THE VELOCITY OF SAPONIFICATION OF METHYL ACETATE BY SODIUM HYDROXIDE AT 25°

By Wilby T. Gooch and Ethel M. Terry

Received August 17, 1928 Published July 5, 1929

As a part of a systematic study of catalysis in homogeneous solution carried out in this Laboratory[1] under the direction of Professor Julius Stieglitz, an exact measurement has been made of the rate of saponification of methyl acetate of about one hundredth molar concentration in aqueous sodium hydroxide solution at 25°.

Experimental Detail

Except for the case of the ester the preparation of materials, the method of measurement, the exclusion of carbon dioxide of the air from contact with reagents, etc., were the same as described elsewhere.]

Methyl acetate was prepared, first, by fractionation of Kahlbaum's best grade of ester, second. by the reaction of acetic anhydride and methyl alcohol and, third, by the reaction of acetic acid and methyl alcohol catalyzed by sulfuric acid as described by Wade2 and purified by the method of Wade and Merriam.[3] All samples were neutral to azolitmin in water solution. No difference was found for the rate of reaction of the ester of these samples.

In this work and in part of the work of Wilson and Terry[4] a special apparatus was used to take the samples of the reaction mixture for analysis at noted times. The apparatus, which was developed jointly with Wilson, will now be described with the assistance of Fig. **1.** The main parts are as follows: **(1)** the flask **A** which held the reaction mixture, **(2)** the valve tube B connecting A with the mercury pipet C from which mercury was discharged into **A,** producing simultaneously the discharge of an equal volume of the reaction mixture from e, the delivery tube of A, into the receiving bottle at M, **(3)** the reservoir E from which mercury was forced into C as it was needed, **(4)** the device **H** by means of which the delivery tube A could be freshly filled with solution just prior to the discharge of mercury from C, and (5) the coiled copper tube F through which water from the hydrant passed into E, thus supplying the pressure

---

[1] See ref. **2** of Terry and Stieglitz, This Journal, 49, **2216** (1927), for details of this study. The present paper is based on the thesis of Dr. Gooch, which was presented in **1916.**

which caused the flow of mercury from E whenever Stopcock 1 was opened. The apparatus was contained in a de Khotinsky thermostat, the water level of which is indicated by the horizontal broken line in the diagram.

Although much of the apparatus will be evident from the diagram, the following details and explanations are given to complete the very brief description of the apparatus which space permits. The glass to metal, glass to rubber and the glass to glass seals f at z and z′) were made with de Khotinsky cement. Each unit of the apparatus was equipped with a stopcock used only in filling it. These stopcocks are s and 2, 5, 6, 7 and 8.

The mercury pipet C, which was of 98-cc. capacity, had a small cap f with a two-millimeter hole through the top The cap could be removed when it was necessary to clean C.

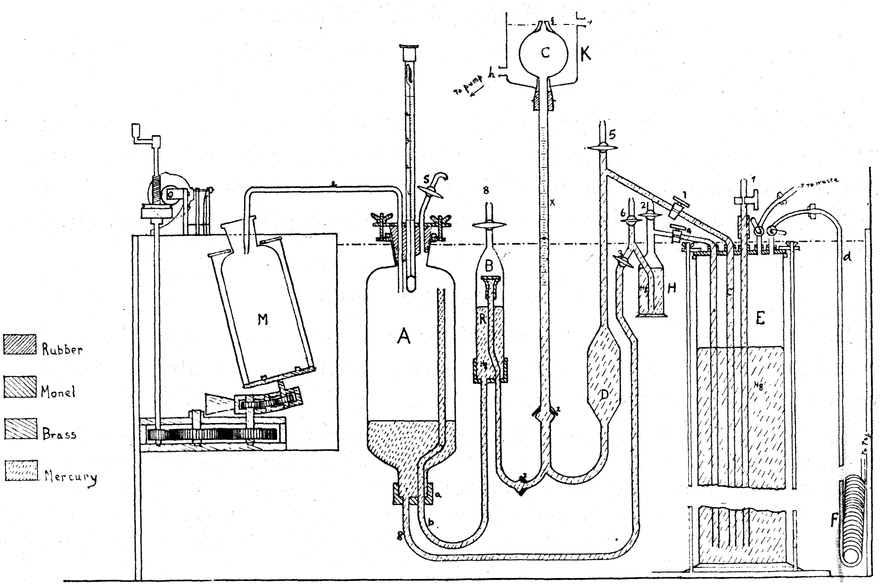

Fig. 1.

Before a bottle had been put in place at M, the operator stopped the exit of e with a finger and opened Stopcock 1. Mercury then flowed upward in C to fill it. Stopcock 1 was then closed and the hole at f was closed with a finger, the operator being careful to leave no air bubble in C. The tip of e was then released and prepared for the discharge of a sample from A in the manner used commonly for pipets. The operator removed his finger from f at the desired instant, thus permitting the entrance of air to C and the discharge of mercury from C through R into the water layer in the top of B. An equal quantity of mercury was simultaneously discharged into A. R was a monel metal cap carrying an adjustable annular slit so narrow that the momentum acquired by the falling mercury in C was expended in forcing the last portion through the aperture into water. With this device the mercury in C descended quietly to a position of rest at a nearly constant level in the graduated stem of C, and a reading was quickly made of the exact location of the meniscus in order to determine the exact volume discharged from A to M. The valve R was designed and made for us by Captain A. de Khotinsky, now of Pentwater, Michigan, who was associated with this Laboratory at the time this work was done.

When an experiment was begun the apparatus had already been filled with mercury to the levels shown in Fig. 1 except in the case of Flask **A,** which was empty. The lugs of the cover of A (see diagram) had been unscrewed and the stopper with its equipment of Beckmann thermometer, discharge tube e and air tube had been removed. After the reaction mixture had been prepared in **A,** the stopper, etc., was clamped in place, mercury was forced into A from E through C and B until all the air was displaced in A, the last bubbles under the stopper being forced out through stopcock s, which was then closed for the remainder of the experiment. The diagram shows the apparatus ready for the first discharge of a measured sample of the reaction mixture.

Constant temperature in C was maintained by means of the water jacket K through which water was pumped from the thermostat in which the main apparatus stood.

The bulb "D" was simply a trap to prevent grease from Stopcock 1 from being carried into C.

The chamber H contained a constant quantity of air under pressure imposed by opening Stopcock 4, thus connecting H with E. When Stopcock 4 was closed and **3** was opened the air compressed in H forced the required amount of mercury into A, thus causing fresh liquid to displace that already in the discharge tube, e. This operation was carried out just before taking a reaction mixture sample. H could be dispensed with when economy of material was not important.

The advantage of the above-described apparatus over that first used in this Laboratory' was that greater ease and speed of operation were possible with it. Only when it was necessary to remove samples every minute was more than one operator needed. Under these conditions two were required instead of three as with the older form.

Another apparatus that simplified work, this time of titration, was the mechanical shaker already referred to. This could be used as shown in Fig. 1 or to shake the samples during titration. The sample taken from the reaction mixture was always discharged into a measured amount of hydrochloric acid sufficient in quantity to more than neutralize the free base present. The titration of the excess acid, which was acetic acid because of double decomposition of hydrochloric acid with sodium acetate, required careful observation of the end-point, as the solutions were dilute. This was made tedious by the necessity of removing mist from the surface of the container, which was at 0° (see ref. 1 for these details).

Captain de Khotinsky, therefore, designed and made for us the shaker in question. It was controlled by a foot switch so that the operator had both hands free for the necessary manipulations. The efficiency of shakers of this type is evinced by the fact that they are still in use (1915–1928) at this Laboratory in cases where the titration samples are large and the observation of the end-point is difficult.

The construction of the shaker, shown at M of Fig. 1, is described briefly as follows. The titration bottle is supported on a circular base and held in place by two rods connected to a semicircular collar that easily slips into place around the neck of the bottle. This circular base is mounted at a slight angle to the horizontal on one end of a counterbalanced frame which is made to whirl by an intermittent electric clutch driven by a small motor (not shown in the diagram). The angle of the base is so adjusted to the height of the bottle that while the base of the bottle is moving in a circle, the opening in its neck does not change its position and thus permits the presence of the buret tip without contact with the neck of the bottle. Thus the frame and the bottle revolve about a perpendicular line (see dotted line at M of Fig. 1) while an equal counter rotation of the bottle itself, produced by a series of compensating gears, prevents the bottle from revolving about its own axis. The advantage of this is that the liquid is whirled within the bottle and not with the bottle. The clutch is made intermittent

because a continuous whirling motion causes the liquid to form layers at the sides of the bottle without mixing with the solution which is being added.

We take pleasure in acknowledging here our indebtedness to Captain de Khotinsky for the design of the valve and shaker.

Results

Coefficients of the rate of the reaction were calculated by means of the following integrated form of the bimolecular reaction equation

$$k = [2.303/(t_2 - t_1)(B - E)] \log (B - X_1)(E - X_2)/(B - X_2)(E - X_1) \quad (1)$$

The initial concentration of ester and base are indicated by the letters B and E, respectively; the concentration of ester or base changed up to the time t is called X; K is the coefficient of the reaction.

In Table I are given the results of a representative experiment. The term $(b-x)$ is the composition of the solution with respect to base in terms of f, the normality of standard acid, which was 0.009917. Obviously $(b-x)f = (B-X)$ but the implied multiplication is not carried out since f would subsequently be canceled when (B—X) is substituted in the above equation. The term (b—e) is the composition of the solution at the end of the reaction in terms of f. Obviously $(E-X) = f[(b-x) - (b-e)] = f(e-x)$, e being the concentration of the ester in terms of f, and $(e-x)$ may be used in place of (E—X) in Equation 1. The value of B given in the table was calculated from the dilution of the stock solution used to make the reaction mixture.

as in the case of ethyl acetate diffuse daylight has no effect on the speed of the reaction.

In Part 4 are given the results of experiments with mixtures near to 0.02 molar with respect to sodium hydroxide and 0.016 with respect to ester. The difference between the first series of Part 1 and this series is slight and within the limits of experimental error.

Table III gives the results of experiments carried out one year later than the others. The results will be seen to be in good agreement with the earlier ones.

TABLE III

SUMMARY OF RESULTS OF THE SECOND SERIES OF EXPERIMENTS (1916)

B	E	Tem (average?: °C.	K	$K_{25.00}$

			Av.	11.686

The widest deviation of value of $K_{obs.}$ in a single experiment was 1.63%. The average deviation was 0.93%. The maximum deviation of the mean coefficient of each experiment from the average of all is 0.65%. The expected error in timing and measurements of samples was 0.75%. Therefore it may be stated that the value 11.67 has an error not greater than 1%.

Comparison of Results with the Work of Others.—Although various workers[6] have made measurements on the reaction under consideration, only one experiment, that of Walker,[7] is comparable with the present experiments. Professor Walker used the conductivity method. Although he felt uncertain of the first and last quarter of his experiment and his results varied as much as 3%, still his average coefficient was 11.7, differing from the value obtained in this work by only 0.3%.

Summary

Measurements are reported of the rate of saponification of methyl acetate at 0.008 and 0.016 molarity in aqueous solutions of sodium hydroxide of 0.01 and 0.02 molarity, respectively. The coefficient of the reaction for 25.00° was found to be 11.67 moles per minute with a possible error not greater than 1%. It was demonstrated that diffuse daylight has no effect upon the rate of the reaction.

[6] Reicher, ***Ann.*, 228, 278** (1885), experiments at 9.4°; Bugarsky, *Z. physik. Chem.*, ***8***, 398 (1891), measurements at 19.4°; Volkmann, "Dissertation," Freiburg, i/Br, experiments at 0, 10, 20, 30, 40 and 50°.

[7] Walker, *Proc. Roy. Soc. London*, **78A,** 158 (1906).

Two special pieces of apparatus are described. One is a machine for the rapid measurement of samples of a solution without exposure of the latter to air. The other is a device for shaking a solution while it is being titrated.

A NEW QUALITATIVE REAGENT FOR SODIUM

EARLE R. CALEY

RECEIVED NOVEMBER 8, 1928 PUBLISHED JULY 5, 1929

It is generally acknowledged that the usual methods for detecting sodium in qualitative analysis are far from satisfactory. The flame test is much too sensitive in that it fails to show whether sodium is present as an essential constituent or whether it is present in traces as an accidental impurity, while the pyroantimonate test is not sufficiently sensitive in the presence of large amounts of potassium and in other respects is an unsatisfactory reagent.

The possibilities suggested by Streng's[1] discovery of a specific microscopical reagent for sodium have not been generally appreciated. This worker found that a solution containing properly adjusted quantities of uranyl acetate, magnesium acetate and acetic acid formed characteristic crystals of a sodium–magnesium uranyl triple acetate when added to solutions containing sodium ions. Streng also noted that certain other bivalent metals might be substituted for magnesium in this reaction and this observation suggested, in part, the present experimental work.

In 1923 Blanchetière[2] devised a magnesium–uranyl acetate reagent that could be used as a precipitant for sodium in ordinary analysis. Kolthoff[3] improved this reagent and tested its value for qualitative purposes. These results were confirmed by Crepaz.[4] Noyes and Bray[5] also showed the value of Blanchetière's magnesium–uranyl acetate reagent as a confirmatory test for sodium in systematic qualitative analysis. In 1927 Kolthoff[6] described a reagent of the same type in which zinc was substituted for magnesium and found that this was an even more sensitive reagent for sodium.

While the two reagents mentioned above are quite sensitive toward sodium, they possess the disadvantage of giving precipitates with potassium when moderate amounts of this ion are present in the solution tested,

so that when using gram samples, as is usual in qualitative analysis, these reagents cannot be used safely without effecting a separation of the two elements before applying the test for sodium. It has been found that a cobalt–uranyl acetate reagent of the above type is sufficiently sensitive toward sodium for the ordinary purposes of qualitative testing and yet is less sensitive toward potassium than the reagents containing zinc or magnesium, so that it may be safely used for detecting sodium in the presence of potassium when prepared and applied in the manner described below.

Preparation of Cobalt–Uranyl Acetate Reagent.—It was found that the most suitable manner of preparing the reagent is in two portions as follows.

Solution A		Solution B	
Crystallized uranyl acetate	40 g.	Crystallized cobalt acetate	200 g.
Glacial acetic acid	30 g.	Glacial acetic acid	30 g.
Distilled water to	500 cc.	Distilled water to	500 cc.

Each solution is separately warmed to about 75° until all of the salts are in solution and then the two solutions are mixed at this temperature and allowed to cool to 20°. The vessel containing the mixed reagent is then placed in water at 20°, and held at this temperature for an hour or two until the excess of salts has crystallized out. The reagent is finally filtered through a dry filter into a dry bottle.. The solution thus prepared keeps indefinitely.

Experimental Part

General Technique.—In common with the triple acetates containing magnesium and zinc, the triple acetate containing sodium, cobalt and uranyl exhibits a marked tendency to form supersaturated solutions. This tendency is readily overcome by shaking the reagent vigorously with the test solution used. For qualitative purposes it was found that the most satisfactory procedure was to mix the reagent and the solution to be tested in a test-tube and then to stopper the tube and shake vigorously for two to three minutes, finally setting aside for five minutes before making the observation. In the following experiments, standard solutions of pure salts were prepared and tested in this manner. The precipitates formed with this reagent are best observed by holding the test-tube above the level of the eye and then looking at the bottom of the tube, by which means the heavy yellow precipitate that settles to the bottom of the tube may readily be seen in contrast to the deep red reagent.

Reactions of Cobalt–Uranyl Acetate Reagent with Pure Sodium Chloride Solutions.—Table I shows the results of a series of experiments made on solutions of pure sodium chloride.

It will be seen that two milligrams of sodium give an immediate precipitate with the reagent, while one milligram may, with certainty, be detected by allowing the mixture of reagent and sodium solution to stand for an hour or two. The results also indicate the necessity of keeping the volume of sodium solution down to a minimum so as not to dilute the reagent unduly and lead to the non-separation of the triple acetate.

TABLE I

REACTIONS OF COBALT–URANYL ACETATE REAGENT WITH PURE SODIUM CHLORIDE SOLUTIONS

Reagent, cc.	Sodium soln., cc.	Sodium present, g.	Ppt. after shaking and standing for 5 min.	Ppt. after one hour
10	1	0.0020	Marked	Heavy
10	2	.0020	None	Slight
20	1	.0030	Heavy	Heavy
20	1	.0020	Marked	Heavy
20	2	0020	None	None
20	1	.0015	Slight	Marked[a]
20	1	.0010	None	Slight[b]
20	1	.0005	None	None[c]

[a] Marked ppt. in ten minutes. [b] Marked ppt. after several hours. [c] No ppt. in 24 hours.

The reason for using relatively large volumes of reagent appears under the experiments on potassium solutions.

Reactions with Potassium Chloride Solutions.—Table II shows the results obtained in a similar series of experiments in which one cc. of potassium solution was used in each case.

TABLE II

REACTIONS OF COBALT–URANYL ACETATE WITH POTASSIUM CHLORIDE SOLUTIONS

Reagent, cc.	Potassium present, g.	Ppt. after 5 min.	Ppt. after 1 hour	Ppt. after 24 hours
5	0.0500	None	None	....
5	.1000	Heavy	Heavy	....
10	.0500	None	None	....
10	.1000	None	None	Slight
10	.1500	Heavy	Heavy	....
20	.1000	None	None	None
20	.1500	None	None	Slight
20	Sat. KCl soln.	None	Slight	Heavy
20	Sat. K_2SO_4 soln.	None	None	None
10	Sat. K_2SO_4 soln.	None	None	....

It is evident from these results that the use of sufficiently large volumes of reagent favors the non-precipitation of the triple acetate of potassium, cobalt and uranyl. Evidently the concentration of potassium in the total volume of reagent plus solution governs the amount of precipitation and not the concentration of potassium in the original test solution. These experiments showed that a saturated solution of potassium sulfate gives no precipitate with 20 cc. of this reagent and that even a saturated solution of potassium chloride gives no immediate reaction.

Experiments on Precipitating Sodium in the Presence of Potassium.—To determine whether or not the presence of potassium would reduce the sensitivity of the reagent toward sodium, pure sodium and potassium chloride solutions were mixed, evaporated until their total volume was reduced to 1 cc. and then tested with 20 cc. of the reagent in the usual manner. Table III shows the results.

TABLE III

DETECTION OF SODIUM IN THE PRESENCE OF POTASSIUM WITH COBALT–URANYL ACETATE REAGENT

Sodium present, g.	Potassium present. g.	Ppt. after shaking and standing for 5 min.	Ppt. after 15 min.
0.0010	0.0500	Slight	Fair
.0010	.1000	Slight	Fair
.0010	.1500	Slight	Fair
.0020	.1000	Fair	Good
.0030	.1000	Heavy	Heavy

It was therefore concluded that the presence of potassium does not decrease the sensitivity of the reagent toward sodium. If anything, the presence of potassium appears to tend to increase the rapidity of the formation of the sodium–cobalt uranyl triple acetate.

Reaction of Cobalt–Uranyl Acetate Reagent with Various **Ions.**—Solutions of salts of lithium, ammonium, magnesium, calcium, barium and strontium, known to be free from all but traces of sodium, were also tested with the reagent. It was found that the reagent gave no reaction with these ions with the exception of lithium. Even in the case of lithium it is much less sensitive than the corresponding reagents containing zinc and magnesium since 10 mg. of lithium in 1 cc. of solution gave no precipitate and even 20 mg. gave only a faint precipitate after standing for several hours. For the usual student courses in qualitative analysis, the behavior toward lithium is, of course, of no significance. It has been found that most heavy metals give no reaction with this reagent. Phosphates and other anions that would precipitate the metallic constituents of the reagent must be absent, a condition that is automatically provided for in systematic qualitative analysis.

Quantitative Possibilities of this Reagent.—Several experiments were also directed toward determining the possibility of using this reagent for the quantitative determination of sodium, but it is apparently not suited to this purpose. Several analyses of the triple acetate precipitates obtained by this reagent showed that they approximate the composition represented by the formula $3UO_2(C_2H_3O_2)_2 \cdot Co(C_2H_3O_2)_2 \cdot NaC_2H_3O_2 \cdot 6H_2O$. It was found, however, that they tend to vary in composition so much that they are worthless for quantitative purposes.

Application to the Usual Scheme for Qualitative Analysis.—In applying this reagent to the usual plan for the qualitative analysis of the common metals it is preferable to precipitate magnesium along with barium, calcium and strontium according to the well-known procedure of Noyes.[7]

---

[7] A. A. Noyes, "Qualitative Chemical Analysis," The Macmillan Company, **1920,** 8th ed.

The filtrate resulting from the ammonium carbonate group may then be treated as follows.

MODIFIED PROCEDURE FOR THE ALKALI GROUP

Acidify the filtrate from Group IV with dilute sulfuric acid and evaporate carefully to dryness in a porcelain dish, finally heating to expel ammonium salts. After cooling treat the residue with 2 cc. of cold distilled water and stir for several minutes to bring the sulfates into solution. Finally filter through a small filter. Divide the filtrate into two equal parts.

Part I.—Test for potassium in the usual way with sodium cobaltinitrite, confirming by means of the flame test.

Part II.—Add **10–20** cc. of cobalt–uranyl acetate reagent, stopper the test-tube and shake thoroughly for two to three minutes. Allow the mixture to stand for at least five minutes. The formation of a yellow precipitate indicates the presence of sodium.

NOTES ON THE PROCEDURE

1. In case large amounts of these alkalies are present the sulfate residue will not all go into solution. This is no disadvantage since the usual tests will be obtained.

2. Care must be taken to use not more than 1 cc. of solution for the sodium test.

3. The amount and speed of formation of the triple acetate precipitate in the test for sodium afford a valuable indication of the probable amount present.

Summary

1. There has been described a new qualitative reagent for sodium composed of a solution of uranyl and cobalt acetates in normal acetic acid.

2. The application of this reagent in the qualitative scheme for the common metals has been indicated.

THERMAL DATA ON ORGANIC COMPOUNDS. V. A REVISION OF THE ENTROPIES AND FREE ENERGIES OF NINETEEN ORGANIC COMPOUNDS

BY GEORGE S. PARKS, KENNETH K. KELLEY AND HUGH M. HUFFMAN

RECEIVED DECEMBER 10, 1928 PUBLISHED JULY 5, 1929

In four preceding papers[1] the entropies and free energies of eighteen organic compounds have been calculated from heat capacity data by means of the third law of thermodynamics. In these calculations the entropy increase for each compound between zero absolute and 90°K. was obtained by use of the "n formula" of Lewis and Gibson,[2] as in most cases the heat capacity data did not go much below the latter temperature. This formula was recognized as being only a rough first approximation but its simplicity and ease of application justified its use for comparative purposes.

---

[1] Parks, THIS JOURNAL, **47,** *338* (1925); Parks and Kelley, *ibid.,* **47, 2094 (1925);** Parks and Anderson, *ibid.,* 48, **1506 (1926);** Parks and Huffman, *ibid.,* 48, ***2788*** **(1926).**

[2] Lewis and Gibson, *ibid.,* **39,2565 (1917).**

However, recent measurements down to liquid hydrogen temperature's, made on a number of these substances by one of us (K. K. K.) at the University of California, have demonstrated that in the case of organic compounds the "n formula" gives results for the entropies at 90°K. which are 20 to 30% too high. Since our entropy and free energy calculations were primarily for comparative purposes, this fact does not invalidate the important conclusions drawn in the preceding papers. However, the desirability of now putting the results on an absolute basis has rendered necessary a revision of our earlier values.

In the case of at least twelve organic compounds heat capacity data for the crystalline state are at present available down to or below 20°K. With the aid of these data we have developed a simple, accurate method for estimating the entropy increases for organic substances between 0 and 90°K. The molecular heat capacity curves for the twelve compounds[3] fall naturally into two classes—one for aliphatic and one for cyclic compounds. In each class the various experimental curves are essentially similar in character and we have been able to construct a type or standard curve. For any particular substance in either class the molal heat capacity at each temperature is given quite accurately by the equation

$$C_p \text{ (per mole)} = (A + BT)C_p^\circ \qquad (1)$$

where A and B are characteristic constants for each substance and C_p° refers to the heat capacity on the standard curve at the temperature T. It then follows that

$$S_{90} = AS_{90}^0 + B\int_0^{90} C_p^\circ \, \mathrm{d}T \qquad (2)$$

where S_{90} is the molal entropy of the substance at 90°K. and S_{90}° is that for the standard. To evaluate A and B it is merely necessary to know C_p for the substance at two different temperatures, 90 and 120°K. for instance, whereupon two independent equations, similar to (1) and involving these constants as unknowns, may be set up and solved. Applying this method to the twelve compounds referred to, we have calculated the respective values of S_{90} and have compared these with the corresponding experimental ones. The average difference is 0.3 E. U., or about 2.6%, and is probably not much greater than the average error in the experimental values.

By means of this extrapolation method we have revised the entropies of the eighteen aliphatic compounds studied in the four preceding papers.

---

[3] We are here using the data of Lange, *Z. physik. Chem.*, 110,350 (1924), for quinone and hydroquinol, the results of Simon, *Ann. Physik*, 68, 258 (1922), for glucose, and those of Gibson and Giauque, THIS JOURNAL, 45, 93 (1923), and of Simon and Lange, *Z. Physik*, **38**, 227 (1926), for glycerol. The data for the remaining eight compounds (methyl alcohol, ethyl alcohol, n-hexyl alcohol, *iso*propyl alcohol, acetone, toluene, m-xylene and cyclohexanol) were obtained by the second author in recent work at the University of California.

The new values are given in Table I. For purposes of completeness we have also included formic acid, which was studied by Gibson, Latimer and Parks[4] in a still earlier investigation. In Col. 2 appear the entropy increments from 0 to 90°K., calculated by Equation 2. The third column then contains the entropy increments from 90 to 298°K., as calculated previously from the heat capacity data.

TABLE I

THE REVISED MOLAL ENTROPIES OF NINETEEN ORGANIC COMPOUNDS

Substance	Entropy increment 0–90°K.	Entropy increment 90–298°K.	S_{298}
Methyl alcohol	8.2	22.82	31.0
Ethyl alcohol	9.3	29.13	38.4
n-Propyl alcohol	10.4	35.69	46.1
Isopropyl alcohol	10.2	32.91	43.1
n-Butyl alcohol	11.9	42.56	54.5
Tert.-butyl alcohol	10.8	34.47	45.3
Ethylene glycol	8.5	31.39	39.9
Glycerol	9.9	39.82	49.7
Erythritol	10.6	29.25	39.8
Mannitol	15.3	41.68	57.0
Dulcitol	14.4	41.64	56.0
Formic acid	7.1	23.59	30.7
Acetic acid	10.2	27.98	38.2
Butyric acid	12.8	41.30	54.1
Palmitic acid	35.0	78.66	113.7
Oxalic acid	9.2	19.50	28.7
Ethyl ether	14.0	46.45	60.4
Acetone	12.9	34.93	47.8
Glucose	13.2	37.54	50.5

The entropies at 298°K. appear in the last column of the table; they are probably accurate to within 1 or 2% in all cases. As compared with the results previously published, the present values represent corrections varying from 1.7 E. U. in the case of oxalic acid to 16.2 E. U. for palmitic acid. However, the general principle that the entropy of an organic compound changes in a definite, additive manner with changes in its constitution still holds true. Thus in the normal alcohol series the average entropy increase per CH_2 increment is 7.8 E. U. in going from methyl to n-butyl alcohol. Likewise in the fatty acid series the change from formic acid to liquid palmitic acid at 25° is accompanied by an entropy increase of 120.4 or an average of 8.0 E. U. per CH_2 group.

Employing these revised entropy values, we have also recalculated the free energies of formation of the nineteen compounds by means of the thermodynamic equation $\Delta F = \Delta H - T\Delta S$. The essential data appear in Table II. For obtaining the figures (Col. **3**) for the ΔH_{298} of formation

---

[4] Gibson, Latimer and Parks, THIS JOURNAL, 42, 1540 (1920).

of these organic substances, we have used the heats of combustion[5] given in the preceding column in conjunction with the values 68,320 cal.[6] and 94,270 cal.[7] for the heats of combustion at 25° of hydrogen and graphitic carbon, respectively. Column 4 contains the entropy of formation of each compound, which is simply the difference between its S_{298} and the corresponding values for the entropies of the elements contained therein. For this purpose the respective entropies of carbon, hydrogen and oxygen were taken as 1.3,[8] 14.8[9] and 24.5[10] E. U. per gram atom. The resulting

[5] For the four alcohols, methyl, ethyl, n-propyl and n-butyl, we have utilized substantially the results of Richards and Davis as recently revised by Swietoslawski and Bobinska, THIS JOURNAL, **49**, 2478 (1927). For isopropyl alcohol and acetone we have used the values calculated by Kelley, THIS JOURNAL, 51, 1149 (1929). In the case of the remaining compounds we have employed the data which will appear in "The International Critical Tables" (private communication from Dr. M. S. Kharasch). In all instances the heats of combustion have been calculated to 25° for our present purpose.

[6] The value selected for "The International Critical Tables" is 68,380 cal. at 18° (private communication from Dr. F. R. Bichowsky); this is equivalent to 68,323 cal. at 25°.

free energies appear in the last column of the table. The differences between these results and those which were given in the preceding papers vary from 100 cal. in the cases of mannitol and glucose to 5000 cal. for palmitic acid. The accuracy of these revised values is now almost entirely limited by the accuracy of the heats of combustion involved.

THE KINETICS OF THE OXIDATION OF IODIDE ION BY ACID DICHROMATE SOLUTIONS IN PRESENCE OF A NEUTRAL SALT

BY RALPH F. BEARD[1] AND NELSON W. TAYLOR

RECEIVED DECEMBER 14, 1928 PUBLISHED JULY 5, 1929

Introduction

Many ionic reactions show kinetic anomalies in the sense that the order of reaction does not come out an integral number. BrGnsted[2] has made the suggestion that if sufficient neutral salt be added to fix the activity coefficients of the ions, such reactions can be rendered normal.

The oxidation of iodide ion by means of potassium dichromate in acid solution is a reaction of this type.

DeLury[3] and also Kernot and Pietrofesa[4] concluded from their work that the reaction was first order with respect to $Cr_2O_7^{--}$ ion, nearly second order with respect to H^+ ion and between first and second with respect to I^- ion. In the preliminary work of this investigation the data confirmed the results of the above-named workers, but the order of reaction with respect to I^- ion was found to be more nearly second than first. Thus the reaction considered as a whole appeared to be approximately a fifth order one.

The purpose of this work is to test Bronsted's prediction regarding the effect of neutral salt on the kinetics of the reaction and, if possible, to obtain experimental evidence bearing on the activity rate theory of reaction mechanism.

Outline of Experimental Work

A preliminary investigation was made over a wide range of salt concentration. The salt used was sodium chloride and the source of H^+ ion was perchloric acid. Sixteen reaction mixtures were made up with the concen-

[3] DeLury, J. *Phys. Chem.*, 7,239 (1903).

[4] Kernot and Pietrofesa, Rend. *accad. sci. fis. mat. Napoli, IIIA,* 275 (1911).

tration of sodium chloride as shown in Table I. The intial concentrations of the reactants were the same in all determinations and were as follows: $K_2Cr_2O_7$, 2.02 X 10^{-4} *M;* KI, 142 X 10^{-4} *M;* $HClO_4$, 364 X 10^{-4} *M.*

The reaction time was twenty minutes in each case, the extent of reaction being determined by titration with *N*/100 sodium thiosulfate, using starch solution as the indicator. All the solutions except the potassium iodide were mixed in a 250-cc. Erlenmeyer flask. The iodide was placed in a similar flask, both flasks being placed in a constant-temperature bath at 25°. When the temperature of the bath had been assumed, the mixed solutions were poured rapidly into the flask containing the iodide solution and then immediately returned to the first flask, both flasks then being replaced in the water-bath. The total volume of the reaction mixture was 100 cc. At the end of the chosen time interval, 25 cc. of a solution containing 110 g. of sodium acetate and 10 g. of sodium bicarbonate per liter was added to stop the reaction. The titration with sodium thiosulfate was then immediately made. A 5-cc. buret graduated to 0.02 cc. was used in making all titrations.

Calculation of the Velocity Constant

Since the concentrations of acid and iodide were greatly in excess over the dichromate, the velocity of reaction could be assumed to be proportional solely to the concentration of the latter. Under these conditions the work of DeLury, and of Kernot and Pietrofesa, and also the results presented in this paper, indicate pretty clearly that the reaction is first order with respect to dichromate (note the constant values of k in Tables III and IV). As a basis for the calculation, the "infinity" value for the reaction was taken as the average of the last two thiosulfate readings shown in Table I, Col. 3. The experimental results are exhibited in Table I and Fig. 1.

Discussion of Figure 1

In Fig. 1 the logarithm of the first-order velocity constant, k, is plotted against the square root of the ionic strength, $\sqrt{\mu}$. The rather surprising results obtained are difficult to interpret. In general, the curve in the figure is very similar to activity curves for strong acids when plotted as a function of $\sqrt{\mu}$. The minimum in the curve appears at an ionic strength of about 0.5, which is about the point at which the minimum occurs in activity curves for strong acids. Unfortunately, little is known concerning the variation of the activity of dichromate and hydriodic acid over this range of ionic strength. If data on this point were available it might be possible to interpret the minimum in the reaction velocity in more detail. However, in the light of Bronsted's theory it is possible to explain the results obtained in the more dilute solutions. For the detail of the Bronsted theory, the reader is referred to the original papers.[5] The following is a brief outline of some of the more essential features.

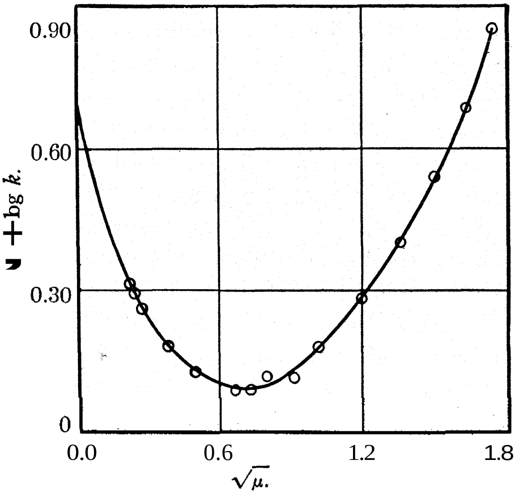

Fig. 1.—Curve showing the effect of neutral salt on the first-order constant, the initial concentrations of H^+, I^- and CrO_{27}^{--} being maintained constant throughout.

According to the classical theory, the expression for the velocity of reaction in the case of a trimolecular reaction may be written h = $k_1c_Ac_Bc_C$. The corresponding expression derived from the "activity theory" is h = $k_2a_Aa_Ba_C$. In these expressions c and a represent concentrations and activities, respectively. Bronsted drives the expression h = $kc_Ac_Bc_Cf_Af_Bf_C/f_x$ for a trimolecular reaction, where $f_Af_Bf_C$ and f_x denote the activity coefficients of A, B, C and x, respectively. x is a complex ion formed by the collision of A, B and C. Since in dilute solutions the activity coefficients of ions depend largely on the charges borne by the ions, and since the charge of x is the algebraic sum of the charges of A, B and C, the application of the Bronsted equation to the calculation of reaction velocities is made possible. Combining the Bronsted with the classical expression we obtain $k_1 = kf_Af_Bf_C/f_x$. For the calculation of the "kinetic activity

---

[5] Bronsted, *Z. physik.* Chem., 102, 169 (1922); Bronsted, *ibid.*, 115, 337 (1925); Brönsted and Delbanco, *Z. anorg. Chem.*, 144,248 (1925).

factor," $f_Af_Bf_C/f_x$, the Debye expression,[6] $-\log f = Az^2\sqrt{\mu}$, may be employed. In this last equation z is the valence of a particular ion, μ is the ionic strength and the factor A has a value of about 0.5 and is so taken for the calculation. Bronsted's development finally leads to the relation: $\log k_1 = \log k + (z_Az_B + z_Az_C + z_Bz_C)\sqrt{\mu}$ for *a* trimolecular reaction. If now $\log k_1$ as ordinate is plotted against $\sqrt{\mu}$ as abscissa, a straight line should result with a slope equal to $(z_Az_B + z_Az_C + z_Bz_C)$ and with an intercept log k on the ordinate axis. Considerable evidence[7] has been presented in support of this theory, but so far as the authors are aware no previous attempt has been made to apply the Bronsted theory to trimolecular or more complex reactions.

Assuming for the sake of argument that our reaction is trimolecular, we may let A, B and C be $Cr_2O_7^{--}$, H^+ and I^-, respectively. Thus $z_A = -2$, $z_B = 1$, $z_C = -1$. Substituting these values in the above equation, it becomes, $\log k_1 = \log k + (-1)\sqrt{\mu}$. *A* plot of $\log k_1$ *versus* $\sqrt{\mu}$ would have a slope of (-1) under these conditions.

On the other hand, if the reaction be pentamolecular, as the work of DeLury and others and many of the experimental results obtained in the preliminary work of this research seem to indicate, it can be shown that this would lead to the equation

$$\log k_1 = \log k + (z_Az_B + z_Az_C + z_Az_D + z_Az_E + z_Bz_C + z_Bz_D + z_Bz_E + z_Cz_D + z_Cz_E + z_Dz_E)$$

Letting A represent $Cr_2O_7^{--}$, and B and C represent H^+, and D and E, I^-, the expression simplifies to $\log k_1 = \log k + (-2)\sqrt{\mu}$.

Later on in this paper evidence will be given showing that the reaction really consists of two simultaneous reactions, one involving $Cr_2O_7^{--}$, H^+ and I^- to the first power and the other involving $Cr_2O_7^{--}$ to the first power and H^+ and I^- to the second power. Furthermore, calculations

from the data show that about 65% of the transformation is brought about by the pentamolecular reaction. Consequently, if a plot of log k_1 against $\sqrt{\mu}$ be made, the slope of the resulting line should be -1.65 at low ionic strength. The data of Table II were thus plotted in Fig. 2. It will be seen that the experimental curve is asymptotically tangent to the theoretical slope -1.65. The magnitude of the ionic strength in these experiments is, of course, too great to expect that the points would actually fall on a line with the theoretical slope. Actual coincidence of such experimental curves with the theoretical is only obtained at ionic strengths $\sqrt{\mu} = 0.15$ or less (see work of Bronsted cited above). Unfortunately, data are not available over a lower range of concentration owing to the marked slowing down of the reaction. Figs. 1 and 2 will be discussed further, later in the paper. Table II presents results of additional experiments in the more dilute sodium chloride solutions. Fresh solutions of the reactants were made up in practically the same concentration as before.

When Expts. 1 of Tables I and II are closely compared, it will be noted that different values for log k are obtained for solutions of the same ionic strength. This inconsistency was due to some undetermined source of error, perhaps caused by incorrect standardization of the sodium thiosulfate used in the second set of experiments. However, the error is a constant one and does not invalidate the conclusions drawn from the data. All of the runs in Table II were performed within a few days and it is improbable that any change occurred in the strength of the thiosulfate during that period.

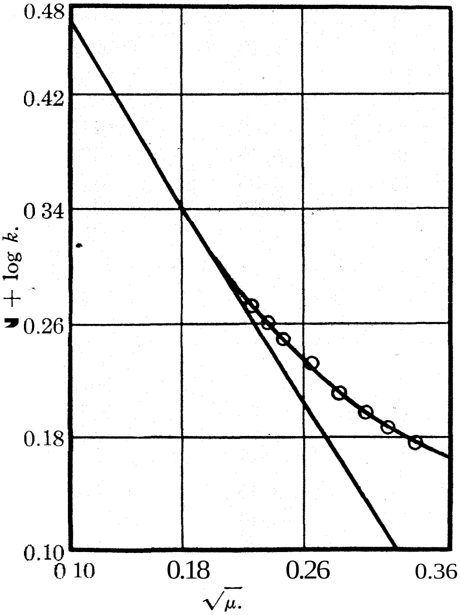

Fig. 2.—Showing the variation in the first-order constant with the sodium chloride concentration. The curve approaches a theoretical tangent of about -1.65.

Experiments at High Neutral Salt Concentration

In carrying out this series of experiments, the data from which are given in Table III, 1.5 M sodium chloride solution was used in each of the seven runs, the first four involving change of iodide concentration only and the last three change of acid concentration. The concentration of the dichromate was 2.02×10^{-4} *M* in all the runs. Table IV gives similar data for three runs in which no salt was added.

