from the Arrhenius equation of 24.7 kg. cal. The average deviation of this quantity is 0.42 kg. cal. They illuminated their nitrogen pentoxide with infra-red radiation of approximately $\lambda = 1.16\mu$, corresponding to the energy values of the heat of activation, but found that there was no increased reaction due to illumination. Later investigations[2] have provided ample confirmation that neither this nor any other wave length in the infra-red causes appreciable decomposition of nitrogen pentoxide. Daniels and Johnston illuminated nitrogen pentoxide and a mixture of nitrogen pentoxide and nitrogen peroxide contained in a glass vessel by direct sunlight and found that nitrogen pentoxide decomposes only in presence of nitrogen peroxide. They isolated the region from 4000 to 4600 Å. (blue light) by filters and found that these were active wave lengths. By interposing a filter of nitrogen peroxide they showed that decomposition did not take place. Fazel and Karrer[3] proposed that the effect was due to the absorption of light by the nitrogen peroxide molecule, which then transferred its energy by a collision of the second kind to the nitrogen pentoxide molecules.

---

[7] These observations are also in accord with the conclusion of Pauling and Hendricks (ref. 1) regarding the stability of certain inorganic isomers.

[1] Daniels and Johnston, THIS JOURNAL, 43, 53, 72 (1921).

[2] Daniels, *ibid.*, **48**, 607 (1926); Taylor, *ibid.*, **48**, 577 (1926); Mayer, *ibid.*, **49**, 3933 (1927).

[3] Fazel and Karrer, *ibid.*, 48, 2837 (1926).

The effect of light on nitrogen peroxide has been studied by Norrish,[4] who concluded that there is an equilibrium established according to the equations

$$NO_2 + h\nu \longrightarrow NO_2'$$
$$NO_2' + NO_2 \longrightarrow 2NO + O_2$$
$$2NO + O_2 \longrightarrow 2NO_2$$

He then assumed that the photochemical decomposition of nitrogen pentoxide was a secondary dark reaction represented by the equation

$$NO + N_2O_5 \xrightarrow{\text{Dark}} 3NO_2$$

Dickinson and Baxter[5] confirmed Norrish's view that gaseous NO_2 is decomposed by light into NO and O_2; they determined the quantum yield of the reaction at sufficiently low pressures that the rate of recombination of NO and O_2 was negligibly slow. The quantum yields secured were 0.0046 at 4350 Å., 0.36 at 4050 Å. and 0.77 at 3660 Å.

Busse and Daniels[6] then showed that nitric oxide and nitrogen pentoxide react very rapidly to give nitrogen peroxide according to the last equation; they also showed that the addition of inert gases to the nitrogen pentoxide–nitrogen peroxide mixture does not inhibit the photochemical decomposition. This indicates that the mechanism of Fazel and Karrer is not the correct one, because quenching of the excited nitrogen peroxide molecules should recur under these conditions. It appears that the mechanism is the photochemical production of nitric oxide molecules, which then react with the nitrogen pentoxide molecules to form nitrogen peroxide.

Recently Harris[7] has studied the absorption spectra of nitrogen peroxide and nitrogen tetroxide. The absorption spectrum of NO_2 molecules consists of a large number of bands, many with fine structure, from 6000 to 2250 Å.; the absorption due to N_2O_4 in the gaseous phase is continuous. Two bands, one with a maximum at 3500 Å. and another with a maximum further in the ultraviolet, merge at high pressures of N_2O_4 into one continuous band which extends from 4000 Å. into the far ultraviolet.

The Absorption Spectrum of Nitrogen Pentoxide.—Since the ultraviolet absorption spectrum of nitrogen pentoxide has not been studied previously, we have investigated it and present the results in this paper. We have photographed the ultraviolet absorption spectrum and found it to be continuous, with no evidence of a banded structure. The absorption begins at about 3050 Å. and extends into the Schumann region. Nitrogen pentoxide was distilled through a long absorption cell at low pressures. Any gases produced by photochemical decomposition were removed by a

vacuum pump and liquid–air traps. Weak bands due to nitrogen peroxide were always present on our plates when the experiments were carried out in this way. These weak bands disappeared when the nitrogen pentoxide was treated with ozone before taking the absorption spectrum, but the continuous spectrum was unchanged. Light of wave length longer than 3000 or 3050 Å. is always transmitted.

The Energy of Dissociation of Nitrogen Pentoxide.—If we assume that the Franck theory for the dissociation of diatomic molecules by light can be applied to these more complicated molecules, it leads to the conclusion that the molecule is disrupted into two or more fragments by the absorption of light. The heats of dissociation of nitrogen pentoxide into nitrogen dioxide and oxygen or nitrogen dioxide, nitric oxide and oxygen are

$$N_2O_5 = 2NO_2 + \frac{1}{2}O_2 - 16.0 \text{ kg. cal.}$$

$$N_2O_5 = NO_2 + NO + O_2 - 27.7 \text{ kg. cal.}^{8}$$

Taking the heat of dissociation of oxygen[9] as 160,000 cal., we obtain for the heat of dissociation of nitrogen pentoxide into two molecules of dioxide and an atom of oxygen the value

$$N_2O_5 = 2NO_2 + O - 96 \text{ kg. cal}$$

Nitrogen pentoxide commences to absorb at 3050 Å., which is equivalent to 93.2 kg. cal.; this agrees very closely with the last equation and indicates that the primary photochemical reaction may be dissociated into an oxygen atom and two nitrogen dioxide molecules. It is, of course, possible that the primary photochemical reaction is any reaction which has an energy change less than 93.2 kg. cal., corresponding to the long wave length limit of the continuous spectrum of nitrogen pentoxide; several diatomic molecules are known whose energy of dissociation is considerably less than that corresponding to the wave length at which they begin to absorb.

The Mechanism of the Thermal Dissociation of Nitrogen Pentoxide.—The energy of activation for the thermal decomposition is well established as 24.7 kg. cal. and accordingly[10] this is equal to the difference between the mean energy of the molecules which react and the mean energy of all the molecules. This is very close to the amount of energy necessary to dissociate N_2O_5 into NO_2, NO and O_2, leaving these molecules with only a small amount of energy. Using the I.C.T. values for the energies of formation we find that

$$N_2O_5 = NO_2 + NO + O_2;\ \Delta E = 29.0 \text{ kg. cal.}$$

---

[8] "International Critical Tables," Vol. 5, p. 178.

[9] Birge and Sponer, *Phys. Rev.* (N. S.), 28, 259 (1926). Birge, *Phys. Rev.*, 34, 1062 (1929) has recently revised the value for the heat of dissociation of oxygen. His suggested value will change the calculated energy change of the reaction $N_2O_5 = 2NO_2 + O$ to $-\sim 85$ kg. cal. This does not disagree with our conclusions.

[10] See Tolman, THIS JOURNAL, 47, 2657 (1925).

This is the energy at constant volume required to produce NO_2, NO and O_2 molecules having the mean translational, rotational and vibrational energy at 18° from an N_2O_5 molecule also having the mean energy at this temperature. If an excited N_2O_5 molecule decomposes during the time of free flight, its translational energy must appear as translational energy of the dissociated molecules in order that the linear momentum may be conserved. Therefore the NO_2, NO and O_2 molecule produced in this way must have this much translational energy, namely, about 0.6 kg. cal., but may have no more translational energy and no rotational or vibrational energy. Using the heat capacity data for these gases from the I.C.T., assuming that the heat capacity of NO_2 is the same as that of CO_2 and also assuming that the heat capacity, C_v, is constant to absolute zero, the total energy of vibration, rotation and translation of these molecules is found to be about 4.8 kg. cal. Subtracting from 29.0 and adding the 0.6 kg. cal. of translational energy, we find that the energy required to decompose the average N_2O_5 molecule at 18° to NO_2, NO and O_2 having no vibrational or rotational energy and the 0.6 kg. cal. of translational energy is 24.8 kg. cal. This agrees very closely with the energy of activation, namely, 24.7 kg. cal., and since either may be in error by considerable amounts, this calculation shows that, so far as energy relationships are concerned, the N_2O_5 molecule may undergo a primary unimolecular dissociation into these three products.

It seems possible that the dissociation of nitrogen pentoxide is analogous to radioactive decomposition as discussed recently by Gurney and Condon.[11] Applying their ideas to the dissociation of nitrogen pentoxide we can say that it is possible that sufficient energy may be localized in the right degree of freedom to cause dissociation of the molecule and yet the molecule will exist in a quantized steady state for a finite length of time and then spontaneously dissociate, the time of dissociation being determined by pure probability.

Another possible mechanism would be the dissociation from a steady state in which the energy is not localized in the particular degree of freedom involved in the dissociation. This case would be similar to the dissociation of the excited hydrogen molecule into two normal atoms as proposed by Rlackett and Franck[12] to account for the continuous hydrogen spectrum. The hydrogen molecule in the $2^3\Sigma$ state spontaneously dissociates[13] into two normal atoms and the energy of excitation of the hydrogen molecule appears as kinetic energy of translation of the hydrogen atoms. This is essentially the theory proposed by Rice and Ramsperger and by Kassel.[14]

The present authors do not believe that any evidence presented as yet

will permit us definitely to decide between these two mechanisms; there is also the possibility that there are other mechanisms which will give a unimolecular rate.

Summary

1. The absorption spectrum of nitrogen pentoxide has been measured and shows continuous absorption commencing at 3050 Å. and extending to the far ultraviolet.

2. The long wave length limit of this continuous spectrum corresponds very closely to the energy change in the reaction $N_2O_5 = 2NO_2 + O$ and indicates that this may be the primary photochemical reaction.

3. The mechanism of the thermal decomposition has been discussed and two possible mechanisms have been pointed out which are analogous to the radioactive decomposition of nuclei and the spontaneous dissociation of the excited hydrogen molecule.

THE HEAT CAPACITY OF NITRIC OXIDE FROM 14°K. TO THE BOILING POINT AND THE HEAT OF VAPORIZATION. VAPOR PRESSURES OF SOLID AND LIQUID PHASES. THE ENTROPY FROM SPECTROSCOPIC DATA

BY H. L. JOHNSTON AND W. F. GIAUQUE

RECEIVED MARCH 11, 1929 PUBLISHED NOVEMBER 8, 1929

In a recent paper[1] the entropy of oxygen has been discussed. This was particularly interesting due to the effect of two spinning electrons. **In** this paper nitric oxide will be considered.

Jenkins, Barton and Mulliken[2] have measured the fine structure of the β-bands of nitric oxide and have given a very satisfactory interpretation of them. It is evident from their work that the nitric oxide gas molecules exist in a double electronic level under ordinary conditions. This arises from one-half unit of electronic spin which may couple with or against the one unit of electronic angular momentum which is directed along the figure axis of the molecule. The energies and probabilities associated with the rotation of the molecule as a whole are much influenced by the nature of the electronic coupling and are correspondingly different for the two cases referred to above.

The unbalanced angular momentum responsible for the strong paramagnetism of the nitric oxide molecule has a considerable effect on the entropy to be considered in the latter part of this paper. The theoretical treatment of the magnetic susceptibility of the nitric oxide molecule has

---

[2] Jenkins, Barton and Mulliken, Phys. Rev., 30, 150 (1927).

been considered by Van Vleck,[3] who arrived independently at the same electronic configuration for the molecule as was indicated by the band spectra. The above spectroscopic data and interpretation make possible the calculation of a very accurate value of the entropy.

The object of the present investigation was to obtain reliable heat capacity data for solid and liquid nitric oxide from the boiling point of nitric oxide to temperatures obtainable with liquid hydrogen under reduced pressure. Our object was to determine whether the third law of thermodynamics, as ordinarily used, would give a value for the entropy agreeing with that calculated from spectroscopic data. In the light of opinions advanced in earlier papers[4,5] it may be expected that for some substances, due to lack of thermodynamic equilibrium or to effects occurring close to the absolute zero, or both, the integral $\int C_p \mathrm{d} \ln T$ might give too small a value.

The entropy of nitric oxide from the calorimetric data is considerably lower than that obtained from spectroscopic data although the entropy calculated from the latter may be considered reliable.

Preparation and Purification of Nitric Oxide.—The difficulty of preparing pure nitric oxide has been recognized by various investigators and probably accounts for the discordant data on the physical properties. Adwentowski[6] expressed doubt that the gas could be prepared in a high state of purity. Difficulty arises from the fact that all processes for the preparation of the gas depend on the reduction of either NO_3^- ion or of NO_2^- ion and the NO produced always contains traces of other oxides or reduction products not easily removed, particularly NO_2, N_2O_3 and N_2. A comparatively large amount of nitric oxide was desired in a higher state of purity than any previously obtained in order to fix certain physical constants with great accuracy. A careful study was made to determine the best method of preparation and purification. The investigations of Moser[7] indicated that the best method for the preparation is that described by Winkler.[8] A dilute solution of sulfuric acid is dropped into a solution of potassium nitrite and potassium oxide. The nitric oxide is produced by the reaction $2NO_2^- + 4H^+ + 2I^- = 2NO + I_2 + 2H_2O$. When the preparation is carried out under proper conditions and the product is passed through wash bottles containing in turn sulfuric acid and potassium hydroxide solutions, Moser finds that nitric oxide of 99.8% purity may be produced. Germann[9] showed that fractional distillation was usually more

effective for final purification than the use of chemical purifying agents, Gray,[10] however, has shown that the usual methods of fractionation become ineffective for nitric oxide and describes an effective means of distillation which relies for its efficacyon the high solubility of the oxides in liquid nitric oxide and their low vapor pressures at the boiling point of nitric acid. Nitrogen is best removed by evacuating the freshly sublimed solid.

The preparation and purification were based on the suggestions above. The measurements were carried out with three different preparations of nitric oxide. In Preparation I a six-liter pyrex round-bottomed reaction flask was employed. This could be emptied or filled with fresh reagents through a pyrex stopcock without contamination with air. It was initially half filled with a nearly concentrated solution made by dissolving 5 kilograms of potassium nitrite and 2.5 kilograms of potassium iodide in 15 liters of distilled water. Nitric oxide was generated by dropping a 50% solution of sulfuric acid from an acid reservoir. Regulation of stopcocks controlled the rate at which the gas was generated. During operation the mixture was stirred by an electromagnetic stirrer. Platinum–iridium in the form of a wire spring, which served to prevent injury to the apvaratus, was the only material other than pyrex glass in contact with solution or evolved gas. It was necessary to refill the reaction flask several times in the course of a preparation in order to obtain the amount of nitric oxide desired. Some annoyance was experienced in this operation due to the precipitation of large amounts of iodine, and to the formation of hard crystals of potassium sulfate which clogged the drainage tube. Accordingly in Preparations II and III a 20-liter bottle was substituted, which held enough of the reagents to avoid the necessity of refilling. This was made of common glass and was fitted with a two-holed rubber stopper through which projected the dropping stem from the acid reservoir and the outlet tube for the gas. To make certain that it was vacuum tight the stopper was covered externally with de Khotinsky cement. The solution was unstirred but the gas generated was subjected to one more fractionation in the later stages of purification than Preparation I and, as the data will show, there was no appreciable difference in purity between Preparation I and Preparations II and III.

As a practical precaution, the 20-liter bottle was placed in a small barrel to avoid danger in case it should collapse when evacuated. This precaution was found necessary for on one occasion a similar bottle which had been previously tested and frequently evacuated collapsed under a vacuum and threw pieces of glass with considerable violence.

From the generator the crude gas entered the purifying train. It was first bubbled through a tall column of 90% sulfuric acid and then through a tall column of 50% potassium hydroxide solution. Both columns contained glass beads to break up the bubbles. Next was included a trap immersed in a bath of solid carbon dioxide and ether. The principal purpose of this trap was to remove the bulk of the moisture but it also served to condense a further portion of the higher oxides that might have passed through the potassium hydroxide. The gas was condensed in a bulb surrounded with liquid air. When sufficient nitric oxide had collected, the generator was stopped, and the gas was distilled, passing on its way through about two meters of tubing packed alternately with phosphorus pentoxide and plugs of glass wool, the first and last portions being discarded. Following this the nitric oxide was distilled into a bubbling bulb until it had collected to a depth of four or five centimeters, after which the depth was kept constant by regulating the height of liquid air in an unsilvered Dewar flask while

---

[10] Gray, J. Chem. *Soc.*, **87**, 1601 (1905).

the remainder was slowly bubbled through in accordance with the suggestion of Gray, mentioned above. Two such stages of bubbling were included in each cycle, the liquid in the first stage, with the relatively non-volatile other oxides of nitrogen being discarded, and the liquid remaining in the second bubbling bulb being transferred to the first to serve as the initial concentrate for the next operation. The nitric oxide was then solidified, pumped for several minutes, sublimed under a pressure of about 5 cm. of mercury and pumped again for several minutes. Finally the nitric oxide was returned to the beginning of the cycle and the distillation and sublimation process repeated. This cycle was carried through three times for Preparation I and four times for Preparations II and III. During the process about 450 cc. of liquid nitric oxide initially collected was reduced to about 150 cc. of purified liquid. The middle 105 or 110 cc. was then distilled into the calorimeter. Except during the sublimation process the pressures in the generator and purifying line were kept close to atmospheric. The pressures were observed on five manometers, which also served as safety valves in case of need.

Great care was taken to avoid contamination by air since Moser[7] had shown that small amounts of air had a catalytic action in the decomposition of nitric oxide. Except for the reaction bottle and its rubber stopper the entire generating and purifying system was constructed of pyrex glass with fused joints. The stopcocks used were special high vacuum stopcocks and were greased with rubber stopcock grease[11] previously saturated with nitric oxide gas at 150°. Before the liquid reagents were added to the generator or purifying columns, the entire line was evacuated to a pressure of about 10^{-5} mm of mercury and was pumped for several days with occasional sparking and heating to remove adsorbed gases from the phosphorus pentoxide and from the walls of the glass line. All solutions were boiled to expel air. After supplying the reagents the system was again evacuated for several hours. A slow stream of nitric oxide was passed through the line for several minutes before any was collected. The gas was generated slowly in order to avoid loss of efficiency in the purifying columns. For the same reason distillation and sublimation were carried out at a moderate rate. With continuous day and night operation a period of four or five days was consumed from the time that the generator was started until the nitric oxide was distilled into the calorimeter.

No analyses of the gas were made since accurate melting point and heat capacity data provide a more sensitive test of impurity than are given by chemical analysis. Following the presentation of the data there will be given a full discussion of the question of purity.

Heat Capacity Measurements and Data.—The calorimetric measurements and the measurements of the amounts of material were carried out in the same manner and with the same apparatus described for the measurements on oxygen.[1] The discussion given in the latter work relative to the sources of error and treatment of the data applies practically without change in the work on nitric oxide. Since the amount of gas was measured volumetrically, we made use of certain physical constants of nitric oxide which are given below. The molecular weight was taken as 30.008.[12] The density used was 1.34018 as given by Scheuer.[13] The

mean coefficient of expansion between 0 and 25° as given by Leduc[14] is 0.003677. The coefficient of deviation from Boyle's law per atmosphere is given by Batuecas[15] as —0.00112.

Two series of measurements, described as IIIa and IIIb, were carried out to determine the heat capacities of solid and liquid nitric oxide. Both were made with Preparation III. Within each series the measurements were made in order of rising temperature and between the two series a small measured amount of nitric oxide was removed from the calorimeter in the process of removing the plug of solid nitric acid which had distilled into the glass tube above the calorimeter during the period of recooling. The two series of measurements taken together covered the temperature interval from about 14.3 to about 122.1°K. The data are recorded in Table I, in which the first column gives the serial number of the run, the second column the mean absolute temperature, the third column the temperature interval covered and the fourth the heat capacity in calories per mole per degree.

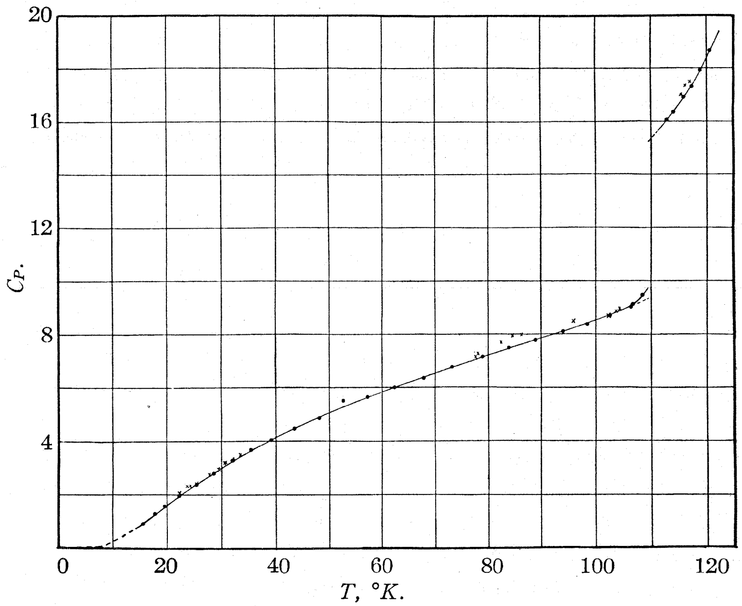
to reveal any factor to which might be assigned an error within reasonable limits sufficient to account for the deviation. It is possible that a transition of very small energy change has been included. A transition heat of about 1.3 calories per mole would account for this point. It is also possible that the point falls on the maximum of a gradual transition. This region could readily have been studied in detail had this situation been suspected but unfortunately the calorimeter was emptied before it was discovered. From the standpoint of the entropy calculation this is immaterial since the area concerned, if real, would affect the entropy by only 0.02 of an entropy unit.



●, This Research; ×, Eucken and Karwat.

Fig. 1.—Heat capacity in calories per mole of nitric oxide.

The short interval runs taken in Series IIIa just below the melting point were for the purpose of evaluating the degree of impurity and will be discussed in a later paragraph. The sharp rise in the solid curve is assumed to be due to the influence of premelting and the dotted curve represents the extrapolation for the pure solid.

For the sake of comparison the results of Eucken and Karwat[16] have been plotted and are represented by crosses. It will be observed that their values are in general higher than ours and show large deviations among themselves. Compared with the curve of Fig. 1, their results for solid nitric oxide from 22 to 34° show an average deviation of 2.3% with a maxi-

---

[16] **Eucken** and Karwat, *Z. physik. Chem.*, **112, 467** (1924).

mum deviation of 6%. In the region from 82 to 104°, their results differ from the curve by 2.5% on the average and show a 5% maximum deviation. These deviations are somewhat larger than the probable error claimed by those authors, who believed their values for solid nitric oxide to contain no larger maximum error than 2% with an average error of only 1%. The points they secured for liquid nitric oxide agree more closely with ours and the deviations are within the limits of error which they claimed.

Among our values, with the exception of these points already discussed, only six of the points above 30° deviate from a smooth curve by more than 0.1 of 1%. Of these only two deviate by more than 0.2 of 1%. It is believed that for the region from 35° to the boiling point the smooth curve represents correct values of C_p to within 0.2 of 1%. Below 35° the accuracy is lessened somewhat, due partly to the lowered heat capacity but principally to the lower temperature coefficient of the resistance thermometer. At 20° the error may be 0.7 of 1% and at 14° may be as large as 2 or 3%.

Melting Point.—The melting point was determined for each of three preparations of nitric oxide. On each occasion readings were taken at intervals of three or four hours over a period of about two days. When constancy of successive readings indicated that thermal equilibrium was attained, a further fraction of the solid was melted and more readings were taken at subsequent intervals. This was done to avoid the influence of impurity in the final value chosen for the melting point, although the data make it evident that very little influence of this sort existed. Table II records the measurements. The data for Preparations I, II and III are arranged in order. Column one indicates the date and approximate hour at which observations were recorded. Column two indicates the approximate percentage melted. Column three records the absolute temperatures determined. These were calculated from the reading of the standard thermocouple soldered to the bottom of the calorimeter. The readings of the thermocouple are ordinarily reproducible to 0.01°, so differences of that amount are without significance in this column. For that reason, there is included in column four the resistance (in ohms) of the gold resistance thermometer wound on the outer surface of the calorimeter. The readings of this thermometer are ordinarily reproducible to 0.001 or 0.002 of an ohm and the resistance at this temperature is changing by almost exactly an ohm per degree. The comparison of resistance is only significant as between values in a single series of measurements, since in the period between the readings on Preparations I and II the wire had been subjected to strain and the calibration changed, and between the measurements of Preparations II and III a new resistance thermometer was wound. These are referred to as thermometers A, A' and B.

TABLE II

MELTING POINT OF NITRIC OXIDE

Date and time		Percentage melted	T, °K. (from thermocouple)	R, ohms, from resist. thermometer
		Preparation I		
12/14/27	4:00 P.M.	Heated into melting point		Thermometer A

	2:00 P.M.	50	109.51	.....

Accepted value, 109.49 ± 0.05°.

It will be observed that among the temperatures recorded by the thermocouple at various times, only four differ by more than 0.01° from the value chosen as the melting point. In other words, they lie within the precision of the thermocouple to distinguish them. The resistance thermometer likewise shows this constancy of temperature since the extreme readings

in any one series differ by only 0.005 of a degree. The chosen value, 109.49°, is then subject only to the uncertainty of temperature scale, which amounts to about 0.05°.

For the sake of comparison, in Table III are listed melting point values reported by various authors. Values of the triple point pressure are also included.

Heat of Fusion.—The heat of fusion was measured in the usual manner. Correction was applied for $\int C_p dT$ and also for the small amount of premelting that had occurred below the temperature at which the energy input was begun. The latter correction was determined from the area between the solid and dotted curves in Fig. 1.

The results are given in Table IV, in which column one gives the amount of material melted (in moles); column two the temperature interval covered; column three the total heat input in calories corrected for all factors except $\int C_p dT$ and the premelting correction referred to above; column four the total of these last two corrections for calorimeter plus contents; and columns five and six the individual values and the mean value of our determinations. The latter value is believed to be correct to within 0.2 of 1%. Both measurements were made with Preparation III. At the bottom of the table, for comparison, are included the experimental values obtained by Eucken and Karwat and the values calculated by Henglein and Kruger and by Goldschmidt from vapor pressure measurements.

Heat of Vaporization.—The heat of vaporization was measured in the manner previously described[1] for oxygen. During the determinations the surroundings were maintained at a temperature slightly above the boiling point of the liquid in order to avoid errors due to condensation. By means of the automatic pressure control device referred to in a previous paper,[1] the pressure during the measurements was kept constant at 76 cm. of mercury within 0.1 mm. Heat was supplied to the bottom half of the calorimeter and no measurements were taken after the liquid level had fallen close to the heated portion. They were all made with Preparation III. Energy was supplied for a period of fifty-three minutes in each case. The results are given in Table V, in which the first column gives the number of moles evaporated in each determination, column two the values of the heat of vaporization obtained from the individual measurements and column three the mean value. It will be observed that no individual value differs from this mean by more than 0.02 of 1%. We believe 0.1 of 1% to be the limit of error of this determination.

TABLE V

HEAT OF VAPORIZATION OF NITRIC OXIDE

Boiling point, 121.36°. Molecular weight, 30.008

Moles of NO evaporated	0.21677	0.21729	0.21711	0.21646

No other calorimetric values for the heat of vaporization of nitric oxide are to be found in the literature.

Vapor Pressures of Nitric Oxide.—The best recent determinations of the vapor pressures of solid and liquid nitric oxide are those of Henglein and Kruger[17] and of Goldschmidt.[18] Both claimed high accuracy for their values, yet there is comparatively wide disagreement between the two sets of data. Since we had very pure nitric oxide and since the calorimetric apparatus employed was likewise admirably suited to the accurate measurement of vapor pressures, it seemed desirable to make a redetermination of vapor pressures. The data were obtained by the procedure already used by Giauque, Johnston and Kelley[20] for oxygen and hydrogen. For each vapor pressure point the calorimeter, nearly full of the liquid or solid nitric oxide, was heated to the desired temperature and allowed to stand for nearly an hour to insure thermal equilibrium before the temperature and pressure were taken. To avoid distillation the surroundings were maintained at a temperature slightly above that of the calorimeter. Pressures were read with the aid of a standard meter scale and a Société Génévoise Cathetometer. Corrections for temperatures of mercury and scale and for meniscus height were applied as described in connection with the measurement of the amount of gas in a previous paper.[1] The measurements were obtained with a precision of 0.002 cm. The measurements for solid nitric oxide began at 94.62°K. and were all made with Preparation II. Those for the liquid were begun with Preparation II and carried to about 116°. An accident occurred which interrupted the measurements at this point and subsequently the measurements were repeated with Preparation III and extended to nearly 123°K. The triple point pressure was investigated with Preparations I, II and III in turn.

The results are tabulated in Table VI. In this table the first column gives the preparation number; the second, the observed temperature in degrees absolute; the third, the observed pressure in international centi-

The data are represented by vapor pressure equations which take the form, for solid

$$\log_{10} p(\text{cm.}) = \frac{-867}{T} + 0.00076\,T + 9.05125$$

and for liquid

$$\log_{10} p(\text{cm.}) = \frac{-776}{T} - 0.002364\,T + 8.562128$$

As shown from the ΔT column of Table VI, the agreement between experimental values and the values given by these equations is exceptionally good. Almost without exception the experimental points fit these equations within the limits of the thermocouple readings. The results are shown graphically in Fig. 2, where log p is plotted against $1/T$. The nearly linear curves intersecting at the triple point represent the above two equations. Our experimental points are plotted in dark circles. For comparison the results of Henglein and Kruger are plotted in dark squares and those of Goldschmidt in dark triangles. The scale of the graph is really too insensitive to indicate the extent of the disagreement. Table VII shows a comparison of the smoothness of these data with those of Henglein and Kruger and of Goldschmidt, by comparing the mean deviations and the extreme deviations of each observer's data from the vapor pressure equations derived by the respective workers. The comparison is made over the same range of temperature for each set of data, a little above 90° to the boiling point. The first line lists the research, Line 2 the extremes of AT from the vapor pressure equation derived to fit and the third line the average deviation in degrees absolute.

Average AT, °K.	0.12	0.08	<0.01

Comparisons of triple point pressures are made in Table III, where the triple point temperatures were recorded. The present value is the mean of the six direct determinations recorded in Table VI and is consistent for three separate lots of nitric oxide. It is believed to be correct to within

0.004 cm. The triple point pressure of Henglein and Kruger was not determined from direct measurement but was calculated from their vapor pressure equations, and was likewise their triple point temperature. Goldschmidt's value was obtained from a single direct measurement.

In Table VIII are given the values for the boiling point of nitric oxide as determined by the vapor pressure measurements of various observers.

TABLE VIII

BOILING POINT OF NITRIC OXIDE

Observer	T, °K.	Observer	T, °K.
Olszewski[19]	119.5	Henglein and Kruger[17]	122.4
Ramsey and Travers[21]	123.2	Goldschmidt[18]	121.87
Adwentowski[S]	122.8	This Research	121.36 ± 0.05

Differences in temperature scales undoubtedly are a contributing factor to the vapor pressure differences found by various observers. This cannot account, however, for differences in the triple point pressure. It is believed that the difficulty of preparing nitric oxide in a high state of purity has been a prominent factor. It is a significant fact that the present measurements, which were carried out with very pure nitric oxide, lead to a lower value for the boiling point and to higher vapor pressures for the liquid than do other recent researches.

Purity of Nitric Oxide.—Measurements of heat capacity just below the melting point serve as a very sensitive test of impurity. Measurements were purposely made close to the melting point in order to make such a test. Insoluble impurities would not cause premelting but they could hardly be present under the circumstances of preparation and purification.

For the most probable case of pure solid in equilibrium with impure liquid, we have, assuming Raoult's law, the equation

$$\ln N_1 = \frac{-\Delta H}{R}\left(\frac{T_m - T}{T_m T}\right)$$

where N_1 refers to the mole fraction of nitric oxide, ΔH is its heat of fusion and T_m is the melting point. This equation gives us the mole fraction of nitric oxide in any liquid which may be formed by premelting at temperature T. The heat effect accompanying premelting will depend on $\Delta H \times$ (A" − A'), where A'' and A' refer, respectively, to the amounts of liquid nitric oxide at T'' and T'. The heat effect is obtained by taking the difference between the observed input from T' to T'' and that which would be calculated from an assumed curve such as is indicated by the dotted line in Pig. 1. We now have sufficient information to solve for the number of moles of impurity, which must be a constant. The results are given in Table IX. The amount of impurity is expressed in mole percentage rather than in mole fraction.

---

[21] This value was quoted in Ref. 17.

TABLE IX

MOLE PERCENTAGE OF IMPURITY IN NITRIC OXIDE

Preparation III

T'	T''	Heat of pre-melting calories	N'_1	N''_1	Impurity. mole per cent.
104.71	108.59	0.171	0.8956	0.9795	0.00079
107.63	109.15	.365	.9580	.9922	.00064
From melting point change of Preparation II					.0004

At the bottom of the table a value obtained from the less sensitive method of melting point rise is included. In determining the melting point of Preparation II, a measurement was purposely made with only about 3% melted in order to make as severe a test as possible. From the data recorded in Table II the amount of impurity was evaluated. It should be a reasonable conclusion that the nitric oxide contained less than 0.001 mole per cent. of impurity.

Some Physical Characteristics of Liquid and Solid Nitric Oxide.—The assignment of physical characteristics to solid and liquid nitric oxide has been influenced by the recognized impurity of the substance examined by those who have reported. Adwentowski[6] describes the liquid as colorless in thin layers and light blue in thick layers and ascribes the blue color to the presence of nitrogen trioxide impurity. Henglein and Kruger refer to the liquid as pale blue, resembling liquid oxygen. Nearly all writers refer to the solid as a "snow white" solid and this description is accepted without question in books of reference. In this investigation, we dealt with large quantities of solid and liquid in a high state of purity. The liquid was blue in color, a much darker and more brilliant blue than liquid oxygen with which we had every opportunity of comparison since in the course of the oxygen investigation liquid oxygen was collected in some of the same collecting bulbs used for the nitric oxide. If this blue were due to the small traces of impurity present a marked change in color intensity should have been observed in the course of the purification; no such change was observed. The appearance of the solid depended on our method of freezing it. If collected as a sublimate on the walls of the collecting bulb it had the appearance of a white frost, the "snow white" solid of the literature, but if this same sublimate were allowed to warm to the melting point, it was converted into a clear blue ice. Freezing the liquid always produced this clear blue ice, resembling in shade and intensity the coloration of the liquid. If a glass bulb filled with this clear blue solid was suddenly immersed in liquid air the nitric oxide became filled with innumerable cracks which made the solid appear white and opaque, although blue splotches of varying shades of intensity remained in places where the cracking was not as complete. Further investigation convinced us that the white appearance of the solid secured under certain conditions of freezing is a purely superficial effect caused by the crystalline state of aggregation throughout the mass and that the true color of the solid is blue. Thus both liquid and solid are blue in color.

Entropy from Heat Capacity Data.—The entropy of nitric oxide gas at the boiling point of the liquid was calculated from the calorimetric measurements by integration of the heat capacity data with respect to the logarithm of temperature. A summary of the entropy calculation is given in Table X. The extrapolation below 14.35°K. was carried out by means of a Debye function with a $\beta\nu = 119$.

TABLE X

ENTROPY OF NITRIC OXIDE FROM HEAT CAPACITY DATA

	Cal. per degree per mole
0 to 14.35°K. (extrapolated)	0.27
14.35 to 109.49° (graphical)	8.79
Fusion 549.5/109.49	5.02
109.49 to 121.36 (graphical)	1.73
Vaporization 3292.6/121.36	27.13
Entropy of nitric oxide gas at the boiling point	42.94 ± 0.1 E. U.

This value is for the actual gas. For the purpose of later comparison with the entropy derived from band spectra, it is necessary to have the entropy of the hypothetical perfect gas. Assuming Berthelot's equation of state, a correction of 0.09 cal./deg. per mole results, leading to a value of 43.03 for the entropy of nitric oxide gas in the hypothetical ideal state at 121.36°K.

The entropy has also been calculated with the assistance of the thermodynamic equation $dP/dT = \Delta S/\Delta V$ and our vapor pressure data for both solid and liquid. The entropy of vaporization was calculated at the triple point temperature in each case, making use of Berthelot's equation in order to correct for gas imperfection. The entropy of solid or liquid at the melting point may be obtained from Table X. In order to obtain the entropy change in heating the gas from the triple point to the boiling point, we assumed that C_p was 7/2 R and corrected for the error in this assumption by an approximate calculation of the entropy change accompanying the changing distribution of the $^2P_1$ and $^2P_2$ states. From the solid $S_{NO} = 43.3$ E. U., and from the liquid $S_{NO} = 43.0$ E. U., each calculated to the temperature of the boiling point, as compared to 43.0 E. U. obtained from the calorimetric measurements. This agreement is all that could be expected of the vapor pressure calculations and we give these two calculations no weight as compared to the calorimetric data.

The heat of vaporization at the boiling point has also been calculated from the vapor pressure data for liquid nitric oxide, again using Berthelot's equation to represent gas imperfection. The value obtained for $\Delta H_{121.36°K.}$ is 3316 cal. per mole as compared with the more accurate calorimetric value 3293. Similar calculations by Henglein and Kruger[17] and by Goldschmidt[18] from their respective vapor pressure data lead to the values 3023 and 3199.

Spectroscopic Interpretation of Nitric Oxide.—Jenkins, Barton and Mulliken[2] have obtained measurements of the fine structure of the β-bands of nitric oxide and have made an analysis of the lines in keeping with Hund's theory[22] of molecular electronic states and with recent developments in the interpretation of band spectra as reviewed and extended in a number of papers by Mulliken.[23] The classification of the lines revealed the presence of two distinct band systems. The application of the combination principle taken in conjunction with the positions of missing lines in the various branches led to the assignment of proper j values and to the proper term formulation for the initial and final electronic levels of the two band systems. The term formulations show that the two band systems originate from respective transitions from a double initial electronic level to a double final electronic level $({}^2P_1 \longrightarrow {}^2P_1)$ $({}^2P_2 \longrightarrow {}^2P_2)$. In the lower states the ${}^2P_2$ level has a higher energy than the ${}^2P_1$ level. The separation is 124.4 cm.$^{-1}$. The magnitude of separation was obtained from the analysis by Frl. Guillery[24] of the y-bands of nitric oxide, which are likewise a double band system, having the same final double electronic state as do the β-bands. From the fact that both β- and y-systems appear in the absorption spectra of nitric oxide,[25,26] it is evident that this lower double level is the normal state of the nitric oxide molecule.

A physical concept of alignment and quantization of momenta within the molecule is desirable to make clear the assignment of j values and of *a priori* probabilities necessary in the application of the spectroscopic data to the calculation of entropy. Hund has shown that molecules containing resultant electronic angular momentum and electron spin will have their rotation states defined by the three vectors: σ_k, the component of electronic angular momentum directed along the figure axis of the molecule; S, the electron spin and m, the rotational momentum of the molecule. Any component of electronic angular momentum other than that directed along the axis of the molecule is assumed to be without effect on the molecular motion due to the rapid procession. This latter assumption is, of course, in agreement with the observed facts of band spectra.

For nitric oxide $s = {}^1/_2$ and $\sigma_k = 1$. Neglecting at first the molecular rotation, the spin s sets itself either with or against σ_k, thus leading to the

[26] Sponer and Hopfield, *Phys. Rev.*, **27**, 640 (1926).

doublet state referred to above. In the $^2P_1$ state s opposes, σ_k and in the $^2P_2$ state, s is with σ_k. When the rotation of the molecule is taken into account, Hund has shown that for increasing values of m, the influence of σ_k is relatively weakened as compared to that of m. The spin, s, gradually breaks away from its close coupling with σ_k and, in the limit, aligns itself either directly with or directly against the vector j_k (j_k is the vector sum of σ_k and m).

The vector sum of σ_k, s and m leads to the single vector j, which represents the total angular momentum of the molecule. Under all circumstances j is rigidly quantized. It is significant to observe in this connection that in meeting the conditions of quantization in the several instances referred to above, m itself is not quantized and, except for the special case of a molecule with $\sigma_k = 0$, cannot be quantized. Indeed, when a σ_k is present, the various m states not only differ by non-integral amounts of momentum but even the increments in momentum change in passing from one pair of rotation states to the next. The various rotational energy states are thus correlated with quantized terms which are j terms. Particular attention is called to this point because in the past m rather than j has frequently been regarded as the significant quantity in applying band spectra to the heat capacity and the entropy calculations.

It may be seen from the geometry of the model built up in the paragraphs above that j may be equal to the vector sum of σ_k and s (for $m = 0$) but never less. Hence the $^2P_1$ state has associated with it j values $= {}^1/_2$, ${}^3/_2$, ${}^5/_2 \ldots$, while the $^2P_2$ state can include no value $j = {}^1/_2$ but has associated with it the j values $= {}^3/_2$, ${}^5/_2$.

In fixing the *a priori* probability of a particular state of the molecule j, and not m, is the significant quantity to be considered. The *a priori* probability of a particular state is given by the wave mechanics as $(2j + 1)$.

The above was shown very definitely by the fine line structure photographed by Jenkins, Barton and Mulliken and by the intensity measurements of the same authors.[27] The j values used by the latter and by Mulliken[23] are larger by ${}^1/_2$ unit than the wave mechanics j values, hut as they used $2j$ as the *a priori* probability, the same results are attained. In the tables the wave mechanics values for the vibrational quantum number n are used to replace the values given in their tables, which were one-half unit lower.

One further important consequence of the theory of Hund must be considered. From the equations of Hund it follows that for a molecule like nitric oxide, possessing a component σ_k, associated with every value of j there should be not two (corresponding to $^2P_1$ and $^2P_2$ states) but four states of the molecule of equal *a priori* probability. This should lead to four series of bands provided the energies corresponding to the states of

---

[27] Jenkins, Barton and Mulliken, Phys. *Rev.*, 30, 175 (1927).

the last two members of the multiplet were sufficiently different from the first two. Jenkins, Barton and Mulliken did find a fine scale doubling in the lines of the $^2P_1$ band series and, where resolution was sufficiently great for intensity measurements, the intensity relations corresponded to the equal *a priori* probability assignment. No such fine scale doubling was found in the lines of the $^2P_2$ band system but it is probable that double states of almost equal separation existed in the initial $^2P_2$ level as well as in the final level so that the doubling could not be observed in the spectra. This type of superfine doubling is well recognized in other spectra of molecules possessing a component σ_k and is referred to as a-type doubling. Mulliken[23] refers to the energy levels that give rise to the members of the doublets as A and B sub-levels.

The Entropy Calculated from the Spectroscopic Data.—The entropy of nitric oxide gas has been calculated for a temperature of 121.36°K. and also for 298.1°K. To obtain that portion of the entropy resulting from the translational energies of the molecules, we have employed the Sackur equation for the entropy of a monatomic gas

$$S = \frac{3}{2} R \ln M + \frac{3}{2} R \ln T + R \ln V - 11.06$$

M is the molecular weight, T the absolute temperature, V the molal volume in *cc.* and R is the gas constant taken as 1.9869 cal./deg. per mole.

To obtain that portion of the entropy contributed by the degrees of freedom other than translation, we have used the summation method[28,1]

$$S_{E+R+V} = R \ln \Sigma_{e,n,m} p_{e,n,m} e^{-\epsilon_{e,n,m}/kT} + \frac{1}{kT} \frac{\Sigma_{e,n,m} p_{e,n,m} \epsilon_{e,n,m} e^{-\epsilon_{e,n,m}/kT}}{\Sigma_{e,n,m} p_{e,n,m} e^{-\epsilon_{e,n,m}/kT}}$$

$\epsilon_{e,n,m}$ is the energy of a certain state with respect to electronic configuration, molecular vibration and molecular rotation, respectively; $p_{e,n,m}$ is the corresponding *a priori* probability, *e* the base of the natural logarithms and k the gas constant per molecule.

The above equation has been used in conjunction with the data and spectroscopic interpretation of Jenkins, Barton and Mulliken[2] as outlined above.

In carrying out the required summations in the calculations which follow, it has been convenient to make the summations as though a-type doubling did not exist. Then each sum was doubled before incorporating it in the entropy equation. This method is justified since the energy differences of A and B substates are so small that the same energy may be assigned for each state (the spectroscopic measurements were taken at the middle of the double lines) and the total energy and total numbers in both A and B states will be double that in either one.

Table XI shows the values obtained for the significant sums which appear in the entropy equation for T = 121.36°K.

---

[28] Giauque and Wiebe, THIS JOURNAL, 50, 101 (1928).

TABLE XI

SUMS IN THE ENTROPY EQUATION FOR NITRIC OXIDE

$n = 1/2 \quad T = 121.36°K.$

e	$\Sigma_m p_m e^{-\epsilon_m/kT}$	$1/kT\ \Sigma_m \epsilon_m p_m e^{-\epsilon_m/kT}$
$^2P_1$	51.364	50.529
$^2P_2$	11 053	27.553
$\Sigma_{e,n,m}$	62.417	78 082
Doubled for u-type doubling	124.834	156 164

It is interesting to note that the distribution of molecules between the $^2P_1$ and $^2P_2$ states at the boiling point of nitric oxide is 82.29% of $^2P_1$ molecules to 17.71% of $^2P_2$ molecules. This unequal distribution is a result of the 124 odd wave numbers difference in energy between the two forms of coupling. The fraction of molecules in higher vibration states has been calculated and found to be inappreciable for this temperature. Putting the above sums into the entropy equation

$$S_{E+R+V} = 12.08 \text{ E. U.}$$

Combining this value with the 31.67 entropy units contributed by the translation of the molecules, the entropy of the hypothetical perfect nitric oxide gas at one atmosphere pressure and 121.36°K. has the value 43.75 calories per degree per mole.

The result of a similar calculation for a temperature of 298.1°K. is given in Table XII.

TABLE XII

SUMS IN THE ENTROPY EQUATION FOR NITRIC OXIDE

$T = 298.1°K.$

e	n	$\Sigma_m p_m e^{-\epsilon_m/kT}$	$1/kT\ \Sigma_m \epsilon_m p_m e^{-\epsilon_m/kT}$
	1/2	124.864	124.107
$^2P_1$	3/2	0.917	5.419
$^2P_1$	5/2	.007	0.078
	7/2	.000	.001
$^2P_2$	1/2	65.721	105 804
$^2P_2$	3/2	0.480	3.131
$^2P_2$	5/2	.004	0 043
$^2P_2$	7/2	.000	.001
$\Sigma_{e,n,m}$		191.993	238 584
Doubled for u-type doubling		383.986	477.168

This leads to the value $S_{298\cdot1} = 50.43$ E. U.

There is one further type of multiplicity which makes a contribution to the absolute entropy of nitric oxide which we have not considered in the above calculation, since it would be expected to affect the spectroscopic and $\int_0^T C_p \mathrm{d}\ln T$ calculations equally. This arises from the one unit of spin associated with the nitrogen nucleus and contributes R ln **3** entropy units to the value of the absolute entropy.

Comparison of Entropy Values.—The theoretical and experimental values of the entropy are compared in Table XIII.

TABLE XIII

COMPARISON OF SPECTROSCOPIC AND THIRD LAW VALUES OF THE ENTROPY OF NITRIC OXIDE

T, °K.	121.36	298.1
Entropy from spect. data, cal./deg./mole	43.75	50.43
$^{T}C_p\mathrm{d}\ln T$ Actual gas	42.94 ± 0.1	...
$^{T}C_p\mathrm{d}\ln T$ Corr. to ideal state	43.0	...

It is clear that the experimental value is in definite disagreement with that calculated from the spectroscopic data.

It appears significant that the entropy obtained from the calorimetric measurements is lower than that obtained by the spectroscopic method by almost exactly $^1/_2$ R ln 2. This can be explained if solid nitric oxide is a solution of two polymerized isomers in equal amount. Liquid nitric oxide is known to be highly associated into N_2O_2 molecules and it appears reasonable that this effect would persist in the solid. Solid isomers would result if, in the process of association, more than one type of pairing could occur between molecules which retained some of the electronic differences they possessed in the gaseous state, such as the differences responsible for a-type doubling. An equimolal mixture of two such isomers of small energy difference would possess an entropy in excess of that obtained from the heat capacity measurements by an amount equal to R ln 2 entropy units per mole of polymerized molecules. This is equivalent to $^1/_2$ R ln 2 entropy units per stoichiometrical mole. The solid nitric oxide would thus appear to go to the absolute zero with 0.69 entropy units per mole still present. The discrepancy between the entropy values obtained from calorimetric and from spectroscopic data, respectively, is 0.72 entropy unit.

We do not regard this as a contradiction of the third law of thermodynamics, although it has an important bearing on the application of that law to thermodynamic problems. In conformity with views expressed in previous papers,[4,5] it is believed that if nitric oxide could be cooled to the absolute zero and be allowed to reach true equilibrium, a transformation would occur to a single species of molecule having zero entropy. This transformation would result from the energy difference which, though small, must exist between the isomeric forms. Expressed in other terms, we believe that if measurements of the heat capacity of nitric oxide could be carried to the absolute zero under equilibrium conditions, the results would fall on a curve which would show a maximum, close to the absolute zero, which would just account for the observed entropy difference.

We wish to thank Mr. J. O. Clayton for assistance in the experimental work and in the calculations. We also wish to thank Professor R. T. Birge for many discussions of the spectroscopic data and their interpretation.

Summary

Nitric oxide containing less than 0.001 mole per cent. of impurity has been prepared. Both solid and liquid were found to be blue in color. The accepted opinion that solid nitric oxide is colorless is apparently based on observations on material in a fine state of subdivision. Under such conditions it was found to have this appearance.

The heat capacities of solid nitric oxide and of the liquid have been measured from 14°K. to the boiling point. From the boiling point to 35°K. the smooth curve through the points is believed to be accurate to within 0.2 of 1%; below this temperature there is a gradual decrease in accuracy. At 20°K. the results are believed to be reliable to 0.7 of 1%, and at 14°K. to 2 or 3%.

The melting point was found to be 105.49 ± 0.05°K.; the boiling point 121.36 ± 0.05°K.

Calorimetric determinations of the heat of fusion and of the heat of vaporization were made. These were found to be 549.5 ± 1.0 and 3292.6 ± 3 calories per mole, respectively.

The vapor pressures of solid and liquid nitric oxide have been measured between 93 and 123°K.

The entropy of nitric oxide gas at 121.36°K. and one atmosphere was calculated from the above data and the third law of thermodynamics, and found to be 42.94 ± 0.1 calories per degree per mole. With the aid of Berthelot's equation of state this value was corrected to the ideal state, the correction being +0.09 calorie per degree per mole. When compared to the value calculated by the accurate summation method from the molecular spectrum of nitric oxide gas, the value obtained from the heat capacity measurements proved to be too low to the extent of 0.72 calorie per degree per mole. This is not taken as a contradiction of the third law of thermodynamics but is believed to arise from the presence of equimolal amounts of two forms of N_2O_2 in the solid state. This situation, which would lead to a difference of $^1/_2$ R ln 2 or 0.69 E. U. in comparison with the experimental amount of 0.72 ± 0.1 E. U., might be expected from the selective combination of molecules in the A and B substates resulting from the axial component of momentum of the nitric oxide molecule.

The two substates of nitric oxide are practically identical in energy and it is not surprising that the heat capacity measurements do not extend, and possibly cannot be extended, to sufficiently low temperatures to make the thermodynamic equilibrium produce a perfectly ordered crystalline state. This is a matter of considerable practical importance since it indicates that the correct use of the third law of thermodynamics will occasionally require information in addition to that supplied by heat capacity measurements.

BASIC CATALYSIS IN THE DECOMPOSITION OF DIACETONE ALCOHOL

BY C. CLEMENT FRENCH

RECEIVED MARCH 29, 1929 PUBLISHED NOVEMBER 8, 1929

Introduction

In recent papers Åkerlöf[1] has presented the results of a careful study of the catalytic decomposition of diacetone alcohol by strong bases in aqueous solution, with and without added salt. This decomposition takes place according to the equation $C_6H_{12}O_2 \longrightarrow 2(CH_3)_2CO$. An attempt was made to explain the salt effect as a function of the individual ion activity of the hydroxyl ion. In the aqueous solutions of potassium, sodium and lithium hydroxides, in the absence of added salts, a direct proportionality was found between the activity of the hydroxide and the velocity of the reaction. As it appeared that this relation failed to remain valid below an hydroxide concentration of 0.1 M, measurements of the velocity in solutions of sodium and potassium hydroxides below this concentration have been carried out in order to determine what relation exists in the more dilute solutions.

In the study of the effect of salts on the rate of this decomposition, Åkerlöf used a 0.1 *M* alkali solution, with the concentration of added salt varying from 0 to 5 M at 0.5 M intervals. In connection with the investigation of the velocity in solutions of base more dilute than 0.1 M, it was thought advisable to examine the effect of a few salts in concentrations up to 1 M. The purpose of these experiments in the presence of neutral salts was to determine the salt effect in the region where the Bronsted theory predicts a linear salt effect and to determine whether the magnitude of the salt effect changes with change in the concentration of the catalyst.

The study by Åkerlöf[2] of the decomposition of diacetone alcohol by some amine bases suggested the possibility that this decomposition might be catalyzed by negative ions other than the hydroxyl ion. To test this possibility, a few experiments were made in phenol–sodium phenolate buffers.

Experimental Method

The apparatus, as well as the experimental method used, was the same as that described by Åkerlöf in the papers mentioned above and does not require further discussion. Since the half time of all measurements reported here is greater than twenty minutes, there was always sufficient time available for the reacting solution to come to thermal equilibrium in

---

[1] Åkerlöf, THIS JOURNAL, 48, 3046 (1926); *ibid.*, 49, 2955 (1927).

the thermostat before readings were begun. Consequently, in only a few cases were values of k obtained showing a drift of more than 2%. In these cases the measurements were repeated with new solutions.

Experimental Results and Discussion

A. Aqueous Solutions of Potassium and Sodium Hydroxides.—A summary of the measurements with these solutions is given in Table I. All concentrations are expressed in molality or moles of solute per 1000 g. of water. The diacetone alcohol was present in a concentration of about 0.15 M. Experiments were reproducible to within 2%. The velocity constants are expressed with the minute as the unit of time. All experiments were carried out at 25°.

TABLE I

DECOMPOSITION VELOCITY OF DIACETONE ALCOHOL IN SOLUTIONS OF POTASSIUM AND SODIUM HYDROXIDES

	Potassium hydroxide		Sodium hydroxide

.0755	...	..	156.4	.202
.0800	164.1	.205	..	..
.0850	173.9	.204	...	..
.100	208.0	.208	206.0	.205
	(211.0)[a]	..	(208.0)[a]	..
	Average	.205	Average	.204

[a] These values are taken from the paper of Åkerlöf, THIS JOURNAL, 49, 2960 (1927), Table IV and show the agreement obtained.