As before, the values of k were calculated on the assumption that the velocity of the reaction was proportional solely to the concentration of the dichromate, owing to the fact that the concentration of the other two reactants was high in comparison to that of the dichromate. The assumption of fixed H^+ and I^- is not entirely justified, particularly in Runs 9 and

12, as may be seen by comparing the concentrations in Table III. However, in evaluating the expression $k/(H+)^2(I^-)^2$, used in Figs. 3, 4, 5 and 6, a correction was made to take into account the change in iodide and hydrogen-ion concentration during the course of a run. This was made by

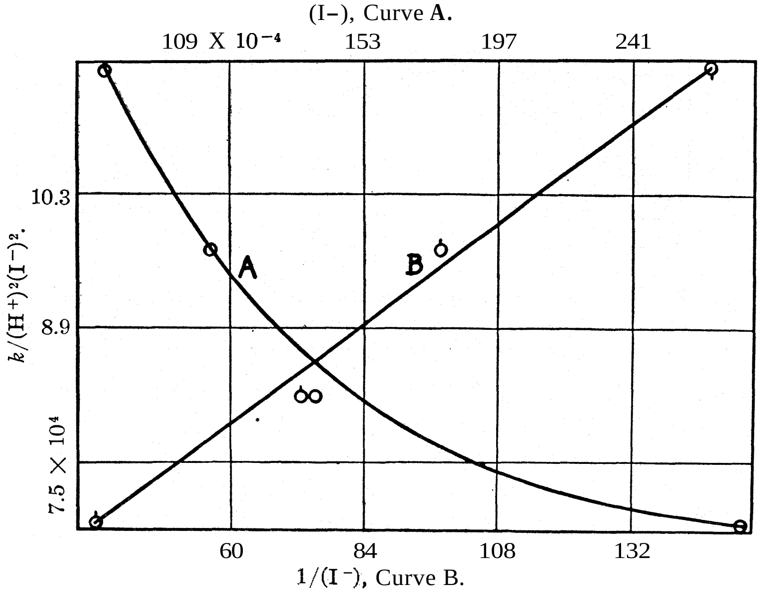

Fig. 3.—Curve A shows that the reaction is not second order with respect to (I^-). Curve B shows that the reaction consists of two simultaneous reactions, one involving (I–) and the other $(I^-)^2$.

calculating the concentration of the iodide and acid left at the end of each time interval and dividing the product of the squares of these values into the corresponding value for *k* previously determined. The following example shows the method of calculation. In Run 10 the iodide used up in the first five minutes was equivalent to 3.36 cc. of 0.00986 N sodium thiosulfate. Consequently, $3.36 \times 0.00986 \times 10^{-3} = 3.31 \times 10^{-5}$ (the number of moles used up in 100 cc. of the reaction mixture), or 3.31×10^{-4} per 1000 cc. of the reaction mixture. The concentration of the iodide at the end of the first five minutes will then be equal to 284×10^{-4} minus 3.31×10^{-4} or 280.69×10^{-4} moles per liter. Multiplying 3.31×10^{-4} by 7/3 and subtracting from 364.8×10^{-4} will give the concentration of the acid at the end of the first five minutes, 357.07×10^{-4} moles per liter. The corresponding value of the velocity constant is seen to be 0.0640. Consequently $k/(H^+)^2(I^-)^2 = 0.0640/(280.69)^2(357.07)^2(10^{-8})^2 = 6.39 \times 10^4$.

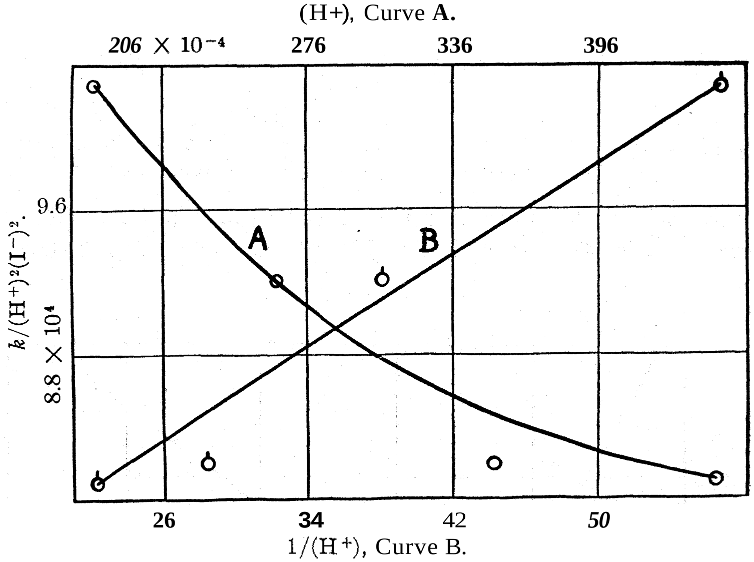

Fig. 4.—Curve A shows that the reaction is not second order with respect to (H^+). Curve B shows that the reaction consists of two simultaneous reactions, one involving (H^+) and the other $(H^+)^2$.

While the usual method is to use the initial values of the concentration of those reactants which are in excess, we believe that this method of calculation is a more accurate treatment of the experimental results. In Table V is given the average value of $k/(H^+)^2(I^-)^2$ for each run, computed in this way, as well as the other data used in Figs. 3, 4, 5 and 6.

In Fig. **3** are shown plots of these values against the iodide concentration (Curve A) and against the reciprocal of the iodide concentration (Curve B) for Runs 8, 9, 10 and 11. Curve A, Fig. 3, shows that the reaction is not

second order with respect to iodide concentration, because if this were so $k/(H^+)^2(I^-)^2$ would be constant from run to run and a straight horizontal line would be obtained in the plot. If two simultaneous reactions were going on here, one of which was first order and the other second order

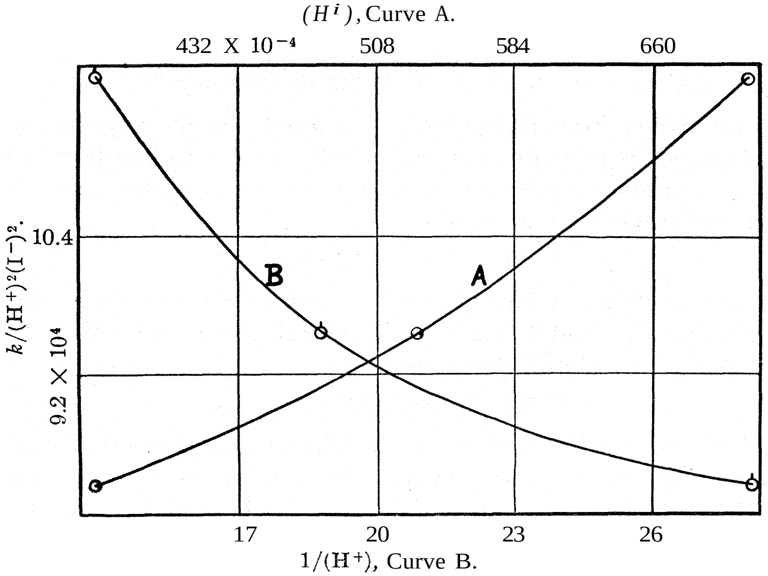

Fig. 5.—Showing that no simple interpretation of the data is possible in the absence of neutral salt. Straight line relations are not obtained.

with respect to I–, the general expression for the velocity constant would be $k = k_1I^- + k_1k_2(I^-)^2$. Dividing through by $(H^+)^2 \times (I^-)^2$, this expression becomes $k/(H^+)^2(I^-)^2 = k_1/(H^+)^2(I^-) + k_1k_2/(H^+)^2$. Consequently, if $k/(H+)^2(I^-)^2$ be plotted against $1/(I^-)$, a straight line should be obtained, since in the four series of experiments the concentration of acid was not varied. In Curve B, Fig. 3, the points fall approximately on a straight line.

The data for Runs 8, 12, 13 and 14 were treated similarly with results as shown in Fig. 4. Curve A shows that the reaction is not second order with respect to (H^+). Curve B indicates that the reaction is really composed of two simultaneous reactions, one of which is first order and the other second order with respect to (H^+).

Figure 5 shows the results of similar plots in the case of Runs 1R, 2R and 3R. Again Curve **A** is the plot of $k/(H^+)^2(I^-)^2$ against H^+, while curve B is the plot against $1/H^+$. Here it is seen that neither curve is capable of any simple interpretation. In this series of experiments no salt was present to-fix the activity coefficients. Not only is Curve B not a straight line, but even the direction of B is reversed, the slope being negative instead of positive. The slope is also reversed in A. A comparison of Figs. 4 and 5 clearly indicates the beneficial effect of adding a neutral salt in making velocity studies of this type. It is important to note that the data in the absence of salt are incapable of any simple interpretation, as may be seen from Fig. 5, but when salt is added the difficulties of interpretation disappear as seen from the straight-line relation in Fig. 4.

Rate Constants for the Two Simultaneous Reactions

The discussion from this point bears entirely on the experimental results obtained in presence of 1.5 M NaCl. If the assumption is made that two simultaneous reactions occur, the observed velocity constant may be split into two factors, as follows

$$k = k_a(H^+)(I^-) + k_ak_b(H^+)^2(I^-)^2$$

where one reaction involves H^+ and I^- each to the first power and the other involves H^+ and I^- each to the second power. Dividing through by $(H^+)^2(I^-)^2$, we obtain the relation

$$k/(H^+)^2(I^-)^2 = k_a/(H^+)(I^-) + k_ak_b$$

where k_a is the velocity constant for the trimolecular reaction and k_ak_b the corresponding velocity constant for the pentamolecular reaction. In Fig. 6 the "5th order constant" $k/(H^+)^2(I^-)^2$ has been plotted as a function of $1/(H^+)(I^-)$. It follows from the equation just given that the slope of the best straight line through these points should be k_a. This has a value of 14.62. The pentamolecular constant has been evaluated from the data and found to be $k_ak_b = 53{,}000$. Taking these values as correct, one may calculate what the "observed velocity constant" should be to give exact agreement with this line. The data are recorded in Table VI. The calculated values of k were obtained from the straight line of Fig. 6 by picking off the values of $k/(H^+)^2(I^-)^2$ corresponding to the different values of $1/(H^+)(I^-)$ and solving for k.

TABLE VI

VELOCITY CONSTANTS IN RUNS INVOLVING 1.5 M NaCl

Run	8	9	10	11	12	13	14	
Av. k, obs.	0.0189	0.0070	0.0646	0.0127	0.0063	0.0122	0.0293

Deviation, %	3.0	3.0	0.0	2.0	7.0	1.0	3.5	**Av.,** 3.0

The average percentage deviation of 3% is within the limit of error for the actually observed constants, k.

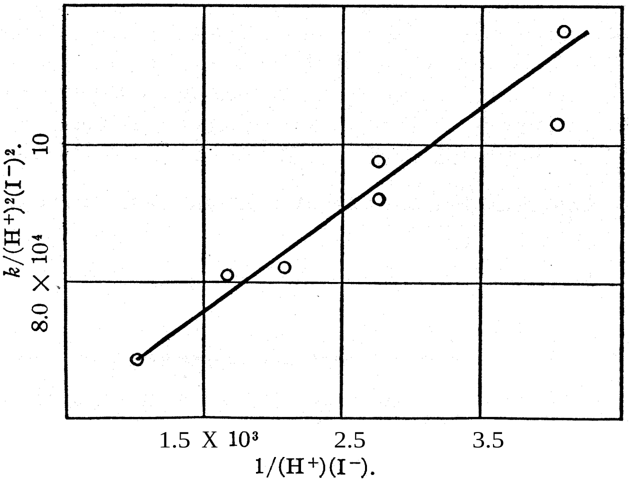

Fig. 6.—A combination of the two B curves in Figs. 3 and 4, showing that the reaction consists of two simultaneous reactions, one involving (H^+) and (I^-), the other $(H^+)^2$ and $(I^-)^2$.

Discussion of Figures 1 and 2

In the experiments recorded in Table II and Fig. 2, on the effect of varying sodium chloride concentration on the reaction velocity, the H^+ and I^- ion concentrations were 0.03643 and 0.0142 M, respectively. Substituting these values in the equation $k = 14.6(H^+)(I^-) + 53{,}000(H^+)^2(I^-)^2$, one obtains the following result, $k = 0.0076 + 0.0142$. Thus, μ being 1.55, the fraction $0.0142/(0.0142 + 0.0076) = 0.651$ (or about 65%) of the iodide is oxidized by the pentamolecular reaction.

As will be seen from an inspection of Fig. 1, the rate is practically the same in solutions of ionic strength ranging from $\sqrt{\mu} = 0.1$ to $\sqrt{\mu} = 0.2$ as it is in a 1.5 M sodium chloride where $\mu = 1.55$ or $\sqrt{\mu} = 1.25$. If hydriodic acid is like hydrochloric acid, the activity coefficient of hydriodic acid (i. e., $f_H f_I$) is also practically the same in these two solutions, namely, about 0.9. It is a consequence of the Bronsted theory that the ratio of the pentamolecular to the trimolecular rate will be proportional to $f_H f_I$.[8]

---

[8] $h_5/h_3 = [(H^+)(I^-)k_5/k_3]f_{H^+}f_{I^-}$.

Consequently, about 65% of the oxidation should take place by the pentamolecular reaction in *the dilute solution.* The theoretical Brönsted slope should therefore be not -1 nor -2 but about -1.65, and is so drawn in Fig. 2. The lowest ionic strength investigated, $\sqrt{\mu} = 0.226$, is still too high for the simple Debye–Hückel equation to apply, but the trend of the experimental curve is such as to indicate -1.65 as being a reasonable value for the limiting slope in the most dilute solutions. It is therefore felt that Bronsted's treatment gives the correct interpretation of the experimental data in the less concentrated sodium chloride solutions. We do not wish to claim that -1.65 is the exact limiting slope, since $f_H f_I$ increases from about 0.9 to 1 as the ionic strength changes from $\sqrt{\mu} = 0.15$ to $\sqrt{\mu} = 0$, but merely to emphasize the point that on account of the two simultaneous reactions the limiting slope cannot be an integral number. However, the limiting slope cannot be far from -1.65.

Discussion of the Probable Chemical Changes

DeLury[3] has stated that his measurements indicate the possibility of two simultaneous reactions which affect the measured rate. Bray[9] has suggested that these may be

$$2I^- + 2H^+ + Cr_2O_7^{--} = 2IO^- + H_2Cr_2O_5 \qquad (1)$$

$$I^- + 2H^+ + Cr_2O_7^{--} = IO^- + 2HCrO_3 \qquad (2)$$

It is evident from the experimental results presented in this paper that Reaction 2 involving $2H^+$ ions per I^- ion cannot be a slow reaction and affect the rate. If this were so the plot of $k/(H^+)^2(I^-)^2$ against H^+ in Fig. 4 would be a horizontal straight line or, in other words, the "5th order constant," $k/(H^+)^2(I^-)^2$ would be independent of the H^+ ion concentration. Fig. 4 shows a definite linear relation of $k/(H^+)^2(I^-)^2$ to $1/H^+$.

The fact that a satisfactory representation of the experimental results in high neutral salt concentration is given by the equation

$$k = 14.6\,(H^+)(I^-) + 53{,}000\,(H^+)^2(I^-)^2$$

indicates that the two slow steps in the reaction are probably

$$(I)\quad H^+ + I^- + Cr_2O_7^{--} \longrightarrow \text{..} \quad \text{and}$$

$$(II)\quad 2H^+ + 2I^- + Cr_2O_7^{--} \longrightarrow \text{......}$$

Although the experimental evidence points clearly to the occurrence of a tri- and a pentamolecular reaction, it is not necessary to assume the simultaneous collision of more than two molecules. Starting with the Bronsted rate equations for only rapid reversible *bimolecular* reactions, one may readily combine them to obtain the correct kinetic equations for reactions of the third and fifth order, which satisfy the experimental data. The following equations were thus obtained

$$k_3 = k_3(H^+)(I^-)(Cr_2O_7^{--}) \times f_{H^+}f_{I^-} \times f_{Cr_2O_7^{--}}/f_{X_1^{--}}$$

$$k_5 = k_5(H^+)^2(I^-)^2(Cr_2O_7^{--}) \times f^2_{H^+} \times f^2_{I^-} \times f_{Cr_2O_7^{--}}/f_{X_2^{--}}$$

---

[9] *Bray, Z. physik. Chem., 54, 491 (1906).*

Summary

Measurements have been made on the velocity of the stoichiometrical reaction $Cr_2O_7^{--} + 6I^- + 14H^+ = 2Cr^{+++} + 7H_2O + 3I_2$ at various concentrations of the reacting ions and in presence and absence of a neutral salt, sodium chloride. All experiments were carried out at 25°.

In dilute solutions the results offer confirmation of the Bronsted activity rate theory of reaction velocity.

In more concentrated solutions in the absence of a neutral salt, the kinetic behavior is incapable of any simple interpretation.

In the presence of 1.5 M sodium chloride as neutral salt, the kinetic anomalies disappear. The experimental results clearly indicate that two simultaneous reactions are taking place which may be represented as follows

$$H^+ + I^- + Cr_2O_7^{--} \longrightarrow HI\cdot Cr_2O_7^{--} \qquad (1)$$

$$2H^+ + 2I^- + Cr_2O_7^{--} \longrightarrow (HI)_2\cdot Cr_2O_7^{--} \qquad (2)$$

The observed velocity constant k is given to within an accuracy of 3% by the expression $k = 14.6\,(H^+)(I^-) + 53{,}000\,(H^+)^2(I^-)^2$.

THE RATE OF RECOMBINATION OF ATOMIC HYDROGEN

BY HUGH M. SMALLWOOD

RECEIVED JANUARY 31, 1929 PUBLISHED JULY 5, 1929

It has been pointed out by a number of investigators[1] that certain exothermic reactions of the type A + B ⟶ AB cannot result from simple binary collisions of molecules A and B since, in such a collision, there is no means by which the energy corresponding to the heat of the reaction may be removed from the colliding molecules. In order to react the molecules must collide in the immediate neighborhood of some other object such as another molecule or the wall of the containing vessel. In other words, the reaction can only take place as the result of triplet impacts or three-body collisions.

A few limitations must be made to the foregoing statement. Thus, if there is a possibility of radiation occurring during the collision of molecules A and B, combination may result from a single collision since the energy of combination may be radiated from the system as light. Further, if molecules A and B are relatively complex, the energy of combination may be taken up by their internal degrees of freedom.

[1] Boltzmann, "Gastheorie. II," Leipzig, 1912; Herzfeld, *Z. Physik*, 8, 132 (1922); Born and Franck, *Ann. Physik*, **76**, 225 (1925); *Z. Physik*, 31, 411 (1925); J. H. Jeans, "The Dynamical Theory of Gases," 4th ed., Cambridge University Press, p. 195.

There are therefore only a few reactions which may be expected to proceed according to the predicted three-body mechanism. One of these, however, is the recombination of atomic hydrogen, represented stoichiometrically by the reaction $H + H \longrightarrow H_2$. The present paper describes a measurement of the rate of this reaction at various pressures. The results obtained are in agreement with the predicted mechanism.

The method used was to allow dissociated hydrogen drawn from an electric discharge to pass along a straight tube.[2] The degree of dissociation of the hydrogen at varying distances along this tube was determined by measuring the heat effect produced upon a piece of platinum foil placed in the flowing gas at the desired distance from the discharge. Wood[2] has shown that metals cause the complete recombination of the atomic hydrogen. Since the heat of this recombination is known and since the rate of flow can be measured, the degree of dissociation is readily calculated.

Experimental

Source of Hydrogen.—Throughout these experiments the hydrogen was taken from a water-cooled electrolytic generator using as electrolyte a 30% solution of potassium hydroxide containing a little barium hydroxide. The hydrogen so obtained contains about 3% of water vapor. Since the presence of this water vapor has been shown to be necessary for the production of the atomic hydrogen, no attempt was made to remove it.

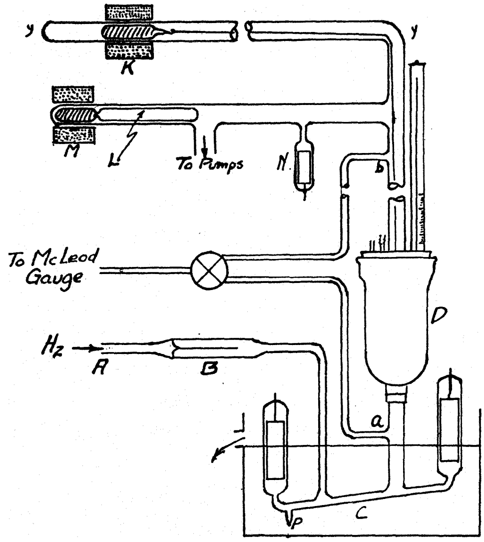

Fig. 1.

Apparatus.—Figure 1 shows the essential parts of the apparatus finally adopted. Hydrogen from the generator (not shown) was admitted at A and expanded through the capillary B to a pressure of a few tenths of a millimeter. It was then led to the discharge tube C, which was immersed in a water-bath. While in the discharge tube the hydrogen was almost completely dissociated, so that recombination took place along the vertical tube, ab. The pressure at each end of this tube could be measured on a McLeod gage by means of the connections shown in the sketch. D is a calorimeter (shown in detail in Fig. 2) which could be slid up or down the tube ab. The calorimeter was made in the shape of a small Dewar flask with a hole in the bottom, the joint between the calorimeter and the central tube ab being made water tight by means of a short piece of gum tubing, E. The calorimeter was flared slightly at the top to permit the insertion of a rubber stopper

[2] R. W. Wood, Proc. Roy. *Soc.* London, 97A, 455 (1920); **102A,** 1 (1925); ***Phil. Mag.,*** 42, 729 (1921); 44, **538** (1922); Bonhoeffer, *Z. physik.* ***Chem.,*** 113, 199 (1924).

carrying a stirrer, F, a Beckmann thermometer, G, and a platinum heating unit, H, used to determine the heat capacity of the calorimeter. J was the catalytic surface causing the recombination of the atoms of hydrogen. It consisted of a cylinder of platinum foil fitting snugly inside the central tube and suspended from a fine nickel wire. The other end of this wire was fastened to a glass tube containing soft iron which could be moved along the tube yy by means of the electromagnet K (Fig. 1). In this way the platinum could be moved along the central tube with the calorimeter. The pressure in the apparatus was regulated by sliding the core I, into or out of the gas stream by means of the electromagnet M. N is an auxiliary electrode whose use will be described below.

The tube ab was approximately one meter long and 0.8 cm. in internal diameter. The discharge tube was made of thin-walled 0.6-cm. tubing to facilitate cooling, the distance between the inlet and outlet taps being about 10 cm. The distance between the discharge and tap a was 8 cm. The electrodes were the usual cylinders of aluminum foil fastened to tungsten wires which were sealed through the pyrex. Rapid streams of water played over the exposed ends of the electrodes, thus preventing the conduction of heat from the discharge to the calorimeter. The volume of the calorimeter was slightly greater than 100 cc. The calorimeter stirrer was rotated by a small electric fan motor.

Procedure.—The primary consideration for experiments with atomic hydrogen is that the regions where it is to be produced and studied must be absolutely free from substances which may catalyze the recombination. Apparently all metals are active catalysts, together with porous or adsorbent surfaces. With this in mind the apparatus was designed to permit washing in *situ*. Each apparatus was made from new pyrex glass. After complete assembly aqua regia was forced through the arm P up to the top of the tube ab and then allowed to drain back. Of course, during the washing the platinum catalyst J was lifted out of range of the acid. The apparatus was then rinsed repeatedly with distilled water, after which the arm P was sealed off and the pump started. Before making any runs a discharge was passed from the auxiliary electrode N to the discharge tube. Bonhoeffer[2] has previously shown that this is useful in preparing a catalytically inert tube.

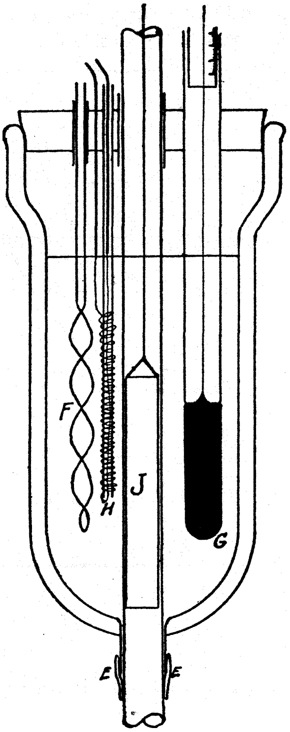

Fig. 2.

The foregoing procedure has been found in practically every instance to give apparatus in which reproducible results can be obtained. Presumably the aqua regia removes any metallic dust from the tube wall, the water fills up the pores in the wall and the discharge melts into the glass any active spots not removed by the acid. The discharge tubes show a pronounced fatigue effect after twenty to thirty hours of running. This fatigue is gradual and coincident with the appearance of appreciable quantities of sputtered material from the electrode. No successful method has so far been found for rejuvenating a spent tube.

The actual measurements were carried out as follows. The calorimeter and catalyst were set at the desired distance from the discharge and the pressure was allowed to reach the desired value; 100 cc. of distilled water, one or two degrees below room temperature, was pipetted into the calorimeter and the stirrer started. After the warming of the calorimeter had reached a steady rate the Beckmann thermometer was read at one-minute intervals (timed by an electric clock) for a period of five minutes, in order to obtain the rate of warming at the start of the run. At the end of this period the discharge was turned on and the temperature readings were continued until the temperature rise was great enough to ensure the desired accuracy. This required ten minutes or less. The temperature measurements were continued for five minutes after the discharge was turned off to determine the final cooling curve. Fig. 3 shows several typical temperature–time curves. The pressure in the apparatus was measured at points a and b twice each during each run. The room temperature was maintained constant within 0.5° throughout each run.

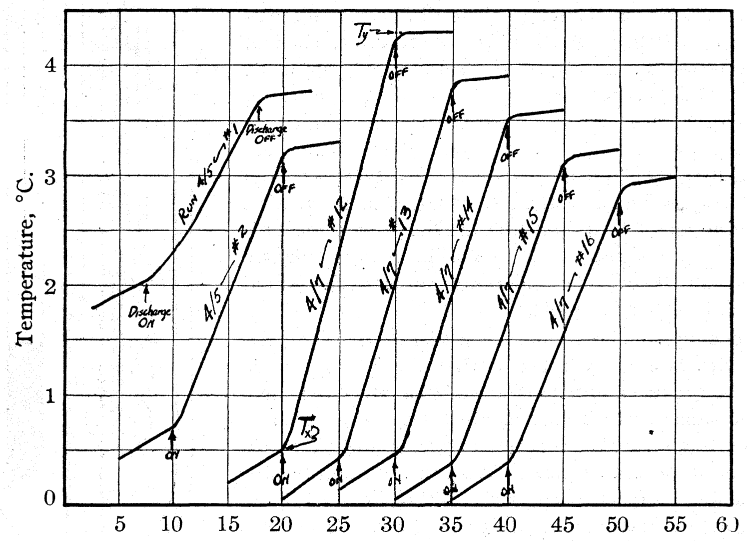

Fig. 3.

The heat capacity of the calorimeter was determined by noting the temperature rise caused by passing a current through the heating unit, H, the power input being measured by means of a milliammeter and millivoltmeter. The rate of flow of hydrogen was measured by disconnecting the hydrogen generator and allowing the hydrogen to be drawn instead from a gas buret.

Results

A series of preliminary experiments showed the qualitative conditions that must be fulfilled for the best production of atomic hydrogen. Aside from the necessity of the absence of catalysts, all the other variables affect the degree of dissociation of the hydrogen at a point some distance from the discharge. Thus the degree of dissociation is increased by high current density in the discharge and by water cooling the discharge. These two factors are, however, of secondary importance compared to the pressure and the quantity of hydrogen flowing. If the pumping capacity is approximately constant, these last two quantities are roughly proportional, the pressure increasing if the quantity of hydrogen admitted to the apparatus is increased. Since the degree of dissociation at a point removed from the discharge decreases rapidly as the pressure increases, there will be some set of conditions for each apparatus at which the greatest *amount* of atomic hydrogen is obtained at a point outside the discharge. The pressure and the rate of flow at which the greatest amount of atomic hydrogen is obtained are determined by the efficiency of the pumps and the dimensions of the apparatus.

The best series of measurements of the rate of recombination are summarized in Table I and plotted in Fig. 4. The degree of dissociation is expressed by α, the fraction of the total amount of hydrogen which is present in the atomic form x cm. from the point of measurement of the initial pressure (P_0).

TABLE I

RESULTS OF MEASUREMENTS

Rate of flow of $H_2 = n_0 = 1.03 \times 10^{-5}$ moles/second. Primary current to transformer = 25 amps. Internal diameter of tube ab = 0.848 cm. Length ab = 108.3 cm. Heat capacity of calorimeter = C = 121.5 Cal./deg.

The pressures recorded are each the average of two readings taken during the particular run. During each of the runs the discharge was on for ten minutes except Run 4/7 No. 7, the time of which was eight minutes. The temperature–time readings were plotted on a large scale as soon as obtained.

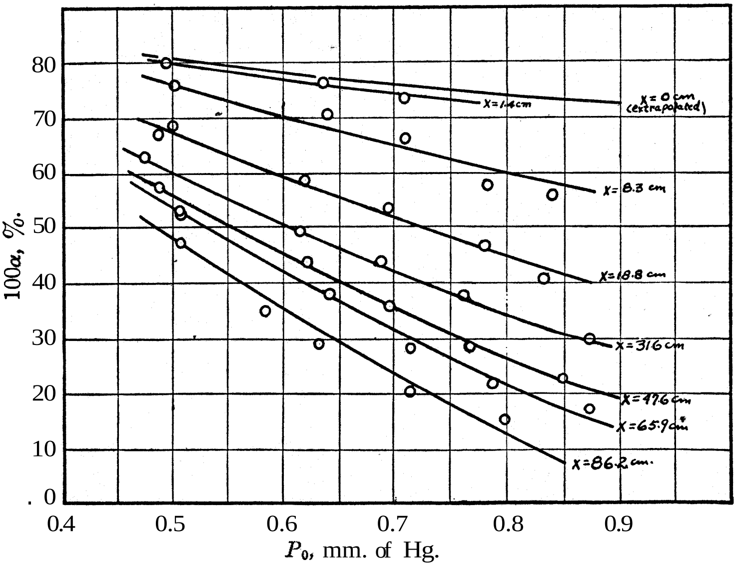

Fig. 4.

The observed temperature rise was obtained by subtracting the temperature at the start of the period when the discharge was on from the temperature obtained by extrapolation of the final cooling curve back to the time at which the discharge was turned off ($T_{obs.} = T_y - T_x$, Fig. 3). The correction for radiation and conduction of heat to or from the surroundings and for the heat of stirring was obtained by averaging the rate of cooling at the start and at the end, multiplying this average rate by the time during which the discharge was on and adding or subtracting, as the case might be, to the observed temperature rise. The figures so obtained are tabulated under the heading "$T_{corr.}$"

The fraction dissociated was calculated from the relation

$$\alpha = \frac{CT_{corr.}}{60\, n_0 t \Delta H} \tag{1}$$

where ΔH is the heat of formation of one mole of molecular hydrogen from the atoms. This quantity was taken to be 100,400 Cal., which is an average of the values reported by Dieke and Hopfield,[3] and Witmer[4] from studies of the molecular spectrum of hydrogen. The "t" of Equation 1 stands for the time in minutes during which the discharge was on. The other symbols have the meanings assigned in Table I.

It will be noticed that the starred (") runs of Table I are omitted from the plot of Fig. 4, since it was apparent from the varying slopes of the respective temperature–time curves that conditions changed during these runs. This discrepancy is of common occurrence and is undoubtedly due to a temporary catalytic effect. For example, if the apparatus is filled with air and left overnight, it requires from fifteen to twenty minutes' running before the degree of dissociation of the hydrogen outside the discharge builds up to a reproducible value, possibly due to a slow clean-up of oxygen adsorbed on the glass. This effect accounts for the first three inconsistent runs of Table I. It is readily recognized on the temperature–time curve, as may be seen by comparing the first two curves of Fig. 3. It is not evident in the first experiment of the third day since the discharge was run for thirty minutes before the runs were started. The other inconsistent run may have been caused by a catalytic particle working into the discharge and then being rendered inactive. It must be emphasized that, once active catalysts have been removed, the results do not depend on the apparatus. Duplicate runs which checked well within the experimental error have been made in different apparatus and at intervals of several weeks.

As will be pointed out below, an interpretation of the results requires a knowledge of the manner in which the pressure varied along the tube ab. An attempt was made to measure this, at the conclusion of the experiments, by sealing a number of taps into the tube and connecting these taps through stopcocks to the McLeod gage. The results so obtained are shown in Fig. 5, the dotted portions of the curves corresponding to the pressure drop caused by the presence of the platinum foil. Unfortunately some catalytic substance must have been present during these runs because the curves corresponding to the dissociated gas have the same slope as those for the molecular hydrogen. This would mean that the mixture of atomic and molecular hydrogen has the same viscosity as pure molecular

---

[4] Witmer, *Phys. Rev.*, 28, 1223 (1926).

hydrogen. That this is not the case has been shown by Harteck.[5] It is much more probable that very little atomic hydrogen reached the Tube ab due to the presence of an active catalyst. There was no way of checking this point since the calorimeter was necessarily removed during the remodeling of the apparatus.

It was hoped at first that the method could be used to measure the rates of the gaseous reactions of atomic hydrogen, This could not be done, however, because these reactions take place along such a short interval of the tube (5–20 cm.) that accurate results could not be expected. In the course of the preliminary experiments it was found, however, that if atomic hydrogen is led along a tube lined with a thin coating of sulfur, from $^1/_6$ to $^1/_5$ of the atomic hydrogen reacts to form hydrogen sulfide. This is to be expected since the first hydrogen sulfide formed rapidly catalyzes the recombination of the remainder of the hydrogen atoms.[6]

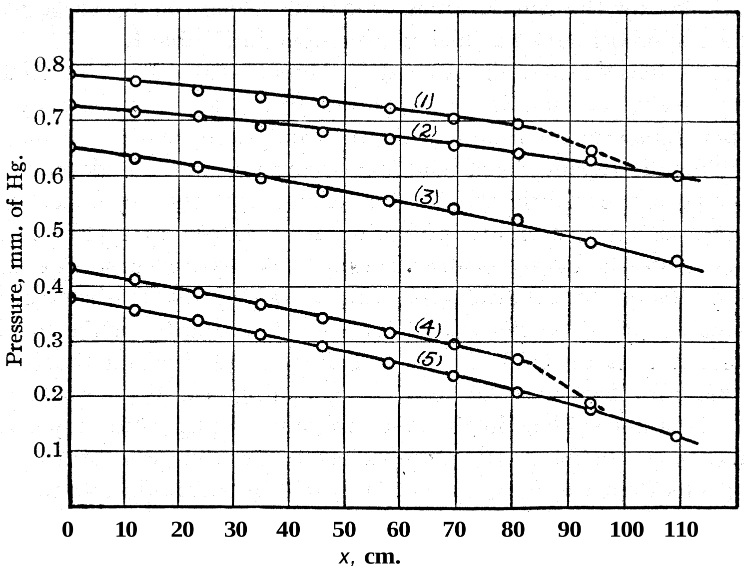

Fig. 5.—Curves 2, 3 and 5 obtained with discharge off and platinum out of outlet tube. Curves 1 and 4 obtained with discharge on and platinum at x = 83 cm.

It was also found that nitric oxide catalyzes the recombination without itself being reduced. Analysis of the gases leaving the mixing chamber showed that over 99% of the nitric oxide was unchanged. However, a very minute amount of ammonia was formed in each case. Thus in one experiment 2.8×10^{-5} mole of ammonia was found while there were available 0.01 mole of atomic hydrogen and 0.0088 mole of nitric oxide.

---

[5] P. Harteck, Z. *physik. Chem.*, 139A, 98 (1928).

[6] Boehm and Bonhoeffer, *ibid.*, 119,385 (1926).

This ammonia may have been due to the presence of nitrogen oxide as an impurity in the nitric oxide. Blank experiments showed that it was not present in the original hydrogen or nitric oxide and that it did not come from the combination in the discharge of the hydrogen with a small contamination of nitrogen. It is difficult to explain the catalysis of nitric oxide by means of a chain mechanism such as has been used by Bonhoeffer for the similar effect of hydrogen sulfide, hydrochloric acid, etc., since if the nitric oxide molecule is ever broken up it is extremely unlikely to form again under the conditions of the experiment. Possibly an unstable molecule of the type H—NO is formed, in which case the mechanism would be

$$H + NO \longrightarrow H—NO$$
$$H—NO + H \longrightarrow H_2 + NO$$

The H—NO molecule might be quite short-lived and yet account for the effect.

The errors incident to this method of determining atomic hydrogen may be classified under four headings. In the first place the method is liable to the usual errors of calorimetry. These probably predominate in the present experiments, limiting the accuracy to 2–3%. Second, the method depends upon a knowledge of the heat of recombination of atomic hydrogen. This quantity, however, is now known with an accuracy within the above limits. Third, the heat effect registered in the calorimeter may be too small either because the recombination is not completely catalyzed by the platinum or because some of the heat is conducted away by the hydrogen stream. The first effect is extremely improbable since the rate of diffusion of atomic hydrogen under the conditions of the experiment is so high that a minute speck of metal in front of the calorimeter completely stops the heat effect. Further, in some of the preliminary experiments a thermometer with a silvered bulb was hung in the gas leaving the calorimeter and showed no temperature rise. Since the quantity of hydrogen flowing was small it would have had to be heated to an unreasonably high temperature to remove an appreciable amount of heat from the system. Finally, heat may be brought to the calorimeter in other ways than by the recombination of the atoms. Thus heat may be conducted from the discharge along the glass walls. This, however, was too small to affect the results since, when the whole discharge tube was water cooled, numerous runs in catalytically active apparatus showed no heat effect. This fact also removes the possibility of metastable molecules bringing energy to the calorimeter. It might also be supposed that, since the atomic hydrogen is recombining along the tube between the calorimeter and the discharge tube, sufficient heat could be liberated to affect the results. This is unlikely since in some of the preliminary experiments this tube was water cooled without affecting the results.

The accuracy of the method, therefore, is limited by the errors involved in the calorimetry of quantities of heat which, in this case, varied from 5 to 40 Cal. per minute.

The Three-Body Mechanism

It will now be shown that the results summarized in Table I are in accord with the predicted mechanism of recombination by triple impacts. The fundamental assumption is that at constant pressure

$$\frac{-\mathrm{d}N_\mathrm{H}}{\mathrm{d}t} = 2\Sigma\nu_3 \tag{2}$$

where N_H is the number of hydrogen atoms per cc. at the time t and $\Sigma\nu_3$ is the number of triple impacts per second per cc. in which at least two of the colliding bodies are hydrogen atoms.

There is considerable uncertainty as to the quantitative definition of a three-body collision. Whatever be the definition, however, $\Sigma\nu_3$ may be set equal to

$$\Sigma\nu_3 = K_1N_\mathrm{H}^2 + K_2N_\mathrm{H}^3 + K_3N_\mathrm{H}^2N_{\mathrm{H}_2} \tag{3}$$

where K_1, K_2 and K_3 are proportionality constants and N_{H_2} is the number of hydrogen molecules per cc. The first term on the right of Equation 3 takes account of triple imparts in which the wall is the third body. In the second term the third body is a hydrogen atom and in the third a hydrogen molecule.

To express the present results it will be necessary to take account of the fact that the atomic hydrogen is recombining at variable pressure while flowing along the tube. This may be accomplished by writing the equation of continuity of the hydrogen atoms

$$\frac{\partial N_\mathrm{H}}{\partial t} - \frac{\partial(N_\mathrm{H}u)}{\partial x} = 0 \tag{4}$$

where u is the linear velocity of the gas at the point x

$$u = \frac{n}{\pi r^2\left(N_{\mathrm{H}_2} + \frac{1}{2}N_\mathrm{H}\right)} \tag{5}$$

Here n is the number of hydrogen molecules admitted to the apparatus per second ($n = n_0N_A$). Since

$$N_\mathrm{H} + N_{\mathrm{H}_2} = \frac{P}{kT} \tag{6}$$

and

$$\alpha = \frac{N_\mathrm{H}}{2N_{\mathrm{H}_2} + N_\mathrm{H}} \tag{7}$$

$$N_\mathrm{H} = \frac{P}{kT} \times \frac{2\alpha}{1+\alpha} \tag{8}$$

$$N_{\mathrm{H}_2} = \frac{P}{kT} \times \frac{1-\alpha}{1+\alpha} \tag{9}$$

Substituting Equations 2, 3, 5, 8 and 9 in Equation 4, there is obtained

$$\frac{-\partial\alpha}{\partial x} = \frac{\pi r^2}{n} \times K_1 \frac{4\alpha^2 P^2}{(1+\alpha)^2 k^2T^2} + K_2 \frac{8\alpha^3 P^3}{(1+\alpha)^3 k^3T^3} + K_3 \frac{4\alpha^2(1-\alpha)P^3}{(1+\alpha)^3 k^3T^3} \tag{10}$$

Equation 10 cannot be integrated except by means of a series development. It is possible, however, that any one of the three terms may predominate. To integrate these three simplified equations it will be necessary to know P as a function of x. This pressure gradient could be calculated from the data of Harteck[5] but this would make the computations quite complicated. Since Harteck found that the viscosity of mixtures of atomic and molecular hydrogen does not differ greatly from the value for molecular hydrogen alone, it is believed that an empirical method will be sufficiently accurate for the present purposes. It will therefore be assumed that

$$P = \sqrt{P_0^2 - \beta x} \tag{11}$$

where β is a constant to be evaluated from the data of each experiment. This equation is equivalent to the assumption that the viscosity of the gas is constant along the tube. In order to calculate the constant β it may reasonably be assumed that, since all of the hydrogen is molecular after leaving the calorimeter, the curves of Fig. 5 give the true pressure gradient for this part of the flow. If this is the case it is possible to determine the pressure P at the calorimeter from the measured value of P_1, by interpolation. Since P, P_0 and x are known, β may be calculated for each run. Although this method of calculation is approximate, the results seem fairly certain for large values of x. Thus in the first five of the runs calculated in Table II β varies irregularly between 3520 and 4440 (pressure expressed in dynes/cm.^{2}). In the last five runs β decreases fairly regularly from 4160 to 3190. The calculated value of β for molecular hydrogen is 3570.

Using the assumption of Equation 11 and setting alternately K_2 and K_3, K_1 and K_3, K_1 and K_2 equal to zero, the following equations are obtained

$$K_1 = \frac{nk^2T^2\left[\frac{1}{\alpha} - \frac{1}{\alpha_0} + 2\ln\frac{\alpha_0}{\alpha} + \alpha_0 - \alpha\right]}{4\pi r^2\left(P_0^2x - \frac{\beta x^2}{2}\right)} \tag{12}$$

$$K_2 = \frac{5\beta nk^3T^3\left[\frac{1}{2}\left(\frac{1}{\alpha^2} - \frac{1}{\alpha_0^2}\right) + 3\left(\frac{1}{\alpha} - \frac{1}{\alpha_0}\right) + 3\ln\frac{\alpha_0}{\alpha} + \alpha_0 - \alpha\right]}{16\pi r^2[P_0^5 - (P_0^2 - \beta x)^{5/2}]} \tag{13}$$

$$K_3 = \frac{5\beta nk^3T^3\left[4\ln\frac{\alpha_0}{\alpha} + 8\ln\frac{1-\alpha}{1-\alpha_0} + \frac{1}{\alpha} - \frac{1}{\alpha_0} - (\alpha_0 - \alpha)\right]}{8\pi r^2[P_0^5 - (P_0^2 - \beta x)^{5/2}]} \tag{14}$$

Equation 12 embodies the assumption that the recombination of hydrogen atoms is largely heterogeneous; Equation 13 that it is homogeneous, but that only the hydrogen atoms can act as the third body; and the last equation that only the hydrogen molecule can act as the third body. Table II summarizes the values of these constants calculated from some of the experiments of Table I. The values of α_0 used in the calculations were taken from the extrapolated curve of Fig. 4.

TABLE II

SUMMARIZED VALUES OF CONSTANTS

P_0	x	α_0	α	$K_1 \times 10^{16}$	$K_2 \times 10^{32}$	$K_3 \times 10^{32}$
0.508	86.2	0.810	0.475	4.20	4.20	12.40
.584	86.2	.790	.350	4.24	3.60	9.04
.632	86.2	.778	.290	4.68	4.16	8.24
.714	86.2	.758	.202	5.04	4.72	6.32
.798	86.2	.740	.151	5.20	4.96	4.84
.508	65.9	.810	.534	3.84	3.48	14.44
.642	65.9	.775	.380	3.76	2.84	7.44
.716	65.9	.758	.282	4.24	3.24	6.04
.788	65.9	.743	.217	4.44	3.48	4.88
.874	65.9	.728	.170	5.12	3.60	3.88

Each of the three constants shows a well-defined drift so that it may be concluded that none of the three equations expresses the actual mechanism of recombination. The variation of the constants, however, is such as to make it seem probable that the differential Equation 10 does express the correct mechanism. Thus as the pressure is increased the apparent value of K_1 increases, K_2 first decreases and then increases and K_3 decreases. The increase in K_1 indicates that there is relatively less recombination taking place on the wall at the high pressures. Similarly, the decrease of K_3 shows that there are relatively more effective collisions involving two hydrogen atoms and one hydrogen molecule at the higher pressures. These two effects combined can account for the changes in K_2. Thus increasing the pressure lessens the relative amount of wall reaction, which would cause K_2 to decrease, and increases the relative amount of recombination caused by the molecules, which would cause K_2 to increase. Since the wall reaction varies as the square of the pressure and the "molecule reaction" as the pressure cubed, the first effect predominates at the low pressures and the second at the higher pressures. K_2, therefore, passes through a minimum.

An attempt was made to calculate the constants directly from the differential equation, by obtaining the slope graphically. This is a very unfavorable way of calculating the data since the determinants of the various sets of equations nearly vanish. Thus a change of 2% in the slope changes the constants by a factor of 100 or more.

A series of approximate calculations, however, indicated that the data would be satisfied if K_1, K_2 and K_3 are of the orders of magnitude 10^{-16}, 10^{-32} and 10^{-32}, respectively.

The approximate values of the constants so obtained may render possible a more quantitative definition of a three-body collision. Thus a three-body collision in which the wall is the third body may be defined as a collision between two hydrogen atoms occurring less than a short distance, 6, from the wall. In other words, the number of such collisions per second per cc. equals the number of collisions between hydrogen atoms per sec. per cc. times the volume of a cylindrical shell of radius r, thickness δ and length such that the volume inclosed by the shell shall be 1 cc. That is

$$\nu_{3(\text{wall})} = 2N_{\text{H}}^2\sigma_{\text{H}}^2\sqrt{\frac{\pi kT}{m_{\text{H}}}} \times \frac{2\delta}{r} \tag{15}$$

where σ_{H} is the diameter and m_{H} the mass of the hydrogen atom. Therefore

$$K_1 = \frac{4\sigma_{\text{H}}^2\delta}{r}\sqrt{\frac{\pi kT}{m_{\text{H}}}} \tag{16}$$

In arriving at this relation it is assumed that the tube wall is perfectly smooth. Although this cannot be the case, the actual area of the wall is probably not greatly different from the assumed value since the small adsorbing pores of the wall are filled with water. Substitution of numerical values in Equation 16 shows that 6 is of the order of magnitude of 10^{-7} cm. Irregularities in the wall would decrease this figure. In the calculation the diameter of the hydrogen atom has been assumed to be 2×10^{-8} cm.

A three-body collision involving three molecules may be defined in a number of different ways. For example, Tolman[7] defines it as one in which the distances between Molecule I and Molecule II and between Molecule II and Molecule III are equal to or less than some short distance, 6. From the relation obtained by him it follows that

$$K_2 = 32\pi^2\sigma_{\text{H}}^4\delta\sqrt{\frac{kT}{\pi m_{\text{H}}}} \tag{17}$$

and

$$K_3 = 16\pi^2\sigma_{\text{H}}^2\left(\frac{\sigma_{\text{H}} + \sigma_{\text{H}_2}}{2}\right)^2\delta\sqrt{\frac{kT}{\pi m_{\text{H}}}}\left(1 + \sqrt{\frac{m_{\text{H}} + m_{\text{H}_2}}{m_{\text{H}_2}}}\right) \tag{18}$$

where σ_{H_2} and m_{H_2} are, respectively, the diameter and mass of the hydrogen molecule. From either equation it is found that 6 is of the order of magnitude 10^{-9} cm.

The definition suggested by Herzfeld[1] and used by Bodenstein[S] in his calculations of the rate of the reaction between NO and O_2 is identical with the above except that 6 is identified as the diameter of the colliding molecules. The expressions obtained from the two definitions for the number of triple collisions differ only by a numerical factor of the order ten.

---

[7] Tolman, "Statistical Mechanics with Applications to Physics and Chemistry," The Chemical Catalog Co., New York, 1927, p. **247.**

[8] Bodenstein, Z. *physik. Chem.*, **100,** 68 (1922).

Syrkin[9] has calculated the number of multiple collisions between point molecules by defining a multiple collision as one in which the colliding molecules are within a small sphere of radius r. Applying his general equation to the present case, there are obtained the equations

$$K_2 = \frac{\left(\frac{4}{3}\pi r^3\right)^2}{3!r} \times \frac{2}{3}\sqrt{\frac{2\pi kT}{m_H}} \tag{19}$$

$$K_3 = \frac{\left(\frac{4}{3}\pi r^3\right)^2}{2!r} \times \frac{2}{3}\sqrt{2\pi kT}\sqrt{\frac{\frac{2}{m_H} + \frac{1}{m_{H_2}}}{3}} \tag{20}$$

From either equation r is found to be of the order 10^{-8} cm.

It may therefore be concluded that the recombination of hydrogen atoms proceeds according to the predicted three-body mechanism. The experimental proof, however, is not as definite as might be desired since no integral of Equation 10 was obtained. For this reason the experimental method was not considered suitable for an investigation of the effect of mixing other gases with the dissociated hydrogen.

There are a number of other possible mechanisms for the recombination of atomic hydrogen. Thus it might be supposed that even under the best circumstances the walls of the containing vessel still exert a specific catalytic power at relatively isolated points. If, however, this were the principal means of recombination, K_1 calculated from Equation 12 should be constant. It might further be supposed that the water vapor present in the gas might enter into the mechanism. The fact that Bonhoeffer[10] and Mohler[11] have shown that the OH bands are excited by atomic hydrogen might be cited as evidence in favor of this statement. Since, however, the reaction

$$H + H_2O \longrightarrow H_2 + OH - 12 \text{ Cal.}$$

is endothermic, it may be ruled out. It seems more probable that unexcited OH molecules are produced in the discharge tube and that the bands result from triple impacts between these and two hydrogen atoms. Under the conditions of the present measurements such an effect would be too small to influence the results.

No account has been taken of the possibility of recombination taking place in the adsorbed phase. Langmuir[12] has shown that atomic hydrogen is appreciably adsorbed by glass surfaces at room temperature but in his experiments the glass was thoroughly baked out prior to the adsorption while in the present case the tube wall was covered with a film of water. Furthermore, if the wall were covered with a reactive adsorbed film the

[12] I. Langmuir, THIS JOURNAL, 34, 1310 (1912); 36, 1711 (1914); 37, 417 (1915); 38, 2270 (1916).

recombination would be at least 10^5 times more rapid. In the light of these facts it seems extremely improbable that the wall as a whole adsorbs atomic hydrogen. There remains the possibility that isolated points on the wall are absorbent and hence catalytic. Such a possibility is unlikely since if this were the case duplicate results could not be obtained in different apparatus.

In conclusion the author wishes to express his indebtedness to Dr. H. C. Urey and to Professor K. F. Herzfeid for their advice during the course of this work.

Summary

1. A calorimetric method for the estimation of the amount of atomic hydrogen obtained from a Wood tube is described, together with the application of this method to the measurement of the rate of recombination of the hydrogen atoms.
2. This rate has been measured through the pressure range 0.5–0.9 mm. of mercury.
3. It was found that, under the conditions of the experiment, one-fifth to one-sixth of the atomic hydrogen present reacted with solid sulfur and that nitric oxide catalyzes the recombination of the atomic hydrogen.
4. The data obtained for the rate of recombination are discussed and it is concluded that they are in accordance with the predicted three-body mechanism.

THE REACTIVITY OF IODINE CYANIDE IN DIFFERENT ORGANIC SOLVENTS

BY ERWIN CHARGAFF[1]

RECEIVED FEBRUARY 1, 1929 PUBLISHED JULY 5, 1929

F. Feigl and the author have stated[2] that the reactivity of iodine toward the silver salt of saccharin depends upon the solvent used. In the so-called active solvents, which give brown solutions of iodine (*viz.*, ethyl ether, ethyl alcohol, etc.), almost only AgI is formed. In the inactive solvents (*viz.*, carbon disulfide, carbon tetrachloride, etc.), in which iodine dissolves with a violet color, there apparently is formed an addition compound 
$NAg...I_2$, which, being unstable, easily decomposes into

silver saccharate and iodine. This remarkable difference in reactivity is attributed by the authors to the fact that in the brown solutions the iodine is present in a molecular compound with the solvent, whereas in the violet solutions we are dealing with uncombined molecules of iodine. The absorption spectra of these violet solutions are almost identical with that of iodine vapor. Therefore it was of some interest to compare the reactivity of an interhalogen compound with that of iodine in the same solvents. For this purpose the reaction of silver saccharate in solutions of iodine cyanide with different solvents has been investigated under identical conditions.

Experimental Part

The silver saccharate used was prepared by adding a boiling aqueous solution of 8 g. of silver nitrate to a boiling solution of 10 g. of sodium saccharate The precipitate was washed with water, acetone and ether. By analysis it was shown to be pure silver saccharate. The best method for preparing iodine cyanide proved to be that recommended by V. Grignard and P. Crouzier,[3] which consists in passing a stream of chlorine through a solution of iodine in aqueous sodium cyanide, and subsequently removing the iodine cyanide by extraction with ether. In order to obtain a good yield of the cyanide it was found to be desirable to remove the ether by distillation in a vacuum at room temperature and not on a steam-bath, as iodine cyanide is very volatile even below 40°. Out of the highly concentrated ether solution the iodine cyanide is then precipitated by adding carbon tetrachloride. The product thus obtained is almost pure (m. p. 145.5° instead of 146.5'). For ordinary purposes the very unpleasant sublimation thus may be avoided. However, for the experiments given here the original product was slowly sublimed in small portions at 40°, whereupon the melting point rose to 146° in the closed capillary tube. From 31.5 g. of iodine 35.2 g. of iodine cyanide was obtained (92.6% of the iodine used). The solvents were all freshly distilled and dried. The carbon disulfide was shaken with mercury and calcium chloride and then distilled.[4]

In all cases the reactions were carried out by refluxing 0.6 g. of silver saccharate with solutions of 0.8 g. of iodine cyanide in 80 cc. of the respective solvents for two hours. Longer heating does not change the results. When still hot the solution then was decanted from the silver salt and the latter heated with fresh solvent several times until a sample of the solvent did not liberate iodine from a potassium iodide solution. To determine the silver in the reaction product the previous method of analysis could not be employed. A method was necessary which allowed the determination of silver iodide and at the same time of the amount of silver cyanide which may have been formed. Therefore, each time a weighed sample of the product was heated with dilute nitric acid and the liquid separated from the silver iodide and silver cyanide with a filter crucible. In the filtrate the amount of silver, which came from unchanged silver saccharate, was determined by titration with 0.1 *N* ammonium thiocyanate solution after the method of Volhard. The residue in the crucible was washed with warm aqueous ammonia after weighing and the loss of weight indicated the amount of silver cyanide dissolved by the ammonia. However, as the amounts of silver iodide and silver cyanide insoluble in nitric acid were very slight, great accuracy

could not be expected for the determination of the silver cyanide. Some of the results obtained are given in Table I.

Carbon disulfide	2	.3968	.0021	....	13.59	.3940	99.29

Discussion of the Results

The experiments described above gave the result that iodine cyanide does not act on silver saccharate at all, whereas iodine does, and there cannot be found any influence due to the nature of the solvent used. In Table II are recorded the respective amounts of silver iodide expressed as percentage of the reaction products in the cases of both iodine and iodine cyanide.

Table II

Silver Iodide Expressed as Percentages

	Abs. ether	Ether	Abs. alc.	Benzene	Chloroform	Carbon tetrachloride	Carbon disulfide	Pet. ether
Reaction with I_2	90.15	95.76	91.30	88.20	86 94	24.57	0	0
Reaction with ICN	0.53	0.59	092	0.36	0.58	068	0.74	..

In the reaction with iodine there appears to be a decisive difference according to the use of an active or inactive solvent (with the exception only of chloroform and benzene),[5] while with iodine cyanide no influence of the solvent can be stated at all, the amount of silver iodide formed being very small in all cases. The statement of F. Ephraim[6] that the reactions of the interhalogen compounds are merely weakened reactions of the free halogens does not prove to be correct at least in this case. In order to explain these facts two assumptions could be made. Either it could be assumed that, contrary to the case of iodine, iodine cyanide does not give addition compounds with the active solvents and that to these addition compounds is due the formation of silver iodide in brown solutions of iodine, or (and this may be the more plausible explanation) that iodine cyanide—and perhaps other interhalogen compounds, too—

does not function as a "mixed halogen," but as a salt of hydrocyanic acid with the weak base iodine hydroxide.[7] The salt-like behavior of the iodine-halogen compounds is emphasized by several investigators.[8] In conclusion it may be said that according to the results which have been obtained the hypothesis that the structure of the iodine cyanide molecule is different from that of the iodine molecule is confirmed, and that it is to the different chemical nature of iodine cyanide that we may attribute its divergent reactivity.

Summary

The reactivity of iodine cyanide toward silver saccharate in various solvents has been investigated. It is shown that contrary to the behavior of iodine the reactivity of iodine cyanide is independent of the nature of the solvent. From this fact the conclusion may be drawn that iodine cyanide represents a heteropolar compound and does not function as a "mixed halogen." The yield of iodine cyanide has been increased by modifying the purification methods.

THE DENSITIES OF COEXISTING LIQUID AND GASEOUS NITROUS OXIDE

By Elton L. Quinn and Grant Wernimont

Received February 19, 1929 Published July 5, 1929

During an investigation of the internal pressure of liquid nitrous oxide by the measurement of its surface tension, the authors found that no data existed on the densities of the liquid and its saturated vapor at temperatures below zero. As these data were necessary for calculating the surface tension, it became necessary to interrupt the investigation and to attempt a set of measurements for supplying these values. This paper describes the method of making these determinations and the results obtained over a temperature range from 30 to $-50°$.

The densities of liquid nitrous oxide and its saturated vapor were determined between the temperatures of 30 and 0° by Villard[1] in the year 1894. While the reliability of these determinations has never been questioned, the temperature range covered is not great enough for the work at hand. The advisability of extrapolating these values to the lower temperatures was carefully considered but it seemed best under the circumstances to make direct measurements.

As it was necessary to make measurements below the freezing point of mercury the usual method in which mercury is used as a confining liquid could not be used. The method of Young[2] seemed to be the only one applicable under these conditions and after slight modification was found to give quite satisfactory results. Several glass tubes of different lengths were filled to about two-thirds of their capacity with liquid nitrous oxide; the volumes of the liquid and saturated vapor were determined at different temperatures and the weight of the compound in each tube was measured. From these values by means of simultaneous equations it was possible to calculate the densities of the two phases at each temperature at which measurements were made.

Experimental Method

The five pycnometers used in this work were simple straight "soda-glass" tubes having an outside diameter of 12 mm. and a wall thickness of 2 mm. These tubes varied in length from 10 to 20 cm. and were graduated on the outside in mm. divisions. The greatest care was necessary in their manufacture as it was necessary for them to withstand at times a gas pressure as high as 68 atmospheres. It was found that proper annealing after working in the gas flame was much more important than the thickness of the tube wall, provided, of course, that it had a reasonable thickness. The two-thirds capacity filling of the tubes was also important because tubes having very much less than this amount could not be used over the whole temperature range. Stewart[3] showed in the case of carbon dioxide, which behaves much the same as nitrous oxide, that the liquid in a tube filled to less than about two-thirds of its volume contracts on cooling until some temperature is eventually reached where the liquid condensed from the gaseous phase, due to the lowering of the temperature, is equal to the contraction of the liquid phase. It is quite obvious that measurements made under such conditions would be of no value for density determinations.

The nitrous oxide used in this investigation was taken from a commercial cylinder of the liquefied gas manufactured by the Ohio Chemical and Manufacturing Company. The gas was carefully analyzed qualitatively using the tests suggested by Hackh[4] and found to be free from other oxides of nitrogen, halogens, carbon dioxide, sulfur compounds and ammonia. A small quantity of air was present but the most troublesome impurity was water vapor. In order to remove these impurities as well as any other substance that might be present in small amounts the liquid was fractionally distilled several times in an apparatus represented by the drawing in Fig. 1. The pycnometer, e, was cemented to the exit tube with de Khotinsky cement and the whole apparatus evacuated with an oil pump until the pressure was less than 3 mm., as indicated by a mercury manometer. During the evacuation the pycnometer was heated with a hand blast lamp until it was much too hot to permit touching with the bare hand. Nitrous oxide was then admitted to the apparatus and when the pressure reached that of the atmosphere the vacuum pump was stopped, the valve on the safety line closed and the safety valve adjusted. Then after a slight pressure had been put on the system, the valve to the safety line was opened and the pressure increased until the safety valve operated. While in this condition a Dewar flask containing solid carbon dioxide and ether, the temperature of which had been lowered to −100° by means of a vacuum

pump, was pushed up over Tube a. Gaseous nitrous oxide was admitted from the cylinder fast enough to keep the safety valve close to the opening point until a sufficient quantity of the liquid had collected in Tube a. The supply of nitrous oxide was then cut off and the valve to the safety line closed. The freezing mixture was then transferred to Tube b and the liquid in a was permitted to distil into b, after which a Dewar flask containing liquid oxygen was substituted for the carbon dioxide freezing mixture. As soon as the nitrous oxide was frozen the vacuum pump was connected and the system evacuated to **3** mm. or less. As Tube b was cooled with liquid oxygen before all of the liquid in a had evaporated, a residue of liquid nitrous oxide was left in a which usually changed to a solid as soon as vapor pressure was decreased by lowering the temperature of Tube b. This residue was removed by heating after the vacuum pump had been operating for a few minutes. The residual gases were able to pass to the pump without coming in contact with the solid nitrous oxide. This procedure was repeated by distilling to a liquid in c and freezing to a solid and pumping in d and finally distilling the proper amount into the pycnometer e, freezing and evacuating. The pycnometer containing the proper amount of solid nitrous oxide was sealed while the vacuum pump held the pressure to less than **3** mm. and after the heated end of the tube had cooled it was removed from the liquid oxygen and the whole tube warmed slowly to room temperature. That this process was effective in removing the water from the gas is indicated by the fact that in preliminary experiments in which the gas was dried by passing it through a 50-cm. tower of calcium chloride, crystals of some impurity, supposedly water, separated from the liquid nitrous oxide on cooling to about —20°. Liquid nitrous oxide distilled in this apparatus failed to show such an impurity at any temperature. Weighing the tubes was delayed for several days so as to permit them to stand at room temperature long enough to give some assurance that they would not explode in the balance case. Several tubes exploded during this period, usually very soon after filling but none caused any trouble after starting the measurements, some even being heated to the critical temperature.

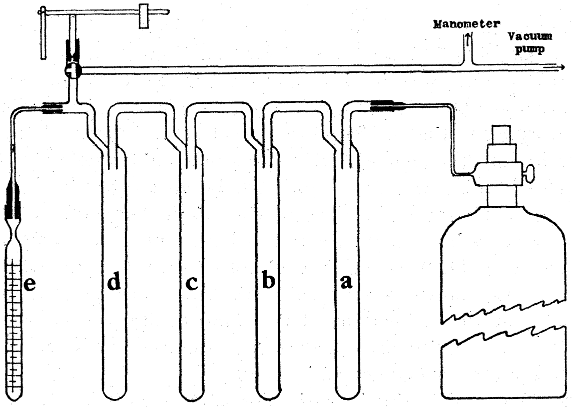

Fig. 1.

After weighing, the pycnometers were placed in long glass tubes having one end closed. A wad of cotton prevented the pycnometers from touching the bottom and a roll of paper held the top end securely in place. These tubes made it easy to handle the pycnometers and to clamp them in position in the thermostat. The thermostat used has already been described.[5] The temperature was kept constant by expanding

---

[5] Quinn, THIS JOURNAL, 49, 2704 (1927).

liquid carbon dioxide through a cooling coil submerged in an alcohol-bath. Some improvement was made when a so-called "siphon cylinder" was substituted for the inverted carbon dioxide cylinder. This made handling easier and prevented water and oil from being forced through the coils. The temperature was adjusted every thirty seconds during the period of measuring and it was not difficult to hold it within ±0.25° of the desired temperature down to −60°. Temperature measurements were made with a pentane thermometer which had been calibrated twice by the U. S. Bureau of Standards. The last calibration was made during the summer of 1928.

The routine procedure of reading the volumes of liquid in the several tubes was as follows. The tubes were submerged in the alcohol-bath at the desired temperature for ten minutes. They were then removed and quickly shaken thoroughly and returned to the bath. At the end of six to seven minutes a reading was taken of the position of the meniscus on the tube graduations and it was again removed, quickly inverted and returned to the bath. In three to four minutes or as soon as the liquid nitrous oxide had drained from the sides of the tubes a second reading was made and if the two readings checked this value was used as the volume of the liquid at that temperature. The time necessary to reach equilibrium in the tube was determined several times by taking readings every twenty seconds until they became constant. It never took over seven minutes to reach this point.

After the readings had been completed the temperature of the tube was lowered in a solid carbon dioxide and ether bath and a small hole made in the tip of the pycnometer with a hand blast lamp. The tubes were then removed and the nitrous oxide permitted to escape. The last of this compound was removed with a vacuum pump and its place taken by air, the weight of which was easily determined. The weight of the tube was then determined, after which it was filled to the top with freshly boiled distilled water and again weighed. From these weighings and the temperature of the water the total volume of the pycnometer was determined. The top of the tube was then removed and the lower portion calibrated by filling with water to the marks reached by the liquid nitrous oxide at the various temperatures. The curvature of the meniscus in the case of water was, of course, different from that of the nitrous oxide and a correction for this difference had to be applied at each temperature.

The weight of the water in the meniscus was found in the following manner. A tube of the same size as that used for the pycnometers partly was filled with mercury and a little water placed on top. It was then put in a projection lantern and its image, enlarged 23 times, was projected on a white piece of paper. A drawing was made of the two menisci which is represented by Fig. 2, abcd being the meniscus of the water and efgh that of the mercury. These areas were then cut from the paper and weighed. The weight of abcd divided by the weight of abcd + efgh times 100 gave the percentage of the total area due to water above the line bc which was found in three determinations to be 62, 61 and 61%, respectively.

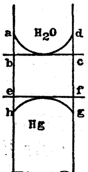

Fig. 2

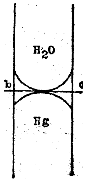

Fig. 3.

The same tube was dried and weighed with mercury, after which water was added and sucked out until the meniscus of the water just touched the meniscus of the mercury as in Fig. 3. The weight of the water was then determined and 61% of this was taken as the weight above the line bc. A tube containing liquid nitrous oxide was then warmed to 30° and a drawing made of its meniscus. The surface came so near to being flat that it was assumed that no appreciable error would be introduced by so considering it. An attempt was made to get a drawing of the nitrous oxide meniscus at a low temperature. This was unsuccessful and it was therefore necessary to be content with the apparent similarity of the meniscus of the liquefied gas at −60° and that of water at +30°. It was quite evident that if any correction was needed at this point it was very small. The correction at 30° was 0.05 g. This was the weight of the water in the curved meniscus above the comparatively flat surface of the liquid nitrous oxide. The correction at −60° was 0. By interpolation the correction to be subtracted at each temperature was determined.

The thermal expansion of the tube from −60° to the temperature at which the calibration was made was calculated and it was found that this made a difference in the volume of the tube of about 1 part in 500. As this correction was less than the probable error in the readings, it was not applied.

The dilation of a glass tube under a pressure practically the same as in this case was measured experimentally with liquid carbon dioxide[6] and was found to be less than 0.1%. This correction could, therefore, be neglected in these calculations.

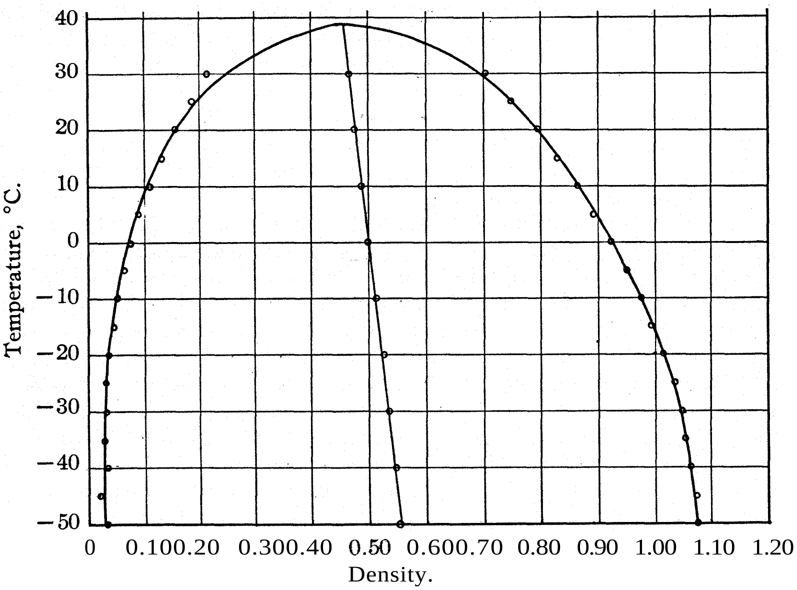

Fig. 4.

In order to eliminate as far as possible the experimental errors involved in determining the volume of the liquid nitrous oxide at the various temperatures, the volumes obtained by calibrating the tubes were plotted on coordinate paper 50 × 80 cm. and a curve was constructed for each set of readings. The agreement between the points on each curve was very satisfactory, only a few points failing to fall in the proper position. The values used for the calculations of the density of the liquid and the density of the gas were read from these curves. Tube No. 1 was discarded at the outset as it was quite evident that the volume of the liquid was too great to give reliable results for the gaseous density. Readings from Tube No. 3 also had to be discarded although the curve seemed to be quite regular. Apparently the trouble was due to an error in the total weight of the nitrous oxide or its total volume. As the tube had been cut it was quite

---

[6] Quinn, THIS JOURNAL, 50, 675 (1928).

impossible to check back on either of these points. The densities were determined by setting up simultaneous equations between different sets of volume readings. Five calculations were thus made at each temperature and the values plotted in Fig. 4 were the averages between these results. In constructing this curve the value obtained by Villard for the critical temperature was used, that is, 38.8°. It is quite evident from an inspection of the curve that the values reported at times around 35° could not be used. The critical density was determined by the method of Cailletet and Mathias[7] in which the values for $(D + d)/2$ were plotted against the temperature and the straight line thus produced was extrapolated to the critical temperature. This gave a value of 0.459 for the critical density, while the value reported by Villard was 0.456.

Experimental Results

The results of these measurements are tabulated in Table I. Villard's results were plotted and values read from his curve at corresponding temperatures are given in the table for comparison. It will be noted that the agreement is, in general, very satisfactory. Lowry and Erickson[8] de-

TABLE I

THE DENSITIES OF COEXISTING LIQUID AND GASEOUS NITROUS OXIDE

	Quinn and Wernimont				Villard	
Temp., °C.	D Obs.	D Calcd.	d Obs.	d Calcd.	D	d
38.8	0.451	0.459	0.459	0.459	0.456	0.456
30	.704	.721	.217	.216	.680	.240
25	.750	.780	.181	.166	.740	.196
20	.793	.805	.153	.155	.784	.160
15	.826	.837	.133	.133	.820	.135
10	.861	.866	.111	.116	.856	.114
5	.894	.892	.090	.102	.886	.099
0	.925	.916	.073	.088	.912	.087
−5	.952	.939	.062	.077		
−10	.975	.960	.051	.066		
−15	.995	.980	.042	.058		
−20	1.013	.999	.038	.049		
−25	1.033	1.018	.030	.042		
−30	1.044	1.036	.029	.034		
−35	1.053	1 054	.028	.028		
−40	1 062	1 070	031	.022		
−45	1.071	1.087	.020	.017		
−50	1.079	1.103	.032	.013		

The experimental error for the liquid densities is estimated as about ±0.25%. The error of measurement of the gaseous phase is much greater. Neglecting the two highest and two lowest values, which are obviously much in error, the average deviation will run about ±2.0%.

---

[7] Cailletet and Mathias, *Compt. rend.*, **102**, 1202 (1886); **104**, 1563 (1887).

[8] Lowry and Erickson, THIS JOURNAL, 49, 2731 (1927).

veloped equations for the relation between the values for $(D + d)/2$ and the densities of the gaseous and liquid phases of carbon dioxide. These equations when applied to nitrous oxide take the following form

$$D = 0.459 + 0.00111\,(t_k - t) + 0.1222\,\sqrt[3]{t_k - t}$$
$$d = 0.459 + 0.00111\,(t_k - t) - 0.1222\,\sqrt[3]{t_k - t} \quad \text{and}$$
$$(D + d)/2 = 0.459 + 0.00111\,(t_k - t)$$

In these equations D is the density of the liquid phase and d the density of the gaseous phase. The values of D and d calculated by means of these equations have also been tabulated and it will be noted that the agreement is not especially good and this disagreement is more pronounced at the higher temperatures. Lowry and Erickson, in the case of carbon dioxide, obtained excellent agreement between the calculated and observed values.

It is of some interest to use these results for calculating the molecular volume at absolute zero, using for this purpose the equation proposed by Sugden.[9] If the equation is written in the form $D - d = D_0(1 - T/T_K)^{3/10}$ D_0 being a constant which in the case of nitrous oxide has a value of 1,566, then the molecular volume at absolute zero would be 4411.566 or 28.1 ce. The actual volume occupied by each molecule could be calculated easily from this value by the use of Avogadro's number.

Summary

The densities of the coexisting gaseous and liquid phases of nitrous oxide have been determined over a temperature range of 80°. The critical density was found to be 0.459 and the molecular volume at absolute zero to be 28.1 cc. when calculated from Sugden's equation. The values for the density of the liquid and its saturated vapor show a very good agreement with those obtained over part of the temperature range by Villard.

THE LEAD DIOXIDE–LEAD SULFATE ELECTRODE[1]

BY WARREN C. VOSBURGH AND D. NORMAN CRAIG

RECEIVED FEBRUARY 21, 1929 PUBLISHED JULY 5, 1929

Although the lead storage cell has been extensively studied from the practical side, the value of the lead dioxide–lead sulfate electrode, which is generally considered to form the positive electrode of the storage cell, is known only approximately. Gerke[2] gives **1.7** v. for the value of this electrode, the second figure being considered uncertain. This value is based on the work of Kendrick.[3] Vinal[4] has tabulated the values of different observers for the electromotive force of the lead storage cell. There is an average variation from the mean of 0.02 v. in the values for cells with the same acid concentration when all the results tabulated are considered.

In this investigation the electromotive force of the cell

$$\mathrm{Hg} \mid \mathrm{Hg_2SO_4}, \mathrm{PbSO_4}, \mathrm{H_2SO_4}\ (a = x) \mid \mathrm{H_2SO_4}\ (a = x), \mathrm{PbO_2}, \mathrm{PbSO_4} \mid (\mathrm{Pt}) \qquad (1)$$

was measured. The lead dioxide and lead sulfate were prepared chemically or, in the case of a few preparations of the former, by an electrolytic process different from that used in forming the positive plates of storage cells. From the electromotive force of Cell 1 the value of the lead dioxide–lead sulfate electrode was calculated.

By combining the electromotive force of Cell 1 with that of the cell[5]

$$\mathrm{Pb} \mid \mathrm{PbSO_4}, \mathrm{SO_4}^{--} \mid \mathrm{SO_4}^{--}, \mathrm{PbSO_4}, \mathrm{Hg_2SO_4} \mid \mathrm{Hg} \qquad (2)$$

the electromotive force of the cell

$$\mathrm{Pb} \mid \mathrm{PbSO_4}, \mathrm{H_2SO_4}\ (a = x) \mid \mathrm{H_2SO_4}\ (a = x), \mathrm{PbO_2}, \mathrm{PbSO_4} \mid (\mathrm{Pt}) \qquad (3)$$

was calculated.[6] This was found to agree as well as could be expected with the observed electromotive force of the lead storage cell.

Materials

Mercury.—Commercial redistilled mercury was purified by passing it repeatedly through a column of mercurous nitrate solution, and by fractionally redistilling it at least twice under reduced pressure in a current of air.

---

[6] The electromotive force of Cell **3** could not be measured directly on account of the difficulty of reproducing the lead sulfate–lead amalgam electrode when the electrolyte was a sulfuric acid solution. Lewis and Brighton, THIS JOURNAL, 30, 1908 (1917), have reported this difficulty, and their observations were confirmed in this investigation.

Lead Amalgam.—The lead amalgam was prepared electrolytically from purified mercury and twice recrystallized lead nitrate. It contained 10% of lead by weight.

Mercurous Sulfate.—The mercurous sulfate was prepared by adding at a slow rate a mercurous nitrate solution, made from twice recrystallized mercurous nitrate, to a hot 2 M sulfuric acid solution, which was made from C. P. acid. The precipitated mercurous sulfate was digested for nineteen hours on a steam-bath under 2 M sulfuric acid solution.[7]

Lead Nitrate.—Lead nitrate of C. P. quality was recrvstallized twice by the addition of concd. nitric acid to a hot concentrated solution of the salt. In the second recrystallization redistilled nitric acid and redistilled water were used.

Lead Sulfate.—Five hundred cc. each of a 0.5 M lead nitrate solution and 0.5 M sulfuric acid solution were added simultaneously drop by drop with constant stirring to 2 liters of boiling 0.1 M sulfuric acid solution. The lead sulfate was digested for twelve hours on a steam-bath under 2 M sulfuric acid solution.

Sulfuric Acid Solution.—The sulfuric acid solutions to be used as electrolytes in the cells were made by diluting concentrated C. P. acid to the required concentration with redistilled water.

The concentrations were determined by titrating a known weight of the solution with a standard carbonate-free sodium hydroxide solution. The latter was standardized by titrating in a similar manner a known weight of a hydrochlorioacid solution, which in turn had been standardized gravimetrically by the silver chloride method. Duplicate determinations agreed within one part in a thousand. The method of Randall and Scalione[8] was tried also as a check. Duplicate determinations did not agree quite so well, but the mean values agreed within an average of less than two parts in a thousand with the results of the first method. The concentrations given below are expressed in moles per 1000 g. of water.

Preparation of the Lead Dioxide

Several methods for the preparation of lead dioxide were tried because agreement of preparations made by different methods can be considered as evidence that the material is of sufficient purity and has a stable physical form.

Method 1.—Lead hydroxide was prepared by precipitation from a dilute lead nitrate solution by means of sodium hydroxide. It was well washed and then dissolved by means of sodium hydroxide solution. The resulting sodium plumbite solution was maintained at about 93°, stirred mechanically and bromine or sodium hypobromite solution added. It made little difference whether the oxidizing agent was bromine carried in by a current of air, bromine water or sodium hypobromite solution. In all cases the addition of the oxidizing agent was continued until the precipitate which was formed had turned dark brown or black.

Method 2.—The second method was similar to the first except that gaseous chlorine was used as the oxidizing agent. The chlorine was generated by the action of concd. hydrochloric acid on potassium permanganate and was washed by bubbling through water.

Method 3.—The third method consisted in hydrolyzing sodium plumbate. Lead dioxide was prepared by electrolysis and dissolved with hot concentrated sodium hydroxide solution. The solution was filtered and added drop by drop to a large volume of water kept at about 93° and mechanically stirred.

---

[7] See Vosburgh and Eppley, THIS JOURNAL, 46, 110 (1924).

[8] Randall and Scalione, Met. *Chem. Eng.*, 13, 787 (1915).

Method 4.—Lead dioxide was also prepared by the electrolysis of a solution of 100 g. of lead nitrate and 400 cc. of concd. nitric acid in a total volume of three liters with a platinum gauze anode. The cathode was a platinum wire sealed into glass and was surrounded by a porous cup. The current density was kept in the vicinity of 2.5 amperes per square decimeter and the temperature was 93°.

A few preparations were made with the solution at room temperature. This material was not as satisfactory as that made at the higher temperature.

Lead dioxide was also deposited electrolytically directly on coils of platinum wire to be used later as cell electrodes. The electrolysis was carried out in hot solutions with various concentrations of lead nitrate and nitric acid and various current densities. Smooth as well as previously platinized wires were used. These electrodes were not satisfactory.

Other Methods.—Lead dioxide preparations made by hydrolyzing sodium plumbate with cold water and by oxidizing sodium plumbite with hydrogen peroxide were not satisfactory.