In Fig. 1, 0.434 k X 10^4, the observed velocity constant, has been plotted against the alkali hydroxide concentration. The figure shows that up to 0.1 M base, the velocity is almost directly proportional to the hydroxide concentration. Also, from Table I it can be seen that the values of 0.434 k/M deviate from the average value within the experimental error, and give a satisfactorily constant value for 0.434 k/M.

Åkerlöf[3] found that a close relationship existed between the activity of the hydroxide and the reaction velocity in solutions of sodium and potassium hydroxides above 0.2 M. For the concentration range from 0.2 to 2.0 M, the expression $\gamma M/K$, where γ = the activity coefficient of the hydroxide, M the molality of the hydroxide and K the observed velocity constant, was a constant within the experimental error. A similar calculation has been carried out here to show how widely this expression deviates

---

[3] Åkerlöf, THIS JOURNAL, 49, 2962 (1927).

from a constant value when the molality of the alkali hydroxide is 0.1 M or less. The results are shown in Table II. The activity coefficients were calculated from the equation

$$\log \gamma_{\mathrm{MeOH}} = \frac{-0.354\sqrt{2m}}{1 + A\sqrt{2m}} + B2m - \log\left(1 + \frac{36m}{1000}\right)$$

where γ is the activity coefficient, A and B are empirical constants and m is the molal concentration of the base. The values of ***A*** and B are given in Table II and are those calculated by Warned and Åkerlöf.[4]

For values of m above 0.2, the values of $\gamma M/0.434\ k \times 10^2$ for both sodium and potassium hydroxides remain constant.

The statement made by Harned and Åkerlöf[5] that this relation was probably not valid in the concentration range shown here is confirmed by the results in the table above. Therefore, it seems there is no doubt that in aqueous solutions of sodium and potassium hydroxides, below 0.2 M concentration, the decomposition velocity of diacetone alcohol is determined by the concentration of the hydroxide present and not by its activity. It is in this range of concentration that the activity of the alkali hydroxides is changing most rapidly, so that an agreement of the velocity with the change in activity of the hydroxide rather than with its concentration would show a marked deviation from the straight line relation in Fig. 1.

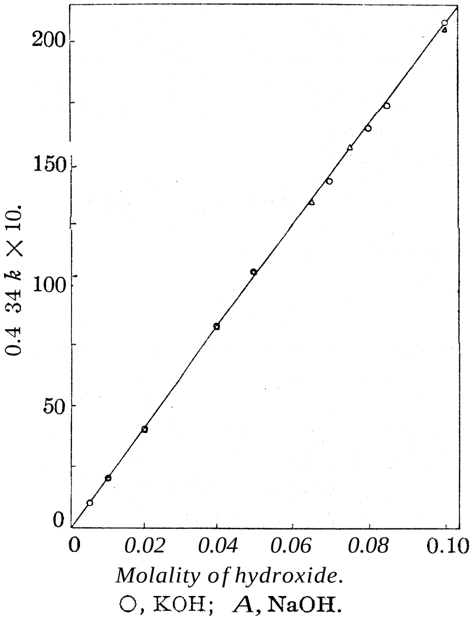

Fig. 1.—Effect *of hydroxyl ion on* the decom*position of diacetone alcohol.*

According to the Bronsted theory, the velocity of a reaction of this type would be expressed by the equation

$$v = kc_{\mathrm{A}}c_{\mathrm{OH}^-}\frac{f_{\mathrm{A}}f_{\mathrm{OH}^-}}{f_{(\mathrm{A,\,OH})^-}}$$

which in dilute solution would reduce to the simple equation

$$v = kc_{\mathrm{A}}c_{\mathrm{OH}^-}$$

since $f_{\mathrm{A}}f_{\mathrm{OH}^-}/f_{(\mathrm{A,\,OH})^-}$ will equal unity. In the concentration range considered here, this simple equation appears to express correctly the decomposition rate.

B. Alkali Hydroxide-Alkali Salt Solutions.—These experiments were all carried out with an alkali hydroxide concentration of 0.05 M and with the added salt concentration varying from zero to one molal. Concentrations are all expressed in molality. All solutions were made up by weighing in a known quantity of standard alkali solution, then adding a sufficient weight of water to make the solution 0.05 M. To this solution was added the calculated weight of dried salt. Table III summarizes the results for the sodium salts in the presence of sodium hydroxide and Table IV those for the potassium hydroxide–potassium salt solutions. The velocity constants have been calculated with the minute as the unit of time. The temperature of all experiments was 25°.

The total equivalent salt concentration in Col. 3 is the sum of the molality of the base and the molality of the added salt.

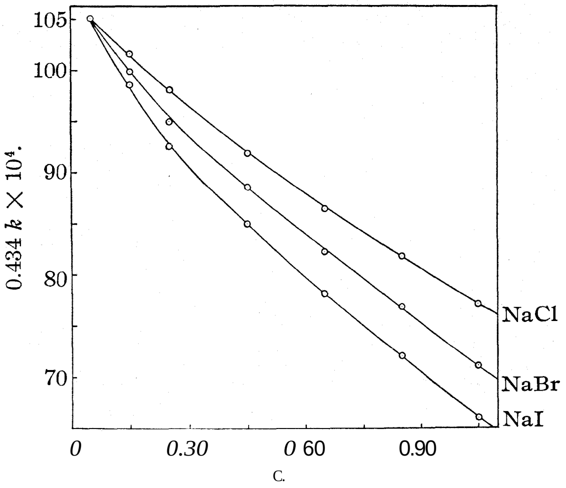

Fig. 2.—Effect of sodium salts on the decomposition of diacetone alcohol, c = $m_{\text{base}} + m_{\text{salt}}$.

The variation of the observed velocity constant, 0.434 k, with the total electrolyte concentration has been plotted in Fig. 2 for the sodium hydroxide–sodium salt solutions and in Fig. 3 for the potassium hydroxide–potassium salt solutions.

The fourth column in Tables II and III gives the observed velocity constant and the fifth column shows this constant divided by the concentration of hydroxyl ion, *i. e.*

$$k_2 = \frac{k_{\text{observed}}}{\text{molality of base}}$$

k_2 is then the molal velocity constant for the diacetone alcohol decomposition. In Fig. 4 0.434 k_2 is plotted against total electrolyte concentration (molality of base + molality of added salt) for the sodium hydroxide–sodium salt solutions and for the potassium hydroxide–potassium salt solutions, up to a total electrolyte concentration of 0.25 M. The salt effects of the base and of the added salt are taken as equal in the first approximation. The extent to which this approximation is incorrect may be judged from Fig. 4. Straight lines have been drawn through the various points at total electrolyte concentrations of 0.15 and 0.25 M, in such a way that all of these lines would meet at a point at zero electrolyte concentration. The two points at electrolyte concentration of 0.05 M represent the values for the bases in absence of added salt. The extent to which these points fail to lie on the various lines represents the error caused by assuming that the salt effect of the base and of the added salt will be equal. The smaller the concentration of the base in the total electrolyte concentration, the smaller will be the error introduced by this assumption, because the point on the plot for the base without added salt will be nearer the point of convergence of the various lines.

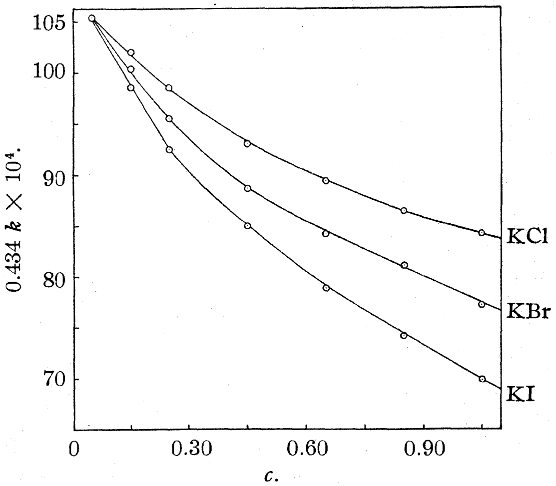

Fig. 3.—Effect of potassium salts on the decomposition of diacetone alcohol, $c = m_{\text{base}} + m_{\text{salt}}$.

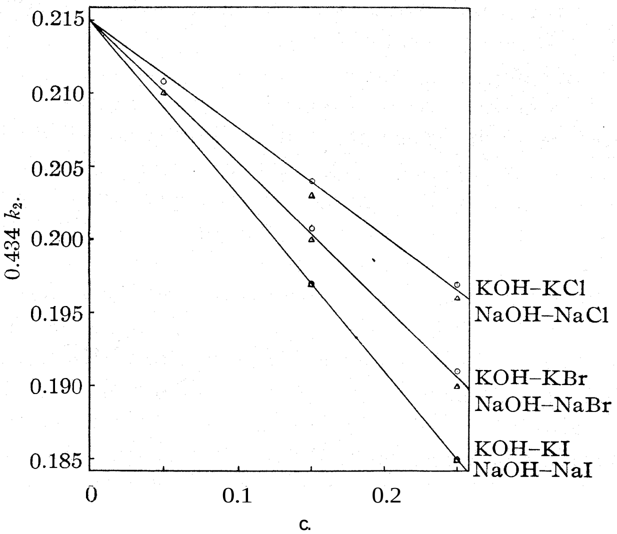
Above a total electrolyte concentration of 0.25 M the linear relationship which is found to exist in all six cases up to that concentration fails. For the concentration range below that value, the catalytic constant for diacetone alcohol in the various salt solutions may be represented by the following equations, where m is the total electrolyte concentration.

NaOH–NaCl, KOH–KCl $0.434\ k_2 = 0.215 - 0.074m$
NaOH–NaBr, KOH–KBr $0.434\ k_2 = 0.215 - 0.10m$
NaOH–NaI, KOH–KI $0.434\ k_2 = 0.215 - 0.12m$

From the above equations it is seen that the primary salt effect varies from about 3% for alkali chlorides to about 5.5% for alkali iodides.

Within the experimental error the equations for 0.434 k_2 depend upon the anion only.

In a consideration of the primary salt effect on the decomposition of nitrosotriacetone-amine, Kilpatrick[6] concluded that when the concentrations of the amine and of the salt were kept constant, and the hydroxyl ion concentration was varied, the salt effect was greater the lower the concentration of the hydroxyl ion. It is possible to test that conclusion for the diacetone alcohol reaction by a comparison of the results obtained here in 0.05 molal alkali solution, for given concentrations of added salts, with those obtained by Åkerlöf[7] for the same concentrations of added salts, but at 0.1 M alkali concentration. Table V contains such a comparison at added salt concentrations of 0.5 and 1 M.



○, KOH–KX; △, NaOH–NaX.

Fig. 4.—Variation of molal velocity constant with total electrolyte concentration, $c = m_{\text{base}} + m_{\text{salt}}$.

The values in Cols. 2 and 3 of Table V represent the percentage decrease in velocity at the salt concentrations indicated, referred to the velocity in the base alone at the concentrations of base shown for the two columns.

The suggestion of Kilpatrick regarding nitrosotriacetone-amine, mentioned above, does not appear to hold for this reaction. The differences between the percentage decreases for the same concentration of added salt in the different concentrations of base are no greater than would be

---

introduced by the experimental error of the original velocity constant determinations. While in solutions of a lower hydroxyl ion concentration such a difference might be noticeable, it does not appear to be true where the hydroxide concentration is as high as 0.05 M or more.

C. Phenol-Sodium Phenolate Buffer Solutions.—Bronsted[8] defines a base as a substance which can take up hydrogen ions. Since the phenolate ion combines with a hydrogen ion to form phenol, it is a base by this definition, and a comparatively strong base since phenol is a weak acid. Consequently, it might be expected that the phenolate ion would decompose diacetone alcohol and an attempt was made to determine whether such was the case. Three buffer solutions were made up of phenol and sodium phenolate with the following concentrations: No. 1, 0.2 N sodium phenolate and 0.2 N phenol; No. 2, 0.15 N sodium phenolate, 0.05 N sodium chloride, 0.15 N phenol; No. **3,** 0.1 N sodium phenolate, 0.1 N sodium chloride, 0.1 N phenol. All three had a total electrolyte concentration of 0.2 N and a 1:1 ratio of phenol to sodium phenolate. The results are tabulated in Table VI.

TABLE VI

DECOMPOSITION OF DIACETONE ALCOHOL IN PHENOL-SODIUM PHENOLATE BUFFER SOLUTIONS

Solution no.	1	2	3
$0.434\ k_{\text{observed}}$	2.06×10^{-5}	2.02×10^{-5}	2.00×10^{-5}

The apparatus used was not designed to measure accurately very slow reactions, and for reactions such as those recorded above, with half times in excess of twenty-one days, an experimentally observed infinity value could be very greatly in error. Therefore the graphical method suggested by Guggenheim[9] has been used to obtain the above values of k. While the accuracy obtainable in the rest of the work cannot be expected here, the results clearly indicate that any catalytic effect of the phenolate ion must be very small compared to the effect of the hydroxyl ion.

In all cases where catalytic effects by other acid molecules than hydrogen

---

[8] Brönsted, *Chemical Reviews*, 5,286 (1928).

[9] Guggenheim, *Phil. Mag*, [7] 2, 538 (1926).

ions or by other basic molecules than hydroxyl ions, have been found, a water or spontaneous reaction has been found to occur.[10] Because of the slight catalytic effect of the phenolate ion, an attempt was made to determine the spontaneous reaction in the case of diacetone alcohol. The experiment was carried out in acid solution with a hydrogen-ion concentration of 1×10^{-5} mole per liter in a sealed dilatometer of the type used by Bronsted, Kilpatrick and Kilpatrick.[11] The reaction was very slow, but from the calculation from the total volume change in *a* suitable experiment with sodium hydroxide, it was estimated that the velocity constant 0.434 k was less than 3×10^{-7} min.$^{-1}$. This corresponds to a half time of more than 800 days. With the very slight catalytic effect of the phenolate ion, a negligible water reaction was to be expected.

A calculation of the classical dissociation constant of phenol at 0.2 M salt concentration is possible from the results in buffer solutions. The hydroxyl ion concentration is obtained by dividing the observed velocity constant by the constant for molal hydroxyl ion at the same electrolyte concentration. In the absence of a specific linear equation for the salt effect of sodium phenolate, the molal constant has been calculated from the equation

$$0.434\ k_2 = 0.215 - 0.074m$$

which was found previously to serve for chlorides. This was chosen because sodium chloride was used as the salt in the buffer solutions to keep the constant total electrolyte concentration of 0.2 M. From this, we get

$$[\mathrm{OH}^-] = \frac{2.02 \times 10^{-5}}{0.200} = 1.01 \times 10^{-4} \text{ moles per liter}$$

using 2.02×10^{-5} as the average of the observed values of 0.434 k in Table VI. The concentration of hydrogen ions in the solution is then calculable from the relation

$$[\mathrm{H}^+] = K_w/[\mathrm{OH}^-]$$

Brönsted[12] predicted that the rapid decrease in the activity coefficients of the ions of a weak electrolyte must lead to an increase in the dissociation constant. Harned and others[13] have confirmed this prediction by the measurement of suitable cells and have calculated the dissociation constant of water in the presence of various alkali salts. If we take from the measurements mentioned a probable value at 0.2 M salt concentration of 1.95×10^{-14} as the value for K_w on the basis of 1.005×10^{-14} for

---

[10] Kilpatrick, This Journal, 50, *2891 (1928);* Bronsted, *Proc. Faraday Soc.*, November *(1928).*

[11] Bronsted, Kilpatrick and Kilpatrick, This Journal, 51, 428 *(1929).*

[12] Brönsted, *J. Chem. Soc., 119, 574 (1921).*

[13] Harned, This Journal, 47, *930 (1925);* Harned and Swindells, *ibid.*, 48, *126 (1926);* Åkerlöf, *ibid., 48,* 1160 *(1926);* Harned and James, *J.* Phys. *Chem.*, **30,** *1060 (1926)*; Harned, *Trans. Faraday Soc.*, *No.* 77, **23,** August *(1927).*

the value of K_w in water of zero salt concentration, we can now calculate the H-ion concentration in our buffer solutions.

$$[H^+] = \frac{1.95 \times 10^{-14}}{1.01 \times 10^{-4}} = 1.93 \times 10^{-10} \text{ moles } \textit{per liter}$$

Then the dissociation constant of the phenol in 0.2 M salt solution can be calculated.

$$K_{\text{phenol}} = \frac{[H^+][\text{phenolate}^-]}{[\text{phenol}]} = [H^+] = 1.93 \times 10^{-10}$$

The value for the dissociation constant of phenol at 25° given in the literature is 1.09×10^{-10}.[14] This value was determined by conductance and refers to zero salt concentration. Since phenol is a weak electrolyte, its dissociation constant would be expected to increase in salt solution, as has been found here. The great extent to which K_c varies with the salt concentration shows the necessity of stating the region of salt concentration in which the "constant" is to serve as the measure of acid or base strength. This same point has been shown in a study of secondary salt effects on the rate of decomposition of nitrosotriacetone-amine.[15] Consequently, values of K_c determined by methods such as have been used here for the given salt concentrations at which they were determined, should be much better than values of K_c which do not take this factor into consideration.

The decomposition of diacetone alcohol by other bases is being investigated and will be the subject of a later communication.

The author is indebted to Dr. and Mrs. Martin Kilpatrick, Jr., for the determination of the rate of the spontaneous decomposition of diacetone alcohol.

Summary

1. The velocity of decomposition of diacetone alcohol in solutions of sodium and potassium hydroxides has been measured at 25°. The hydroxide concentration was decreased from 0.1 to 0.01 M and it was found that over this range the velocity is proportional to the concentration of the hydroxide. The wide deviation from a rate proportional to the activity of the hydroxide has been shown.

2. The decomposition rate has been measured in 0.05 M hydroxide solutions in the presence of various alkali salts. The molal velocity constant varies linearly with the total equivalent salt concentration up to a total concentration of 0.25 M, as predicted by the Rronsted theory. The linear equations obtained depend only on the anion of the salt present, when the cations of the base and the salt are the same. There appears to be no regular relation between the magnitude of the salt effect and the concentration of the catalyst.

[15] *Bronsted and* King, THIS *JOURNAL*, 47,2530 (1925).

3. A few measurements were carried out with phenol–sodium phenolate buffer solutions to investigate the possibility of catalysis by the phenolate ion. If present, such catalysis must be quite small compared to the hydroxyl ion catalysis.

4. If this reaction has a spontaneous water reaction, its half time is greater than 800 days.

5. A value of 1.93×10^{-10} for the dissociation constant of phenol in 0.2 molal salt solutions was calculated.

OXIDATION OF SELENIUM DIOXIDE AND OF TELLURIUM DIOXIDE WITH LEAD DIOXIDE[1]

BY FRANK C. MATHERS AND FRANK V. GRAHAM[2]

RECEIVED APRIL 15, 1929 PUBLISHED NOVEMBER 8, 1929

Introduction

DeCarli[3] tested the action of lead dioxide in the dry state upon several other oxides at temperatures varying from 250 to 300°. Barium, cuprous, stannous, ferrous, manganous, cobaltous and nickelous oxides reacted with the lead dioxide to form higher oxides. The lead dioxide was reduced to the monoxide. There was no evidence of reaction with calcium, cadmium, plumbous, zinc, magnesium, cupric, aluminum and titanium oxides. The less metallic oxides like arsenious, antimonous, chromium, molybdenum and tungsten reacted with the lead peroxide to form lead salts of the type of lead arsenate, lead antimonate, etc. He concluded that lead dioxide had a notable tendency to react with other oxides at relatively low temperatures.

This research was merely an extension of the above reaction to include selenium dioxide and tellurium dioxide, two oxides that had not been tried by DeCarli.

Lead selenate can be changed[4] easily to ammonium selenate. The ammonium selenate thus formed can be changed[5] into other selenates by crystallizing solutions of it with various metallic nitrates. The lead tellurate can be changed by sulfuric acid into telluric acid. There have been, heretofore, only indirect methods[6] of making lead selenate and lead

tellurate. Short direct methods for the rapid preparation of these salts are desirable as furnishing materials for making various selenates and tellurates.

Materials Used.—Two different samples of lead dioxide were used, one containing 90.09 and the other 94 94% of lead dioxide. The purity was always considered in calculating the weight to be used for a reaction.

Pure selenium dioxide was made by dissolving metallic selenium in nitric acid. This solution was filtered through asbestos and was then evaporated to dryness. The selenium dioxide thus formed was dissolved in water and filtered. This filtrate was evaporated to dryness and the solid selenium dioxide was sublimed. Its purity by analysis was 99.9%.

Tellurium dioxide was made by dissolving the 'commercial tellurium dioxide in hydrochloric acid. This strong acid solution was filtered through asbestos. The filtrate was hydrolyzed by the addition of a large volume of water. This precipitate of tellurous acid was washed and dried. Analysis showed its purity to be 98%

The ammonium carbonate was the ordinary "ammonium carbonate" commonly bought for laboratory use.

Methods of Analysis.—The selenates and tellurates were determined by the iodometric method of Gooch and Howland.[7] The selenite and the tellurite were determined by the potassium permanganate method of Brauner.[8]

Reaction of Selenium Dioxide with Lead Dioxide.—Preliminary experiments at 90, 100, 110 and 120° showed that very satisfactory results could be obtained at 100°. The rest of the experiments were made at this temperature because of the ease with which the 100° could be maintained on a steam-bath.

Two ways were tried for obtaining intimate contact between the reacting substances. The "dry" way was to grind the dry materials thoroughly together in a dry mortar. The "wet" way was to grind the ingredients thoroughly in the mortar with just enough water to give a thick paste. The various samples were then placed in small beakers and set in the steam-bath.

TABLE I

VARIATION IN QUANTITY OF LEAD DIOXIDE AND IN TIME OF HEATING

Formula weights of PbO_2 to one of SeO_2	Selenium dioxide changed to selenate, %					
	0 5 hour		3 hours		12 hours	
	Wet	Dry	Wet	Dry	Wet	Dry
1	91.8	88.5	94.6	92.5	98 9	93.1
1.05	97.9	93.5	98.3	94.5	97.9	95.3
1.1	97.7	94.6	99.5	95.8	99.9	96.1

The "wet" sample containing the 10% excess of lead dioxide was practically completely converted to selenate by heating for three hours or longer in the steam-bath. The "dry" mixed samples were not so com-

---

[7] Gooch and Howland, *Z. anorg. allgem. Chem.*, **7**, *132* (1894); Am. J. *Sci.*, [3] *48*, 375 (1894).

[8] Brauner, J. *Chem. Soc.*, **59**, 240 (1891).

pletely oxidized. It is thought that the better oxidation of the "wet" mixtures was due entirely to better contact. At the end of the experiments the water had been completely evaporated from all of the beakers and the residues were all dry. The results shown in this table are entirely satisfactory. This is the best method yet described for making lead selenate.

Making Ammonium Selenate from the above Lead **Selenate.**—A previous paper[4] showed that ammonium selenate can be made easily by the digestion of lead selenate with ammonium carbonate. The lead selenate in those experiments was prepared by precipitation and was pure. This lead selenate was made by a dry method and was not pure. This difference in the physical condition of the lead selenate made desirable new experiments on its action with ammonium carbonate. Five grams of lead selenate and **3** g. of "ammonium carbonate" were used. This was a ratio of one formula weight of lead selenate to about 2.6 "CO_3" radicals.

TABLE II

CONVERSION OF LEAD SELENATE INTO AMMONIUM SELENATE

Water, cc.	Temp., °C.	Time in hours	Selenate obtained as ammonium selenate, %	
			Unstirred	Stirred
25	25	1	74.1	84.6
25	25	2	85.0	90.7
20	25	1	79.7	89.8
20	25	2	85.0	95.9
15	25	1	82.2	93.4
15	25	2	92.6	97.5
10	25	1	80.6	95.1
10	25	2	90.6	97.3
10	47	1	93.0	99.1
10	47	0.5	90.6	98.3
10	47	0.25	87.9	97.5
10	47	0.083	84.6	94.3

The yields were determined by filtering, washing the residues of lead carbonate and unchanged lead selenate with water and analyzing the filtrates for selenate. In the column marked "unstirred" the beakers were not agitated after the beginning of the experiment but the ammonium carbonate was dissolved before starting the experiment. In the column marked "stirred" a mechanical stirrer kept the mixtures in motion during the entire experiment. The table shows a yield of 99% using 10 cc. of water, 5 g. of lead selenate, *3* g. of ammonium carbonate, a temperature of 47° and stirring for one hour.

Crystals of ammonium selenate were easily obtained by evaporating the filtrate from this action of ammonium carbonate upon the lead selenate.

Reaction of Tellurium Dioxide with Lead Dioxide.—The amount of mixing of the tellurium dioxide and the lead dioxide affected the degree of oxidation. The materials in Table III were ground together in a dry mortar for one minute.

TABLE III

TELLURIUM DIOXIDE WITH LEAD DIOXIDE

Formula weights of PbO_2 to one of TeO_2	Temp., °C.	Tellurium dioxide converted into tellurate, % 1 hour	2 hours
1	300	62.9	71.2
1	205	58.6	79.2
1	170	85.1	89.8
1.05	170	93.5	93.7
1.1	170	98.1	99.8
1.1	155	89.7	92.7
1.1	185	94.1	97.5

This table clearly shows that 10% excess of lead dioxide is desirable and that 170° is the best temperature. Further experiments relative to the effect of the degree of mixing showed that the addition of enough water to form a paste after the tellurium dioxide and the 10% excess of lead dioxide had been ground together gave a yield of 99.5% at 170° for one hour. This result is compared to 97.3% when no water was used. However, grinding of the dry materials for two minutes gave the same yield of 99.9%.

Pure telluric acid was made from this lead tellurate by treatment with enough sulfuric acid to combine with all of the lead present in the mixture. This is a well-known old method.[6a] Three grams of sulfuric acid was used for each 10 g. of the lead tellurate mixture. All the telluric acid became soluble. The filtrate was evaporated nearly to dryness and the telluric acid was precipitated by an excess of nitric acid. The supernatant liquid was decanted and the residue was washed with a little concd. nitric acid to remove all the sulfuric acid. The residue was warmed on a water-bath until the nitric acid volatilized. This residue was dissolved in water and pure crystals of telluric acid, $H_2TeO_4 \cdot 2H_2O$, were prepared by slow evaporation.

Summary

1. The oxidation of selenium dioxide to selenate by heating with lead dioxide has been investigated under various conditions. The reaction proceeds very satisfactorily at 100°, the degree of completion varying with the time of heating and the mixing of the sample. The lead selenate produced may be converted to ammonium selenate by digestion with ammonium carbonate, followed by crystallization.

2. The process has been applied to the oxidation of tellurium dioxide, the optimum temperature being 170°. The yield varies with the amount of lead dioxide used and the intimacy of mixing of the sample taken. Telluric acid may be prepared from the lead tellurate produced by treatment with sulfuric acid and subsequent crystallization.

THE OXIDATION OF CALCIUM TELLURITE BY HEATING AND THE PREPARATION OF TELLURIC ACID PROM THE CALCIUM TELLURATE[1]

BY FRANK C. MATHERS AND GAIL M. BRADBURY[2]

RECEIVED APRIL 15, 1929 PUBLISHED NOVEMBER 8, 1929

Synopsis.—Tellurium dioxide mixed with five equivalents of calcium hydroxide was almost completely oxidized to calcium tellurate by heating for one hour at 975°. The percentage oxidation was less at lower temperatures and with smaller proportions of calcium hydroxide. The calcium tellurate thus formed was treated with an excess of concentrated nitric acid, whereby soluble calcium nitrate and insoluble telluric acid were formed. This telluric acid, after filtration or decantation, was dissolved in water and crystallized until pure.

Review.—Many methods are described in the literature for oxidizing tellurium or tellurium dioxide to telluric acid. Perhaps the method most generally used was suggested by Staudenmaier.[3] The tellurium dioxide, in nitric acid solution, is oxidized with chromic acid. The separation of the telluric acid from the chromium nitrate is rather slow and difficult. The slowness and the complexity of this method, commonly considered the best, is a proof of the difficulty of making telluric acid. All of the methods proposed can be criticized from the standpoint of expensive or difficultly obtainable reagents, of difficulties in manipulation, of the introduction of troublesome impurities or of low yields.

Aim of this Research and Outline of the Method.—The method developed in this research was based upon the observation of Lenher and Wolesensky[4] that many tellurites are oxidized to tellurates by heating in the air. However, they found that sodium or potassium tellurite required heating for fifty hours at 460° for complete oxidation.

The purposes of this research were, first, to improve the method of Lenher and Wolesensky for the oxidation of tellurites by heating; second, to find a suitable way of preparing telluric acid from these tellurates.

The extreme slowness of the oxidation in their experiments was thought to be due the fusion of the salts, whereby only the surface of the mass was exposed to oxygen. Calcium tellurite, or a mixture of it with hydrated lime, was heated in these experiments. Such a salt or mixture remained porous during the heating and therefore allowed more rapid oxidation.

[4] Lenher and Wolesensky, *ibid.*, 35, 729 (1913).

Method of Analysis.—The method of Brauner[5] using potassium permanganate was employed for the determination of the tellurite. The iodimetric method of Gooch and Howland[6] was used for the determination of the tellurate.

Materials Used.—The commercial tellurium dioxide[7] contained 49.59% of tellurium dioxide, 46.12% of sodium tellurite and 0.9% of selenium. This material was dissolved in concentrated hydrochloric acid and the solution thus formed was filtered through asbestos. The filtrate was evaporated to a small volume. The tellurium hydroxide or tellurous acid was precipitated by hydrolysis with a large volume of water. The precipitate was washed until free from chlorides and dried. This purified tellurium dioxide was a heavy, finely divided, slightly yellow powder.

The calcium hydroxide was a commercial high calcium "chemical" hydrated lime.

Experimental

All heating, unless otherwise noted was done in a Hoskins electric muffle furnace. The temperatures were measured with a platinum–rhodium thermocouple.

The tellurium dioxide and the lime were thoroughly mixed on a paper and then ground together in a mortar. The final mixtures, weighing from 10 to 30 g., were heated in small porcelain dishes. After heating, the entire mass of each mixture was ground to insure an accurate sample for analysis.

In all the early experiments, the heating was done at rather low temperatures because Lenher and Wolesensky had used 460°. It was soon found that the speed of oxidation increased as the temperature increased. A mixture of one formula weight of tellurium dioxide to two formula weights of calcium hydroxide was used in Table I.

TABLE I

EFFECT OF INCREASE OF TEMPERATURE

Temperature, ° C.	475	575	675	775
Heating, hours	25	25	20	5
Oxidation, %	21.4	44.7	64.7	39.3

The use of sodium carbonate with the calcium hydroxide and the tellurium dioxide greatly increased the speed of oxidation. However,

TABLE II

[6] Gooch and Howland, *Z.* anorg. *chem.*, 7, 132 (1894); *Am. J. Sci.*, [3] 48, 375 (1894).

[7] The authors wish to thank Mr. Skowronski of the Raritan Copper Company, Perth Amboy, New Jersey, for furnishing this material.

sodium carbonate without the lime was not satisfactory as is shown by Expt. 4 in Table II. The temperature of the experiments recorded in this table was 575°.

Although the rapidity and the completeness of oxidation of these mixtures containing sodium carbonate and hydrated lime were entirely satisfactory, the presence of the sodium salts made difficult the preparation of the pure telluric acid.

Table III

Effect of Higher Temperatures and Greater Proportions of Calcium Hydroxide

Formula weights of calcium hydroxide to one of TeO_2	3	4	5	0	8	5	6
Temperature, °C.	975	975	975	975	975	1075	1075
Heating, hours	5	5	5	5	5	5	5
Oxidation, %	817	894	97.5	95.8	94.9	99.8	974

This table shows that the ratio of five formula weights of calcium hydroxide to one formula weight of tellurium dioxide is sufficient for maximum oxidation; also, that a temperature of 975° is sufficient, although 1075° does not lessen the yield through decomposition. The stability of the calcium tellurate at this high temperature was a great surprise.

Experiments were then made to determine the optimum time of heating required under these other optimum conditions of 975" and a mixture containing five formula weights of calcium hydroxide to one formula weight of tellurium dioxide.

Table IV

Time of Heating Required

Heating, hours	025	0 5	1	2	4	5	6
Oxidation, %	93.6	957	98.7	98.8	99.3	98.7	98.1

Based upon experiments in which silver strips (melting point 960°) were embedded at different places in the mixtures being heated, it is thought that oxidation is practically complete as soon as the temperature has reached-975" throughout the mass.

Heating in a gas-fired pot furnace at a final temperature of 1100° gave about as good results as the careful heating in the electric furnace. A 25-g. mixture gave 98.1% oxidation in one hour. A 230-g. mixture gave 87.2% oxidation in two hours. These lower yields with the larger samples indicate that there was not enough air circulating through the mass. One important point that favors this method is that a carefully controlled heating temperature is unnecessary; it is important only to heat at 975 to 1100". Higher temperatures could not be tried with the methods of heating that were available.

Barium hydroxide and barium carbonate mixtures with the tellurium dioxide gave almost no oxidation. Calcium carbonate gave as good results as calcium hydroxide under the same conditions.

Preparation of Telluric Acid from the Calcium Tellurate.—A description of one quantitative experiment will suffice to make clear the general conditions and method of operation for easily making telluric acid crystals. Seventy-five grams of the tellurium dioxide and 177 g of calcium hydroxide (a 1:5 mixture) were placed in a clay crucible and heated in a gas furnace for a total of two hours with the final temperature reaching 1100°. The percentage oxidation was 88.5. Two hundred grams of this mixture was treated with 300 cc. of concentrated nitric acid, heated to boiling and cooled overnight. The supernatant liquid was decanted and 200 cc. more concentrated nitric acid was added to the residue of telluric acid. This was heated to boiling, cooled and again the supernatant liquid was decanted. The residue of telluric acid was dissolved in hot water and filtered to remove traces of insoluble matter. This filtrate, after evaporation to a small volume, smelled strongly of nitric acid. Again, after cooling overnight, the liquid was decanted. The residue of telluric acid was dissolved in water and crystallized. The weight of the pure crystals of telluric acid equaled 75.4% of the total telluric acid in the material used. The exact quantities of the acid used in this experiment need not be followed. Indeed, less nitric acid can be used in the washing. No research was made to determine the best quantities of reagents for the maximum yields.

Attempts to decompose the calcium tellurate with dilute sulfuric acid, whereby calcium sulfate was precipitated, were unsuccessful. So much calcium sulfate always remained in solution that its final separation from the telluric acid was difficult. Carbon dioxide or oxalic acid would not decompose the calcium tellurate.

It is possible to treat the calcium tellurate with an equivalent amount of nitric acid, evaporate to dryness and extract the calcium nitrate from the residue with alcohol, in which the telluric acid is insoluble.

The authors wish to thank the Grasselli Chemical Company for their fellowship, which was held by Mr. Bradbury during the progress of this work.

Summary

Maximum speed and completeness of oxidation were obtained by heating a mixture of one formula weight of tellurium dioxide with five formula weights of hydrated lime at 975 to 1075° for an hour.

Telluric acid was easily prepared from the calcium tellurate thus formed by the addition of an excess of concentrated nitric acid. The soluble calcium nitrate was decanted from the precipitate of crude telluric acid. Pure telluric acid was obtained from this residue by crystallization from water.

GRAVIMETRIC DETERMINATION OF SODIUM BY THE URANYL ZINC ACETATE METHOD. II. APPLICATION IN THE PRESENCE OF RUBIDIUM, CESIUM, POTASSIUM, LITHIUM, PHOSPHATE OR ARSENATE

By H. H. Barber and I. M. Kolthoff

Received May 13, 1929 Published November 8, 1929

In the first paper[1] of the general procedure for the determination of sodium by the uranyl zinc acetate method, it was shown that the method is quite specific for sodium, though lithium and large amounts of potassium have an interfering action. As the determination of sodium in the presence of other alkali metals is of great practical importance, we present in this paper the results of a study made in this direction. With regard to the interfering anions, we consider especially the removal of the phosphate and arsenate ions.

Rubidium and Cesium.—A solution of 100 mg. of pure rubidium chloride and cesium chloride, respectively, in 1 cc. of water does not give a precipitate with 10 cc. of the reagent after long standing. It was shown that Kahlbaum's salts of these elements contained a trace of sodium: the rubidium chloride, 0.45%; the cesium chloride, 0.13%. The general procedure outlined in the first paper is to be followed in determining sodium in rubidium and cesium compounds.

Potassium.—In the first paper it was shown that if a solution contains more than 50 mg. of potassium per cc., potassium uranyl zinc acetate will be precipitated; therefore, in cases where sodium is to be determined in large amounts of potassium, the larger part of the latter has to be removed.[2] It is not necessary to remove all of the potassium in a quantitative way, as small amounts of this element do not interfere with the sodium determination. For the precipitation of the larger part of potassium, we used ammonium perchlorate in a medium of 72% alcohol. A test for purity of the ammonium perchlorate is made by dissolving 1 g. of the salt in 10 cc. of the reagent. A clear solution should be ob-

---

[1] Barber and Kolthoff, This Journal, 50, 1625 (1928).

[2] In order to avoid any misunderstanding, it may be remarked that if more than 50 mg. of potassium per cc. is present, the solution can be correspondingly diluted, provided that in the precipitation of sodium for each cc. of solution 10 cc. of the reagent is used. If the ratio of sodium to potassium is very unfavorable, the application of the above procedure would require large amounts of reagent and therefore would be uneconomical and impracticable.

In the general procedure for the precipitation of sodium, it should be noted that as long as a ratio of 1 cc. of solution to 10 cc. of reagent is maintained, satisfactory results will be obtained. Each 10 cc. of reagent will completely precipitate from 1 cc. of solution 8 mg. of sodium. If 5 cc. of solution were used, 50 cc. of reagent should be added. This amount of reagent would precipitate, if present, 40 mg. of sodium.

tained with no separation of crystals after standing for one hour. If the perchlorate contains sodium, the latter can be removed easily by recrystallization from water.

Procedure

One gram of potassium chloride is dissolved in 5 cc. of water. To this add a hot solution of 2 g. of ammonium perchlorate in 3 cc. of water and 25 cc. of 95% alcohol. Cool the mixture to room temperature, filter and wash the precipitate five times carefully with 2-cc. portions of 95% alcohol. Evaporate the filtrate to dryness, take the residue up in 1 cc. of water and add 10 cc. of reagent. If the potassium salt contains more than 1% of sodium, the residue should be taken up in more water and an aliquot part weighed out. As a matter of fact, one may start in this case with less potassium salt. A qualitative test for sodium in the potassium salt will give an approximate idea of the amount of sodium present (see first paper). The following table shows that traces of sodium down to 0.1% may be determined in potassium chloride with an accuracy of 1 to 2%.

TABLE I

DETERMINATION OF TRACES OF SODIUM IN THE PRESENCE OF 1 G. OF POTASSIUM CHLORIDE

.0077	.2028	.0077	.0037	.0954	.0036
.0077	.2034	.0077	.0023	.0597	.0023
.0070	.1794	.0068	.0020	.0520	.0020

It should be mentioned that the outlined procedure is useful for the qualitative detection of traces of sodium in potassium salts. In that case it is not necessary, of course, to wash the potassium perchlorate with alcohol.

In the way described 0.005% of sodium can easily be detected in potassium salts.

Lithium.—Many more difficulties were encountered in the determination of sodium in the presence of lithium. Lithium triple salt is very slightly soluble. A solution of 0.2 mg. of lithium in 1 cc. of water with 10 cc. of reagent forms a crystalline deposit after a few hours' standing. The reaction would be more sensitive if the reagent was saturated to the lithium compound. We are planning to make a study on the application of the reagent for the determination of lithium.

For the determination of sodium in the presence of lithium, the latter has to be quantitatively removed. We first tried the alcohol–ether method of S. Palkin,[3] but did not find this method suited to our purpose as in his

---

[3] Palkin, THIS JOURNAL, 38, 2326 (1916).

procedure all the alkali metals have to be in the form of chlorides. Commercial salts of lithium and even C. P. products appeared to contain sulfate as an impurity; it is necessary to remove this anion, as lithium sulfate is insoluble in the alcohol–ether mixture. The extraction method in the regular course of analysis will give satisfactory results. In cases where traces of sodium have to be determined in lithium compounds, we prefer to remove the latter in the form of an insoluble salt; therefore, we precipitated lithium as the fluoride.

In our first experiments we attempted to purify C. P. products of lithium chloride according to the alcohol–ether method of Palkin.[3] The purified salt still contained traces of sodium.[4] A better product for our purpose was obtained by precipitation of lithium as a carbonate with pure ammonium carbonate.

The separation of sodium from lithium by-the fluoride method is a tedious procedure. Though the solubility of lithium fluoride in water is small, alcohol should be added to precipitate the lithium quantitatively. However, if too much alcohol is added, or if too much lithium is present, some sodium may be carried down by the precipitate. On the other hand, if too little alcohol is added, too high results are found due to incomplete precipitation of lithium. Under special conditions a compensation of errors may lead to results agreeing with the theoretical.

TABLE II

SEPARATION OF LITHIUM PROM SODIUM

Concn. of alcohol, %	NaCl, g.	LiCl, g.	NaCl found, g.	Error, %
10	0.05712	0.10	0.05887	+3.0
15	,05903	.05	.06224	+5.4
15	.05850	.22	.05840	−0.2
15	.06004	.33	.05828	−3.0
20	.06048	.22	.05743	−5.0
25	.05860	.22	.05495	−6.6
25	.06145	.24	,05607	−9.0
30	.05741	.22	.05029	−12.5
40	.06935	.10	.06709	−3.3

In the final procedure a 10% solution of ammoniacal ammonium fluoride was used. (The reagent should be kept in paraffined or hard rubber bottles.) The ammonia has to be added to decompose fluosilicate, which occurs as an impurity even in chemically pure products of ammonium fluoride and interferes in the separation, and also to prevent the action of the fluoride on glass. A 25% solution of hydrochloric acid and 95% alcohol are the other reagents.

Though ammonium fluoride does not precipitate with uranyl zinc acetate, it prevents the precipitation of sodium; therefore, the fluoride

---

[4] Compare, also, T. W. Richards and H. H. Willard, THIS JOURNAL, 32, 4 (1910).

has to be removed before the sodium is precipitated with the reagent. This can be done easily by evaporation with hydrochloric acid. The ammonium fluoride and hydrochloric acid should be tested for purity. In a platinum crucible place about 1 g. of ammonium fluoride, add 10 cc. of 25% hydrochloric acid and evaporate to dryness. Add to the residue 5 *cc.* of the reagent and transfer to a test-tube. The solution should be clear after standing for one-half hour. The ammonium hydroxide used has to be sodium free. Evaporate 5 cc. to dryness and test residue with the reagent. All the solutions of ammonia tested contained sodium. It was necessary to redistil and keep in paraffined bottles.

Procedure

To not more than 0.1 g. of the salt add 10 cc. of water and 5 cc. of 95% alcohol. After the salt has dissolved, add 5 cc of the ammonium fluoride solution. Allow to stand for twenty hours, or longer, and then filter off the precipitate through a glass filter crucible. The lithium fluoride is washed five times with 2-cc. portions of a 50% alcohol solution containing 0.5% of ammoniacal ammonium fluoride. The filtrate and wash liquor are evaporated carefully in a platinum crucible and the residue is evaporated three times with 5-cc. portions of hydrochloric acid. The residue is now transferred with water to a weighing bottle of known weight. The solution is evaporated to a volume of 2 to 5 cc. and weighed after cooling. An aliquot part is weighed out and the sodium determined by the regular procedure.

If amounts of sodium of the order of 1.5% or less have to be determined in lithium salts, one may start with 0.5 g. of salt and treat this according to the above procedure. Finally, the residue is taken up in 2 cc. of water and 20 cc. of uranyl zinc acetate reagent is added. In this way we found that sodium could be determined with an accuracy of 1 to 2%.

TABLE III

SEPARATION OF LITHIUM PROM SODIUM

Concn. of alcohol, %	NaCl, g.	LiCl, g.	NaCl found, g.	Error, %
25	0.06306	0.02	0.06321	+0.2
25	,05894	.08	,05888	− .1
25	.05941	.10	,05917	− .4
25	.1135	.10	.1138	+ .3
25	.005936	.35	.00607	+2.0
25	.003994	.38	.00392	−2.0

In Tables II and III the analyses show that when the alcohol concentration is 25%, good results are obtained if the ratio between weight of sodium chloride taken and weight of lithium chloride is 1 to 1 or less where the weight of sodium chloride is 100 mg., or less. However, as soon as the ratio between the weight of sodium chloride and weight of lithium chloride becomes 1 to 2, sodium is carried out of the solution by the lithium fluoride precipitate and low results are obtained. On the other hand, results within 2% of the theoretical were obtained when a few mg. (4–6 mg.) of sodium chloride was present with a much greater quantity (350 mg.) of lithium fluoride.

All of our experimental work in 25% alcohol solution gave consistently low values for sodium when the sodium chloride–lithium chloride content in 20 cc. of solution was 100 mg., or less, of sodium chloride to 125 mg., or more, of lithium chloride (see Table II), but when the lithium chloride content was 100 mg., or less, excellent results were obtained (see Table III). Consequently, the amount of lithium chloride should not be greater than 100 mg. in 20 cc. of 25% alcohol solution unless small amounts, a few mg., of sodium are to be determined in lithium salts. In this case, 0.3 to 0.4 g. of lithium chloride may be present.

Phosphate and Arsenate.—Phosphate and arsenate give a precipitate with the uranyl zinc acetate reagent. We first tried to remove these ions with a dilute solution of the reagent. (Sodium does not precipitate under these conditions.) However, this procedure cannot be recommended as the slimy precipitate absorbs sodium and too low results are obtained. It is better to remove the phosphate and arsenate by precipitation with magnesia mixture in cold solution to which an excess of ammonia has been added. The filtrate and the wash liquor are evaporated to dryness and the sodium is determined according to the regular procedure. Again, the reagents must be free from sodium and the usual precautions for precipitating phosphate or arsenate with magnesia mixture must be observed.

In our experiments we used monopotassium phosphate and dipotassium arsenate. Both salts were recrystallized three times from water. In the following table we show that satisfactory results are obtained.

TABLE IV

SEPARATION OF PHOSPHATE AND ARSENATE FROM SODIUM

K_2HPO_4, g.	NaCl, g.	NaCl, found, g.	Error, %	K_2HAsO_4, g.	NaCl, g.	NaCl found, g.	Error %

.019	.01048	.01053	+0.5				

Summary

The determination of sodium in the presence of the alkali metals, phosphate or arsenate has been investigated and the following ascertained.

1. Cesium and rubidium in amounts of 0.1 g. do not interfere.
2. Interfering amounts of potassium may be removed by precipitation with ammonium perchlorate in 72% alcoholic solution.
3. Lithium must be removed quantitatively. Ammonium fluoride in 25% alcoholic solution is used to precipitate the lithium.
4. Phosphate and arsenate interfere and are removed by precipitation with magnesia mixture.

ZIRCONIUM. V. DETECTION OF TRACES OF POTASSIUM IN THE PRESENCE OF ZIRCONIUM[1]

BY RUFUS D. REED AND JAMES R. WITHROW

RECEIVED MAY 23, 1929 PUBLISHED NOVEMBER 8, 1929

Zirconium sulfate can be used to detect potassium,[2] but the completeness of precipitation of potassium by zirconium sulfate is not easily measured, as zirconium sulfate also gives a precipitate with sodium cobaltic nitrite. Obviously zirconium must be eliminated, if present, prior to testing for potassium, so a study of delicate methods of detection of traces of potassium under these conditions was made. The results indicated that while phosphates will remove the zirconium, they interfere with the subsequent detection of traces of potassium. Ammonium hydroxide, however, was found to remove all of the zirconium without interfering materially with subsequent detection of potassium. Also a quicker and less objectionable method was found to be the transformation of the zirconium into a complex ion with tartaric acid, and after adjusting the acidity with sodium hydroxide and acetic acid, testing for potassium with sodium cobaltic nitrite.

Discussion of Literature

Zirconium can be removed by phosphates in excess under proper condition~. Bray[4] found that dilute sodium phosphate solution gave no precipitate with sodium cobaltic nitrite; but according to solubility records[5] approximately 39 cc. of water at 20° would be needed to dissolve the 7.5 g. of sodium phosphate which we found was needed to remove 0.1134 g. of zirconium sulfate used in the test. If the original concentration of potassium was 1 mg. per cc., this dilution would lower the concentration to 0.02 mg. per cc.—a smaller concentration than sodium cobaltic nitrite will detect.[2]

Smaller concentrations of phosphoric acid, microcosmic salt or ammonium phosphate would remove the zirconium but the interfering ammonium salts would have to be expelled before testing for potassium. The gelatinous zirconium phosphate might adsorb any traces of potassium salts. The use of ammonium hydroxide to remove the zirconium risked the same objections.

The possibility of avoiding these dangers of loss of potassium by volatilization or adsorption, by the elimination of zirconium as a complex ion was suggested by the statement of Fresenius,[6] "tartaric acid prevents the precipitation (of zirconium) by alkalies."

Experimental

Detection of Potassium after Removal of Zirconium.—Samples containing 0.113 g. of zirconium sulfate, varying amounts of potassium and 1634 g. of hydrogen sulfate were prepared. Some were treated with an excess of 5 times the calculated needed amount of either phosphoric acid, ammonium phosphate or microcosmic salt. To avoid evaporation of large amounts of solution the final volume was kept at 50 cc. After standing for several hours the solutions were filtered and the filter washed four times with cold water. The filtrate and washings were evaporated to a sirup. This was transferred with washing to a platinum crucible, the evaporation continued to dryness and the residue ignited short of red heat until no more fumes were noticed. If a drop of a solution prepared by adding 1 cc. of water to the residue gave no test for ammonium salts with Nessler's reagent, the remainder was neutralized with sodium hydroxide, about 3 cc. of 30% acetic acid was added and then an equal volume of sodium cobaltic nitrite solution. Preliminary experimentation showed that if this excess acid was not added a flaky precipitate was obtained whether potassium was present or not. This amount of acetic acid did not prevent the detection of 0.3 mg. of potassium in a test solution. Other samples were treated with ammonium hydroxide instead of phosphates to remove the zirconium and the filtrates were tested for potassium in the same way except that no acetic acid was added. The results appear in Table I.

TABLE I

DETECTION OF POTASSIUM BY SODIUM COBALTIC NITRITE AFTER REMOVAL OF ZIRCONIUM

1	0.00053	Flaky ppt.	Flaky ppt.	Clear. sev. hrs.	Ppt., 4 min.
2	.00031	Clear, 20 min.; cloudy, 2 hrs.	Ppt., 45 min.	Clear, no ppt., sev. hrs.	Ppt., 5 min.
3	.00012	Clear, no ppt., 1 hr.	Clear, no ppt., 1 hr.	Clear, no ppt., sev. hrs.	Sl. ppt., standing hrs.
4	.00000	Clear, no ppt., 15 min.; cloudy, 1 hr.	Clear, 1 hr.	Clear, 20 min.; cloudy, 40 hrs.	Clear, no ppt., 1 day
5	.00176	......	......	Ppt. at once	

Discussion.—The precipitates (Run 1) where zirconium had been removed by phosphoric acid or microcosmic salt were flaky and brownish, not the usual yellow color of potassium cobaltic nitrite. They resembled the precipitates obtained (preliminary work) by adding sodium cobaltic nitrite to a solution of phosphoric acid neutralized by sodium hydroxide which had added thereto but a small excess of acetic acid.

The results in Cols. 2, 3 and 4, where zirconium was removed by phosphates prior to testing for potassium, indicated that either the zirconium phosphate adsorbed the potassium or the prolonged heating, needed to

---

[6] Fresenius, "Qualitative Chemical Analysis," translated by C. A. Mitchell, John Wiley and Sons, Inc., New York, 1921, 17th German ed., p. 181.

drive off the excess acids and ammonium salts, volatilized most or all of the potassium. When zirconium was removed by ammonium hydroxide (Col. 5), prior to testing for potassium, there were no such difficulties in detecting potassium. Therefore phosphates are not suitable and *ammonium hydroxide is suitable for removing zirconium prior to testing for potassium by sodium cobaltic nitrite.*

Detection of Potassium in the Presence of Zirconium by Changing the Zirconium into a Non-Interfering Complex Ion with Tartaric Acid.—Preliminary experimentation showed that if a 2-cc. solution of zirconium sulfate be treated with 0.3 g. of tartaric acid and the acidity controlled by neutralizing with 25% sodium hydroxide, making slightly acid with acetic acid, no precipitate is obtained with sodium cobaltic nitrite. If any potassium was added, a test for it was obtained. To determine the sensitiveness of sodium cobaltic nitrite for potassium under these conditions, a series of experiments was run. The manipulation was exactly as described above. The amount of zirconium sulfate was 0.1131 g. per test, the tartaric acid 0.3 g. and the amount of potassium varied. The results appear in Table II.

TABLE II

SENSITIVENESS OF SODIUM COBALTIC NITRITE FOR POTASSIUM WHEN ZIRCONIUM IS PRESENT IN COMPLEX ION

Expt.	K, g. per sample	Results of test for potassium with $Na_3Co(NO_2)_6$ Presence of zirconium	Absence of zirconium K_2SO_4 alone present
1	0.00107	Cloudy at once; ppt., 5 min.	Ppt., 5 min.
2	.00072	Cloudy, 5 min.	Sl. ppt., 5 min.
3	,00053	Cloudy, 10 min.	Very sl. ppt., 10 min.
4	.00030	Very sl. cloudy, 15 min ; ppt , 1.5 hrs.	Very sl. ppt., 10 min.
5	.00014	Very sl. cloudy, 1.5 hrs.; no ppt., 2 hrs.	Ppt., 2.5 hrs.
6	.00000	No ppt.; clear, 1.5 hrs.	Clear, no ppt., 23 hrs.

Discussion.—The suppression of zirconium by tartaric acid did not prevent the detection of 0.3 mg. of potassium (Expt. 4) by sodium cobaltic nitrite. The slight difference between the time for appearance of a precipitate in the test for potassium in the presence (Expt. 4) and absence of zirconium was doubtless due to dilution of potassium solution from 1 cc. to 3 cc. with zirconium present.

This method of suppression of zirconium ions is much to be preferred to removal of zirconium by either phosphates or ammonium hydroxide prior to testing for potassium by sodium cobaltic nitrite, as it is shorter and avoids danger of adsorption or volatilization of potassium.

Summary

1. The use of phosphates to remove zirconium prior to testing for potassium by sodium cobaltic nitrite is not advisable because of loss or dilution of potassium.

2. When phosphoric acid is neutralized with sodium hydroxide and the solution tested with sodium cobaltic nitrite, a misleading precipitate is secured unless a considerable excess of acetic acid is added.