Digestion of the Lead Dioxide.—Two advantages may be gained by digesting lead dioxide with sulfuric acid at an elevated temperature. The lead dioxide may be brought to a more stable physical form[9] and any lead monoxide present may be converted to lead sulfate. Since lead sulfate was to be mixed with the lead dioxide in setting up the cells it was not an objectionable impurity.

The lead dioxide used in all but the preliminary experiments was digested under **3** M sulfuric acid solution on a steam-bath for several days. The color of the digested lead dioxide was nearly black, even in those cases in which the color was dark reddish-brown before digestion.

Apparatus

The electromotive forces were measured by means of a Leeds and Northrup Type K potentiometer, which was calibrated by the method described by the manufacturers.[10]

The standard cells were of the saturated type and were kept in an oil thermostat at 25°. They have been previously described.[11]

The experimental cells were kept in an oil thermostat. During the measurements at temperatures other than 25° two thermostats were used, one at 25° for the standards and the other containing the experimental cells. The temperatures were measured by a thermometer checked by the Bureau of Standards and are probably accurate to ±0.03°.

Preliminary Experiments

A number of separate lead dioxide–lead sulfate electrodes were set up in order to find out which methods of preparing lead dioxide gave the best results. They were combined, by means of an intermediate vessel containing some of the electrolyte, with two mercurous sulfate electrodes **and** the

---

[9] (a) Vosburgh and Eppley, ref. 7, found that digestion of the mercurous sulfate with a sulfuric acid solution at boiling temperature helped in the preparation of reproducible Weston standard cells. The digestion probably brought the mercurous sulfate to a more stable physical form. See also (b) Cohen, "Physico-Chemical Metamorphosis and Some Problems in Piezochemistry," McGraw-Hill Book Co., Inc., New York, 1926, p. 50 and (c) Vosburgh, THIS JOURNAL, 50,2391 (1928).

[10] Leeds and Northrup Company, Bulletin No. **755,** 1923, p. *22.*

[11] Ref. 9 c, p. 2389.

resulting cells were measured at room temperature. The electrolyte was 0.1 M sulfuric acid solution throughout. The lead dioxide–lead sulfate electrodes were made by mixing lead dioxide and lead sulfate with the electrolyte and allowing this paste to flow around a coiled platinum wire in the electrode vessel. The platinum wire, which was 0.4 mm. in diameter (No. 26) and 4-cm. long, was sealed into a glass tube and connected with a copper wire terminal by means of mercury.

The preliminary experiments showed that different samples of undigested lead dioxide prepared by the same method gave cells differing by as much as 5 mv. Samples prepared by different methods gave cells differing by 10 to 15 mv. in some cases. When the lead dioxide was digested with a sulfuric acid solution on a steam-bath for several days, samples prepared by different methods gave cells agreeing within 2 mv. or better. The concentration of the sulfuric acid in which the lead dioxide was digested was of some influence. The best results were obtained when the acid concentration was from one to six molar. Nine-molar acid led to some erratic results. Therefore three-molar acid was used in digesting the lead dioxide for the final cells.

The preliminary experiments also led to the choice of Methods 1, 2, 3 and 4 described above as the best methods of preparing lead dioxide. When lead dioxide was deposited directly on the platinum coils by electrolysis, the resulting cells decreased in electromotive force steadily over periods of several weeks and were never observed to become constant.

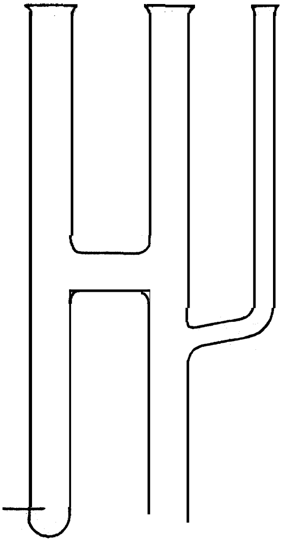

Fig. 1.—Cell vessel.

The Cell Hg | Hg_2SO_4, $PbSO_4$, H_2SO_4 | H_2SO_4, PbO_2, $PbSO_4$ | Pt

Preparation of the Cells.—The final cells were set up in vessels of the type shown in Fig. 1. The leg bearing the sealed-in platinum wire was used for the mercurous sulfate electrode and that with the side arm was used for the lead dioxide electrode. The sulfuric acid solutions used had been carefully standardized as described above. The lead dioxide had been digested in all cases.

In preparing some of the mercurous sulfate electrodes, air-free solutions were used. These had been standardized after freeing from air. Precautions were taken also to protect the mercurous sulfate from air by means of an atmosphere of carbon dioxide while the cell was being set up.[12] Others, as indicated in the tables below, were set up without protection from oxygen. Some lead sulfate was mixed with the mercurous sulfate paste and the layer of this mixture in the cell, at least 1 cm. deep, was covered with a layer of lead sulfate.

---

[12] Vosburgh, This Journal, 47, 1258 (1925).

In setting up a lead dioxide–lead sulfate electrode, the tube bearing the platinum coil was first fixed in place. The glass tube was passed through a hole in a paraffined cork disk and the disk was pushed into the tube of the cell vessel for a distance of two or three centimeters. Melted beeswax was poured on top of the cork disk. Then a paste of about equal parts of lead sulfate and lead dioxide was introduced through the side arm. Enough was introduced to cover completely the platinum coil. This mixture was covered with a layer of lead sulfate. The opening of the vessel on the mercurous sulfate electrode side and the opening of the side arm were closed with paraffined cork disks pushed in for some distance and covered with a layer of beeswax. The finished cells were mounted on racks and connected as described by Vosburgh.[11]

Effect of Dissolved Oxygen.—Randall and Young,[13] whose paper appeared while this investigation was in progress, have shown that the presence of dissolved oxygen has an appreciable effect on the electromotive force of a calomel electrode with an acid electrolyte. Vosburgh[14] found that in setting up Weston standard cells protection from the air was of less importance when the electrolyte contained some sulfuric acid than when it was nearly neutral. Therefore, the effect of dissolved oxygen in the present cells is of interest. Table I gives a comparison of four cells prepared with and four prepared without precautions against dissolved oxygen.

TABLE I

EFFECT OF DISSOLVED OXYGEN

PbO_2	H_2SO_4, M	E.m f.[b] 1 day, v.	Change of e.m.f. 6 days, v.	2 wks., v.	4 wks, v.
1A	0.1000[a]	0.82587	0.13	0.23	....
2	.1000[a]	.82593	.06	.05	....
1A	.1035	.82874[c]	− .37	− .70	−0.85
2	.1035	.82833[c]	− .30	− .78	− .98

[a] Oxygen was excluded in the preparation of these cells by means of an atmosphere of nitrogen.

[b] Each value is the average value for two cells.

[c] On the basis of these values the value for a **0.1000** M electrolyte would be **0.82687** v.

The electromotive forces of cells made with oxygen present decreased, while the electromotive forces of the cells made in the absence of air[15] increased slightly but were more nearly constant than the others. The average initial electromotive forces of the two groups differed by about 1 mv. when that of the second group was calculated to an acid concentration of 0.1000 M. Tables II and III indicate that the presence of oxygen has a smaller effect on the constancy when the acid concentration is larger. In Table II a group of cells made without protection from the air and with 1.036 M acid as the electrolyte is compared with a group made with protection from the air and with an electrolyte of 1.964 M acid. In this table also each electromotive force value is an average of the values of duplicate cells.

---

[13] Randall and Young, THIS JOURNAL, **50,993 (1928).**

[14] Ref. **12,** p. **1266.**

[15] Nitrogen was used rather than carbon dioxide in these cells.

TABLE II

EFFECT OF DISSOLVED OXYGEN. CONSTANCY

PbO$_2$	H$_2$SO$_4$ M	Electromotive force at 25°				
		2 wks., v.	5 wks., v.	7 wks., v.	12 wks., v.	16 wks., v.
1	1.036	.....	.....	0.95255	0.95253	0.95247
2	1.036	.....	.....	.95256	.95254	.95250
1	1.964[a]	1.00129	1.00132	1.00133	1.00126	
2	1.964[a]	1.00118	1.00123	1.00123	1.00120	

[a] Oxygen was excluded from the electrolyte of these cells.

The values of the electromotive forces were not measured at 25° previous to the measurements recorded in Table II. Measurements at higher temperatures indicated that the electromotive forces increased slowly during the first week or two. In the case of the last group of cells, at least, constancy was attained within two weeks and the electromotive forces remained constant for at least ten weeks. Table III will show that values for the cell with unit sulfuric acid activity calculated from the two groups agreed within 0.3 mv. It is to be concluded, therefore, that the effect of dissolved oxygen is largest in the cells with the most dilute electrolytes, and that it causes an uncertainty in the electromotive force of not more than 1 mv.

Electromotive Force.—The electromotive forces of all the cells set up were measured frequently over a period of several weeks. From the series of values so obtained the best value for the electromotive force was selected. In the case of the cells with the more dilute electrolytes from which oxygen was excluded, the initial values were taken as the best. In the case of cells with oxygen-free electrolytes in which the concentration was 1 M or larger, constancy was attained within a week or two after the cells were set up and the constant value was taken as the best one. For the other cells also the constant values were accepted as the best. Table III summarizes

[a] Oxygen was excluded from the electrolytes of these cells.

[b] The numbers 1, 2, 3 and 4 refer to the method by which the lead dioxide was prepared.

the best electromotive force values for each acid molality and for lead dioxide prepared by the four different methods. Each value in the table is an average value for at least two cells, and in a few cases for four cells.

The different lead dioxide preparations gave cells agreeing within about 1 mv. at most, and in the case of the 1.065 M acid to within 0.1 mv. Commercial lead dioxide even after digestion gave cells with electromotive forces about 4 mv. higher than the others but of good reproducibility and constancy.

Cells with electrodes made by electrolytic deposition of lead dioxide on the platinum wire electrodes from hot solutions of lead nitrate agreed fairly well with each other, though not with the other cells, but were never satisfactory as to constancy. They showed a continuous decrease in electromotive force which did not come to an end during the two months' period of observation. Consequently their electrsmotive forces are not included in the table.

In the next to the last column of Table III is given the average value for each acid molality. From these the values of E° given in the last column were calculated by means of the equation

$$E^\circ = E + \frac{RT}{F} \ln \frac{a_{H_2O}}{4\gamma^3 m^3}$$

where m is the molality of sulfuric acid, γ is its activity coefficient and a_{H_2O} is the activity of the water. Values for the activity coefficients of sulfuric acid were obtained by graphic interpolation from the values of Lewis and Randall.[16] The values for the activity of water were calculated by the method described by Randall and Young.[17] The values so obtained agreed with corresponding values calculated from the vapor pressure data of Grollman and Frazer.[18]

The cells with the smallest acid concentrations were the least reproducible and the most variable when made with oxygen-free electrolytes. The E° values for these cells are therefore to be given less weight than the others. The activity coefficients of sulfuric acid have been less well established for the larger concentrations than for concentrations in the vicinity of 1 or 2 M. . Therefore, the last value may be considered questionable. The others give $E^\circ_{25} = 1.060 \pm 0.001$ v. as the best value for Cell 1.

The electromotive force of the cell

$$H_2\ (Pt)\ |\ H_2SO_4\ (a = 1)\ |\ H_2SO_4\ (a = 1),\ PbO_2,\ PbSO_4\ |\ (Pt) \qquad (4)$$

which on the basis of the usual conventions can be called the potential of the lead dioxide–lead sulfate electrode, can be calculated from the electromotive force of Cell 1 and that of the hydrogen–mercurous sulfate cell.

[16] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book *Co.*, New York, 1923, p. 357.

[17] Ref. 13, p. 1002.

[18] Grollman and Frazer, THIS JOURNAL, 47, 712 (1925).

The electromotive force of the latter when the sulfuric acid electrolyte has unit activity is given by Gerke[19] as 0.6213 v. Therefore the electromotive force of Cell 4 at 25° is $E_{25}^{\circ} = 1.681 \pm 0.001$ v.

Temperature Coefficients

The electromotive forces of a number of representative cells were measured at five-degree intervals of temperature between 20 and 40°. The temperature was changed successively from 25 to 20, 30, 35, 40, 35, 30 and 25°. The cells were maintained at each temperature for a period of three or four days, except at 20° at which temperature they were kept for two days. Readings were taken at frequent intervals. The standards were kept at 25° in a separate bath. In general the cells showed no change greater than 0.01 mv. after the third day. The values given in Table IV are the averages for all cells with the same acid molality. The changes in the electromotive force of the individual cells with the same acid concentration showed an average variation from the mean of ±0.02 mv.

TABLE IV

CHANGE OF ELECTROMOTIVE FORCE WITH TEMPERATURE

H_2SO_4, M	No. of cells	E_{25}, v.	$E_t - E_{25}$, mv. 20°	30°	35"	40°	35°	30°	25°
0.1000	11	0.82617	$1.98	−1.92	−3.81	−5.69	−4.03	−2.02	−0.15
.5154	6	,91076"	....	....	....	−2.32	−1.57	−0.79	....
1.036	6	.95267	$0.30	−0.26	−0.47	−0.66	−0.47	−0.25	−0 00
1.964	4	1.00128"	....	....	....	....	+0.35	+0.18	....
3.499	4	1.06378[a]	....	....	....	....	+0.62	+0.34	....

[a] *These values at 25° are the values obtained after the series of temperature changes rather than before. In the first case (0.5154 M electrolyte) the cells appeared to be variable during the early part of the run, while in the other two cases the cells were set up only shortly before the second measurements at 35°.*

It is to be noted that the temperature coefficient varies with the molality of the electrolyte. It is negative in the cells with the most dilute electrolyte, passes through zero as the molality increases and becomes positive for cells with electrolytes having a molality larger than about 1.5 M.

The change of 0.15 mv. in the electromotive force of the cells with 0.1000 M electrolyte was permanent. Such a change might be expected in cells with dilute electrolytes. For cells with 1.036 M electrolyte the change in electromotive force with temperature as determined with rising temperature showed excellent agreement with corresponding values determined with decreasing temperature. These cells had apparently attained constancy at 25° before the temperature was changed. Furthermore, the electromotive forces returned to their original 25° values soon after the temperature was lowered and showed constancy for some time thereafter. Their temperature coefficients are probably the most reliable of all.

---

[19] *Ref.* 2, p. *385*

The Lead Storage Cell

The electromotive force of Cell **3**

$$Pb \mid PbSO_4, H_2SO_4\ (a = 1) \mid H_2SO_4\ (a = 1), PbO_2, PbSO_4 \mid (Pt)$$

can be calculated by combining the electromotive forces of Cell 1, Cell 2 (with a lead amalgam electrode) and the cell[20]

$$Pb \mid Pb^{++} \mid Pb(Hg);\ E = 0.0057 + 0.000165\,(t - 25) \qquad (5)$$

For the cell with an electrolyte of unit activity the calculated electromotive force is $E^{\circ}_{25} = 1.060 + 0.9648 + 0.0057 = 2.0335$ v.

Cell *3* represents the lead storage cell according to the double sulfate theory[21] of the action of the storage cell. It would not, however, represent the action of the storage cell on the basis of the higher oxide theory of Féry.[22]

To facilitate comparison of the electromotive force of Cell **3** with that of the lead storage cell, the acid molalities were converted to specific gravities. Then electromotive force was plotted against the specific gravity of the electrolyte and electromotive forces for certain specific gravities were read from the graph. These electromotive forces are compared in Table V with the most concordant of the values compiled by Vinal[4] for the lead storage cell, and also with the values of Kendrick.[3]

TABLE V

COMPARISON OF THE ELECTROMOTIVE FORCE OF CELL 3 WITH THAT OF THE LEAD STORAGE CELL

Sp. gr. 25°/25°	1.040	1.050	1.100	1.150
Gladstone and Hibbert, v.	1.898	1 913	1 963	2.003
Kendrick, v.	1.890	1.905	1.957	2.000
Dolezalek, v.	...	1.906	1.965	2.010
Vinal and Altrup, v.	1.890	1.903	1.956	2.000
Cell **3**, v.	1.894	1.909	1.962	2.006

Cell **3** agrees with the storage cells measured by Gladstone and Hibbert,[23] Kendrick,[3] Dolezalek[24] and Vinal and Altrup[4] as well as could be expected. This agreement makes it probable that the lead storage cell is not essentially different from Cell **3** and supports the double sulfate theory of its action.

Activity of Sulfuric Acid

It was suggested above that the apparent decrease in E° for Cell 1 (Table III) for the most concentrated acid solutions might be explained by an error in the value of the activity. It is of interest to calculate the values

---

[20] Ref. 2, p. 382.

[21] Originally proposed by Gladstone and Tribe, *Electrician*, 9, 612 (1882); see also ref. 4, p. 146.

[24] Dolezalek, "Theory of the Lead Accumulator," 1904, p. 55.

of the activity coefficients from the results for Cell 1 and compare them with the values of Lewis and Randall. This comparison is made in Table VI. Each value for the electromotive force represents the mean value for duplicate cells. The cells in question were all made from the same preparation of lead dioxide with the exception of those with the 1.065 M electrolyte. In this case the lead dioxide was prepared by the same method but at a later time. In the third column of the table the electromotive forces corrected to unit water activity are given. From these the values for the activity coefficient in the fourth column were calculated, the value $\gamma = 0.149$ for 1.036 M acid being obtained by graphic interpolation from the data of Lewis and Randall.[16]

There is a fairly large difference between the two sets of activity coefficients in the most dilute solutions and also in the most concentrated. In the former case the activity coefficients based on Cell 1 are of doubtful reliability on account of the lower degree of reproducibility of the cells with the most dilute electrolytes. The activity coefficient for the 3.5 M acid solution, however, should be reliable.

TABLE VI

ACTIVITY COEFFICIENTS OF SULFURIC ACID

H_2SO_4, M	E.m.f., Cell 3, v.	E.m.f., $a_{H_2O} = 1$, v.	γ, Cell 3	γ, L. and R

Thermochemical Data

From the value E = 0.9526 v. and the temperature coefficients given in Table IV for the cell with the 1.036 M electrolyte, the values for the free energy change, entropy change and heat of reaction for the reaction

$$PbO_2 + 2Hg + 2H_2SO_4\ (1.036\ M) \longrightarrow Hg_2SO_4 + PbSO_4 + 2H_2O$$

are found to be $\Delta F_{25} = -43{,}960$ Cal., $\Delta S_{25} = -2.58$ Cal. and $\Delta H_{25} = -44{,}730$ Cal.

The heat of reaction can be calculated from the following thermochemical data, which have been taken from "International Critical Tables," except as noted: heat of formation of lead dioxide, $\Delta H_{18} = -62{,}600$ Cal.; heat of formation of lead dioxide (Millar[25]), $\Delta H_{25} = -65{,}960$ Cal.; partial heat

---

[25] Millar, THIS JOURNAL, 51, 212 (1929).

of formation of sulfuric acid in 1.036 M sulfuric acid solution,"[26] $\Delta H_{25} = -206{,}700$ Cal.; heat of formation of mercurous sulfate, $\Delta H_{18} = -171{,}580$ Cal.; heat of formation of lead sulfate, $\Delta H_{18} = -214{,}600$ Cal.; partial heat of formation of water in 1.036 M sulfuric acid solution, $\Delta H_{25} = -65{,}340$ Cal. Combining these to give the heat of reaction, using the value from "International Critical Tables" for the heat of formation of lead dioxide, gives $\Delta H = -46{,}860$ Cal. Using Millar's value for the heat of formation of lead dioxide, the heat of reaction is $\Delta H = -43{,}500$ Cal.

Summary

1. The conditions necessary for the preparation of reproducible lead dioxide–lead sulfate electrodes have been determined.

2. Cells of the type Hg | Hg_2SO_4, $PbSO_4$, H_2SO_4 (xM) | H_2SO_4 (xM), PbO_2, $PbSO_4$ | (Pt) have been set up and their electromotive forces have been measured over a period of seven to sixteen weeks at 25° and also at 20, 30, 35 and 40°.

3. From the results the following have been calculated: the value of E^{0}_{25}, the electrode potential of the lead dioxide–lead sulfate electrode, the activity coefficients of sulfuric acid at various molalities, the electromotive force of the lead storage cell and the free energy change, the entropy change and the heat of reaction for the reaction $PbO_2 + 2Hg + 2H_2SO_4 \longrightarrow PbSO_4 + Hg_2SO_4 + 2H_2O$. The last compares favorably with the value calculated from thermochemical data.

THE HEAT OF ADSORPTION OF OXYGEN ON CHARCOAL

BY MELVILLE J. MARSHALL AND HAROLD E. BRAMSTON-COOK

RECEIVED FEBRUARY 28, 1929 PUBLISHED JULY 5, 1929

Keyes and Marshall[1] found 73,000 calories per mole for the differential heat of adsorption of oxygen on activated charcoal for initial amounts of gas adsorbed. This heat dropped slowly as the concentration increased to about 0.15×10^{-4} moles per gram of charcoal. As the concentration increased beyond this value the heat of adsorption fell off rapidly to *a* practically constant value of about 4300 calories per mole.

The course of the curve of differential heat of adsorption against concentration of adsorbed gas at very small concentrations is of considerable theoretical interest, particularly from the point of view of the hypothesis that adjacent carbon atoms may vary greatly in adsorptive character.

[26] Interpolated with the help of data of Bronsted, *Z. physik. Chem.*, 68, 702 (1910), for the differential heat solution of sulfuric acid.

[1] Keyes and Marshall, THIS JOURNAL, 49, 156 (1927).

The earlier work,[1] while emphasizing the importance of obtaining adsorptive data at small concentrations, suffered from a limitation with respect to the amount of charcoal used in the measurements. In the present work ten times the amount of charcoal was employed, making it possible to follow the relation between the heat of adsorption and concentration to very much smaller concentrations than have previously been reported.

Apparatus.—The arrangement of the apparatus is shown in Fig. 1, and is similar in many respects to that of the earlier work.[1] The chief difference lies in the arrangement of the ice calorimeter, which was supported in a silvered Dewar flask, C, after the arrangement described by Griffiths.[2] The interior of the Dewar flask was rendered water-tight by a large rubber stopper through which the neck of the calorimeter passed.

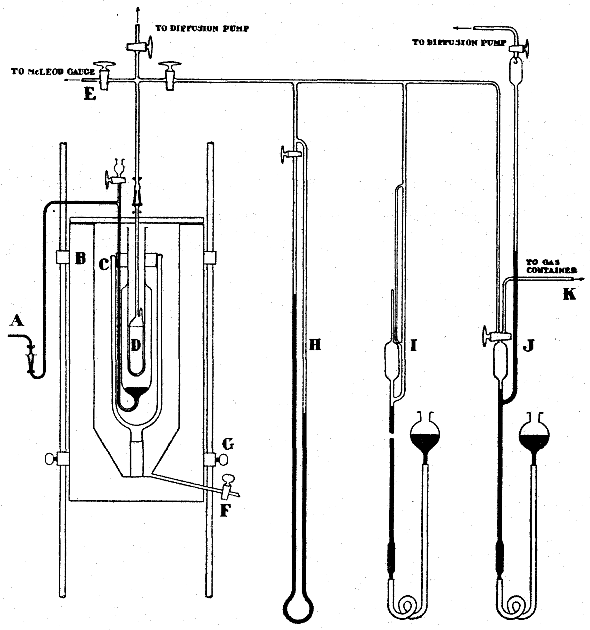

Fig. 1.

The Dewar flask was in turn supported inside the vessel B, which was provided with double walls, the space B being packed to the top with wool waste. The space C was filled with cracked ice and sufficient distilled water to fill the voids between the pieces of ice. This water did not quite reach the mouth of the calorimeter, which was closed with a thick piece of wool waste. The vessel B was covered with a piece of felt about 0.5 inch thick, which prevented a too rapid melting of the ice in C. As the ice melted, more was added every few hours, and the equivalent amount of water drained from F. The entire calorimeter could slide vertically and make contact with the fixed capillary tube at A in a manner similar to that described in the previous work.

The ice mantle was produced by the use of a mixture of solid carbon dioxide and ether contained in an open tube of slightly larger diameter than D. We found this

---

[2] Griffiths, *Proc. Phys. Soc. London,* **36,** *1 (1913).*

method preferable, as the rate of freezing of the ice mantle could be easily controlled by dropping in small amounts of carbon dioxide at a time. The above arrangement of the ice calorimeter has the advantage that it can be operated for long periods of time. In the present investigation the ice mantle was found intact after being in continuous use for a week.

The oxygen was admitted to the apparatus from the gas pipet J, the bulb of which had a capacity of about 5 cc. The McLeod gage I had a low multiplying power of ten, and was used for intermediate pressures, while higher pressures were measured by the manometer H. A McLeod gage of ordinary size was connected at E for low pressure measurements when outgassing the charcoal.

The charcoal[3] used was a sample of activated coconut charcoal produced by the National Carbon Company It was washed in a Soxhlet extractor with hydrochloric acid and afterwards treated with hydrofluoric acid, the final ash content being 0.267%. Before use it was outgassed for about sixty hours at 1000°, using a platinum-wound resistance furnace. The outgassing was continued in every case down to a pressure of about 1×10^{-4} mm. After outgassing the charcoal weighed 25.792 g. During the preliminary outgassing the gas continued to come off for such long periods of time that interaction between the silica tube and the charcoal was considered possible. In the final measurements a lining of platinum foil was employed to prevent contact of the charcoal with the silica.

Experimental Procedure.—After outgassing the charcoal the calorimeter was raised into position until the quartz tube just touched the bottom of the inner tube. For the initial reading about 0.8 cc. of gas was admitted from the gas pipet. The position of the mercury thread was noted every ten minutes until the normal heat leak was resumed. Another increment of gas was added and the procedure repeated until about 250 to 300 cc. in all were added.

The data in the tables to follow give the oxygen added in moles per gram of charcoal, designated c. The quantity q is the total heat attending adsorption for the correspondingly tabulated values of c. To obtain these values of q allowance was made for the heat capacity of the gas admitted to the calorimeter, since the temperature of the former was in every case different from zero. Values of q were plotted against values of c and the slope $(\partial q)/(\partial c)$ was measured for various values of c. The quantity $(\partial q)/(\partial c)$ is the differential heat of adsorption per mole of oxygen at constant temperature, and is represented by Q. Data from two series of measurements are given in Table I. The corresponding values of Q, obtained by plotting the above p, c data suitably, are given in Table II.

The equilibrium pressures in Table I were originally measured for the purpose of correcting for unadsorbed gas in the calorimeter and connecting parts. As the low initial pressures gave negligible corrections they were not recorded. These initial pressures are, in fact, so low that they can be measured only by means of a specially sensitive McLeod gage. Such measurements are now being made in this Laboratory.

A marked discontinuity appeared in both Q–c curves at the point $c = 0.75 \times 10^{-4}$. Whether this is part of the phenomena or due to the method

---

[3] The charcoal used previously was prepared from a sample of French gas mask charcoal. This latter charcoal was made from wood.

of experimentation is not known at this time so the curves were drawn to follow the data obtained. The resulting values of Q are plotted in Fig. 2 and the curve so obtained is smoothed at this point as shown.

Interpretation of Results

Like the curve of Keyes and Marshall, the present curve shows a tendency to flatten in the vicinity of 70,000 calories. Instead of ending abruptly at 72,000 calories, however, the data indicate a rapidly increasing differential heat not differing much from 89,600 calories for zero concentration. The final heats of adsorption at large values of c are practically the same as those of Keyes and Marshall. The numerical accord between the earlier work and the present indicates that the general adsorptive characteristics of wood and coconut charcoal are not different, at least as far as the adsorptive heats of oxygen are concerned.

With few exceptions the Q–c curves obtained by other investigators have shown a maximum value of Q at zero concentration. This can be explained in terms of the hypothesis suggested by Langmuir[4] for adsorption and Taylor[5] for contact catalysis, that the surface atoms are of unequal activity. The gas would be expected to adsorb on the more active atoms first, and assuming that the heat of adsorption is an approximate measure of the activity of the surface atoms, a maximum differential heat of adsorption would be obtained at the lower concentrations. In the case of the adsorption of hydrogen on metal catalysts, which forms an exception to the above rule,[6] it must be assumed that here the heat of adsorption is not a measure of the activity of the surface atoms.

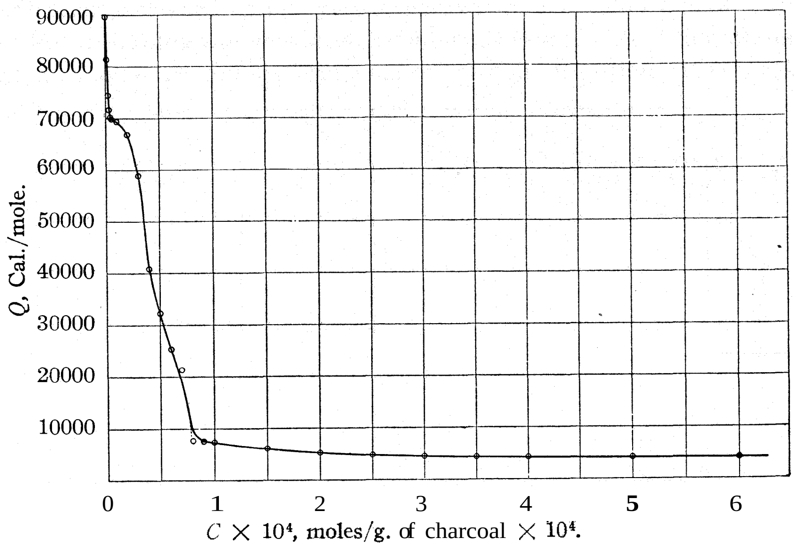

Fig. 2.

If some value c_0 is considered to represent the concentration at which the surface is covered, we can plot $c_0 - c$ against the corresponding values of Q and obtain an integral distribution curve giving values of Δc equal to those from Fig. 2, but with a positive sign. From the slopes of this last curve at various values of Q we obtain $\mathrm{d}(c_0 - c)/\mathrm{d}Q = -\mathrm{d}c/\mathrm{d}Q$. These values of $-\mathrm{d}c/\mathrm{d}Q$ were accordingly obtained from Fig. 2 by measuring graphically at various values of Q the slopes of the curve, and their sign was then changed. These results are given in Table III and plotted in Fig. 3.

This last curve (Fig. 3) is a distribution curve of the type used to describe the distribution of gas velocities. In such curves the area under the

curve between any two energy values represents the fraction of the total number of molecules present having energy values between these limits. In the present case, because the number of molecules required to cover the surface is still a matter for debate, we have preferred to choose our variables

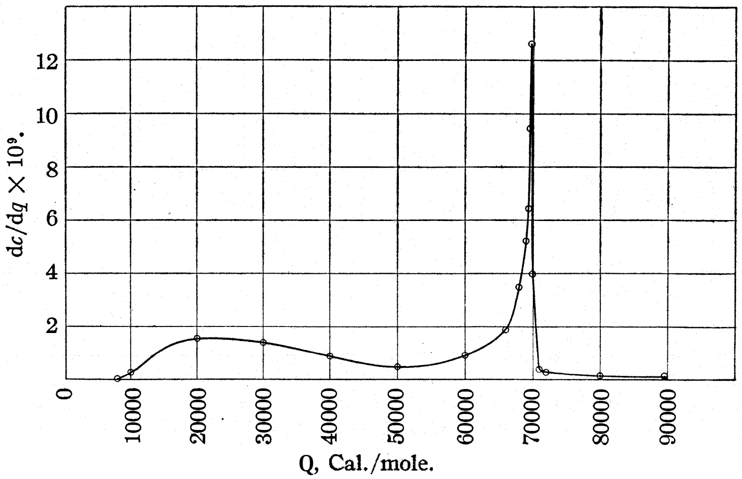

Fig. 3.

to make the area between any two values of Q equal to the number of moles of oxygen per gram of charcoal with heats of adsorption between these limit. That is, $\int_{Q_1}^{Q_2} dc/dQ.\ dQ = \int_{c_1}^{c_2} dc$. As pointed out previously, this change of c between Q_1 and Q_2 can be obtained from Fig. 2. These integral values of c can be regarded as equivalent to Langmuir's elementary spaces per gram of charcoal. It is difficult to discuss the relative activities of individual carbon atoms, as all the surface atoms probably cannot hold the same amount of oxygen. Furthermore, one carbon atom can represent two different heats of adsorption, a high heat for the first addition of oxygen, and a lower heat for a later second addition.

It is evident that the curve, as a whole, does not resemble a probability curve in form. Probability distribution in the present curve would be most likely to exist above 70,000 calories, although the probability function

$y = 2h/\sqrt{\pi} \times e^{-(hx)^2}$ could not be made to fit the curve over this range. The present curve shows a much more uniform distribution in this region than the error curve. It is evident that a slight relative error in the values of q in the extremely low concentration range would alter the shape of the distribution curve (Fig. 3) considerably, so that a large amount of exact experimental data is necessary before a decision can be reached regarding the application of such distribution functions. A knowledge of the distribution of surface activities is very desirable, as it would enable a study of cataiyzed reactions to be made under controlled conditions of surface activity and distribution.

That a similar distribution of the more active centers occurs on some other adsorbents as well is shown by the Q-c curve of Beebe[7] for carbon monoxide on a copper catalyst, and a similar curve for carbon dioxide on charcoal by Magnus and Kälberer,[8] which resemble the present curve in the particular that the curve becomes almost parallel with the Q axis as c approaches zero. Even for the heat of adsorption of hydrogen on nickel, where the initial heat is abnormally low, Fryling[6b] assumes that extrapolation of the final portion of the curve back to small values of c would cause it to approach the Q axis in the same manner.

The flattening of the Q–c curve, similar to that at 70,000 calories for the previous work[1] and the present investigation, is not so common. Polanyi and Welke[9] obtain Q-c curves for sulfur dioxide on charcoal which increase rapidly with decreasing c and show a tendency to flatten at the same molecular concentration ($c = 0.1 \times 10^{-4}$) as the present curve. The resulting maximum in the distribution curve (Fig. 3) at about 70,000 calories possibly represents some definitely recurring state or position of the surface carbon atoms.

Thickness of the Adsorbed Layer.—Keyes and Marshall have found linear relations between the final heats of adsorption at high concentrations and certain constants of the normal molecule which led them to the conclusion that the final heats of adsorption resulted from adsorption on previously adsorbed layers. If, then, we assume for the time being that the entire extent of the Q–c curve represents the formation of multiple layers, the point at which a single primary layer is completed would in general be represented by a zero or a minimum value of $-\mathrm{d}c/\mathrm{d}Q$, provided that extensive overlapping of layers does not occur. There are two points on the Q-c curve which approach this condition, first, the steep part of the curve at $c_a = 0.35 \times 10^{-4}$, and second, the inflection resulting from smoothing of the discontinuity at $c_b = 0.78 \times 10^{-4}$. If the data were followed strictly $-\mathrm{d}c/\mathrm{d}Q$ at c_b would be zero, as can be seen from the

position of the points in Fig. 2. For the construction of the distribution curve (Fig. 3) this zero slope at c_b has been used, although in the actual Q-c curve (Fig. 2) we have given $-\mathrm{d}c/\mathrm{d}Q$ a small positive value at this point, as zero slope would not be expected experimentally either at c_a or c_b due to some overlapping of layers.

Three possible explanations occur to us for the peculiar form of the distribution curve (Fig. 3). (1) The range to $c_b = 0.78 \times 10^{-4}$ represents the formation of a monomolecular or monatomic layer. Fig. 3 gives the variation in activity of the elementary spaces on the surface. (2) As c_b is about twice c_a, the point c_a could represent the completion of a primary layer and c_b a second layer. **(3)** Adsorption of oxygen on one elementary space would tend to decrease the activity of an adjacent space. Thus it can be shown that the heat evolved when an atom of oxygen combines with an atom of gaseous carbon to form carbon monoxide is several times as great. as that evolved when an atom of oxygen combines with a molecule of carbon monoxide to form carbon dioxide. This decrease in the activity of adjacent spaces might create a preponderance of elementary spaces having the lower heats of adsorption, and possibly cause a deficiency among the spaces with intermediate heats. Such a state of affairs would produce the minimum found on the curve (Fig. 3) at intermediate Q values, thus showing the characteristics of a second layer.

The only other investigation which shows an inflection at c_b is that of Fryling[6b] for hydrogen on nickel, while a minimum value of $-\mathrm{d}c/\mathrm{d}Q$ corresponding to that at c_a is more common. Consequently c_a most probably represents the limit of the primary layer. This rarity of occurrence does not necessarily mean that the c_b inflection is due to experimental errors. It is evident that an overlapping of layers would obscure both inflections, but that at c_b more readily than that at c_a. This would be particularly true for vapors or easily condensible gases whose initial heats of adsorption are low. The above considerations favor (2) or **(3)** but cannot distinguish between them. The authors consider that more data are necessary before forming a definite hypothesis, and the above statement of possibilities is presented with the hope that it will assist in the production of such data.

It is difficult to utilize the Q-c data below c_b for the construction of a distribution curve of the type represented by Fig. 3, because of the comparatively small variation of Q with c. Considerations of kinetic equilibrium would require the formation of an equipotential surface as the layers increase in thickness, the concentration of adsorbed gas being greatest around the most active centers. Over this region the surface would be of uniform activity, which is in accordance with the small variation in Q actually obtained.

Applicability of the Theory of Monomolecular Layers.—From the point of view of the monomolecular layer theory we must assume that oxygen is adsorbing on elementary spaces of the free carbon surface, even at $c = 5.0 \times 10^{-4}$. Examination of the Q–c curve shows that at least 85% of the total elementary spaces have heats of adsorption below 8000 calories. Investigations covering other adsorbents and adsorbates show similar almost constant final heats. The curve of Keyes and Marshall shows practically the same proportion of elementary spaces below 8000 calories as that quoted for the present results. Outgassing of the charcoal between runs should alter considerably this abnormal distribution of elementary spaces by removing some of the carbon atoms as oxides of carbon. The steep part of the Q–c curve would be affected to a much smaller degree, as the distribution over this range is more in accord with probability. In accordance with this possibility, we have noted during our experiments slight variations about a mean of the shape of the curve in this region. On the other hand, the position of the sharp change in slope at c_b varied so little that the proportion of low activity spaces could be considered to remain practically constant. The sum total of evidence at hand seems to show that the position of this change of slope depends mainly on the specific surface of the charcoal, which in turn is a function of the material from which the charcoal is made.

We might, of course, assume that only the more active carbon atoms can activate the oxygen molecule, causing a kind of surface chemical combination, and that the low final heats are due to combination of oxygen molecules with less active carbon atoms by secondary valence only. This would explain the constancy of the low final values, but the hypothesis is still open to the previous objection that it should be possible to shift considerably the position of the change of slope at c_b by heat treatment. Consequently, comparing the assumptions involved in the two opposing views, we believe that the phenomena herein described receive a more plausible explanation from that form of the multimolecular layer theory suggested by Keyes and Marshall.

Calculation of the Specific Surface.—Calculation of the specific surface of the adsorbent from the amount of gas adsorbed is always uncertain, as some assumption must be made regarding the manner in which the molecule is adsorbed. Assumption of a monatomic layer would give the largest surface, while assumption of orientation normal to the surface would give the smallest. As a mean between the two extremes we will consider the total number of molecules which can be packed in a single-layer on 1 sq. cm. of surface to be 0.77×10^{15}, as computed by Langmuir from the molecular volume of liquid oxygen. Assuming completion of the first layer at $c = 0.35 \times 10^{-4}$, we have $(0.35 \times 10^{-4} \times 6.06 \times 10^{23})/(0.77 \times 10^{15}) = 2.8 \times 10^4$ sq. cm. per gram of charcoal. If, on the other hang, we assume the surface layer to be complete at $c = 0.78 \times 10^{-4}$, the specific surface would be 6.1×10^4 sq. cm. per gram.