3. Zirconium can be removed by ammonium hydroxide and potassium detected in the filtrate by sodium cobaltic nitrite, after eliminating the ammonium.

4. The best and shortest way of eliminating zirconium prior to testing for potassium by sodium cobaltic nitrite is by throwing the zirconium into a complex ion with tartaric acid and controlling the acidity with sodium hydroxide and acetic acid.

THE SYSTEM SODIUM SULFIDE–FERROUS SULFIDE[1]

BY L. V. STECK, MORRIS SLAVIN AND O. C. RALSTON

RECEIVED MAY 27, 1929 PUBLISHED NOVEMBER 8, 1929

This investigation deals with the composition diagram of the system Na_2S–FeS obtained from cooling curves on melts of several compositions and by microscopic examination of polished surfaces of frozen samples of the melts. The principal interest from an industrial standpoint was in the liquidus curves and no great effort was made completely to determine the nature of the phases or phase changes at temperatures beneath the liquidus. Therefore the phase diagram as presented is incomplete but contains the reasonable conclusions and certain inferences that seem to be justified by the data.

Preparation of Sodium Sulfide.—Several methods for preparing pure sodium sulfide were considered: reduction of sodium sulfate with carbon; the Hugot[2] method of reacting with sulfur on a solution of sodium in liquid ammonia with subsequent evaporation of excess ammonia; the Hugot method of reacting on molten sodium with hydrogen sulfide; the Sabatier[3] method of dehydrating the hydrated salt, $Na_2S\cdot 9H_2O$; and the reaction[4] obtained by heating sodium carbonate in sulfur vapor. All of these methods were tested by Friedrich,[5] who found that a reasonably pure product could be obtained by heating the hydrated salt in a rapid stream of hydrogen. The hydrated salt first melts in its water of crystallization, solidifying when the mass has reached about 70% of sodium sulfide by weight and leaving a porous mass from which the remainder of the

[5] Friedrich, *Metall und Erz*, **11**, 79 (1914).

water evaporates. The solid material loses part of its sulfur by hydrolysis so that the final product contains sodium hydroxide. Friedrich's preparation melted at 920°. .

This latter method was used in the present investigation because it was the only convenient one by which large quantities could be prepared. The first stage of evaporation was done in a large vacuum desiccator with a small electric heater, whose temperature never exceeded 50°, leaving a product with about 80% of Na_2S. When heated to 150° the final product in the desiccator, when using phosphorus pentoxide as desiccant, contained about 95% of sodium sulfide. This material when melted in a graphite crucible under nitrogen (losing more water during the heating) and cooled slowly indicated by its cooling curve that it froze at 970°. The melting point of the pure material is probably slightly above this temperature.

Preparation of Pure Iron Sulfide.—Two methods were tested: the thermal decomposition of pure pyrite, FeS_2, and the synthesis from iron and sulfur by absorbing sulfur vapor in fused pure iron.

The first method was used by Mostovitsch[6] in preparing iron sulfide analyzing 63.67% of iron and 36.33% of sulfur; the theoretical analysis is 63.52% of iron and 36.48% of sulfur.

In this research some 200 g. of iron sulfide, analyzing 63.5% of iron and 36.4% of sulfur, was made by the following method. A large specimen of very pure Chinese pyrite was ground through 65 mesh, packed in a graphite crucible under charcoal and covered with a graphite cover. It was heated in an electric resistance furnace to 1000°, cooled, reground, repacked in the crucible, heated just above the melting point and cooled in the furnace. A small amount of siliceous slag that had floated to the top was broken off and discarded. The balance had a rainbow luster and could be broken with the fingers into eighth-inch pieces.

When larger quantities of the iron sulfide were required the limitations of the supply of pure pyrite necessitated the use of some other method of preparation. Approximately a hundred grams of Armco iron turnings was mixed with distilled sulfur and placed in a graphite crucible in an Ajax Northrup Induction Furnace. As the furnace heated, the iron and sulfur united and formed a molten pool into which Armco iron strips and sulfur were alternately fed until there was approximately 1500 g. of material in the crucible. Sulfur was then dropped on the molten material until no more was taken up by the melt, which could be determined by observation. The melt was cooled, ground through 65 mesh, mixed with sulfur and remelted. It was kept in the molten condition for ten minutes, the furnace action providing very efficient stirring. The current was shut off and the temperature was taken every thirty seconds, using the thermocouple arrangement described later. While a very sharp freezing point was not obtained (see Fig. 1), the iron sulfide solidified within a few degrees of 1174". Check analyses gave the composition as 62.84% of iron and 36.92% of sulfur; 99.95% total. Analysis for carbon and oxygen may show the remainder.

Carbon in varying amounts was known to be present in all the melts, coming from the Acheson graphite crucible in which the work was done. The theoretical analysis of pure iron sulfide calls for 63.52% of iron and 36.48% of sulfur. Our preparation therefore consisted apparently of 98.9% of iron sulfide with the remainder excess sulfur and a small amount of carbon. The excess sulfur is probably present as pyrrhotite,

---

[6] Mostovitsch, *Ann. First Tomsk Siberian Technological Inst.*, [47] *1*, 1–74 (1925).

Fe_xS_{x+1}, where the subscript x is likely to have a high value. In the amounts of material with which we worked we did not arrive at a product which was slightly deficient in sulfur and which is reported by Allen and co-workers.? According to their experience ferrous sulfide dissociates slightly in the vicinity of its melting- point, losing sulfur by volatilization and leaving a material with a slight excess of free iron. They located the melting point of pure ferrous sulfide at 1170 ± 5°. Our slightly impure product gave an arrest in its cooling curve at 1174°, showing thereby very good agreement in thermometry with their work.

Apparatus.—Our mixtures of iron sulfide and sodium sulfide were melted in Acheson graphite crucibles with graphite lids in a high frequency induction furnace, the heat being generated by induced currents in the graphite crucibles. Crucibles of about 3 inches outside diameter and containing from 500 to 1000 g. of melt were used. They were placed in the center space of the induction furnace, which consisted of a vertical cylindrical tube of vitreosil around which was packed finely powdered electrically fused magnesia as an insulator. The bottom of the furnace was also of powdered magnesia. The thickness of this thermal insulation was about 3 inches and outside of everything were the copper tubing coils which constituted the inductors of the high frequency furnace. Sufficient electrical capacity was available to start cold and bring a melt to the desired temperature within five minutes, although the usual practice was to use three or four times as long an interval in order to establish a thermal diffusion gradient.

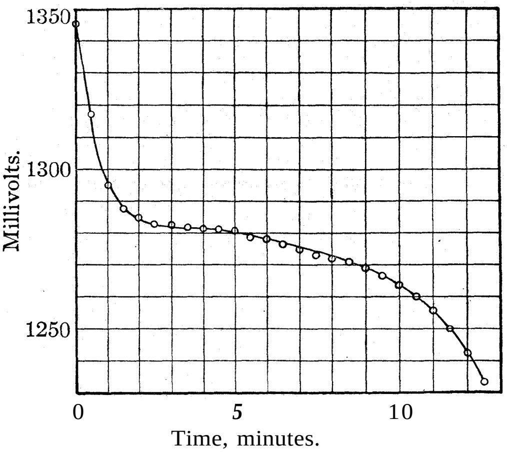

Fig. 1.—Cooling curve of FeS.

Temperatures were read with a platinum–platinum-rhodium couple, frequently calibrated against a similar standard couple which had been standardized by the Bureau of Standards. The Leeds and Northrup Type K potentiometer was used for e.m.f. measurements except where specified. The couple was protected by thin-walled chemical porcelain tubes manufactured especially for this work by Coors, the tubes having an outside diameter of 0.25 inch and being introduced into the melt through a small hole in the graphite cover of the crucible. Melts were not allowed to cool to the 298" polymorphic transition of iron sulfide because at this point the volume change was sufficient to crush the porcelain protecting tube. Therefore, after a cooling curve had been followed to about 400° the crucible was reheated until the protection tube could be withdrawn through remelting of the charge. A new porcelain tube was used with each melt, thereby maintaining adequate protection of the couple. The sodium sulfide was kept under nitrogen and the furnace was swept with nitrogen during melting and cooling. Sodium sulfide was weighed under nitrogen only after cooling with an ice-bath.

Results

In all, eleven cooling curves were obtained which could be used for preparing the phase diagram. The curve for pure iron sulfide, as shown in Pig. 1, has already been mentioned. The arrests in the other cooling

---

[7] Allen and co-workers, **Am. J.** *Sci.,* [4] **33,** 169 (1912).

curves have been tabulated in Table I. Four of them were made with mixtures of iron sulfide and sodium sulfide and the remainder, which were higher in sodium sulfide content, were made by adding more sodium sulfide to the product of a previous melt which was merely reheated in the same crucible, to which was added the new sodium sulfide and a sufficient sample withdrawn for analysis.

In addition to our own work, three other points in this system have been reported by F. Thomas,[8] but he has placed an erroneous interpretation on his meager data. His points are shown by crosses in circles in our phase diagram, Fig. 2.

In all cases the mixtures wetted the graphite crucibles and the greater the percentage of sodium sulfide the greater the apparent wetting. The only ocular evidences of segregation in the melts are mentioned in the column of "Remarks" in Table I.

The analyses of the samples from the various melts are indicated in Table II. No difficulty was encountered in analysis of the pure iron sulfide samples, but in all cases where sodium sulfide was present more or less graphite was present from the walls of the crucibles and it was not evenly distributed. Even quadruplicate determinations did not check well until chunks of the melts were rapidly pulverized in a porcelain mortar and screened through a 10-mesh sieve to remove coarse pieces of graphite. There are considerable differences between the analyses expected and those

actually found in several of the samples. In addition to the difficulty due to suspended graphite, there was probably also inhomogeneity due to segregation during cooling and a certain amount of unavoidable oxidation of sodium sulfide to sulfate. Calculating the iron and sodium to sulfide

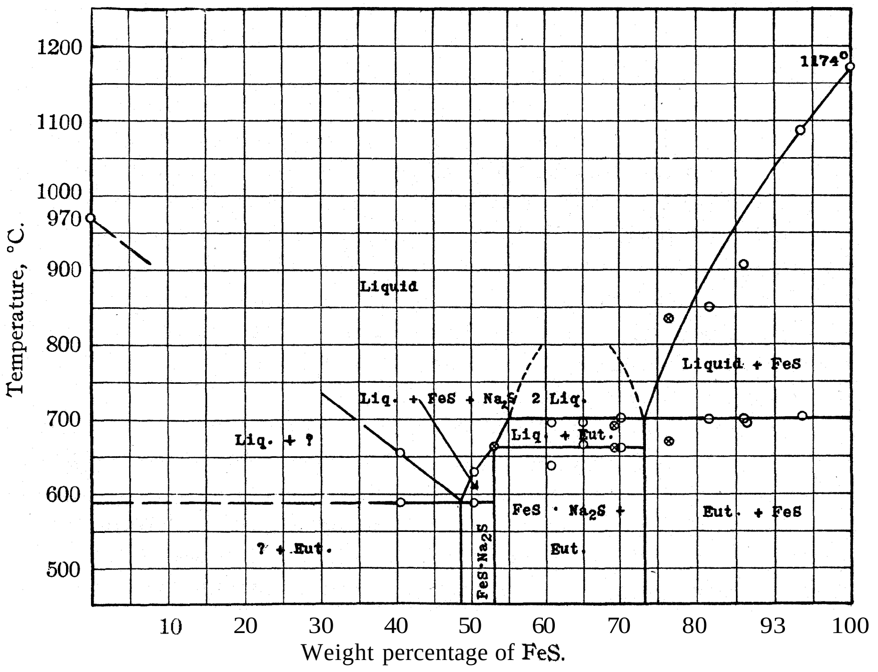

Fig. 2.—The system FeS–Na₂S. ⊗, Thomas; ○, Authors.

in these analyses, there is a slight excess of sulfur remaining in all cases, reaching a maximum of 2.8% in Run 11, but usually much less than this. Due to all these possible sources of error, the "observed" analyses were not used in preparing the phase diagram.

Every melt containing sodium sulfide oxidized rapidly if left in air and an odor of hydrogen sulfide arose from the action of moisture. They would crumble to a powder in a short time if left in the open air. All samples were therefore preserved in sealed containers. Contrary to expectation, the melts which reacted with air most quickly were those containing the higher percentages of iron sulfide.

Phase Diagram.—Based largely on the cooling curves and the ratios of iron sulfide and sodium sulfide used, the phase diagram of Fig. 2 was sketched, giving the temperature–composition relationships as far as it was possible to judge them from the few data. To a certain extent this diagram is supported by the metallographic examination of polished sections which is described below. The liquidus of this diagram is fairly well determined, although melts between pure sodium sulfide and 38% iron sulfide were not prepared and the vacant part of the diagram may be more complex than that sketched. The research was financed mainly to determine the liquidus and much work beyond this objective was not justified.

The secondary arrests in the cooling curves were somewhat difficult of interpretation but it is believed the diagram satisfactorily accounts for them. A separation into two conjugate liquids in the region between 55 and 73% of iron sulfide is necessary, although no direct evidence of this was obtained. Furthermore, the formation of a transitory double compound, $Na_2S\cdot FeS$, is assumed in this area of the diagram. The physical evidence supporting this latter conclusion is the presence of a white constituent in the polished surfaces under the microscope, whereas pure iron sulfide is yellowish and is found in the specimens with greater than 73% of iron sulfide. The composition of the white constituent was not determined but is assumed to be a double compound, probably $Na_2S\cdot FeS$, which seems to fit the cooling curves best.

The exact composition of the transitory double compound, while we believe it to be $Na_2S\cdot FeS$, is insufficiently determined. Stromeyer[9] once prepared what he thought to be $Na_2S\cdot 2FeS$ and it is this double compound which Thorpe[10] assumes caused difficulty in the Blythe and Kopp process of making soda. One of Thomas' points is at the composition $Na_2S\cdot FeS$ and shows only one arrest. He may or may not have missed the eutectic arrest at 585°. Therefore further work in the "two liquids" region of the diagram is urgently needed.

Our interpretation of these meager data is somewhat influenced by the work of F. Friedrich[11] on the system $Na_2S:Ni_3S_2$, which is very similar as far as the form of the phase diagram is concerned.

Metallographic Examination.—Lumps of about one inch diameter were used for preparation of polished surfaces. To protect them from attack by the atmosphere they were soaked in molten paraffin wax, which was adequate for the period of time necessary in polishing a surface, examining it under the microscope and photographing it. In place of water, kerosene was used on the polishing wheels. The polished surfaces, on account of difficulty of manipulation, are far from perfect, so caution must be used in implying inconsistences between the phase diagram and the micro-structure.

In general the melts high in iron sulfide showed the characteristic yellow iron sulfide dendrites. As melts lower in iron sulfide were approached, the yellow color diminished and in the two-liquid region the crystals seemed to be white. While magnifications up to 1000 diameters were used, a definite eutectic structure was usually difficult to find and especially the temporary eutectic (B) was disappointing from this standpoint.

The notes on the polished sections prepared are given herewith and also four photomicrographs to accompany them.

Examination of Polished Sections

Melt **No.** 10 (**91.1% of FeS**) (Plate I).—Structure consists of rounded grains of yellow iron sulfide in transparent matrix which appears dark under the microscope.

Melt **No. 11** (**90% of FeS**).—The iron sulfide is in the form of long dendrites in the transparent matrix. The dendrites can be seen with the naked eye.

Melt **No. 18** (**78.3% of FeS**).—Similar to No. 10. Irregular patches of yellow iron sulfide, although some are white.

Melt **No. 12** (**76.4% of FeS**) (Plate 2).—Dendrites of iron sulfide in dark matrix. The iron sulfide is much lighter in color than in previous specimens. The iron sulfide areas are much smaller and are very irregular.

Melt **No. 17** (**62.7% of FeS**) (Plate 3).—Small white crystals in the form of squares and triangles in a brown colored matrix which shows no sign of a eutectic structure.

Melt **No.** 15 (50% **of FeS**) (Plate 4).—Tiny specks of the white constituent of previous specimen in groundmass of very coarse eutectic. The groundmass, as can be seen from the photograph, is entirely different from that of the previous specimen.

Melt **No. 16** (37.5% of **FeS**).—Two constituents are present; both are dark by reflected light so that structure cannot be distinguished. Under the binocular microscope it is barely possible to distinguish between them on account of a slight relief due to difference in hardness. One constituent is more sectile than the other and shows a slightly metallic streak when scratched. The absence of eutectic may be due to smearing of the soft constituent when polishing.

Polished sections of Melts 10 and 17 were examined at the highest magnification of which our apparatus is capable (1000 diameters). Both appear to have the same groundmass, which may be a very fine-grained eutectic, but the structure is beyond the resolving power of the apparatus, so that a definite conclusion is impossible. No light colored constituent could be distinguished in the groundmass of either constituent.

Plate 1.—91.1% of FeS. Mag. × 85.

Plate 2.—76.4% of FeS. Mag. × 35.

Plate 3.—62.7% of FeS. Mag. × 170.

Plate 4.—49.8% of FeS. Mag. × 35.

Summary

Eleven melts and cooling curves have been prepared in the system Na_2S–FeS which have allowed preparation of a satisfactory liquidus in the temperature–composition phase diagram but insufficient points were taken to determine fully the solidus and a complete outline of the phase diagram. Such points as have been obtained indicate a region between 53 and 73% iron sulfide in which two liquid phases can form, one being a double compound, probably $FeS \cdot Na_2S$, saturated with iron sulfide, and the other being iron sulfide saturated with double compound, or something similar to it. One true eutectic is found at 46% of iron sulfide and 585°. The melting point of sodium sulfide has been determined as 970°, although its purity was such that the melting point of pure sodium sulfide can be expected to be slightly higher. No mixture containing less than 37% of iron sulfide was investigated.

EQUILIBRIUM IN THE SYSTEM $Co–H_2O–CoO–H_2$. FREE ENERGY CHANGES FOR THE REACTION $CoO + H_2 = Co + H_2O$ AND THE REACTION $Co + {}^1/_2O_2 = CoO$

BY P. H. EMMETT AND J. F. SHULTZ

RECEIVED MAY 28, 1929 PUBLISHED NOVEMBER 8, 1929

Introduction

In the course of some experiments with cobalt catalysts, we desired to know the ratio of steam to hydrogen above which cobalt is oxidized to cobaltous oxide. The only determinations in the literature seemed to be those of Chaudron[1] and of Wohler and Balz.[2] The former obtained a value of 20 at 1000°. The latter workers obtained a value of 14 at 450° and 19 at 750°. The apparatus and method of procedure used in both of these researches, however, were those used by Deville[3] in the study of iron oxide equilibria. Such a procedure is not well adapted to the determination of the equilibrium constant in the case of cobalt, since the partial pressure of hydrogen in equilibrium with 25 mm. of water vapor will be a millimeter or less. Any occluded gases in the solid material would cause one to obtain too low a value for the steam–hydrogen ratio. It was, therefore, probable that one or both of the above experiments might be in error, especially since preliminary observations indicated that the equilibrium ratio of steam to hydrogen was 50 or greater at 450°.

Accordingly, the present work was undertaken with a view to determining accurately, at several different temperatures, the equilibrium ratio of water vapor to hydrogen for the reaction $CoO + H_2 = Co + H_2O$. This paper outlines the essential details of procedure, and presents typical equilibrium data for 335, 450, 515 and 570°.

Apparatus and Materials

For the equilibrium determinations a flow system has been employed, similar in most respects to that used by Pease and Cook[4] in their investigation of the system $NiO–H_2–Ni–H_2O$. The apparatus as finally adopted is shown in Fig. 1. It consists essentially of a steam generator A, an electrolytic hydrogen generator B, a pyrex glass tube C containing the charge, an electric furnace D, a water-jacketed weighing tube E for catching and weighing the condensed steam and a special 100-cc. eudiometer F for measuring the hydrogen. The steam boiler used is similar to the one described by Kuentzel,[5] except that the steam exit has been so modified as to reduce the probability of tiny droplets of liquid water being carried over with the steam. The hydrogen cell was fitted with platinum electrodes and contained potassium hydroxide as an electrolyte. The hydrogen was purified by passage over soda lime and hot platinized asbestos. The tube containing the charge was heated in a furnace 48-cm. long, consisting of an alundum tube wound with nichrome ribbon embedded in magnesia and finally surrounded by an iron jacket. The bulb containing the charge was placed in the alundum tube and packed tightly with mossy copper. Temperature was measured by means of an alumel-chromel thermocouple in conjunction with a Leeds and Northrup portable potentiometer. It was found to remain constant within ±1° during a run.

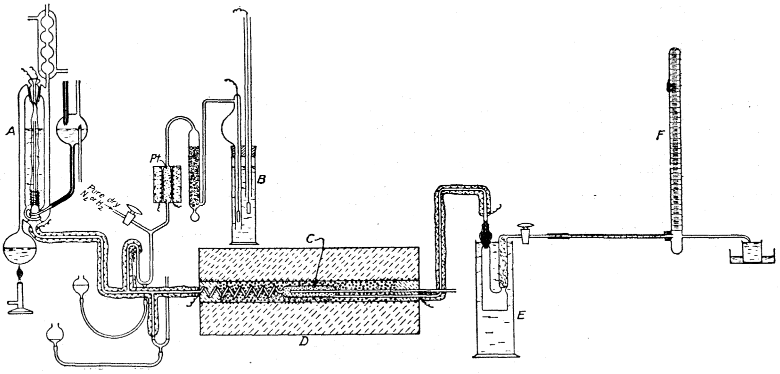

Fig. 1.—Apparatus.

The temperature gradient along the length of the catalyst was found to be less than 2°. It was obtained by moving a thermocouple along the thermocouple well extending coaxially along the entire catalyst tube. In several of the experiments an auxiliary thermocouple was placed in contact with the outside wall of the catalyst container. It showed the transverse temperature gradient to be less than 2° for half the width of the catalyst tube.

The flow of gases through the apparatus was regulated by mercury cut-offs rather than by dry stopcocks, since the latter when used are inclined to leak. The mercury

---

[4] Pease and Cook, THIS JOURNAL, 48, 1199 (1926).

[5] Kuentzel, unpublished material.

in the cut-offs was always covered with a centimeter or more of water and hence did not come directly in contact with any heated portion of the tubes. The top of the steam generator was water-sealed during all runs in order to preclude any possibility of air diffusing into the apparatus. The lead wires to the hydrogen generator were welded to tungsten which in turn was sealed through the pyrex glass of the generator.

Two different cobalt oxide preparations were used in the present experiments. Catalyst No. 1 was prepared by fusing a sample of nickel-free metallic cobalt with an oxyhydrogen flame in a crucible of cobalt coated with cobaltous oxide. Excess oxygen was blown into the melt during the fusion. The resulting oxide analyzed very nearly pure cobaltous oxide. It was used in the form of 10- to 14-mesh materiai.

Catalyst No. 2 was prepared by first gently and finally strongly igniting a sample of C. P. recrystallized cobaltous nitrate. The first gentle heating was in an open porcelain dish. The final higher heating to approximately 500° was of several hours duration and took place in a glass tube with a stream of air passing continually. The apparent density[6] of catalyst No. 1 was 2.65, and of No. 2, 0.76. The composition of this latter material was very nearly Co_3O_4. It accordingly had to be reduced for some hours with a steam–hydrogen mixture in which the ratio of steam to hydrogen was slightly too high to permit the reduction of the CoO formed. By such procedure a pure CoO was obtained.

Experimental Procedure

The reaction tube filled with 20 to 25 cc. of one of the cobalt oxides was packed into the furnace, connected to the steam and hydrogen generators and brought to the desired temperature in a slow stream of oxygen-free nitrogen. After being suitably reduced by hydrogen, the catalyst was subjected to various definite steam–hydrogen mixtures and the effluent gases were analyzed for water and hydrogen. The inlet and exit steam–hydrogen ratios were determined by three measurements: (1) the weight of exit steam condensed in the water jacketed U-tube in a given time; (2) the volume of exit hydrogen (corrected to S. T. P.) collected during the same period of time; and (3) the current passed through the hydrogen cell during the run. The effluent hydrogen, in addition to being corrected to S. T. P. on a dry basis in the usual way, had also to be corrected first for the volume of the gas displaced into the measuring buret by the condensation of steam in the U-tube, and second for the volume forced out of the U-tube by slight heating resulting from the rapid flow of steam. The first of these two corrections was, of course, easily and accurately made. The second was also definitely determined by using as the inlet tube to the eudiometer F a pipet stem graduated in 0.1 cc. divisions and easily readable to 0.01 cc. Immediately on shutting off the steam flow at the end of a run, the water from the eudiometer quickly sucked back into the pipet entrance tube as the heated portions of the U-tube rapidly cooled. This heating correction was usually of the order of **0.3** cc. It was very constant and easily obtained under a given set of conditions.

Experiments in general were repeated many times at each particular temperature, using first, Catalyst No. 1 and then Catalyst No. 2. Equilibrium was approached at each temperature from both the steam and the hydrogen sides.

Experimental Results

In order to obtain approximate values for the equilibrium constant and to learn how rapidly equilibrium could be attained, numerous preliminary experiments were carried out over a temperature range of **335**

---

[6] By "apparent density" of a sample is here meant its weight in grams divided by its approximate apparent volume as measured in a graduated cylinder.

to 515°. During these runs 6 or 7 different types of apparatus were tried. By a process of elimination the poor features of different analytical devices were remedied and eventually the final apparatus described in Fig. 1 was obtained.

In the three hundred or more preliminary runs it became apparent that the material was often not very active, particularly at 335°. Even at 450° considerable trouble was experienced in getting sufficiently large changes in the exit as compared to entering gas ratios. However, these preliminary results in spite of analytical difficulties give a fair approximation to the equilibrium constants.

TABLE I

PRELIMINARY RUNS AT 335°

	Inlet mixture		Exit totals			
Run no.	Steam, cc./min.	Hz, cc./min.	Water, g.	Hz, cc. (S. T. P.)	H_2O/H_2 In	Out
			50 Grams of Catalyst No. 1			
36	49.3	1	0.469	6.79	49.3	85.9
126	94.2	1	1.006	14.99	94.2	83.5
127	95.7	1	1.032	15.00	95.7	85.6
128	93.5	1	1.023	14.97	93.5	85.0
252	99.3	1	1.212	17.24	99.3	87.4
			14.5 Grams of Catalyst No. 2			
193	67.7	1	0.448	7.03	67.7	79.3
196	94.5	1	.473	6.76	94.5	87.0

From the results, part of which are shown in Table I, it is believed that the equilibrium constant at 335° is 85 ± 5. Due to the slowness with which a gas mixture attained equilibrium over the oxide mixtures at this low temperature, no final measurements at 335° were attempted. The 450 and 515° preliminary results are not listed since the final results are much more significant and more closely indicative of the true equilibrium constants. The preliminary results at these temperatures indicated that the value of the constant at 450° would be 65 ± 5, and at 515° would be 53 ± 5.

The final runs were all made using the apparatus as described in Fig. 1. Each experiment was continued until 90 to 100 cc. of effluent hydrogen was collected in the eudiometer. The 450° values are shown in Table II. Herein are included only those final runs in which the exit ratio differs by 5% from the entering and in which the final value is within the range of 63 to 71. None of the omitted values contradicts any of the values in Table II. The single contradiction in the runs at 450° (Run 393) is included in Table II, and is believed to have been caused by some unaccountable experimental error. Furthermore, the first two readings after either a 100% steam treatment or a reduction with pure hydrogen (designated in Tables II and III by *a* and b, respectively) have not been included in the final choosing of the equilibrium constant, in that the former are usually low by about 5 to 10% and the latter high by about the same amount. It is believed from the results obtained that a value of 67 ± 1, represents closely the equilibrium constant of the reaction.

[a] Pure steam was passed over catalyst for thirty minutes or more immediately prior to this run. [b] 200 cc./min. of pure hydrogen was passed over catalyst for five minutes or more immediately prior to this run.

The values obtained for 515° are given in Table III. All values obtained have been included (excepting 4 values to be listed and explained in connection with Table V) in which the entering and exit ratios differ by 5% or more and the final value lies between 55 and 60. From the data thus obtained, the equilibrium constant for 515° appears to be 57 ± 0.3. At this temperature, too, the results of the first run following treatment with 100% steam or with pure hydrogen are higher or lower, respectively, than the normal equilibrium values and accordingly are not considered in choosing the equilibrium constant.

In Table IV are given the results obtained at a temperature of 570°. Except for one group of 8 runs, reserved for Table V, all of the final 570° experimental values are included. The equilibrium constant at 570° is 50.5 ± 0.2.

437	171.3	3	3.381	82.96	57.1	50.7	61

One group of experiments was carried out to ascertain whether or not the same equilibrium constant prevailed even when the solid phase consisted of a small amount of oxide and a large amount of metal. A definite shift in the equilibrium constant would indicate the formation of solid solutions over a limited range. The results of the twelve runs thus made are shown in Table V.

TABLE V

RESULTS OF EXPERIMENTS

Run no.	Inlet mixture Steam, cc/min.	H_2, cc/min.	Exit totals Water, g.	H_2, cc.	H_2O/H_2 In	Out	Approx. % of metallic cobalt
			Temperature, 515"				
412	97.9	2	3.516	85.15	49.0	51.4	80
413	107.2	2	3.639	85.17	53.6	53.2	80
414	134.8	2	3.687	84.83	67.4	54.0	80

423	187.4	4	3.313	84.47	46.9	48.8	88

Run 412 was made immediately after reducing a sample until it contained only 20% of cobaltous oxide. Just before Run 420, additional reduction dropped the oxide content to approximately 12% of the sample. It was at first thought that the results indicated a definite shift in equilibrium constant. Unfortunately time limitations prevented the obtaining of further data upon this point. If due allowance is made for the already noted tendency of ratios immediately following long reduction to be low, the results in Table V are believed to be explainable without assuming the formation of solid solutions. Particularly, Runs 420, 421 and 422 suggest the probability that the low ratios are the result of the long reduction, for the exit ratio is in these runs definitely increasing toward the 50.5 value, believed to be the true equilibrium constant. Furthermore, as will be seen from the x-ray photographic data given below, no evidence of solid solutions for these samples is furnished by the powder photographs taken.

It should be noted that Runs 429 to 444 shown in Tables II to IV were all taken after those in Table V, the only change being that between Runs 428 and 429 the catalyst was steamed for seventeen hours at 500°. Hence it is certain that the analytical apparatus was operating in the same way before and after the twelve runs of Table V.

From the data presented in Tables I to V, it can be concluded that the equilibrium ratios of steam to hydrogen in contact with the oxide–metal mixture present are as follows:

Temperature, °C.	335	450	515	570
Ratio	85 ± 5	67 ± 1	57 ± 0.3	50.5 ± 0.2

The 335° value is only approximate and was determined in preliminary runs.

It was next necessary to establish definitely that the cobalt oxide in the above experiments was CoO and not Co_3O_4, Co_2O_3 or a solid solution of two of the oxides.

We were fortunate in having facilities available for checking the composition of all the materials used in these determinations by x-ray photograph~.~

In Table VI are listed the samples of which powder photographs were taken as a means of ascertaining definitely the solid phases existing in the equilibria measurements. These photographs were made with MoKα radiation. Since all the substances present in these samples have been previously examined by means of their x-ray powder diffraction patterns, it was not considered necessary to list in detail the results obtained.

TABLE VI

POWDER PHOTOGRAPH RESULTS

	History of sample	Phases revealed by powder photographs
a	Pure CoO (Sample of Catalyst No. 1)	CoO
b	Co_3O_4 (Sample of Catalyst No. 2)	Co_3O_4
c	Catalyst No. 1, 9% reduced at 283°	CoO and hexagonal Co
d	Catalyst No. 1, 75% reduced at 288"	CoO and hexagonal Co
e	Mixture of Sample c and CoO	CoO (no line displacement) and hexagonal Co
f	Mixture of Sample d and CoO	Same as in e
g	Final material remaining after Run 444 in the equilibrium measurements	Cubic Co and CoO
h	Sample obtained by steaming a completely reduced Co_3O_4 sample for eight hours at 500° with rapid flow of steam. During this time the sample was 70% reoxidized, as detd. by hydrogen formed	Cubic Co and CoO
i	Sample prepared by passing a mixture containing steam and hydrogen in the ratio of 70 to 1 over a sample of Co_3O_4 at 500° for ten hours	Strong CoO Faint Co_3O_4
j	Co_3O_4 reduced at 310°	Hexagonal Co
k	Co_3O_4 reduced at 340°	Hexagonal Co
l	Co_3O_4 reduced at 383°	Cubic cobalt
m	Co_3O_4 reduced at 360°	Cubic and hexagonal cobalt

---

[7] For these powder photographs and their interpretation we are indebted to Dr. S. B. Hendricks of this Laboratory. We wish to express our appreciation for his cooperation.

Substances identified by the powder lines on the photograph are indicated in the table.

With the exception of Samples a and b, all the materials listed in the above table were examined without allowing them to come in contact with the atmosphere.

These photographic results we believe enable us to conclude (1) that cobaltous oxide and cobalt were the only solid phases present during the equilibrium measurements; (2) that no evidence for the existence of a solid solution between cobaltous oxide and cobalt under the conditions of these experiments can be found in the powder photographs obtained.

In view of the above facts, it seems justifiable to conclude that the equilibrium results summarized above apply to the equilibrium Co–CoO–H_2O–H_2.

The results summarized under j, k, 1 and m were taken by Dr. Hendricks in order to fix the transition temperature of cobalt. It has previously been known that cobalt obtained by reduction of the oxide at 600°, has a "face-centered" cubic structure while that usually present in cast cobalt has a "close-packed" hexagonal structure. The transition temperature was not even approximately known nor could it be determined by the usual method of thermal analysis, since the rate of transformation of one form to another is very sluggish at 300–400°. From the information listed in Table VI, it can be concluded that the transition temperature is between 340 and 360°.

It should be noted in the results in Tables I, II, III, IV and V that values for the effluent ratio of steam to hydrogen are higher than normal immediately after oxidation and lower immediately after reduction. Such runs are. designated by *a* and b, respectively, as described in Table II. This is analogous to the effect mentioned by Richardson, Vibrans and Bell[8] for iron oxide reduction, and by Pease and Cook[4] in the case of the equilibrium determination of hydrogen-steam ratio over Ni–NiO mixtures. A similar phenomenon is reported for metallic iron catalyst by Almquist and Black.[9] In this latter case the circulation over an iron catalyst of a 3:1 hydrogen–nitrogen mixture containing from 0.008 to 0.32% of water vapor was found to form small but definite amounts of oxide upon the surface of the iron. This oxide has been interpreted by Almquist[10] as being due to the oxidation of surface atoms having free energies of the order of 10,000 calories greater than that of normal surface iron atoms. Eastman and Evans[11] have noted the tendency of the equilibrium hydrogen–steam ratio over Fe–FeO to increase as the

[8] Richardson, Vibrans and Bell, *Science*, **56**, 27 (1922).

[9] Almquist and Black, THIS JOURNAL, 48, 2814 (1926).

[10] Almquist, *ibid.*, 48, 2820 (1926).

[11] Eastman and Evans, *ibid.*, 46, 888 (1924).

oxygen content of the solid phases decreased, and have mentioned it as being indicative of a solid solution existing between iron and ferrous oxide. This phenomenon, however, quite probably is distinct from the one noted by Almquist and Black in that it was obtained under conditions making solid solution much more likely than in the case of their experiments. In the present work the values marked with a a or b in Tables II, III and IV are of such magnitude and obtained under such conditions as probably to be due to a surface effect rather than to the formation of a solid solution. Furthermore, as already pointed out, powder photographs reveal no shifting of lines of cobaltous oxide containing small amounts of cobalt or cobalt containing small amounts of cobaltous oxide, making the existence of solid solutions between these solid phases improbable.

One difference between the above-mentioned effect on nickelous oxide as reported by Pease and Cook and on cobaltous oxide as recorded in the present work should be noted. The former authors give data showing a rather high hydrogen consumption by nickelous oxide on passage of a steam–hydrogen mixture. Thus, one 84-g. sample of NiO when treated with 150 cc. per minute of a 150–1 steam–hydrogen mixture permitted no hydrogen to pass during the first twenty hours. Had the exit gases contained the normal equilibrium hydrogen some 554 cc. of hydrogen would have been collected during this time. Accordingly, hydrogen equivalent to about 2.1% of the oxygen of nickelous oxide was consumed before any appeared in the effluent gas. In contrast to this, the cobaltous oxide samples of the present work never absorbed more than a few cc. of hydrogen when similarly treated. The very first reading usually differed from the true equilibrium value by only 5 or 10%. Complete equilibrium usually resulted within an hour of the first passage of steam–hydrogen over the oxide. This excessive consumption of hydrogen by nickelous oxide as compared to cobaltous oxide may indicate an unusually large surface effect by the nickelous oxide preparation as compared to the cobaltous oxide. On the other hand, it may in part at least be due to the consumption of some hydrogen by small amounts of Ni_2O_3 present in the NiO. This possibility would necessitate that the oxide be of the empirical composition $NiO_{1.021}$ approximately. The highest percentage of oxygen reported by Pease and Cook was 21.8% in contrast to the 21.43% theoretically needed for NiO. This corresponds to a composition of $NiO_{1.018}$. Furthermore, Benton and Emmett[12] reported certain samples of NiO which were prepared by ignition of the nitrate in air at 360 to 400° for many hours to have a composition as rich in oxygen as $NiO_{1.032}$. Accordingly, it does not seem unreasonable that part of the effect reported by Pease and Cook was in reality due to the reduction of small amounts of one of the higher oxides of nickel. Hence, in nickelous oxide the true "surface" effect

---

[12] Benton and Emmett, THIS JOURNAL, 46,2728 (1624).

causing hydrogen from a steam–hydrogen mixture in contact with pure metal to be consumed in excess of equilibrium requirements may not be different from that found for cobaltous oxide.

Free Energy Calculations.—From the equilibrium data obtained in the present investigation, the standard free energy and heat content changes for the reaction

$$CoO + H_2 = Co + H_2O \qquad (1)$$

can easily be calculated. Inserting the values 67, 57.0 and 50.5 for K at 723, 788 and 843°, respectively, into the equation[13]

$$\Delta F^\circ = -RT \ln K$$

one readily obtains ΔF°_{723}, ΔF°_{788} and ΔF°_{843}, as −6045, −6335 and −6574 calories, respectively. In the absence of specific heat data for cobaltous oxide, we have used a value of 10, obtained by Kopp's law as outlined in Noyes and Sherrill[14] and for cobalt a value of 6. These specific heat values, together with those for water vapor and hydrogen given by Lewis and Randall, yield a ΔC_p value of $-1.69 - 0.0028T + 0.00000222T^2$. Inserting ΔF° values for the three temperatures given above in the equation

$$\Delta F^\circ = \Delta H_0 - \Delta\Gamma_0 T \ln T - {}^1/_2\Delta\Gamma_1 T^2 - {}^1/_6\Delta\Gamma_2 T^3 \ldots\ldots + IT$$

and solving the three sets of resulting equations for I, values of −18.91, −18.83 and −18.87 are obtained. Using an average **I** value, an average ΔH_0 value of −1040 calories is obtained. Whence $\Delta H_{298} = -1646$ calories, and $\Delta F^\circ_{298} = -3678$ calories for Reaction 1 above.

In Fig. 2 the smooth curve represents a plot of $1/T$ against the logarithm of the equilibrium constant as calculated for temperatures between 335 and 1050° from the ΔF° equation given above, using for ΔH_0 −1040 calories, for **I** a value of −15.87 and for ΔC_p the expression $-1.69 - 0.0028T + 0.00000222T^2$. It is realized that the high temperature extrapolation of our own values hereby obtained is uncertain because of the assumptions as to the specific heats of cobalt and cobalt oxide. More dependable extrapolations to the higher temperatures must await specific heat data on cobaltous oxide. From the figure, assuming the above extrapolation to be approximately correct, we conclude that our own data are consistent with the value of 20 ± 10, obtained by Chaudron, for the constants at 1050°. The results of Wohler and Balz, however, are much lower than our own. It is tempting to suggest that the value 34 reported by them to be the constant for the oxidation of CoO to Co_3O_4 by steam may actually have been obtained when CoO and Co were present and may accordingly refer to the equilibrium measured in the present research.

[13] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923.

[14] Noyes and Sherrill, "Chemical Principles," The Macmillan Co., New York, **1928**, **p. 93.**

By combining the free energy for Reaction 1 with that[13] for the reaction

$$H_2O = H_2 + {}^1/_2O_2 \qquad (2)$$

one obtains the ΔF°_{1373} for the reaction

$$CoO = Co + {}^1/_2O_2 \qquad (3)$$

as +32,050 calories. By the equation $\Delta F^{\circ} = -RT \ln K$, the dissociation pressure of the oxide at 1373° is given as 0.5×10^{-7} mm. This value is consistent with the experiments of Foote and Smith[15] in which the dissociation pressure of cobaltous oxide was too small to be measurable at 1373°.

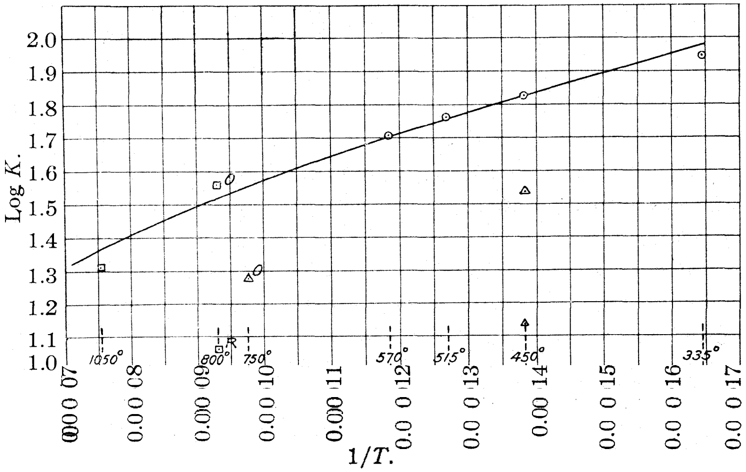

Fig. 2.—⊙, Emmett and Shultz; ⊡, Chaudron; △, Wohler and Balz.

Experimental ΔH values of Mixter[16] for Reaction 3 above are 57,587 calories for crystalline CoO and 50,180 calories for "amorphous" cobalt oxide. The so-called "amorphous" values were obtained by the indirect oxidation of cobalt by means of sodium peroxide rather than the direct oxidation with gaseous oxygen used in determining the 57,587 value. It is quite probable, accordingly, that this difference in procedure rather than the difference in fineness of subdivision of the final product causes the discrepancy between the two values for the heat of oxidation of cobalt to cobaltous oxide.

It is interesting to calculate indirectly from our own data the ΔH value for Reaction 3. By combining the ΔH_{298} value obtained above for Reaction 1 and the well known ΔH_{298} value for Reaction 2, one obtains $-1646 + 57{,}800 = 56{,}154$ calories as ΔH_{298} for Reaction 3. This compares favorably with Mixter's value of 57,587 calories.

---

[15] Foote and Smith, **This Journal**, 30, 1349 (1908).

[16] Mixter, *Am. J. Sci.*, 30, 193 (1910).

As confirmation of the fact that no Co_3O_4 was obtained by passage of steam over CoO, a combination of the ΔF° value for the reaction

$$Co_3O_4 = 3CoO + {}^1/_2O_2 \qquad (4)$$

as calculated from the dissociation pressure of (4) given by Foote and Smith[15] and Reaction 2, above, yields ΔF°_{603}, ΔF°_{788} and ΔF°_{1073} values for the reaction

$$Co_3O_4 + H_2 = 3CoO + H_2O \qquad (5)$$

of −34,197, −36,539 and −44,717 calories, respectively. Corresponding ratios of steam to hydrogen necessary to produce oxidation of the CoO to Co_3O_4 are 2.4×10^{12}, 1.3×10^{10} and 1.3×10^{9}. Hence, no formation of Co_3O_4 under the conditions of the above experiments would be expected.

This conclusion is in agreement with our own experimental values but is in direct contradiction to the results of Wohler and Balz,[2] who reported a value of 34 for the above ratio at a temperature of 450°.

In the above calculations nothing has been said about the possible free energy change involved in the transformation from hexagonal to cubic cobalt. All experiments except those at 335° were carried out in the temperature region in which the cubic modification of cobalt is the stable one. In the absence of the necessary data no correction has been made for any free energy change involved in the transformation from hexagonal to cubic cobalt.

Summary

1. The ratios of steam to hydrogen in equilibrium with a mixture of cobalt and cobaltous oxide have been determined by a flow method. The values obtained for this ratio are 67 ± 1, 57.0 ± 0.3 and 50.5 ± 0.2 at 450, 515 and 570°, respectively. An approximate value of 85 ± 5 has been obtained at 335°.

2. ΔF°_{298} for the reaction $CoO + H_2 = H_2O + Co$ has been calculated as −3678 calories.

3. The calculated value of ΔH_{298}, −1646 calories, for the above reaction is to be compared with a value, −300 cal., obtained by the combination of Mixter's experimental heat of formation of cobaltous oxide and the well-known heat of formation of water.

4. The failure of steam passage over CoO at 500° to form Co_3O_4 has been verified by x-ray photographs. A calculated value has been obtained for the theoretical steam–hydrogen ratio necessary to effect such an oxidation. This was obtained by a combination of the dissociation pressure measurements of Co_3O_4 made by Foote and Smith, and the value for the ΔF° change involved in the formation of water from hydrogen and oxygen. It is believed that the calculated value is approximately correct and accordingly confirms the impossibility of any appreciable amount of Co_3O_4 having been formed by passage of steam–hydrogen

mixture over cobaltous oxide in the temperature range of 330 to 570° in the above experiments.

5. ΔF°_{1373} for the formation of cobaltous oxide from cobalt and oxygen has been calculated by combining the free energy change involved in forming water vapor from hydrogen and oxygen with that found experimentally in the present research for the reduction of cobaltous oxide to cobalt by hydrogen. A value of 32,030 calories so obtained yields a value of 0.5×10^{-7} mm. for the partial pressure of oxygen in equilibrium with CoO–Co mixture at 1100°, that is, in agreement with Foote and Smith's failure to detect measurable dissociation of cobaltous oxide at that temperature.

6. The temperature of transformation of hexagonal to cubic cobalt has been fixed as lying between 340 and 360°.

AN APPARATUS FOR TESTING DÜHRING'S LAW FOR CORRESPONDING BOILING POINTS

BY ERWIN F. LINHORST

RECEIVED JUNE 3, 1929 PUBLISHED NOVEMBER 8, 1929

Introduction

In 1577 Dühring[1] found that a linear relation existed between the boiling temperatures of two liquids boiling under the same pressures. So far this law has been tested indirectly by plotting corresponding boiling points from vapor-pressure data obtained for the two liquids separately. If the two liquids could be boiled in different parts of a closed system, then as the pressure is varied in the system, the corresponding boiling temperatures could be observed directly. This was tried out and it has given satisfactory results. The apparatus is of simple construction and is easy to manipulate.

Discussion

The apparatus is illustrated in Fig. 1. Bulbs are blown at the bottom of two upright reflux Liebig condensers. At the top the condensers are connected to each other and to a vacuum pump, which may be an ordinary aspirator. In the latter case a water trap should be provided in the evacuating train. In order to condense the vapors of the boiling liquids at low temperatures ice water should be led through the condensers.

The liquids to be boiled are poured into the bulbs to about the level indicated in the figure. Porous plate or bisque fragments are added to minimize bumping. The boiling temperatures are obtained by two

---

[1] Dühring, *Wied. Ann.*, **11**, **163** (1880).

thermometers entering the bulbs through necks on the bulbs. Airtightness is secured by pieces of rubber tubing fitting over the thermometers and the necks. A cloth gasket is desirable in the case of an organic liquid in order to minimize contact of the liquid with the rubber.

The heating may be done by small flames of Bunsen burners. The bulbs containing the liquids are shielded by asbestos sheets having small holes in the center to permit local concentrated heating and thus help to reduce bumping.

In actual operation it is best to evacuate first and start the liquids boiling at low temperatures and to let a slow leak into the apparatus gradually raise the boiling temperatures. Another advantage of starting at low temperatures is that the liquids are then most likely to bump, but the pores of the porous plate contain then more air than later and are thus more effective in reducing bumping. The air leak may be controlled by a screw clamp over a rubber tubing on the exhaust tube. The temperatures may be read conveniently at degree intervals. A continuous rise in temperature of 1° in three to five minutes is found to be slow enough for accuracy. When the pressure is back to atmospheric, it may be carried a little above by admitting compressed air at low enough pressure so as not to endanger the apparatus.

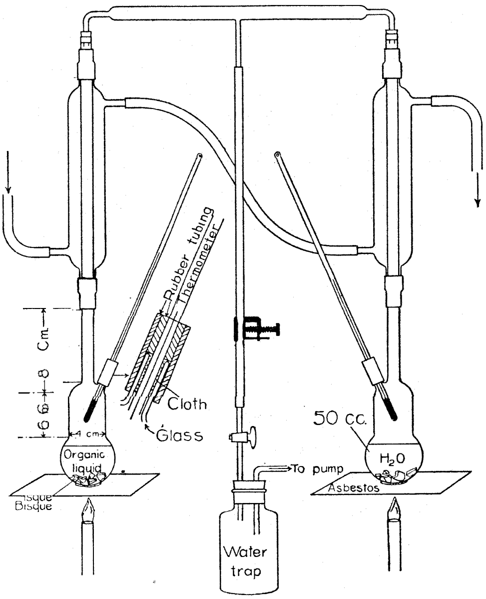

Fig. 1.

The observed temperatures have to be corrected for the length of the mercury thread exposed to room temperature. This correction is to be added to the reading of the thermometer. It is expressed by the formula

$$C = 0.00016 \times l_{\mathrm{Hg}} (t - t_{\mathrm{R}})$$

where l_{Hg} is the length of the exposed mercury column in degrees, t is the reading of the thermometer and t_{R} is the room temperature.

The apparatus was tried out for benzene and ethyl alcohol against water. The equation of the corresponding boiling-point curve for alcohol was found to be

$$t_{\mathrm{A}} = -12.23 + 0.9062\, t_{\mathrm{W}} \tag{1}$$

The maximum deviation of observed readings from this relation was less than 0.07' in absolute value and nowhere was there a trend toward either algebraic sign of the deviations. The boiling temperature at one atmosphere calculated from the equation is 78.39'. The value given in "International Critical Tables," Vol. III, p. 217, is 78.32°.

The results obtained for benzene do not follow a single linear relation so well; they form a curve slightly concave upward. The data may, however, be represented closely by three line segments, each holding for part of the curve. From 54 to 70° on the water axis the line

$$t_B = -30.49 + 1.0948\, t_W \tag{2}$$

holds, from 70 to 90° the line

$$t_B = -32.39 + 1.1222\, t_W \tag{3}$$

and from 90 to 105' the line

$$t_B = -34.77 + 1.1491\, t_W \tag{4}$$

The maximum deviations of observed values from these lines was less than 0.08' in absolute value. The boiling point of benzene at one atmosphere therefore is 80.14". Smith and Menzies[2] found it to be 80.12'. Both the benzene and alcohol were of high purity and were used for molecular weight determinations. The experiment for the benzene was repeated with another sample and practically the same results were obtained.

Figure 2 represents the data graphically. In Table I are shown some vapor-pressure values of alcohol and benzene as calculated from Equations 1, 2, 3 and 4 and a reliable table of the vapor pressure of water. The corresponding values found by others are also given in the table for comparison.

[a] "International Critical Tables," Vol. III, p. 217.

---

[2] Smith and Menzies, THIS JOURNAL, 32,1448 (1910).

Any inherent errors in the apparatus are present in both halves, and if the two temperatures are close together, these errors largely cancel each other. To make this more certain the two halves of the apparatus should be as nearly alike as possible. High-grade thermometers of the same type should be used.

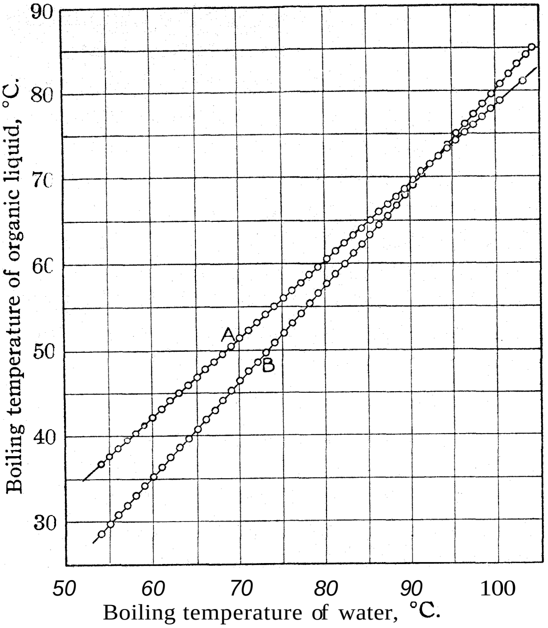

Fig. 2.—A, Ethyl alcohol; B, benzene.

This apparatus as shown is applicable only to pure liquids, where the vapor has the same chemical composition as the liquid, not to solutions or mixtures, where this is not in general, true.

Summary

An apparatus was developed for testing Dühring's law of corresponding boiling points. It was tried out for benzene and ethyl alcohol. The law was found to hold for the alcohol over the range observed but not for the benzene.

PH MEASUREMENT WITH THE GLASS ELECTRODE AND VACUUM TUBE POTENTIOMETER

BY L. W. ELDER, JR.

RECEIVED JUNE 7, 1929 PUBLISHED NOVEMBER 8, 1929

In a previous communication a single tube vacuum tube potentiometer was described which gave satisfactory potential readings in acid and alkali when a suitable glass was used.[1,2] The present paper deals with a further modification of this apparatus and presents the results of a direct comparison of the vacuum tube instrument with a Lindemann quadrant electrometer. In an effort to produce a glass electrode with predictable characteristics there are also reported measurements made on five different soft glass stocks in a buffer series standardized by the hydrogen electrode. Particular interest has been centered in the slope of the line relating potential and PH, the magnitude of the asymmetry potential,[3] and electrical resistance.

Modification of the Vacuum Tube Apparatus.—The circuit for the vacuum tube potentiometer as shown in Fig. 1 has been slightly modified. The high sensitivity galvanometer in the grid circuit is, of course, quite unnecessary for ordinary work. It was inserted only for the purpose of measuring grid leakage while testing various tubes and the effect of varying grid bias potential. Higher sensitivity can be obtained without the shunt around the plate circuit galvanometer, using the latter as a microammeter null instrument, but this arrangement restricts the choice of plate potential, which is determined by the type of galvanometer used and by the construction of the vacuum tube. With the Leeds and Northrup Type P galvanometer (Cat. No. 2239-b, 1000 meg. sensitivity) and Type CX299 tube, a plate potential of 22.5 volts was employed in most of the measurements reported below. The critical grid potential

---

[1] Elder and Wright, Proc. *Nat.* Acad. Sci., 14, 936 (1928).