Other Investigations.—Ward and Rideal[10] have obtained curves for the heat of adsorption of oxygen on four varieties of charcoal. They did not measure initial values of Q, although the curves shown resemble corresponding parts of the present curves. They object to the multimolecular layer theory of Keyes and Marshall because of the dye adsorption work of Paneth,[11] and because the pressure increases indefinitely with the concentration and does not tend to a limiting value at constant temperature. We feel that much work must still be done before the conclusions of Paneth regarding the specific surface of charcoal can be accepted without question. The mode of variation of p with c can hardly be quoted in support of the monomolecular layer theory, as it can be made to fit either theory by making appropriate assumptions regarding the mechanism of the adsorption. The question of layer thickness is reviewed by Rideal.[12]

Garner and McKie[13] report a heat of adsorption for oxygen on charcoal of 5000 calories per mole at 18° between $c = 0.001 \times 10^{-4}$ and $c = 0.006 \times 10^{-4}$, jumping to 60,000 calories at $c = 0.04 \times 10^{-4}$, and then increasing slowly to 71,000 calories at $c = 0.15 \times 10^{-4}$. The present results show no evidence of this low initial value. We could not, of course, investigate the region between $c = 0.001 \times 10^{-4}$ and 0.006×10^{-4}, but from $c = 0.01 \times 10^{-4}$ to $c = 0.04 \times 10^{-4}$ our values are abnormally high rather than abnormally low, as required by the curve of these authors. Further, between $c = 0.0136 \times 10^{-4}$, our lowest measured concentration, and $c = 0$ the slope of the q–c curve shows a marked tendency to increase as it approaches the origin, which is a real point on the curve. Finally, we note that these authors report only one really low value, no heat values between 5000 calories and 60,000 calories having been measured. Since completion of this paper, McKie[14] has described their experimental method in detail. It would be desirable to repeat the above measurements with thermocouples placed at different points throughout the mass of the charcoal and so arranged that the average temperature of the charcoal could be obtained by integration of the results.

Summary

1. The differential heat of adsorption of oxygen on activated coconut charcoal has been measured as a function of the gas concentration on the charcoal, special attention being paid to these values at low concentrations. The maximum heat of adsorption at zero concentration was found to be 89,600 calories per mole of oxygen.

[13] Garner and McKie, *J. Chem. Soc.*, 130, 2451 (1927).

[14] McKie, *ibid.*, 130, 2870 (1928).

2. Similarity of the resulting curve, of heat of adsorption against gas concentration on the surface, to that obtained in previous investigations emphasizes the specific nature of the adsorption and the constancy of the charcoal surface.

3. A distribution curve is obtained showing the apparent distribution of activities of the elementary spaces on the carbon surface. Several possible explanations are advanced for the shape of this curve.

4. From a comparison of the shapes of the initial portions of various Q–c curves certain regularities are noted and it is concluded that there is a possibility of obtaining a mathematical expression for the distribution of the more active elementary spaces on the surface.

5. The conclusion is reached that the results support best that form of the multimolecular layer theory previously suggested by Keyes and Marshall.

6. The specific surface of the charcoal is estimated to lie between 2.8×10^4 and 6.1×10^4 sq. cm. per gram.

GERMANATE GELS OF THE ALKALINE EARTHS

BY JOHN HUGHES MÜLLER AND CHARLES E. GULEZIAN

RECEIVED MARCH 5, 1929 PUBLISHED JULY 5, 1929

The soluble salts of the alkaline earths cause no precipitation in neutral or acid solution of germanium dioxide but when such solutions are made alkaline with ammonium hydroxide most of the germanium is thrown down as a bulky gelatinous mass. Under such circumstances, however, it is not easy to form homogeneous or firmly set gels owing to the flocculating influence of the ammonium salt simultaneously produced. If calcium hydroxide solution be substituted for the salt of the same base the reaction with aqueous germanic acid takes on a surprisingly different character, for the precipitate then assumes the form of a firm, transparent gel even in highly dilute solutions. The direct formation of calcium, strontium and barium germanates by neutralization of aqueous germanic acid results in the formation of insoluble or difficultly soluble salts under conditions most favorable to colloid formation, as water is the only by-product in the reaction. At the same time this reaction is peculiarly characteristic for germanium, for all of the other semi-metallic dioxides in the fourth periodic group are quite insoluble in water.

It is the purpose of this paper to describe the alkaline earth germanates when prepared in the form of highly dispersed systems with particular attention to the calcium salt, which appears to give permanent gels of extraordinary water content.

Preparation of Reagents

Germanic Oxide.—The pure dioxide was obtained by hydrolysis of the redistilled tetrachloride and subsequent ignition of the product in superheated steam. The nearly pure oxide so obtained was frequently moistened, dried and ignited to 900–950° to effect the complete removal of traces of chlorine and finally fused to a glassy mass at 1100–1150° in a platinum crucible. (This can be carried out in an electric resistance furnace with careful exclusion of any reducing gases, but any direct flame touching the crucible results in quick reduction and destruction of the platinum crucible.) The glassy mass of oxide was dissolved in boiling water, using approximately one liter of water for each 5 g. of oxide. After determination of the GeO_2 content of aliquot portions of this solution the bulk was diluted to definite molarity.

Calcium Hydroxide.—Selected crystals of Iceland Spar were ignited in platinum and the residual lime was dissolved in freshly distilled water. The saturated solution of lime water was siphoned off into paraffin-lined flasks and sufficient carbon dioxide-free water was added to dilute beyond the saturation point at room temperature. The exact content of calcium oxide was determined in aliquot portions gravimetrically as calcium sulfate.

Strontium Hydroxide.—Baker's Analyzed $Sr(OH)_2 \cdot 8H_2O$ was dissolved in redistilled water and preserved in paraffin-lined flasks.

Barium Hydroxide.—Baker's Analyzed $Ba(OH)_2 \cdot 8H_2O$ was dissolved in redistilled water. The nearly saturated solution was siphoned off into paraffin-lined flasks and subsequently diluted to solutions of definite concentration.

Water.—The distilled water of the laboratory was redistilled in fresh portions as required, rejecting first and last fractions, collecting middle fractions in paraffin-lined flasks.

Alcohol.—Alcohol was distilled first from lime and then from shavings of metallic calcium.

Ether and benzene were redistilled and dehydrated over metallic sodium.

Flasks, pipets and burets were calibrated at 22–25°.

Calcium Germanate Gels

Preliminary experiments were made with 0.0279 N calcium hydroxide and solutions of germanic acid of gradually decreasing concentration, as indicated in Table I. It was immediately observed that calcium germanate formed translucent or transparent gels throughout wide ranges of dilution of acid and base but also that homogeneous gels could only be obtained when the reacting base and acid were rapidly and thoroughly mixed. The following procedure gave most satisfactory results: base and acid were separately drawn off from burets into paraffin-lined beakers and simultaneously poured into a third beaker in which gelation took place. If kept free from dust particles the fresh surface of paraffin allows complete transference of the measured volumes in the few seconds between initial mixing and subsequent gelation.

In the first series of experiments calcium hydroxide and germanic acid were mixed in the calculated ratio for the formation of the salt of hypothetical ortho-germanic acid, ($2CaO:GeO_2$), carrying out the gel formation at 25°. At this temperature, if the mixture is quickly made, the combining acid and base stiffens to an opalescent gel in three to five seconds and during the next minute or two the somewhat uneven cloudiness in the gel mass disappears, leaving an almost clear and colorless permanent gel.

A firm gel was obtained by mixing 108.4 cc. of calcium hydroxide solution containing 0.1122 g. of CaO with the same volume of aqueous germanic acid containing 0.1045 g. of GeO_2. These quantities correspond to $2CaO:GeO_2$ (molar weights expressed in mg.). The volume of the gel was then 216.8 cc. and must have contained 0.2167 g. of total anhydrous solids ($CaO + GeO_2$). The gel appeared perfectly dry and was firm enough to allow inversion of the containing beaker (250 cc.) without loss. The extraordinary dispersion of the calcium salt is evident, for the gel contained 99.90% of water bound or trapped by as little as 0.10% of anhydrous constituents. Otherwise expressed, 0.0184 M CaO reacts with 0.00922 M GeO_2 with the formation of a solid gel, although the gel contains no more than 1/1000 of its weight of anhydrous oxides

Properties of Calcium Germanate Gel.—Samples of the solid gel prepared as above were preserved in a large desiccator over dilute sodium hydroxide to prevent drying and contamination by carbon dioxide and after standing for nearly a year showed no sign of syneresis. Exposed to air some drying takes place with slow formation of an opaque white surface as carbon dioxide is taken up. Other samples were broken down by stirring rapidly with a spatula or glass rod and when the mechanically broken gel was thrown on a Büchner funnel it was found that almost all of the trapped liquid could be removed by suction alone, leaving a small residue of the calcium salt on the filter. This residue closely resembles macerated filter paper pulp and after drying at room temperature or at 100° can be almost completely removed from the filter in a single piece. It is almost infusible, but on strong ignition shrinks considerably with the loss of 14–20% of water held by the air-dried salt. The hydrogel is dissolved by 0.2 M calcium chloride and by ammonium chloride but is nearly insoluble in the fixed alkali chlorides. Before and after ignition calcium germanate is insoluble in water but is readily soluble in dilute mineral acids. 0.2 N hydrochloric acid slowly dissolves the ignited salt and as germanic acid has no effect on methyl orange the CaO content of the salt can be determined by titrating back the excess of acid with standard sodium carbonate. This method gives a rapid check on the composition of the salt.

Microscopically examined the gel itself appears to be amorphous but under highest power (1700–1800 diameters) some indication of crystalline structure appears indistinctly, especially in the ignited salt.

Effect of Temperature.—As calcium germanate gel is so easily broken down by mechanical means, such as violent agitation or suction filtration, it was thought that elevation of temperature would bring about a rapid syneresis, but unexpectedly the gel when once produced resisted temperature changes up to near the boiling point of water. A number of tubes containing the gel were tightly stoppered and immersed in thermostatic baths. The gels all remained unchanged up to 75°. At 100° numerous entrapped bubbles in the gel greatly increased in size, causing separation of a small amount of liquid. Gels which had been heated to 90–95° showed practically no change.

An attempt was made to reproduce the gel by combining hot solutions of both acid and base but under such conditions no gelation occurred. At 60–70° calcium hydroxide and germanic acid gave only well flocculated white precipitates of small volume which settled rapidly and could not be subsequently deflocculated. The solutions of acid and base were then chilled to 0° before mixing and on combining these it was found that gelation did not take place in the cold. The mixtures remained liquid and perfectly clear for some time but on allowing the temperature to rise slowly to 25° almost water-clear solid gels resulted. From these experiments it would appear that the velocity of gelation is greatly cut down by small reduction in temperature and that any appreciable rise above room temperature results in too rapid a precipitation of the salt for any colloidal structure to build up. The latter condition is connected with imperfect mixing of the acid and base, for it was impossible to obtain any homogeneous gel unless an appreciable interval of time was allowed for a fairly good mixture of the two reacting liquids. With the warm acid and base precipitation was instantaneous. The best temperature for gel formation lies between **15** and **25".**

Several gels prepared at 25° were chilled to −17°. The expanding ice crystals increased the volume of the gel, which assumed a rounded or dome-shaped surface. After complete freezing the hard mass was allowed to melt slowly. All signs of gelation had disappeared, leaving a comparatively small precipitate from which the separated liquid could be poured off.

Substitution of the Water of the Hydrogel by Other Liquids

Ethyl Alcohol.—Hydrogels containing **99.90%** of water were prepared under conditions favoring firmest set. Conditions are shown in Table III, Expts. 1 and **2,** but employing larger volumes. Gel masses of **250** cc. each were used. The hydrogel was immersed in a large excess of **95%** alcohol. The gel became much firmer to the touch when so treated and could then be more easily cut up into smaller blocks or cubes. Cubes of about **8** cc. each were selected and again washed with fresh alcohol until most of the water had been removed. Complete extraction was carried out in the Soxhlet apparatus using absolute alcohol. The return alcohol was discarded a number of times, using fresh, dry alcohol and continuing the extraction until the return liquid gave approximately the same density over twenty-four-hour periods. A portion of the gel was selected and the trapped alcohol removed on a dry suction filter. The filtrate protected from moisture gave a density of **0.7949.** The original alcohol was d_{16}^{16}, **0.7943,** which value corresponds to **99.8** to **99.9%** alcohol by volume.

As alcohol substituted the water of the hydrogel there was a corresponding fall in specific gravity of the immersed gel and near the end of the extraction the cubes of gel became light enough to remain suspended in the surrounding liquid for a few moments and at the same time the gel mass, which was easily visible beneath the alcohol as long as water was present, became scarcely visible when nearly all of the water was removed. The changes in both specific gravity and refractive index conveniently show the end-point in the extraction process, making a larger number of density determinations unnecessary.

Methyl Alcohol.—The hydrogel was extracted with pure dry methyl alcohol in the same manner as that described above. In this case the gel volume decreased somewhat more than **50%.** The methyl alcohol gel although smaller in volume was softer and less easy to handle than the ethyl alcohol gel. It could, however, be cut into thin slices with a sharp knife without loss of any liquid and was permanent when kept in a well-stoppered flask.

Ethyl Ether.—Half of the alcohol gel prepared as above was extracted for a number of days with dry ether (distilled over sodium), frequently changing the extracting liquid for fresh ether. As in the case of the ethyl alcohol gel formation there was little change in volume of the gel mass and at the end of several days the cubes of ether gel became specifically light enough to remain suspended for some time in the surrounding ether. Extraction with fresh dry ether was continued until the density of the return ether reached the value for the pure extracting liquid (determined by hydrometer). Some of the cubes of gel were removed from the ether and were found to be much firmer to the touch than either the alcohol or water gel from which they had been prepared. Exposed to dry air the ether gel rapidly diminished in volume to a very small irregular fragment which crumbled to a dry powder between the fingers.

Action of Benzene on the Ether Gel.—A part of the ether gel was treated with pure benzene (redistilled over sodium). It immediately contracted to about 40–50% of the original volume, at first becoming milky white and opaque. The opacity was probably due to the formation of some emulsion of benzene and ether, as these two liquids are not miscible in all proportions After long standing the contracting gel again became transparent, especially on the outer portions of the immersed cubes, but complete extraction of the ether was not possible in several weeks' contact with fresh excess of benzene.

All of the above gels have been preserved in tightly-stoppered vessels and appear to be quite permanent, both in the dry state and when immersed in excess of the same liquids trapped by the gel structure. They are all capable of yielding most of their trapped liquid by strong pressure or suction filtering, especially after the gel has been mechanically broken down by violent stirring. Suction filtering yields a residue of the dry or nearly dry salt which appears absurdly small when compared to the original volume of gel. A whole liter of the hydrogel, for example, can be transferred completely to a 9-cm. filter if a platinum cone and suction be applied. The residue on drying at room temperature or at 100° can then be taken out of the filter in a single piece, leaving almost nothing adhering to the filter paper.

While any conjecture as to the actual nature of the highly dispersed calcium germanate in the above gels would be purely speculative, it seems clear that such gels are entirely structural in character, that is to say, practically all of the liquid present appears to be simply trapped by an enormous number of minute filaments of the dispersed calcium salt. At present it is impossible to say whether these are crystalline or amorphous, for the high power microscope at 1700 diameters fails to show more than a faint suspicion of crystalline structure. Further information in this direction may be obtained by x-ray spectral examination of the gel or its dried residue and an effort to obtain such evidence is being made.

Composition of Calcium Germanate.—108.4 cc. of calcium hydroxide containing 0 1122 g. of CaO treated with the same volume of germanic acid containing 0.1045 g. of GeO_2 gave a firm gel of 216.8 cc. After preserving this gel for some hours in a desiccator over dilute caustic alkali, it was broken up by stirring and the whole was transferred to a suction filter. The small mass left on the filter was washed with very little cold water. The residue and filtrate were separately analyzed.

The Residue.—The residue dried at 100° was detached from the filter almost in one piece, leaving scarcely anything on the paper; the latter was separately ashed in a weighed crucible before adding the main bulk of salt. Ignition at bright red heat, weighing before and after, showed that. the dried mass had retained about 13.9% of water at 100°. The ignited salt was dissolved in 6 N hydrochloric acid and all of the germanium removed by saturation with hydrogen sulfide under pressure. The sulfide was filtered off and converted to dioxide in the usual way, weighing as GeO_2. The filtrate containing all of the calcium and much acid was evaporated nearly to dryness and the residual calcium salt was converted to sulfate by continuing the evaporation with excess sulfuric acid, weighing the residual ignited $CaSO_4$. Results of this analysis were 36.43% of CaO and 63.40% of GeO_2 for composition of the ignited salt.

The Filtrate from the Mechanically Broken Gel.—The combined filtrate and wash water was made 6 N with hydrochloric acid and saturated with hydrogen sulfide. Only a very small precipitate of GeS_2 appeared, requiring three or four hours to form. Converted to dioxide this amounted to only 0.0003 g. The filtrate from this small amount of germanic sulfide was examined for calcium by converting the residue obtained by evaporation to calcium sulfate as before. Results showed that the suction filtrate from the original gel was practically pure lime water and that the precipitation of germanium had been about quantitative.

It is also evident that the calcium salt of hypothetical orthogermanic acid cannot be formed by uniting the base and acid in the ratio calculated for this salt, and that the solid produced in the dispersed condition approaches the theoretical composition of calcium metagermanate, $CaGeO_3$ (theoretical values are $CaO = 34.93$, $GeO_2 = 65.07$), about half of the lime water originally added remaining in the free state. An attempt was now made to produce the metagermanate in purer form by combining the base and acid in the calculated ratio for this salt. In this series of gels (some of which are shown in Table II), the expected metagermanate did appear in purer form but a very noticeable change took place in the gelation dilution limit when compared with the gels made in the presence of excess calcium hydroxide. In addition, the second series of gels differed greatly from the first in their lack of clarity, for all of these were milky white or nearly opaque.

Gelation Dilution Limit for Calcium Germanate Gels.—Tables I, II, III and IV show the influence of varying ratios of base and acid upon the gelation dilution limit of calcium germanate gel, the gelation dilution limit being arbitrarily defined as the maximum dilution at which the dispersed salt sets firmly enough to permit the inversion of the container without loss of its contents and without separation of any visible untrapped liquid over a period of several days, gelation being carried out at 22–25° in all experiments.

TABLE I

GELS FORMED BY MIXING CALCIUM HYDROXIDE AND GERMANIC ACID IN THE CALCULATED RATIO FOR THE HYPOTHETICAL ORTHOGERMANATE, $2CaO:GeO_2$

	$Ca(OH)_2$, cc.	CaO, g.	GeO_2, cc.	GeO_2, g.	Gel. vol., cc.	H_2O in gel, %	Remarks
1	30	0.02345	8.85	0.02177	38.8	99.884	Firm gel, sl. cloudy, permanent
2	30	.02345	11.8	.02177	41.8	99.892	Same as 1
3	30	.02345	14.75	.02177	44.7	99.899	Firm gel, clearer than 1 and 2
4	30	.02345	14.75	.02177	44.7	99.899	Same as 3
5	30	.02345	17.7	.02177	47.7	99.905	Firm gel, nearly cl., no water sep.
6	30	.02345	23.6	.02177	53.6	99.915	Stronger gel than 7
7	30	.02345	29.5	.02177	59.5	99.924	Very clear, fairly firm set
8	15	.00782	15.0	.00729	30.0	99.950	Not firm, falls from inv. cont.
9	15	.01172	17.7	.01088	32.7	99.931	Poor gel, some water sep.
10	15	.01172	23.6	.01088	38.6	99.941	Not very firm set gel
11	15	.01172	24.1	.01088	39.1	99.942	About same as 10
12	30	.02345	29.5	.02177	59.5	99.924	Fair gel, not very firm set
13	108.3	.11218	108.3	.10450	216.6	99.900	Quite firm, clear gel, remains in inverted container

The results shown in Table I indicate that the gelation dilution limit for mixtures of calcium hydroxide and germanic acid lies between fairly narrow limits of water content, for those gels containing more than 99.92% of water do not set firmly, while those containing less than 99.88% of water are cloudy and give evidence of too rapid a precipitation of the calcium salt to allow the highest dispersion. All gels in this table are prepared by combining acid and base in the $2CaO:GeO_2$ ratio and inspection of the other tables (II, III and IV) will show that varying the proportions of acid and base results in noticeable change in dilution limit.

The best working conditions for the formation of good gels for this ratio of acid and base appear to be found at dilutions corresponding to 99.90% of gel water, as shown in Table I, Expt. 13.

Table II

Calcium Germanate Gels Produced by Combining Acid and Base in Calculated Ratio to Form the Calcium Salt of Hypothetical Metagermanic Acid, $CaGeO_3$, Showing Gelation Dilution Limit for Gels So Prepared

	$Ca(OH)_2$ soln, cc	CaO, 6	GeO_2 soln, cc.	GeO_2, g.	Vol of gel	H_2O in gel, %	Remarks
1	30	0.02345	29.5	0.04354	59.5	99.887	Cloudy white, not very firm gel
2	30	.02345	29.5	.04354	59.5	99.887	Cloudy wh., few water drops sep.
3	25	.01954	14.85	.03653	39.85	99.859	Cloudy white, fairly solid
4	25	.01954	18.8	.03653	43.8	99.872	Poor gel, water sep.
5	25	.01954	29.7	.03653	54.7	99.897	Very poor gel, white, not firm
6	30	.01172	8.85	.02177	38.85	99.914	No gel at all, ppt. sep.
7	25	.01954	13.9	.03653	38.9	99.856	Fairly firm, white gel
8	25	.01954	9.9	.03653	34.9	99.839	Like 7 but little firmer
9	80.3	.05609	80.3	.10450	160.6	99.900	Very poor gel with sep. water
10	160.6	.11218	160.6	.20900	321.2	99.900	About same as 9

From the ten experiments shown in Table II it will be seen that the combination of calcium hydroxide and germanic acid in the $CaO:GeO_2$ or 1:1 ratio also brings about gelation at relatively high dilution but the gelation dilution limit in this case is reached when the water content becomes 99.83 to 99.85%; the gels in Table I made in the $2CaO:GeO_2$ ratio of base to acid reached limiting dilution at about 99.90% of water (see No. 7, Table I, and compare with No. 7, Table II, as representing dilution limit in these two systems). In these gels it is seen that No. 7, Table I, offers a gel containing 0.04322 g. of total anhydrous solids per 59.5 cc. of gel and No. 7, Table II, a gel containing 0.05607 g. of anhydrous constituents per 38.9 cc. of gel volume. Calculating these to the same volume of gel in each case, the limiting values for anhydrous oxides in the two become 0.07596 g. per 100 cc. of gel of the ortho, ratio $2CaO:GeO_2$ for Table I, and 0.15138 g. of anhydrous oxides per 100 cc. of gel of the meta, ratio $CaO:GeO_2$ for Table II. These values show the real difference in gelation dilution limit in the two series of gels more clearly than simple expression of their respective water percentages and point out that the content of anhydrous oxides per cc. of gel made as in Table I is only about half that required for a gel of similar consistency made as in Table II.

In addition to variation in dilution limit in the two series of gels it is to be noted that those in Table II are all white and almost opaque and lack the almost water-clear, homogeneous character of those formed under the conditions in Table I.

The previously described analyses of the gels of Table I showed that the composition of the dispersed solid, mechanically freed from trapped water and ignited, approached the theoretical composition of calcium metagermanate and that the trapped water was almost pure lime water which had remained uncombined with germanic acid. These facts together with the poorer gelation obtained under the conditions in Table II indicate that a certain excess of free or uncombined base greatly favors gelation, although the dispersed calcium salt approaches the composition of calcium metagermanate in both cases.

A large quantity of gel was prepared under the conditions shown in Table II, Expt. 7, and the milky white mass was broken up mechanically and sucked as dry as possible on a Büchner funnel; residue and filtrate with wash water now were separately analyzed in the way already described. The residue on the filter after ignition contained 64.12% of GeO_2 and 35.80% of CaO (the theoretical values for $CaGeO_3$ are 65.07 and 34.93). The filtrate drawn from the original gel mass contained germanium which had evidently escaped precipitation in the solid structure of the gel. Complete analysis of this filtrate showed that the total solids present amounted to only about 10% of the total solids present in the original gel and that of this dissolved portion 34.44% was CaO and 65.66% was GeO_2. Evidently germanium is not completely precipitated by mixing calcium hydroxide and germanic acid in the $CaO:GeO_2$ ratio, as in Table II, although $CaGeO_3$ is produced in both this or the former ratio $2CaO:GeO_2$ of Table I. On the other hand, analyses of the gels of Table I showed that the germanium was completely precipitated by the excess lime water and was to be found in the solid gel structure and not in the trapped water.

The fact that the dispersed calcium salt is the same in composition ($CaGeO_3$), whether the base is added in considerable excess as in Table I or in the calculated amount to produce this salt as in Table II, naturally leads to the belief that a certain excess of base is required to favor the formation of homogeneous gels at high dilution as well as to quantitatively precipitate the germanium in the solid or filterable structure of the gel. In the next series of gels, described in Table III, the base and acid were added in a ratio intermediate between those of the former two tables, that is, the $4CaO:3GeO_2$ ratio. Examination of this table will show that by so uniting the base and acid the gelation dilution limit was still further advanced and firm gels of the highest dilution could be so obtained. It was at first thought that the better gelation under these circumstances was connected with the formation of the calcium salt of a hypothetical trigermanic acid but analyses of these gels, seen under Table III, show that again the salt produced was nearly pure calcium metagermanate and that the union of base and acid in the above ratio simply furnished a still more favorable hydroxyl-ion concentration for best gelation.

TABLE III

CALCIUM GERMANATE GELS FORMED BY UNITING BASE AND ACID IN THE CALCULATED RATIO, $4CaO:3GeO_2$, SHOWING GELATION DILUTION LIMIT FOR THIS RATIO

	$Ca(OH)_2$ soln., cc.	CaO, g.	GeOz soln., cc.	GeO_2, g.	Gel vol., cc.	Gel comp.,		Remarks
						% H_2O	CaO + GeO_2	
1	**89.64**	0.07478	**89.64**	0 10450	**179.28**	99.90	0.10	**Firm clear gel in 10 sec.**
2	**26.9**	.02243	**26.9**	.03135	**53.8**	**99.90**	**.10**	**Same as 1**
3	**40.7**	.02243	**40.7**	.03135	**81.4**	**99.935**	.065	**Firm clear gel in 2 min.**

5	53.5	.02243	53.5	.03135	107.0	**99.947**	.053	**Bulky mass, will not set**
6	78.68	.08971	85.28	.1254	163.96	**99.869**	.131	**Firm, clear gel in 2–3 sec., remains in inv. vessel on shaking**

Results indicated in Table III show that the mixture of calcium hydroxide and germanic acid in the $4CaO:3GeO_2$ ratio gives the conditions which favor greatest dispersion of the precipitated calcium salt. Experiments 3 and 4 mark the gelation dilution limit between 99.93 and 99.94% of water. Gel No. 3 is particularly interesting because, as far as the writers can ascertain, no gel of comparable water content has thus far been reported in the literature of colloids either in the organic or inorganic field; the total anhydrous oxides present in this dispersed salt is less than a fifth of the anhydrous components found in previously known colloidal dispersions. A liter of this gel (No. 3) contains 0.27579 g. of CaO and 0.38510 g. of GeO_2 or *a* total solid content of 0.66089 g. It will keep indefinitely (over a year), without any syneresis and if kept in a tightly-stoppered vessel will resist any change up to near the boiling point of water. Any quantity of this gel can be prepared by quickly combining equal volumes of 0.009837 *M* CaO and 0.00737 *M* GeO_2.

The $4CaO:3GeO_2$ gel prepared as in Expt. 6, Table III, and containing 0.08971 g. of CaO and 0.1254 g. of GeO_2 in the gel volume of 163.96 cc. was broken up by actively stirring and the whole was filtered by suction, using a platinum cone and filter paper. The small residue on the filter after washing with a small amount of cold water was ignited and analyzed by the method before described. The ignited salt contained 36.42% of CaO and 63.48% of GeO_2. The filtrate plus wash water contained less than 0.001 g. of GeO_2 and 0.0087 g. of CaO, nearly all of which was present as free base. Again it is seen that the insoluble structure of the gel is essentially calcium metagermanate. The GeO_2 found in the ignited salt is low by about 2% when compared with the theoretical value for GeO_2 in this salt and the value for calcium is correspondingly high. It is believed that this discrepancy can be explained in two ways—first, the complete washing of the colloidal residue is difficult on account of adsorbed calcium hydroxide and, second, the alkaline filtrate or trapped gel water quickly takes up carbon dioxide if exposed to the air during filtration—both of these effects result in apparent rise in CaO content of the salt and corresponding low values for GeO_2 found in the filtered residue.

TABLE IV

Calcium Germanate Gels Obtained by Combining Calcium Hydroxide and Germanic Acid in the Ratio $3CaO:2GeO_2$, Showing Gelation Dilution Limit

	$Ca(OH)_2$ soln, cc	CaO, g	GeO_2 soln, cc	GeO_2, g	Gel vol., cc.	Gel comp., % H_2O	% solids ($CaO + GeO_2$)	Remarks
1	94.32	0.08414	94.32	0.10450	188.63	99.900	0.100	Firm clear gel, sets in 1 min.
2	25.0	.02140	33.5	.02670	58.5	99.918	.082	Not firm gel, some liq. sep
3	25.0	.02140	32.2	.02670	57.2	99.916	.084	Fairly firm, some water sep.
4	25.0	.01290	25.0	.01610	50.0	99.942	.058	No geln., ppt. settles to bottom
5	22.5	.01290	22.5	.01610	45.0	99.936	.064	Only partial geln., much liq. sep.
6	26.0	.02140	26.0	.02670	52.0	99.908	.092	Fair gel, sets in 2-min. diln. limit in this series

Table IV shows that the gelation dilution limit for mixtures of calcium hydroxide and germanic acid in the $3CaO:2GeO_2$ ratio is reached at a water content of 99.908 or total solid content of 0.092% but brings out the fact that no gelation will take place at the maximum dilution for gels of the $4CaO:3GeO_2$ ratio in Table III (compare Expts. 3 and 4, Table III, with Expt. 4, Table IV).

Analysis of the gel obtained in Table IV, Expt. 6, showed that the filtrate obtained by mechanical destruction of the gel and suction filtration was essentially free lime water but 0.0023 g. of GeO_2 had escaped precipitation and was also present in the alkaline filtrate. The insoluble portion, which had previously built up the gel structure, on ignition contained 65.40% of GeO_2 and 39.52% of CaO. These results are close to the calculated values for $CaGeO_3$.

Combining all of the results obtained from Tables I to IV, inclusive, it can be safely concluded that more or less pure calcium metagermanate is precipitated by any excess of calcium hydroxide on germanic acid and that this salt alone is responsible for the gelation phenomena observed. Also solid gels are obtained at maximum dilution when acid and base are combined in the $4CaO:3GeO_2$ ratio, Table III, Expt. 3, giving conditions for the most highly dispersed salt obtainable in any known circumstances. This gel contains 99.935% of water and 0.065% of total anhydrous constituents.

Strontium Germanate

Solutions of strontium hydroxide and germanic acid do not form homogeneous gels at dilutions comparable to those used in the formation of the colloidal calcium salt. Strontium germanate gels can be formed, however, if the solutions of acid and base are made up to concentrations of four or five times the molarity of those used under the calcium gels. For this purpose 0.047 M SrO (4.9040 g. of SrO per liter) and 0.049 *M* GeO_2 (5.1450 g. of GeO_2 per liter) were used for preliminary experiments.

Strontium germanate gels were prepared under the same general conditions as those described under the calcium salt, combining acid and base in ratios analogous to those already given. All of the strontium gels were opaque or almost opaque in distinction to the transparent or nearly water-clear calcium gels. The strontium gels set much more slowly and under no conditions could be obtained free from enclosed flocculated masses or aggregates of precipitated salt which interfered with the direct passage of light through the solid gel.

Analyses of the strontium gels were made in exactly the same manner as under the calcium gels. The results of these analyses showed that an excess of strontia ($2SrO:GeO_2$) precipitates nearly all of the germanium which appears in the insoluble and filterable solid structure of the gel, the filtrate obtained by suction and violent agitation of the gel being nearly pure strontium hydroxide. On the other hand, in the formation of the strontium germanate under circumstances where the acid and base were combined in any other ratio approaching the 1:1 molecular ratio, there always resulted an incomplete precipitation of the germanium, much of which then passed into the entrapped gel water. The gel residues obtained by suction were all ignited and analyzed and as under the calcium salt it was found that the salt of metagermanic acid in a greater or less degree of purity was always produced, no matter what excess of strontia had been added to the solution of germanic oxide. In mixtures containing the greatest excess of base ($2SrO:GeO_2$), the residual salt after suction filtration contained 56.10% of GeO_2 and 44.01% of SrO. Calculated values for $SrGeO_3$ were 50.21% of GeO_2 and 49.79% of SrO. The gels formed by combining the strontia and germanic acid in the $SrO:GeO_2$ ratio gave 50.66% of GeO_2 and 49.30% of SrO for the composition of the similarly obtained residue.

The gelation dilution limit for strontium germanate is shown in Table V, but as this salt does not show the unusual dispersion of the corresponding calcium compound, only a few typical experiments are shown, combining in one table the limiting dilutions for various mixtures of base and acid.

From the results shown in Table V it may be concluded that strontium germanate gels cannot be obtained with more than 99.75% of water. The gelation dilution limit for these gels is reached at about 0.25% total

TABLE V

STRONTIUM GERMANATE GELS

Showing gelation dilution limit for mixtures of base and acid in several molecular ratios: $2SrO:GeO_2$; $SrO:GeO_2$; $4SrO:3GeO_2$

solid content ($SrO + GeO_2$), which is about twice the amount of anhydrous material present in solid gels of the calcium compound. The solid structure of these gels is made up essentially of strontium metagermanate, $SrGeO_3$, although the pure salt is rather difficult to isolate from excess of adsorbed strontia. There appears to be no indication of the formation of any other germanate of strontium no matter what excess of strontia is mixed with germanic acid.

Barium Germanate

Unlike the corresponding calcium and strontium salts, barium germanate is appreciably soluble in water, so that mixtures of baryta and germanic acid at dilutions comparable to those used under the calcium and strontium gels gave nothing more than clear solutions in which only partial precipitation of the barium salt occurred on long standing.

Experiments were carried out with more concentrated solutions, using baryta containing **0.00927** g. of BaO per cc. and germanic acid containing **0.00372** g. of GeO_2 per cc.

Sixty-six and two-tenths cc. of barium hydroxide containing **0.61348** g. and **56.2** cc. of germanic acid containing **0.2090** g. of GeO_2 were combined. **A** fine crystalline precipitate formed almost immediately and on standing for some time larger crystals were deposited which collected in shining aggregates on the sides and bottom of the beaker. The crystalline mass was filtered off on a suction filter, washed with a small amount of cold water, dried, ignited and weighed. This amounted to 0.2947 g., representing only 35.8% of the total oxides in the original mixture. Analysis of the ignited salt gave 58.68% of BaO and 41.30% of GeO_2 (theoretical values for $BaGeO_3$ are 59.41 and 40.58). The alkaline filtrate from the original precipitation of the crystalline barium salt contained 0.089 g. of GeO_2 which had escaped precipitation, although the base had been added in double the amount required to form the metagermanate. It will be noted that a corresponding excess of either calcium or strontium hydroxide would have quantitatively precipitated the germanium.

A portion of crystalline barium metagermanate was prepared by combining barium hydroxide and germanic acid in the calculated amounts to form pure $BaGeO_3$, warming the solution of acid and base before mixing the two. In this case the solution remained clear for a few moments and on standing for some time partial precipitation took place as before but the crystals were much larger. Analysis of this distinctly crystalline mass gave 59.64% of BaO and 40.46% of GeO_2, values which are fairly close to the calculated composition of $BaGeO_3$. Under the microscope the crystals appeared to be octahedral in habit and further examination under the polarizing prism showed them to be isotropic. The crystals are very fragile and possibly metastable. The isometric habit of barium germanate is in agreement with the crystalline form of the naturally occurring metatitanate perovskite ($CaTiO_3$) of analogous chemical composition.

Solubility of Barium Germanate.—An excess of finely-powdered crystals of the barium salt prepared as above was shaken with water for a number of days. Using a thermostatic bath at 25°, 100 g. of the solution saturated at 25° contained 0.07536 g. of $BaGeO_3$.

Summary and Conclusion

1. The neutralization of dilute germanic acid by calcium hydroxide produces a colloidal calcium germanate of unusually high dispersion. Firmly set gels are obtained in which the total anhydrous constituents may constitute as little as 0.065% of the gel mass. Gelation at maximum dilution occurs when acid and base are combined in the $4CaO:3GeO_2$ ratio.

2. Calcium germanate hydrogels ranging from 99.90 to 99.94% of water content are permanent dispersoids if protected from dry air and carbon dioxide. Gels may be kept at least a year without syneresis.

3. The water present in dispersed calcium germanate appears to be simply trapped water, nearly all of which can be removed by pressure or suction filtration. The solid structure or filterable mass is pure or nearly

pure calcium metagermanate. All of the germanium is present in the insoluble or filterable structure if the proportion of calcium hydroxide reaches or exceeds the amount present in the molecular ratio $2CaO:GeO_2$.

4. The water of the hydrogel may be replaced by a number of other liquids such as methyl and ethyl alcohol or acetone and these non-aqueous liquids may in turn be replaced by ethyl ether or benzene, yielding a series of non-aqueous dispersoids which are permanent if protected from evaporation.

5. Excess of lime water gives a very delicate and characteristic test for germanic oxide. A small fraction of a milligram of GeO_2 in 20 cc. of water may be recognized on account of the extraordinarily bulky nature of the hydrogel.

6. Strontium germanate yields a dispersoid similar to the calcium salt but gels are not obtained at dilutions comparable to those used in the preparation of the calcium salt.

7. Barium germanate is distinctly different from the calcium and strontium salts. This salt is very distinctly crystalline and appreciably soluble in water. Crystalline $BaGeO_3$ is formed in shining aggregates, probably octahedral. Under the polarizing prism it is shown to be isotropic.

NOTE ON THE VACUUM CONTRACTION OF DENSITY BULBS[1]

BY MARCEL BECKERS[2]

RECEIVED MARCH 6, 1929 PUBLISHED JULY 5, 1929

Having undertaken the systematic study from a physicochemical point of view of the easily liquefied saturated hydrocarbons, we have been led to assemble at the start a considerable body of experimental material, in order to free ourselves from anxiety over apparatus problems during the measurements.

We had already calibrated a series of gas density bulbs for our measurements of the weight of a liter of *n*-butane,[3] but as regards contraction on evacuation, the values obtained differed in general by 25% from those calculated by the formula of E. Moles and R. Miravalles.[4]

[1] This paper contains the results of an investigation carried out as part of Project No. **32** of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund donated by the Universal Oil Products Co. This fund is being administered by the Institute with the cooperation of the Central Petroleum Committee of the National Research Council. Professor J. Timmermans is Director of Project No. **32.**

[2] Research Fellow, American Petroleum Institute.

[3] Beckers, *Bull. soc chim. Belg.*, **36**, 559 (1927).

[4] Moles and Miravalles, *J. chim. phys.*, **21**, 1 (1924).

We have thought it worth while to reopen the question with new measurements. They have been carried out on bulbs numbered **3** to 10, previously calibrated, and on nine new ones, numbered 11 to 20. All the bulbs, whose capacity varied from 600 to 2000 cc., were constructed of Thuringian glass; although we do not know the age of this glass, only bulbs Nos. 6 and 7 devitrified in the flame, and we have not used them further in our work.

The uncertainty of the results obtained by the method of Travers being generally accepted, we have attempted to check them by a method different in principle, namely, the hydrostatic method. Six bulbs (Nos. 6, 15, 16 and 17; 12 and 13) have been measured in both ways. Due to the good agreement obtained, the other bulbs were studied by Travers' method alone.

To attain the desired accuracy, we have had continuously to overcome a number of experimental difficulties. The different investigators who have carried out measurements of this kind have also mentioned meeting obstacles, but unfortunately they have been reticent of details as to their mode of operation. Therefore, we think it worth while to describe our technique in detail, especially as such measurements are slow to make, and their accuracy depends on small factors.

Hydrostatic Method.—The technique adopted differs from that of Moles and Miravalles[4] as follows. The bulb, immersed in a water-bath, is weighed successively evacuated and filled with air. To effect this, the bulb was ballasted by a mass of iron, nickel plated and polished, whose weight was slightly greater than the buoyant force. The iron sinker was suspended by a sort of net made of three pliable brass wires, symmetrically placed in three meridians of the glass sphere, and joined together at the base where the weight was attached by a hook. The upper ends were fastened to another wire forming a concentric loop about one centimeter from the neck of the bulb. In this way, the weight is practically evenly distributed about the neck of the bulb; this region is particularly rigid, and one may assume that no sensible change is made in the amount of contraction by this method of procedure.

The calculation of the results requires knowledge of the weight of air included in the bulb. This quantity is determined by filling the bulb with dry air, freed from carbon dioxide by appropriate washing,[5] and by the knowledge of the interior volume. The pressure of the gas and the temperature of the room must also be noted.