[2] The wiring diagram is shown in Fig. 1. The plate potential of 19.5 volts was supplied from 13 dry cells. Operating on a negative grid bias of 2.3 volts, the UX 222 tube drew less than 10^{-9} ampere in the grid circuit and showed a sensitivity of ±1 millivolt with a Leeds and Northrup wall type galvanometer (sensitivity 10^{-8} ampere) and variable shunt in the plate circuit. The method of measurement was a modification of that proposed by Morton [Trans. Faraday *Soc.*, 24, 14 (1928)] in which an ordinary ("student type") potentiometer was connected in opposition to the cell being measured in the grid circuit. With the paraffin block switch S (Fig. 1) in position "a," the galvanometer was set for *a* certain "zero reading." Then the cell was cut in by throwing S to position "b" and the potentiometer setting changed to bring the galvanometer back to its "zero" position. Thus nearly constant current flow was maintained in the plate circuit and difficulties due to fluctuation in plate potential were minimized. The unknown potential is, of course, the difference between the "zero" and second settings of the potentiometer, which has been independently calibrated against a standard cell in the usual manner.

[3] W. S. Hughes, J. *Chem. Soc.,* 491 (1928).

as estimated by Goode's method[4] for a plate potential of 22.5 volts and filament potential of 2.4 volts for this type of tube is −1.5 volts with reference to the negative filament lead. Any grid bias of greater negative value will be satisfactory in eliminating grid leakage, except that a very large negative grid potential will bring the plate current down to a point where it is less sensitive to change in grid potential. −2.3 Volts is still a satisfactory value for the grid bias of this tube.

The "direct reading hydrogen ion meter" described by Pope and Gowlett[5] offers certain advantages over Goode's apparatus in that the high voltage "B" battery is eliminated and the plate circuit millivoltmeter can be calibrated readily in terms of PH readings before and after each measurement. Both of these circuits, depending on calibration of the indicating instrument in the plate circuit, seem to be fundamentally less reliable than those of the type suggested independently by Morton[2] and Partridge[6] in which the unknown e.m.f. is measured by compensation with a calibrated potentiometer in the grid circuit.[7] The author prefers the single tube outfit since it involves less "B" battery equipment, and with the improvement in sensitivity mentioned above it is possible to measure to ±0.5 millivolt (0.008 PH unit). This sensitivity is more than adequate for work with the glass electrode.

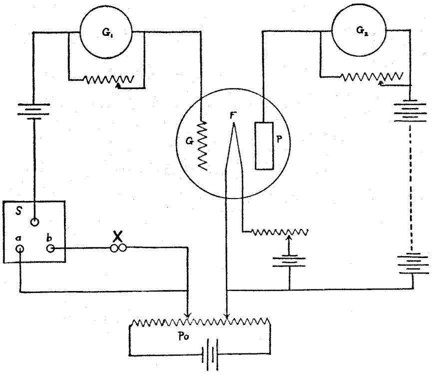

Fig. 1.—G, grid; F, filament; P, plate; G_1, high-sensitivity galvanometer; G_2, wall galvanometer; P_0, potentiometer; S, paraffin block, mercury cup switch; X, glass electrode—Ag, AgCl cell.

Filament temperature is probably the most important variable. Although Goode recommends the oxide-coated filament on account of its longer life, the author found that the thoriated filaments (222 and 199 types) gave approximately 1000 hours of satisfactory service, with only 0.1 ampere from the "A" battery as compared with 0.85 ampere used in Goode's 101-D and 102-D tubes. The lower current consumption is consistent with more constant filament temperature when the ordinary 60 or 100 ampere-hour storage battery is used.

[6] H. M. Partridge, This journal, 51, 1 (1929).

[7] Since this paper was submitted for publication, a description of a "balanced Wheatstone bridge circuit" which also employs the compensation principle, but makes possible the use of a high sensitivity galvanometer as null instrument, has been published by W. C. Stadie [J. *Biol. Chem.,* **83,** 477 (1929)].

When the vacuum tube and its socket are placed in a small tubulated desiccator provided with a drying agent and the leads brought out through a paraffin block in the tubulature, no difficulties are experienced from atmospheric conditions.

Comparison with the Lindemann Electrometer.—The glass cell and potentiometer were connected in series between the electrometer needle and ground, the potential readings being found from the potentiometer setting, with the electrometer functioning as a null instrument.

The electrometer readings were consistently lower than those recorded by the vacuum tube apparatus. The differences *(AE')* varied roughly between 2 and 100 millivolts, the larger differences being consistently associated with high resistances for the glass cells. Table I shows the magnitude of *AE'* for electrodes made from two different soft glasses, measured in a series of buffers. It is obvious that $\Delta E'$ is reasonably constant over the PH range from zero to ten, and about five times as large for the high-resistance electrodes as for those of low resistance.

Average $\Delta E'/R$	0.123	0.062	0.026	0.077	0.121
Av. R, megohms	134	256	1270	1450	40

In Table II are listed values of $\Delta E'$ for electrodes all blown from the same glass, but varying widely in resistance. The constancy of the ratio $\Delta E'/R$ as shown in the last line of this table leaves little room for doubt that the difference in apparent potential of the same glass electrode as measured by the two instruments is directly connected with the resistance of the cell as a whole. The value of this ratio, while constant for electrodes prepared from any one glass stock, varies considerably among the five varieties of glass used, as shown in Table III.[8]

The general conclusion to be drawn from the above data is that when a high-resistance cell is connected in series with the grid of a vacuum tube, the latter tends to acquire a free grid potential approximating the critical grid potential which is always more positive than the bias potential. On open circuit the difference is equal to that between the bias potential and critical grid potential, or 800 millivolts. One electrode which showed a resistance of more than 5000 megs. gave a difference of potential on the two instruments amounting to 112 millivolts. The constancy of this difference for any one electrode, however, is responsible for the fact that no error is introduced when P_H values are measured on the vacuum tube apparatus, provided that the glass electrode is checked against at least one standard buffer. Table IV shows the slope $\Delta E/\Delta P_H$ calculated from the data of Table I over the P_H range from 0.02 to 7.92. Within the limits of error indicated (average deviation of the mean of four values) the slope for Sample E agrees with the theoretical, while Sample W shows

[8] Stadie has also pointed out that the free grid potential, $\Delta E'$ (see next paragraph) varies not only with the external grid resistance, but also with those factors which influence plate current, notably filament temperature.

a low value, in agreement with Hughes' results on the same glass. Average slopes for the other three glasses are also included in the table.

Resistance Measurement.—A Leeds and Northrup Type R galvanometer (Cat. No. 2500-b 2000 megohm sensitivity) was roughly calibrated by a 10-megohm grid leak, showing a sensitivity of 2040 megohms. Using these calibration data and the same source of potential (1.5 volts), the resistances of the various glass cells were calculated directly from the observed deflections, making corrections for the resistance of the electrolyte from blank measurements. The lower resistances can be taken as reliable to ±1 megohm, but the higher values are proportionately uncertain and this fact may be responsible for the variations in $\Delta E'/R$ shown in Table III.[8]

Glass Stocks.—The symbols used in this paper indicate the following soft glasses: E, a special glass made in this Laboratory as described in the preceding paper (ref. 1, p. 938); CG, Corning soft glass G8, Corning Glass Co., Corning, N. Y.; W, Wood Bros. "white flint," Wood Bros. Glass Co.,[3] Barnsley, Yorkshire, England; K, Kimball machine drawn tubing, Kimball Glass Co., Vineland, N. J.; Gl, unidentified.[9]

Asymmetry Potential.—As pointed out in the preceding paper,[1] an electrode for PH measurement must be reversible and readily reproducible, or else it must be frequently checked against one or more standard buffers. The latter procedure is recommended by Kerridge for the glass electrode.[10] In the hope of finding conditions under which a glass electrode could be made reproducible, the effects of strenuous polarization and of annealing on the asymmetry potential have been studied. The latter has been described by Hughes.[3] Its value is given by the difference between the potentials of the following two cells.

$$\text{Cell 1.}\quad \begin{array}{c|c||c|c|c|c} \text{Hg} & \text{Satd.} & 1.0\ \text{N} & & 1.0\ N & \text{Hg} \\ \text{Hg}_2\text{Cl}_2 & \text{KCl} & \text{HCl} & \text{Glass} & \text{HCl} & \text{Hg}_2\text{Cl}_2 \end{array}$$

$$\text{Cell 2.}\quad \begin{array}{c|c||c|c} \text{Hg} & \text{Satd.} & 1.0\ \text{N} & \text{Hg} \\ \text{Hg}_2\text{Cl}_2 & \text{KCl} & \text{HCl} & \text{Hg}_2\text{Cl}_2 \end{array}$$

Repeated measurements of Cell 2, after one or two hours' standing to allow diffusion to set up a constant junction potential, show a value of the e.m.f. of 0.0315 volt.[11]

---

[9] This glass, taken from our laboratory soft glass stock, was traced to Glasco Products, Chicago, Ill., who described it as their "special cut glass." A sample which was kindly sent to the author by the above firm as a first approximation to the original shows the following properties: asymmetry potential, +0.0125; $\Delta E'/R$, 0.178; slope, 0.0510; average resistance high, about 300 to 400 megohms for electrode.; of the bulb type. Further efforts are being made to duplicate the original sample.

[10] Kerridge, *Biochem.* J., 19, 611 (1925).

[11] From the data of Scatchard [THIS JOURNAL, 47, 696 (1925)] on the cell, Hg, Hg_2Cl_2 | Satd. KCl || HCl, 1.0008 M | AgCl, Ag with flowing junction, and from the data of Gerke [*ibid.*, 44, 1684 (1922)] on the cell Ag, AgCl | Cl^- | Hg_2Cl_2, Hg, the value of the e.m.f. of Cell 2 is calculated to be 0.0295. The difference of 2 millivolts is probably due to the fact that Scatchard's measurements refer to a cell with flowing junction, whereas the cell measured by the author had a diffusion junction.

TABLE V

ASYMMETRY POTENTIALS

Electrode glass	Controls untreated	Treated Electrodes Polarized neg.	Polarized pos	Annealed	Prepd. by method of MacInnes and Dole
E	+0.0049 ± 0.0011	+0.0098	+0.0030	+0.0035	......
CG	− .0413 ± .0040	+ .0035	− .0410	− .1055	+0 0010
W	− .0144 ± .0033	......	......	......	......
G1	− .0103 ± .0024	......	......	− .0615	......
K	− .0640 ± .0062	......	......	− .1550	+ .0045

On account of the free grid potential effect which is observed in using the vacuum tube apparatus, all the above measurements (Table V) were made on the Lindemann electrometer.

Treatment of Electrodes

Polarization.—To test the reversibility of the phase boundary equilibrium at a glass surface, a number of the electrodes listed in Table V were connected across a source of 110 volts d. c. by means of platinum wires and left in the circuit for fifteen to twenty hours. The electrolyte used was 1 N hydrochloric acid, inside and out. As shown in the table, the electrodes whose inside connection was positive (anodic polarization) came back after about three days to a value which agrees with the average for the control electrodes within the limits of variability of the latter. Measurements repeated after nine days on the same electrodes showed no further variation beyond these limits. Those electrodes whose inside connection was negative (cathodic polarization) showed an appreciably higher potential after three days, the potential again being constant for the six days subsequent. Thus it appears that the passage of hydrogen ion into the outer surface of glass is the less reversible process.

Annealing.—On the assumption that the asymmetry potential may be due, at least partly, to a difference in total surface energy between the inner and outer surfaces of the glass bulb, it was thought that a mild annealing process, tending to reduce mechanical strains, might also affect the asymmetry potential. The electrodes in question were put in an oven immediately after they were blown (with one exception, *viz.*, CG83) and heated to 120° for fifteen to twenty hours. The surprising results are shown in Table V.

With one exception (E8) all the electrodes which were annealed showed potentials from 50 to 100 millivolts low as compared to the average of the controls. The potentials listed in the table for Glass CG were read nine days after annealing and are about thirty millivolts more positive than they were one day after annealing. Thus there is a slow continuous drift back to the normal value as represented by the control electrodes. From these experiments it appears that whatever effect annealing may have on reducing mechanical strain is overshadowed by some other effect, the nature of which is still obscure.

Method of Preparation.—Unless otherwise indicated all the electrodes were prepared as thin-walled bulbs blown from 10 to 14-mm. tubing. MacInnes and Dole have described an alternative method for preparing very thin glass membranes which seems to offer decided advantages.[12] Electrodes were prepared by this method from the two glass stocks which showed the highest asymmetry potentials among the untreated electrodes (CG and K). In each case the electrodes so prepared had asymmetry poten-

---

[12] MacInnes and Dole, Ind. *Eng. Chem. Analytical Edition*, **1,** 57 (1929).

tials no greater than the probable uncertainty of the controls. It is interesting to note that one of these, K4, has a resistance of the order of 5000 megohms, while CG813 measures only 5.7 megohms.

P_H Measurement by the Glass Electrode without the Use of Standard Buffers.—Since the asymmetry potential seems to be specific for any one stock of glass and independent of age or resistance, it is suggested that the above data might be employed in measuring an unknown P_H with an electrode prepared from one of the glasses listed.

For example, the P_H of a solution in which an electrode prepared from the Corning glass and filled with 1.0 N hydrochloric acid shows a potential against saturated calomel of the value "E" is given as

$$P_H = 0.085 - \frac{E - (-0.0413 + 0.0315)}{0.0581}$$

Summary

The vacuum tube potentiometer as described by Elder and Wright has been modified with a view to increasing the sensitivity and simplicity of the apparatus.

Comparative measurements on the vacuum tube potentiometer and Lindemann electrometer show that the apparent potentials of high resistance glass cells measured on the former instrument include a free grid potential which is constant over the P_H range from zero to ten, and directly proportional to the glass cell resistance.

Four commercial stock soft glasses and one laboratory preparation were studied in a series of buffers which had been standardized by the hydrogen electrode.

The asymmetry potentials of electrodes of the bulb type measured in 1 N hydrochloric acid are constant for any one glass stock and vary from 5 millivolts ior the laboratory preparation to 64 millivolts for one of the commercial stocks.

The effect of anodic polarization by 110-volt d. c. for fifteen to twenty hours disappeared completely after three days. Cathodic polarization by the same applied voltage for the same time produced a polarization potential of 40 to 50 millivolts after three days which persisted for six days more.

Annealing for fifteen to twenty hours at 120° caused a decrease in potential which was variable and very slow in disappearing.

The asymmetry potentials of electrodes prepared by the method of MacInnes and Dole were uniformly low, irrespective of the glass used.

Methods are suggested whereby the data presented in this paper could be used for P_H measurement by the glass electrode without employing standard buffers.

THE USE OF DICHLOROFLUORESCEIN AS AN ADSORPTION INDICATOR FOR THE ARGENTOMETRIC TITRATION OF CHLORIDES

BY I. M. KOLTHOFF, W. M. LAUER AND C. J. SUNDE

RECEIVED JUNE 10, 1929 PUBLISHED NOVEMBER 8, 1929

Introduction

K. Fajans and his collaborators[1] have recently described a new type of indicator for the argentometric titration of halides to which the name of adsorption indicator was given. The substances used as indicators are not sensitive to dissolved silver or halide ions, but change their color at the equivalence point where colored compounds are formed on the precipitate due to adsorption phenomena. Other investigators[2] have confirmed the results of Fajans and his collaborators and obtained accurate results with the new type of indicator. Fluorescein has been used as the indicator in the titration of chlorides but its application is limited. Good results are obtained only if the chloride concentration is greater than 0.005 N and if the solution has a neutral or weakly alkaline reaction. Other indicators which were applicable in weakly acid solutions have been found, but the color changes are less distinct than is the case with fluorescein.[3]

When chloride ions are titrated with silver nitrate, the silver chloride adsorbs silver ions at the equivalence point or better slightly beyond. The "silver body" then adsorbs fluorescein ions from the solution and dark red silver fluoresceinate is formed on the surface of the precipitate. Fluorescein possesses a weak acidic character; in weak acid solution the concentration of fluorescein ions is so small that the color change no longer takes place. The introduction of halogen atoms into the fluorescein molecule has two effects: the dissociation constant is increased and the adsorbability of the dye anions by the silver halide increases. It would therefore be expected that substances with a stronger acid character than fluorescein could be used as indicators in weak acid solutions. On the other hand, the stronger adsorbability might either interfere or be favorable. During the titration of chloride ions with silver nitrate the silver chloride formed at the beginning of the titration adsorbs chloride ions. In the presence of the anions of the indicator, the latter also have a tendency to be adsorbed and if their adsorption is larger than that of the chloride ions, the color change will take place during the early stages of the titra-

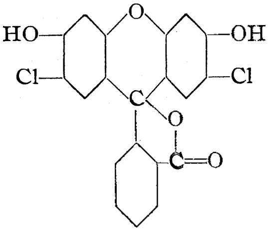
tion. Such is the case when eosin is used. Therefore this indicator cannot be used in the argentometric determination of chlorides, even though it gives highly accurate results when bromides, iodides and thiocyanates are titrated even in weak acid solutions. On the other hand, stronger adsorbability may exert a favorable influence in that it might make possible the titration of very dilute chloride solutions. In this case, the absorption of fluorescein ions is too small and no color change is observed.

The indicator in order to be better than fluorescein must have a larger dissociation constant and greater adsorbability than fluorescein. The adsorbability, however, must not be so great that it replaces the chloride ions from silver chloride. It was expected that dichlorofluorescein would serve the purpose, and as is shown in the following part of this paper it proved to be an excellent indicator for the titration of chlorides under different conditions. That dichlorofluorescein is a stronger acid than fluorescein can easily be shown by the fact that its color change interval from green-yellow (without fluorescence) to a strongly fluorescent yellow-green lies between P_H 3 to 5; so that the dissociation constant is of the order of 10^{-4}.

Dichlorofluorescein.—Dichlorofluorescein was prepared by condensing monochlororesorcinol with phthalic anhydride. It was purified by converting it into the diacetate and then saponifying the diacetate with alcoholic potassium hydroxide, in accordance with the procedure used by Orndorff and his collaborators.[4] Dichlorofluorescein prepared from dichlorophthalic anhydride and resorcinol has been known for some time, but dichlorofluorescein containing two chlorine atoms in the "resorcinol part" of the molecule has not been described hitherto. The most probable formula for the dichlorofluorescein here described is that indicated. All attempts to prepare a dichlorofluorescein by the direct chlorination of fluorescein failed.



Experimental

The Preparation of Dichlorofluorescein

Monochlororesorcinol was first prepared by the action of sulfuryl chloride on resorcinol: 100 g. of resorcinol was dissolved in 360 g. of absolute ether. This solution, placed in a 2-liter round-bottomed flask fitted with an efficient reflux condenser, was then treated with 120 g. of sulfuryl chloride (added dropwise). This operation was carried out in a well-ventilated hood. After the addition of the sulfuryl chloride the ether was distilled off on a steam-bath. After the low-boiling material had been removed completely, the residue was subjected to vacuum distillation. Since monochlororesorcinol has a lower boiling point than resorcinol, the unchanged resorcinol was separated by vacuum frac-

---

[4] Orndorff and Hemmer, THIS JOURNAL, 49, 1275 (1927), and various other studies by Orndorff and co-workers.

tional distillation. The monochlororesorcinol distilled at 131° under a pressure of 6–7 mm. It was analyzed for chlorine by the method of Carius.

Anal. Calcd.: Cl, 24.54. Found: Cl, 24.50, 24.72.

Dichlorofluorescein.—Ten grams of phthalic anhydride mixed intimately with 19.7 g. of monochlororesorcinol was heated to 160° in an iron crucible by means of an oil-bath. Five grams of anhydrous zinc chloride, finely ground, was then added with stirring during a period of about ten minutes. The temperature was then raised to 175–180° and maintained for about two and one-half hours. After cooling, the reaction product was ground and then boiled for fifteen to twenty minutes in dilute hydrochloric acid (10 cc. of concd. acid to 200 cc. of water) and filtered.

The precipitate was dissolved at room temperature in a saturated aqueous solution of sodium bicarbonate, filtered, heated to boiling and then acidified with hydrochloric acid (approx. 4 N). After cooling and filtering, the precipitate was refluxed with acetic anhydride for several hours (2 g. of crude dichlorofluorescein to 10–12 cc. of acetic anhydride). The diacetate crystallized out upon cooling. It was filtered off and the above process repeated four or five times. The diicetate (almost colorless) was then digested with a small amount of alcohol, cooled and filtered. After drying for several hours at 100° it was analyzed for chlorine.

Anal. (Carius). Calcd.: Cl, 14.64. Found: Cl, 14.49, 14.98.

The diacetate was then saponified by refluxing 2–3 g. with alcoholic potassium hydroxide (6–7 *g.* of base in 40 cc. of alcohol) for two hours. Water was then added, the solution transferred to a distilling flask and the alcohol removed by distillation. The solution was then filtered (if necessary), heated to boiling and acidified with hydrochloric acid. An ochre-colored product was obtained.

Application to Halide Titrations

Indicator Solution.—One-tenth gram of the indicator was dissolved in 60 cc. of alcohol, 2.5 cc. of 0.1 *N* sodium hydroxide was added and the volume of the solution was then made up to 100 cc. with distilled water. An aqueous alcoholic solution (60–70%) of approximately the same concentration of unneutralized indicator may also be used.

Procedure.—For every 10 cc. of chloride solution 2 drops of indicator are added and the titration is started with silver nitrate. The silver chloride remains in colloidal solution which, near the end-point, has a yellowish-orange appearance. About 0.5% before the equivalence point the silver chloride flocculates in voluminous flocks; the titration is then conducted carefully. At the end-point the silver chloride suddenly turns dark red.

Note 1.—Concentrated chloride solutions should be diluted to a salt-concentration of about 0.025 N. In this case the color change is extremely sharp. In six titrations 100 cc. of 0.025 *N* sodium chloride required 25.00 to 25.03 cc. of 0.1 *N* silver nitrate.

Note 2.—Even very dilute chloride solutions can be determined satisfactorily. In these cases it is recommended not to add more than 2 to 4 drops of indicator to 50 cc. of solution.

A 0.01 *N* chloride solution can be titrated with an accuracy of 0.5%. Near the end-point the liquid appears more brownish; the titration is finished when the color changes to distinct orange. One or two drops of 0.01 *N* silver nitrate in excess deepens the color to pink or reddish.

If the end-point is passed the excess of silver nitrate can be titrated back with a chloride solution of known constant. This reverse titration should be made immediately after the addition of silver nitrate. After longer standing the adsorbed indicator reacts slowly.

The following data show that the method gives satisfactory results.

TABLE I

TITRATION OF DILUTE CHLORIDE SOLUTIONS

Sodium chloride, cc.	10 of 0.01 *N*	50 of 0.002 *N*	100 of 0.001 *N*
0.01 *N* $AgNO_3$, cc.	10.02 to 10.05[a]	10.05 to 10.15	10.10 to 10.15[b]
0.01 *N* $AgNO_3$ calcd., cc.	10.00	10.00	10.00

[a] End-point of an orange color which turned pink after addition of 10.07 to 10.09 cc. of 0.01 *N* silver nitrate solution.

[b] With a larger excess of silver nitrate the color became more intense.

Especially in these very dilute solutions the back titration with chloride gives a sharp end-point.

Solutions containing as little as 15 to 20 mg. of chloride in a liter can be titrated with an accuracy of 1 to 2%. Therefore the method is superior to the ordinary Mohr procedure, as the latter has an appreciable titration error (at those dilutions). It might be expected that the indicator can be used advantageously in the titration of chloride in tap water. Special tests were run in order to see if calcium bicarbonate, magnesium bicarbonate and other salts had an interfering action. Though larger amounts of salts, especially those containing higher valence cations affect the color change a little, the results were still accurate to about 2% in 0.002 N chloride solution.

The tap water of Minneapolis contains only 2.6 mg. of chloride in a liter, which is too small to be titrated. Moreover, it seems that the tap water of this city contains some interfering substance. If a 0.001 N chloride solution prepared in tap water was titrated, no color change at all was observed. With artificial water of the same chemical composition as the tap water of Minneapolis and containing 1 milliequivalent of chloride in a liter a good end-point was observed. Even in the titration of 0.01 *N* chloride solution the tap water had a distinct retarding action on the formation of the color change. In all these cases it was observed that in the presence of tap water the silver chloride did not flocculate at all or very slowly with an excess of silver nitrate. Therefore it was thought that protecting colloids in the tap water might interfere with the observation of the end-point. The influence of different hydrophyllic colloids was tested. Some of them, especially gelatin even in small concentration, make the color change much less distinct and the end-point appears late. The presence of traces of colloidal material may explain the peculiar behavior of the Minneapolis tap water. On the other hand, it was shown that a dilute solution of silicon dioxide (from sodium silicate and acid) did not affect the color change of the indicator.

Another advantage of the new indicator over potassium chromate is that the titration can be carried out in weakly acid solution. If the acidity is regulated by some buffer in such a way that the PH is larger than about

4.0, the color change is still very distinct. In the titration of 0.025 N sodium chloride solution in the presence of an acetate buffer with a PH equal to or greater than about 4.4, the first color change to orange occurred after overstepping the end-point 0.1 to 0.2%. An advantageous application of the method is a direct chloride titration of those salts of heavy metals which are slightly hydrolyzed. Mohr's method gives unsatisfactory results in the above cases. In the titration of 0.025 N (to chloride) solutions of copper, zinc, manganese, nickel, aluminum, calcium, strontium, barium and magnesium chloride, the end-point was very sharp and appeared at the right place. In most cases the silver chloride flocculated 50 to 20% before the end-point was reached. Near the equivalence point the precipitate was slightly colored. At the equivalence point the sudden increase of the color to intense red could be observed with an accuracy of 0.05 cc. of 0.1 N silver nitrate. In the titration of very dilute solutions it is better to work at neutral reaction.

Bromides and iodides can be titrated in the same way as chlorides, even in very dilute solutions. In the application of fluorescein as an indicator, K. Fajans and H. Wolff[1] found that a mixture of iodide and chloride required an excess of silver nitrate, the error being +1 to 1.5%. Therefore, the use of the dichlorofluorescein for this purpose was tested. During the titration the same phenomena are observed that Fajans and Wolff described; about 2% before the end-point the silver iodide and chloride flocculate, the precipitate has a yellowish-brown color which turns brown-orange at the equivalence point and changes to orange-pink with an excess of about 0.5% silver nitrate. Though the color change is not as sharp as in the titration of both halides separately, the end-point still can be detected with an accuracy of 0.5%, if the mixture is so far diluted that its concentration is no more than 0.01 N to halide. The change in color in this case is much sharper than with fluorescein as an indicator.

Summary

Dichlorofluorescein is a very suitable indicator for the argentometric titration of chlorides in very dilute as well as in weakly acid solutions.

THE PERMEABILITY OF HOT METALS TO HYDROGEN[1]

BY B. CLIFFORD HENDRICKS AND ROBERT R. RALSTON

RECEIVED JUNE 10, 1929 PUBLISHED NOVEMBER 8, 1929

A paper[2] which appeared in December, 1923, reported a preliminary study of the diffusion of hydrogen through hot metals. In July of that year Lombard[3] published the results of a study of the diffusion of hydrogen through nickel and the following year Johnson and Larose[4] presented their work upon the diffusion of oxygen through silver. A second paper from Johnson and Larose[5] gives both improved apparatus and a changed interpretation. Lombard has published two papers[6] upon diffusion since his first. The first of these makes a comprehensive analytical study of the available data upon hydrogen diffusion through nickel. The second deals with experiments with other gases including argon, nitrogen and helium, and with other metals such as copper, iron and platinum. In his last paper he also attempts to formulate a generalization for all such diffusion.

It is proposed in this paper to give a restudy of copper and zinc as diffusion diaphragms for hydrogen and to measure diffusions through nickel under varying temperatures and pressures of the gas. The results obtained, as well as those of other students of diffusion, are to be studied for the relation of diffusion values to the different conditioning factors.

This work, while using essentially the same apparatus as that already described,[2] has introduced certain modifications of that practice. By introducing Swartz tubes filled with phosphorus pentoxide, in addition to soda-lime tubes used in the former research, "blank values" have been reduced from 1.5 mg. per hour to 0.4 mg. per hour or less. By permitting the outlet[2] from the hydrogen chamber to terminate in a pipet dipping beneath the surface of a carefully graduated cylinder of mercury, the hydrogen pressure has been regulated and maintained at the desired value in spite of fluctuations of the atmospheric pressure and changes in other variable influences in the train.

Varying pressures of the diffusing gas, hydrogen, have been secured by mixing hydrogen and nitrogen in varying proportions. The gasometer used was calibrated and read within an accuracy of 0.5%. Lom-

bard[7] found by experiments with similar mixtures that the diffusion rate of the hydrogen was independent of the presence of the nitrogen in the mixtures. He[8] also found that the diffusion rate of hydrogen through nickel varied inversely with the thickness of the metal. Thus Fick's law correctly describes the diffusion of hydrogen through nickel. By the aid of Fick's law the specific diffusion of hydrogen through hot metals is here expressed as the number of milligrams of hydrogen diffusing per square meter of surface per millimeter thickness of metal per hour. In arriving at this specific diffusion for different temperatures, corrections were made, in every instance, for the increase of both the diaphragm area and thickness due to thermal expansion. This increase varied both with the kind of metal used and with the temperature change.

The temperatures were measured by a chromel–alumel thermocouple calibrated for the melting points of Mallinckrodt C. P. tin and zinc and General Chemical Company aluminum. The millivoltmeter for the thermocouple was read to 0.1 millivolt, which corresponded to less than 3°. The cold junction of the couple was kept in an ice pack in a Dewar container.

The gases used were secured and purified as described in the previous paper except for the before-mentioned drying.

The diffused hydrogen, as in the former work, was oxidized to water by hot copper oxide and collected by absorption in phosphorus pentoxide-filled U-tubes. These were always weighed counterbalanced by a U-tube of equal volume kept in the balance case. The tube to be weighed was always cooled and filled with dry air before weighing.

Zinc.—The sample of zinc[9] used in this study contained not more than 0.1% of lead, 0.005% of cadmium and 0.008% of iron, Its purity was the same as that of the sample used in the work[2] previously reported. The disk used had a thickness of 0.515 mm., while 1.643 mm. was the thickness of the sample tested in the earlier work. Its diffusion area at the temperatures of the experimental work was 1.7% greater than at room temperature. Table I exhibits the summarized results of over twenty hours of work with this metal. The temperature deviation from the

[9] Generously supplied by the New Jersey Zinc Company.

mean value was in all cases, in this and in the following tables, less than the precision of the thermocouple.

These values leave no doubt that zinc is hydrogen permeable and that it becomes increasingly so with higher temperatures. A study of the plate before and after the diffusion experiments showed a decrease in crystal size as a result of its exposure to hydrogen at these temperatures near its melting point.

Copper.—Sieverts,[10] after a series of tests, concluded that pure copper was permeable to hydrogen above 640° with no effect upon the copper. However, he found that commercial copper tubes changed, "became brittle and fissured," in an atmosphere of hydrogen. A similar result was reported by Deming and Hendricks in a previous paper.[2] Lombard[11] states that a trial with copper resulted in "a rapid and progressive increase in the diffusion value even when the temperature and pressure were held constant."

The copper used in the present work had been carefully deoxidized by phosphorus.[12] It was 99.900% pure before this phosphorus reduction. Even though pure and oxygen-free, some difficulty was experienced in getting the limited data presented in Table II.

TABLE II

RESULTS WITH COPPER

Thickness, 0.385 mm.; area, 46.56 sq. cm. at 20°; average "blank" for two runs, 0.2 mg. per hour; hydrogen pressure, 1.000 ± 0.007 atm.

Mean temperature, °C.	497	568	632
Water collected, mg. per hour	2.2 ± 0.3	3.35 ± 0.5	6.5 ± 0.7
Sp. diff. of hydrogen through copper	17.3 ± 1.8	28.9 ± 0.4	57.7 ± 6.5

Microscopic examination of this sample, after the diffusion tests, showed a decided increase in crystal size. A similar change was reported in the previous paper[2] though the intercrystalline cracks were there attributed to the reducing action of hydrogen upon inclusions of cuprous oxide. The previous treatment of the copper samples, here used, would make that explanation untenable. A more plausible hypothesis might well be that increased crystal size gives rise to larger crystalline planes of cleavage. These planes, as they more and more nearly extend through the thin plate, presently become mechanical openings or fissures, rendering the copper more permeable as well as more brittle.

The above results, it should be noted, do not agree with Sievert's either in regard to the lowest temperature at which diffusion through copper takes place or in the effect of diffusion upon the pure copper metal.

[12] These samples were generously prepared and furnished by the American Brass Company.

Nickel.—The nickel used[13] was electrolytically refined. After **100** or more hours of exposure to hydrogen gas at high temperatures, this metal showed no change either in crystal size or in diffusion rate. Such consistency was very advantageous to work which sought both the effect of temperature variations upon diffusion rate and the influence of pressure changes upon that phenomenon. Results for three different pressures of the diffusing hydrogen through nickel are presented in Table III A, B and C.

719	10.4 ± 1.0	94.2 ± 4.4

Diffusion and Pressure.—In order to study the relation of diffusion rate to pressure at constant temperatures, the data presented in Table III A, B and C above were put in graphic form as in Fig. 2 in the first paper.[2] From these curves the values tabulated in the first horizontal line, for each temperature, in Table IV were obtained.

Richardson, Nicol and Parnell,[14] Lombard[15] and Johnson and Larose[16] have all intrepreted their experimental data for pressure variation by a relationship expressed by $D = K\sqrt{P}$, in which D is the specific diffusion, P is the partial pressure of the diffusing gas and K is a constant varying with the temperature. For this paper this constant was determined for each of the four temperatures by the graphic method. The values found were: 76.2 for 550°, 116.0 for 600°, **152.2** for 650° and **190.0** for 700°. The second horizontal line under each temperature of Table IV records specific diffusion values calculated by use of this constant in

	2		190.0	136.2	73.5
	3	(703°)	202.4±16.9		

the equation above. The third horizontal line in the table exhibits specific diffusion values, with their deviations from the mean, obtained directly by experiment for the temperatures shown in parentheses. The calculated values, it should be noted, show no greater deviation from the observed values than do the observed from their own mean.

Diffusion and Temperature.—Three different expressions have been put forth for the correct relation of diffusion rate to temperature: $D = KT^b$; $D = K \times 10^{at}$ and $D = KT^{1/2}e^{-q/4T}$.

The first was proposed by Ryder[17] and was used by Johnson and Larose[4] in 1924 in connection with their study of the diffusion of oxygen through silver. The expression may be put in the form $\log D = \log K + b \log T$, which lends itself to graphic representation. The authors find that when their data for the diffusion of hydrogen through nickel are so plotted, the result is not a first-order curve. Johnson and Larose in their second paper,[5] for the same reason, decided against this expression for the temperature–diffusion relationship. In other words, this formulation is inadequate either for the diffusion of oxygen through silver or the diffusion of hydrogen through nickel.

The second equation, $D = K \times 10^{at}$, is that which Lombard[18] claims to represent acceptably the relation of diffusion to temperature for his study of hydrogen and nickel as well as for other gases through other metals. His evidence for his conclusion is that when log D is plotted against T, the curve resulting is of the first order. A critical examination of Lombard's curves does not lead the authors to his conclusions. Neither does such graphic treatment of their own data lead to his generalization. In fact they have found that whether Lombard's work with hydrogen and nickel, their own work with hydrogen and nickel, Johnson and

[17] Ryder, *Elect. J.*, 17, 161 (1920).

[18] Lombard, *J. chim. phys.*, 25, 597 (1928).

Larose's work with oxygen and silver or Richardson, Nicol and Parnell's work with hydrogen and platinum, is given this graphic form, the curve is invariably concave toward the temperature axis and convex toward the diffusion axis.

Johnson and Larose in their second paper[5] show that $D = KT^{1/2}e^{-q/4T}$ gives a much more satisfactory generalization for the diffusion of oxygen through silver than did the Ryder formulation, $D = KT^{b}$, which they first used. The expression is a derivation from the more general form: $D = K/dP^{1/2}T^{1/2}e^{-q/4T}$, when P and d are assumed as constants. This general equation was set up from thermodynamic considerations[19] and connects specific diffusion, D, with absolute temperature, T, diaphragm thickness, d, and pressure, P. In it "e" is the base for the natural system of logarithms, q is a constant representing the heat of dissociation of the gas within the metal and K is a general constant. A simple method of applying this relationship to a set of data is to plot the reciprocal of the temperature, $1/T$, against log D − $^1/_2$ log T. The authors show the graph resulting for data from their Table III A in Curve H and in Fig. 1. For comparison purposes they have also included curves for hydrogen through platinum, R, oxygen through silver, J, and hydrogen through

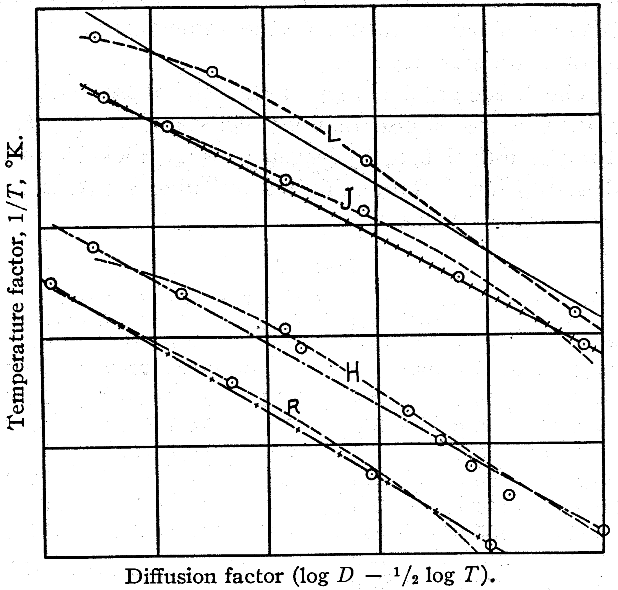

Fig. 1.—Relation of diffusion rate to temperature for: R, Richardson's hydrogen through platinum; J, Johnson's oxygen through silver; H, authors' hydrogen through nickel; L, Lombard's hydrogen through nickel.

---

[19] Richardson, *Phil. Mag.*, [6] 7, 266 (1904).

nickel, L, in the same figure.[20] The essential point sought in the figure is to show that, within the limits of experimental error, Richardson's equation represents the temperature–diffusion relationship for the diffusion of hydrogen through platinum and nickel and of oxygen through silver.

The authors cannot refrain, however, from pointing out that the broken-line curves, as drawn in Fig. 1, are not an undue distortion of the points as located. The graph, L, of Lombard's data especially makes evident the concavity of these curves toward the origin. For work so far reported, experimental values probably deviate from their means by amounts sufficient to "iron out" such concavity. Yet why do all four of these curves consistently show curvature in the same direction? Probability can hardly account for such regularity.

In order to check the applicability of the Richardson equation to data under study in a more precise manner, constants q and K have been determined for the diffusion of hydrogen through nickel and the specific diffusions calculated for all data exhibited in Table III A, B and C. The results are presented in Table V.

TABLE V

COMPARISON OF CALCULATED RATES OF DIFFUSION WITH THOSE OBSERVED

Temp., °C.	Diffusion Observed	Diffusion Calcd.	Dev. of calcd. from obs.
Hydrogen pressure, 760 mm.			
478	34.2 ± 7.0	38.1	+3.9
503	50.6 ± 0.7	48.6	−2.0
553	82.3 ± 9.0	75.3	−7.0
570	88.6 ± 16.3	86.3	−2.3
640	144.7 ± 8.5	144.3	−0.4
678	176.7 ± 4.5	185.0	+8.3
703	202.4 ± 16.9	215.6	+13.2
747	238.6 ± 14.4	277.5	+38.9
798	369.2 ± 8.8	362.6	−6.6
Hydrogen pressure, 390.6 mm.			
471	28.7 ± 6.5	25.6	−3.1
532	54.8 ± 3.5	45.2	−9.6
597	81.7 ± 13.5	76.2	−5.5
619	109.4 ± 2.0	89.4	−20.0
665	122.4 ± 10.0	122.1	−0.3
677	133.4 ± 21.3	131.8	+2.4
Hydrogen pressure, 115 mm.			
498	23.1 ± 8.0	18.0	−5.1
577	39.7 ± 2.4	35.3	−4.4
658	65.4 ± 3.5	63.0	−2.4
719	94.2 ± 4.4	91.8	−2.4

Table V tabulates, in the third column, not only the average observed specific diffusion but the deviation of other observed values, for that temperature, from the average. A comparison of the values in the fifth column with these deviations is the essential purpose of the table. As a summary of this comparison, the average deviation of specific diffusion values from their means in Table III A, B and C is 9.8%, while the average deviation of the calculated values from the observed as exhibited in Table V is 7.9%. The calculated results check the observed to within the experimental error.

---

[20] The reader should bear in mind that Curves L, R and J are not drawn to the same scale as H.

The *Heat* of Hydrogen Dissociation.—The constant, q, represents the heat of dissociation of the gas within the metal. For hydrogen in nickel this quantity (average for ten different determinations) is 20.8 ± 2.2 kilogram calories. Using data from Lombard's first paper,[3] an average of 29.7 ± 14.1 kilogram calories was found. These values are surprisingly low.

Richardson, Nicol and Parnell's value for the heat of dissociation of hydrogen in platinum was found to be **36.5** kilogram calories. The energy of molecular hydrogen's dissociation is commonly given as 100.0 kilogram calories. Richardson's lower value can be reconciled with this by assuming that platinum's energy of hydrogen-adsorption has reduced hydrogen's energy of dissociation within the metal. Johnson and Larose also found a lower value, 43.2 kilogram calories, for oxygen's dissociation within silver than the usual 160.0 kilogram calories, the heat of dissociation for molecular oxygen. This can be accounted for as was hydrogen's value in platinum.

Extending the same reasoning to the heat of dissociation of hydrogen in nickel requires that nickel's energy of adsorption for hydrogen be greater than that of platinum. The fact that nickel's coefficient of thermal expansion is one and one-half times that of platinum might aid in an explanation if greater expansion could be interpreted to mean greater internal surface for adsorption and so greater activation. This would mean that this heat of dissociation should become less at higher temperatures. **A** preliminary examination of the data for the diffusion of hydrogen through nickel indicates that this last statement is roughly true. A more thorough study of this might prove profitable.

Conclusions

1. Zinc has been shown to be permeable to hydrogen at temperatures between 305° and its melting point.
2. Pure copper, or at least oxygen-free copper, has been shown to be permeable to hydrogen from 500° and above. The hypothesis is advanced that its tendency to become brittle and fissured is due to the development of larger planes of cleavage as the crystal size increases rather than to the reducing action of the diffusing gas.
3. Within the limits of experimental error the diffusion of gases through metals is best related to temperature and pressure by $D = KP^{1/2}T^{1/2}e^{-q/4T}$.
4. It is suggested that more precise technique in this field may lead to a modification of the preceding generalization.
5. The heat of dissociation of hydrogen gas within nickel has been determined as 20.8 ± 2.2 kilogram calories. The "constancy" of this constant has been questioned.

SOME REACTIONS OF ATOMIC HYDROGEN

BY H. C. UREY AND G. I. LAVIN[1]

RECEIVED JUNE 22, 1929 PUBLISHED NOVEMBER 8, 1929

The preparation and properties of atomic hydrogen have been described by a number of investigators.[2] Langmuir[3] has shown that tungsten filaments at high temperatures cause the dissociation of molecular hydrogen and has used this method to study the reactions of the atomic species with various solids. Wood[4] while working on the Balmer series of the hydrogen spectrum, obtained by passing a high tension electric discharge through moist hydrogen at low pressures, showed that it was possible to remove hydrogen atoms from the discharge tube. He also pointed out that if atomic hydrogen is to be obtained from the tube the hydrogen must be moist; he assumed that the moisture poisoned the walls, thus preventing the catalytic recombination of the hydrogen atoms. Cario and Franck[5] found that hydrogen atoms are formed when a mixture of molecular hydrogen and mercury vapor is illuminated with light of wave length 2536.7 Å., the resonance line of mercury, and Taylor[6] gives an account of an improved method of using the Cario and Franck method. Bonhoeffer[7] using Wood's method has shown that atomic hydrogen reduces a wide variety of metallic oxides and salts and Boehm and Bonhoeffer[8] found that atomic hydrogen reacts with several gases. The reaction of atomic hydrogen with organic compounds has been investigated by Marshall,[9] who was unable to find any reaction between methane and atomic hydrogen. Taylor and Marshall[10] found that atomic hydrogen would react with ethylene to give ethane, and Bates and Taylor[11] found that ethylene probably reacts with atomic hydrogen to give ethyl, C_2H_5, and that there was a marked tendency for higher hydrocarbons to be formed. Recently Wartenberg and Schultze[12] have studied the action of atomic

hydrogen on methane, ethane, ethylene and acetylene, and have found no reaction with methane, a catalytic recombination of the atomic hydrogen with ethane and acetylene, and a reaction of atomic hydrogen with ethylene to give ethane. Taylor and his collaborators,[13] have found that other products than ethane are produced if a large excess of hydrogen is not present. The purpose of this investigation was to try the effect of atomic hydrogen on several organic compounds in the solid and gaseous states. Since Wood's method gives atomic hydrogen in the largest amounts, this method was used in its preparation. Also, since water vapor seems to play an important role in the production or the preservation of atomic hydrogen, we have made some preliminary experiments on the active gases coming from a Wood's discharge tube when only water vapor is passed through it. The results of these experiments will be described in the following paper.

Experimental

Figure 1 represents diagrammatically the apparatus used in the work with atomic hydrogen on solid organic compounds. Hydrogen from a tank was led through a cotton wool filter, B, through a water bubbler, C and then to a system of capillaries. D. The T-tube, A, maintained a constant pressure on the incoming gases. The stopcock to which the capillaries were attached was so constructed that connection could be made to *any* one of the four capillaries or so that the system could be cut off entirely from the supply of hydrogen. The rate of flow of hydrogen through the capillaries with one atmosphere of pressure on one side and a few mm. on the other was 12, 22, 40 and 60 cc. per minute of hydrogen measured at atmospheric pressure. From the capillaries the hydrogen passed to the discharge tube, E, which was about a meter in length with the inlet and outlet about 25 cm. apart, and cooled by a water-bath through which water circulated continually. A trap H protected the pumps from water vapor and also served to condense any volatile reaction products. The large stopcock I was used to cut off the apparatus from the pumps. The pumping system consisted of a three-stage Gaede all steel mercury vapor pymp, backed up by a large capacity oil pump; with this arrangement it was possible to pump 60 cc. of hydrogen per minute through the apparatus and still maintain a pressure of about a half mm. of mercury. The pressure in the discharge tube was measured by a McLeod gage connected at a point between the capillaries and the discharge tube. The substances to be exposed to the active hydrogen were placed in the apparatus through the ground glass joint, F. A 2 KVA transformer was

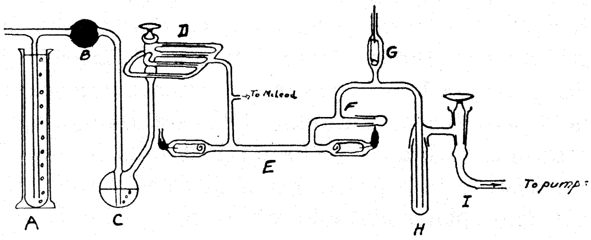

Fig. 1.

---

[13] Taylor and co-workers, *Z. physik. Chem.*, **2,449** (1929).

used to excite the discharge. The auxiliary electrode, G, described by Bonhoeffer' was used to clean out the exit tube.

It is well known that active spots may develop on the walls, causing the recombination of the atomic hydrogen, and it was, therefore, necessary to prove the presence of atomic hydrogen at the point where the solid substances were to be placed. This was done before every run by placing a small piece of platinum wire beyond this point, and being certain that the platinum was heated to a red heat before introducing the substances to be investigated. The wire was removed before the substances were introduced.

Reactions with Solid Organic Compounds.—Azoxybenzene was first exposed to the action of the atomic hydrogen; a reduction of the azoxy group to the azo group would be accompanied by a color change from yellow to red, and so would be easy to detect. Azoxybenzene was placed in a porcelain boat about 20 cm. from the discharge tube. When the discharge was turned on there was an immediate change from the yellow azoxy- to the red azobenzene. This change was accompanied by a bubbling and melting of the red mass, and aniline was detected in the trap. Azobenzene was next used and became white, indicating the reduction to hydrazobenzene. Thus we probably have the reduction Azoxybenzene ⟶ Azobenzene ⟶ Hydrazobenzene ⟶ Aniline.

Copaux, Perepot and Hocart[14] have shown that atomic hydrogen will decolorize such dyes as Indigo, Orange II and Safarine T and that the color is partially restored by exposure to atmospheric oxygen. Orange II, Pontamine Diazo Black, Auramine O[15] and Indigo were exposed to the action of atomic hydrogen. The method used in exposing the dyes was to make a paste with a few drops of distilled water; this paste was placed on small glass plates and allowed to dry. The dye-covered plates were then placed in the apparatus (about 20 cm. from the discharge tube) through the ground-glass joint, F (Fig. 1). In every case the dyes immediately turned white. When the white substances were taken from the apparatus and allowed to stand in the air some of the color reappeared, showing that the dyes had been reduced to a stage from which reoxidation to the colored compound could take place and that they had not been entirely destroyed by the reaction with atomic hydrogen. Indigo was immediately reduced to indigo white by the atomic hydrogen. That the white substance formed was indigo white was shown by the fact that it oxidized to the colored compound when dissolved with dilute sodium hydroxide.

Although benzoic acid and acetamide both catalyzed the recombination of atomic hydrogen, we secured no evidence for any reaction between these two substances and the atomic hydrogen. The work on these solid compounds seems to indicate that the atomic hydrogen is only a comparatively mild reducing agent, and that it attacks the more easily reduced groups first.

[15] These were kindly furnished us by the E. I. du Pont de Nemours Co.

Reaction with Gaseous Organic Compounds.—In order to study gaseous organic compounds the apparatus was modified by placing a 750-cc. bulb between the discharge tube and the ground joint, the reactions being allowed to take place in this bulb. This bulb gave the gases a longer time in which to react and it may also prolong the life of the atomic hydrogen, since Kaplan[16] has shown that the life of atomic hydrogen is decidedly increased when the volume-to-surface ratio of the containing vessel is increased. To this bulb was sealed an inlet for the gases consisting of a capillary stopcock and small flask. The flask was attached to the stopcock by a ground-glass joint so that it could be removed in order to introduce volatile compounds. The rate at which vapors were introduced into the apparatus could be regulated by the size of the capillary and the temperature of the flask. Formic acid was found to catalyze the recombination of the hydrogen atoms. This was indicated by the increased temperature of the tube where the formic acid entered the apparatus. Color tests were secured for formaldehyde; the formic acid used did not give these tests. The amount of formic acid caught by the trap was determined by titrating with sodium hydroxide and it was found that very nearly all of the formic acid which entered the apparatus was recovered. It seems probable that the formic acid may have been decomposed by the hot glass walls to water and carbon monoxide and that the formaldehyde detected was the result of a reaction between carbon monoxide and atomic hydrogen. Bonhoeffer showed that in the case of oleic acid the COOH group is not attacked.

Freshly distilled acetaldehyde was polymerized to paraldehyde, but no further reaction could be detected except that the condensed material had a slightly yellow color, indicating that some decomposition or resinification had taken place. During these tests the bulb developed some active spots which became incandescent when the atomic hydrogen was led in. These glowing points were extinguished by the admission of acetaldehyde and they reappeared when the supply of acetaldehyde was cut off. The acetaldehyde seemed to "poison" these active spots.

It was noticed that when the acetaldehyde was first admitted to the bulb there was a flash of light, and if the supply was suddenly cut off, there was a similar flash. It was found that if just the correct amount of acetaldehyde was allowed to enter the bulb, a continuous glow could be maintained. The light was blue-green in color and when photographed with a small Hilger quartz spectrograph was found to consist of three bands in the region of 4000, 4250 and 4260 Å.; Bonhoeffer and Harteck[17] have found that saturated and unsaturated hydrocarbons react with atomic hydrogen with the emission of bands which lie in this region. Even with

---

[16] Kaplan, *Phys. Rev.*, **30**, 639 (1927).

[17] Bonhoeffer and Harteck, *Z. physik Chem.*, **139**, 64 (1928).

a three-hour exposure the bands were too weak to permit exact measurements and all attempts to increase the intensity failed. It was found that the solid acetaldehyde condensed in the trap also glowed under the influence of the active gas, the color being about the same as that given by acetaldehyde in the vapor state.

Summary

The action of atomic hydrogen prepared by Wood's method on some solid and gaseous organic compounds has been studied. It has been found that atomic hydrogen for the most part acts as a rather mild reducing agent, reducing azoxybenzene at least partially to azobenzene and azobenzene partially to hydrazobenzene with aniline as the final product. Certain solid dyes are reduced to colorless compounds which are partially reoxidized to the colored form on exposure to air. Benzoic acid and acetamide catalyze the recombination but are not noticeably reduced.

Atomic hydrogen recombines in the presence of formic acid. A small amount of formaldehyde is produced, probably due to the decomposition of the acid by heat into water and carbon monoxide and the subsequent formation of the aldehyde from carbon monoxide and atomic hydrogen. Acetaldehyde is polymerized to paraldehyde. A faint blue chemiluminescence was observed.

REACTIONS OF DISSOCIATED WATER VAPOR

BY H. C. UREY AND G. I. LAVIN

RECEIVED JUNE 22, 1929 PUBLISHED NOVEMBBR 8, 1929

It is well known that if an electric charge is passed through water vapor at low pressures the Balmer series of hydrogen and the so-called water bands appear with great intensity. Thus it appears that water is dissociated into H and OH in the electric discharge. Also the fact that the OH bands are emitted[1] by the gases leaving Wood's tube as used in the production of atomic hydrogen shows that the OH molecule can be pumped to considerable distances from the discharge tube. It was thought worth while to see whether atomic hydrogen and OH molecules formed by the dissociation of water vapor in an electric discharge could be detected outside the tube.

Experimental

The only change in the atomic hydrogen apparatus described in the preceding paper was the substitution of a flask of water for the tank

---

[1] *See* **Bonhoeffer,** *Z. physik. Chem.,* **116,391 (1925).**

of hydrogen and the bubbler C. The oil pump was of the type which permitted the collection of gases coming from the apparatus. An analysis showed that more than two-thirds of the gases leaving the apparatus was hydrogen. Two typical analyses are given below. In the last column is given the excess of hydrogen over that necessary to react with the oxygen to form water.