One of the inconveniences of the hydrostatic method lies in the size of the corrections to be made for a variation in temperature of the water-bath, *e.* g., a variation of 0.14° with a volume of 1393 cc. leads to a correction of 0.034 g. In order to reduce these corrections as much as

[5] E. Saerens, *Bull. soc. chim. Belg.*, **33**, **28** (1924).

possible, we arranged to have the temperature of the bath close to that of the room. It must also be noted that the total volume of the bulb, sinker, net, etc., must be taken into account in these calculations. This volume is determined by the loss in weight of the bulbs fitted with the same equipment as at the moment of construction of the counterpoises.

The bulb is completely immersed in the bath and the capillary above the stopcock is filled with distilled water before immersion.

The weighings were done on a balance sensitive to one milligram. The suspension between water and air was made of a flexible copper wire 0.2 mm. in diameter; without taking special precautions, the measurements were easily reproducible to about one milligram.

One important source of error was due to bubbles of air which clung accidentally to the sides of the bulb; to prevent this the exterior surface was carefully freed from grease.

As an example of the calculation, the results on Bulb 15 are given.

Exterior volume of bulb, sinker, etc., 1385 cc.
Interior volume of bulb, 1161.4 cc.
Mean temperature of bath, 16.30".
Change in density of water per 0.01° in the region of 16.30°, 155×10^{-8}.

Weighing (a) Bulb filled with air, 68.437 g., bath at 16.31°
Correction for bath temp., $155 \times 10^{-8} \times 1 \times 1385 = 0.002$ g.
Corrected weight, 68.439 g.

Weighing (a') Bulb evacuated, 67.293 g., bath at 16.32°
Diff., (a) − (a') = 68.439 − 67.293 = 1.146 g.
True weight of air from weight (a) =

$$1161.4 \times 1.293 \times \frac{273}{273 + 16.4} \times \frac{737.7}{760} = 1.375 \text{ g.}$$

Loss due to contraction = 1.375 − 1.146 = 0.229 g.
Value corr. for density of water at 16.3° = 0.2292 cc.[6]
Contraction, corrected to 760 mm. = 0.236 cc.

Later we found

Weighing (b) Bulb filled with air, 68.455 g., bath at 16.32°
True weight of air =

$$1161.4 \times 1.293 \times \frac{273}{273 + 16.4} \times \frac{738.4}{760} = 1.376 \text{ g.}$$

Diff., (b) − (a') = 68.445 − 67.293 = 1.152 g.
Loss due to contraction = 1.376 − 1.152 = 0.224 g.
Corrected to 760 mm. = 0.2305 cc.

Weighing (b') Bulb evacuated, 67.295 g., bath at 16.32°
Diff., (b) − (b') = 68.445 − 67.295 = 1.150 g.
Loss due to contraction = 1.376 − 1.150 = 0.226 g.
Corrected to 760 mm. = 0.233 cc.

Mean contraction for the three measurements = 0.2332 *cc.*

For the six bulbs studied by this method the contraction has been determined by measurements (a), (a'), (b) and (b'), made in the same

---

[6] This correction is negligible.

way. From the four measurements we get three values for the contraction, differing in the most unfavorable case by only 2.5% from the mean (Table II). We may say here that the values deduced from (b) and (b') are in all cases the closest to those obtained by Travers' method.

Travers' Method.—In this method the bulb is placed in a strong and rigid vessel, and the space between the bulb and the wall of the vessel is filled with water. The vessel is provided with a passage for the inlet tube of the bulb, and also for a vertical capillary filled with water. On evacuating the bulb, the water descends in the capillary owing to the diminution in the volume occupied by the bulb. We have already[7] described the method of operation in our first experiments. We could not then obtain a steady meniscus; what is more, the readings on contraction did not agree with those on expansion. We thought that the precision of the thermostat might play a role in this discrepancy, so our first effort was to employ a more sensitive thermostat;[8] during the new measurements, the temperature variations from the mean were about 0.002°. The dead space being 7 liters, and assuming a variation in the interior of the vessel of 0.001°, the displacement possible in the capillary would be

$$7 \times 10^6 \times 2 \times 10^{-7} = 1.4\ \text{mm.}^3$$

which is the order of precision desired in these measurements.

The cover of the vessel this time was curved and had a neck pointing up, larger on top than bottom. This was the manner of filling: the cover is fitted, in addition to the experimental bulb, with the calibrated capillary tube T, (see Fig. 1), and also a tube, H, with stopcock. The cylindrical vessel, placed in the thermostat, is filled with air-free distilled water to such a height that, on putting on the cover with bulb attached, the water does not quite reach the ground surface. Two weights, P, of 500 *g.* are tied to the stopcock in order to counterbalance approximately the buoyancy of the bulb. The cover is then closed tightly, taking care that the lubricant is evenly spread. Weights are placed on the cover so as to compensate largely for the buoyancy of the bulb.

First the bulb is evacuated[9] and then, by means of the tube, H, the space above the water in the cylinder. Due to the difference of pressure, air-free distilled water can then be slowly introduced through the capillary, T, until the space beneath the cover is almost filled. It is left under vacuum for a quarter of an hour, shaken lightly to detach bubbles from the bulb, then filled completely and the stopcock, L, closed. The distilled water used to fill the cylinder is stored in an auxiliary thermostat, maintained 0.2" higher than the thermostat used in the measurements, so as to compensate approxi-

---

[8] L. Maricq and M. Beckers, Bull. *soc. chim. Belg.*, **37**, 12 (1928).

[9] To prevent the plug leaving the barrel of the stopcock when the space above the water containing the bulb is evacuated.

mately for the lowering of temperature caused by evaporation in *vacuo.* After two hours the meniscus in the capillary is constant to about 1 mm.^{3} After this lapse of time, all of the small bubbles in the apparatus are dissolved.

In our first experiments we did not succeed in preventing a rapid descent of water in the capillary. After various trials, we became sure that this difficulty was due to a slow rise of the cover as a result of the pressure of the water in the capillary, which was placed vertically. For, if the capillary has a length of 50 cm., the pressure is 50 g./cm.^{2}. The cover having a surface of about 300 cm.^{2}, it would take 50 g. × 300 = 15 kg. to balance this force. Obviously it is necessary to avoid the slightest movement of the cover, for it would require a rise of only $^1/_{25}\ \mu$ to cause a displacement of 1 mm.^{3} in the capillary. To lessen as much as possible the pressure produced by the water in the capillary, we bent the tube above the neck so as to render it nearly horizontal, thus reducing the pressure to a few cm. of water. In all our measurements the cover was held down by 10 kg. distributed equally over the surface.

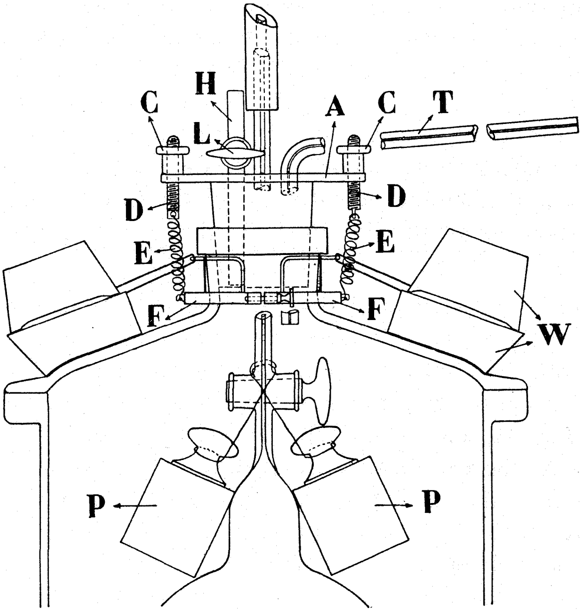

Fig. 1.

From the time this artifice was used, we were able to hold the level constant in the capillary; but, in the first experiments, it slowly dropped during the measurements. Later we were able to complete a series of experiments during each of which the level remained constant within 1 or 2 mm.^{3} from the beginning to the end of the measurement, i. e., for several hours. This difference of behavior can only be attributed to acquired skill in manipulating. For lubricating the ground joint we used anhydrous lanolin, which appeared to have the strongest adhesion.

To fasten the bulb and the other attachments to the cover, we tried two procedures. (1) A round disk of rubber with three holes was fixed in the neck and then covered with melted beeswax. In spite of all precautions, the wax cracked as it cooled, and even if one managed to cool it in one piece, it finally detached itself from the neck, as a result of the contraction on cooling. We had to abandon this method.

(2) A three-holed rubber stopper was solidly fixed in the cover as follows: a heavy metal plate, A, pierced also with three equally spaced holes, was placed above the stopper, B, and held tightly against it by three nuts, C, acting on threaded rods, D, flattened on one side. These screws are connected by means of springs, E, with a collar, F (in two pieces), which is rigidly attached to the neck of the cover by two screws. One could thus attain a progressive compression of the stopper, but, in spite of its strength, the stopper contracted slightly under an auxiliary pressure of 100 g. However, the level in the capillary came back very exactly as soon as this auxiliary pressure was removed. If any secondary action on the stopper is avoided, the level in the capillary remains very constant during a whole experiment, as we have already said. We may cite, by way of example, the results obtained with bulb No. 15; the level in the capillary decreased slightly during the experiment, and corresponding corrections have been made to the readings.

TABLE I

CONTRACTION AND EXPANSION DATA

Atmospheric pressure = 758.3 mm.

Contraction	0.2331	0.2343	0.2355	0.2343	0.2323	0.2331	Mean, 0.2338
Expansion	2331	2375	2351	,2343	.2319	.2331	Mean, ,2341

Mean of the two series, 0.2340 cc. Contraction corrected to 760 mm., 0.2345 cc.

The mean of the values obtained on contraction and on expansion do not differ as a rule by more than 0.2%, although in a few cases they reach 0.4%.

Concordance of the Two Methods.—This is shown by the following figures for six bulbs.

TABLE II

CONCORDANCE OF TWO METHODS

Bulb	Vol., cc.	Contraction obs., cc. Hydrostatic	Contraction obs., cc. Travers	Mean contr., cc.	Dev. from mean, %
6	906	0.1412	0.1330	0.1371	2.9
15	1161	,2332	.2345	2337	0 3
16	1176	.2593	2661	.2627	1 3
17	1165	.304	.3121	.308	1.3
12	2159	.3738	.3922	.383	2 4
13	2146	.374	3836	3788	1 3

It follows that the mean value of the two methods does not differ from the values obtained from either by more than 2%. We may therefore be permitted to conclude that the values obtained by each method may be considered correct to within 2%.

The hydrostatic method seemed to offer chances for more important accidental errors than that of Travers, so that henceforth we will only consider the results obtained by this latter method.

There follows a table showing the contractions found by the method of Travers, and also the values of η and K in the formula proposed by Moles and Miravalles

$$\eta = \frac{KV}{w} 10^{-3} \text{ cc.}$$

where η is the compressibility of the bulb under one atm., reduced to one liter, V is the volume in cc., w is the weight of the glass (minus that of the stopcock), and K is a constant, equal to 15.5, according to the authors.

TABLE III

CONTRACTION DATA

Bulb	Vol., cc.	Wt. of glass (minus wt. of the stopcock), g.	Obs. contr. reduced to 760 mm.	η	$K = \eta \frac{w}{V}$
3	609	70	0.0867	0.1423	16.4
4	624	56	.1178	.1890	17.0
5	630	71	.0884	.1403	15 8
6	906	101	.1330	.1468	16.4
7	910	113.5	.1160	.1275	16.0
8	1158	110	.2210	.1909	18.1
9	1174	93	.2758	.2351	18.6
10	1264	106	,2852	.2255	18.9
11	2162	143.5	.5287	.2446	16.2
12	2159	186	.3922	.1817	15.6
13	2146	192.5	.3836	.1788	16.0
15	1161	103	.2345	.2019	17.9
16	1176	89	.2661	.2264	17.1
17	1165	80	.3121	.2678	18.4
18	778	133	.0743	.0955	16.3
19	794	142	.0735	.0980	17.6
20	785	142	.0714	.0909	16.4
				Mean	17.0

The mean value of K is 17.0, with a maximum experimental deviation of 11%, and a deviation of 10% from the value 15.5 proposed by Moles and Miravalles. We should point out that the mean value of K found for the three bulbs of two-liter capacity is 15.9. The low value for these three (11, 12, 13) is due to the necks of the bulbs being only one cm. long, while all the others were about 4 cm. long. If these latter had also been made with short necks, thus diminishing the weight of glass, K would have been lowered by 5 or 10%, and thus would have approached considerably nearer the value of Moles and Miravalles.

Our experiments lead us to the following conclusion. The contraction under vacuum of bulbs of capacity from 600 to 2200 cc., and whose wall thickness varies appreciably, can be represented to within a few per cent. by the empirical formula

$$\eta = K \times \frac{V}{w} \times 10^{-3}$$

in which K has a value of about 16.0, if, in establishing the weight, a deduction is made for the neck of the bulb.

Our results thus correspond with those of Moles and Miravalles and confirm these authors in the opinion they have expressed, thus: "From the preceding, it necessarily follows that the empirical formula we have established gives the values of the compressibility of density bulbs more exactly than those measured by the authors, by a single method, and without taking excessive precautions."

The values obtained for Bulbs 3 to 10 of the preceding determinations diverge markedly from those considered above. We have repeated the calculations of these results, and have recalibrated the capillaries used. This has led us to make only a few small corrections to the old numbers. We give in the following table the corrected old values, new values and the concordance between the two.

TABLE IV

VALUES FOR BULBS 3–10

Bulb	Atm. press. during expt., mm.	Old values		New values	Ratio, new:old values
		Contraction in cc. corr. to 760 mm.			
3	766	0.067		0.0867	1.30
4	751	.0845		.1178	1.395
5	738	.065		.0884	1.36
6	745	.099	0.0955	.1330	1.39
	770	.092			
7	749	.0847	0.085	.1160	1.36
	763	.0855			
8	763	.1555		.2210	1.42
9	766	.1885		.2758	1.46
10	753	.2005	0.198	.2852	1.44
	769	.196			

Leaving out Bulb 3, the mean value of the ratios in the last column is 1.403, and it would require a diminution of the contraction of Bulb **3** by only 0.004 cc. to bring this also to the 1.4 ratio.

The remarkable constancy of this ratio of new to old values, in spite of its great sensitivity to small variations of the value obtained for the contraction, leads logically to the admission of some systematic error in our first measurements. The thorough examination to which we have subjected them ourselves did not lead us to discover it.

It seems difficult to attribute this to the fact that in our older measurements the water surrounding the bulb had not been freed from air. Whatever the cause may be we must admit that our first experiments are in error due to imperfection of the technique. It is to these same causes, so it seems, that the erroneous values obtained in this field by most investigators are due.[10] Fortunately, they do not introduce any large error into the gas density; in the case of butane, for instance, the density should be corrected by about one part in 20,000.

Variation of the Contraction as a Function of the Pressure.—In the determination of the density of a gas under reduced pressure ($^1/_3$ to $^2/_3$ atm.) it is necessary to know the contraction of the bulb with the same relative precision as under a pressure of one atmosphere. Until now one has been forced to accept the hypothesis that the contraction was a linear function of the pressure difference to which the bulb was subjected.[11] We wished to make an experimental verification of this hypothesis. Our measurements, by the Travers method, were carried out on three bulbs, on two of which the contraction under $^1/_3$ atm. was measured, and on the other at $^2/_3$ atm.

Our results are, in the three cases, completely in accord with the hypothesis advanced. The table shows the results obtained on Bulb 13.

TABLE: V

RESULTS ON BULB 13

Interior volume of the bulb, 2146 cc. Contraction reduced to 760 mm , 0.3836 cc.

Red. press., mm.	Values obtained in cc. On contraction	On expansion	Mean value	Calcd. value
479.4	0.2408	. . .	0 2408	0.2416
483.3	,2421	0,2443	.2432	.2436
479.9	.2411	.2411	,2411	.2419
477.6	.2399	.2399	.2399	.2407

To M. Timmermans, who has accepted the direction of our researches, we would like to express here our sincere gratitude for his aid and his willing support.

Summary

The contraction of density globes on evacuation has been investigated in connection with a physicochemical examination of easily liquefied saturated hydrocarbons. A hydrostatic method of measurement has been applied to the problem, as well as the method of Travers; the results by both methods are in good agreement.

The empirical equation proposed by Moles and Miravalles for the calculation of the compressibility of density globes is given additional confirmation by the results of the measurements.

Data have been obtained which lend support to the hypothesis that the

---

[10] Ref. 4, p. 8.

contraction of density globes is a linear function of the pressure difference to which the bulb is submitted.

THE DIELECTRIC POLARIZATION OF LIQUIDS. V. THE ATOMIC POLARIZATION

BY C. P. SMYTH

RECEIVED MARCH 6, 1929 PUBLISHED JULY 5, 1929

In previous communications[1] the total polarization, P, of a substance has been divided into three parts, P_E, the electronic polarization, P_A, the atomic polarization and P_M, the orientation polarization due to the permanent moments of the molecules. This series of papers is concerned mainly with the conclusions to be derived from the values of P_M for liquids, but, as P_M is commonly obtained from the total polarization, P, by subtracting P_E and P_A, it is evident that no treatment of the problem can be complete without consideration of the two latter quantities. As P_E is discussed in another paper,[2] the present treatment will be confined to the significance of P_A, especially in its relation to molecular structure.

The polarization is commonly obtained from dielectric constants measured at frequencies up to 3,000,000 cycles or wave lengths down to 100 meters. For much higher frequencies or shorter wave lengths, the orientation of the dipoles in an applied field often becomes less and P_M diminishes, being negligible for frequencies in the infra-red region. In the range of visible light the frequency of the alternating field is so great that, for the most part, the electrons only are affected by it, the polarization being P_E alone. P_E is thus determined as the molar refraction for visible light. In the absence of anomalous dispersion, the small variation of P_E with wave length may be calculated by a simple dispersion formula such as that of Cauchy or Sellmeier[3] and the value of P_E obtained for the comparatively low frequencies, virtually infinite wave length, at which the dielectric constant is measured. However, the presence of oscillators with frequencies in the infra-red region causes anomalous dispersion and, in consequence, polarizations greater than the values obtained by extrapolation with the simple formulas. Actually these oscillators are displaced in the electric field, forming electric doublets and thus contributing to the polarization of the medium. Although some of these oscillators may be electrons, the majority are atoms, ions or radicals and, for this reason, their contribution

to the total polarization is termed the "atomic polarization" and designated by P_A. P_A is usually so small and difficult to determine with accuracy[4] that any attempt to subdivide it into the contributions of atoms, radicals, ions, etc., seems rather futile in the present state of our knowledge.

Since $P = P_E + P_A + P_M$ and P and P_E can always be determined, P_A is obtained by difference when P_M is known. P_M can be calculated from the temperature variation of the polarization of a gas or of dilute solutions, from which the polarization at infinite dilution can be obtained From measurements of dielectric constant[1b,5] in the solid state at temperatures sufficiently low and frequencies sufficiently high to prevent all orientation of the dipoles in the alternating field, a value can be obtained for the polarization from which P_M is eliminated, so that P_A can be obtained by subtracting P_E.[4,6]

Errera[3] has assembled a considerable number of values of P_A from the literature, calculating several not previously known. These are regrouped in Table I together with new values calculated by the writer and others taken from the literature. The values of the electric moment of the molecule, μ, are shown in order that it may be ascertained whether there is any connection between μ and P_A. For the gases, $P_E + P_A$ is determined from the temperature variation of the dielectric constant and P_A then obtained by subtracting P_E. A similar method is employed for $CHCl_3$, C_4H_9Cl, C_2H_5Br, C_4H_9Br, C_2H_5I and C_6H_5Cl, the substances being measured in solution. For the liquids without moment, P_A is determined by subtracting P_E from P, and for the majority of those with moment by subtracting P_E for the liquid from P for the solid. A small error in these calculations is caused by the fact that the value of P_E for the liquid may often be slightly different from those for the solid and the vapor, which are usually unknown. In the case of liquids for which μ is given as 0, it is sometimes impossible to distinguish between a very small value of μ and 0, which means that P_M may have a small finite value, instead of 0. This would, of course, cause a small error in P_A. As, in general, P_A is determined as a small difference between relatively large quantities, all the errors of experiment and method are accumulated in its values. A number of values obtainable from the literature, in particular several for vapors, are obviously so much in error that they are excluded from Table I, and the decimal places for many have been rounded off. The literature sources from which the values of μ and P_A have been obtained are indicated by the numbers following their values. Where no number is given after P_A, the value has been calculated by the writer from the data used in obtaining μ

Van Vleck[7] has calculated from infra-red intensity measurements that the vibrational polarization, which is P_A, is negligibly small for HCl, HBr, CO, CO_2, NH_3 and CH_4 and attributes to experimental error the difference found between the extrapolated refraction and the total induced polarization. He indicates, however, that this does not necessarily mean that, in other kinds of molecules, there may not be infra-red vibrational or electronic bands of such large amplitude, high effective charge or low frequency

---

[7] Van Vleck, Phys. Rev., 30, 31 (1927).

as to cause a difference between the extrapolated refraction and the total induced polarization, thereby giving significant values for P_A. There appears to be reasonable doubt as to whether the value 1.2 of P_A for hydrogen chloride can be due in the main to experimental error, and this is true also of the value 0.9 for sulfur dioxide and especially of the value 1.9 for acetylene. However, the values for argon, nitrogen, oxygen and ethane are virtually 0, and that for ethylene, 0.37, differs from 0 by no more than the probable error. At this point one may inquire whether P_A, which is obtained usually as a small difference between relatively large quantities, really exists as a quantity of significant size or whether it appears merely as the result of the combined errors of P, P_E and P_M. The question may be answered by pointing to the fact that, except in the case of a very few results obtained from notably inaccurate measurements, experiment yields no negative values for P_A.

Since P_A is due to electrical dissymmetry caused by the displacement of atomic nuclei or groups within the molecule, one would expect it to be greater, the greater the number of the nuclei or groups in the molecule. Some evidence of such an increase is given by the paraffins in Table I. The possible error in P_A for methane is so large that this value has little significance and P_A for ethane is very small. The values for hexane, the nine isomers of heptane and the octane, 2,2,4-trimethylpentane, are obtained from measurements of P and P_E carried out with care upon the same samples of material. The temperature variation of P for five of these substances leads to the belief that P_M may be taken as 0 for all of them. The values of P_A thus obtained as $P-P_E$ should be more accurately comparable with one another than the others in the table. Although P_A for the heptane isomers varies somewhat with the structure, it is evident that there is an increase in passing from hexane to heptane to octane. A more striking increase of P_A with increase in the number of nuclei or groups is brought out by comparison of the value 28.4 for cane sugar with that of 5 for ethyl alcohol. Ebert[4] has calculated that each mole of water of hydration in $Na_2CO_3 \cdot 10H_2O$ contributes 4.75 to the value of P_A, each mole in $BaCl_2 \cdot 2H_2O$, 4.25, and each mole in $CuSO_4 \cdot 5H_2O$, 4.06, which shows a definite dependence of P_A upon the number of nuclei.

Since P_A depends upon the displacement of the nuclei or groups in the molecule, it should depend upon the forces binding these nuclei or groups, that is, the valence forces. Bates and Andrews[8] have used thermal data to calculate the force necessary to pull apart two atoms from their positions of equilibrium, and have obtained results which are of the same order of magnitude as the approximate values calculated by the writer[9] from molar

---

[8] *Bates and Andrews, Proc. Nat. Acad. Sci., 14, 124* **(1928);** *Andrews,* ***Chem. Rev.,*** **5, 533 (1928).**

[9] Smyth, *Phil. Mag., 50, 361 (1925).*

refractions for the forces necessary to displace bonding electrons from their normal locations. In many cases where the actual forces cannot be calculated from the refractions, an idea of their relative magnitudes can be obtained from the refractions calculated for the electron groups. In this way, it is indicated that the C–O and H–O bonds are probably more rigid than the C–C and C–H bonds, in spite of which the values of P_A for the alcohols and ethers are larger than those for the paraffins. Although the values of P_A obtained for water by different methods do not agree well with one another, the correct value is almost certainly higher than that for hydrogen sulfide, while the refractions indicate that the forces of linkage are stronger in the water molecule. On the other hand, the forces linking carbon to halogen are lower than the C–C and C–H forces and the values of P_A for the compounds containing halogens are higher than those for the hydrocarbons. The marked rise in P_A on passing from carbon tetrachloride to titanium tetrachloride to stannic chloride is consistent with the decrease in binding force indicated by the refractions, the refractions of the chlorides in stannic chloride being almost those of free chloride ions. The different behaviors of the acetylene dihalides and the dihalogenated benzenes cannot be explained in terms of these forces alone. It seems probable that the smaller forces required to bend rather than stretch bonds may play an important role, but our knowledge of these is at present very meager. In any event, it is evident that the forces which have been considered do not provide an adequate explanation of the differences in P_A.

It is possible that the small molecules like hydrogen chloride and sulfur dioxide, which have electric moments, have larger values of P_A than the small molecules without moments, but this is uncertain because of the small values of P_A and the large errors. It is certain, however, that many small molecules with moments have values of P_A smaller than those of large molecules without moments. The values of P_A for the chlorine-substituted methanes are not sufficiently accurate to permit of definite conclusions. One may say, however, that CH_3Cl, CH_2Cl_2, $CHCl_3$, CCl_4 and also C_2H_5Cl and C_4H_9Cl have values of P_A of about the same size, considerably larger than those for the paraffins. It would appear that the presence of electric doublets in the molecule, even if they oppose and cancel one another to give zero moment to the molecule as in carbon tetrachloride, is conducive to higher values of P_A. The doublets are presumably larger in titanium tetrachloride and still larger in stannic chloride, although as they are symmetrically located in the molecules, the total moments are zero. The value of P_A for liquid ethyl bromide is very uncertain, and the negative value, -5, calculated for the vapor from the measurements of Mahanti and Sen Gupta and not included in Table I shows only the uncertainty of the measurements.[10] The values calculated for the vapors of methyl and ethyl

---

[10] Mahanti and Sen Gupta, *Indian J. Phys.*, **12,** 191 (1928).

iodide from the measurements of the same investigators and shown in the table in parentheses merely indicate that P_A is probably large for these substances, being thus far in agreement with the high value for liquid ethyl iodide, which is more accurately determined. The reason for the abnormally high values for these substances and also for dimethyl sulfate, determined by a different method, is not apparent. It may be in part experimental error and in part the large doublets and small binding forces. There is evidently need of measurements upon the alkyl halides in the solid state.

Among the acetylene dihalides the czs-compound, which has a considerable moment, always has a value of P_A larger than that of the corresponding trans-compound, which has no moment, although P_A increases when chlorine is replaced by bromine and bromine by iodine, while the moment of the cis-compound decreases. Among the dihalogen-substituted benzenes the value of P_A decreases from the ortho to the meta to the para compounds, as the moment becomes smaller, and also decreases on passing from the chlorine to the bromine to the iodine compounds, in contrast to the increase among the acetylene dihalides. P_A for cyclohexane is about the same as that for the heptanes and differs from that for n-hexane by no more than the possible error. The value for benzene is a little larger and *p*-xylene, which contains two small opposed doublets where the methyl groups are attached, has a still larger P_A, but the difference between it and that for benzene lies within the possible error. When a considerable doublet is present, as in chlorobenzene, P_A is appreciably increased, and the large doublet in nitrobenzene causes a large value of P_A.

It may be concluded that P_A is not generally an additive quantity but that it tends to be greater, the greater the number of atomic nuclei or groups in the molecule; probably, also, the smaller the forces binding these nuclei or groups, the greater the number of the electric doublets in the molecule and the more unsymmetrical the arrangement of these doublets in the molecule. However, unknown factors make it difficult to explain many of the differences found between different types of molecules.

Small changes in P_E have been found to accompany change of state and change of temperature,[2] but similar changes in P_A would have to be very large to be apparent, because of the relatively large errors involved. Thus, for chloroform the values obtained from the work of two different investigators for the solid differ from one another far more than do those for the vapor and the liquid and one of those for the solid. For water the best value for the solid is much lower than the value for the vapor, but other values for the solid not listed are close to that for the vapor. One can conclude only that the variation of P_A with temperature and change of state is less than the error usually occurring in the determination of its value.

In the majority of the determinations of the electric moments of the molecules of substances in the liquid condition, P_A has been neglected entirely and P_M obtained as the difference between P and P_E. As the electric moment is calculated from the square root of P_M, the inclusion of P_A in the value of P_M usually increases the value of μ by little more than the possible error when P_M is large. Thus, inclusion of P_A with P_M in the calculation increases the value of μ for C_6H_5Cl by 0.05 X 10^{-18} and for o-$C_6H_4Cl_2$ by 0.06 $\times$ 10^{-18}. Williams and his collaborators[11] working at only one temperature have been compelled to disregard P_A and, instead of obtaining P_E by extrapolation to infinite wave length, have subtracted the molar refraction for the sodium D-line from P and calculated μ from the difference. As the molar refraction for the D-line is slightly larger than P_E for infinite wave length, this procedure reduces the error caused by the failure to subtract P_A. When P_M is small or zero, disregard of P_A may introduce a relatively large error into the value calculated for the moment. If, for p-$C_6H_4Cl_2$, the value of $P_A = 3.4$ is added to that of $P_M = 0$, the moment calculated from the sum, 3.4, is 0.45 $\times$ 10^{-18}, instead of zero, as given by the correct value $P_M = 0$. In certain calculations of the moment made by the writer, Table I, ref. 18, μ was calculated from the difference between P and P_E. In this way values of 0.20 X 10^{-18}, 0.23 X 10^{-18} and 0.43 $\times$ 10^{-18} were obtained for benzene, p-xylene and carbon tetrachloride, respectively, for which Table I shows zero values of μ and not inconsiderable values of P_A. It was recognized at the time that values of μ less than 0.4 $\times$ 10^{-18} were, in many cases, indistinguishable from zero by the method of calculation employed, but the calculation for p-$C_6H_4Cl_2$ given above shows that neglect of P_A may give a value of μ larger than 0.4 X 10^{-18} when it is really zero and, for an electrically symmetrical molecule possessing a larger value of P_A, like trans-CHI—CHI, the error in μ would be larger. It is evident that the value 0.13 X 10^{-18} for the chlorine molecule calculated by the author in the same paper merely shows the moment to be small, if not actually zero, and that the value 0.58 $\times$ 10^{-18} for the bromine molecule is probably high because of the neglect of P_A. The small difference between this and the value 0.40 X 10^{-18} recently found by Anderson[12] indicates that P_A is small for bromine.

It is evident that if the moment is high and the molecule is small and contains only one or two electric doublets, P_A may be disregarded in the calculation of μ without, as a rule, introducing serious error in the result. If, however, the moment is small and the molecule is large and contains several electric doublets, it is unsafe to neglect P_A in the calculation of the moment.

Summary

Values for the atomic polarization of a large number of substances have been calculated or taken from the literature.

[11] Williams, *Physik. Z.*, 29, 174 (1928).

[12] Anderson, *Proc. Phys. Soc.*, 40, 62 (1928).

The binding forces calculated by Bates and Andrews from thermal data and by the writer from refractions are found inadequate to account for the differences between the displacements of the different nuclei and groups in the molecules.

The atomic polarization is not generally an additive quantity, but tends to be greater, the greater the number of atomic nuclei or groups in the molecule, the greater the number of electric doublets and the more unsymmetrical the arrangement of these doublets in the molecule.

In the calculation of the electric moment of a molecule, the atomic polarization may be disregarded without risk of introducing appreciable error only when the moment is high and the molecule is small and contains but one or two electric doublets.

THE PHOTOSENSITIZED AND PHOTOCHEMICAL DECOMPOSITION OF HYDRAZINE

BY JOSEPH C. ELGIN AND HUGH S. TAYLOR

RECEIVED MARCH 19, 1929 PUBLISHED JULY 5, 1929

Perhaps the most important fact now necessary for a complete understanding of the manner in which reactions are brought about by light energy is a knowledge of the action produced directly upon its absorption by the molecule. Taylor[1] has proposed, as a generalization of the facts now known, to state a Second Law of Photochemistry as follows: "The absorption of light is a quantum process involving one quantum per absorbing molecule (or atom). The photochemical yield is determined by the thermal reactions of the system produced by the light absorption." The resultants of this sequence of secondary thermal reactions are determined by ordinary physicochemical methods. The nature of the quantum process presents a more difficult problem. It has been possible in many cases from a complete kinetic study of the reaction to set up a mechanism, based on a postulated primary process, which yields satisfactory agreement with experimental observations. The postulated primary process is then assumed to be that actually occurring. For conclusive evidence as to the primary light action we must turn to that on the optical side furnished directly by molecular spectra. Thus far it has been possible to correlate satisfactorily the nature of the absorption spectrum with a definite primary action only in cases involving diatomic molecules. Those more complex give spectra showing complicated band systems which resist analysis. As a result of

[1] Taylor, "First Report of the Committee on Photochemistry of the Division of Chemistry of the National Research Council."

these two lines of approach the nature of the primary processes and the sequence of secondary reactions appear to be definitely established for several photochemical reactions. These are mainly those involving the halogens and hydrogen halides.

The photochemical decomposition of ammonia has been the subject of more or less exhaustive study.[2] No mechanism has as yet been derived for this reaction which is in complete agreement with experimental facts, nor has the primary process been established beyond question. The simple reaction of an activated ammonia molecule on collision with a normal one to yield nitrogen and hydrogen

$$NH_3' + NH_3 \longrightarrow N_2 + 3H_2$$

does not satisfactorily account for the low quantum yield at high pressures, nor the observation[3] that a rapid decomposition takes place at a pressure of 0.001 mm. of mercury. Photochemical decomposition should cease and fluorescence enter at this low pressure. The ultraviolet absorption bands of ammonia, also, do not show the fine structure ordinarily expected for cases where light absorption leads only to the activation of the molecule. Bates and Taylor[4] pointed out that a primary process of the type

$$NH_3' \longrightarrow N + H + H_2$$

proposed by Kuhn[5] is impossible if the recent values of the heats of dissociation of nitrogen and hydrogen molecules be accepted, and that his postulated secondary reactions are not consistent with several experimental facts.

From considerations involved in the facts that ammonia is decomposed by excited mercury atoms with an energy content of 112,000 calories and that the gaseous reaction products contain hydrogen in appreciable excess of the stoichiometric proportion N_2:$3H_2$, the above authors suggested that all molecules might undergo decomposition on light absorption, hydrazine formation being an intermediate stage. The proposed mechanism is

$$NH_3 + h\nu \longrightarrow NH_3' \tag{1}$$

followed by either

$$NH_3' + NH_3 \longrightarrow N_2H_4 + H_2 \tag{2}$$

or

$$NH_3' \longrightarrow NH_2 + H \tag{3}$$

$$NH_2 + NH_3 \longrightarrow N_2H_4 + H \tag{4}$$

$$NH_2 + H_2 \longrightarrow NH_3 + H \tag{5}$$

This would then be followed by secondary photochemical hydrazine decomposition, presumably into nitrogen and hydrogen. Such a mechanism,

although more satisfactory than those previously advanced, does not account for several observations of earlier investigators.[2]

Under the above assumptions hydrazine decomposition would determine materially the characteristics of the ammonia decomposition. It was hoped that an investigation of the photochemical decomposition of hydrazine might lead to a removal of some of the difficulties in the case of ammonia. Hydrazine, while more complex than ammonia, offers a case of a solely nitrogen–hydrogen compound. Its behavior might then lead to a better understanding of the action of radiation upon the nitrogen to hydrogen linkage and perhaps increase our knowledge of such reactions in general.

Hydrazine has been found to be decomposed by ultraviolet light and by excited mercury more readily than ammonia. The results obtained do not support its formation as an intermediate stage in the ammonia decomposition. They do, however, favor a mechanism of the general type as that suggested by Bates and Taylor.

Experimental Method

Apparatus.—Preliminary experiments were made with the flow apparatus and mercury arc described by Bates and Taylor.4 The usual static system was employed throughout the remainder of the decomposition studies. This consisted of a quartz reaction chamber of about 150-cc. capacity joined by a quartz to pyrex seal and capillary tubing to a constant volume mercury manometer, oil pump and to a hydrazine reservoir through a three-way stopcock. The latter provided means for the admission of various other gases to the reaction chamber. A liquid-air trap in the vacuum line prevented contamination of the pump.

Temperature control was obtained by immersing the reaction vessel in a copper tank through which water was continuously flowing. The water was heated to any desired temperature by previous passage through electric heaters. In the sensitized experiments a large battery jar was substituted for the tank. In any case the temperature could be controlled to about one degree by proper variation of the temperature and rate of flow of the entering water. A stream of air gave efficient stirring.

The total radiation from a vertical Cooper–Hewitt mercury arc of the ordinary type provided the source of illumination. Light reached the reaction vessel through a quartz window in the copper tank. In the purely photochemical experiments the arc was run on 110 volts and 3.5 amperes, cooled only by an air blast. Its distance from the wall of the reaction vessel was about 2.0 cm. In the photosensitized experiments the arc was water cooled, being placed in the tank with the reaction vessel. It was run on 110 volts and 5.0 amperes, and its distance from the reaction vessel was varied from 0.5 cm. to 6 cm. For the sensitized study, which was made after the completion of the photochemical experiments, mercury vapor was supplied by about 0.5 cc. of mercury forced into the reaction vessel from the manometer.

In order to determine the relation of the reaction rate to the incident light intensity a metal frame containing a slit the width of the arc and half its length was soldered to the copper tank. The distance from slit to the quartz window was about 4 cm. Copper gauze screens of suitable dimensions and blackened by oxidation to cut down stray light served to vary the amount of light. reaching the reaction vessel These could be fixed rigidly in the metal frame between the slit and quartz window. Relative light intensities were measured with a Moll thermopile. A shutter controlled from the position of the galvanometer scale governed the admission of light to the vessel and to the thermopile. For these experiments the arc was placed in a water-bath separate from the reaction vessel and run at a constant temperature of 30° on 110 volts and 5.5 amperes. It was started by breaking down the space charge with a high tension coil so that its position was unchanged throughout the series.

The experiments on the thermal decomposition were carried out in the same system described above, the reaction vessel being surrounded by an electric furnace.

Preparation of Materials.—Hydrazine hydrate, $N_2H_4 \cdot H_2O$, was first prepared from Kahlbaum's C. P. hydrazine sulfate, $N_2H_4 \cdot H_2SO_4$.[6] A concentrated solution of the latter was mixed with the calculated amount of highly concentrated potassium hydroxide solution, an equal volume of alcohol added and the precipitated potassium sulfate removed. The mixture was then distilled up to 118° under ordinary pressure, decanted from a further precipitate of potassium sulfate and fractionated at 121–122 mm. pressure. An all-glass distillation apparatus was employed. The portions distilling between 73 and 74°, consisting of 85 to 97.5% of hydrazine hydrate, served for the preparation of anhydrous hydrazine.

The preparation of anhydrous hydrazine was carried out according to the method of Hale and Shetterly[7] with the modifications suggested by Welsh.[8] The all-glass apparatus described by the former authors was employed. The method consists, briefly, in dehydrating the hydrazine hydrate by refluxing for several hours with a large excess of barium monoxide and then distilling the hydrazine in an atmosphere of hydrogen at a pressure below 300 mm. of mercury. This method avoids action of the hydrazine on glass and has been shown to give a product containing 99.7% of hydrazine. A glass tube with a stopcock attached was sealed directly to the distillation apparatus and evacuated. The liquid hydrazine (b. p. 113.5°) was run into this from time to time during the distillation. It was then sealed off and fused to a second such reservoir attached to the reaction bulb. Contact with air was thus avoided. The hydrazine could then be freed from dissolved gases before use by isothermal distillation from the first container into the second. Dissolved ammonia was removed by evacuation at room temperature. The liquid hydrazine was preserved in *varuo* during the entire research. A sample of its vapor burned over copper oxide gave a pressure of nitrogen closely approximating the theoretical to be expected from a 100% sample of hydrazine. This result, together with the amount of pressure increase upon total decomposition and analysis of the decomposition products, renders the presence of an appreciable amount of the hydrate in the hydrazine vapor employed improbable.

Electrolytic hydrogen and nitrogen from cylinders were used. Hydrogen was purified over hot platinized asbestos and phosphorus pentoxide, and nitrogen pver hot copper turnings and phosphorus pentoxide. The ammonia gas employed was a carefully prepared sample stored in a cylinder over sodium.

Procedure.—Before each experiment the hydrazine container was carefully evacuated in case slight decomposition might have occurred by diffusion of the vapor up to the greased stopcock surface. The reaction system was flushed several times with the vapor. The reaction vessel was filled by allowing hydrazine to vaporize into it under its own vapor pressure at room temperature. The initial pressures thus obtained could be varied from about three to ten millimeters. The arc was then started and the reaction followed by noting the increase of pressure at suitable time intervals. An electric contact between a sealed-in tungsten wire and the mercury of the manometer

[8] Welsh, *ibid.*, 37, 499 (1915).

allowed a delicate adjustment to constant volume. The manometer scale was so arranged that readings could be made to about 0.3 of a millimeter with a fair degree of accuracy. Numerous checks were made on all experiments.