Total quantity of gas, cc.	O_2, cc.	H_2, cc.	Excess H_2, %
21.50	5.90	15.10	21.85
21.80	6.20	15.60	20.51

Hydrogen peroxide was detected in the water condensed in the trap, which seems to account for the excess hydrogen in the gaseous products. These results are in accord with some old observations of Thompson, who showed that if water vapor is decomposed by an electric spark, an excess of hydrogen over that necessary to react with the oxygen to form water is obtained, and also with those of Kernbaum,[2] who passed a brush discharge through water vapor and found that hydrogen peroxide was formed.

The gases leaving the discharge tube were found to be very active. A strip of platinum exposed to these gases glowed with greater intensity than when exposed to atomic hydrogen produced in the same tube. It was heated almost white hot. From the considerations mentioned in the introduction it seems probable that atomic hydrogen and OH molecules are both present in these gases. The following experiments were carried out to prove the existence of these two constituents.

Evidence for the Presence of Atomic Hydrogen.—Langmuir,[3] Cario and Franck,[4] and Bonhoeffer[5] have shown that atomic hydrogen will reduce copper oxide at room temperatures. A piece of copper gauze was oxidized in the Bunsen flame, part of the gauze being left unoxidized in order to determine whether the active gas was oxidizing or reducing. The gauze was placed in the bottom of a trap, H, as shown in Fig. 1 of the preceding paper, which was about 25 cm. from the discharge tube. The copper oxide was reduced to bright metallic copper and the bottom of the trap became quite warm during the reaction. Evidently the gases are reducing rather than oxidizing in character. A crystal of copper sulfate placed in the apparatus was immediately reduced to the metal. At the beginning of the reaction the crystal appeared to be black, indicating that the salt was probably decomposed into copper oxide and some other product before final reduction took place. The copper was smooth,

giving the impression of having been fused. The water condensed in another trap which was surrounded by liquid air gave a test for sulfate. Indigo was exposed to these active gases and as in the case when it is exposed to atomic hydrogen it was reduced to indigo white. Small portions of the solid indigo were torn off and became incandescent. No such violent action was observed in the experiments with atomic hydrogen described in the preceding paper.

The chemiluminescence observed when acetaldehyde was exposed to the action of atomic hydrogen[6] was also observed when acetaldehyde was exposed to these gases. Moreover, mercury exposed to the action of these gases emitted a visible violet light which consisted of the HgH bands and also the 2536 Å. line of mercury. The mercury was placed in the bottom of the trap used to study the reduction of copper oxide; a beaker containing water at about 50° was placed around the trap. As the mercury warmed up the luminous region separated into two parts, one of which traveled slowly up the walls of the trap and the color changed from violet to green. The separation is due to the fact that distillation took place and the mercury condensed in the upper, cooler portions of the trap. As Bonhoeffer has shown,[5] mercury is excited by atomic hydrogen only in the neighborhood of liquid mercury. Thus the separation of the luminous region into two parts is explained. The interesting point in this observation is that atomic hydrogen must have passed through a region containing mercury vapor without exciting the mercury vapor to emit light and without being destroyed by recombination to molecular hydrogen. A quartz window was attached to the side of the trap and a photograph taken with the small Hilger quartz spectrograph. The mercury hydride bands were obtained along with the 2536 Å. line of mercury. All these observations have been made previously when atomic hydrogen alone is present in the exit gases.

Experiments Indicating the Presence of the OH Molecule.—The gas coming from a water discharge tube seems to be even more active than atomic hydrogen. Bonhoeffer was unable to effect the reduction of nickel chloride and iron chloride with atomic hydrogen, but these two salts are reduced to the metal by the gases leaving the water discharge tube.

Olson and Meyers[7] have found that ethylene reacts with atomic hydrogen to form methane, ethane, propane and butane. This suggests that OH molecules might react with ethylene to give an addition product containing oxygen, as, for example, ethyl alcohol or glycocoll. The ethylene was allowed to mix with the active gases coming from the discharge tube and any products resulting were collected in a trap cooled

---

[6] Urey and Lavin, THIS JOURNAL, 51, 3286 (1929).

[7] Olson and Meyers, *ibid.*, 49, 3131 (1927).

with liquid air. Blank tests were first run, without passing the discharge through the streaming water vapor. The liquids caught in the trap did not give the iodoform test for alcohol nor did they reduce Fehling's solution. The discharge was then turned on and a similar experiment made.[8] No back diffusion of the ethylene gas took place, for otherwise there would have been a change in the spectrum of the discharge tube, which was not observed. Moreover, simple calculations showed that with the approximately known velocity of the water vapor leaving the discharge tube such back diffusion could not have taken place. The liquid which condensed in the trap had the odor of acetaldehyde, gave the iodoform test and reduced Fehling's solution. This seemed to indicate the presence of acetaldehyde. With the amounts which we were able to secure it was impossible definitely to identify any ethyl alcohol or glycocoll in the reaction products. The presence of the acetaldehyde indicates, however, that some active molecule containing oxygen must he present in the outlet gases.

An attempt was made to prove the presence of OH by taking the absorption spectrum of the gas coming from the discharge tube. No absorption coming from the known band at 3064 Å. was observed. This may not prove the absence of the OH molecule but it does seem to indicate that it must be present in rather small amounts.

Several unsaturated oils such as cottonseed oil, linseed oil, etc., were exposed to the action of the dissociated water vapor. In every case a white solid insoluble in the common organic solvents was obtained. A report of this work will appear in a forthcoming publication.

The authors are indebted to Dr. E. E. Reid for valuable suggestions and criticisms.

Summary

1. Water vapor, dissociated in a discharge tube, gives reactions which are characteristic of atomic hydrogen. From these results we conclude that atomic hydrogen is present in the active gas.

2. Water vapor seems to be more active than atomic hydrogen, in that it will reduce metallic salts which are not reduced with atomic hydrogen.

3. Active gas is prepared from water vapor with greater ease than from hydrogen.

4. It has been indicated that there is another active constituent, probably the OH molecule, present in the active gas.

ABSOLUTE MEASUREMENTS OF THE SURFACE CONDUCTIVITY NEAR THE BOUNDARY OF OPTICALLY POLISHED GLASS AND SOLUTIONS OF POTASSIUM CHLORIDE

BY JAMES W. McBAIN, CHARLES R. PEAKER AND A. MILLICENT KING

RECEIVED JULY 1, 1929 PUBLISHED NOVEMBER 8, 1929

This communication is the result of measurements initiated at Bristol University with W. F. Darke in 1919[1] and continued by R. T. Dale, C. S. Salmon, W. J. Elford and ourselves, subject only to long delays in supply, measurement, remeasurement and replacements of optically polished slits of adhesed glass; it was necessary to carry out the final measurements with slits of poor quality delivered in a damaged condition.[2]

J. Stock[3] found that quartz powder, dropping through nitrobenzene, ether or toluene, imparted a distinct additional conductivity to the system; this he interpreted in accordance with the suggestions of Smoluchowski.[4] Since our work was begun, several investigators found an enhanced conductivity in the presence of powders and other finely divided materials of unknown surface area. Thus Miss Laing[5] found that soap curd conducted better than the mother liquor entrained among the curd fibers; similarly, Fairbrother[6] with quartz glass and carborundum, Stamm[7] with wood fibers, and in particular Briggs[8] with cellulose. All these rendered the existence of excess conductivity in the neighborhood of surfaces extremely likely, but quantitative evaluation would require measurement of the obstruction offered by the fibers as well as the extent and accessibility of the surfaces. Likewise, the origin of such enhanced conductivity, whether due to free mobile ions corresponding to uncovered or unbalanced charges on the interface or due to mere concentration or positive sorption of salt solution in the neighborhood of the interface, remained uncertain. However, another[9] experimental measurement of absolute surface con-

Chem.*) will deal with results which we have obtained in a much simplified, easily made apparatus, permitting rapid comparisons of surface conductivity and quantitative determinations of its absolute amount.

ductivity leaves little room for doubt that the conductivity is due to the mobile ions corresponding to those attached to the interface. These experiments measured the conductivity in the neighborhood of the monomolecular film of fatty acid on water and showed that such a film is composed to the extent of about one-ninth of fatty ions, the remaining molecules being undissociated. Hence the conductivity is due to the free mobile hydrogen ions corresponding to the fatty ions in the thin film. Once any absolute measurements have been made, it is easy to standardize other experiments involving the same materials.

The experiments of Darke and the subsequent ones of Dale and Salmon were carried out with fine capillaries of fused silica. To magnify the conductivity, these were mounted in a large group in parallel, passing through a partition of shellac melted on and around them so that only their ends projected. Enhanced conductivity was observed, but such measurements could not be regarded as definitive, owing to the possibility of a leak or defective insulation between the tubes and the shellac. This was obviated by making two partitions of shellac with an accessible air gap between, the whole being enclosed in glass tubing. This arrangement yielded low values or excess conductivity and was discarded because of the impossibility of ensuring that the interior of the quartz surfaces had not become contaminated by the necessary manipulations. These results will be referred to in the discussion.

The next extensive series was made by Elford, using a pile of fifteen parallel quartz plates with optically polished surfaces. They were held in a rectangular cell made of optically polished glass, adhesed to form a unit. This was made by A. Hilger, Ltd. (London), and the dimensions (supplied at a much later date in place of those first communicated) were determined by them in a specially developed interferometer with a probable error of only 4000 Å. The results were definitely positive, but the method was ultimately abandoned on account of the difficulty of accurately evaluating dead spaces between the plates and cell, especially with the slight ledges necessary to hold the quartz plates in "position." The quartz plates were piled horizontally to minimize the chance that an optically polished edge might touch a true surface and introduce comparatively large resistance. The results are given later.

The next design made use of during the past six years (whenever available) consisted of a single rectangular slit with optically polished surfaces in a flat piece of glass one inch square. The first three slits, made by Mr. C. Ord of Adam Hilger, Ltd., were very satisfactory, and the dimensions of the slit were known to about one-eighth of the wave length of light. Unfortunately cracks gradually extended from one or more of the adhesed surfaces of the slits during the series of measurements made with them. An anonymous description of the mode of manufacture which appeared in *Nature*[10] may be quoted as follows: "The thickness of a piece of plain parallel quartz some $1^{1}/_{4}''$ X $1^{1}/_{4}''$ X $^{1}/_{8}''$ was being measured on a Michelson interferometer. The half coating of silver had been removed from one of the mirrors of the instrument, and the specimen was then 'contacted on' to this mirror so as to cover one-half of it. The whole was then half silvered, and the distance between the two surfaces was measured in air. What appeared to be a slight scratch in the center of the specimen was in reality a slit in the glass, of width only 16 wave lengths of light (λ 5461). This slit was made in the manner illustrated in the accompanying diagram (Fig. 1). It will be seen that the quartz plate was in reality built up of four pieces, all accurately finished with extreme accuracy. Starting with 1, 2 and 3 were contacted on and heated sufficiently to make these three join up into one piece, but, of course, not too much, or the optical perfection of the surfaces would be spoiled. The protruding edges of 2 and 3 where they meet 4 were then ground and polished so that they extended beyond 1 a distance equal only to 16 wave lengths. This distance was measured with the Michelson interferometer, and then 4 was contacted on and the heating process repeated."

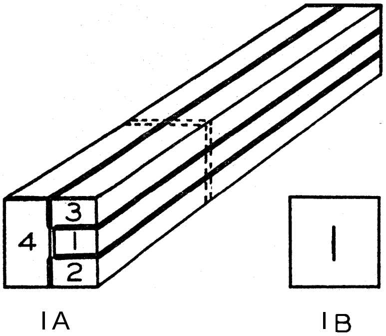

Fig. 1.—1A. Method of preparing slits by "adhesion" of optically polished glass surfaces. The dark lines show the surfaces which have been heated until they "adhered" or united. 1B. Cross section of glass showing slit.

These slits were actually made from four pieces of glass about 10 cm. long so that a number of cross sections could be cut, yielding slits of identical dimensions. At a later date no more of this batch could be supplied, and, although one of us went through the measurements of the glass pieces for the final batch at the factory, the slits actually supplied were of different dimensions which could, of course, no longer be determined interferometrically. The widths of the slits were therefore determined by means of a microscope fitted with a calibrated eyepiece scale, or with a calibrated micrometer eyepiece. Various objectives and eyepieces were used (both Leitz and Zeiss). Measurements were made at intervals of 0.5 to 1.0 mm. along the slit. The lengths of the slits were determined with a traveling microscope, reading to 0.001 mm., the scale of which had been calibrated. The thicknesses of the slits were determined (1) by examination at intervals along the edges of the block with a microscope fitted with a calibrated eyepiece scale, or with a calibrated micrometer eyepiece; (2) by examination at intervals around the edges of the block with a

---

[10] *Nature*, **112**, 223 (1923).

traveling microscope; (3) by means of a micrometer caliper, reading to 0.0001 in.

The dimensions obtained by these methods agreed fairly well with those given by Hilger for slits Nos. 1 and 2, but not for the later slits Nos. 4, 5, 6, 7 and 10, the results for the widths of the narrow slits (Nos. 4, 6, 10) being about 10% lower than those of Hilger and about 2% lower for the wider slits (Nos. 5, 7). These were just about the differences Hilger stated might exist due to sagging of the glass, hence the microscopic measurements have been taken as being correct for these slits, while Hilger's measurements have been used for slits Nos. 1 and 2. According to a statement by Hilger, the narrower slits (4, 6, 10) were all cut from the same block, and the wider slits (Nos. 5, 7) from another. It was decided, therefore, that the best procedure would be to average all the values obtained for the widths of the narrower slits (and similarly for the wider slits) and use this average value as the width of all the narrower slits (and similarly for the wider slits) instead of the average values obtained from the measurements of each slit alone. Table I records the dimensions of the slits which have been used in this investigation.

TABLE I

DIMENSIONS OF SLITS

Slit No.	Width, mm.	Length, mm.	Thickness, mm.	Observer
S	0.00939	10.000	0.983	Hilger
1	.0344	10.03	...	Hilger
	.0337	10.10	0.999	King
2	.00634	10.06	...	Hilger
	.00667	10.11	1.001	King
4	.0125	10.01	1.066	Peaker
6	.0125	10.01	1.058	Peaker
10	.0125	10.01	5.014	Peaker
	(.014)	(10.00)	...	Hilger
5	,0567	10.02	1.033	Peaker
7	.0567	10.02	2.101	Peaker
	(.058)	(10.00)	...	Hilger

The accuracy of the final values obtained in this investigation depends greatly on the accuracy with which the dimensions of the slits are known. The possibility of error is greatest in the widths of the slits, since this is the smallest dimension; we estimate that it is probably known to within 2% for the narrower slits used and within 0.5% for the wider slits. The error in the lengths of the slits is probably not over 0.1% and in the thicknesses not over 0.3%.

Procedure for Cleaning Cells and Slits.—The electrode arms of the "main cell" were thoroughly cleaned with nitric acid (1:1), conductivity water, distilled alcohol and distilled ether. Mercury for the electrode arms was cleaned by allowing it to stand in contact with nitric acid (1:1) for a short time, washing with distilled water and filtering through pin-holes in filter paper until clean and dry.

The main cell was cleaned thoroughly with cold dichromate–sulfuric acid mixture and thoroughly rinsed with conductivity water, distilled alcohol and distilled ether. Then it was rinsed out with distilled alcohol and conductivity water. The optically polished "central cell," previously used by Elford to hold quartz plates, was subjected to similar treatment before use.

The glass blocks containing the slits were cleaned externally with dichromate mixture, rinsed with conductivity water, and rubbed lightly with a clean cloth dipped in distilled alcohol. (Treatment with dichromate mixture was omitted in the case of slits Nos. 1 and 2.) After assembling the cell, the slits were cleaned as follows. The cell was filled with fresh dichromate mixture and this drawn back and forth through the slit by applying suction. Then the cell was rinsed out thoroughly in turn with conductivity water, distilled alcohol, distilled ether, distilled alcohol and conductivity water, suction being used to draw the liquids through the slit. (Treatment with dichromate mixture was omitted in the case of slits Nos. 1 and 2.)

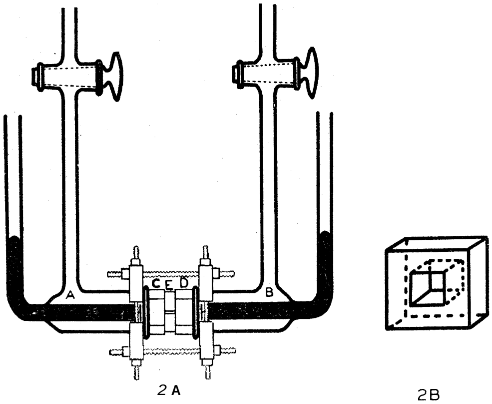

Fig. 2.—2A. The conductivity cells. 2B. Central cell. one is placed on each side of the slit.

The Conductivity Cells.—The type of cell used for measuring the conductivity of potassium chloride solutions in glass capillaries is shown in Fig. 2. It consists of three parts: (1) the two half cells (A, B) containing the electrodes designated as "main cell"; (2) two glass blocks (C, D) about 1 inch square with an opening through them about 1.3 cm. square designated as "central cell"; (3) a glass block (E) containing the optically worked capillary slit. (In some of the measurements made by one of us, the central cell was not used) These various parts are then clamped into the positions shown in the diagram. The clamp was made of square ebonite frames. pulled toward each other by four brass screws at the outside corners, the ebonite being separated from the glass by thick rubber tubing.

In the earlier work a water thermostat was used; the later results were obtained with a thermostat filled with Transil Oil, as used by Grinnell Jones and R. C. Josephs.[11]

The conductivity measurements were made by the method of Kohlrausch, using the improved apparatus designed by Washburn[12] and supplied by Leeds and Northrup. (Some modifications were made in the apparatus used by one of us (C. R. P.) to conform with the recent work of Jones and Josephs.[11] Instead of the fixed ratio slide wire described by them, a Kohlrausch drum-type slide wire (Leeds and Northrup) was used; the grounding resistance was another slide wire of the same type. Since most of the readings were taken at the center of the wire, this arrangement is equivalent to that of Jones and Josephs.) The slide wire was carefully calibrated by the method of Strouhal and Barus,[13] and the necessary corrections were applied. The resistance box was of the five decade type, supplied by Leeds and Northrup; coils of 1000 ohms resistance and

above were of the Curtis design. Variable air condensers were shunted across the resistance box. The balance point of the bridge was determined by the use of a set of tuned telephones (one of us (C. R. P.) used a one-stage vacuum tube amplifier in conjunction with the telephones). Alternating current was supplied to the bridge from a Vreeland oscillator at a frequency of 1000 cycles per second (or, by one of us (A. M. K.), from a high frequency generator, or vacuum tube generator).

Preparation of Potassium Chloride Solution.—Various types of stills were used for the preparation of conductivity water,[14] but the conductivity of the water obtained was rarely better than 0.7 X 10^{-6} mhos at 25° and averaged about 1.0 X 10^{-6} mhos at 25". The water was collected and stored in flask.: of Jena glass, which had been thoroughly cleaned with dichromate mixture and which were steamed out each time before use. Correction for the conductivity of the solvent has been made in the tables of data which follow.

The potassium chloride used was Kahlbaum's "for analysis, with guarantee." It was heated in a clean quartz or porcelain dish over a hot Bunsen flame until all crackling ceased and was allowed to cool in a desiccator over phosphorus pentoxide. It was kept in the desiccator at all times except for brief periods when solutions were being made up.

The solutions of potassium chloride were made up by the weight method, the details of which are described by Kraus and Parker.[15] The amount of potassium chloride required was weighed out onto a clean, dry watch glass and transferred to a clean flask (just previously steamed out and rinsed with conductivity water) through a clean funnel (just previously rinsed with conductivity water). The residue on the watch glass and funnel was then rinsed into the flask with conductivity water and the necessary amount of conductivity water added to the flask. The amount of solution was determined by substitution weighing, and from the data the exact concentration of the solution could be obtained. The solution was then well shaken and allowed to stand for several hours before use. In practically every case freshly made solutions were used.

Procedure in Making Determinations of the Specific Conductivity of Potassium Chloride Solutions in Slits.—After assembling and cleaning the conductivity cell as previously described, it was rinsed out three or four times with the most dilute solution to be used (0.001 N potassium chloride), suction being used to draw the solution through the capillary. The cell was then filled with this solution and placed in the thermostat. Usually about half an hour was allowed to elapse before beginning measurements. The resistance of the cell was measured at intervals until a series of constant resistances over a period of, say, one hour, were obtained. The solution was then drawn back and forth through the slit by suction several times and measurements continued until the resistance was again constant. This was repeated several times and the mean of all the constant values for the resistance of the cell taken.

The solution was then emptied out and the cell rinsed two or three times with fresh samples of solution; it was filled again and placed in the thermostat ready for a second series of measurements. Three such independent fillings, giving agreeing results, were considered sufficient; in later work two fillings giving agreeing results were accepted.

After finishing a series of experiments with one concentration, the cell was rinsed with the next most concentrated solution, suction being used as previously; then it was filled and the above procedure repeated. During the transition from 0.001 *N* to 1 N solution the cell was not taken apart.

The following tables record the results which have been obtained in this investigation.[16] The first column gives the actual concentration of the solution used. The second column gives the resistances in ohms for each individual experiment. The values in the third column are the means of the values in Col. 2 for each concentration, corrected for the conductivity of the solvent and also corrected to round concentration (in making this slight correction, specific conductivity is assumed to be a linear function of concentration).

Time Effect.—In the case of the dilute solutions, drawing the solution in the cell back and forth through the slit after equilibrium had been established (as shown by constant resistances over a period of time) generally caused the resistance to rise somewhat, and then it fell off with time until a value comparable with the previous value had been reached, after which the resistance remained fairly constant. This is what one would expect if the excess conductivity is ascribed to the mobile ions existing free in the solution. For the more concentrated solutions (0.1–1.0 N), drawing the solution through the slit caused slight, irregular variations. In the preliminary work of Dale, Darke and Salmon it was found that a new capillary on its first filling showed diminished conductivity (due to sorption) which was replaced by enhanced conductivity (ordinary bulk conductivity plus conductivity of mobile ions) upon drawing further solution through the capillary.

Precision of the Recorded Data.—For 0.01 to 1.0 N solutions the values averaged to give the recorded value for each experiment in the preceding tables do not differ by more than 0.1–0.2% from this value. The mean obtained for each concentration (Col. 3 of tables) is probably correct to 0.1–0.2%. For dilute solutions (0.001-0.002 N) the values averaged to give the recorded value for each experiment are within 0.5% of the mean. The mean values for each concentration are probably correct to about 1%.

Specific Conductivities of Potassium Chloride Solutions in **Bulk.**—Table XII gives the values of the specific conductivities of the potassium chloride solutions used in this investigation, as obtained from the literature.

5	124,030	62,546	12,892	1,412.3	162.79
7	252,260	127,210	26,220	2,871.9	331.11

In order to decide whether there is any change in the specific conductivity of potassium chloride solutions in capillaries compared with that measured in bulk, it is necessary to determine from the observed resistances of main cell, central cell and slit the resistance of the slit alone. Comparison of the resistances so obtained with those given in Table XIII will then show whether or not there is any change in the conductivity when measured in capillaries.

In the early stages of this investigation it was thought that by subtracting the resistance of the main cell and central cell, measured separately, from the resistance of main cell, central cell and slit, the result would be the true resistance of the solution in the slit; but when this was done, a decrease in the specific conductivity was obtained for the more concentrated solutions, and only for the dilute solutions was an increase observed. This decrease in conductivity observed in the concentrated solutions was evidently to be ascribed to a "pinch" effect,[17] operating in all concentrations and due to bending of the lines of current flow through the slit, and equivalent to a series resistance. In other words, the whole cross section of the main cell and central cell is not available for carrying current in the immediate neighborhood of the slit. A similar "pinch" effect operated in the experiments of Elford, referred to previously.

In order to eliminate the "pinch" effect, it was decided to use two slits together; in this way the resistance of one slit (say No. 1), obtained by

---

[17] We satisfied ourselves with ad *hoc* measurements that the "pinch" effect not only exists but that its magnitude has been correctly deduced. For this purpose we used, for example, a fine platinum wire of the same diameter in place of the slit and found that the total resistance between the electrodes was about equal to the resistance between the central platinum wire and either of them. The resistance between the central wire and one of the electrodes was again doubled by putting a glass plate behind the platinum wire. In other experiments the half cell was closed with a paraffin block, into the surface of which a platinum wire had been crushed and then platinized, and a similar large "pinch" effect was found.

subtraction of the observed resistance of slit No. **2,** main cell and central cell from that for both slits, main cell and central cell would be independent "pinch" effect. Since the slits used for this purpose were not of the same width (one being roughly five times the width of the other), the assumption is made in such a calculation that the "pinch" effect is the same for a slit, say, 0.05 mm. wide as for one only 0.01 mm. wide. In the early part of this investigation the truth of this assumption could not be checked because we had difficulty with cracking of the glass blocks containing the slits; later data, obtained on slits which were not cracked, showed that the assumption was not valid. If we consider the data for slits No. 5 and No. 6, this will be quite apparent.

For 1.0 N solution the resistance of main cell, central cell and slit No. 5 is 204.45 ohms (Table X). If we assume that for this concentration surface conductivity is negligible compared to bulk conductivity and consider that the resistance of the slit itself is 162.79 ohms, as calculated in Table XIII, then the "total effective resistance" of the main cell and central cell is 41.66 ohms. This is the sum of the "pinch" resistance and the true resistance of the main cell and central cell, measured separately. Since the measured resistance of the latter is 14.14 ohms, the former is 27.52 ohms.

Similarly, considering the data for main cell, central cell and narrow slit No. 6 for 1.0 N solution, we find the measured resistance of this combination to be 957.40 ohms (Table XI), while the resistance of the slit itself is 757.08 ohms (Table XIII). The "total effective resistance" of the main cell and central cell is then 200.32 ohms, and the "pinch" resistance is 186.18 ohms.

The ratio of the "total effective resistance" of the main cell and central cell in the two cases is 200.32/41.66 or 4.81; the ratio of the widths of the slits, which is the only dimension which need be considered, is 0.00567/0.00125 or 4.53. Thus, as a first approximation we may say that the "total effective resistance" of the main cell and central cell is inversely proportional to the width of the slit; the "pinch" resistance, on the other hand, appears to be an exponential function of the width.

Considerable difficulty was encountered in evaluating some of the results, owing to the fact that cracks developed, radiating from the slit, during the course of the experiments. Since the cell was not dismantled during the transition from 0.001 N to 1.0 N solution, it is difficult to say where the cracks first developed and to what extent. However, it seems very probable that the conductivity of such cracks is negligible compared to the conductivity of the solution in the slit itself. Under a microscope, using very high magnification, the crack appears only as a line, whose width cannot be estimated, while the slit covers about $^1/_6$ of the field (in the case of the narrow slit No. 4, for example).

It seems best, therefore, to include any effect of the crack in the term which is called the "total effective resistance" of the main cell and central cell, rather than attempt to make a special correction term for this effect. The following pages give typical methods of calculating the results.

1. Method of Calculating the Results for Slits Nos. **1, 5, 6 and** 10 (Tables **III, IX, X** and **XI**).—For narrow slit No. 6 (Table XI) the resistance of main cell + central cell + slit No. 6 for 1 *N* solution, 957.40 ohms, less the calculated resistance of the slit for 1 *N* solution, 757.08 ohms, leaves the "total effective resistance" of main cell + central cell for 1 N solution equal to 200.32 ohms. Now the "total effective resistance" must be proportional only to the specific resistance of the solution for a given cell and slit. Hence the "total effective resistance" of the main cell + central cell for 0.001 *N* solution is $(200.32 \times 0.11169)/0.0001466 =$ 152,620 ohms. But the resistance of the main cell + central cell + slit No. 6 for 0.001 N potassium chloride was 529,710 ohms, leaving for the resistance of the slit alone 377,090 ohms. The resistance of the slit as calculated from its dimensions and specific conductivity (Table XIII) is 576,790 ohms. The percentage increase in specific conductivity for 0.001 N potassium chloride within the slit is then

$$\left(\frac{1/377{,}090 - 1/576{,}790}{1/576{,}790}\right) \times 100 = \left(\frac{576{,}790 - 377{,}090}{377{,}090}\right) \times 100 = 52.96\%$$

The specific conductivity of a 0.001 N solution in bulk is 0.0001466 mho at 25.00°. Hence the conductivity due to the surface would be 52.96% of 0.0001466 mho or 0.00007764 mho, if 1 cc. of 0.001 N potassium chloride solution were to be confined in a cell, the area of whose walls bore the same ratio to the volume as the area of the actual slit did to the volume of the slit.

It is essential to calculate the surface conductivity in absolute units. Volume conductivity is always expressed by specific conductivity, that is, the conductivity in reciprocal ohms of a cube of solution placed between parallel electrodes 1 cm. square and 1 cm. apart. Similarly, we must invent a specific surface conductivity in two dimensions instead of three (as regards the actual surface area), defining it as the conductivity in reciprocal ohms between two parallel electrodes 1 cm. long, placed 1 cm. apart on the surface. The surfaces in our slits conform to this requirement in that they are parallel to the lines of current flow. As long as the volume and area are varied in the same proportion, the ratio between volume and surface conductivity will remain constant. Hence from the determination given above, since the area of slit No. 6 was 1601.6 times its volume in cc., the specific conductivity of one square centimeter is $0.00007764/1601.6 = 4.85 \times 10^{-8}$ mhos.

The value for the "total effective resistance" just calculated for the uncracked slit No. 6 had to be used for the results of Tables V, VII and

VIII. Slit No. 4 (Table VIII) evidently cracked before the measurement of 1.0 N potassium chloride, although the results for 0.001 N and 0.01 N agree with Table XI. For Table V the "total effective resistance" for 1.0 N potassium chloride is 242.58 ohms, obtained by multiplying the 200.32 ohms by that for the main cell (92.46) in Table V divided by that for the main cell + central cell (76.35) in Table VIII. Again for Table VII, the "total effective resistance" of the main cell for 1.0 N potassium chloride is $(242.58 \times 22.29)/200.32 = 26.38$ ohms; but slit No. 7 had become so badly cracked that the conductivity even of 1.0 N potassium chloride was slightly increased. Hence the volume conductivity of the crack had to be taken into account, and the surface conductivity of dilute solutions was apportioned between crack and slit in the ratio of their lengths.

For Table VI using wide and narrow slits, No. 7 and No. 4 together, the total effective resistance was taken as the mean of the two separately. Then the resistances within each slit were obtained by subtracting the values for the separate slits from the value of the two slits together. Therefore, the surface conductivities are both low on account of the neglected "pinch" resistance between the slits, the wide slit being most affected.

In Table II the original slit No. S was broken after measuring 0.1 N potassium chloride. Assuming the surface conductivity to be of negligible influence in 0.1 N in place of 1.0 N potassium chloride, the calculation gives 7.51×10^{-8} mhos per sq. cm. for the surface conductivity in 0.01 N potassium chloride. Based upon 1.0 N potassium chloride, this would have been a few per cent. higher, but it is in good agreement with the later work.

The earlier work of Dale with fused silica tubes and of Elford with plates of quartz is calculated in the same way. Dale's results (1921) are given for the last three cells he used. With 0.01 N the increased conductivity observed was 1.2 and 1.4%, corresponding to 16.1 and 17.2 X 10^{-8} mhos per sq. cm., respectively. That for 0.002 N was 2.7% or 3.6 X 10^{-8} mhos. The results with quartz plates for higher concentrations are omitted on account of the magnified experimental error. For 0.001 and 0.002 N potassium chloride the increased conductivity was 11.4 and 8.2%, and the specific surface conductivity was 3.9 and 5.6×10^{-8} mhos, respectively.

The data for slit No. 2 alone are omitted because of a wide crack which caused the 1.0 and 0.001 N potassium chloride solutions to exhibit an apparent increase of 42 and 93%, respectively. The difference, 51%, corresponds to a specific surface conductivity of 2.4 X 10^{-8} mhos.

Tables XIV and XV present the evaluation of the results by the methods just described, showing the percentage increase ascribable to surface conductivity and the magnitude of the surface conductivity in absolute units.

[a] Plus conductivity offset by not allowing for "pinch" between slits.

Results and Discussion

In Table XVI are collected the values obtained for the specific surface conductivities, including those of Dale (1821) with capillary tubes of fused silica and of Elford (1922) with optically polished plates of quartz. Since the surface conductivity remains of the same order of magnitude with different concentrations of the solution, whereas the specific conductivity (volume) increases nearly a thousand-fold between 0.001 and 1.0 N, it follows that accurate determinations of surface conductivity may only be made with dilute solutions, the experimental error for stronger solutions mounting almost in proportion to the concentration. Hence the results for 0.001 N potassium chloride are the most significant. Thus in some of the cells the surface conductivity is quite half of the conductivity of the solution in the capillary.

The results in Table XVI not only demonstrate the existence of surface conductivity but also yield approximate numerical values for the absolute specific surface conductances at optically polished glass surfaces. The surface conductances at smooth surfaces of fused silica or of optically polished quartz are the same as with polished glass. The surface conductivity of an insoluble film of fatty acid on water is of about the same magnitude.

Contrary to expectation on the basis of the dissociated double layer of Gouy, the surface conductivity seems to increase with increasing concentration of salt. Evidently the surface conductivity has a finite value even in the presence of 1.0 N salt, although it is less than 0.1% of the bulk conductivity even in the narrowest capillary spaces here used. Experiments on electroosmosis likewise show that, although fairly low concentrations of such salts as potassium chloride slow down the flow of liquid markedly, even large concentrations do not entirely stop it.

The negative ions which give the negative charge to the glass might be either OH^- or Cl^-, or even a mixture of the two.[18] Indeed it would be remarkable if there were not a small proportion of positive ions such as H^+ and K^+ also adsorbed on the glass. The corresponding free mobile ions in the solution would not be H^+ (or OH^-) because of the prolonged rinsing with further solution of potassium chloride, which would leave mostly K^+ (and for any positive ion adsorbed, a corresponding excess of Cl^-).

If the surface conductivity is entirely due to free mobile ions (K^+ and Cl^- whose mobility is in both cases 75 at 25°) then the specific surface conductivity, 4.3×10^{-8} mhos, equals 5.7×10^{-7} gram equivalents or 3.5×10^{14} actual ions. Now the distance between centers in a cubic face of potassium chloride crystal is 2.81×10^{-8} cm., when it follows that such a face comprises 12.7×10^{14} ions. Therefore, the surface conductivity in the presence of 0.001 N potassium chloride, if interpreted as free mobile ions, corresponds to one-third of the ions which could be accommodated in a monomolecular layer. That for higher concentrations approaches the value for a monomolecular layer.

One of us[19] has pointed out the erroneous voltages which necessarily

---

[18] H. J. Weiland, THIS JOURNAL, 40, 131 (1918), found that the addition of ground quartz raised the conductivity of 0.001 *N* potassium chloride by 0.02% and that of conductivity water (1×10^{-6}) by 10 or more per cent. The ratio between the area of quartz surface and the volume in cubic centimeters is about 80. He interpreted his figures to the effect that 88×10^{-12} equivalents of potassium chloride were adsorbed per sq. cm. of quartz surface. Elford in similar experiments with bundles of fine fibers of fused silica likewise found that the conductivity of 0.001 *N* potassium chloride was raised by 0.1% and that of conductivity water (1.8×10^{-6}) by 69%. Weiland called the effect on water "pollution." We interpret it as adsorption of OH^-, creating an excess conductivity through liberation of H^+. With potassium chloride, if only Cl^- is adsorbed, the conductivity is to that extent diminished; if, as the other extreme, only OH^- were adsorbed, the conductivity would be greatly increased. The balance observed would indicate that about five times as much Cl^- as OH^- is adsorbed. Our interpretation is reinforced by Weiland's figures, which, according to his interpretation, show an adsorption equal to only a few per cent. of that required to explain the actual surface conductivity here found. Several observers have noted that electrokinetic phenomena are rather fluctuating or ill defined with solutions of potassium chloride and glass.

[19] J. W. McBain, *J. Phys. Chem.*, 28, 706 (1924). It is 56 volts for an interspace of 1×10^{-8} cm. between the two layers, and the same for 80×10^{-8} cm. if the di-

arise, from the formula for a condenser, if a complete monomolecular layer of ions all of one sign is compensated by an equal number of opposite sign. This might be reduced somewhat if the ions primarily adsorbed were not all of one sign, but the even more obvious alternative here is to ascribe some of the surface conductivity to mere concentration of the salt solution in the neighborhood of the surface. If this were the chief effect, the concentration of 0.001 N potassium chloride in the neighborhood of the glass surface would be raised to $^1/_2 \times 5.7$ N or $^1/_2 \times 0.57$ N, depending upon whether 10×10^{-8} or 100×10^{-8} cm. were taken as the effective range of molecular attraction. The concentration of hydrogen ions in equilibrium with a monomolecular layer of insoluble fatty acid appears to be about one-ninth of the total number of molecules in the oil film, no easy alternative being available. For comparison with the results of Table XVI it may be mentioned that 15.5×10^{-8} mhos would be the conductivity of free potassium ions taken equal in number to the atoms in a square centimeter of a surface of potassium chloride crystal.

To the many objections[19] revealing the fictitious nature of electrokinetic potential, ζ, may be added the assumption that the conductivity in the neighborhood of the surface is the same as the bulk conductivity, an assumption sufficiently disproved by the present work.

Another method of evading the fact that the surface conductivity corresponds to enough ions to cover quite one-third of a monomolecular layer is to assume that the mobility of a potassium ion in the neighborhood of the surface is different from that in the bulk of the solution. However, if the mobility is less, the concentration of ions must be more, and it is in proportion to the change in magnitude of the mobility that the number of ions deduced changes. It is very difficult to justify an *ad hoc* assumption that the actual mobility of the ions is much greater in the neighborhood of a solid surface of opposite charge. Adhesion tests in shear on such optically polished surfaces as are here studied show that the resistance encountered is of the order of one ton per square inch of polished surface,[20] negativing the idea of slip or facile flow.

One possibility remains, arising from the general formulations of Miss Laing[21] for movement in an electrical field, where it is shown that the movement with reference to the solvent is the same in electroösmosis as

---

electric constant of water be taken as usual at 80. The suggestion made by several adherents of the theory of complete dissociation, that the dielectric constant of water in the neighborhood of ions is to be imagined as 6, raises the latter voltage to $80/6 \times 56 = 747$ volts, as, for example, between a solution and its glass container, provided, of course, that the layer is complete.

[20] J. W. McBain and W. B. Lee, *Proc. Roy. Soc. London*, **113A,** 606 (1926); *J. Soc. Chem. Ind.*, *46*, 321T (1927); *Ind. Eng. Chem.*, *19*, 1005 (1927); *J. Phys. Chem.*, **31,** 1674 (1927).

[21] M. E. Laing, *ibid.*, 28, 673 (1924).

in electrophoresis. If that is the case here and if the movement of solvent relative to the glass is about the same as the movement of the potassium ions through it, the total movement would about double the absolute velocity of the positive ions and would therefore halve the number deducible from the conductivity, giving only about $^1/_6$ of the number required to build a monomolecular layer. If the average distance of the mobile ions from the sessile charges on the glass is 80 X 10^{-8} cm., this would be equivalent to *a* condenser of about 9 volts: or: if the average separation of the mobile ions from the sessile ions is the same as the average distance between the ions throughout a normal solution of any salt such as potassium chloride, 10 × 10^{-8} cm., the voltage would be about one. However, if the mobile ions are not all of the same sign, which is almost inevitable, the voltage is very greatly reduced, although the Laing effect would be less than that just indicated for the extreme case. This conception assumes that the sessile ions are both positive and negative, the majority being negative.

Finally, it has been common knowledge for a generation or more that a glass surface, once exposed to an aqueous solution, is partially leached out so that it is superficially porous, and the less well-known facts may be recalled that the very best optically polished surfaces are full of infinitesimal cracks; therefore the actual surface of glass is much greater than appears from macroscopic examination. With surfaces such as here used, possibly true to 2–300 Å., these effects do not invalidate or possibly do not even appreciably change our results, although they are in the direction emphasizing the incompleteness of any layer of charges upon the glass, fused silica or polished quartz.

In our experiments with ordinary pyrex tubing[8] the value of the specific surface conductivity for 0.001 potassium chloride is 13 X 10^{-8} mhos as compared with the 4.3 × 10^{-8} mhos here found for optically polished glass.

Surface conductivity exists and has to be taken into account in any discussion of the electrical behavior or sorption equilibria of capillary spaces, or finely divided matter such as colloids or organisms containing an ionizing solvent.

Summary

For the first time absolute measurements of specific surface conductivity have been made. For aqueous 0.001 N potassium chloride at 25° the extra conductivity in the neighborhood of optically polished glass, fused silica and optically polished quartz amounts to a specific surface conductivity of 4.3 X 10^{-8} mhos. Thus in capillary spaces of less than 0.01 mm. half the conductivity may be surface conductivity, ascribable to free mobile ions corresponding to sessile ions of opposite charge upon the solid interface, which are probably not all of negative sign. These mobile

ions are not sufficiently numerous to form more than about one-eighth of a monomolecular layer. This is of the same order as that found in our measurements of specific surface conductivity of an insoluble fatty acid on conductivity water.

THE DIELECTRIC POLARIZATION OF LIQUIDS. VI. ETHYL IODIDE, ETHANOL, NORMAL-BUTANOL AND NORMAL-OCTANOL

BY C. P. SMYTH AND W. N. STOOPS

RECEIVED JULY 1, 1929 PUBLISHED NOVEMBER 8, 1929

The extreme complexity of the dielectric behavior of the alcohols as observed by various investigators over a limited range of temperature or of concentration, together with the importance of the electric moments of this group of substances, has made it desirable to measure several alcohols from the pure liquid to the most dilute solutions in non-polar solvents over the entire range of temperature within which they are liquid. The methods of measurement and calculation used in the present work have been described in the first two papers of the series on dielectric polarization.[1] In these earlier measurements, benzene and hexane were employed as non-polar solvents, the latter being particularly useful because of the wide range of temperature within which it is liquid. Since pure normal heptane can now be obtained much more readily than hexane of a comparable purity and, at the same time, is liquid over a wider temperature range, it has replaced hexane in the present determinations. Although it had been found that none of the isomers of heptane had detectable electric moments and the similarity of heptane to hexane[2] indicated that it would give identical results as a non-polar solvent, three solutions of ethyl bromide in heptane were measured for comparison with those in hexane previously studied. The results showed the expected agreement and are, therefore, omitted from this paper. However, measurements upon the similar substance, ethyl iodide, are reported and ethyl alcohol has been studied in both hexane and heptane with results that show similar behavior in the two solvents.

Method of Measurement

The densities were determined with the same type of pycnometer used in the earlier work and the dielectric constants were measured with the

capacity bridge previously described, a frequency of 5 X 10^5 cycles, corresponding to a wave length of 600 meters, being used as before. The constancy of the wave length was checked by means of a wave meter, and the platinum resistance thermometer was calibrated at −95.1°, the freezing point of toluene, at 0°, and at 100° and checked occasionally at the ice point to make sure that there was no change. In addition to the condenser cell with platinum cylinders used in the earlier work, a cell, similar in form but consisting of three concentric brass cylinders, heavily gold plated, was employed. This differed further from the platinum cell in that the cylinders had separate leads and could thus be connected together in different combinations having capacities of 66, 40, 27 and $17\mu\mu$f., as compared to the $200\mu\mu$f. of the platinum cell, the outer cylinder always being grounded as in the latter.

The errors involved are not very different from those in the earlier work. The probable error in the densities measured at low temperatures was 0.07% and in those above 0° not more than 0.03%. The dielectric constants of mixtures whose maximum value did not exceed five were measured in the platinum cell by direct substitution on the precision condenser. The probable error here was 0.2%, although the error within a given series of measurements was less. For other mixtures, measured either with the platinum cell in series with another variable air condenser or with the gold-plated cell, the accuracy was less, the probable error being 0.5%. Again the accuracy within a given series of measurements was greater. When considerable resistance was required in the balancing arm to compensate for conductance or absorption in the cell, the dielectric constants are probably not accurate to more than 2%. These large resistances were necessary only in the case of the pure alcohols and their most concentrated solutions at low temperatures. The effect of the resistance was to cause the apparent values of the dielectric constants to be too large. The change in concentration due to evaporation of the more volatile component at the highest temperatures was troublesome in the dilute mixtures, but error from this source was corrected by comparison of measurements made at room temperature before and after the high temperature determinations.

Preparation of Materials

Heptane.—Pure normal heptane was obtained from the Ethyl Gasoline Corporation. A portion of it was washed with sulfuric acid, then with dilute sodium carbonate solution and with water. It was dried over calcium chloride, and finally distilled over sodium. As the boiling point, refractive index and dielectric constant were not appreciably different after this treatment, the heptane was normally used without purification.

Ethyl **Iodide.**—C. P. ethyl iodide was washed repeatedly with water, dried over fused calcium chloride and fractionally distilled; b. p. 72 4–72.5" at 773.7 mm.

Benzene.—Merck's C. P. benzene was washed three times with sulfuric acid, then with dilute sodium carbonate solution and with water, dried over calcium oxide and twice fractionally crystallized. It was then dried over sodium and fractionally distilled; b. p. 80.1°; n_D^{20} 1.50139.

Cyclohexane.—Eastman's purified grade cyclohexane was fractionally crystallized. The fractions melting at 6.2 and 6.0° were mixed, dried over sodium and fractionally distilled; b. p. 80.90–80.95°.

Ethyl Alcohol.—Ninety-five per cent. ethyl alcohol was refluxed over freshly ignited calcium oxide for twenty-four hours, the lime being changed once during this time, and fractionally distilled; b. p. 78.4°; n_D^{20} 1.36139.

Butyl Alcohol.—Normal butyl alcohol from the Commercial Solvents Corporation, b. p. 114–117°, was refluxed over freshly ignited lime and fractionally distilled; b. p. 117.2–117.4"; n_D^{20} 1.39922. A sample prepared by Dr. H. B. Glass at Johns Hopkins University was used in some of the work; b. p. 117.2–117.3°; n_D^{20} 1.39920.

Octyl Alcohol.—n-Octyl alcohol was obtained from the Eastman Kodak Company and fractionated by Dr. H. B. Glass and Dr. G. B. Malone working with Professor E. Emmet Reid of Johns Hopkins University.

Experimental Results

The densities, which showed only a small departure from a linear dependence upon temperature, were determined at 20–25° intervals and the dielectric constants at approximately 15° intervals, except when the temperature variation of the latter was so great as to necessitate 5–10' intervals. The densities, *d*, and dielectric constants, ϵ, in Table II were obtained at 10° intervals by graphical interpolation and the polarizations, P_2, of the polar components were calculated from them by means of the equations

$$P_{12} = \frac{\epsilon - 1}{\epsilon + 2} \times \frac{c_1M_1 + c_2M_2}{d} \text{ and}$$

$$P_2 = \frac{P_{12} - P_1}{c_2} + P_1$$

in which P_{12} is the polarization of the mixture, and c_1 and c_2, M_1 and M_2, and P_1 and P_2 are, respectively, the mole fractions, molecular weights

and polarizations of the individual components. The values of P_2 for ethyl iodide are omitted as they vary regularly with concentration. In Table I the dielectric constant values for pure ethyl alcohol and butyl alcohol are given, together with the compensating series resistances, R, in ohms which had to be used to balance out the effects of conductance or absorption in the measuring cell. This resistance gives an indication of the magnitude of the conductance and of the absorption of the liquid for a wave length of 600 meters.

Discussion of Results

In Table I the high compensating resistance for ethyl alcohol (freezing point −117.3') at low temperatures shows a considerable absorption although the dielectric constant has not begun to fall off even at −110.4'. For butyl alcohol, with its larger molecules, the absorption is noticeable at higher temperatures and the dielectric constant begins to fall off nearly 20° above the freezing point, −89.8°. On solidification the dielectric constant shows a tremendous decrease as the dipole contribution drops out and the absorption becomes negligible. The measurements on the heptane solutions of ethyl alcohol do not extend down to temperatures at which absorption is considerable, but the concentrated butyl alcohol solutions show an increasing absorption at low temperature and a decrease in the dielectric constant as −90° is approached. The effect is negligible in the concentrations measured below mole fraction 0.4451 of butyl alcohol. *n*-Octyl alcohol (freezing point −16.3°) was not measured at temperatures low enough to cause strong absorption, but the slight absorption observed in the pure alcohol diminished in the 0.7360 solution and was negligible in the 0.4374 solution at the same temperatures.

With rising temperature the compensating resistance decreases as the absorption decreases, then passes through a minimum and increases up to the highest temperatures measured, presumably because of electrolytic conductance which increases with rising temperature. The increase is not apparent in n-octyl, is considerable in butyl, large in ethyl and so large in methyl alcohol that the apparatus is inadequate for the measurements at higher temperatures. The minimum occurs at a lower temperature, the smaller the alcohol molecule. In the heptane solutions the effect decreases with decreasing concentration and is not evident in the concentrations measured below $c_2 = 0.6$.

When P_{12} at different temperatures is plotted against c_2, the mole fraction of ethyl iodide in the heptane-ethyl iodide mixtures, the curves obtained resemble those for ethyl bromide, passing through a maximum, which, however, is less pronounced than in the ethyl bromide curves. The P_2–c_2 curves also resemble those for ethyl bromide but possess a slightly smaller curvature. The polarization of the pure substance decreases slightly with rising temperature instead of increasing as does that of ethyl bromide. These facts indicate that the effect of orientation is less in ethyl iodide than in ethyl bromide, as would be expected from the slightly smaller electric moment, 1.66 X 10^{-18}, as compared to 1.86 X 10^{-18}, and the screening effect of the iodine atom, which should be greater than that of the bromine. When the P_2–c_2 curves are extrapolated to $c_2 = 0$, the values of P obtained give a straight line when plotted against $1/T$, as required by the Debye equation: $P = a + b/T$. The values of the constants a and b are obtained graphically from the values of P, in Table III and in order to show the linearity of the variation of P, with $1/T$, the values of $(P, - a)\ T = b$ are shown. There is evidently no departure from the linearity demanded by theory, the maximum deviation from the value b = 17,000 being less than 1%. The electric moment μ is calculated from b; the value of P_E, the electronic contribution to the polarization, is obtained by extrapolation to infinite wave length of the molar refraction for visible light, and the somewhat doubtful atomic contribution is obtained as $P_A = a - P_E$. The dipole contribution P is, of course, $P_\infty - a$. The value of the electric moment, 1.66 X

10^{-18}, agrees well with that obtained by Williams, 1.7×10^{-18}, from measurements at one temperature, and with the value 1.62×10^{-18} of Mahanti and Sen Gupta from measurements on the vapor.[3]

Table III

Polarization Contributions of Ethyl Iodide

T, °A.	P,	$(P_\infty - a)T$	T, °A.	P_∞	$(P_\infty - a)T$	T, °A	P_∞	$(P_\infty - a)T$
173	134.7	17150	233	108.9	17080	293	93.7	17020

223	112.6	17160	283	95.8	17040	343	85.0	16950

$a = 35.6$; $b = 17000$; $P_E = 23.3$; $P_a = 12.3$; $\mu = 1.66 \times 10^{-18}$.

An attempt to apply the Debye equation to solutions of ethyl alcohol in heptane meets with serious difficulties. The values of P_{12} and P_2 for dilute alcohol solutions increase with rising temperature instead of decreasing as the theory requires (Figs. 1 and 2). In these and the subsequent diagrams, one circle sometimes represents several almost coincident points on different curves. At slightly higher concentrations (c_2 = 0.12–0.20) of alcohol the P_{12}–c_2 and the P_2–c_2 curves at different temperatures intersect, the polarization becoming practically independent of tempera-

ture. Just beyond this point they rise sharply, go through a maximum and finally decrease to the values for the pure alcohol. Thus, in very dilute solutions and in the pure alcohol, the polarization increases with the temperature. At intermediate concentrations the polarization decreases with rising temperature, with the result that the P_2–c_2 curves intersect both in the dilute and concentrated regions. The values of P obtained by extrapolating the P_2 curves to zero concentration of alcohol obviously

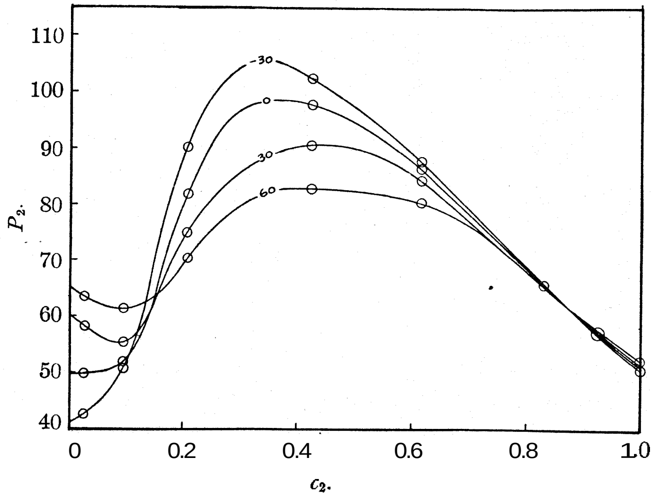

Fig. 2.—Polarizations (P_2) of ethyl alcohol in solution in hexane and in heptane.

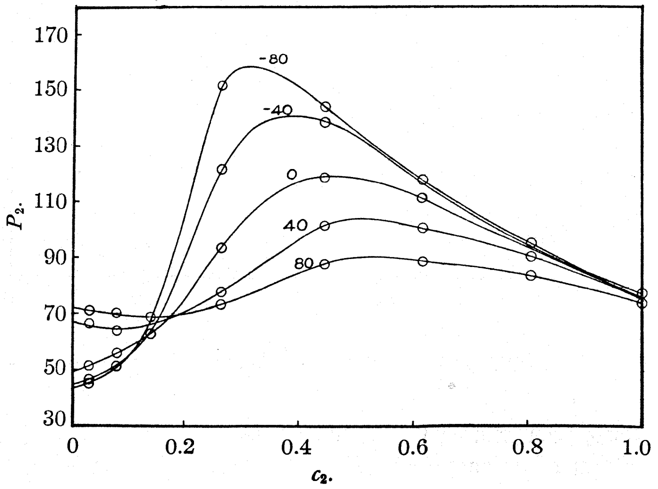

Fig. 3.—Polarizations (P_2) of butyl alcohol in solution in heptane.

do not correspond to the unassociated state, since they increase with rising temperature instead of decreasing.

The P_{12}–c_2 and the P_2–c_2 curves (Fig. 3) for butyl alcohol in heptane show a less sharply defined maximum and a greater dependence of polarization upon temperature in the concentrated solutions. For octyl alcohol in heptane, the maximum has disappeared in the P_{12}–c_2 curves (Fig. 4) and is less pronounced in the P_2–c_2 curves (Fig. 5). This decrease in the effect of orientation is also evident in the variation with temperature of the polarization in the pure alcohols. Whereas the polarization of ethyl alcohol increases with temperature over the entire range, that of butyl alcohol at first increases, then becomes practically constant and finally decreases with rising temperature. The polarization of the normal octyl alcohol, however, decreases with rising temperature over the entire temperature range within which it is measured. Another indication of this effect is given by the variation in P_M for these alcohols. The values of $P_M = P - MR_D$ at 20° for ethyl, butyl and octyl alcohols are, respectively, 38.8, 55.1 and 78.6. In dilute solution this progressive variation of the effect of orientation does not occur, the curves for the three alcohols all being quite similar.

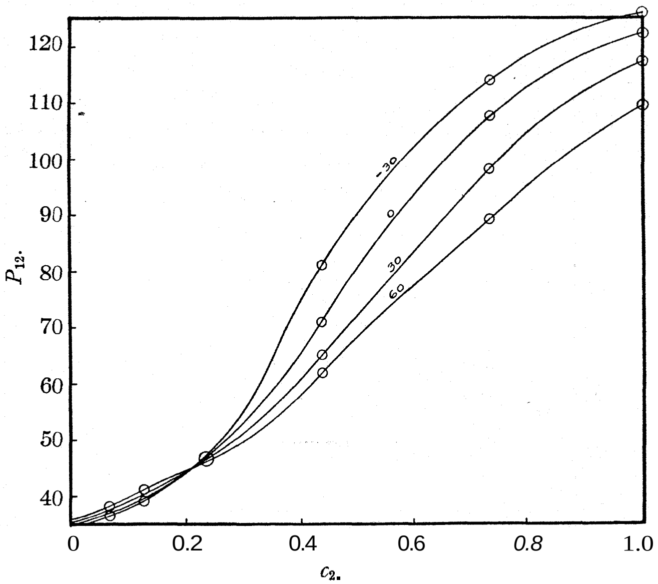

Fig. 4.—Molar polarizations (P_{12}) of heptane-*n*-octyl alcohol mixtures.

It should be explained at this point that, in the absence of a value of *a* determined from the temperature variation of P,, the small quantity P_A is neglected and *a* is set equal to MR_D, the molar refraction for the sodium D line. The error thus introduced is negligible in comparison to the uncertainties caused by molecular orientation.

These P_{12}–c_2 and P_2–c_2 curves resemble those calculated by Debye[4] from the data of Philip at 16° for solutions of ethyl alcohol in benzene in that they possess a maximum, but differ from those of Debye in that the P_2–c_2 curves generally show a minimum. The P_2–c_2 curve for butyl alcohol in benzene (Fig. 6) at 70° resembles that of Debye for ethyl alcohol, but at 50° a slight minimum appears in the region of low alcohol concentration, and at 16° it is more pronounced, showing that the same orientating influences are at work in these solutions as in those in heptane, although the intensity of the influences is somewhat less. The difference in behavior is shown by the fact that the increase in dielectric constant over that of the pure solvent is very much greater for a solution in benzene than in heptane. For example, a solution of butyl alcohol in benzene, mole fraction alcohol = 0.0525, has a dielectric constant of 2.505 at 20°. The dielectric constant of the sample of benzene used in the solution is 2.294 at 20°, and the increase in dielectric constant due to the alcohol is 2.505 − 2.294 = 0.311. The increase caused by alcohol in heptane at the same concentration and temperature is 2,001 − 1.930 = 0.071, less than one-fourth that in benzene.

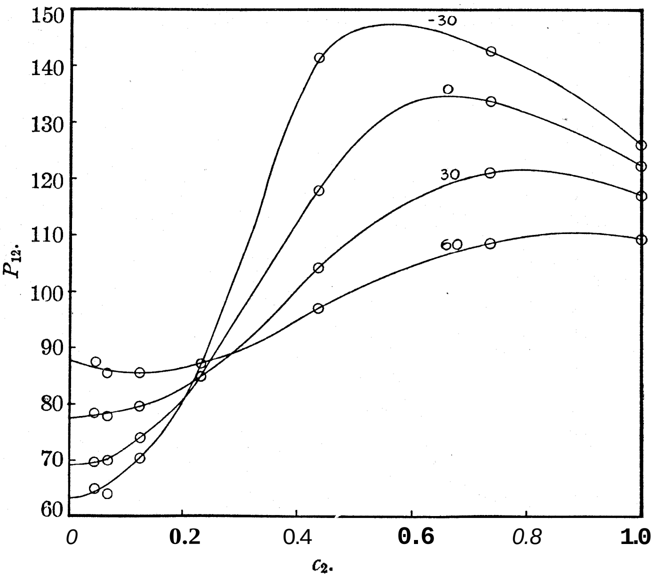

Fig. 5.—Polarizations (P_2) of n-octyl alcohol in solution in heptane.

---

[4] Debye, "Polar Molecules," The Chemical Catalog Company, New York, 1929, p. 47.

The results of Lange show maxima in the curves for propyl, n-butyl and *iso*butyl alcohols in benzene with some irregularities or points of inflection in the dilute solutions, and a curve for dimethylethylcarbinol resembling in form the P_2–c_2 curves for ethyl iodide, while the two maxima appearing in the curve for iso-amyl alcohol may be attributed to the presence of two isomers in the material used for the measurements. The values of P_2 given by Krchma and Williams[5] for methyl and ethyl alcohol in solution in carbon tetrachloride at 25° indicate the presence of a minimum as well as a maximum in the curves. The course of the P_2–c_2 curves for dilute solutions of methyl alcohol in carbon tetrachloride at different temperatures determined by Stranathan[6] shows a slight minimum between 20 and 50° and a probability of intersection in a somewhat more concentrated region, the apparent value of P increasing with rising temperature. Similar curves for ethyl, propyl and iso-amyl alcohols in benzene show no minimum, but indicate the possibility of one if the measurement could be extended below 0°. They also show the usual rise toward a maximum. These results of other investigators are evidently consistent with those of the present paper.

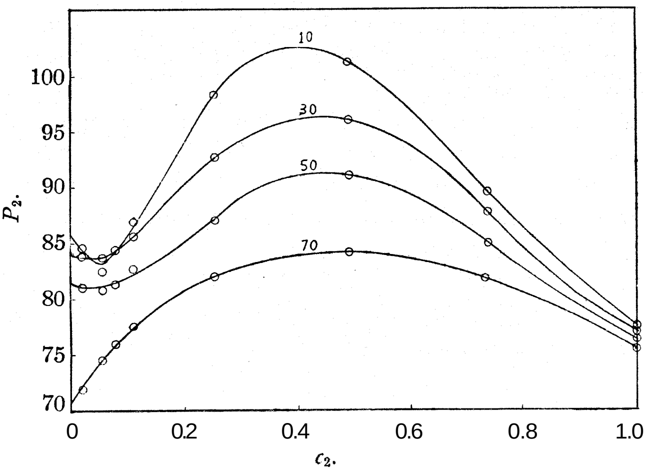

Fig. 6.—Polarizations (P_2) of butyl alcohol in solution in benzene.

In order to study further the effect of the solvent upon the variation of polarization with concentration and temperature, solutions of butyl alcohol in cyclohexane were measured. The values of P_2 check very closely with those obtained in heptane solution, showing that the effect of orientation is the same in these two solvents and somewhat different from that in benzene. It appears that in very dilute solution in heptane,

[6] Stranathan, Phys. *Rev.*, 31,653 (1928).

hexane, cyclohexane and carbon tetrachloride, and at lower temperatures in benzene, there is a tendency toward an orientation which decreases the polarization. With increasing concentration this tendency is soon obscured by an orientation which increases the polarization until, in the more concentrated solutions, a maximum is reached. In the most concentrated solutions the effect of orientation is to decrease the polarization once more. In the benzene, which has a slightly higher dielectric constant to weaken the forces of attraction between the solute molecules, the orientation which diminishes the polarization in the most dilute solutions is too weak at higher temperatures to be detected. It is apparent only in benzene at lower temperatures and in the other solvents at higher temperatures, being obscured or superseded in the latter at lower temperatures by the stronger tendency toward the orientation which increases the polarization. The possible mechanism of these orientations of primary alcohols will be discussed in the next paper of this series in connection with the isomers of the octyl alcohols.

The results on the solutions in benzene may be extrapolated to obtain P,, from which the moment may be calculated. The small temperature range obtainable in benzene prevents an accurate determination of the moment by plotting $P_\infty T$ against T, as was done for ethyl iodide, but b may be obtained with sufficient accuracy as (P, $- MR_D)T$ and used to calculate the values of μ shown in Table IV, which gives the results obtained at different temperatures. The values at 10° are omitted because they are more seriously affected by orientation, as in the heptane solutions.

TABLE IV

ELECTRIC MOMENTS OR ALCOHOLS CALCULATED AT DIFFERENT TEMPERATURES IN BENZENE SOLUTION

	n-C_4H_9OH ($MR_D = 22.2$)			n-$C_8H_{17}OH$ ($MR_D = 40.7$)

303	84.1	18750	1.74	100.7	18200	1.72
313	83.2	19100	1.76	98.0	17900	1.70
323	81.0	19000	1.76	95.7	17800	1.70
333	75.5	17700	1.70	93.3	17500	1.69
343	71.0	16750	1.65	91.4	17400	1.68
		Mean,	1.74		Mean,	1.70

The approximate constancy of the values of (P, $- MR_D)T$ and μ indicate that molecular orientation is slight in the very dilute solutions in benzene. In heptane solution the polarization curves indicate that marked orientation occurs even in the most dilute solutions which can be measured. However, the values of P_2 at the highest temperatures approach closely those observed in benzene solution at the same temperatures, indicating that the effects of orientation are becoming less at high temperature. If the orientation is decreasing with rising temperature, the values of $(P, - MR_{\mathrm{D}})T$ plotted aginst T should approach a constant value. Actually the values for butyl alcohol are found to approach 17,800 asymptotically, from which the moment 1.70×10^{-18} is calculated, in good agreement with that obtained from the solutions in benzene. The **P,** values for ethyl alcohol in hexane and heptane are not as accurate as those of butyl alcohol, but the $(P, - MR_{\mathrm{D}})$T values show an approach to constancy at high temperatures, the value of the moment calculated at 60° being 1.68×10^{-18}, in excellent agreement with the values 1.74×10^{-18} obtained by Stranathan for the liquid and 1.69×10^{-18} by Miles[7] from measurements upon the vapor. The close agreement of these and other values for the moment of ethyl alcohol in the liquid state with that of Miles for the vapor shows the incorrectness of Sanger's[8] value 1.1×10^{-18} for the vapor. These results taken in conjunction with those of the other investigators to whom reference has been made indicate that the moments of the primary alcohols differ from a value of 1.68×10^{-18} by no more than the experimental error. It may, therefore, be concluded that the electric moment of the molecule of a primary alcohol is independent of the length of the carbon chain.

Summary

The dielectric constants and densities of solutions of ethyl iodide in heptane and of ethanol, n-butanol and n-octanol in a number of non-polar liquids have been measured over a wide range of temperature and concentration. A qualitative indication of the anomalous dispersion and absorption for a wave length of 600 meters has been obtained for the pure alcohols and their solutions.

The dielectric polarizations of ethyl iodide give further evidence of the applicability of the Debye equation to liquids in very dilute solution. The polarizations of the alcohols are greatly affected by molecular orientation, being increased in some regions of temperature and concentration and decreased in others. These complicated effects of orientation interfere with the exact application of the Debye equation, but do not prevent the calculation of the electric moments of the molecules.

It is concluded that the electric moment of the molecule of a primary alcohol is independent of the length of the carbon chain.

THE DIELECTRIC POLARIZATION OF LIQUIDS. VII. ISOMERIC OCTYL ALCOHOLS AND MOLECULAR ORIENTATION

BY C. P. SMYTH AND W. N. STOOPS

RECEIVED JULY 1, 1929 PUBLISHED NOVEMBER 8, 1929

As the material in the preceding paper of this series showed the exceedingly complicated effect of molecular orientation upon the polarization of primary alcohols, it seemed important to study the variation of this effect with variation in the position of the hydroxyl group in the molecule and with branching of the carbon chain. The preparation of twenty-two isomers of octyl alcohol by Dr. H. B. Glass, Dr. G. B. Malone and Dr. G. L. Dorough working with Prof. E. Emmet Reid of Johns Hopkins University has given an exceptional opportunity for studying the dependence of dielectric behavior upon these factors. The quantities of material available have not been sufficient to permit of measurements in solution except in the cases of octanol-1, which has been treated in the preceding paper, and 2-methylheptanol-3, but preliminary conclusions may be drawn from the behavior of the pure liquids, taken in conjunction with that of the two very different octyl alcohols in solution, and it is expected that more measurements in solution will be possible in the near future.

The measurements were carried out in the manner described in the previous paper, the dielectric constants being determined with a capacity bridge at a wave length of 600 meters. Table I gives the densities, d, and dielectric constants, ϵ, of solutions of 2-methylheptanol-3 in benzene obtained at 10° intervals by graphical interpolation from measurements made at 10 to 20° intervals, and the polarizations, P_2, of the alcohol calculated from them. The polarizations are shown graphically in Figs. 1 and 2. In the pure alcohols at low temperatures, anomalous dispersion and absorption made it necessary to increase the series resistance in the balancing arm of the bridge, which was used to compensate for conductance in the measuring cell. The introduction of large resistances so reduced the accuracy of the dielectric constant measurements that the values at these low temperatures are sometimes given to only one decimal place in Table II, which also gives the value of the compensating resistance R in ohms as a rough indication of the magnitude of the absorption. A resistance of an ohm or less may be regarded as indicative of a negligible effect and it is only when the resistance approaches 10 ohms or more that the absorption may be regarded as considerable. In the case of 2-methylheptanol-2, the compensating resistance increased somewhat at higher temperatures because of slight decomposition and resulting conductance in the liquid. That the effect of this decomposition on the dielectric constant was negligible was shown by the last value obtained for the liquid after cooling down again to 19.1°. The high resistance required for 5-methylheptanol-2 was the result of rapid decomposition of the liquid, which made the values of ϵ very uncertain. Because of the effect of molecular orientation, the dielectric constants of several of the alcohols decrease with decreasing temperature instead of increasing in accordance

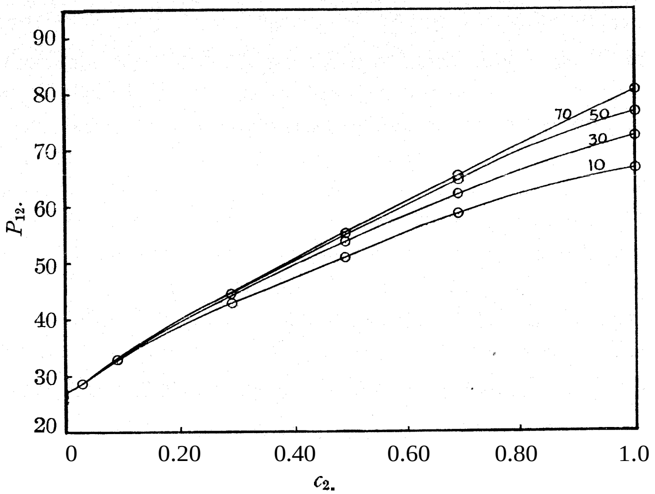

Fig. 1.—Molar polarizations (P_{12}) of benzene-2-methylheptanol-3 mixtures.

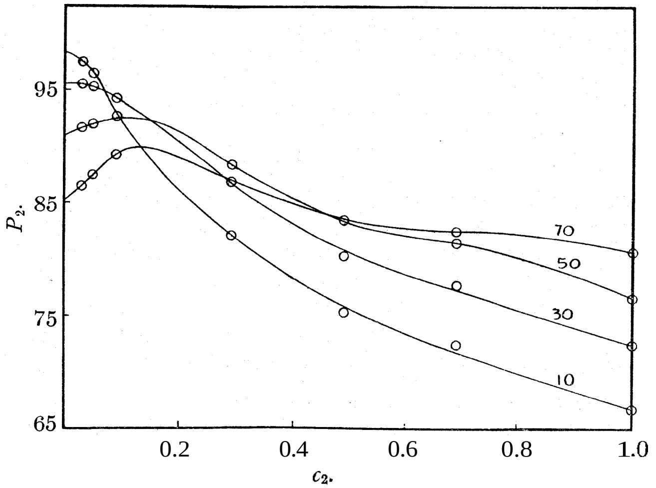

Fig. 2.—Polarizations (P_2) of 2-methylheptanol-3 in solution in benzene.

with the Debye equation, but it is only in a few cases that the measurements have been carried to temperatures at which the anomalous dispersion is sufficient to cause a measurable lowering of dielectric constant with decreasing temperature.

In Table III are given the polarizations of twenty isomeric octyl alcohols which are represented as methylheptanols, the first number at the top of each pair of columns indicating the position of the methyl group and the second that of the hydroxyl. The only methylheptanols omitted are 2-methylheptanol-3, given in Table I, and 5-methylheptanol-2, which decomposed too rapidly in the cell to give reliable results. The densities used in the calculation of the polarizations were obtained by linear extrapolation of the values at 0 and 25° determined by Dr. G. B. Malone. Since the densities of ethyl, n-butyl and n-octyl alcohols are practically linear functions of temperature below 25°, the use of these extrapolated values should not introduce serious error in the polarizations, which

When the polarizations, P_{12}, of the mixtures of 2-methylheptanol-3 in benzene are plotted against c_2, the mole fractions of the alcohol, the curves obtained (Fig. 1) show so little deviation from the theoretical linearity as to suggest that molecular orientation in the mixtures is slight. When P_2, the polarization of the alcohol, is plotted similarly against c_2, curves are obtained (Fig. 2) which, if only one or two concentrations

and one temperature had been measured in the dilute region, would have been extrapolated to $c_2 = 0$ in a shape resembling the P_2–c_2 curves given by ethyl bromide or ethyl iodide, the polarization increasing more and more rapidly up to infinite dilution. Moreover, the value of the moment calculated from the value of P_∞ by subtracting the molar refraction, MR_D, would not have been seriously in error. However, the determination of a number of points in the dilute region makes it clear that the curves possess a maximum or, at least, a tendency toward one, which is much less prominent than in the curves for the primary alcohols in the preceding paper. The curves in the dilute region given on a larger scale in Fig. 3 are linear at the higher temperatures. The values of P_∞ obtained as their intercepts at $c_2 = 0$ are given in Table IV and used to calculate the values of the moment μ shown in the last column. The slight decrease in $(P_\infty - MR_D)T$ and μ with rising temperature may indicate that the effect of orientation is not wholly eliminated by the extrapolation, but the mean value 1.62×10^{-18} is certainly not far from correct.

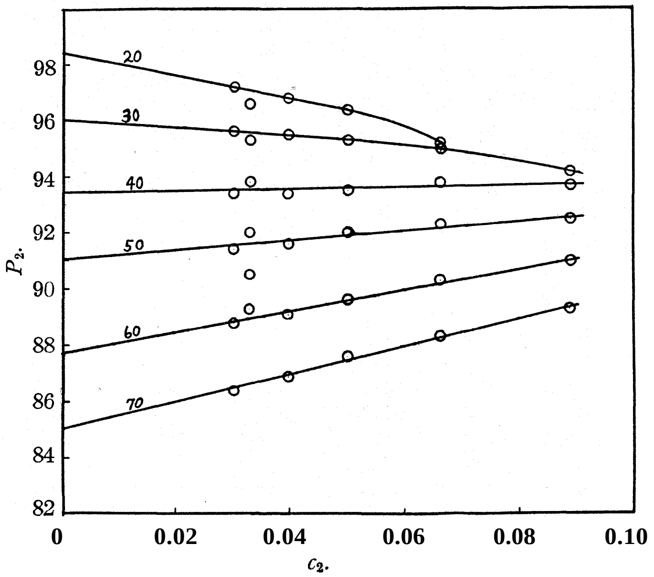

Fig. 3.—Polarizations (P_2) of 2-methylheptanol-3 in benzene solution.

TABLE IV

ELECTRIC MOMENT OF 2-METHYLHEPTANOL-3 CALCULATED AT DIFFERENT TEMPERATURES ($MR_D = 40.5$)

T, °A.	P_∞	$(P_\infty - MR_D)T$	$\mu \times 10^{18}$
293	98.4	16900	1.66
303	96.0	16800	1.65
313	93.5	16600	1.64
323	91.0	16300	1.62
333	87.7	15700	1.60
343	85.0	15300	1.57
		Mean =	1.62

The moment of 2-methylheptanol-3 appears to be slightly lower than that of octanol-1, although the difference may be the result of error caused by molecular orientation. It has been shown that the electric doublet in the alcohol molecules lies at the hydroxyl group and really consists of two doublets, the resultant of which gives the observed moment.[1] This, taken in conjunction with the fact that the moments of the primary alcohols are practically independent of the length of the carbon chain, at least, up to eight carbon atoms, leads one to expect the differences in moment among the octyl alcohols to be small, as in the case of the two just considered. The dielectric constants at 20° of the nine isomeric heptanes, which have no moments, differ from 1.93 by no more than 0.015 and their polarizations, which consist of P_E plus a very small P_A, differ from 34.50 by no more than 0.26.[2] The molar refractions, MR_D of the twenty-two isomeric octyl alcohols determined by Dr. H. B. Glass differ from 40.90 by no more than 1.30. As the polarization is made up of P_M, the contribution of the moment, P_E, the electronic contribution, which differs from MR_D by hardly one unit, and the small P_A, the polarizations of the different isomers should be nearly the same in the absence of molecular orientation. From these values of the moment and the refraction, the polarization at 25° is calculated to be approximately 100 and the dielectric constant, 5.4. Marked deviations from these values are to be attributed to the effect of molecular orientation.

The orienting effect of the molecules of a liquid upon one another must depend not only on the size of their doublets, but also upon the location of the doublet or doublets in the molecule, and upon the mere geometrical shape of the molecule. There are two possible simple orientations which two doublets in adjacent molecules may be expected to adopt relative to one another. The negative end of one doublet may attract the positive end of the other so that the axes of the two doublets fall in line and the two support one another. This will be referred to as an orientation of the first type. The two molecules may associate to act as one, but, if they do not, they should still attract one another and tend to orient more or less with respect to one another so that, when a field is applied externally to measure the dielectric constant, the orientation would be greater than that calculated, and the polarization would be abnormally higher. The shape of the molecules would commonly prevent an exact lining up of the doublets and their axes would, consequently, make an angle of somewhat less than 180° with one another. As this angle decreases, the polarization diminishes and the common effect of orientation is to decrease the polarization instead of increasing it. When the angle between the axes becomes zero, that is, when the doublets are parallel and pointing in opposite directions, the moments cancel one another and the doublet contribution to the polarization becomes zero. This position of

[2] Smyth and Stoops. *ibid.,* 50, 1883 (1928).

the doublets, which will be referred to as the second type of orientation, would result in a polarization for a polar substance differing little from its molar refraction. More than two molecules may line up if the first type of orientation prevails and one may imagine a high polarization built up in this way. The stability of the orientation of one molecule relative to another must depend to some extent upon the forces exerted upon it by the other neighboring molecules. It appears probable, therefore, that, when there is not much difference between the energies of two different orientations, one orientation may change to the other as the mean distance between the dipole molecules changes. Thus, when a polar liquid is dissolved in a non-polar, the orientation of the polar molecules relative to one another may change from one type to another with change in concentration. Of course, when the polar molecules are in very dilute solution and, on the average, far away from one another, they should assume a random orientation unless they actually associate to form a definite complex molecule which is not much dissociated even in the dilute solution, as appears to be the case with acetic acid in benzene solution. Change in temperature also might affect the type of orientation.

The interaction of the dipoles in the majority of liquids decreases the polarization in the manner of the first type of orientation, but hydroxyl doublets lie close to the surface of the molecule and produce a strong localized external field. Molecules of the formula ROH may hypothetically be fitted together in such a way as to arrange the doublets according to either type of orientation. The structure of the associated alcohol molecules proposed by Sidgwick[3] would correspond to the first type, but, on paper at least, a double molecule corresponding to the second type may be equally easily obtained. The somewhat hazardous juggling of these formulas on paper has been treated briefly by one of the authors in *a* paper to appear shortly.

The variation of the polarization of the alcohols with concentration and temperature is so complicated that the correctness of a detailed explanation in terms of orientation cannot be assured, but there are certain obvious facts upon which a possible explanation may be founded. An orientation of the first type must occur to some extent in order to cause the maximum observed in the P_2–c_2 curves. The approximate conformity of the polarizations in the very dilute benzene solutions to the Debye equation and the excellent agreement of the moments obtained from them with the values obtained for several of the alcohols in the vapor state show that in these solutions the alcohol molecules must be nearly all single and oriented practically at random. The approach to the correct values of P_∞ in the heptane solutions at the highest temperatures indi-

cates an existence mainly as single molecules oriented at random in the most dilute solutions at high temperatures in heptane, which, with its lower dielectric constant, has less dissociating power than benzene. With increasing concentration in the very dilute solutions, these single dipole molecules acting upon one another appear to bring about an orientation of the second type, by which the polarization is decreased, as in the case of ethyl iodide and ethyl bromide. As this effect is increased by decreasing temperature, it is so strong even in the very dilute heptane solutions of the primary alcohols as to make the extrapolated values, P,, decrease with decreasing temperature instead of increasing as required by the Debye equation. At the same time, however, molecules are coming together and orienting according to the first type, probably forming aggregates and tending to increase the polarization. At the low temperatures in heptane this effect more than counterbalances the decrease in polarization with increasing concentration in the very dilute solutions, which has just been discussed; at the high temperatures in benzene it does so as well, since here the effect of the single molecules upon one another is small. At the lower temperatures in benzene and the higher in heptane, this latter effect for a short range of concentration more than counterbalances the increase in polarization caused by the formation of the aggregates. Since the formation of aggregates must be greater the lower the temperature, the rate of increase of the polarization with concentration is also greater the lower the temperature and the maximum reached is higher. As the concentration of these aggregates increases, they may act upon one another as the single molecules are supposed to do in the very dilute solutions. This effect opposes the increase in polarization due to the formation of more aggregates with increasing concentration and becomes stronger and stronger so that the polarization passes through a maximum and decreases. The effect is greater the lower the temperature, with the result that the decrease in polarization is greater, the curves intersect, and the polarization of the pure liquid is lower at the lower temperatures in the case of ethyl alcohol. In the case of butyl alcohol, in which the longer carbon chain produces a greater mean separation of the doublets, the polarization of the pure liquid decreases with temperature only at the lower temperatures, and in %-octyl alcohol, where the separation or insulation of the doublets is still greater, it increases with decreasing temperature down to the region of anomalous dispersion. The interaction of the molecular aggregates in producing an effect equivalent to that of the second type of orientation may be treated in terms of the potential energy of the system. The increase of orientation of the first type with increasing concentration should increase the field surrounding the dipole molecules and thus increase the potential energy. If this increase in potential energy is sufficiently great, the resulting instability may cause a change to orientation of the second type with resulting decrease in polarization.

In 2-methylheptanol-3 the hydroxyl doublet is near the middle of a branched carbon chain, which should partially screen it, reduce the external field due to it, and so lessen the chances for orientation of the first type. In the dilute solutions in benzene at high temperatures, the formation of aggregates is sufficient to increase the polarization with increasing concentration over a short range, but, at lower temperatures and at higher concentrations, the orientation of the second type predominates over the rather weak tendency to form aggregates with orientation of the first type. The polarization therefore decreases with decreasing temperature and increasing concentration. So great is the effect that not only the polarization but also the dielectric constant increases with rising temperature, and this is found to be true of all the tertiary and several of the secondary octyl alcohols measured.

In the majority of cases where an abnormally high dielectric constant indicates that the alcohol molecules are probably forming aggregates in an orientation of the first type, the x-ray diffraction measurements of Professor G. W. Stewart, who has very kindly made his results available to us, point to the existence of double molecules, while the x-rays indicate single molecules in the majority of cases in which the low dielectric constant is attributed to the interaction of single molecules in an orientation of the second type. There are exceptions, however, as is true also of the anomalous dispersion and absorption.

The tendency toward anomalous dispersion and absorption is greater in those alcohols which are indicated by high dielectric constants as forming molecular aggregates with orientation of the first type, which would be expected from the dependence of the dispersion and absorption upon the cube of the molecular radius. It is a striking fact that, of the ten methylheptanols which show little or no absorption at the temperatures investigated, eight have either the methyl or the hydroxyl on the third carbon, and the only alcohol with the third carbon occupied by methyl or hydroxyl to show absorption is octanol-3, in which it is less pronounced than in any of the other three octanols. All of these alcohols which show little or no tendency toward dispersion and absorption are indicated by the x-ray measurements as existing as single molecules. 2-Methylheptanol-2 has a low dielectric constant, which at low temperatures above the region of anomalous dispersion decreases with rising temperature and then increases, indicating an orientation of the second type. However, the x-rays indicate existence in double molecules and, in conformity with this, it shows a marked tendency toward anomalous dispersion and absorption. It seems probable, therefore, that the molecules of this substance tend to double up in an orientation of the second type, in which the dipoles oppose one another. It is obvious that our ignorance of the details of the molecular shapes renders impossible the accurate prediction of properties which must be strongly influenced by them, hut it appears to be possible to explain, in qualitative fashion, the complex dielectric behavior of the alcohols on the basis of simple and not unreasonable assumptions.

Summary

The dielectric constants of twenty-two isomeric octyl alcohols have been measured over a wide range of temperature and an indication of their tendency toward anomalous dispersion and absorption for a wave length of 600 meters has been obtained.

Solutions of 2-methylheptanol-3 in benzene have been measured in order to obtain the electric moment of the molecule, which is close to that of *n*-octyl alcohol and the lower alcohols.

The great differences among the dielectric constants of the isomers are attributed to the effects of molecular orientation, which causes the dielectric constants of the tertiary methylheptanols and two of the secondary to increase with rising temperature instead of decreasing in the normal manner.

The explanation of the values of the dielectric constants in terms of molecular orientation is consistent with the observed tendencies toward anomalous dispersion and absorption and with the results of the x-ray diffraction measurements of Stewart.

CHEMICAL KINETICS IN HIGHLY DILUTE SOLUTION. BROMO-ACETATE AND THIOSULFATE IONS IN THE PRESENCE OF SODIUM ION AT 25°

BY VICTOR K. LA MER[1]

RECEIVED AUGUST 20, 1929 PUBLISHED NOVEMBER 8, 1929

It has been shown by Slator[2], as well as others,[3] that reactions of the type

$$BrCH_2COO^- + S_2O_3^{--} \longrightarrow S_2O_3CH_2COO^{--} + Br^- \qquad (1)$$

in which a halogen is replaced by thiosulfate are bimolecular and singularly free from side reactions. Since thiosulfate can be determined with great precision and comparative ease, reactions of this type are particularly well adapted for testing quantitatively, theories of salts catalysis, since the reaction rate can be followed very accurately in the region of high

---

[1] Paper presented at the Minneapolis Meeting of the American Chemical Society, September, 1929.

[2] Slator, J. *Chem. Soc.*, *87,* 485 (1905), and earlier papers.

[3] Krapivin, *Z. physik. Chem., 82,* 439 (1913); see also J. *Chim. Phys., 10, No.* 2, 289 (1912), for data on the chloro-acetate reaction.

dilution. In addition no change in ionic strength occurs during the progress of the reaction. In this paper we shall present preliminary data for the reaction rate in the presence of sodium ion by extending the data of Krapivin[3] at 25° from a concentration of 0.01 N (0.025μ) to concentration as low as 0.0005 N (0.00125μ).

According to Brönsted,[4] a bimolecular reaction follows the scheme

$$\mathrm{A} + \mathrm{B} \rightleftarrows \mathrm{X} \longrightarrow \text{Resultants} \tag{2}$$

where X is a critical collision complex of great instability whose charge Z_X should equal the algebraic sum of the charges on the reactants; namely, $Z_\mathrm{X} = Z_\mathrm{A} + Z_\mathrm{B}$. The general velocity equation for Scheme I becomes

$$\frac{-\mathrm{d}x}{\mathrm{d}t} = k_0 \times C_\mathrm{A} \times C_\mathrm{B} \times \frac{f_\mathrm{A} \times f_\mathrm{B}}{f_\mathrm{X}} \tag{3}$$

where k_0 is the true velocity constant independent of salt effects for a given reference medium and the factor $F_\mathrm{A} = f_\mathrm{A} \times f_\mathrm{B}/f_\mathrm{X}$ takes account of the change in velocity with changing environment.

Inasmuch as *individual ion* activities like f_A and f_B are not accessible to direct measurement owing to uncertainties in liquid junction potentials, and particularly since the very fugitive nature of X itself precludes any attempt to determine the individual behavior of f_X by any of the customary thermodynamic methods, it is evident that the quantitative verification of this theory must be obtained in the region of such highly dilute solutions that the activity coefficients of the individual ions may reasonably be expected to follow the Debye-Hückel[5] limiting law, *i. e.*, they are determined solely by the valence type and the concentration.

Although the colorimetric and conductimetric experiments of Bronsted and Livingston[6] furnish the most striking and most convincing evidence that Equation **3** is correct in principle, yet owing to irregularities in the data one cannot state definitely whether the discrepancies which they observed from the behavior predicted by the Debye limiting law arise primarily from unavoidable experimental errors or whether the deviations really represent specific individual properties which do not vanish completely in the concentration range $\mu = 0.00135$ to 0.01. In fact, the authors are careful to point out that "the character of these deviations is of great interest in the study of chemical kinetics, and ought to be the object of a more careful investigation." When we recognize that the critical complex in their Reaction II is of the tetravalent type, and that the activity coefficients of trivalent ions do not follow the limiting law even qualitatively at dilutions as low as 0.001μ in the presence of divalent ions

of opposite sign, as has been shown in numerous recent publications from this Laboratory,[7] it would not have been surprising if still more conspicuous deviations had intruded. That they do not appears to be due to the fact that the authors' choice of solvents was such that the ions of opposite sign were always of the univalent type.

Before extending our kinetic studies to include the complications of high valence ions of opposite sign, it seemed advisable to prove that Reaction I actually obeys the Debye limiting law when the ion of opposite sign is univalent. While these experiments were in progress, a paper by Kappana,[8] working under the direction of J. C. Ghosh, has appeared in which the same reaction is followed at 30, 40 and 50° for the primary purpose of proving that the temperature coefficient is practically independent of the salt concentration, as predicted by the theories of Debye and of Ghosh and which make it desirable to record our results without further delay.

Experimental

The reaction was followed by mixing equivalent quantities of dilute solutions of sodium thiosulfate and sodium bromo-acetate in a thermostat kept at 25 ± 0.005° and removing appropriate aliquots (10–25 cc.) at definite time intervals. The reaction was stopped by adding excess iodine solution followed by back titration with thiosulfate. In the more dilute solutions (See Tables I and II), where the half time of the reaction is slow (about 55 hours at 0.001 N) and the volume of an appropriate aliquot should be between 100 to 200 cc., it was found more convenient and accurate to measure out the reactants separately in each flask and titrate the entire contents directly with the standard iodine. The normality of the iodine and thiosulfate solutions was changed from 0.01 to 0.001 N to meet the requirements of each experiment. They were carefully restandardized against each other just before starting a run. In Runs 25, 26 and 27 it was found that the titer of the very dilute thiosulfate solutions changed slightly during the two and one-half day period of observation, and the initial value for a was taken as the mean value, since it is reasonable to suppose that the same change was occurring in the reaction flask as in the absence of bromo-acetate.

The sodium bromo-acetate solutions for each run were made by weighing into a volumetric flask an appropriate amount of Kahlbaum's bromoacetic acid, kept over phosphorus pentoxide. Boiled water was added and the contents neutralized with 0.2 N sodium hydroxide to a faint pink color with phenolphthalein. This procedure gives a double check upon

the concentration of bromo-acetate. Unless the weight of bromo-acetic acid and the alkali necessary to neutralize agreed to 0.1%, the mixture was made up again. Carefully performed experiments showed that the titration value of the acid was exactly that given by the formula. The purity was further tested by mixing 25 cc. of approximately 0.1 N bromo-acetic acid, neutralizing and then adding 25 cc. of 0.3020 N thiosulfate. Under these conditions the reaction is complete in twenty-four hours. The ratios of the equivalents of thiosulfate consumed to equivalents of sodium hydroxide to titrate the acid in five experiments were 0.997, 1.014, 1.000, 1.007 and 0.957, or an average of 1.005 (calcd., 1.000).

We emphasize the matter of purity since our first preparation of bromo-acetic acid, furnished by a well-known manufacturer, contained only 90% of the theoretical amount of replaceable bromine although the sodium hydroxide titration was almost 100%.

Moisture was in some way present when the batch was bottled and slow hydrolysis to glycolic acid occurred on storage. Although this hydrolytic reaction is very slow in neutral solution and does not affect our results, it is sufficiently rapid in acid solutions that one cannot make up stock solutions of bromo-acetic acid as is customary in kinetic technique and expect to use them over any considerable period of time without obtaining erroneous results.

The chief source of error seems to reside in the determination of the starch–iodide end-point. Titrations were made rapidly to avoid oxygen error, which should be slight in neutral solution. The effect of access of air during the course of the reaction deserves further study.

Detailed data are given only for the extremely dilute experiments. The probable errors are the arithmetic mean of the individual k values. All volumetric glassware was calibrated and the two stop watches when used over a period of twenty-four hours were checked against jeweler's time.

Discussion

The data of Table II are plotted as crosses in Fig. 1, the upper curve being plotted to a scale to take in Krapivin's data (circles), while the lower curve emphasizes the data in dilute solution.

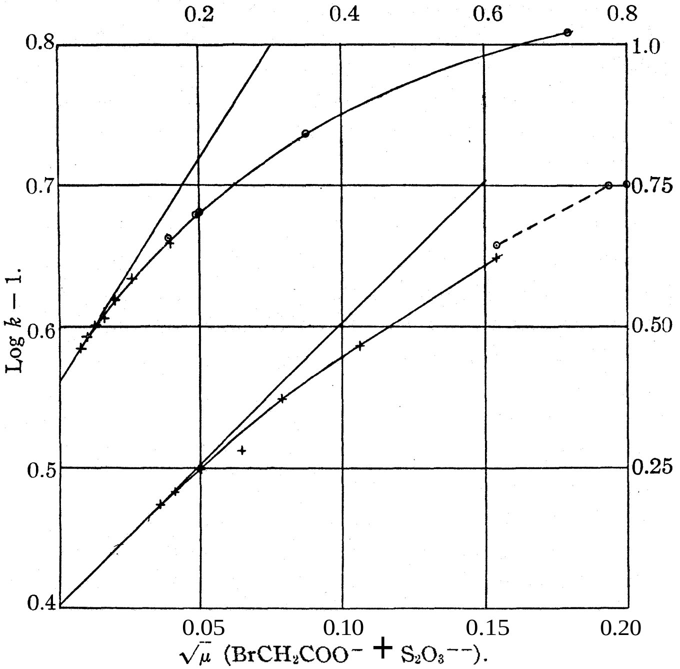
Introducing the Debye–Hückel limiting law, $\log_{10} f_i = -0.50 Z_i^2 \sqrt{\mu}$ in Equation 2, one gets

$$\log k_{\text{obs.}} = \log k_0 + Z_A Z_B \sqrt{\mu} \tag{4}$$

so that on plotting $\log k_{\text{obs.}}$ against the square root of the ionic strength, the data approach a straight line having a slope $Z_A Z_B = (-2)(-1) = +2$, with an intercept leading to a value of $\log k_0 = 0.42$ or $k_0 = 0.263$.

Our results when combined with those of Krapivin show clearly that although the slope in the region 0.35μ is only one-fourth that predicted by (4), the slope of the experimental curve continuously approaches and finally reaches the limiting value at $\mu \leqq 0.0025$ or $\sqrt{\mu}$ 6 0.05. The manner of approach is also what would be expected from the equation containing the factor of ion size in the first approximation of the Poisson–Boltzmann equation (ref. 7).

The data lend no support whatsoever to the theory of Soper,[9] that the theoretical slope should be two-thirds the value Z_AZ_B. Soper's theory[9] is not only unsound from both a thermodynamic and kinetic point of view, but in developing it the author is obliged to ignore all of the accurate solubility data supporting the Debye theory that have accumulated. The apparent agreement with the two-thirds slope which he obtains in many cases is fortuitous and results from a misunderstanding of the range of applicability of the limiting law. Kappana has also obtained data at concentrations as low as 0.0025μ. His data are sensibly parallel to ours; however, he draws a Debye limiting slope through his data at 30° up to 0.015μ, followed at this point by an abrupt change in slope to a value approximately two-thirds of the theoretical. On plotting his data at GO" we find that the transition is not abrupt but as smooth as the accuracy



⊙, Krapivin; +, La Mer.

Fig. 1.

[9] Soper, J. Phys. Chem., 31, 1790 (1927); **32**, 67 (1928).

of the data warrant. We feel confident that some of the data at 30° must be in error.

It is of interest to note that in Krapivin's data at 0.01 N the addition of 0.01 N sodium bromide, iodide or nitrate produced identical effects, as did the further addition of 0.01 *N* bromo-acetate, *i. e.*, k increased from 0.455 to 0.502–0.505. This is in agreement with the principle of specific interaction, (see ref. 7b). On the other hand, addition of 0.01 N sodium thiosulfate gave a value of k = 0.504, while 0.01 N sodium sulfate increased *k* to 0.516, even though the ionic strength is the same as in the presence of sodium thiosulfate.

Our experiments are being continued from the standpoint of specific salt effects and the effect of the relative position of the charge and the bromine atom upon the velocity.

The assistance given by Mr. R. W. Fessenden is gratefully acknowledged.

Summary and Conclusions

The velocity data of the reaction $BrCH_2COO^- + S_2O_3{}^{--} \longrightarrow S_2O_3$-$CH_2COO^{--} + Br^-$ studied by Krapivin for the sodium salts at moderate dilutions have been extended from 0.01 N to 0.0005 N. The data strongly support Bronsted's theory of reaction velocity. In the presence of sodium ions the limiting slope predicted from the Debye theory holds from 0.001 N (0.0025~) down to the lowest concentration studied. At higher concentrations the slope falls off, reaching a value of one-fourth the theoretical value at 0.35~. The experiments are being continued.

NEW YORK, N. Y.

NOTES

A Simple Laboratory Vacuum Regulator.—Among various methods of maintaining a constant temperature in the range from room temperature to nearly red heat, the vapor-bath with boiling liquid under constant, automatically controlled, reduced pressure is perhaps the most convenient and satisfactory. The device described in this note for controlling the degree of vacuum and thus the temperature is not new in principle, but its simplicity and utility make it available to any chemical laboratory. A device based upon similar principles has recently been described.[1] The chief difference between the two devices consists in the use of a glass stopcock in the present instance instead of the combination of a rubber stopper and capillary tube to control the ingress of air.

The essential features of the apparatus are shown in Fig. 1. The mercury in the manometer AA' is adjusted by means of the leveling bottle F to such a position that when contact is broken with the platinum wire sealed into the closed arm A, the height h corresponds to the degree of

---

[1] S. P. Miller and P. V. McKinney, *Ind. Eng. Chem.*, **20**, 552 (1928).

vacuum desired. Upon closing the electrical switch S, current flows from a 6-volt storage battery through the magnet coils of an ordinary door-bell buzzer, the terminals of which are connected directly to the binding posts so that the vibrator operates like the armature of a relay. The extended armature is attached at right angles to an extension of the stopcock handle in such a way that magnetization of the coils closes the stopcock C, allowing gas to be withdrawn from the condenser E and boiling tube G by means of the service vacuum or any other suitable source of suction. When the pressure in the system falls below the height h, the electrical circuit is broken, the armature is released and the stopcock opens by spring action of the relay. The influx of the air then increases the pressure until the electrical circuit is again closed, when the cycle is repeated. The manometer AA' is constructed of two wide tubes connected by a narrow tube to minimize surges.

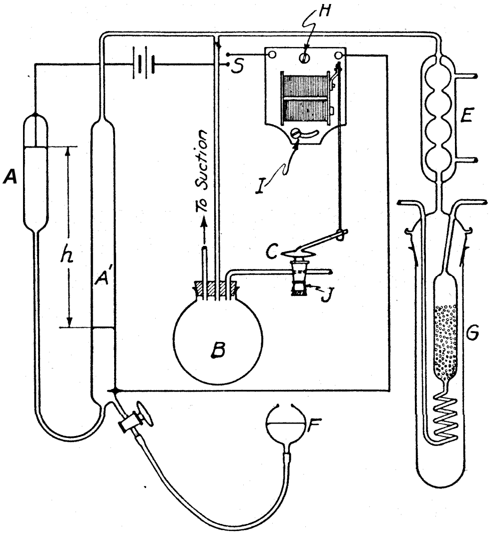

Fig. 1.

An essential feature of the automatically operated stopcock is the attachment of a short glass tube J to the small end of the stopcock barrel with de Khotinsky cement. This tube is slightly tapered and is fitted with a small cork which presses against the end of the stopcock plug to prevent the latter from settling tightly into the barrel. The stopcock is lubricated thoroughly with vaseline or a light stopcock grease. The stopcock handle may easily be extended by sealing a piece of 3-mm. diameter glass rod or tubing to it with de Khotinsky cement. A 3- or 4-liter flask B in the system serves as capacity to minimize surges. The pressure as observed on an open manometer attached to the system was constant to within less than 1 mm. of mercury at all pressures ranging from slightly less than atmospheric down to 1 cm. of mercury.

A slight adjustment of the degree of opening of the stopcock C is required for different pressures. This is accomplished by moving the relay about the screw H until the proper position with respect to the stopcock is found and then securing it in position by means of the screw I. The bore of the stopcock should be small, 1 mm. or less, so that only a slight movement entirely opens or closes it.

This device has been used continuously day and night for several months, interrupting the operation only over week ends, with only a very occasional failure, which has invariably been due to the battery running down. This device may readily be adapted to the control of vacuum distillations and other work in which a constant vacuum is desired.

Automatic Cut-off Device for a Gas Fired Laboratory Mercury Still.— The distillation of mercury is an operation that is usually carried out in connection with other work and the still should therefore be so designed as to require the minimum of attention. The type of glass still described by Dennis,[1] with a ring type gas burner, gives excellent results but has the disadvantage that if care is not exercised to shut off the flame when the mercury gets low in the boiler, destruction of the still results. The sketch shows diagrammatically an automatic cut-off device which enables the operator to start the still and, except for an occasional filling, then go about other business and forget that it is going.

The still itself is the usual vacuum type, consisting of a boiling vessel M and condenser L, with a 2-mm. bore capillary tube outlet of slightly greater length than the barometric column. Drops of mercury falling from the condenser into the capillary tube capture threads of gas ahead of them and thus maintain the high vacuum in the still by Sprengel pump action.[2] The mercury to be distilled is poured into the open tube A and flows through B into the still-head M. The flow stops when the difference between the

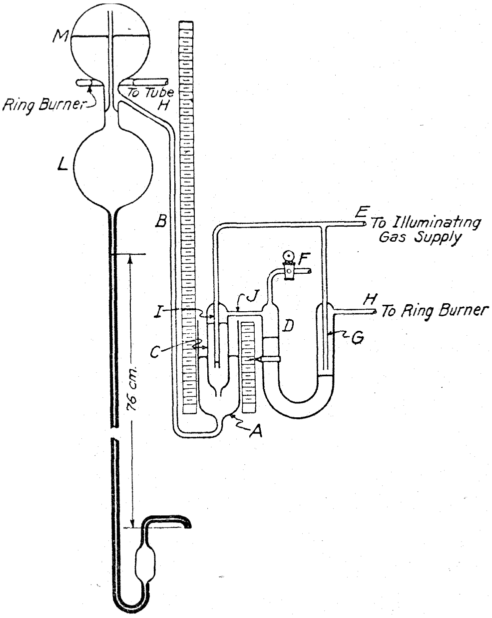

Fig. 1.

mercury levels in the still head and in **A** is equal to the prevailing barometric pressure less any slight pressure in the still. This difference in levels is maintained as the mercury distils, the level in A falling at the same rate as that in the still-head. Advantage is taken of this fact to operate the automatic cut-off device.

To start the still a slight suction is applied at F to displace the mercury in D, thus unsealing the tube G. The stopcock F is then closed so as to maintain this condition. Gas may now flow through EGH to the ring burner. The gas pressure is also communicated to I, which is immersed in the mercury in the filling tube A. As distillation proceeds, the mercury levels in M, A, C and I gradually fall until the effective seal on the tube I becomes less than that of the gas pressure within I. Gas then escapes through the mercury seal into CJD. The mercury in the U-tube is thus displaced so as to seal the open end of tube G and stop the gas flow to the burner. The tube C is extended below the open end of I sufficiently to prevent gas bubbling out through the mercury in A when the still-head cools.

The entire cut-off device is mounted to the frame carrying the still by means of a clamp (not shown) and is connected through H to the ring burner and through E to the gas supply by means of rubber tubing. The device may therefore be moved up or down to vary the depth of immersion of the tube C in the mercury in A. The depth of immersion is so adjusted that sufficient mercury remains in the still-head at the time of cut-off to cover the glass surface exposed to the flame. The level of the mercury in the still will, with a given setting of the device, vary with the mercury vapor pressure in the still-head and with the barometric pressure. The former may be held constant through the use of a constant pressure gasometer or other device to insure approximately the same rate of vaporization in the still. The latter may be corrected for if necessary by adjusting the depth of immersion of C. This may be facilitated by the use of the scale and pointer arrangement shown in the sketch. The required depth of immersion is first determined by actual operation. The still is partly filled with mercury and started with the device immersed to its full extent. When the mercury level in M reaches the cut-off position, the level of mercury in A is marked and the cut-off device slowly raised until cut-off occurs. The pointer is then fastened rigidly to D so as to coincide with the mark on A. A millimeter scale carrying the notations **720** to 780 mm. to include the normal range of barometric pressures is then mounted on A so that the pointer indicates the barometric pressure at the time of adjustment. Thereafter, in order to have the cut-off occur at the same position in M, it is only necessary to raise or lower the device until the pointer indicates the prevailing atmospheric pressure. A second scale may be attached from which the barometric pressure may be read utilizing the mercury levels in the still-head and filling tube before starting the still. This latter method has the added advantage that any slight pressure in the still is automatically compensated for.

Adaptation of the Diphenylcarbazide Test for Mercury to the Scheme of Qualitative Analysis.—The diphenylcarbazide test for mercury is very delicate, detecting 0.0005 mg. per 2 cc., but its use so far has been restricted to practically neutral solutions.[1]

However, in the confirmation of mercury, both in Group I and in Group II, the solutions are decidedly acid. It has been found that by adding an excess of solid sodium carbonate to such solutions, the presence of considerably less than 0.1 mg. of mercury per cc. can be detected very readily. The procedure outlined below has been used for the past two years with marked success in qualitative analysis courses in this University.

The mercury precipitate in Group I is dissolved in aqua regia, that of Group II is dissolved in hydrochloric acid and sodium chlorate. In either case the solution is evaporated to a volume of about 1 cc., placed in a test-tube and diluted with 5 to 6 cc. of water. Four to eight drops of a saturated alcoholic solution of diphenylcarbazide is added and a large excess of solid sodium carbonate is gradually dropped into the solution. When mercury is present, the foam produced on neutralization assumes a blue tinge, and after the addition of an excess of carbonate the entire solution turns blue.

At the conclusion of the experiment the solution should either be blue or orange to pink in color. If the solution remains colorless, it indicates that the diphenylcarbazide solution has deteriorated.

Freshly prepared diphenylcarbazide solution is colorless, but soon develops a pink to red color. This color does not seem to affect its use for the test. However, on standing for several weeks it finally fails to give a blue color in the presence of mercuric salts. Aqua regia does not interfere provided the test is completed soon after the addition of the diphenylcarbazide solution. If the test solution containing aqua regia is allowed to stand for some hours after the addition of diphenylcarbazide, it will fail to develop any color when an excess of sodium carbonate is added.

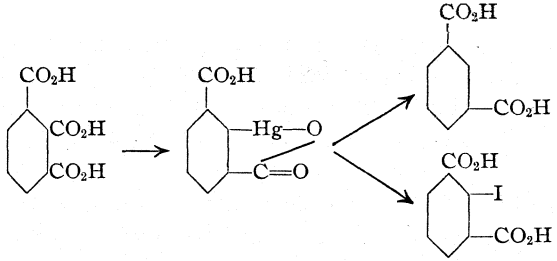
THE MERCURATION OF HEMIMELLITIC ACID

BY FRANK C. WHITMORE AND R. P. PERKINS

RECEIVED JANUARY 15, 1929 PUBLISHED NOVEMBER 8, 1929

Since the treatment of 3-nitrophthalic acid with mercuric acetate[1] gives over 90% of the calculated amount of the product in which the 2-carboxyl group is replaced by mercury, it seemed desirable to study the effect of other groups on the replacement of one of two ortho carboxyl groups. The simplest case of this kind is presented by hemimellitic acid (benzene-1,2,3-tricarboxylic acid). It was found that the 2-carboxyl is replaced by mercury. No evidence of any replacement of the 1- or 3-carboxyl was found. The structure of the mercury compound was determined by replacing the mercury by hydrogen to give isophthalic acid and by iodine to give 2-iodo-isophthalic acid.



The best method of obtaining the 2-halogen isophthalic acids is undoubtedly by this procedure, starting with hemimellitic acid prepared from acenaphthene.

Experimental

Hemimellitic acid was prepared by a modification-of the method of Graebe and Leonhardt.[2] From 100 g. of naphthalic anhydride was obtained 46 g. of hemimellitic acid (44% yield), m. p. 201–203° with decomposition to form the anhydride.

A method is being developed in this Laboratory for the preparation of hemimellitic acid by the direct oxidation of acenaphthene.

A solution of 40 g. (0.2 mole) of hemimellitic anhydride in 110 cc. of 6 N sodium

---

[2] Graebe and Leonhardt, *Ann.*, 290, 218 (1896).

hydroxide and 170 cc. of water was treated with a solution of 43.3 g. (0.2 mole) of mercuric oxide in 40 cc. of glacial acetic acid and 70 cc. of water and refluxed for sixteen hours. At the end of that time no more carbon dioxide was evolved and the precipitate which had formed was soluble in sodium hydroxide. The product was separated by filtration, washed and dried to constant weight at 105°; weight, 70.2 g. of anhydro-2-hydroxymercuri-isophthalic acid (96% yield).