Analysis of Reaction Products.—This could be carried out in the reaction system by means of a small side tube, attached as closely as possible to the quartz bulb and sealed to an electrically heated copper oxide tube through a stopcock. The method of analysis was briefly as follows. Hydrazine remaining after an experiment was first removed by surrounding the side tube with a carbon dioxide–ether freezing mixture, and ammonia determined by replacing this with liquid air. The gases non-condensable in liquid air (H_2 and N_2) were admitted to the copper oxide and the hydrogen burned, the water formed being simultaneously frozen out. The decreases in pressure thus obtained give the amounts of the various gases present; nitrogen was determined by difference. It was necessary to remove any residual hydrazine before admitting the gases to the copper oxide since it was found to reduce this latter in the cold, giving nitrogen and water.

The above method for separating ammonia from hydrazine vapor was shown to give accurate results by analyses of known mixtures of the two. It cannot be employed when the pressure of ammonia gas exceeds approximately 30 mm., the vapor pressure of liquid ammonia at the temperature of a carbon dioxide–ether mixture (–79°).

As carried out, this method of analysis offers the disadvantage that five to six hours are required for its completion. This is due to the slow diffusion of the gases to the freezing zone and the copper oxide. If many analyses are to be made it is desirable to arrange a means of circulating the gases through the system.

Photochemical Decomposition

Course of the Reaction and Products.—Upon illumination with the total radiation from the mercury arc, gaseous hydrazine undergoes decomposition. As will be later discussed, hydrazine vapor shows a marked light absorption in the ultraviolet below about 2400 Å. It is evident, therefore, that it is the portion of the mercury radiation below this wave length which is effective.

As the decomposition progresses the pressure in the system increases to a value three times that of the initial hydrazine,[9] after which no further change occurs. This tripling of the pressure indicates that the final reaction products are nitrogen and hydrogen only, hydrazine decomposition being complete. Analysis of the gaseous products at the end of the reaction confirms this. One experiment gave 64% of hydrogen and 36% of nitrogen, a second, 65% of hydrogen and 35% of nitrogen. The theoretical is 66.7% of hydrogen and 33.3% of nitrogen.

Hydrazine, however, does not decompose directly into the elementary constituents, but into ammonia, nitrogen and hydrogen according to the stoichiometric equation

$$2N_2H_4 \longrightarrow 2NH_3 + N_2 + H_2 \qquad (1)$$

The ammonia subsequently decomposes photochemically into nitrogen and hydrogen

$$2NH_3 \longrightarrow N_2 + 3H_2 \qquad (2)$$

---

[9] In several experiments slight overrunning of this three-fold value was obtained. This is undoubtedly to be attributed to traces of hydrazine condensed or adsorbed on the walls of the quartz vessel.

at a slower rate. These facts were ascertained by analysis of the gaseous products at various stages of the reaction. Ammonia was found present up to the end of the reaction. The ratio of ammonia to nitrogen and hydrogen decreased as the reaction proceeded. Table I gives the results of analyses made after varying amounts of decomposition. The initial pressures of hydrazine were constant to about 0.5 of a millimeter.

TABLE I

VARIATION OF COMPOSITION OF PRODUCTS WITH EXTENT OF DECOMPOSITION

Expt.	Press. of total prod., mm.	Press. of NH_3, mm.	Comp. of total products			Comp. non-condensed gases	
			NH_3, %	H_2, %	N_2, %	H_2, %	N_2, %
37	6.1	2.2	38	32	30	52	48
35	12.2	3.8	32	34	34	50	50(?)
38	13.4	4.2	31	39	30	56	44
36	16.2	5.1	31	38	31	55	45
39	24.1	1.8	8	55	37	60	40
28	26.5	<0.5	0	65	35	65	35
Theoretical for no decomp. of NH_3			50	25	25	50	50

As the table shows, the actual quantity of ammonia found in the products first increases and then decreases upon continued illumination. All ammonia finally disappears as the pressure attains a three-fold value.

On account of the fact that the rates of hydrazine and of ammonia decomposition are of the same relative order of magnitude, the two reactions could not be isolated in the photochemical experiments. The use of monochromatic light would not affect this since the two substances absorb in practically identical spectral regions. The maximum amount of ammonia obtained in any experiment corresponded to 77% of that to be expected from decomposition according to Equation 1. It will be seen later that a sharp separation was made in the sensitized experiments.

It is of interest to note that gaseous hydrogen azide (HN_3) is photochemically decomposed[10] by ultraviolet radiation from an aluminum spark. In this case, also, the products of the reaction are hydrogen, nitrogen and ammonia (ammonium azide). It is probable that the formation of ammonium azide, noticed on longer illumination, is the result of a secondary reaction between the ammonia produced and hydrogen azide

$$NH_3 + HN_3 \longrightarrow NH_4N_3$$

Rate of the Decomposition.—The photochemical decomposition of hydrazine is more rapid than that of ammonia. In Table II are given the data for a typical experiment. The rates in the last column are the average increases of pressure per minute taken over the intervals of time between manometer readings. It will be noticed that a definite change in rate occurs at a pressure approximately double that of the initial. The apparent constancy over successive periods is due to the method of averaging

---

[10] Beckman and Dickinson, THIS JOURNAL, 50,1870 (1928).

and to the fact that pressure could not be read to less than several tenths of millimeter.

In Fig. 1 time of illumination is plotted against pressure increase for several representative experiments. Under the experimental conditions,

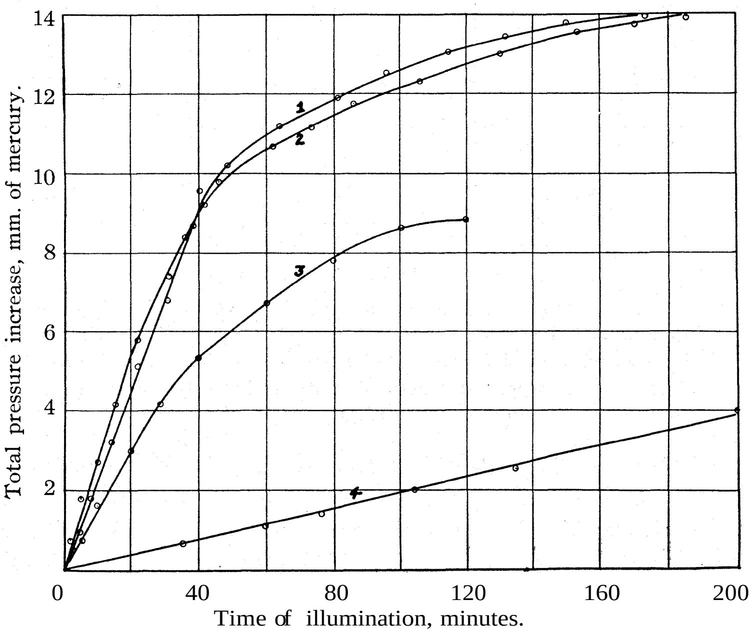

Fig. 1.—Rates of the photochemical decomposition. Curves 1, 2 and 3, hydrazine at initial pressures of 9.8 mm., 8.6 mm. and 4.3 mm., respectively. Curve 4, ammonia at an initial pressure of 14 mm.

doubling of the pressure generally occurred in thirty to forty minutes, tripling, in four to five hours. The initial hydrazine pressures varied from six to ten millimeters. The half-time values determined from the curves of Fig. 1 indicate the reaction to be unimolecular in character. The apparent unimolecularity is without meaning, since the pressures obtained are the resultants of those given by two reactions. A unimolecular reaction order is also to be expected if the light absorption is not nearly complete. The amount of light absorbed then becomes directly proportional to the concentration of reactant. The first portions of the rate curves are predominantly hydrazine decomposition, the last portions predominantly ammonia. It was impossible with the present experimental arrangement to vary the initial hydrazine pressure sufficiently to determine its effect, but the rate is approximately directly proportional to it (see Figs. 1 and 2).

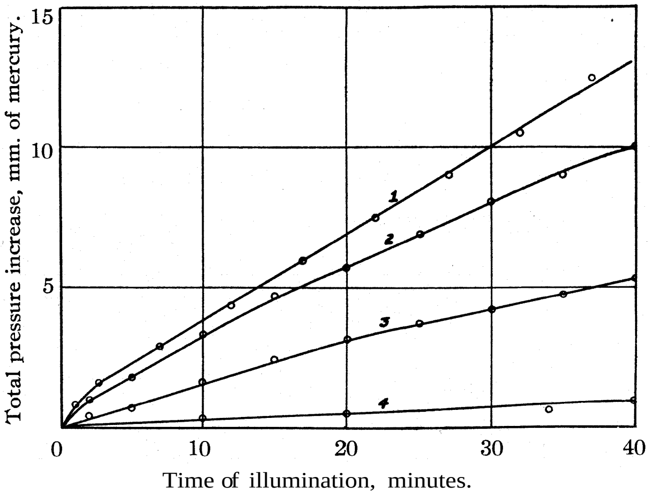

Fig. 2.—Rates of the photochemical decomposition for the first half of the total reaction. Curves 1, 2 and 3, hydrazine at initial pressures of 12.6 mm., 9.9 mm. and 4.3 mm., respectively. These curves represent practically entirely hydrazine decomposition. Curve 4, ammonia at initial pressure of 14 mm.

Temperature.—The rate of decomposition is independent of the temperature over the range studied, 15 to 45°. Experiments were made under practically identical conditions of illumination and hydrazine concentration, the only controllable variable being temperature. The increase in rate of ammonia decomposition in this temperature range is negligible.

Comparison of Hydrazine and Ammonia.—The rate of photochemical ammonia decomposition was investigated in the same system. The conditions of illumination and temperature were identical with those used in the hydrazine experiments. In Fig. 2 the rate curves for hydrazine, up to a doubling of the pressure, are plotted for experiments with conditions comparable to those where ammonia was studied. The ammonia curve is shown on Figs. 1 and 2. The curves given in Pig. 2 represent practically entirely hydrazine decomposition over the initial two-thirds, since ammonia decomposition is slow. Both hydrazine and ammonia curves may be taken'as straight lines without appreciable error. A comparison of the slopes, where the pressures are comparable, shows that the hydrazine reaction proceeds at ten times the rate of the ammonia reaction. This result is probably correct within 10%.

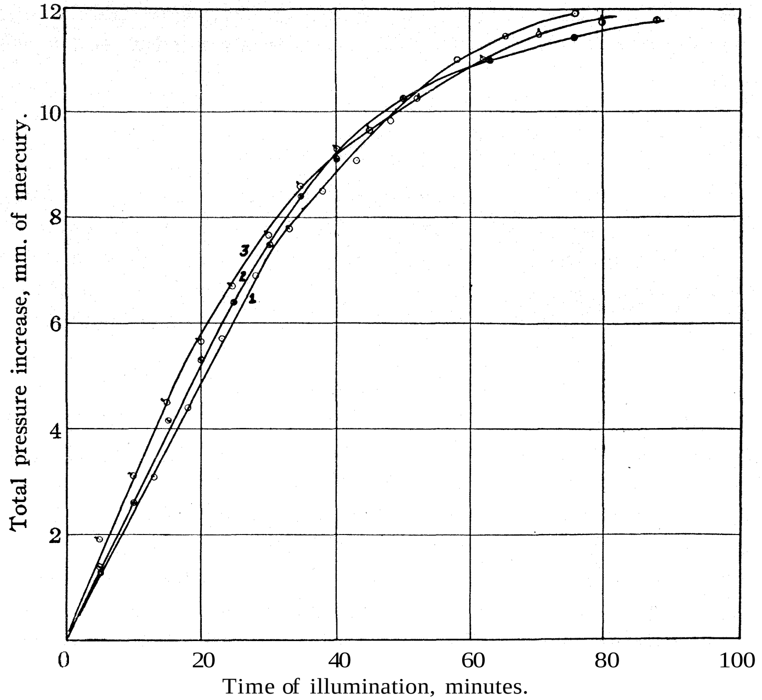

Fig. 3.—Effect of added gases on the rate of photochemical decomposition. Curve 1, hydrazine alone, initial pressure 8.9 mm. Curve 2, hydrazine with hydrogen present; pressure of hydrazine 8.6 mm., pressure of hydrogen, 8.0 mm. Curve 3, hydrazine with ammonia present; pressure of hydrazine 9.1 mm., pressure of ammonia 18.6 mm.

Effect of Added Gases.—Addition of nitrogen, hydrogen or ammonia to the hydrazine does not affect its rate of decomposition. Experiments were made in which these gases were added to hydrazine in concentrations up to twice its concentration. Fig. 3 contains rate curves for experiments with hydrazine alone and with ammonia and hydrogen present initially. The curves coincide within experimental error. Small variations from one experiment to another occurred with hydrazine alone. These may be attributed to small variations in the intensity of the arc and in initial hydrazine pressure. Ammonia decomposition is of course occurring simultaneously with that of hydrazine where ammonia is present, but the increase in rate due to this is negligible as compared with that of the latter.

Thermal Decomposition of Hydrazine

During the course of the photochemical experiments it was thought of interest to investigate the thermal decomposition of gaseous hydrazine since this could be accomplished readily in the same experimental system. It was found that in a quartz bulb hydrazine begins to decompose thermally at about 250°. The reaction products in this case were mainly ammonia and nitrogen in amount indicating decomposition according to the stoichiometric equation

$$3N_2H_4 \longrightarrow 4NH_3 + N_2 \qquad (3)$$

and not

$$2N_2H_4 \longrightarrow 2NH_3 + N_2 + H_2$$

as was found in the photochemical experiments. The compositions of the reaction products in two experiments were: (1) 71% of ammonia, 24% of nitrogen, 5% of hydrogen; and (2) 68% of ammonia, 26% of nitrogen and 6% of hydrogen; the theoretical on the basis of Equation **3** should be 80% of ammonia, 20% of nitrogen and no hydrogen. Consequently, a small amount of reaction takes place in such a manner as to yield hydrogen. Experiment showed no decomposition of ammonia in the quartz bulb in several hours at 500°. It may be noted that the pressure increase observed on total decomposition of a sample of hydrazine was approximately 5 to 3, which is that to be expected from Equation 3.

Since these results indicated a termolecular reaction order, Mr. Askey has carried out a kinetic investigation of the reaction in this Laboratory. His results[11] show that the thermal hydrazine decomposition is heterogeneous, taking place on the quartz surface, and is unimolecular in character. He has also found that on the surface of a heated platinum or tungsten wire the reaction occurs according to the same equation as photochemically.

Photosensitized Decomposition

When sensitized to light of 2537 Å. by mercury vapor, photochemical decomposition of hydrazine occurs. No decomposition takes place on standing in contact with mercury. The results of the sensitized studies are the most important obtained, since in this case the radiation is practically monochromatic, absorption undoubtedly complete and the concentration of the absorbing material unchanged as reaction proceeds. They enable us to formulate a mechanism for the reaction.

Reaction Products.—The decomposition of hydrazine by excited mercury atoms yields ammonia, nitrogen and hydrogen as products and takes place according to the stoichiometric equation

$$2N_2H_4 \longrightarrow 2NH_3 + N_2 + H_2$$

as does the purely photochemical reaction.

Several experiments were made with the flow system previously men-

---

[11] Unpublished.

tioned.[4] Hydrazine vapor was passed through the arc, condensable products were removed with liquid air and the permanent gases analyzed. In one experiment these gave 47% of hydrogen and 53% of nitrogen; in a second, 48% of hydrogen and 52% of nitrogen. The theoretical for the above equation is 50% of hydrogen and 50% of nitrogen. The slight deficiency in hydrogen is undoubtedly to be ascribed to clean-up of atomic hydrogen on the walls.

When photosensitized by mercury vapor the rate of hydrazine decomposition so greatly exceeds that of ammonia that a nearly complete separation of the two reactions is possible. A very rapid increase in pressure ends when a doubling of the initial has been reached. This corresponds to complete hydrazine decomposition according to the above equation. Table III gives the results of analyses of the products made at this point.

TABLE III

COMPOSITION OF PRODUCTS FROM THE SENSITIZED REACTION

Expt.	Total products NH_3, %	 H_2, %	 N_2, %	Non-condensable gases H_2, %	 N_2, %
44	45	25	30	45	55
45	49	25	26	50	50
Calcd. for no NH_3 decomp.	50	25	25	50	50
Sensitized NH_3 decomposition				72	28

In another experiment where hydrogen was present initially 48% of ammonia was obtained. The quantity of ammonia found corresponds to 90 to 95% of the theoretical. The excess of nitrogen may be attributed to clean-up of hydrogen. Any error is magnified since nitrogen was obtained by difference. Dickinson and Mitchell[12] found 70% of hydrogen in the products of the sensitized decomposition of ammonia in a static system. Our value, 72%, checks this closely.

Rate of the Decomposition.—The decomposition of hydrazine is the most rapid reaction thus far obtained in this Laboratory with excited mercury. In Fig. 4 is plotted increase of pressure with time of illumination for several typical experiments. The temperature used was 30°. Increase of pressure proceeds rapidly to a point corresponding to a doubling of the initial and to complete hydrazine decomposition. As can be seen from the figure a very sharp break in the curves is evident at this point. Beyond, the pressure increases very slowly toward a three-fold value as decomposition of the ammonia formed proceeds. Ten millimeters of gaseous hydrazine are decomposed in less than three minutes with the arc at 5-mm. distance, in four minutes at 20 mm. and in twelve minutes at a distance of 60 mm. In later experiments the reaction rate was followed more readily by cutting down the light intensity with a blackened copper gauze screen.

Comparison of Hydrazine and Ammonia.—A curve for the rate of

---

[12] Dickinson and Mitchell, *Proc. Nat. Acad. Sci.*, 12, 692 (1926).

ammonia decomposition under identical conditions of mercury vapor concentration and illumination with resonance radiation is given on the same figure. The large difference in the rates for hydrazine and ammonia is evident. The curves for hydrazine and for ammonia are linear within experimental error. Comparison of their slopes, $\Delta p/\Delta t$, shows that hydrazine is decomposed at a rate forty times that of ammonia.

The illumination in the purely photochemical and in the sensitized experiments was only roughly the same, as no effort was made to keep it identical. Several experiments with mercury sensitization were made with the arc at a distance of 2 cm., approximately that in the photochemical. The increased intensity of the 2537 Å. line due to water cooling of the arc would be without appreciable influence on the photochemical reaction since hydrazine does not absorb in this spectral region. We may obtain, therefore, a rough estimate of the ratio of the rate of sensitized to photochemical decomposition by comparison of the slope of the curve for these experiments with that of the photochemical. This gives a value for the rate of the sensitized reaction 110 to 120 times the photochemical rate. This value is probably somewhat high since the arc was burning on a slightly

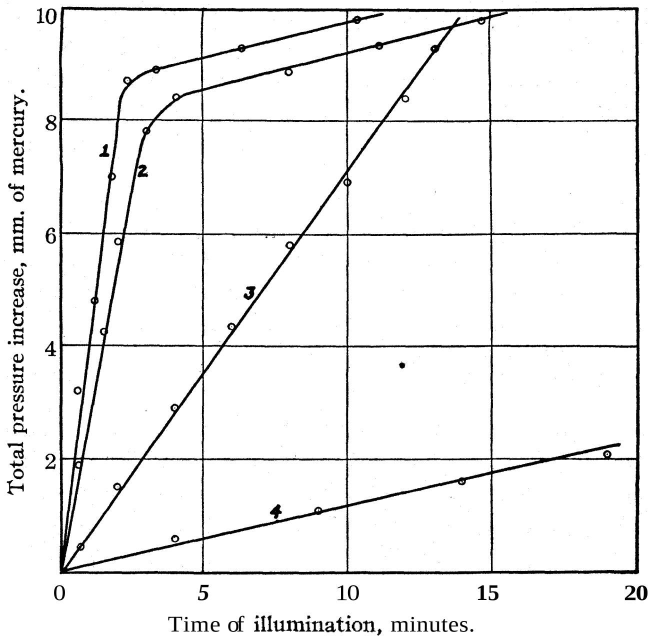

Fig. 4.—Rates of the photosensitized decomposition. Curves 1, 2 and 3, hydrazine; initial pressures 9.4 mm., 9.2 mm. and 10 mm., respectively; arc at distance of 0.5 cm., 2 cm. and 6 cm., respectively. Curve 4, ammonia, initial pressure 16 mm.; arc at distance of 0.5 cm.

higher wattage. From the preceding value we may also calculate that the ratio of sensitized to photochemical ammonia decomposition rate in these experiments is approximately 30 to 1.

Chain Mechanism and Quantum Efficiency.—In order to determine the quantum efficiency in the sensitized hydrazine decomposition, the mercury sensitized combination of hydrogen and oxygen was measured in

[a] With liquid water initially present in the reaction vessel the pressure decrease is the sum of that due to the volume change in the reaction and that due to condensation of water vapor formed; the rate of water formation is, therefore, $^2/_3$ of the total pressure decrease.

[b] Where dry gases were used the rate of water formation is given by twice the pressure decrease. The pressure increase gives directly the rate of N_2H_4 decomposition.

the same system. Mercury vapor concentration and illumination with resonance radiation were identical. Experiments were made with two light intensities. The ratio of hydrogen to oxygen was 2 to 1. It has been shown[13] that the rate of this reaction is independent of total pressure. The results obtained in these experiments are recorded in Table IV.

From the preceding table it is evident that the sensitized decomposition of hydrazine has a rate at least twice that of the combination of hydrogen and oxygen. The latter reaction proceeds through hydrogen peroxide formation,[14] it being possible to obtain practically quantitative yields of this substance by use of a flowing system. In a static system the hydrogen peroxide subsequently undergoes decomposition, the final product being water vapor. Using a flowing method Marshall[14] was able to show that sensitized hydrogen peroxide formation is a chain reaction with chains of at least 4.6 to 6.6 molecules. Since hydrogen peroxide decomposition is represented by the equation

$$2H_2O_2 \longrightarrow 2H_2O + O_2$$

the rate of water formation in the present experiments represents the rate of hydrogen peroxide formation. It is apparent, therefore, that hydrazine decomposition is a chain reaction involving chains at least twice as long as those in the former.

Quantum Efficiency.—With the entire arc cooled with water, the condition in our experiment, a value of 3.3 members was found by Marshall for the chain length and of 6.6 molecules for the quantum efficiency. On the basis of the number of molecules disappearing as indicated by pressure change, a calculation of the quantum efficiency in hydrazine decomposition, from the data of Marshall and that of Table IV, gives a value of 13 molecules *per* absorbed *quantum*. This figure may be regarded as a minimum value. Since collisions of excited mercury atoms with hydrogen molecules are known to be practically inelastic, the higher quantum efficiency for hydrazine cannot be due to difference in collision efficiency. It might very well be that collisions with hydrazine are much less efficient than with hydrogen, which would lead to longer reaction chains in the case of the former.

The rate of hydrazine decomposition was found to be forty times that for ammonia with excited mercury. A value of 13 molecules per quantum would, therefore, correspond to a quantum efficiency of 0.3 molecules for the sensitized ammonia decomposition. While not much confidence may be placed in this figure, it should be noted that Warburg[15] found the quantum yields for the photochemical decomposition to be 0.25 mol./$h\nu$ for light of wave length 2025–2140Å.

Effect of Added Gases on the Rate.—A number of experiments were made in which nitrogen, hydrogen or ammonia was added initially to the hydrazine and the decomposition rate determined. The results are best illustrated by the curves of Fig. 5 and Fig. 6. The hydrazine pressures were from 9 to 11 mm. and the other gases were added in amounts up to 200 mm. In the experiments shown in Fig. 6 the rates were considerably reduced by increasing the distance of the arc and partially screening it with a copper gauze.

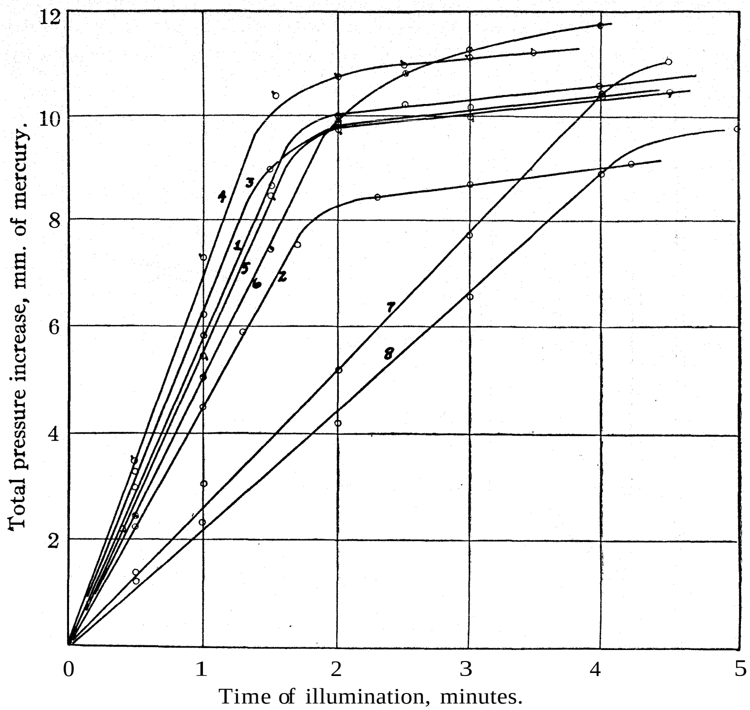

Fig. 5.—Effect of added gases on the rate of the photosensitized decomposition. Curves 1 and 2, hydrazine alone, pressures, 10.5 and 8.5 mm., respectively. Curve 3, hydrazine in presence of nitrogen, pressures, 10.0 and 200 mm., respectively. Curves 4 and 5, hydrazine with hydrogen present; pressure of hydrazine, 10.6 and 9.8 mm., respectively, pressures of hydrogen, 200 mm. and 25 mm., respectively. Curve 6, hydrazine with ammonia present; pressures. 10.8 and 175 mm., respectively. Curves 7 and 8, hydrazine with ammonia and hydrogen present; pressures of hydrazine approximately 10 mm., pressures of ammonia and hydrogen approximately 100 mm. each. Arc at a distance of 0.5 cm. for all these experiments.

Neither the presence of nitrogen, ammonia nor hydrogen exerts appreciable influence upon the rate of the sensitized decomposition; Slight variations in the slopes of the curves occur at random. They are undoubtedly to be attributed to experimental error in reading the time and pressure over small intervals and to slight variations in the arc intensity.

The failure of nitrogen or ammonia pressure to affect the rate is not surprising since their efficiency in quenching excited mercury is known to be very low.[16,17] The failure of hydrogen to affect the rate is, however, interesting. This result is in direct contrast to the sensitized ammonia decomposition which has been shown by Mitchell and Dickinson[17] to be strongly inhibited by small pressures of hydrogen. Practically every collision of excited mercury with hydrogen molecules results in its deactivation.[16] Hydrogen would, therefore, be expected to retard sensitized hydrazine decomposition. Indeed, with hydrogen pressures twenty times that of hydrazine, the retardation would be expected to be directly proportional to hydrogen pressure. The absence of any effect appears to be explicable only on the basis that the energy of those excited mercury atoms colliding with hydrogen molecules is still available for the decomposition of hydrazine.

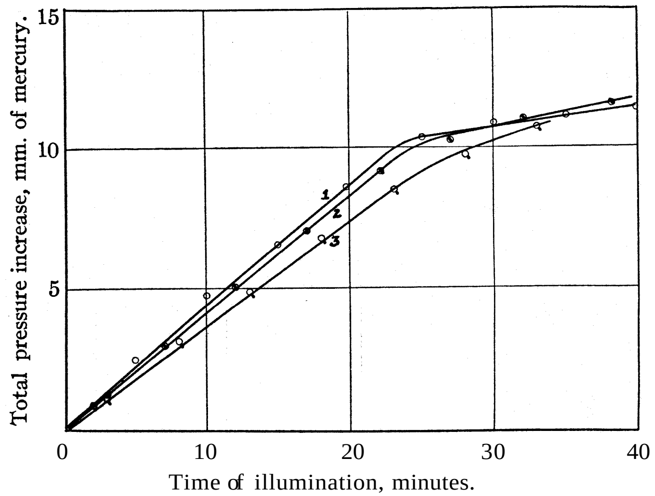

Fig. 6.—Effect of added gases on the rate of the photosensitized decomposition. Curve 1, hydrazine alone; pressure, 10.0 mm. Curve 2, hydrazine with hydrogen present; pressures, 10.0 mm. and 200 mm., respectively. Curve 3, hydrazine with ammonia and hydrogen present; pressures, 9.8 mm, 100 mm. and 100 mm., respectively. Arc at a distance of 6 cm. and screened in these experiments.

We may justifiably assume[18] that a collision of the second kind between

[16] Stuart, Z. *Physik*, **32,** 262 (1925).

[17] Mitchell and Dickinson, THIS JOURNAL, 49, 1478 (1927).

[18] See Taylor, *ibid.*, 48, 2840 (1926), for a partial summary of evidence.

a mercury atom in the 2^3P_1 state and a hydrogen molecule results in the dissociation of the latter

$$Hg' + H_2 \longrightarrow Hg + 2H$$

Hydrogen atoms must, therefore, react with hydrazine. It is our intention to test this conclusion by introducing hydrogen atoms into hydrazine.

Curves 7 and 8 in Fig. 5 for experiments in which mixtures of 100 mm. each of hydrogen and ammonia were admixed with hydrazine show a retardation of the rate, an effect produced by neither gas alone. It cannot, apparently, be attributed to experimental error. We are unable to offer a satisfactory explanation for it.

Effect of Light Intensity.—The reaction rates were considerably reduced by decreasing the light intensity materially and the latter varied by means of the previously described copper gauze screens. Care was taken to prevent variations in the intensity of the 2537 Å. line caused by variations in the running temperature and wattage of the arc. The results are summarized in Table V. Hydrazine pressures were constant to a few per cent. The galvanometer deflections given represent the average of two separate sets of determinations, the average of ten distinct deflections being taken to determine the true deflection for each different intensity. The experiment with no screen intervening was repeated between each of the others as a check. The rates given are the averages for twenty-minute periods taken during the experiment almost to the point of pressure doubling.

Table V

Effect of Incident Light Intensity on the Reaction Rate

	Rates		
	I No Screen	II Screen No 1	III Screen Nos. 1 and 2
Average Δp per 20 min.	2.40	0.91	0.33
Average Δp per 20 min.	2 00	.90	.35
Average Δp per 20 min.	2.20		
Average	2.20 (k_1)	.905 (k_2)	.34 (k_3)
	Relative Light Intensities		
Average galv. deflection	73.39 (l_1)	30.06 (l_2)	12.34 (l_3)
Ratios of reaction rates	$k_1/k_2 = 2.43$		$k_2/k_3 = 2.65$
Ratios of intensities	$l_1/l_2 = 2.44$		$l_2/l_3 = 2.44$

The results show that the velocity of hydrazine decomposition sensitized with mercury vapor is directly proportional to the incident light intensity.

The Absorption Spectrum of Gaseous Hydrazine

The results of studies of molecular spectra have led to the elucidation of the primary photochemical process in several systems involving diatomic molecules. Franck[19] has pointed out that according to the quantum theory

---

[19] Franck, *Trans. Faraday Soc.*, 21, 536 (1925).

of light absorption the immediate result is the formation of an excited molecule, but that the excited molecule may then undergo spontaneous dissociation without the agency of collisions. This is the type of process occurring in the halogens, hydrogen halides and alkali halides. More complex molecules exhibit such complicated band spectra that detailed analysis has been impossible. It now appears quite certain that an entirely continuous molecular absorption spectrum corresponds to a primary dissociation of the molecules. One consisting of bands possessing a fine structure corresponds to a primary excitation of the molecule, which can then undergo dissociation only on collision, provided, of course, that the absorbed energy is comparable with that required for dissociation.

It was first pointed out by Henri[20] that certain molecules give a type of absorption spectrum consisting of diffuse or continuous bands. These bands are not resolvable into distinct lines even with very high dispersion and low pressures. According to Henri, such molecules as NH_3, H_2S, COS and CH_3NH_2 give this type of spectrum. His interpretation of this phenomenon is that the molecule upon light absorption goes into an electronically excited state, no longer quantized as to rotation, in which the molecule is strongly deformed in contrast to ordinary absorption processes. To such a state he gives the name "Predissociation." Bonhoeffer and Farkas[21] have discussed the ammonia spectrum in relation to predissociation, and have presented theoretical and experimental evidence for the assumption that the primary process is a separation of the ammonia molecule into parts, most probably NH_2 and H. They explain the diffuse bands upon the basis of such a process. Kronig[22] has apparently found justification for this idea from a theoretical viewpoint. From considerations based on wave mechanics he calculates that such a process is possible and also calculates the probability that it will occur. In the conclusion to their paper Bonhoeffer and Farkas state that according to the above idea the following cases of molecular decomposition processes must be distinguished. "First, the 'direct' or 'true photolytic processes' in which the molecule decomposes without the agency of outside collisions; secondly, the 'indirect,' in which the molecule is primarily excited and is then decomposed by collision with another molecule. The direct processes can be of various kinds. Either the molecule is primarily dissociated (I_2 in the continuum, HI), or the primarily excited molecule decomposes spontaneously without radiation (NH_3, predissociation spectrum)."

To obtain optical evidence for the primary process following light absorption by the hydrazine molecule we have investigated its absorption spectrum.

Experimental

The continuous ultraviolet spectrum from a hydrogen discharge tube served as a light source for the absorption study. The discharge tube was the water-cooled type first described by Bay and Steiner.[23] It was constructed before their later modifications were published. The tube was run on approximately 10,000 volts and a current of 0.35 to 0 4 ampere. Hydrogen pressures of 8–10 mm. were employed. A side reservoir was attached in such a manner that the addition of hydrogen was simplified. As operated the tube provided a very intense source of continuous ultraviolet light extending to a region somewhat below 2000 Å. One to two minutes were sufficient for an intense exposure with a very narrow slit and the spectrograph at a distance of half a meter. Exposures of five minutes were required at a meter distance. When desired the tube could be operated continuously for several hours. Its spectrum contained several emission lines on the continuous background in the visible and near ultraviolet. No attempt was made to identify or remove them as they were beyond the region in which hydrazine absorbs.

A Type E-2 Hilger quartz spectrograph- giving an average dispersion of 6 Å. per millimeter between $\lambda = 2492$ Å. and X = 2293 A. and 5 Å. per millimeter from $\lambda = 2276$ Å to $\lambda = 2199$ Å. was employed. The spectrum of the copper arc served for reference. The vapor from a sample of the hydrazine used in the photochemical experiments was employed, the absorption tube being refilled before each exposure. Absorption tubes 20 and 80 cm. in length and pressures from several tenths up to ten mm. were used

Results

The spectrograms obtained show that gaseous hydrazine absorbs measurably in the ultraviolet below about 2490 Å. Absorption becomes appreciable below 2440 Å. The spectrum consists of a series of faint diffuse bands which appear to become wider and more diffuse toward shorter wave lengths. Apparently continuous absorption then sets in and becomes stronger toward the ultraviolet. With an absorbing thickness of 80 cm. and a pressure of 0.5 mm. the band absorption commences at about 2490 Å., continuous absorption beginning at about 2370 Å. It was not possible to produce absorption of longer wave lengths by increasing the pressure to 10 mm. With the absorbing thickness reduced to 20 cm. and at about 1 mm. pressure, faint indications of the bands are visible down to 2260 Å. Below, a region of apparently continuous absorption extends. Lowering of the pressure to a few tenths of a millimeter did not extend the beginning of the continuum further toward shorter wave lengths. On account of their faintness the bands are scarcely visible on a reproduction of the spectrograms.

There appear to be six or seven separate diffuse bands between 2490 and 2260 Å., separated by equal intervals of about 3 or 4 Å. Those from 2490 to 2370 Å. are more sharply defined. The bands range in width from 8 Å. to approximately 25 Å. toward the ultraviolet. The limits, however, cannot be indicated with precision. They appear to be absolutely continuous and resemble closely those obtained by Henri[20] with methylamine in the

---

[23] Bay and Steiner, Z. *Physik,* **45, 337** (1927); **Z. *Elektrochem* , 34,** 660 **(1928).**

region from 2362 to 2288 Å. and the bands of ammonia, which occur from 2260 to 1600 Å.,[24] although separated by considerably smaller intervals than in these cases. Conclusive evidence as to whether the bands of the hydrazine absorption spectrum may be resolved into fine lines will have to be obtained with an instrument giving higher dispersion. This was not available during the performance of these experiments. It appears for the present, however, that in hydrazine we have also a case of "predissociation."

Discussion

Hydrazine Decomposition.—While the results of the purely photochemical study may be regarded as only qualitative, those obtained in the sensitized decomposition provide quantitative information from which a reaction mechanism may be obtained. The experimental observations for which a theory of the reaction mechanism must account are, briefly: (1) the nature of the products, (2) speed of reaction and chain mechanism and *(3)* the absence of retardation by hydrogen, which is most easily understandable on the basis that atomic hydrogen reacts with hydrazine.

For the primary process following reception of energy by the hydrazine molecule on a collision of the second kind with excited mercury or by absorption of a light quantum, we need consider only two possibilities. The formation of an activated hydrazine molecule may take place, reaction then occurring only on collision with a normal molecule. Alternatively, the primarily excited molecule may split directly into parts which then undergo reaction with normal molecules.

The mechanism based on the first possibility would be

$$N_2H_4 + Hg' \longrightarrow N_2H_4' + Hg$$
$$N_2H_4' + N_2H_4 \longrightarrow 2NH_3 + N_2 + H_2$$

This leads to a value of two molecules as the maximum possible quantum efficiency. It does not agree with the observed minimum quantum efficiency of 13 molecules or the chain mechanism, nor will it account satisfactorily for the failure of hydrogen to retard the rate.

Formulation of a mechanism based on the second possibility leads to more satisfactory results. Four possible ways in which the primarily excited molecule may split must be considered. These are

$$N_2H_4 + Hg' \longrightarrow N_2H_4' + Hg$$
$$\text{(a)}\quad N_2H_4' \longrightarrow N_2H_3 + H$$
$$\text{(b)}\quad N_2H_4' \longrightarrow 2NH_2$$
$$\text{(c)}\quad N_2H_4' \longrightarrow N_2H_2 + H_2$$
$$\text{(d)}\quad N_2H_4' \longrightarrow NH_3 + NH$$

On the basis of the most recently accepted value of 9.5 volts,[25] or 219,000 calories, for the heat of dissociation of the nitrogen molecule, breakage of

---

[24] Leifson, *Astrophys. J.*, 63, 73 (1926).

[25] Mulliken, *Phys. Review*, 32, 761 (1928).

a N–H bond requires 90,000 calories of energy. The energy available from an excited mercury atom is 112,000 calories, so that (a) is possible from the standpoint of energetics. The heat of formation of anhydrous hydrazine has not been measured, nor are data for the energy of an N–N bond in such a case available. It is, therefore, impossible to calculate with certainty whether the quantum of absorbed energy is sufficient for the other three processes. Some idea as to the energy required ruay be obtained in the following manner. The reaction $N_2 + 2H_2 + \text{aq} \longrightarrow N_2H_4$ (dissolved) is endothermic by 9500 calories.[26] In solution hydrazine exists as the hydrate. There is justification for the belief that the heats of solution and of hydration are positive, which leads to the conclusion that the formation of anhydrous hydrazine from the elements is endothermic by an amount greater than, say, 10,000 calories. If we take this value for the heat of formation of hydrazine, 90,000 calories as the heat of formation of an N–H bond and values of 101,000 calories for the heat of dissociation of hydrogen and 219,000 calories for that of nitrogen, we may calculate that Process (b) requires 49,000 calories and (d) 49,000 calories. On the assumption that the energy required is that for breaking two N–H bonds independently, minus the heat of combination of two hydrogen atoms, we obtain for Process (c) a value of 80,000 calories. All four types would then be possible with the quantum of 112,000 calories. It is uncertain as to how much confidence may be placed in the results of such calculations.

The sequence of secondary reactions which must follow in case (c)

$$N_2H_2 + N_2H_4 \longrightarrow 2NH_3 + N_2$$

and in case (d)

$$NH + N_2H_4 \longrightarrow NH_3 + N_2 + H_2$$

while accounting for the products, eliminate these as possible mechanisms. They will not account for the observed chain mechanism or for non-retardation by hydrogen. It has been found[27] that hydrazine is formed when ammonia is passed through a cooled high tension arc. The authors state that the most probable explanation lies in a decomposition of the ammonia into NH and H_2 by electron impact, and formation of hydrazine by the reaction

$$NH + NH_3 \longrightarrow N_2H_4$$

In this case ammonia should retard the rate if the mechanism were according to (d). This is contrary to experimental fact.