Anal. Calcd. for $C_8H_4O_4Hg$: Hg, 55.0. Found: 55.0.

Ten grams of the mercury compound was dissolved in dilute sodium hydroxide, filtered from a slight residue and refluxed for two hours with enough excess hydrochloric acid to make the solution about 6 *N* in hydrochloric acid. The isophthalic acid obtained weighed 3.6 g. (79% yield). It sublimed without melting or decomposing. The dimethyl ester prepared by means of thionyl chloride and methanol melted at 67–68°.

Ten grams of the mercury compound was powdered and dissolved in 75 cc. of 20% potassium iodide solution. To this was added 7.5 g. of iodine. After standing for one hour, the small excess of iodine was removed by concentrated sodium thiosulfate solution. The mixture was acidified and cooled. Highly twined colorless needles separated almost immediately; weight of 2-iodo-isophthalic acid, 5.9 g. (73% yield), m. p. 241.5–243°. Crystallization from water raised the melting point to 243–244°.[3] Treatment of the acid with thionyl chloride and methanol gave the dimethyl ester, m. p. 49.5–50.50°.[4]

Summary

1. Hemimellitic acid reacts with mercuric acetate with the replacement of the 2-carboxyl by mercury.

2. Treatment of this mercury compound with halogens gives the best method of preparing 2-halogenated isophthalic acids.

THE PYROLYSIS OF HYDROCARBONS: NORMAL-BUTANE AND ISOBUTANE[1]

BY CHARLES D. HURD[2] AND L. U. SPENCE[3]

RECEIVED JANUARY 21, 1929 PUBLISHED NOVEMBER 8, 1929

The present investigation with *n*- and isobutane inaugurates a series of studies dealing with the behavior of individual hydrocarbons at high

---

[3] The melting point of this substance is given as 236–238° by James, Kenner and Stubbings, J. *Chem. Soc.*, 117,774 (1920).

temperatures. The evidence which was obtained with n-butane points to two equations for the representation of the major part of the pyrolysis

$$CH_3CH_2CH_2CH_3 \longrightarrow CH_4 + CH_3CH{=}CH_2$$
$$CH_3CH_2CH_2CH_3 \longrightarrow CH_3CH_3 + CH_2{=}CH_2$$

At 600° the first of these appears to proceed to the extent of about **55%** and the second to 40%. Dehydrogenation reactions into butene or butadiene appear to represent less than **5%** of the total. These results were obtained by exposing the hydrocarbon at 600° for thirty seconds or less by a single passage through a pyrex tube. The rate of flow was about 6 cc. per second, and about one-fifth of the butane suffered decomposition. Similar results were obtained when a temperature of 700° was used. The chief points of difference are these. The extent of the decomposition was 75% instead of 22%. Indicative of secondary reactions, the propylene–ethylene ratio changed so that ethylene was somewhat in excess. This is reasonable since propylene is known[4] to decompose more readily than ethylene, and since ethane is known to pyrolyze into ethylene.

In similar experiments isobutane differed noticeably from n-butane in giving rise to a large production of hydrogen. Except for the considerable excess of methane, which is a characteristic feature, the primary decomposition of isobutane at 600° may be represented by the equations

$$(CH_3)_3CH \longrightarrow H_2 + (CH_3)_2C{=}CH_2$$
$$(CH_3)_3CH \longrightarrow CH_4 + CH_3CH{=}CH_2$$

Since 38.5% of the unsaturated hydrocarbons (formed at 600°) is propylene **and** 50.8% is isobutylene, it would appear superficially that the first reaction takes place to the extent of **51%** and the second, **39%.** However, since the methane–propylene ratio is over 2:1, and since ethylene is present in appreciable quantities, quantities in fact which become rather formidable at 700°, it may be fortuitous that the hydrogen–*iso*butylene ratio is approximately 1:1. In the absence of evidence to the contrary, these facts may be explained by postulating that the hydrogen which was momentarily liberated failed to appear entirely as molecular hydrogen. Instead, it may have caused scission of some of the isobutylene into "methane + propylene," and also have converted part of the propylene into "methane + ethylene." In a subsequent paper we will show that at 700" isobutylene very definitely consumes large quantities of hydrogen with the consequent production of the anticipated excess of methane.

The general course of pyrolysis of isobutane is the same at 700° as at 600°, but the extent of the change was found to be considerably greater and the secondary reactions assumed greater prominence. Whereas more isobutylene than propylene was noted at 600°, the reverse was true at 700°. Small amounts of a liquid tar were formed at 700°, but in

---

[4] Frey and Smith, *Ind. Eng. Chem.*, **20,950 (1928).**

quantities insufficient for identification. Experiments (unpublished data) with olefins lead us to believe that this tar formation was caused by the *iso*butylene or propylene formed in the reaction. As stated above, ethylene was formed in fair amounts at 700°.

It is believed that the results of this study may be interpreted satisfactorily by assuming an initial scission of the saturated hydrocarbons into radials. Such splitting may occur at C–C or C–H bonds. If this is the case, scission with n-butane is largely of the C–C type, division occurring at the terminal position slightly more readily than at the central position. Although rupture of the C–C bond is a large factor in the pyrolysis of isobutane, the C–H type of scission predominates, possibly because of the low attraction which the tertiary butyl radical is known to have for electrons.

Since this work on the butanes has been completed, a paper by Pease[6] has appeared which deals with the decomposition of the butanes as well as of ethane and propane. Pease approached the problem from a different point of view. His chief concern was the rate of dissociation of the various hydrocarbons, rather than the mechanism of the reaction. In his work the individual hydrocarbons which were formed in the pyrolysis were, for the most part, not identified. It was practically assumed, for example, that methane was the only saturated hydrocarbon which was formed, and no effort was made to identify the individual unsaturated hydrocarbons. It is with the latter problem in particular that this paper deals.

Two methods were developed for the analysis of the unsaturated content of the gaseous hydrocarbon mixtures which were produced. In one the olefins were converted in quantity into their bromide derivatives and then, if possible, fractionated into pure fractions or into two-component mixtures. Each such fraction was analyzed by the index of refraction method. For this work it was necessary to construct index of refraction curves for reference from synthetic mixtures of ethylene–propylene bromides, and of propylene-isobutylene bromides.

Another analytical method, better than the first, was developed. In this each of the gaseous unsaturated hydrocarbons was directly absorbed in a modified Orsat apparatus. Acetylene and methylacetylene were dissolved in alkaline potassium iodomercurate[6] solution, following which the remaining unsaturated hydrocarbons were removed in turn by sulfuric acid of progressively greater concentration. This is essentially the method suggested by Dobryanskii,[7] but critical studies were carried out

[5] Pease, This Journal, 50, 1779 (1928).

[6] Lebeau and Damiens, *Ann. chim.*, 8,221 (1917).

[7] Dobryanskii, *Neftyanoe Khozyaistvo*, 9, 565 (1925); *Chem. Zentr.*, I, *97*, 2220 (1926); *Petroleum Domain*, 565 (1925); *C. A.*, 20, 1576 (1926).

with it to adapt it to our needs. Dobryanskii suggested 63–64% sulfuric acid as the proper solvent for isobutylene; 83–84% acid for propylene; and 100–102% acid for ethylene. We obtained more satisfactory results with the acid concentrations, respectively, of 62.4, 82.5 and 100% acid which contained 8% of sulfur trioxide. We found allene to be nearly insoluble in the isobutylene pipet, but readily soluble in the propylene pipet. Although the absorption method, for obvious reasons of convenience, economy and precision, is superior to the bromide method, it must be used advisedly, since more than one hydrocarbon in a hydrocarbon mixture may be appreciably dissolved in the reagents employed.

Experimental Part

Apparatus.—A flow method was used. The gaseous hydrocarbon was passed directly from the tank through a wet test meter, then through a differential pressure flowmeter of the capillary type, was dried by calcium chloride and passed into the reaction tube. This tube was of pyrex, one inch in diameter, and was heated over 30 inches of its length in an unsegmented electric tube furnace. The furnace was supported in a vertical position to facilitate the escape of any liquid products from the heated portions. Butane was passed through the tube at a controlled rate of flow, and the effluent gases were passed through cooling coils at 0° to remove liquid products. The gaseous products were then analyzed.

Gas Analysis.—A modified Orsat gas analysis apparatus was constructed and the values for carbon dioxide, oxygen, total unsaturated hydrocarbons, hydrogen, carbon monoxide and saturated hydrocarbons were determined in the usual way. Presumably methane and isobutane are the only saturated hydrocarbons present in the mixture from isobutane. Combustion analysis is satisfactory for such a mixture. From n-butane, however, it is likely that three saturated hydrocarbons are present, methane, ethane and n-butane; combustion data give the average molecular weight of such a mixture. By assuming that ethane and ethylene are formed in equivalent amounts and that methane and propylene are also, the relative amounts of methane, ethane and butane may be estimated.

To analyze the individual unsaturated hydrocarbons, 3 pipets filled with glass tubes were incorporated in the apparatus. They were for acetylene, isobutylene and propylene[8] in turn, after which ethylene was removed with fuming sulfuric acid (8% SO_3). The acetylene reagent was made up from 500 g. of potassium iodide, 200 g. of mercuric chloride and 40 g. of sodium hydroxide, and diluted with water to one liter. The *iso*-butylene pipet contained 62.4% sulfuric acid and the propylene pipet 82.4% sulfuric acid. The ethylene reagent was prepared by adding 120 g. of sulfur trioxide to 200 cc. of 95% sulfuric acid. The sequence of the analysis is: carbon dioxide, acetylenes, *iso*-butylene, propylene, ethylene, oxygen, hydrogen and carbon monoxide, saturated hydrocarbons. In the sulfuric acid pipets the sample of gas was left in contact with the acid for two minutes, then withdrawn, and the process repeated until constant volume was attained.

With sulfuric acid of 60.7% strength, the rate of solution of diluted isobutylene (mixed with 70% air) was very slow. By changing the acid strength to 62.4%, *iso*-

---

[8] Allene, butene-1 and butene-2 are also rapidly absorbed in the propylene pipet. These three gases were shown, however, to comprise less than 2% of the total gases. Butadiene, also present in traces, would be taken up in this pipet and to some extent also in the isobutylene pipet.

butylene dissolved rapidly. About twenty to thirty minutes was required for complete absorption and most of this time was taken to remove the last 2 cc. of isobutylene from the 70 cc. of air. Propylene (31% by volume, mixed with air) was not dissolved by this 62.4% acid in a total contact time of ten minutes, but pure propylene was absorbed at the slow rate of 0.03–0.08 cc. per minute of contact. Since the gases from a thermal decomposition will never produce undiluted propylene, this becomes a separation of high accuracy. No loss of ethylene could be detected in a total contact time of twelve minutes with either 62.4 or 82.4% sulfuric acid, but a solution of 84.4% acid absorbed it at a rate of about 0.02 cc. per minute. Since propylene was rapidly dissolved in 82.4% acid, this concentration was adopted. The time of complete absorption far a mixture with air (45% C_3H_6) was twenty to twenty-five minutes. Allene, $CH_2{=}C{=}CH_2$, was found to be nearly insoluble in 62.4% sulfuric acid when the allene was of 40% concentration (60% air). It was quickly absorbed by 82.4% acid, however.

In the absorption of ethylene of 75% concentration (25% air) by fuming sulfuric acid (8% SO_3), completion was reached after seven two-minute passes. The final reading was preceded by an alkaline wash. Both butanes interfere in this analysis, but since they appear to be absorbed at a constant rate, a correction may be made for this effect. A measured sample of isobutane was kept in the "ethylene pipet" for two minutes. Then it was transferred to the potassium hydroxide pipet and the volume again read. Six consecutive passes gave a mean loss of 0.71 cc. for a mean volume of 92.5 cc. With *n*-butane, the loss was about 0.6 cc. In mixtures of ethylene with butane, these values obviously depend on the residual volume of butane, but one or two two-minute passes after final absorption of the ethylene will indicate the "constant" for the experiment in question. Correction may then be made.

Refractive Indices of Synthetic Mixtures of Olefin Bromides,—Ethylene brotnide, propylene bromide and isobutylene bromide were purified by vacuum distillation. The svnthetic mixtures used for these determinations were ethylene–propylene bromides and propylene–*iso*butylene bromides. The refractive indices were determined with a water-jacketed Abbé refractometer equipped with a standardized thermometer. The results are listed in Table I.

TABLE I

67.80	32.20	1.5313	0.00	100.0	1.5118
89.20	10.80	1.5356			
100.00	0.00	1.5379			

Temperature Measurements.—The temperature of the reaction was measured by a chromel-alumel thermocouple which was within the reaction tube and which was protected by a thin pyrex tube. This temperature was recorded and automatically controlled by a Leeds and Northrup potentiometer type recorder-controller. The usual sensitivity of this system was ±2°, but with a carbon coating on the protecting tube there was a lag, the extreme case of which was ±8°.

Source and Purity of the Butanes.—Cylinders of the liquefied gases were purchased from the Carbide and Carbon Chemicals Corporation; high purity was claimed for them; combustion analysis showed them to be fairly pure. Analysis of n-butane gave values of 4.04 and 3.96 for n in C_nH_{2n+2}; isobutane gave values of 3.93, 3.92 and 3.97. These are all sufficiently near the theoretical value of 4.00 to be satisfactory. The n-butane contained traces of pentane and 1–2% of isobutane as impurities. *Iso*-butane contained a small amount of propane and 1–2% of n-butane as impurities.

Increase in Volume, Percentage Decomposition, Rates of Decomposition.—In the preliminary experiments the influence of the temperature and the rate of flow of the hydrocarbon into the tube was studied and the progress of the reaction was followed by analyzing the gases for total unsaturated hydrocarbons and hydrogen. The contact time was calculated by dividing the volume of the heated portion of the tube by the mean volume of gas entering and leaving the tube, this mean volume being corrected to the temperature of the tube.

The primary pyrolytic reactions of n-butane are: (1) into $C_3H_6 + CH_4$, (2) into $C_2H_4 + C_2H_6$, (3) into $C_4H_8 + H_2$. The primary changes of isobutane are: (1) into $C_3H_6 + CH_4$, (2) into *iso*-$C_4H_8 + H_2$. Assuming no secondary changes into acetylene, allene, butadiene, etc., it is evident that from 100 volumes of n- or isobutane there

should be produced ((100 − P) volumes of C_4H_{10}) + (P volumes of C_2H_6, CH_4 and H_2) + (P volumes of olefins). The sum of these three quantities represents the total new volume, or V. Thus

$$V = (100 - P) + P + P = 100 + P$$

From this the percentage by volume of olefins, U, in the escaping gas is related to the percentage decomposition, P, of the butane as follows

$$U = \frac{100P}{100 + P} \qquad P = \frac{100U}{100 - U}$$

Experimentally it was determined that the agreement with both butanes was fair at 600°, but the rather wide divergence at 700" indicated considerable secondary decomposition. In these measurements of volume increase, the volumes were measured roughly in bottles of 8-liter capacity and calibrated in 100-cc. divisions. Table II lists a few of the results.

The decomposition of n-butane showed a rapid increase in rate between 500 and 600°. The rates of decomposition at 600" of n- and of isobutane are of the same order of magnitude, as is apparent from Table III. The data also show strikingly the limited extent of the dehydrogenation reaction with n-butane and the importance of it with isobutane, which at 600° is seen to represent 36–47% of the total reaction.

The more representative data for two representative runs at 600° and for two at 700° with n-butane and the same for isobutane are collected in Table IV. It will be noticed that the unsaturated hydrocarbons in one 600" experiment and in one 700° experiment for each of the butanes were determined directly by absorption methods. In the other four runs the olefins were estimated by the bromine method. These two methods are seen to check each other fairly well with n-butane, but not with isobutane. This is due to the more complex olefin mixture in the latter case. For the simple olefins, the absorption method is considered much more trustworthy, but the bromine method was especially useful in the search for butadiene, allene and methylacetylene. From isobutane it is apparent that allene and butadiene either were not present or were present in very limited amounts, since the acetylene values by the absorption method were of the same order of magnitude as the "acetylene and diene" values by the bromine method.

Data for the Bromine Method of Analysis Referred to in Table IV.—From n-butane at 60° the weight of bromides which were fractionated with a Vigreux column was 148 g. The percentage composition of each fraction is taken from the index of refraction curves.

Boiling range mm.	Boiling range °C.	Weight, g.	n_D^{20}	Composition by weight, % $C_2H_4Br_2$	$C_3H_6Br_2$	$C_4H_8Br_2$
25	4243	92.8	1.5259	40	60	..
23	4345	41.7	1.5220	17	**83**	..

6	56–100	5.12	1.5542	..	..	...
4	104–120	7.24	....	Some butadiene tetrabromide		
Residue		7.05	....	Much butadiene tetrabromide		
		Loss, 5 07				

Butadiene tetrabromide was present in quantity in the 104–120" (4 mm.) fraction and the residue. After several recrystallizations from alcohol, there was separated 3 g. of the material which melted at 115–115.5".

Anal. Calcd. for $C_4H_6Br_4$: Br, 85.4. Found: Br, 86.0, 85.9.

The bromides from isobutane at 600° weighed 107 g., and gave these data.

Boiling range mm.	°C.	Weight, g.	n^{20}_D	Apparent composition[a] (% by wt.) $C_3H_6Br_2$	*iso*-$C_4H_8Br_2$
38	54.5-55.0	4.15	1.5175	85	15
32–28	52.3-51.0	40.04	1.5162	72	28
27	51.0-52.0	26.38	1.5144	44	56
27	52.0-52.5	8.09	1.5123	4	96
2	63.0-69.0	11.92	1.5650	Almost pure $CH_3CBr(CH_2Br)_2$	
Residue		4.15	....		

[a] The presence of ethylene bromide is masked by the isobutylene bromide in the n_D values.

The residue represents the tetrabromide fraction (acetylenes and dienes) but it was too small to investigate satisfactorily. The fraction, b. p. (2 mm.) 63–69', was shown to be almost pure tribromo-*iso*butane, formed by the action of isobutylene and bromine water. This material, therefore, represents isobutylene. It was united with similar material from the 700° experiment and was purified by vacuum fractionation. A fraction which weighed **13** g. had these properties: b. p. (3 mm.) 69–70'; d^{20}_4 2.1887; d^{25}_4 2.1803; n^{20}_D 1.5669.

Anal.[9] Subs. 0.1915, 0.2005: *N*/15 $AgNO_3$ soln., 29.25, 30.55 cc. Calcd. for $C_4H_7Br_3$: Br, 81.35. Found: Br, 81.4, 81.2.

The weight of olefin bromides formed from 46.72 liters of *iso*butane at 700' was 212 g. A very small quantity of butadiene tetrabromide, m. p. 113–115°, was isolated from the fraction, b. p. (4 mm.) 91–110°, and the residue.

---

[9] Analysis was by the method of Drogin and Rosanoff, THIS JOURNAL, 38, 713 (1916).

Summary

Two concurrent reactions predominated in the pyrolysis of n-butane at 600°, namely, that into propylene and methane, and that into ethylene and ethane. The first of these reactions was slightly favored. Also, two major reactions occurred in the pyrolysis of isobutane at 600°, the formation of isobutylene and hydrogen, and to a lesser extent the formation of propylene and methane. An explanation is suggested for the observation that considerably more methane was formed from *iso*butane than would be accounted for by the latter reaction. These reactions were still the major ones with n- and *iso*butane at 700°, but not in the same proportions. Secondary reactions of importance were also encountered and studied.

Two methods were developed for the estimation of the individual unsaturated hydrocarbons in the gaseous mixtures which were encountered. One method, with limitations which were noted, consisted in determining the refractive index of the various bromide fractions (obtained from the olefins) and referring the values to index of refraction curves for similar synthetic mixtures. In the second analytical method, which is superior in most respects, the individual unsaturated hydrocarbons were selectively absorbed from the mixture by reagents in a modified Orsat apparatus. The various conditions for the analysis have been indicated.

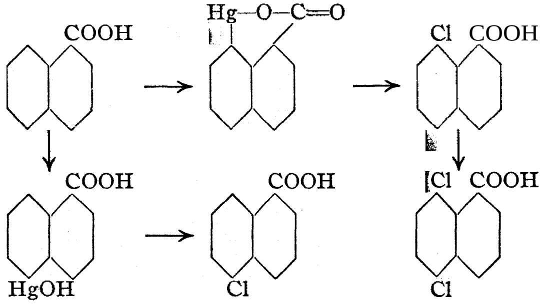
THE MERCURATION OF NAPHTHOIC ACIDS. I. 1-NAPHTHOIC ACID

BY PRANK C. WHITMORE AND ARTHUR L. FOX

RECEIVED JANUARY 23, 1929 PUBLISHED NOVEMBER 8, 1929

The present paper is a continuation of the studies on mercuration and the preparation of organic mercury compounds of higher molecular weight which have been carried on in this Laboratory during the past ten years.

1-Naphthoic acid reacts readily with mercuric acetate to give a mixture of mercurated acids substituted in the 5- and 8-positions. The structure of the mercurated products was determined by replacement of the mercury by chlorine. The structure of the 8-chloro-1-naphthoic acid was confirmed by chlorination to give 5,8-dichloro-1-naphthoic acid.



A considerable by-product of the mercuration was an alkali-insoluble organic mercury compound formed with the loss of carbon dioxide. This product contained two mercury atoms probably in the 1,5-positions.

In the course of the study anhydro-8-hydroxymercuri-1-naphthoic acid obtained from naphthalic acid was changed to the 8-chloro- and the 8-bromo acids. This is the best available way to obtain the 8-halogen-1-naphthoic acids in quantity and in a high degree of purity.

Experimental Part

Preparation of **1-Naphthoic** Acid.—Several methods were studied. Fusion of sodium 1-naphthalene sulfonate with sodium formate gave a 6 to 8% yield. Heating the same materials in kerosene gave none of the desired acid. The use of the calcium salt in the fusion with sodium formate gave a 9% yield. Passage of the vapors of 1-bromonaphthalene over heated potassium ferrocyanide gave no naphthonitrile. Treatment of 1-naphthylamine by the Sandmeyer reaction gave none of the nitrile.

The best methods of preparing 1-naphthoic acid were found to be through its nitrile formed by fusion of sodium 1-naphthalene sulfonate with sodium cyanide and from 1-bromonaphthalene through the Grignard reagent and treatment with carbon dioxide.

Sodium 1-naphthalene sulfonate was prepared by sulfonating naphthalene with concentrated sulfuric acid at 40–50°, neutralization with calcium hydroxide, treatment with sodium carbonate solution, removal of calcium carbonate by filtration and evaporation of the filtrate to crystallization.

A mixture of 920 g. (4 moles) of dry sodium 1-naphthalene sulfonate and 196 g. (4 moles) of sodium cyanide was prepared by grinding the materials together in a meat grinder and passing the mixture several times through a sieve. The retort used was a 3-inch iron pipe about 3 feet long with one end closed by a cap and the other provided with a flange fitted to another flange bearing a half-inch bent pipe about 6 inches long. The large pipe was placed on end and a stick about $^3/_4$ inch in diameter was placed in it. The mixture for fusion was then filled into the pipe to within about 6 inches of the top. A hard asbestos gasket was stuck to the flange with sodium silicate solution. The iron pipe with the stick at the top was then placed horizontally in a gas-heated combustion furnace. The stick was withdrawn, leaving a free space above the whole length of the mixture. The other flange was bolted on and the small pipe was connected with a flask set in an air-bath. This flask was connected with a vertical condenser and five wash bottles containing benzene. The end of the system was connected with a water pump. The combustion furnace was turned on full force. The nitrile started to distil almost immediately. Several runs were made without emptying the receiving system. The crude cyanide was separated from a small amount of water and distilled. The main fraction boiled at 285–300°. A considerable amount was recovered from the benzene wash bottles.

The 1-naphthonitrile was hydrolyzed by the method of Kamm,[1] refluxing 50 g. of nitrile with 100 cc. each of sulfuric acid, acetic acid and water for four hours. Treatment of the precipitated product with ammonium hydroxide dissolved all except 3 g. The filtrate from this material was acidified with hydrochloric acid and the solid collected on a filter; m. p. 145–155°; wt., 55 g. (98% yield). With considerable difficulty the acid was purified to its true melting point of 161° by crystallization from dilute acetic acid, dilute ethyl alcohol or xylene. The best method of purification was by esterification and vacuum distillation of the ethyl ester with subsequent hydrolysis; boiling point of ethyl 1-naphthoate, 183–186° (20 mm.).

The Grignard reagent prepared from 103.5 g. (0.5 mole) of 1-bromonaphthalene and 12 g. (0.5 g. atom) of magnesium in 1.5 Liters of dry ether was treated under vigorous stirring with dry carbon dioxide gas. The Grignard addition product adhered to the walls of the flask as a green tar. The ether was decanted for use in another run. The tar was treated with dilute hydrochloric acid with the formation of crude 1-naphthoic acid. It was dissolved in ammonium hydroxide, boiled with dccolorizing carbon and fuller's earth and filtered. The filtrate was allowed to stand for twenty-four hours to allow a small amount of a very troublesome tar to separate. After the addition of a little fuller's earth and filtration, the light green or straw-colored solution was acidified with hydrochloric acid. Pure white 1-naphthoic acid separated; m. p. 148–152°; wt., 40–45 g. (46–52% yield).

Mercuration of 1-Naphthoic Acid.—The mercuration of this acid took place with extreme ease but the products were most unmanageable. A total of 1357 g. of 1-naphthoic acid was mercurated in 39 experiments with a systematic variation of solvent,

---

[1] Private communication.

concentration, temperature and time of heating. The results of all the experiments were roughly similar. Only one will be given here.

A solution of 172 g. (1 mole) of 1-naphthoic acid in 210 cc. of 5 N sodium hydroxide and 2 liters of water was placed in a flask provided with a dropping funnel, a mercury seal stirrer and a reflux condenser connected with weighed potassium hydroxide traps to catch the carbon dioxide evolved. The stirrer was started and the mixture was heated to boiling. A solution of 318 g. (1 mole) of mercuric acetate in 1.5 liters of water and 60 cc. of acetic acid was added gradually. A white granular precipitate formed at once. Gas was evolved slowly. The mixture was rcfluxed for forty-four hours. The apparatus was then swept out with air free from carbon dioxide. The carbon dioxide absorbed by the potassium hydroxide was 4.98 g. The cream-colored precipitate in the flask was treated with 280 cc. of 5 N sodium hydroxide. Part of it dissolved and the rest turned black, due to the presence of mercurous compounds. The insoluble portion weighed 80 g. The alkaline filtrate was saturated with carbon dioxide. The precipitate formed was filtered and redissolved in sodium hydroxide solution. It was again precipitated by carbon dioxide; wt., 240 g. The filtrate from the mercurated product gave 34 g. of unchanged 1-naphthoic acid when acidified with hydrochloric acid.

As will be shown below the chief product consisted of hydroxymercuri-1-naphthoic acids having the mercury in the 5- and 8-positions. The alkali-insoluble product was mainly a dimercurated naphthalene.

The above mercuration experiment can be summarized as follows

1-Naphthoic acid recovered unchanged, g.	34
1-Naphthoic acid equivalent to 240 g. of Hg compound, g.	110.5
1-Naphthoic acid equivalent to 80 g. of Hg_2 compound, g.	24.5
1-Naphthoic acid not accounted for, g.	3
1-Naphthoic acid started with, g.	172

The amount of mercurous compound formed by oxidation–reduction reactions was not determined. The amount of carbon dioxide recovered was only 80% of the amount calculated from the amount of alkali-insoluble dimercurated product obtained.

Purification and Identification of Mercury Compounds Obtained from 1-Naphthoic Acid.—Literally hundreds of experiments were carried out to separate the mixture of hydroxymercuri-I-naphthoic acids into pure chemical individuals. Many fractionations were obtained by the use of a variety of solvents. In almost all cases fractions were obtained which contained 44 to 55% of mercury (calcd. for anhydro-hydroxymercuri-1-naphthoic acid, Hg, 54.05).

It was finally decided to convert the mixture of mercury compounds to a mixture of halogenated 1-naphthoic acids and to separate these.

Attempts to obtain iodonaphthoic acids by treatment with a chloroform solution of iodine gave only tarry products.

Replacement by bromine was more successful. A solution of 60 g. of the mixed hydroxymercuri-1-naphthoic acids in 60 cc. of 5 N sodium hydroxide and 300 cc. of water was heated with decolorizing carbon, filtered and barely acidified with hydrochloric acid. The chloromercuri compound was separated and suspended in 800 cc. of acetic acid and treated with 28 g. of bromine dissolved in sodium bromide solution. As the bromine solution was added, the color disappeared until the last was added when the red color remained. On boiling, the solution became clear but the color of bromine persisted. This was removed by treatment with a little sodium bisulfite. After boiling with decolorizing carbon and filtering, the solution was cooled. Crystals were obtained which melted at 226–230°. After several crystallizations from glacial acetic acid, the product melted at 248–250°. It was 5-bromo-1-naphthoic acid.[2] The mother liquors gave more of this acid and another acid which was not successfully purified.

Although the replacement of mercury by chlorine is not generally used in determinations of structure, it was decided to attempt it in this case.

An alkaline solution of 132.5 g. of the mixed hydroxymercuri-1-naphthoic acids was treated with 20 g. of sodium chloride, boiled for a few minutes, barely acidified with hydrochloric acid and filtered. The chloromercuri compound after drying-in the air weighed 140 g. It was stirred with 400 cc. of glacial acetic acid and treated at room temperature with a glacial acetic acid solution of 24 g. of chlorine. Reaction took place at once and most of the material went into solution. The mixture was heated to boiling and filtered from a slight residue. The filtrate on cooling and on concentration gave mixtures of acids which were separated by a careful series of fractional crystallizations using as solvents glacial acetic acid, water and xylene. The acid obtained in largest amount melted at 241–242°. This was 5-chloro-1-naphthoic acid. Its melting point was not lowered by mixing with some of the known acid.[3] Smaller amounts of 8-chloro-1-naphthoic acid[4] melting at 171–171.5° were obtained. A known sample of this acid was prepared by treating with chlorine anhydro-8-hydroxymercuri-1-naphthoic acid obtained from naphthalic acid.[5] It melted at 170–170.5°. A mixture of the two melted at 169–170". Examination of the optical properties of the two samples by means of the polarizing microscope also showed their identity. 8-Bromo-1-naphthoic acid, m, p. 176–179°, was made by a similar process.

The mother liquors from the 5-chloro and 8-chloro acids may have contained other acids but none could be isolated.

In a further search for other acids in the mixture it was decided to resort to a fractional distillation of the esters; consequently, 320 g. of the hydroxymercuri-1-naphthoic acids was treated with chlorine as above. The mixed acids were then refluxed with absolute methanol and dry hydrogen chloride for eleven hours. The oil left after the removal of the excess of methanol was washed with sodium carbonate solution. The acid obtained by acidifying the sodium carbonate solution was again treated with methanol and hydrogen chloride. Most of it failed to esterify; wt., 25 g. Several crystallizations from dilute acetic acid and from xylene gave crystals melting at 165–166°. A mixture with a slightly impure sample of known 8-chloro-1-naphthoic acid of m. p. 166–167° melted at 164.5–166.5°. A crystallographic examination proved the identity of the two materials. The interference colors were identical; both were biaxial. One axis of each had an index of refraction of 1.572 ± 0.003, while each had an index of refraction for the other axis between 1.635 and 1.740. To further prove the structure of this acid, a sample was chlorinated at room temperature in acetic acid using iodine as a catalyst. The product was 5,8-dichloro-1-naphthoic acid[6] melting at 186–187°.

The oily esters insoluble in sodium carbonate solution were dried by mixing with dry benzene and distilling off the benzene. The dry ester mixture was submitted to three

careful fractionations at 6-mm. pressure and a fourth at 4-mm. pressure. In this way four fractions were obtained.

FRACTION I. 6.2 g., b. p. 120–125° (4 mm.).—Hydrolysis gave mainly 1-naphthoic acid, m. p. 160–161°. A careful series of fractional crystallizations from boiling water failed to give any other acid. A mixture with known 1-naphthoic acid of m. p. 159° melted at 159–160°. The identity of the known 1-naphthoic acid and the acid from the ester fraction was further determined by crystallographic studies. Both crystallized from xylene in needles. Each had an extinction axis parallel to the long axis of the crystal. Each gave the same type of interference colors. Each had an index of refraction for one axis of 1.550 and for the other axis one above 1.740. A mixture of the acid with a sample of 8-chloro-1-naphthoic acid of m. p. 166–167° melted completely below 150°.

FRACTION II. 5.3 g., b. p. 125–130° (4 mm.).—This proved to be mainly impure 1-naphthoic acid. No other acid was isolated.

FRACTION III. 10.8 g., b. p. 131–133° (4 mm.).—On hydrolysis this gave mainly 5-chloro-1-naphthoic acid, m. p. 236–240°.

FRACTION IV. 10.8 g., b. p. 140–143° (4 mm.).—This gave 5-chloro-1-naphthoic acid, m. p. 244–245°. A mixture with known pure 5-chloro-1-naphthoic acid of m. p. 245–246° melted at 244–246°.

The alkali-insoluble product from the mercuration of 1-naphthoic acid was next studied. It reacted violently with an almost equal weight of bromine. From the tarry product there was obtained only a very small amount of a bromine compound, m. p. 124–146°. This may be impure 1,5-dibromonaphthalene. No other product could be separated from the tar.

Summary

1. Two satisfactory methods have been developed for making 1-naphthoic acid in quantity.
2. 1-Naphthoic acid is readily mercurated in the 5- and &positions, chiefly in the former.
3. During the mercuration some of the product loses carbon dioxide with the formation of an alkali-insoluble di-mercurated product of unknown structure.
4. 5-Bromo-1-naphthoic acid, 5-chloro-1-naphthoic acid and 8-chloro-1-naphthoic acid have been prepared from the mercury compounds.
5. 8-Chloro-1-naphthoic acid cannot be esterified even by long treatment with absolute methanol and dry hydrogen chloride.
6. A useful method has been developed for making 8-halogen-1-naphthalic acids from the mercuration product of naphthalic acid.

THE HYDROLYSIS OF HYDROGEN CYANIDE BY ACIDS[1]

BY VERNON K. KRIEBLE AND JAMES G. MCNALLY

RECEIVED MARCH 20, 1929 PUBLISHED NOVEMBER 8, 1929

In 1909 Walker and Krieble[2] investigated the hydrolytic action of aqueous solutions of hydrochloric and sulfuric acids on amygdalin. Their experiments showed that when strong aqueous solutions of these acids were used their hydrolytic action was quite different. Hydrochloric acid attacked the nitrile group first while sulfuric acid showed little tendency to attack this group but readily removed the two glucose radicals with the formation of mandelonitrile. These experiments were the first ones, so far as we know, which showed radical differences between like concentrations of these acids in regard to their catalytic power on hydrolysis. The present investigation was undertaken to determine whether this is a characteristic peculiar to amygdalin or whether it is general for nitriles.

This communication takes up the hydrolysis of the simplest of all nitriles—hydrogen cyanide. The results with other nitriles will be treated in a future publication. Our results show that there is a marked difference in the rate at which hydrochloric, sulfuric and hydrobromic acids catalyze the hydrolysis of hydrogen cyanide and that the rate for hydrochloric acid increases very rapidly with an increase in concentration of this catalyst.

Preparation of Material and Method of Procedure

Preparation of Hydrogen Cyanide.—This substance was prepared by the usual methods of treating either sodium or potassium cyanide with moderately concentrated sulfuric acid and distilling off the nitrile. By adding a drop of dilute sulfuric acid to the distillate the hydrogen cyanide could be kept for several months without any appreciable change in appearance or concentration. The solution was standardized by either Liebig's soluble cyanide method or by the gravinietric method using the insoluble silver salt.

Procedure.—The hydrolysis was carried out in several different ways. The most satisfactory one was to mix cold standardized hydrogen cyanide with cold standardized acid in a beaker surrounded with salt and ice. From this beaker a series of pyrex test-tubes was filled. These tubes were then sealed off as near as possible to the liquid or else closed with a rubber stopper which was tied down to make a gas tight seal. It is obvious that it is necessary to have the tubes as nearly full as possible to reduce to a minimum the evaporation of the hydrogen cyanide into the air space. We found that our results were the same irrespective of the container used. The tubes were then placed in a constant temperature bath regulated to 0.1°. Tubes were taken out at various time intervals and analyzed for ammonium formate.

Method of Following the Hydrolysis.—The hydrolysis of hydrogen cyanide is usually expressed

$$HCN + H_2O = HCONH_2 \quad (1)$$

$$HCONH_2 + H_2O = HCOONH_4 \quad (2)$$

---

[1] Read at the meeting of the American Chemical Society in Richmond, Virginia, April, 1927.

[2] Walker and Krieble, J. *Chem. Soc.*, **85**, **1369** (1909).

We were interested in the first reaction but we did not follow it directly. Experiments to be described later showed that the rate of the second reaction can be considered to be infinitely greater than the first, making it possible to follow the first by estimating the ammonium salt.[3] This was done by the well-known Folin aspiration method. Aliquot portions of the solution were pipetted into large pyrex test-tubes and an excess of sodium carbonate was added. Air freed of ammonia was sucked through this solution and then through standard acid. The excess acid was titrated and the amount of ammonium salt present calculated.

Experimental Results

Pigure 1 shows the action of 5 N hydrochloric and 5 N sulfuric acid containing 4% amygdalin at 25° in so far as the hydrolysis of the nitrile group in amygdalin is concerned. These results agree with those reported by Walker and Krieble, namely, that hydrochloric acid attacks the nitrile group much more readily than sulfuric acid.

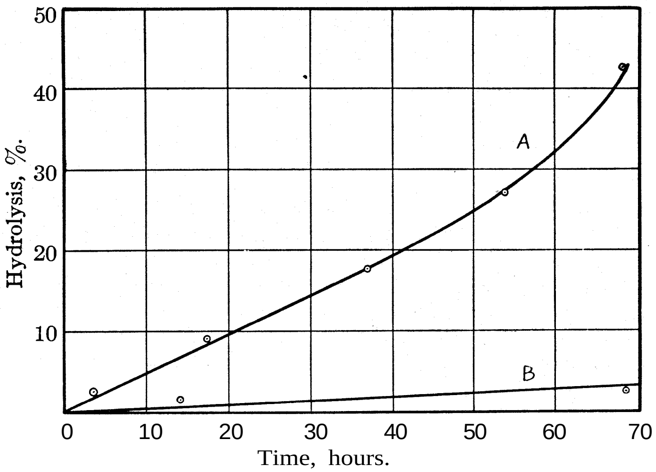

Fig. 1.—The hydrolysis of amygdalin at 25". A, 5 N HCI used as catalyst; B, 5 N H_2SO_4 used as catalyst.

In Pig. 2 we have the action of the same acids at the same concentration and temperature on hydrogen cyanide.[4] Here the difference in rates between these two acids is even more striking than with amygdalin. These two sets of experiments show that the nitrile hydrolysis does not follow the hydrogen-ion concentration of the solution in which the hydrolysis takes place. This conclusion is confirmed by examining a comparison of the rates of hydrolysis with different concentrations of hydrochloric acid. In Pig. **3** we have a comparison of 1.95 *N*, 3.92 *N*, 5.88 N and

---

[3] Subsequent experiments by Mr. Blanchard showed that practically the same values are obtaineed when the disappearance of hydrogen cyanide is measured.

[4] The acid solutions in all of the experiments with hydrogen cyanide contained 0.7 moles of HCN per liter.

7.84 *N* hydrochloric acid solutions on hydrogen cyanide at 30°. The concentration of the acid has increased four-fold while the hydrogen-ion concentration has not increased that much but the time necessary to hydrolyze 25% of the hydrogen cyanide has increased a thousand-fold. We have studied the same reaction at 45°. The results are given in Fig. 4. The relative rates at this temperature for the various acid concentrations are similar to those at 30°. The temperature coefficient between 30 and 45° and between 45 and 65° is about 5. In Fig. 5 we have the comparison of 4 N hydrochloric acid and 4 *N* hydrobromic acid at 45°. Here we have two acids equally dissociated as measured by conductivity or by the lowering of the freezing point but the rate of hydrolysis where the hydrochloric

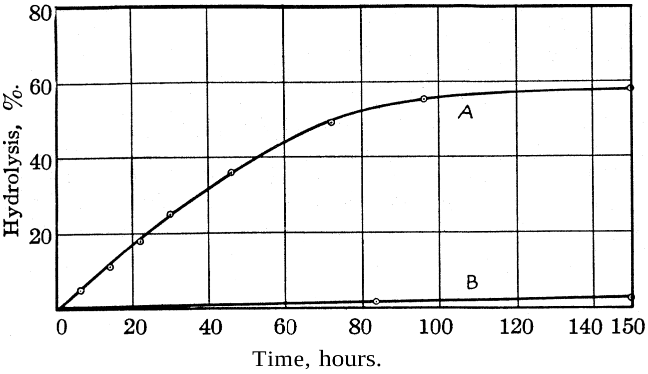

Fig. 2.—The hydrolysis of HCN at 25°. A, 5 N HCl used as catalyst; B, 5 N H_2SO_4 used as catalyst.

acid is the catalyst is very much greater. This is in marked contrast with the hydrolysis of the corresponding amide. Figure 6 shows the rate of hydrolysis of formamide in the presence of 2 *N* hydrochloric acid and 2 *N* hydrobromic acid at 25°. In this case they are equally efficient as catalysts, as one would expect if the catalysis is due to the hydrogen ion. When the time required to hydrolyze 25% of hydrogen cyanide to formamide is compared with the time to hydrolyze 25% of formamide to ammonium formate in Figs. 3 and 6 the ratio is found to be 1400 hours to 6 minutes.

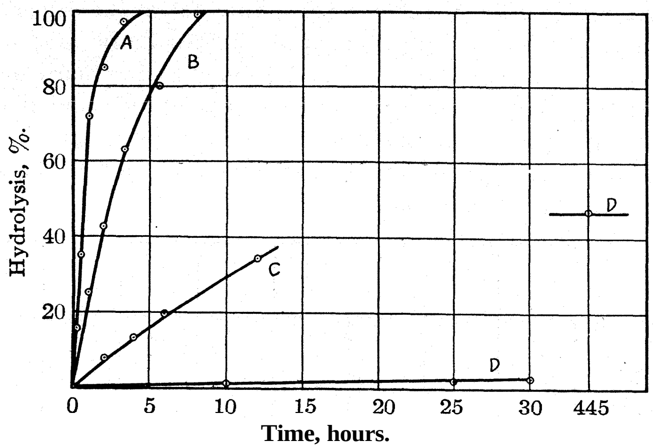

Fig. 4.—The hydrolysis of HCN at 45°. A, 7.84 N HCl used as catalyst; B, 5.88 N HCl; C, 3.92 N HCl; D, 1.95 N HCl.

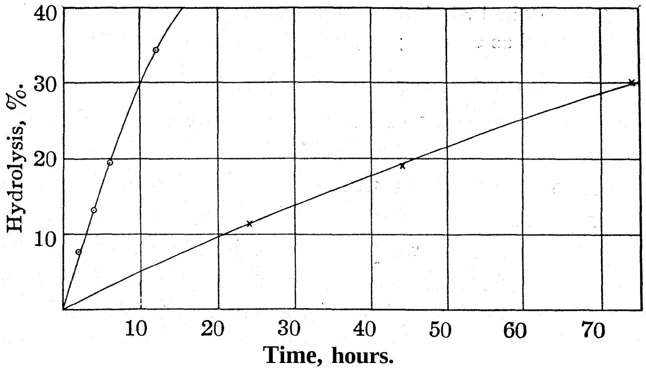

Fig. 5.—⊙, 4 N HCl at 45°; X, 4 N HBr at 45°.

The second molecule of water is therefore added on 14,000 times more rapidly than the first. These results on amide hydrolysis agree with those of other investigators, and when compared with the nitrile hydrolysis show conclusively that the mechanism for the two must be different.

Discussion of Results

No other hydrolytic reaction has been revealed in the literature where the rate went up so rapidly with increase in concentration. Blanksma[5] observed that in the transformation of acetylchloraminobenzene to p-chloro-acetanilide with hydrochloric acid as a catalyst the velocity changed as the square of the concentration of the hydrochloric acid.

Maass and Sivertz,[6] in studying the addition of hydrochloric acid to propylene, observed that the excess acid acted as a catalyst and that the rate increased very rapidly with small increases in concentration. These reactions are not hydrolytic reactions and, therefore, not of the same type described in this communication.

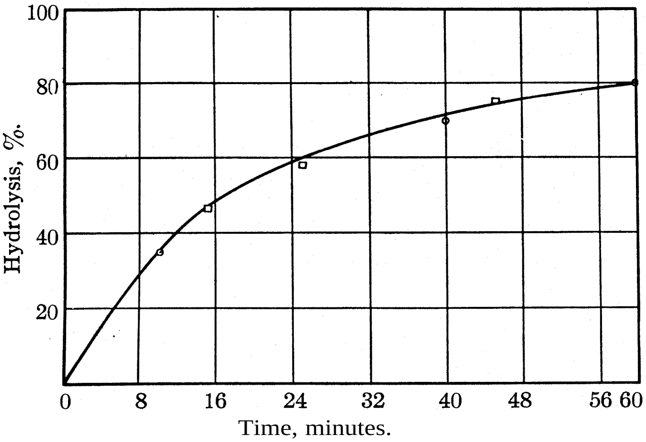

Fig. 6.—The hydrolysis of $HCONH_2$ at 25°. □, 2 M HCl used as catalyst; O, 2 M HBr used as catalyst.

A study of the change in rate with change in acid concentration in Fig. 3 shows that it is of the same order of magnitude as the change of activity of the undissociated hydrochloric acid molecule as indicated by electromotive-force measurements in the literature. To make more suitable the graphical representation of this relationship in Fig. 7 between velocity constants and the activities we plotted the logarithm of the velocity constants[7] for hydrochloric acid concentrations of 1.95, 3.92, 5.88 and 7.84 N as abscissa against the logarithm of the activities[8] for undissociated hydrochloric acid of the same concentrations. The velocity constants were calculated as described below from the data of experiments carried out

[7] Actually the logarithm of $K \times 10^5$ was plotted, which merely shifts the origin.

[8] The values for the activities used are those given by Lewis and Randall for 25°, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923, p. 336.

at 30, 45 and 65°. If the relationship were exact a straight line would be obtained.

This close relationship between the velocity of this reaction and the activity of the hydrogen chloride molecule calculated from physical measurements is remarkable. The literature does not record another like it so far as we know.[9] It suggests a combination between hydrogen cyanide and hydrogen chloride. That such a combination takes place in non-aqueous solutions is well known. A compound $2HCN\cdot 3HCl$ has been isolated in an ethyl acetate solution.[10] That an iminoformyl chloride $ClC{=}NH$ can also be formed is pretty well proved by Gattermann's reaction for the synthesis of aldehydes[11]

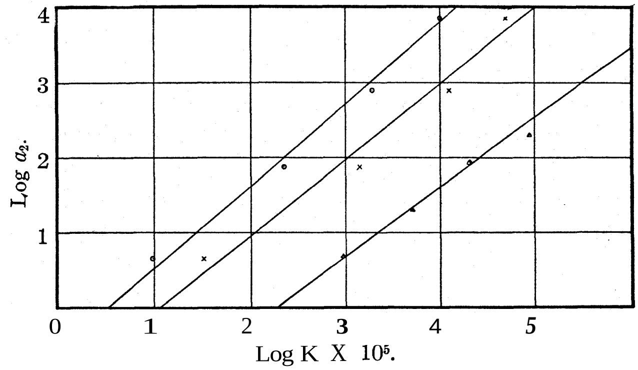

Fig. 7.—⊙, 30°; X, 45°; A, 65°.

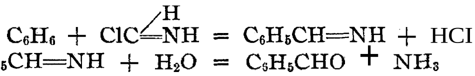
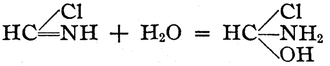


$$C_6H_6 + ClC\overset{H}{=}NH = C_6H_5CH{=}NH + HCl$$
$$C_6H_5CH{=}NH + H_2O = C_6H_5CHO + NH_3$$

Gautier[12] isolated a compound $HCN\cdot HCl$ by passing anhydrous hydrogen chloride into hydrogen cyanide at 35 to 40°. He found it to be a very unstable compound which decomposed spontaneously when added to water, producing formic acid. We, therefore, propose that the hydrolysis to the amide takes place through the following series of reactions

$$HCN + HCl = HC\overset{Cl}{=}NH \qquad (1)$$



$$HC\overset{Cl}{=}NH + H_2O = HC\begin{smallmatrix}Cl\\NH_2\\OH\end{smallmatrix} \qquad (2)$$

---

[9] Maass and Hiebert, This Journal, 46, 299 (1924), found that the decomposition of hydrogen peroxide was catalyzed by the undissociated hydrogen chloride molecule. Their velocity constant, however, did not vary with the activity of the hydrogen chloride molecule.

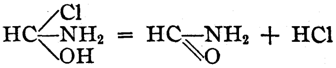
[11] Gattermann, *Ber.*, 31, 1149, 1765 (1898); *Ann.*, 347, 347 (1906); 357, 313 (1907).

[12] Gautier, *Ann. chim.* phys., [4] 17, 129 (1869).



$$\mathrm{HC(Cl)(NH_2)(OH)} = \mathrm{HC(=O)NH_2} + \mathrm{HCl} \tag{3}$$

Gautier found that his hydrogen chloride–hydrogen cyanide compound decomposed with almost explosive violence, so that Reactions 2 and 3 are very fast compared with 1. So the rate of hydrolysis is controlled by the rate of addition of hydrogen chloride to hydrogen cyanide, which in turn is a function of the number of hydrogen chloride molecules present in such a state that they can enter into the reaction. As the hydrogen chloride is only momentarily combined, its concentration for any given set of conditions is a constant; and as the amount of water present is very large, the reaction can for practical purposes be considered a monomolecular reaction. In Table I we have recorded the velocity constants for a few of our experiments calculated on the basis of a monomolecular reaction.

TABLE I

VELOCITY CONSTANTS

3.92 *N* HCl at 30°			7.84 *N* HCl at 30°		
Time, hours	% Hydrolyzed	K	Time, hours	% Hydrolyzed	K
4.08	1.9	0.0020	1	20.85	0.1015
21.13	10.75	.0023	1.91	32.92	.1010
28.33	14.87	.0024	2.71	46.96	.1011

53.75	25.6	.0024	5.65	78.33	.1175
68.12	31.15	.0024	6.88	82.99	.1118

We believe that the mechanism with hydrobromic acid as a catalyst is similar to that with hydrochloric acid. It is interesting to note that in non-hydrolytic reactions, hydrobromic acid has frequently been found to be more reactive than hydrochloric acid. Maass and Sivertz[13] found that hydrobromic acid added on to propylene 200 times faster than hydrochloric acid did. Acree and Johnson,[14] in studying the transformation of acetylchloro-aminobenzene to p-chloro-acetanilide, found that hydrobromic acid was 1000 times more effective than hydrochloric acid.

Whether sulfuric acid reacts in the same way as the halogen acids we shall be better able to say after we have studied it more thoroughly.[15]

Summary

The rates of hydrolysis of amygdalin and hydrogen cyanide when catalyzed by hydrochloric and sulfuric acids have been quantitatively studied. It is found that for 5 N concentrations hydrochloric acid hydrolyzes amygdalin ten times faster than sulfuric. For hydrogen cyanide the difference is even greater.

---

[13] Ref. 6, p. 2888.

[14] Acree and Johnson, Am. Chem. J., 38, 274 (1907).

[15] Recent experiments by Mr. Peiker seem to show that the rate of hydrolysis passes through a minimum when the concentration of sulfuric acid is increased.

When the concentration of hydrochloric acid was varied from 1.95 N to 7.84 N, the velocity in the hydrogen cyanide hydrolysis increased about 1000 times. It is pointed out that this increase in velocity corresponds to the increase in activity for corresponding concentrations of the undissociated hydrogen chloride molecule as measured by electromotive force methods, and it is suggested that this increase in velocity is due to an increase in the concentration of activated hydrogen chloride molecules.

A 4 N hydrochloric acid solution is more than 6 times as effective in hydrolyzing hydrogen cyanide as a corresponding hydrobromic acid solution.

A tentative mechanism for the hydrolysis of hydrogen cyanide is proposed.

A METHOD OF COUPLING ORGANIC RADICALS BY MEAMS OF THE GRIGNARD REAGENT[1]

BY JOHN H. GARDNER AND P. BORGSTROM

RECEIVED APRIL 10, 1929 PUBLISHED NOVEMBER 8, 1929

The coupling of organic radicals by the action of heavy metal salts on organomagnesium compounds has been studied by a number of investigators.[2] However, the use of silver halides for this purpose has not been investigated, although Gilman and Kirby studied the action of certain Grignard reagents on silver cyanide. They observed the coupling of the organic radicals, the cyanide radical reacting as a halogen.[3]

We have investigated the application of the reaction of Grignard reagents with silver bromide to the preparation of symmetrical biaryls and bialkyls. A few preliminary experiments with cuprous chloride failed to give promising results. The bromide was selected in place of the chloride, as dry silver bromide is so little sensitive to light that it may be used in a fairly well lighted room.

The advantage of silver bromide over other heavy metal salts lies in the fact that it is easily prepared pure and dry. Its cost is compensated for by the fact that it can be recovered readily and almost completely. We have found the laboratory accumulation of silver residues *a* cheap and satisfactory source of silver bromide.[4]

---

[1] The major part of this work was done while one of us (G.) was a National Research Fellow in Chemistry.

[2] Gilman and Parker, THIS JOURNAL, 46,2823 (1924), give a very complete review of the literature; see also Moyer and Adams, *ibid.*, 51, 630 (1929).

[3] Gilman and Kirby, *Rec. trav. chim.*, 48, 155 (1929).

[4] We are indebted to Mr. C. F. Brown of West Virginia University for the working up of silver residues into the bromide used in the early part of this work.

The procedure for the preparation of biaryls consists in adding the arylmagnesium halide to a well-stirred suspension of silver bromide in dry ether, adding benzene and decomposing the silver aryl first formed by heating to boiling for a short time. In the case of the alkylmagnesium halides, the silver alkyl which is probably first formed decomposes immediately with the formation of silver and bialkyl.

It has been found possible to prepare biphenyl and 4,4′-dimethoxybiphenyl in quite satisfactory yield by this method. Bi-*p*-tolyl was obtained in good yield and purity in a small run (0.05 mole), but on increasing the amount of the bromide to 0.35 mole the yield was reduced to 25%. Among the aliphatic and alicyclic compounds, *n*-octane, bibenzyl and bicyclohexyl were obtained in fair yield and satisfactory purity. In reacting silver bromide with the Grignard reagents prepared from *iso*- and *sec*-butyl bromides, no pure compounds could be isolated, the products distilling over a considerable range with no detectable break in the distillation curves. Whether this was due to side reactions during the formation of the Grignard reagents or during the reaction with silver bromide cannot at present be stated. This will be further investigated.

We believe that this procedure can be used to couple aryl and alkyl radicals whenever the Grignard reagents can be prepared without excessive side reactions. Obviously, if by-products resulting from intramolecular rearrangements during the formation of the Grignard reagent or the reaction with silver bromide are produced in too great amounts, it will be impossible to obtain a uniform product by this method.[5] It does, however, permit the preparation of symmetrical biaryls and certain bialkyls without the complicated side reactions encountered in the use of the Wurtz–Fittig reaction.[6]

Experimental

General Procedure.—The appropriate Grignard reagent was added, with stirring, to a suspension of the equivalent quantity of dry silver bromide in dry ether. The mixture was stirred for a half hour and then boiled under a reflux for an hour. In the case of the Grignard reagents derived from *p*-bromotoluene and *p*-bromo-anisole, a volume of benzene equal to that of the ether was added to raise the boiling point before refluxing. If the product was solid, the ether and the benzene if present were distilled off and the residue was treated with very dilute hydrochloric acid. After cooling, the mixture was filtered and the residue air dried. The product was extracted from the residue with hot alcohol and purified by distillation or by recrystallization from alcohol.

When the product was a liquid, dilute hydrochloric acid was added to the mixture after refluxing, the solvent and product were distilled off, dried over calcium chloride and distilled. The results are given in Table I.

The absence of the formation of any definite product from *iso*- and *sec*-butyl bromides may be due to intramolecular rearrangement on the

Isobutyl bromide	1.0	......	..	..	89.5–110.5 (b.)
Sec.-butyl bromide	1.0				89–120.5 (b.)

part of free radicals formed by the interaction of the Grignard reagents with silver bromide, assuming the reaction to take place according to the equations

$$\mathrm{RMgX} + \mathrm{AgBr} = \mathrm{R} + \mathrm{Ag} + \mathrm{MgXBr}$$
$$2\mathrm{R} = \mathrm{R{-}R}$$

This is to be further investigated.

Preparation of Silver Bromide.—The silver bromide was precipitated from a warm solution of silver nitrate with sodium bromide, washed with water and with acetone and dried in an oven at a temperature not exceeding 80°. It is important that it be dried at a low temperature as a higher temperature, even 90°, results in larger particles and a less effective product.

Recovery of Silver Bromide.—The silver residues were reduced in the usual way with zinc and sulfuric acid to metallic silver which was converted into silver nitrate.

Summary

Biphenyl, bi-p-tolyl, bi-p-anisyl, bibenzyl, bi-cyclohexyl and *n*-octane have been prepared by the action of the appropriate Grignard reagent on silver bromide.

THE REDUCING ACTION OF ALIPHATIC GRIGNARD REAGENTS

BY F. F. BLICKE AND L. D. POWERS[1]

RECEIVED APRIL 20, 1929 PUBLISHED NOVEMBER 8, 1929

During the course of an investigation, we wished to prepare a number of tertiary carbinols from the interaction of alkylmagnesium halides and benzophenone. Methyl- and ethyldiphenylcarbinol can be obtained in good yields from methylmagnesium iodide and ethylmagnesium bromide, respectively, and benzophenone. Klages and Heilmann[2] state that n-propylmagnesium bromide reacts with the above ketone to form a compound which melts at 65°; this material they considered to be *n*-propyldiphenylcarbinol. When the carbinol was treated with hydrogen chloride a substance was formed which was described as propyldiphenylchloromethane. By reduction of the carbinol, diphenylbutane was supposed to have been produced. We found that the propyldiphenylcarbinol of Klages and Heilmann was, in reality, benzhydrol and that their propyldiphenylchloromethane and diphenylbutane were actually diphenylchloromethane and diphenylmethane, respectively.

In order to prepare propyldiphenylcarbinol Masson,[3] as well as Skraup and Freundlich,[4] allowed phenylmagnesium bromide to react with ethyl butyrate. The former investigator obtained an oil which boiled at 185° under 15-mm. pressure; the latter isolated a product, after distillation under greatly diminished pressure, which melted at 36°. Inasmuch as tertiary carbinols of the type under discussion lose water very readily, with the formation of an ethylene derivative, especially when subjected to heat, we decided to investigate further the compound obtained by Skraup and Freundlich. After the interaction of phenylmagnesium bromide and ethyl butyrate, at a low temperature, we were able to isolate, without distillation, a crystalline compound which melted at 33–35°. The carbinol nature of this substance was shown by the fact that it reacted with ethylmagnesium bromide with the evolution of ethane. Finally, we found that the compound obtained by the action of phenylmagnesium bromide on phenylpropyl ketone, undoubtedly propyldiphenylcarbinol, melted at 33–34°.

It seems remarkable that no secondary carbinol should be formed from the interaction of methylmagnesium iodide and benzophenone, very little from ethylmagnesium bromide and the ketone, while in the case of n-propylmagnesium bromide at least 50% of the benzophenone is converted

into benzhydrol, even though the reaction is carried out at 0°, as a result of the reducing action of the Grignard reagent.

A number of isolated instances of the reducing action of Grignard compounds have been reported from time to time.[5] However, since a systematic study to determine the relative reducing power of an homologous series of alkylmagnesium halides, especially with respect to a given ketone,[6] has not been made, we began an investigation of the action of various alkylmagnesium halides on benzophenone. This ketone is especially adapted for the purpose in view since it cannot enolize and the reduction product, benzhydrol, is a crystalline substance which can be purified and identified without difficulty. Our results are described in the experimental part of this paper.

It seems to us that the reducing action of aliphatic Grignard reagents toward various compounds can be accounted for if the assumption is made that trivalent carbon radicals are produced as intermediate reaction products.[7] It would be expected that these trivalent carbon radicals would be very unstable and that they might undergo, spontaneously, one of the types of transformation which have been found to be characteristic for trivalent carbon radicals of the triarylmethyl type, namely, addition, mutual oxidation and reduction, and polymerization.[8]

---

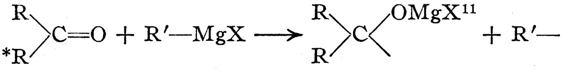
[5] The first observation of this type is that of Grignard (Doctor's "Dissertation," Annales de L'Université de Lyon, 1901, p. 48), who obtained not only phenyl*iso*amylcarbinol but also benzyl alcohol from iso-amylmagnesium bromide and benzaldehyde. Sabatier and Mailhe, *Compt.* rend., 139, **343** (1904); ***Bull.*** *soc.* chim., *[3]* 33, 79 (1905); Ann. chim. *phys.*, [8] 10, 540 (1907), noted that benzophenone and cyclohexylmagnesium chloride yielded benzhydrol and cyclohexene.

[6] Stas, ***Bull.*** *soc.* chim. ***Belg.***, 34, 188 (1925); ibid., 35, 379 (1926), has studied the action of a number of Grignard reagents on several aliphatic ketones; however, since aliphatic ketones may react in the enolic form with alkylmagnesium halides, these ketones are not entirely suitable for a study of the reducing action of Grignard compounds. Recent contributions to somewhat different phases of this subject have been made by the following investigators: Meisenheimer and Casper, Ber., 54, 1655 (1921); Hess and Rheinboldt, ibid., 54, 2043 (1921); Hess and Wustrow, Ann., 437, 256 (1924); Meisenheimer, ibid., 442, 180 (1925); Rheinboldt and Roleff, J. *prakt.* Chem., 109, 175 (1925); Conant and Blatt, THIS JOURNAL, 51, 1227 (1929).

[7] Späth, Monatsh., 34, 1967 (1913), and also Schlubach and Goes, ***Ber.***, 55, 2897 (1922), have already proposed such an explanation to account for the products which are formed when an alkyl- or arylmagnesium halide reacts with an organie halogen compound. Bachmann and Clarke, THIS JOURNAL, 49, 2089 (1927), have assumed the formation of radicals in the Wurtz-Fittig reaction and Wieland and co-workers, *Ber.*, 48, 1098 (1915); ibid., 55, 1816 (1922); Ann., 446, 31, 49 (1925); *ibid.*, 452, 1 (1926), have made an extensive study in order to determine, in certain instances, whether or not radicals are intermediate reaction products. Quite recently Gilman and Fothergill, THIS JOURNAL, 50, **3334** (1928), and Gilman and Kirby, ibid., 51, 1571 (1929), have made several observations on the mutual oxidation and reduction (disproportionation) of radicals.

[8] In some instances it has been found that triarylmethyls also undergo internal rearrangement.

In conformity with this hypothesis the interaction of a ketone and a Grignard reagent would be formulated as follows[9,10]



$$\begin{matrix}R \\ {}^{*}R\end{matrix}\!\!>\!C{=}O + R'{-}MgX \longrightarrow \begin{matrix}R \\ R\end{matrix}\!\!>\!C\!<\!\begin{matrix}OMgX^{11} \\ \end{matrix} + R'{-}$$

I II

The radicals I[12] and II may unite (addition) to form the addition product $R_2C(OMgX)R'$ which, upon the addition of water, would yield a tertiary carbinol; they may undergo mutual oxidation and reduction with the production of $R_2C(OMgX)H$, the magnesium halide derivative of a secondary carbinol, and the unsaturated hydrocarbon R'_{-H}; or, finally, they may polymerize to dimolecular forms $R_2C(OMgX){-}R_2C(OMgX)$ and $R'{-}R'$; the former when treated with water would yield a pinacol,[13] the latter product represents a saturated hydrocarbon.[14]

Experimental Part

Propyldiphenylcarbinol.—Ethyl butyrate, dissolved in benzene, was added to approximately three molecular equivalents of phenylmagnesium bromide which had been cooled to 0°. After twenty-four hours the reaction mixture was decomposed with ice and ammonium chloride. The oily product which was obtained became crystalline after it had been cooled to a low temperature for some time. The material was so soluble that it could not be recrystallized but after it had been washed with petroleum ether (20–40°) it melted at 33–34°.

---

[9] This mechanism applies also to the reaction between a Grignard compound and an aldehyde or an ester. If an aldehyde is used R* is to be replaced by H, in the case of an ester by OR.

[10] It is possible that a molecular addition product may be formed first in all instances.

[11] Radicals of this type have been formulated by Lagrave, *Ann. chim.*, [10] *8*, **372 (1927).**

[12] Compounds of Type I seem to be formed by the action of iodine and magnesium on ketones [Gomberg and Bachmann, THIS JOURNAL, **49, 238 (1927);** *ibid.*, **50, 2762** (1928)] and sodium analogs have been described by Schlenk and co-workers *[Ber.*, **44, 1182 (1911);** *ibid.*, **46, 2840 (1913);** *ibid.*, **47, 486 (1914);** *Ann.*, **463, 1** (1928)]; and by Blicke [THIS JOURNAL, **46,2560 (1924);** *ibid.*, **47,229** (1925)].

[13] An example of what appears to be pinacol formation in the Grignard synthesis has been recorded by Barnett, Cook and Nixon [*J. Chem. Soc.*, *131,* **505** (1927)]. It has been shown by Schonberg and co-workers *[Ber.*, **58, 1796 (1925);** *ibid.*, **60, 235 (1927);** *Ann.*, **454, 37** (1927)] that thioketones react with Grignard reagents to form sulfides of the type  $\underset{\diagdown S \diagup}{R_2C{-\!-\!-}CR_2}$. These sulfides, analogs of α-pinacolines, are formed, undoubtedly, through loss of $XMg{-}S{-}MgX$ from the compound $R_2C(SMgX){-}C(SMgX)R_2$, the dimolecular form of the initial reaction product $R_2C(SMgX){-}$.

[14] The radical $R'{-}$ instead of polymerizing might also undergo oxidation and reduction with the formation of equivalent amounts of the saturated hydrocarbon R'_{+H} and the unsaturated hydrocarbon R'_{-H}.

Phenylpropyl ketone,[15] dissolved in benzene, was added in small portions to a cold ether solution of phenylmagnesium bromide which had been prepared from 1.2 molecular equivalents of bromobenzene. After twenty-four hours the liquid was decanted from the precipitate and the latter was treated with ice and ammonium chloride. After the oily reaction product had been cooled for several days it became solid. The material was washed with low-boiling petroleum ether; m. p. 32–33°.

Reducing Action of Alkylmagnesium Halides.—It is not a simple matter to determine quantitatively the relative reducing power of a series of alkylmagnesium halides. The yields of the latter compounds vary greatly, depending upon the nature of the alkyl halide and other factors, and a complete separation of the secondary carbinol from the tertiary carbinol and other products present in the reaction mixture is a difficult process. In order to isolate benzhydrol we made use of the fact that the MgBr derivative of this carbinol is quite insoluble in a mixture of benzene and ether. To ethylmagnesium bromide, prepared from 13.1 g. of ethyl bromide, 2.9 g. of magnesium and 25 cc. of ether, there was added 9.2 g. of benzhydrol dissolved in 25 cc. of benzene. After twelve hours the precipitate was separated from the ether–benzene layer and decomposed with ice and ammonium chloride. There was obtained 7.5 g. of benzhydrol or 81% of that used originally, which melted at 64–66° without recrystallization.

Procedure.—The ketone, dissolved in the smallest possible amount of dry benzene, was added in small portions with vigorous agitation to an ether solution of the Grignard reagent which had been thoroughly cooled with ice. After twenty-four hours the reaction mixture was treated with ice and ammonium chloride. In those instances in which a precipitate had formed the latter was isolated and decomposed separately. The ether–benzene solution was dried with fused sodium sulfate and the solvents were then allowed to evaporate spontaneously.

In addition to the crystalline secondary carbinols there were obtained in most cases oils from which some solid material deposited after a number of days.

Undoubtedly the reduction of the ketones took place to a greater extent than is indicated in the above table. Some of the secondary carbinol was lost during the final purification and a certain amount could not be separated from other products formed in the reaction. The five-degree range in the melting point of the benzhydrol, obtained from benzophenone and *iso*butylmagnesium iodide, shows that the material was impure; hence the yield recorded is somewhat too high. In all other instances it can be seen from the melting points that the yields of the secondary carbinols are based on quite pure material.

---

TABLE I

RESULTS OF EXPERIMENTS

Alkylmagnesium halide prepared from		Yield of secondary carbinol based on ketone, %	M. p., °C. Found	M. p., °C. Literature	Mixed m. p., °C.
Methyl iodide	Benzophenone	97[a]	...	...	...
Ethyl bromide	Benzophenone	80[b]	...	...	...
n-Propyl bromide	Benzophenone	50[c]	67–68	68[d]	67–68
Isopropyl bromide	Benzophenone	22	65-66	...	...
n-Butyl iodide	Benzophenone	27	65-67	...	...
Isobutyl iodide	Benzophenone	74	61–66	...	...
Iso-amyl bromide	Benzophenone	30	63-67	...	...
n-Propyl bromide	*p*-Bromobenzophenone[e]	24	62–64	63[f]	63–64
n-Propyl bromide	Phenyl-α-naphthyl[g]	65	84–86	86[h]	84–86
n-Propyl bromide	Phenylbiphenyl[i]	48	94–96	96[j]	95–96
n-Propyl bromide	Phenylbenzyl[k]	9	64-66	66-67'	64–65

[a] Tertiary carbinol. There was used **0.025** mole of benzophenone and 0.100 mole of methyl iodide. The tertiary carbinol melted at **81–82'.** Klages [*Ber.*, **35**, **2646 (1902)**] recorded the melting point as **81°**. Schmalfuss [*J. prakt. chem.*, **108**, *88* **(1924)**] reported a 98% yield of this carbinol.

[b] Tertiary carbinol. **0.025** mole of benzophenone and **0.100** mole of ethyl bromide. The tertiary carbinol was recrystallized from a mixture of benzene and low-boiling petroleum ether; m. p. **92–94".** Masson [*Compt. rend.*, **135**, **533** (1902)] prepared ethyldiphenylcarbinol from phenylmagnesium bromide and ethyl propionate; m. p. 91°. Hell and Bauer [*Ber.*, **37**, **231** (1904)] obtained the compound from ethylmagnesium bromide and benzophenone but did not report the yield; m. p. **94–95'.**

[c] In this experiment, as well as in those which follow, there were used **0.100** mole of ketone and **0.120** mole of the alkyl halide.

[d] A sample of benzhydrol was prepared from phenylmagnesium bromide and ethyl formate Masson [Compt. *rend.*, **135**, **533** (1902)]. A part of the benzhydrol obtained as a reduction product was converted by hydrogen chloride into benzhydryl chloride. The latter was dissolved in benzene and shaken with silver benzoate. The benzhydryl benzoate formed melted at **86–88'.** Linnemann [*Ann.*, **133**, **20 (1865)** prepared this benzoate by another method; m. p. **87-89".**

[e] Montagne, Rec. *trav. chim.*, **27**, **335 (1908).**

[f] Montagne, *ibid.*, **27**, *342* **(1908).**

[g] Phenyl-a-naphthyl ketone was prepared by the addition of **20.6** g. of phenyl cyanide, drop by drop, to a-naphthylmagnesium bromide which had been prepared from **49.6** g. of a-bromonaphthalene and **5.8** g. of magnesium. The mixture was heated for one hour on a water-bath, the heavy precipitate removed by filtration and decomposed in the usual manner. The ketone imine was boiled for several hours with a mixture composed of water, acetic acid and sulfuric acid. The crude ketone which was formed was subjected to steam distillation in order to remove traces of naphthalene and phenyl cyanide and was then distilled under diminished pressure. The product melted at **71–73°**.

[h] A much better procedure for the preparation of phenyl-α-naphthylcarbinol than that described by Acree [*Ber.*, **37**, **2757** (1904)] is as follows: **10.6** g. of pure benzaldehyde, diluted with four volumes of absolute ether, was added slowly to the Grignard reagent obtained from **24.8** g. of a-bromonaphthalene and **2.9** g. of magnesium. After twenty-four hours the precipitate was filtered and decomposed with ice and ammonium chloride. The crude product was recrystallized from a mixture of benzene and petroleum ether. The yield of pure carbinol was **16** g.

[i] Montagne, *Rec. trav. chim.*, *27, 356* (1908).
[j] Montagne, ibid., 27, 358 (1908).
[k] Sudborough, J. *Chem. Soc.*, 71,219 (1897).
[l] Hell, *Ber.*, 37, 456 (1904).

In one instance 36.4 g. of benzophenone, dissolved in benzene, was allowed to react with 1.2 molecular equivalents of n-propylmagnesium bromide at approximately 0°. The gas evolved during the reaction was collected over mercury and then passed through bromine dissolved in carbon tetrachloride. Nine and four-tenths g. of propylene bromide was obtained which corresponds to a 23% yield. The bromide boiled from 135–140°. Undoubtedly a considerable part of the propylene remained dissolved in the reaction mixture.

An attempt was made to obtain the carbinol chloride from methyldiphenylcarbinol. The latter was dissolved in absolute ether and the solution was saturated with dry hydrogen chloride. After several days the solvent was removed at ordinary temperature by means of a stream of dry air. An oily residue was obtained, a part of which eventually became crystalline. The oil possessed a penetrating, camphoraceous odor. The crystalline material, after recrystallization from low-boiling petroleum ether, melted at 113–114°. This compound seems to be a polymerized form of 1,1-diphenylethylene and has been obtained by other investigators by a different method.[16]

Summary

It has been shown that a number of diarylalkylcarbinols cannot be made satisfactorily by the interaction of an alkylmagnesium halide and an aromatic ketone because of the reducing action of the Grignard reagent.

A mechanism has been suggested to account for the formation of the compounds produced in the above-mentioned reaction.

THE EFFECT OF TEMPERATURE ON THE REDUCTION RATE OF FURFURAL WITH THE CATALYST FROM $PtO_2 \cdot H_2O$

BY J. STANTON PIERCE AND CHARLEY PARKS

RECEIVED APRIL 26, 1929 PUBLISHED NOVEMBER 8, 1929

Several investigators have noted a decrease in the catalytic activity of platinum black and sponge for hydrogenations when these are heated to a high temperature.[1] Others have noted that temperature affects reduction rates, both with[2] and without[3] the use of a solvent. However, little work has been done on a quantitative study of reduction rate, with platinum black, at temperatures slightly above and below room temperature, which is used generally in such reductions.

This paper deals with the effect of temperature on the reduction rate of furfural, in 95% alcohol, at 0, 20, 40 and 60°, with platinum black from $PtO_2 \cdot H_2O$[4] as catalyst. Using the same catalyst, Carothers and Jones[5] noted that between 50 and 100° increase in temperature caused increased speed in the reduction of aromatic nitriles. Tuley and Adams[6] observed that a rise in temperature caused an increase in the reduction rate of cinnamyl aldehyde, but a lowering of the yield of pure reduction product. Also, with this catalyst, it has been noted that the reduction rates of geraniol,[7] triphenylamine,[8] pyridine hydrochloride,[9] and aromatic nitro compounds[10] increase with rise in temperature, but these studies were not quantitative.

In this paper it is shown that increase in temperature from 0 to 40° causes a marked increase in the reduction rate of furfural, and at 60°, if sufficient catalyst is present, the initial reduction rate is much greater than at 40°. However, at 60° the catalyst is rendered inactive more readily than at 40°, so particularly if only a small amount of catalyst is present, the reduction will proceed faster at 40° than at 60°. Also, it

is shown that, although furyl alcohol is formed readily and quantitatively, without activation of the catalyst, the same catalyst, without activation, will not add hydrogen to the formed furyl alcohol.

Experimental Part

The apparatus used in this work was essentially the same as that used by Vorhees and Adams,[11] except that it was arranged so that the temperature could be kept constant. In order that the results might be comparable, in each case 9.6 g. (0.1 mole) of furfural, dissolved in 75 cc. of alcohol, was reduced in the presence of catalyst from the same batch and 1 cc. of freshly prepared 0.1 M ferrous sulfate, with hydrogen at about 2 atmospheres pressure. Runs were made with 0.122 (see Fig. 1) and 0.244 g. (see Fig. 2) of $PtO_2 \cdot H_2O$[12] at 0, 20, 40 and 60°. In all of these reductions the catalyst was activated at the end of each hour by shaking it for ten minutes with oxygen.[13] The effect on the reduction rate may be noted from the upward trend of each curve at the beginning of the hour, in Figs. 1 and 2.

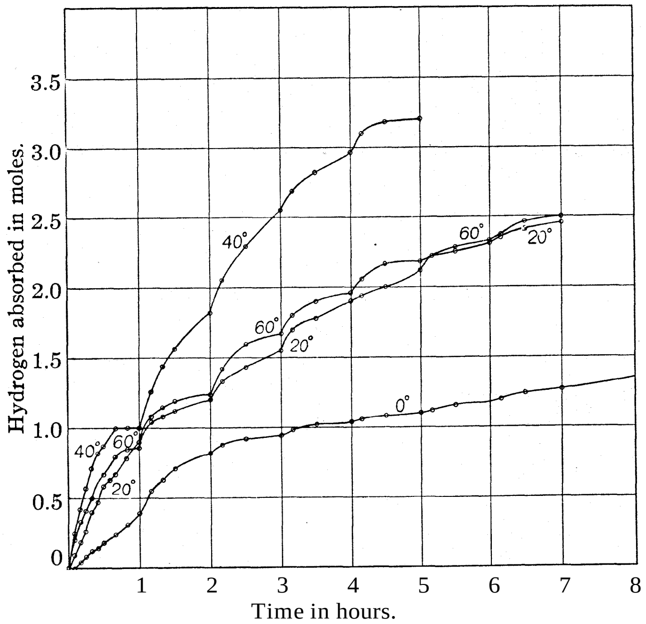

Fig. 1.—Reduction of 0.1 mole of furfural; 0.122 *g.* of catalyst; 1 cc. of *M*/10 ferrous sulfate.

Furyl alcohol was formed quantitatively by the addition of 1 mole of hydrogen to furfural. Kaufmann and Adams[13] showed that with the catalyst used for this work, on complete reduction, furfural yields tetrahydrofuryl alcohol, pentanediol-1,5, pentanediol-4,5 and n-amyl alcohol.

---

[11] Vorhees with Adams, THIS JOURNAL, 44, 1403 (1922).

[12] Note: 0.122 g. of catalyst is 0.005 mole, assuming its formula to be $PtO_2 \cdot H_2O$. Calcd. for $PtO_2 \cdot H_2O$: Pt, 79.95. Found: Pt, 79.73.

[13] Kaufmann with Adams, THIS JOURNAL, 45, 3029 (1923).

As can be seen from the figures, the catalyst becomes active and the absorption of hydrogen becomes rapid much more quickly in the higher temperature than in the lower temperature reductions. $PtO_2 \cdot H_2O$ is brown and the active catalyst is black, so the change in color from brown to black is an indication of the formation of the active catalyst. Usually, in the 60° runs, the catalyst became black in less than forty-five seconds, while in the 0° runs it sometimes took ten minutes or over for the catalyst to become completely black.

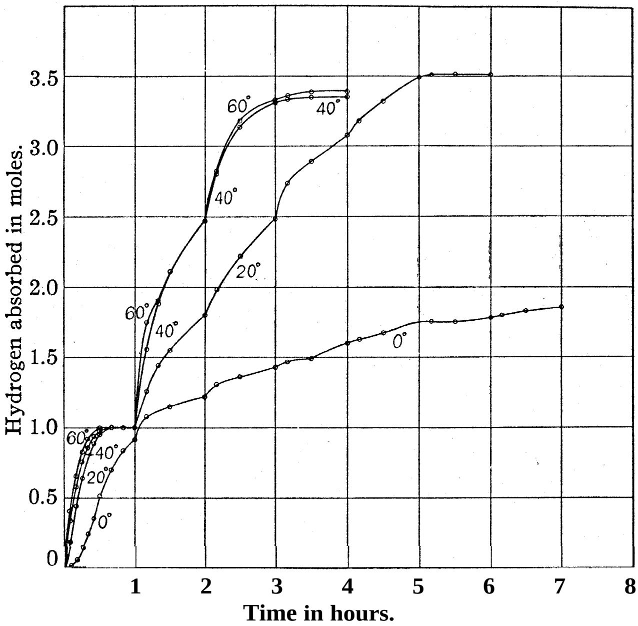

Fig. 2.—Reduction of 0.1 mole of furfural; 0.244 g. of catalyst; 1 cc. of $M/10$ ferrous sulfate.

It was noted that in no case was over 1 mole of hydrogen added to furfural until the catalyst was activated. Attempts were made to cause more to be absorbed by increasing the amount of catalyst and lengthening the time of shaking the reaction mixture. Although 0.122 g. of catalyst at 40° caused 1 mole of hydrogen to be added smoothly in forty minutes, at the same temperature 0.976 g. or eight times as much catalyst caused no more to be added (if a correction is made for the hydrogen required to reduce the $PtO_2 \cdot H_2O$ to the active catalyst, as determined in a control test), although the reaction mixture was shaken for one hour after hydrogen ceased to be absorbed. These facts seem to indicate that the platinum black which has been used as a catalyst for the reduction of furfural is not a catalyst for the reduction of furyl alcohol, and that the only way it can be made to add more hydrogen to the latter compound is to change its surface by activation.

Summary

1. Curves are given for the reduction rate of furfural at **0, 20, 40** and 60°.
2. Activation of the catalyst is necessary to add more than 1 mole of hydrogen to furfural.

THE PREPARATION OF MERCURY DIPHENYL[1] BY USE OF THE GRIGNARD REAGENT

BY P. BORGSTROM AND MARGARET M. DEWAR

RECEIVED APRIL 26, 1929 PUBLISHED NOVEMBER 8, 1929

The reactions that may take place in the preparation of mercury diphenyl by the Grignard reagent are as follows

$$\begin{aligned}
HgX_2 + 2C_6H_5MgBr &= Hg(C_6H_5)_2 + 2MgBrX \qquad (1)\\
HgX_2 + C_6H_5MgBr &= Hg(C_6H_5)Hal + MgBrX\\
Hg(C_6H_5)X + C_6H_5MgBr &= Hg(C_6H_5)_2 + MgBrX\\
HgX_2 + Hg(C_6H_5)_2 &= 2Hg(C_6H_5)X
\end{aligned}$$

HgX_2 may be the iodide, bromide or chloride. Laszczynski[2] measured the solubility of mercuric iodide and chloride in absolute ether at 0° and found it to be **0.62** and 5.98%, respectively. Measurements made on mercuric bromide at 0° gave the solubility as 4.82 g. per **100** g. of solution, using absolute ether. Due to the insolubility of the iodide experiments were made with the bromide and chloride only. The yields as given in Table I show some difference between the bromide and chloride for the same concentration but not sufficient to say that one is much better than the other.

Table I shows that 85 mole per cent. of mercuric halide gives the best yield with the methods used. From published data[3] the yield of the Grignard reagent from bromobenzene is about 94%, which gives an excess over the mercuric halide used of about 9%; this is not too much considering the fact that it must be transferred before using.

---

[1] For the different methods of preparation of mercury diphenyl see "Organic Syntheses," Vol. IX, John Wiley and Sons, Inc., New York, 1929, p. 54. One later method is described in *Ber.*, 62, 1018 (1929). The method in "Organic Syntheses" uses a 3% sodium amalgam. Better yields can be obtained with an 8% amalgam (Michaelis and Loesner, *Ber.*, 27, 264 (1894)) which has been checked by the authors. If a large quantity of mercury diphenyl is wanted this method is recommended over the Grignard. It should always be remembered that the vapors of mercury diphenyl are toxic.

[2] Laszczynski, *Ber.*, 27, 2285 (1894).

[3] Gilman, Zoellner and Dickey, THIS JOURNAL, 51, 1584 (1929).

Hilpert and Grüttner[4] give the yield for Equation 2. They refluxed for four hours 0.16 M phenylmagnesium bromide and 0.20 M mercuric bromide with a yield of recrystallized mercury phenyl bromide of 93%, or nearly quantitative. They state that this was easily prepared but to go from it to mercury diphenyl as shown in Equation *3* required an excess of the Grignard reagent and then gave a poor yield with 40% as the highest (no experiments cited).

From experimental evidence given in this paper the yield in Equation **3** is very close in agreement with the mercury diphenyl formation from mercury dihalide itself and may be the controlling factor in its preparation. The reverse reaction of Equation **3** is probably not sufficient to affect the yield in the presence of the excess Grignard reagent.

Equation 4 shows that if there is once any excess of mercury dihalide and mercury diphenyl present without the Grignard reagent there will be a loss of mercury diphenyl. This was substantiated by experiment.

Fleck[5] studied the reaction between mercury diphenyl and magnesium metal and found a reaction at about 200° with the formation of magnesium diphenyl and free mercury. It may be that this same reaction occurs to a less extent at the boiling point of ether, for if any unreacted magnesium is allowed to remain in the reaction flask the yield is greatly reduced.

Therefore the ideal condition for a large yield for the preparation of mercury diphenyl is as follows: have Grignard reagent in excess, have no magnesium metal present, do not let the mercury diphenyl formed stand with mercuric halide without the presence of the Grignard reagent and use about *85* mole per cent. of mercuric salts.[6]

TABLE I

YIELD OF MERCURY DIPHENYL WITH VARYING CONCENTRATIONS OF MERCURIC HALIDES

	Mercuric chloride			Mercuric bromide		
Runs	3	1	2	1	2	1
HgX_2, moles	0.375	0.425	0.45	0.188	0.415	0.225
C_6H_5Br, moles	1	1	1	0.5	1	0.5
$Hg(C_6H_5)_2$, moles	0.177	0.217	0.174	0.070	0.226	0.096
$Hg(C_6H_5)_2/HgX_2$ X 100	47.2	51.0	38.7	37.2	54.6	42.6

Experimental

Preparation of Mercury Diphenyl.—To the Grignard reagent, which was poured into a dry two-liter flask to separate it from the unreacted magnesium, was added the dried mercuric halide. After the slight reaction had subsided, it was refluxed for seventy-two hours. At the end of the reaction there was usually a gray residue in the flask

---

[4] Hilpert and Gruttner, Ber., 46, 1675 (1913).

[5] Fleck, *Ann.*, 276, 138 (1893).

[6] These experiments were made without the use of mechanical stirrers, Soxhlet [see Gilman and Brown, THIS JOURNAL, 51,928 (1929)], etc., which are now used. The yield should be improved by their use.

with some unreacted mercuric halide. The ether layer was then poured while warm onto ice. White needles separated which were washed and dried. The contents of the flask were washed with 500 cc. of wet ether and the ether extract was washed with a very little dilute hydrochloric acid. The ether was evaporated and crystals of mercury diphenyl separated. The crude mercury diphenyl was dissolved in warm chloroform to which was added an equal volume of warm alcohol; it then was allowed to crystallize. The residue in the flask contained some mercury phenyl halide which could be extracted with hot xylene. The yields are given in Table I.

In one run using 0.75 mole quantity of mercuric chloride and 1.0 mole of bromobenzene, the Grignard reagent was not poured from the magnesium residues. The procedure was the same as with the others. The yield was reduced 15%.

In one run using 0.9 mole quantity mercuric chloride and 1 mole of the Grignard reagent, the experiment was conducted as usual except that the ether was cooled before pouring off from the residues. Crystals of mercury diphenyl separated. Then more ether was added and the contents of the flask was refluxed for several hours. On separation and evaporation of the ether no further mercury diphenyl was recovered and the yield was reduced over 5%. This decrease was probably due to the reaction between mercury diphenyl and the excess mercuric chloride to form mercury phenyl chloride.

Mercury Phenyl Chloride and **Phenylmagnesium** Bromide.—To 0.1 M Grignard (made and poured from the magnesium residues) was added 26.5 g. (0.085 mole) of recrystallized mercury phenyl chloride. There was a slight reaction on addition. This was gently refluxed for seventy-two hours as usual. The reaction product was handled as in the typical case; yield, 15.7 g. of recrystallized mercury diphenyl or 52.2% conversion based on the mercury phenyl chloride used.

Mercury Diphenyl and Mercuric Bromide.—Eighteen grams of recrystallized mercuric bromide and 17.7 g. of mercury diphenyl were gently refluxed in 250 cc. of dry ether for seventy-two hours. The ether was poured off and evaporated. A few tenths of a gram of mercury diphenyl was recovered. There is practically complete conversion to mercury phenyl bromide.

Mercury Diphenyl and Anhydrous Magnesium Bromide.—One hundredth mole of mercury diphenyl in 50 cc. of dry ether was refluxed with anhydrous magnesium bromide for several days. Then dried Michler's ketone was added and it was again refluxed. No color developed with the ketone on decomposition with water, showing no appreciable amount of the Grignard reagent present.'

Summary

The preparation of mercury diphenyl by the Grignard reagent and mercuric halides has been discussed. Some factors influencing the yield are given.

WASHINGTON, D. C.
HONOLULU, T. H.

Gilman and Schulze, THIS JOURNAL, 47,2002 (1925), give the test with Michler's ketone as a qualitative one for the Grignard reagent, but point out that the Grignard reagent might be present in small quantities and still be negative. The results here were either negative or at best a trace. As the magnesium bromide used was prepared by heating $MgBr_2 \cdot 6H_2O$ and NH_4Br in an atmosphere of dry carbon dioxide, it may not have been absolutely pure. This reaction is being studied further.

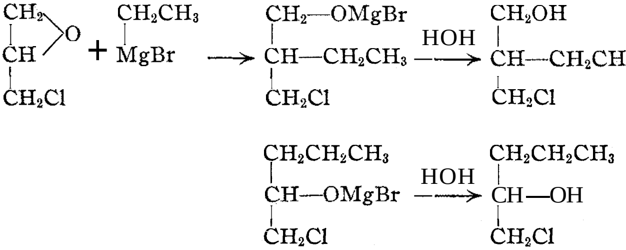
THE REACTION OF ETHYLMAGNESIUM BROMIDE WITH EPICHLOROHYDRIN

BY C. FREDERICK KOELSCH AND S. M. McELVAIN

RECEIVED MAY 2, 1929 PUBLISHED NOVEMBER 8, 1929

In connection with some work being carried on in this Laboratory it was desired to prepare 2-chloromethylbutanol-1 (I). It was thought that the reaction between ethylmagnesium bromide and epichlorohydrin might yield this particular compound, its isomer (11),or both, according to the reactions



(I)

(II)

The reaction was carried out in the usual manner, but when the reaction product was isolated and weighed it was apparent that the reaction had taken a different course from that shown above, for if the product formed was considered to be a chloro-amyl alcohol, the yield was approximately 115% of the theoretical.

The literature was then consulted, and it was found that the above reaction had been studied by a number of investigators, and that there was considerable disagreement as to the products that were formed. Iozitsch[1] reported that he obtained a chloro-amyl alcohol from the reaction between ethylmagnesium bromide and epichlorohydrin but made no mention of any other products. A little later Kling,[2] using methylmagnesium iodide to react with epichlorohydrin, obtained nothing but a glycerol chloro-iodohydrin. Iozitsch repeated his work and stated that he did obtain a glycerol chlorobromohydrin, but that he was able to separate it from the chloro-amyl alcohol by fractional distillation. The yield of neither product was given. Later, Fourneau and Tiffeneau[3] studied the action of ethyl-, propyl-, butyl- and amylmagnesium bromides on

---

[1] The papers of Iozitsch on this subject are J. *Russ. Phys.-Chem. Soc.*, 34, 96 (1902); *ibid.*, 36, 6 (1904); but this journal was not available for reference. Neither could reference to this author's work be found in the *Centralblatt* or in the *British Chemical Abstracts*. *All* of the information concerning Iozitsch's work was found in the articles of Kling and of Fourneau and Tiffeneau.

[2] Kling, *Bull. soc. chim.*, [3] *31*, 14 (1904).

[3] Fourneau and Tiffeneau, *ibid.*, [4] 1, 1227 (1907).

epichlorohydrin under numerous conditions of reaction, and were unable to duplicate Iozitsch's results. Glycerol chlorobromohydrin was the only product that they could isolate from the reaction mixture regardless of which alkylmagnesium bromide was used. These investigators were able, however, to obtain good yields of the expected chloro-alcohols when phenyl-, p-methoxyphenyl- and benzylmagnesium bromides were used instead of the alkylmagnesium bromides, although there was always some glycerol chlorobromohydrin formed. Delaby[4] reported that ethylmagnesium bromide and ethyl glycerol epibromohydrin reacted to form 1,3-dibromopentanol-2, which corresponds to the results obtained by Fourneau and Tiffeneau, and by Kling.

An investigation of the reaction product from ethylmagnesium bromide and epichlorohydrin in this Laboratory showed the presence of at least two different compounds. On repeated fractional distillation under reduced pressure, the product was separated into two fractions, one boiling at 70–75° (20 mm.) and the other boiling at 100–105° (20 mm.). Analyses of these two fractions indicated that the lower-boiling fraction was a chloro-amyl alcohol, and that the higher-boiling fraction was a glycerol chlorobromohydrin. This latter compound was proved to be 1-chloro-3-bromopropanol-2 by preparing the known 1,3-diphenoxypropanol-2 from it.

Since Iozitsch did not determine the structure of the chloro-amyl alcohol which he prepared, the product obtained in this work was further investigated in order to determine which of the two possible isomers it was. Reduction to the corresponding amyl alcohol seemed to be the simplest way of determining the structure, but such reducing agents as zinc dust with acetic or hydrochloric acid, the zinc–copper couple in aqueous alcohol and catalytic platinum with hydrogen were without action. Sodium amalgam removed the halogen, but none of the amyl alcohol could be isolated. Oxidation of the chloro-alcohol with alkaline potassium permanganate converted it into butyric acid, but it is conceivable that both isomers (I and II) might yield butyric acid with this reagent.

The chloro-alcohol was then converted by thionyl chloride into a dichloropentane. This latter compound reacted slowly with sodium iodide in acetone solution to liberate free iodine. This behavior, as van Duin[5] has shown, indicates that the halogens in the dichloropentane were on adjacent carbon atoms and that the chloro-amyl alcohol in question has the structure II. Finally, 1,2-dichloropentane was prepared by the addition of chlorine to pentene-1. The dichloropentane prepared from the chloro-amyl alcohol was identical with the 1,2-dichloropentane prepared from pentene-1.

These results leave no doubt that Iozitsch's observations, rather than those of Fourneau and Tiffeneau, on the products of the reaction between epichlorohydrin and ethyl magnesium bromide were correct and that the particular chloro-amyl alcohol which is formed is 1-chloropentanol-2.

Various reaction conditions were tried in an effort to find the optimum conditions for the formation of the chloro-alcohol, but the maximum yield which it was possible to obtain amounted to only 19% of the theoretical. The remainder of the reaction product was the glycerol chlorobromohydrin mentioned above. With ethylmagnesium chloride approximately the same amounts of the chloro-alcohol along with a corresponding quantity of the glycerol dichlorohydrin were obtained.

Experimental

I–Chloropentanol-2.—The following procedure was found to give the best yield of this product. A solution of ethylmagnesium bromide prepared from 109 g. (1 mole) of ethyl bromide and 26.5 g. (1.1 atom) of magnesium in 300 cc. of ether was added slowly with stirring to 92.5 g. (1 mole) of epichlorohydrin dissolved in 100 cc. of ether contained in a three-necked flask fitted with a stirrer, reflux condenser and dropping funnel. During the addition the flask was cooled with running water. The mixture was refluxed for one hour and allowed to stand for two days at room temperature, the flask being closed with a soda-lime tube. *At* the end of this time, no appreciable precipitate had formed in the reaction mixture. A solution of 75 g. of acetic acid in 200 cc. of water was then added slowly with stirring and external cooling. The ether layer was separated, washed with dilute sodium carbonate solution until neutral, and the ether distilled off on a water-bath at 60°. The remaining oil was fractionated five times under reduced pressure, fractions being taken every 5° from 70 to 105° (20 mm.). The total weight of these fractions was 135–140 g. The fractions boiling to 85° were refractionated three times at atmospheric pressure, the part boiling at 157–160° (735 mm.) being practically pure chloropentanol; yield, 20–23 g. (16–197, of the theoretical); d_{25}^{25} 1.0143; n_{D}^{25} 1.4404.

Anal. Calcd. for $C_5H_{11}OCl$: Cl, 28.9. Found: Cl, 28.7.

The following variations in the preparation were tried. (a) After the reactants had been mixed, the ether was distilled off and simultaneously replaced by higher-boiling inert solvents such as benzene and toluene. There was no appreciable precipitate formed in the benzene (or toluene) solution even after four to five hours of refluxing. When the reaction mixture was fractionated, the boiling point range of the product indicated that only a small amount of chloro-alcohol had been formed. (b) After the reactants had been mixed, the ether was distilled off and the dry addition product was heated on a water-bath.[6] This treatment caused the rearrangement to take place with explosive violence, and a carbonaceous, ash-like mass was left from which none of the chloro-alcohol could be isolated. (c) The reactants were mixed and allowed to stand for two weeks in ether. After about three days, a white precipitate settled out of the solution. On longer standing, an inflammable gas, which analysis showed to be a mixture of ethylene, ethane and hydrogen, was given off from the reaction mixture. Only 6.5 g of chloro-amyl alcohol was obtained when the reaction mixture was worked up in the usual way. (d) n-Butyl ether was used as a solvent instead of ordinary ethyl ether, and the reactants were heated at various temperatures up to the boiling point

---

[6] *Cf.* Grignard Bull. *soc. chim.,* **[3]** 29, 944 (1903).

of the solvent (140°). By these procedures it was not possible to isolate any of the chloro-alcohol. It was apparent, however, that some fundamental change had occurred in the reaction mixture, for when the reactants were mixed in butyl ether, a white crystalline precipitate formed which on further heating changed into a brown, porous, brittle mass from which not even the glycerol chlorobromohydrin could be isolated. If the initial precipitate from the butyl ether was hydrolyzed immediately, glycerol chlorobromohydrin was the only product obtained.

Acetate of I-Chloropentanol-2.—Ten grams of the chloro-alcohol was warmed with an equal weight of acetyl chloride on the water-bath until no more hydrogen chloride was given off. Water was then added, the oil washed with dilute sodium carbonate solution and dried over calcium chloride. The acetate distilled at 186–188° (740 mm.); d_{25}^{25} 1.0825; n_{D}^{25} 1.4328.

Anal. Calcd. for $C_7H_{13}O_2Cl$: Cl, 21.2. Found: Cl, 21.1.

3,5-Dinitrobenzoate of 1-Chloropentanol-2.—A mixture of 2.5 g. of the chloro-alcohol and 4.61 g. of 3,5-dinitrobenzoyl chloride was heated on an oil-bath to 135° until no more hydrogen chloride was given off. The sirupy brown liquid was dissolved in hot alcohol and on cooling the ester crystallized out in colorless plates which melted after another recrystallization from alcohol at 83–84°.

Anal. Calcd. for $C_{12}H_{13}O_6N_2Cl$: Cl, 11.3. Found: Cl, 11.5.

To a solution of 11 g. of potassium permanganate in 100 cc. of water was added 2.5 g. of 1-chloropentanol-2 and the solution refluxed until the permanganate color was destroyed. The manganese dioxide was then filtered off and the filtrate acidified with sulfuric acid and distilled. The distillate, after neutralization with sodium hydroxide, was evaporated to dryness. The resulting sodium butyrate was converted into the *p*-toluidide of the acid, which after recrystallization melted at 70–72°.

1,2-Dichloropentane from I-Chloropentanol-2.—Twelve grams of the alcohol was mixed with 15 g. of freshly distilled diethylaniline in a flask fitted with a reflux condenser. The mixture was cooled while 24 g. of thionyl chloride was added through a dropping funnel.[7] The mixture solidified and became brown during the addition, but it liquefied when all of the thionyl chloride had been added. The reaction was completed by heating on the water-bath until the evolution of sulfur dioxide had ceased. Water was added and the oil steam distilled out. After washing with concd. sulfuric acid and then sodium carbonate solution, and drying with calcium chloride, the oil was fractionated. The yield was 9.6 g. of a product boiling at 145.8–146.2° (739 mm.); d_{25}^{25} 1.0767; n_{D}^{25} 1.4448.

Anal. Calcd. for $C_5H_{10}Cl_2$: Cl, 50.3. Found: Cl, 50.1.

To a solution of 15 g. of dry sodium iodide in 100 cc. of dry acetone was added 5 g. of the dichloropentane as obtained above. The solution was refluxed for about six hours, after which time the solution was distinctly colored with free iodine and a precipitate of about 1 g. of sodium chloride had formed. The acetone was distilled off and water added to the residue. The insoluble oil was taken up in ether, washed with sodium thiosulfate, dried, and after removal of the ether, distilled. The dichloropentane that was recovered amounted to 3.2 g.

1,2-Dichloropentane from **Pentene-1.**—Pentene-1 was prepared according to the method of Kirrmann.[8] Seven grams of pentene-1 was dissolved in 50 cc. of carbon tetrachloride. The solution was cooled with ice and chlorine was passed in under diffused artificial light until the yellow color remained in the solution for about thirty seconds after the current of chlorine had been stopped. After the removal of the carbon tetra-

chloride from the product by fractional distillation, the dichloropentane distilled at 146.0–146.2"; yield, 7 g.; d_{25}^{25} 1.0773; n_D^{25} 1.4453.

Anal. Calcd. for $C_5H_{10}Cl_2$: Cl, 50.3. Found: Cl, 49.8.

1-Chloro-3-Bromopropanol-2.—The fraction boiling at 100–105° (20 mm.) from the preparation of 1-chloropentanol-2 was refractionated under reduced pressure into a part boiling at 95–98° (15 mm.) which was the glycerol chlorobromohydrin described by Fourneau and Tiffeneau.[3] The compound was colorless when freshly distilled but darkened rapidly on exposure to light. It boiled with much decomposition at 190–200° (740 mm.), and for this reason was best purified by distillation under diminished pressure; d_{25}^{25} 1.7456; n_D^{25} 1.5140.

Anal. Calcd. for C_3H_6OClBr: Cl, 20.4; Br, 46.1. Found: Cl, 20.1; Br, 45.3.

No effort was made to secure the maximum yield of this compound. Presumably, however, about 100 g. of it was available from a run of one mole of epichlorohydrin, since the total weight of reaction product was about 140 g. and about 23 g. of chloropentanol was obtained from this. The intermediate fractions weighed 10–15 g.

The chlorobromohydrin was further identified by preparing the known 1,3-diphenoxypropanol-2 from it by the procedure described by Rossing[9] for the preparation of this substance from a-dichlorohydrin. The melting point of the diphenoxy compound after recrystallization from alcohol was 80–81°.

Summary

1. It has been shown that ethylmagnesium bromide reacts with epichlorohydrin to give a chloro-amyl alcohol as well as glycerol chlorobromohydrin.

2. The chloro-amyl alcohol which is formed has been found to be 1-chloropentanol-2.

STUDIES ON HYDRAZINE. THE HYDROLYSIS OF DIMETHYLKETAZINE AND THE EQUILIBRIUM BETWEEN HYDRAZINE AND ACETONE

BY E. C. GILBERT[1]

RECEIVED MAY 3, 1929 PUBLISHED NOVEMBER 8, 1929

One of the most important properties of hydrazine and its organic substitution products is their capacity to react with the carbonyl group of ketones and aldehydes, forming hydrazones or azines by elimination of water. This reaction takes place most generally in neutral or alkaline solution, while in acid the product is to a greater or less extent, depending on the particular componenis, hydrolyzed. A study of this type of hydrolysis, using the product formed in the reaction of hydrazine with the simplest ketone, acetone, has been made in the work here presented.

---

[9] Rossing, ***Ber.,*** 19, 64 (1886).

[1] Fellow of the John Simon Guggenheim Memorial Foundation.

When hydrazine and acetone are brought together under the proper conditions, two molecules of acetone combine with one of hydrazine to form dimethylketazine.[2] This ketazine dissolves readily in water and the solution becomes alkaline. If the free hydroxyl ion is neutralized with acid, more OH^- is then formed. In the presence of strong mineral acids the compound is completely hydrolyzed. The hydrolysis takes place with measurable velocity and the progress of the reaction may be followed by measuring the amount of acid necessary to replace the H^+ which has reacted with the ketazine, adding the acid at such a rate as to maintain a constant PH in the solution. Examination of the reaction, however, showed the probability of there being present also acetone hydrazone, containing one molecule of acetone and one of hydrazine. In addition to this the reaction proved to be highly reversible, coming to equilibrium at PH 5.0 when from 30 to 70% of the ketazine had been hydrolyzed, the extent depending not only on the PH but also on the original concentration of ketazine.

The entire reaction may be formulated, therefore, either as a reaction between dimethylketazine and water to form the acetone hydrazone, which is in turn hydrolyzed to hydrazine and acetone, or as a direct hydrolysis of the ketazine to acetone and hydrazine, with the hydrazone formed by a side reaction between the two latter. The equations are

$$\underset{C}{(CH_3)_2C{=}N{-}N{=}C(CH_3)_2} + H^+ + H_2O \rightleftharpoons \underset{D}{(CH_3)_2C{=}N{-}NH_3^+} + \underset{B}{(CH_3)_2CO} \quad (1)$$

followed by

$$\underset{D}{(CH_3)_2C{=}N{-}NH_3^+} + H_2O \rightleftharpoons \underset{A}{N_2H_5^+} + \underset{B}{(CH_3)_2CO} \quad (2)$$

or, alternatively

$$\underset{C}{(CH_3)_2C{=}N{-}N{=}C(CH_3)_2} + H^+ + 2H_2O \rightleftharpoons \underset{A}{N_2H_5^+} + \underset{B}{2(CH_3)_2CO} \quad (1a)$$

and

$$\underset{A}{N_2H_5^+} + \underset{B}{(CH_3)_2CO} \rightleftharpoons \underset{D}{(CH_3)_2C{=}N{-}NH_3^+} + H_2O \quad (2a)$$

Denoting by subscripts the equations for which the equilibrium constants are valid, the following relations exist

$$K_1 \times K_2 = K_{1a} \text{ and } K_{2a} = 1/K_2$$

The problem may therefore be resolved into three parts: (1) to determine the conditions of Equilibrium 2 or 2a; (2) to determine the conditions of Equilibrium 1 or 1a; (3) to study the kinetics of the hydrolysis. These will be taken up in the order named.

Part I

The Equilibrium between Acetone, Nydrazine and Acetone Hydrazone.—Since Reaction 1 or 1a involves H^+ on the left-hand side of the

---

[2] Curtius and Thun, *J. prakt. Chem.*, 44, 164 (1891).

equation, it is evident that by adding sufficient acid this equilibrium may be shifted completely to the right, while 2 or 2a will be unaffected by acid and may thus be studied independently. This was done by two different procedures.

1A. Determination of Equilibrium 2a by Solubility Measurements.—It has previously been found that hydrazine picrate[3] is an easily prepared salt sufficiently insoluble to be suited for measurements of solubility. The salt moreover contains only one equivalent of acid for each molecule of hydrazine, *i. e.*, it contains the ion $N_2H_5^+$. By measuring the increase in solubility of the salt when acetone is added to the solvent, the equilibrium between acetone, hydrazine and acetone hydrazone readily may be determined. The acidity must be adjusted so that no dimethylketazine is formed. The thermodynamic mass action law applied to Equation 2a yields the expression

$$K_{2a} = \frac{C_{\text{acetone hydrazone}^+}}{C_{N_2H_5^+} \times C_{\text{acetone}}} \times \frac{\mathbf{fl}}{f_1 \times f_0} \tag{3}$$

where f_1 stands for the activity coefficients of the two monovalent ions and f_0 for that of acetone. At low concentrations this factor would be of little import, but some salt effect upon the equilibrium would be expected at higher concentration. It has been shown,[4] however, that in solutions of sufficiently high ionic strength the activity coefficient factor may be neglected and concentration values employed directly in the mass action law and it was thought best to employ this expedient rather than introduce the activity coefficients.

The solubility of hydrazine picrate was therefore determined at 15° in the presence of acetone, 0.2 M sodium chloride and 0.02 M hydrochloric acid (the latter to prevent formation of dimethylketazine). Results are given in Table I. These were further confirmed by measurements in acetone, 0.2 M sodium chloride, and 0.01 *M* hydrochloric acid, Table II; in acetone and 0.04 *M* picric acid, Table III; and finally in acetone, 0.133 *M* sodium chloride, 0.067 M sodium picrate and 0.0033 *M* hydrochloric acid, Table IV.

(a) Materials.—Hydrazine picrate was prepared as previously described and rotated in water at 15° until succeeding samples of the solution gave the same value for the solubility. This material was used for subsequent determinations. Acetone was the best product obtainable, "zur Analyse," and was twice redistilled. A stock solution was made by weighing acetone in sealed ampules and breaking these under the surface of water in a volumetric flask.