Assumption of either (a) or (b) as the primary process leads to a mechanism better in accord with our experimental observations. Thus

$$N_2H_4 + Hg' \longrightarrow N_2H_4' + Hg \longrightarrow N_2H_3 + H + Hg \qquad (1)$$
$$N_2H_3 + N_2H_4 \longrightarrow 2NH_3 + N_2 + H \qquad (2)$$
$$H + N_2H_4 \longrightarrow N_2H_3 + H_2 \qquad (3)$$

[27] **G.** *Bredig and A.* Koenig, *Naturwissenschaften,* **24,493 (1928).**

Reactions such as

$$\left.\begin{array}{r} H + H \longrightarrow H_2 \\ N_2H_3 + H \longrightarrow N_2H_4 \end{array}\right\}\text{ wall reaction} \qquad \begin{array}{r}(4)\\(5)\end{array}$$

woud lead to breaking of the reaction chains. With (b) the mechanism would be

$$\begin{array}{rl} N_2H_4 + Hg' \longrightarrow N_2H_4' + Hg \longrightarrow 2NH_2 + Hg & (1) \\ NH_2 + N_2H_4 \longrightarrow NH_3 + N_2 + H_2 + H & (2) \\ H + N_2H_4 \longrightarrow NH_2 + NH_3 & (3) \end{array}$$

The reactions

$$\left.\begin{array}{r} H + H \longrightarrow H_2 \\ NH_2 + NH_2 \longrightarrow N_2H_4 \end{array}\right\}\text{ wall reaction} \qquad \begin{array}{r}(4)\\(5)\end{array}$$

break the reaction chains. The reaction, $NH_2 + H_2 \longrightarrow NH3 + H$, which may be suggested, is endothermic by about 11,000 cal. and probably does not play a material role at room temperatures. Either of the above mechanisms satisfactorily accounts for the observed facts.

Either of the above mechanisms, on the assumption that reactions such as (4) and *(5)* limit the reaction chains, requires a proportionality of the reaction rate to incident light intensity involving the square root of the latter.[28] In the present instance the rate is directly proportional to the incident intensity. This is reconciled with the postulated mechanisms if we assume that Reactions 4 and 5 take place on the walls of the containing vessel, the rate of disappearance then being unimolecular with respect to the concentrations. It is probable that such reactions never take place except on the walls of the containing vessel. Similar disagreement exists for other photochemical reactions and is thus explained.

The evidence at present available offers no basis upon which to decide which of the preceding mechanisms is the more probable. It may be of interest to record the thermal values for the various secondary reactions given, calculated from the previously assumed thermal date.

$$\begin{array}{r} H + N_2H_4 \longrightarrow N_2H_3 + H + 11{,}000\text{ cal.} \\ H + N_2H_4 \longrightarrow NH_2 + NH_3 + 40{,}000\text{ cal.} \\ N_2H_3 + N_2H_4 \longrightarrow 2NH_3 + N_2 + H + 28{,}000\text{ cal.} \\ NH_2 + N_2H_4 \longrightarrow NH_3 + N_2 + H_2 + H - 1000\text{ cal.} \end{array}$$

While the mechanisms formulated are based on the results of the investigation of the sensitized decomposition, there is no reason to believe that the purely photochemical decomposition proceeds by another mechanism,

The spectral evidence offered by the hydrazine absorption spectrum is not entirely conclusive. It is, however, in accord with our suggested mechanism if we accept the Bonhoeffer and Parkas conclusion[21] concerning the process giving rise to a spectrum consisting of continuous bands. Indeed, we may state that if it can be conclusively shown that the hydra-

---

[28] Kistiakowsky, "Photochemical Processes," The Chemical Catalog Company, Inc., New York, 1928, p. 96.

zine bands do not possess a fine structure our results provide strong evidence in support of this idea concerning the Henri "predissociation spectra." A study of the photochemical decomposition of methylamine, which has been definitely shown by Henri to possess a spectrum of this type, should prove of interest in this connection, Such a study is to be undertaken.

This investigation was carried out during the tenure, by one of us (J.C.E.), of a du Pont Fellowship at Princeton University. We take this opportunity of expressing to the E. I. du Pont de Nemours Company of Wilmington, Delaware, our sincere appreciation of this assistance.

Summary

Gaseous hydrazine is decomposed photochemically by the ultraviolet radiation from a quartz mercury arc. A more rapid decomposition is brought about by optically excited mercury atoms. The products of the reaction in both cases are ammonia, nitrogen and hydrogen in amounts indicating a reaction according to the stoichiometric equation $2N_2H_4 \longrightarrow 2NH_3 + N_2 + H_2$. Decomposition of the ammonia formed follows this reaction.

The products from the thermal decomposition in a quartz bulb indicate reaction mainly according to the equation $3N_2H_4 \longrightarrow 4NH_3 + N_2$. The reaction is heterogeneous and unimolecular in character.

The rate of the purely photochemical decomposition is uninfluenced by temperature or by the presence of large concentrations of ammonia or hydrogen. The photochemical decomposition of ammonia proceeds at a rate one-tenth that of hydrazine under the same conditions.

The sensitized hydrazine decomposition is a very rapid reaction. Its rate is forty times that of ammonia under identical conditions. Hydrazine decomposition is a chain reaction. A minimum quantum efficiency of 13 molecules per absorbed quantum has been found for it. The rate of the sensitized reaction is unaffected by the presence of nitrogen, ammonia or hydrogen in large concentrations. The lack of retardation by hydrogen is explained on the basis that hydrogen atoms react with hydrazine. The rate of the sensitized decomposition is directly proportional to the incident light intensity.

The absorption spectrum of gaseous hydrazine has been investigated. Hydrazine vapor absorbs appreciably in the ultraviolet below 2440 Å. The spectrum consists of a series of faint, apparently continuous bands, followed by a region of continuous absorption. The limits of the regions of absorption depend upon the density of the absorbing layer. With the dispersion employed it cannot be stated conclusively that the absorption bands do not possess a fine structure. It appears for the present that hydrazine presents a case of "predissociation."

The results obtained are satisfactorily explained by a reaction mechanism based upon a dissociation of the primarily excited molecule as a primary process and not one involving an activated molecule. Agreement is obtained if the dissociation is either into N_2H_3 and H or $2NH_2$. Thermal calculations for the various primary and secondary processes discussed are given. The nature of the absorption spectrum is in accord with such a mechanism if the idea of Bonhoeffer and Farkas be accepted.

THE SOLUBILITY OF CALCIUM CARBONATE (CALCITE) IN CERTAIN AQUEOUS SOLUTIONS AT 25°[1]

BY G. L. FREAR[2] AND JOHN JOHNSTON

RECEIVED MARCH 20, 1929 PUBLISHED JULY 5, 1929

The solubility of calcium carbonate in aqueous solutions, as influenced by the partial pressure of carbon dioxide in the system and by the presence of other salts, is of interest because of its significance in relation to the problem of scale formation in steam boilers and pipes, to the study of bone calcification and of blood equilibria in physiological systems, and to a better understanding of the process of deposition of carbonates under geological conditions. The work to be presented comprises precise determinations of the solubility of calcite at 25° in the presence of carbon dioxide at pressures varying from 0.0003 to 1.0 atmosphere, in water and in a series of solutions of sodium chloride and of calcium sulfate, including solutions saturated also with respect to gypsum ($CaSO_4 \cdot 2H_2O$).

The papers on the solubility of calcium carbonate in water, prior to 1915, have been reviewed in an earlier paper;[3] since that time a number of other contributions have been published.[4] A plot of all of the data,

including Kline's results (presented later, in Table 111), leads to the following values.[5]

TABLE I

THE SOLUBILITY OF CALCITE AT 25°

CO_2, partial pressure, atm.	0.00032	0.001	0.01	0.1	1.0	10
$CaCO_3$, millimoles per kilo water	0.53	0.78	1.7	3.9	9.0	22.5

The temperature coefficient of the solubility is, within the accuracy of the measurements, independent of the partial pressure of carbon dioxide, particularly in the range 0.0003–1 atm.; consequently it suffices to give the ratio r of the solubility at $t°$ to that at 25°.

TABLE II

THE RATIO (r) OF THE SOLUBILITY AT $t°$ TO THAT AT 25°

t	0°	10°	20°	25°	30°	50°
r	1.8	1.4	1.1	1.0	0.9	0.6

These values of r are on the line $\log r = 830/T - 2.78$; this formula, when extrapolated to 100°, yields results in harmony with analyses of waters from boilers.

In presenting our results we shall adopt a notation made use of in a previous paper,[6] dealing with equilibrium in solutions of alkali carbonates in terms of activities. The activity of carbonic acid (H_2CO_3)[7] may be written

$$(H_2CO_3) = \gamma\lambda cP \qquad (1)$$

where P is the partial pressure, in atmospheres, of carbon dioxide in the gas phase in equilibrium with the solution; c is the total molal concentration of carbon dioxide in the solution when P is unity and γ and λ are the activity coefficients of H_2CO_3 and of water, respectively. We also write

$$(H^+)(HCO_3^-)/(H_2CO_3) = K_1$$
$$(H^+)(CO_3^=)/(HCO_3^-) = K_2$$
$$(Ca^{++})(CO_3^=) = K_C$$

K_C being the activity product constant for calcium carbonate (calcite); whence by combination with (1)

$$(Ca^{++})(HCO_3^-)^2/P = \gamma\lambda cK_CK_1/K_2 \qquad (2)$$

If α_1 and α_2 denote the activity coefficients of Ca^{++} and HCO_3^-, respectively, and m_1 and m_2 the corresponding molalities, Equation 2 may be written

$$P/m_1m_2^2 = \alpha_1\alpha_2^2(K_2/(K_1K_C\gamma\lambda c)) = f'(m) \qquad (3a)$$

Determinations, in a series of equilibrated solutions, of the quantities P, m_1 and m_2 enable one to calculate directly the corresponding value of the function f'(m). Equation 3a may be more conveniently expressed

---

[5] With respect to the solubility at smaller pressure, see Johnston and Williamson, THIS JOURNAL, 38,975 (1916).

[6] Walker, Bray and Johnston, *ibid.*, 49,1235 (1927).

[7] Parentheses denote an activity; brackets, a concentration.

in terms of the mean molality m and the mean activity coefficient α of $Ca(HCO_3)_2$. By definition $m = \sqrt[3]{m_1m_2^2}$ and $\alpha = \sqrt[3]{\alpha_1\alpha_2^2}$. It follows that

$$P^{1/3}/m = \alpha\sqrt[3]{K_2/(K_1K_C\gamma\lambda c)} = f(m) \tag{3}$$

The function $f(m)$ contains a factor K_2/K_1K_C independent of concentration; as m and P approach zero, α_1 and α_2 by definition approach unity; when $m_1 = 0$, c_0 is the solubility of carbon dioxide in water and we have $c_0\gamma_0\lambda_0 = c\gamma\lambda$. Thus by plotting $f(m)$, evaluated directly from the experimental results, against the concentration, we are enabled to estimate $f(0)$, the value of $f(m)$ obtained by extrapolation to zero concentration of salt and, since $(\alpha_1\alpha_2^2)_m/(\alpha_1\alpha_2^2)_0 = f(m)/f(0)$, by substitution of the appropriate values of the other factors, to calculate, from the intercept $f(0)$, the actual solubility product of calcite applicable at any pressure within the range of solutions investigated if the assumption is made that $(\alpha_2)_0$ is equal to unity, which probably is not seriously in error and is the best approximation than can be made at the present time. In this connection it is important to note that at very small pressures of CO_2, probably of the order of 10^{-14} atm.,[5] the relative amount of Ca^{++} associated with OH^- so far exceeds that present in solution as carbonate and bicarbonate that $Ca(OH)_2$ becomes the stable solid phase in place of $CaCO_3$; thus f(0) is merely a virtual quantity, but this fact does not diminish its significance or interfere with the process of extrapolation.

If, besides calcite, gypsum is in equilibrium with the solution, the additional solid phase imposes the further condition defining the solubility product of gypsum K_G, *i*. e.,

$$(Ca^{++})(SO_4^{=}) = K_G$$

By combination of this condition with relations similar to those developed above, and correcting for incomplete ionization, Stieglitz[8] calculated the saturating concentration of calcium carbonate and of calcium sulfate in sea water as functions of the partial pressure of CO_2 in the atmosphere. Provided that no change in the nature of the solid phases occurs, the equality of the ratios must be valid

$$(CO_3^{=})/(SO_4^{=}) = K_C/K_G \tag{4}$$

However, there is some mineralogical evidence of the possibility of reaction between $CaSO_4$ and $CaCO_3$ (possibly as aragonite) under appropriate conditions with the formation of a solid solution or a double salt, in which event deviations from Equation 4 are to be expected. Thus Doss[9] found that certain fresh water limestones and tuffs contain appre-

ciable quantities of sulfate and of water in proportions approximately equal to their ratio in pure gypsum; the inclusions visible at 2000 diameters' magnification accounted for not more than one-twentieth of the sulfate present. Vater[10] prepared calcite crystals in gypsum solutions and observed that they possessed a high sulfate content which he thought could not be attributed to inclusions of the mother liquor or to ingrown crystals of gypsum.

Little information for the solution of this problem is to be obtained from the results of Shipley and McHaffie[11] in their attempt to investigate, by means of electrometric titration, the influence of calcium sulfate on the hydrogen-ion concentration of carbonate solutions; failure to recognize the interdependence of the equilibria involved in this system led these authors to the unwarranted conclusions that the ionization constants of carbonic acid vary and that alkaline earth bicarbonates do not exist in aqueous solutions.

In unsaturated solutions of $CaSO_4$, the solubility of $CaCO_3$ depends upon the common ion effect and upon the influence of the total ion concentration on the activities of the chemical species involved in the equilibrium. Solubility determinations in solutions of hetero-ionic salts are of interest for the study of the influence of ionic strength on these activities, At best the data of Cameron and his co-workers[12] and of Seyler and Lloyd[13] are of merely qualitative significance as experimental conditions were insufficiently controlled.

The Solubility of Calcite in Water at 25°.[14]—Mixtures of air and carbon dioxide in fixed proportions[15] were passed through reaction flasks, of the type used for the equilibration of solutions of alkali carbonates,[6] containing calcite crystals in contact with conductivity water. After equilibrium had been attained, the partial pressure of carbon dioxide and the total molality of base in solution[16] were determined; the mean results are assembled in the first two columns of Table III. The third column gives the bicarbonate molality $[HCO_3^-]$; the fourth, the ionic strength $\mu = (2[Ca^{++}] + 2[CO_3^{--}] + \frac{1}{2}[HCO_3^-])$; and the last, the function $f(m) = P^{1/3}/m$. The bicarbonate molality was arrived at by deducting from the calcium molality $[Ca^{++}]$ an amount equivalent to the carbonate molality $[CO_3^{--}]$, that of hydroxyl $[OH^-]$ being negligible at the partial pressure of carbon dioxide in these experiments. The correction, which in no case exceeds 2%, may be estimated with sufficient accuracy by introducing into Equation 3 the extrapolated value of $\gamma\lambda c K_1/K_2$ (which is 310)[6] and the activity coeffi-

cient of $MgSO_4$ and of $Ba(IO_3)_2$[17] as approximations to that of $CaCO_3$ and $Ca(HCO_3)_2$ at corresponding ionic strengths; when P exceeds 0.01, the correction is less than the experimental uncertainty in the determination of total base, and so may be neglected. The results so calculated are, we venture to believe, more reliable than any hitherto available.

The Solubility of Calcite in Aqueous Solutions of Calcium Sulfate and of Sodium Chloride.—Calcite for the following experiments was prepared by adding dropwise with constant stirring a solution of ammonium bicarbonate to a purified solution of calcium chloride; after the precipitation had been completed, ammonium chloride was added and the mixture was stirred continuously for several hours at 80°. The product after thorough washing was heated in a Rose crucible in a stream of carbon dioxide to remove any remaining traces of ammonium salts. Examination with a petrographic microscope showed crystals of calcite ranging in average dimensions from 0.01 to 0.1 mm

Natural gypsum, the analysis of which indicated a high purity, was split into small blocks, the fine particles being removed by screening. Sodium chloride was recrystallized from commercial "c. p." stock.

In all of the experiments conducted at roughly one atmosphere of carbon dioxide the procedure employed was very similar to that outlined in the preceding section. In the earlier experiments with lower partial pressures of carbon dioxide, equilibrium was established by causing a motor-driven circulating pump, consisting of mercury valves with a mercury column as piston, to pass a mixture of air and carbon dioxide continuously around a closed glass system consisting of a one-liter pyrex glass reaction flask in series with a group of gas-sampling pipets in parallel with one another. In order to avoid rubber connections, the various parts of the system were joined to one another through mercury seals. The reaction flask was clamped in an air thermostat maintained at a temperature of 25 ± 0.05°. The approach to equilibrium was observed by analyzing the gas phase at intervals; ordinarily a week was allowed for the system to attain equilibrium.

As the circulating system just described did not establish equilibrium so rapidly as had been anticipated, and as the arrangement for sampling was not quite satisfactory, a different form of apparatus (Fig. 1) was devised and used in the later work. The

[17] As given by Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, pp. 344, 375.

purpose of this device is to cause the solution to pass repeatedly back and forth through a filter containing the solid phase so that the movement of the liquid provides the pump action for circulating the gas. The two 200-cc. bulbs (A, A') are joined to a short neck B into each end of which is sealed a perforated glass plate to serve as a partition preventing any of the solid phase from passing into either bulb. Midway between the plates the neck is provided with a wide glass-stoppered side-tube for introducing the crystals of the saturating solute and, if necessary, the wads of cotton to act as filters.[18] Sealed through the ends of the bulbs, Tubes D and D′ are connected by ground-glass joints with the opposite ends of Pipet C, which is provided with suitable stopcocks for isolating a sample of the gas phase. A cam, driven by an electric motor through a train of speed reducers and connected to the equilibrium apparatus through suitable gearing, causes the apparatus to turn from an initially vertical position through a half revolution, to remain upright long enough to allow most of the solution to filter from one bulb to the other and then to return to its original position, where there is another pause before the cycle is repeated. Intermittent oscillation is employed in preference to interrupted rotation as it permits the apparatus to be mounted so that the cylindrical axis of the pipet never occupies a lower level than the solution in the bulbs; thus the danger of blocking the passage of the gas to and through the pipet with solution is avoided. The gas displaced from the lower bulb by the inflowing solution forces an equal volume to bubble from the pipet into the solution in the upper bulb through the upturned tips of Tubes D, D′. This combination of filtration and bubbling affords ample contact of the liquid with the solid and the gas phases without danger of pulverizing the crystals. Trial experiments with calcite at various partial pressures of carbon dioxide indicated that equilibrium conditions are attained in two to three days when the volume of the solution is 100 cc., the weight of calcite is 2 g. and filtration is in progress four minutes of the five in each cycle. The apparatus may be conveniently mounted in a water thermostat. At the end of a run the motion is stopped so as to allow the solution to run completely into the bulb A', the stopcocks on the pipet are closed and the apparatus is removed bodily from the thermostat. The pipet is then disconnected at the ground joints and samples of the equilibrium solution are allowed to run through Stopcock E into tared glass-stoppered flasks containing known weights of standard hydrochloric acid. The stopcock, E, permits regulation of the sample size so as to bring the contents of the titration flasks nearly to the end-point. Owing to the strong tendency of calcium bicarbonate solutions to remain supersaturated when not in contact with solid $CaCO_3$, there is little opportunity for the solution to change in concentration while the samples are being withdrawn.

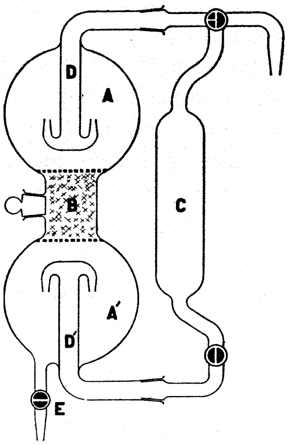

Fig. 1.—Equilibration apparatus.

The data in Table IV were obtained from runs of three or four days' duration. The partial pressure of carbon dioxide in the gas phase was determined by measuring the volume of gas before and after absorption in potassium hydroxide solution; from the known capacity of the pipet

---

[18] When the crystals of the saturating solute are sufficiently large, the cotton may be dispensed with so as to avoid delay in the attainment to equilibrium from absorption effects.

the partial pressure of carbon dioxide could then be computed. The total base content of the solution was then determined in duplicate samples by the customary method except that care was taken to saturate the titrated solution with carbon dioxide gas immediately prior to the addition of the final few drops of standard reagent, the purpose of this precaution being to avoid difficulty in case the carbon dioxide liberated in the titration should be insufficient completely to saturate the mixture. For the determination of sulfate concentrations, precipitation as barium sulfate according to the directions of Johnston and Adams[19] was employed. Sodium chloride concentrations were determined by analysis for chloride either gravimetrically or volumetrically with ammonium thiocyanate and silver nitrate.

The results of the experiments on the solubility of calcite in saturated and in unsaturated calcium sulfate solutions are given in Table IV, which does not include the less precise results secured by means of the mercury circulating pump method except at partial pressures of carbon dioxide under which no corresponding measurements by the improved method were made. The first three columns list the mean experimental determinations of the partial pressure of carbon dioxide in atmospheres and the coexisting molalities of calcium bicarbonate and of calcium sulfate, re-

spectively; the fourth column gives the ionic strength; and the last column contains the values of log $f(m)$ where, as before, $f(m) = P^{1/3}/m$, both experimentally determined.

In Table V are brought together, likewise, the best results of the solubility determinations on calcite in sodium chloride solutions. In most of these experiments the method used was to bubble a stream of carbon dioxide through the salt solution in contact with calcite crystals; the oscillating equilibration apparatus, which was developed later, was employed in the single experiment indicated by the asterisk. A number of results for more concentrated salt solutions than are shown in Table V have not been included because, apparently, complete equilibrium was not attained in spite of the fact that a period of a week was allowed before the final sample was taken. This slowness was especially noticeable in the more concentrated salt solutions, and consequently these results are less concordant. The experimental procedure offers less likelihood of supersaturation than of incomplete saturation, so that the points indicating higher solubility are apparently the more reliable; the single result obtained with the improved form of apparatus is in conformity with this view. The work of Cameron Bell and Robinson[12] indicates a higher solubility than we have observed; their method, however, offers some possibility of supersaturation and their solid phase may not have been pure calcite which, being the most stable, is the least soluble of the three forms of calcium carbonate.

Discussion of Results

The last column of Table III shows again that the concentration of calcium bicarbonate in solution varies roughly as the cube root of the partial pressure of carbon dioxide through the range investigated. Indeed a plot of [$Ca(HCO_3)_2$] against $P^{1/3}$ is the most convenient method of interpolating to ascertain the solubility of calcite at any pressure of carbon dioxide, the graph being nearly linear. When this is done for the data in Table III and IV, we obtain the results listed in Table VI; it also gives, in the fifth column, the saturation concentration [$CaSO_4$] which diminishes as P, and hence [$Ca(HCO_3)_2$] increases.

TABLE VI

COMPARISON OF SOLUBILITY OF CALCITE IN WATER AND IN SOLUTIONS SATURATED ALSO WITH GYPSUM, AT A SERIES OF VALUES OF *P*

		Solubility (millimoles per kilo) of			
		Calcite in		$CaSO_4$ in	
$P^{1/3}$	P	H_2O s	$H_2O-CaSO_4$ s'	$H_2O-CaCO_3$ s''	$s's''/s$
0.5	0.125	4.21	3.16	14.35	10.8
.6	.216	5.13	3.97	14.10	10.9
.7	.343	6.08	4.80	13.83	10.9
.8	.528	7.06	5.76	13.53	11.0
.9	.729	8.04	6.72	13.22	11.1
1.0	1.000	9.02	7.70	12.91	11.0

In order to compare the influence of a change in P upon the solubility of calcite in water and in a calcium sulfate solution of constant concentration, we must make some allowance for the change in the latter which actually occurs when the solution is in contact with solid gypsum. This we have done by computing the quotient in the last column of Table VI; its degree of constancy proves that, for any value of P within this range, the ratio of solubility of calcite in a (dilute) salt solution of constant concentration to that in water is independent of the partial pressure of carbon dioxide. That this is valid follows from Equation 2, for by setting up the corresponding expression for a definite salt solution, and dividing one by the other, we find the ratio of solubilities to be equal to a quotient of corresponding activity coefficients, and this quotient we would expect to be, in general, independent of P. In other words, the solubility of calcite in a given salt solution, if measured at a single partial pressure of carbon dioxide, may readily be calculated for any other pressure through the corresponding slope of the curve in water alone. For this reason we did not trouble to make measurements in sodium chloride solutions except at a single pressure; Table V shows that the influence of salt concentration is very marked, the solubility in 1 molal sodium chloride being practically double that in absence of the salt.

The experimental data are also conveniently treated on the basis of the function $f(m)$. Equation 3 may be written

$$\log f(m) = \log \alpha + {}^1/_3 \log (K_2/K_1\gamma\lambda_C) - {}^1/_3 \log K_C$$

where it is evident that $f(m)$ varies directly as α, since the other terms are constant. As the activity coefficient α is dependent upon the ionic strength, it is of interest to plot the several experimental values of $\log f(m)$ against the square root of the ionic strength; when this is done, the lines for the calcium sulfate and sodium chloride solutions converge to, and then coincide with, the line representing the solubility in absence of other salts.

The value of $f(0)$, derived by extrapolation of this curve to zero ionic strength, is 87.5 ± 0.5. From Equation **3,** since α is now virtually unity, $f(0) = (K_2/K_1\gamma\lambda c)^{1/3}\,(1/K_C)^{1/3} = (\varphi_0)^{1/3}(1/K_C)^{1/3}$; the value of the first factor φ_0 is, from the work of Walker, Bray and Johnston: 310, and therefore K_C, the solubility product constant of calcite in terms of activities is 4.82×10^{-9} at 25°. The difference between this value and that calculated by McCoy and Smith[20] **(9.3×10^{-9})**, by Osaka[21] (7.24×10^{-9}) and by Mitchell[4] (5.88×10^{-9}) is attributable to the different values assumed for the constants and coefficients in the first factor in the equation above.

By applying the expression

$$\log f(0) + \log \alpha = \log f(m)$$

which is derived from Equation 3, to interpolated values of $\log f(m)$ at even values of the total ionic strength, we obtain the activity coefficients of calcium bicarbonate presented in Table VII; these, it may be noted, are higher than usual for salts of the unibivalent type.

In the experiments in which calcium sulfate was one of the solid phases in equilibrium with the solution, the data may be tested as to their agreement with the solubility product of calcium sulfate. Lewis and Randall[22] have compared the results obtained by Harkins and Paine[23] on the solubility of gypsum in the presence of $CuSO_4$, $MgSO_4$ and of KNO_3 by plotting against the ionic strength the ratio $1/m_\pm$ (the reciprocal of the mean molality of calcium sulfate) to γ (the activity coefficient of $MgSO_4$ at the same ionic strength). In our experiments the ionic strength varied only slightly from the average, $\mu = 0.072$ molal; at this strength we find the mean value of the ratio to be 183, as compared with 182 found by Lewis and Randall. This agreement is perhaps as close as can be expected in view of the fact that in one case the common ion is the cation, while in the other it is chiefly the anion.

[20] McCoy and Smith, THIS JOURNAL, **33,468 (1911).**

[21] Osaka, *Mem. Coll. Sci.* ***Kyoto,*** **5, 131 (1922).**

[22] **Ref. 17, p 376.**

[23] Harkins and Paine. THIS JOURNAL, **41,1160 (1919).**

The regularity of the log $f(m)$ curve for calcite, and the agreement of the reciprocal molality–activity coefficient ratio of gypsum with the value obtained by others, may be taken as evidence that the properties of the solid phases are unaltered under the conditions investigated. As a confirmatory test of the view that solid solution and compound formation do not occur under our conditions, it is of interest to consider the effect of the partial pressure of carbon dioxide on the ratio of carbonate ion to sulfate ion in the solution as suggested by Equation 4. A more convenient expression is obtained by dividing **3** by 4, as follows

$$\frac{1}{P}\frac{(Ca^{++})(HCO_3^-)^2}{(Ca^{++})(SO_4^=)} = \frac{(K_1\gamma\lambda_C)\,K_C}{(K_2)\quad K_G} = \varphi_0\frac{K_C}{K_G}$$

or

$$\frac{1}{P}\frac{\alpha^3[Ca^{++}][HCO_3^-]^2}{\beta^2[Ca^{++}][SO_4^=]} = \varphi_0\frac{K_C}{K_G}$$

where by canceling [Ca^{++}][24] and rearranging, we have

$$\frac{[HCO_3^-]^2}{[SO_4^=]} = P\frac{\beta^2}{\alpha^3}\varphi_0\frac{K_C}{K_G}$$

Owing to the slight effect of P upon the ionic strength of the solutions saturated with both calcite and gypsum, α and β are practically constant; a plot of the quotient $[HCO_3^-]^2/[SO_4^=]$ against P should therefore be a smooth, almost linear curve, as it proves to be in spite of the fact that irregularities in the experimental data are accentuated by the presence of a squared term in the quotient. Any marked change in curvature would indicate some change in the solid phases; from its absence we feel justified in concluding that the stable crystalline phases, under the conditions of our measurements, are calcite and gypsum, and that no solid solution or double salt appears. It may be mentioned that there is some evidence[25] that, under similar conditions, aragonite and calcium sulfate do to some extent (apparently up to about 0.7% $CaSO_4$) form solid solutions, an observation which may be of considerable geological significance.

Summary

1. The solubility of calcite at 25° in water saturated with carbon dioxide at partial pressures ranging from 0.0003 to 1.0 atm. has been determined. The solubility product constant of calcite at 25°, in terms of activities, proved to be 4.8×10^{-9}.

2. An apparatus is described which facilitates solubility determinations in systems in which the composition both of the liquid and the gas phase must be ascertained.

3. Measurements are presented of the solubility of calcite at 25° in

---

[24] As α and β are the mean activity coefficients of bicarbonate and sulfate, respectively, the individual ion activities being unknown, it is therefore preferable to cancel the calcium term as a concentration rather than as an activity.

[25] Adverted to earlier, and also in a previous paper, ref. 2f, pp. 508–509.

solutions of calcium sulfate and of sodium chloride under partial pressures of carbon dioxide ranging from 0.1 to 1.0 atm.; from these results the activity coefficients of calcium bicarbonate have been derived. The concentrations of calcium sulfate and carbonate in the solutions saturated with both gypsum and calcite afford no indication of any alteration in the nature of either of these solid phases under these conditions.

THE SOLUBILITY OF MAGNESIUM CARBONATE (NESQUEHONITE) IN WATER AT 25° AND PRESSURES OF CARBON DIOXIDE UP TO ONE ATMOSPHERE[1]

BY WALTER D. KLINE[2]

RECEIVED MARCH 20, 1929 PUBLISHED JULY 5, 1929

The measurements presented in this paper were made with a view to securing more reliable data than were then available[3] on the solubility of magnesium carbonate (nesquehonite, $MgCO_3 \cdot 3H_2O$) in water at 25°, for a range of partial pressures of carbon dioxide extending downward from one atmosphere, and on the limiting pressure at which magnesium hydroxide becomes the stable solid phase in equilibrium with the solution. Such data are of interest in connection with the control of the conditioning of many natural waters and the preparation of pure magnesia, and are a necessary preliminary step toward the solution of the puzzling problem of the mode of formation of dolomite.

[1] From the dissertation presented by W. D. Kline to the Graduate School of Yale University, June, 1923, in candidacy for the degree of Doctor of Philosophy.

[2] Loomis Fellow, 1921–1922; du Pont Fellow, 1922–1923.

[3] (a) Engel, *Ann. chim. phys.*, 13, *344* (1888), determined the equilibrium between $MgCO_3 \cdot 3H_2O$, water and (1) CO_2 at pressures of 0 5–6 atm. at 12°; (2) CO_2 at 1 atm. and several temperatures up to 50°. (b) Leather and Sen, *Memoirs Dept. Agric. India* Chem. Series **3,** No. 8 (1914); sundry measurements, not very reliable. (c) Mitchell, *J. Chem. Soc.*, *123*, 1887 (1923), measured the solubility at 25° at pressures of 6–21 atm. of CO_2. (d) Haehnel, *J. prakt. Chem.*, 108, 61 (1924), made measurements at 18° and pressures 2–56 atm. of CO_2; and at **34** atm. over the temperature range 0–60°. Since, however, the solubility at 18° becomes constant at pressures exceeding 18 atm., this is evidence of a new solid phase, bicarbonate presumably; hence the temperature coefficient of solubility at 34 atrn. does not apply to our solid phase. (e) Cf. also Johnston, THIS JOURNAL, 37,2001 (1915).

In order to compare these several results with ours, they were recalculated in terms of moles per kilo of water by assuming that (a) the solution may be regarded as all bicarbonate; (b) the temperature coefficient of specific gravity of a solution of $Na(HCO_3)$ (given for 18° in "International Critical Tables") is the same as that of water; (c) the ratio of specific gravity of equimolal solutions of $Mg(HCO_3)_2$ and $NaHCO_3$ is the same as that of equimolal solutions of $MgCl_2$ and NaCl. The solubility at 25° was interpolated by means of a plot of log m against $1/T$.

The equations developed in the preceding paper for solutions saturated with calcium carbonate apply equally to magnesium carbonate if for K_c we substitute $K_M = (Mg^{++})(CO_3^{--})$; so that in this case $f(m)$, which is evaluated as $P^{1/3}/m$, is equal to $\alpha\sqrt[3]{K_2/K_1K_M\gamma\lambda c}$.

The form of magnesium carbonate stable in contact with its aqueous solution at 25° is the trihydrate, nesquehonite, $MgCO_3{\cdot}3H_2O$. Numerous basic carbonates have been reported in the literature, but it is doubtful whether any of these correspond to a definite crystalline compound. That some of them at least are indefinite mixtures has been shown by microscopic[4] and by x-ray[6] methods; the probability that all are likewise indefinite may be inferred from a consideration of the factors which determine the stability of hydroxide and of carbonate in aqueous solution. For with decreasing partial pressure of carbon dioxide there corresponds an increase in the ratio $(OH^-)/(CO_3^-)$ and, owing to the fact that magnesium hydroxide is much less soluble than the carbonate, there is a pressure below which the hydroxide becomes the stable solid phase; this limiting pressure was in a previous paper[3]" estimated at about 0.00037 atm. of carbon dioxide, slightly greater than the proportion ordinarily present in air. It is therefore likely that in the precipitation of magnesium carbonate some proportion of hydroxide will also appear unless care is taken to keep the effective concentration of CO_3^{--} high and of OH^- correspondingly low. In any case, if there be any range of carbon dioxide pressure within which a basic carbonate is stable at 25°, this range must lie between the zones of stability of the normal carbonate and the hydroxide; no definite indication of this was observed in the present work.

Experimental

Kahlbaum's magnesium carbonate trihydrate was used as the solid phase in this work, since its analysis and its solubility proved to be identical with those of material prepared with special precautions to obviate contamination by magnesium hydroxide and by double carbonates of magnesium with the alkali metals. Equilibrium was established in three to five days by bubbling mixtures of carbon dioxide and air in constant proportions through conductivity water in contact with the finely divided solid in the manner used for studying the solutions of alkali carbonates;[6] the methods there described were employed in analyzing gas phase and solution. In the determination of total base no attempt was made to correct for incomplete saturation of the titration mixture with carbon dioxide, as the correction was apparently less than the general experimental error. In the determination of bicarbonate, made on 15–20 g.

of the equilibrated solution, the excess of baryta added was limited to 20 milli-equivalents; otherwise the end-point, on titration with acid, was uncertain owing to the gradual re-solution of the magnesium hydroxide precipitated by the excess of baryta.

Table I lists the mean analytical results in the first three columns, respectively, the partial pressure of carbon dioxide, P, and the millimolality (millimoles per kilo water) of magnesium, m_1, and of bicarbonate, m_2. The figures in the fourth column are derived from the relation $[CO_3^{--}] = m_3 = m_1 - {}^1/_2\, m_2$; the ionic strength ($\mu$) in the fifth column is from the data in Cols. 2, 3 and 4; and the values of $[OH-]$, in the last column, as will be described later.

TABLE I

OBSERVED MEAN MOLALITIES OF SOLUTIONS IN EQUILIBRIUM WITH A SERIES OF PRESSURES OF CARBON DIOXIDE AT 25°

.1116	62.66	123.6	0.85	.1889		
.9684	213.5	426.9	..	.6405		

From these data it is obvious that with increase of partial pressure the molality of carbonate increases to a well-defined maximum, when P is about 0.00038 atm., and then decreases more gradually. Corresponding to this it was observed that the appearance of the crystals of $MgCO_3 \cdot 3H_2O$ remained unchanged throughout the course of the experiment at all of the pressures greater than 0.00038; but that at lower pressures the solid phase appeared to become very fine-grained—indicating therefore a change from carbonate to hydroxide, the duration of the experiments being insufficient to ensure complete conversion of the solid phase from carbonate to hydroxide. Accordingly we shall take the transition pressure (P_{tr}) as 0.0004 atm. at 25°, and consider separately the two regions in which carbonate or hydroxide, respectively, is the stable solid phase.

Evaluation of K_M, the Activity-Product Constant of **$MgCO_3{\cdot}3H_2O$.**—By definition $K_M = (Mg^{++})(CO_3^{--}) = m_1m_3\alpha_1\alpha_3$, where m_1 and m_3 represent gross molalities, and α_1 and α_3 the activity coefficients. When the experimental values of log m_1m_3 for pressures above 0.0004 are plotted against $\mu^{1/2}$ they lie—particularly at the more dilute end—on a smooth curve with diminishing curvature, becoming a straight line with the slope 4 (in accordance with the Debye–Hückel theory); the point at which this line cuts the axis $\mu^{1/2} = 0$ (where accordingly α_1 and α_3 are each unity) corresponds to $K_M = 1.1 \times 10^{-5}$.

It may also be evaluated from a plot of log $m_1m_2^2/P$ against $\mu^{1/2}$, extrapolated finally as a straight line of slope **3;** the intersection with the axis corresponds to log K_M + log φ_0, φ_0 being 310.[7] This leads to $K_M = 0.8 \times 10^{-5}$; but we would assign a greater weight to the other value, because this second function is very sensitive. Accordingly we shall adopt for K_M at 25° the value 1×10^{-5}.

Evaluation of K_H, the Activity-Product constant of **$Mg(OH)_2$.**—With a knowledge of K_M and of the transition pressure P_{tr} we may evaluate K_H from the relation

$$K_H = \frac{K_W^2}{\gamma\lambda c K_1 K_2} \times \frac{K_M}{Pt,}$$

which is readily derived by combining[8] the equations of the preceding paper with the definitions $K_H = (Mg^{++})(OH^-)^2$, K_W = (Hf)(OH−). Substituting the values of the several coefficients, we obtain

$$K_H = 2.20 \times 10^{-10} \times \frac{1 \times 10^{-5}}{0.0004} = 5.5 \times 10^{-12}$$

This also may be evaluated in another way. The molality of hydroxyl ion (m_4) is calculated in each case from m_2, P and the appropriate constant~; the resulting values are listed in the last column of Table I. When log $m_1m_4^2$ is plotted against $\mu^{1/2}$ and extrapolated, as before, on an initial slope of **3,** we find an intercept corresponding to $K_H = 2.7 \times 10^{-12}$.

These two values agree as well as could be expected under the circumstances; we consider the higher to be the more reliable. This constant has been given as 12×10^{-12} at 18°, derived from conductivity measure-

---

[7] Cf. preceding paper and ref. 6.

[8] This equation was developed, in slightly different notation, in ref. 3 *e*.

[9] As discussed in ref 6; $[OH^-] = 8.42 \times 10^{-7}[HCO_3^-]/P$.

ments of saturated solutions of magnesium hydroxide[10] and from hydrogen electrode determinations;[11] that it is higher than ours is to be ascribed in part to the difference of temperature (the solubility of magnesium hydroxide is thought to decrease with increase of temperature) and to the method of calculation, but may be largely due to the fact that such direct determinations tend to be high unless carbon dioxide is rigorously excluded from the solution. It may be added that Greenfield and Buswell,[12] from observations of the PH at which magnesium hydroxide is precipitated by alkali, conclude that K_H should be slightly less than 12×10^{-12}.

The general agreement of these values corroborates the view that there is at 25° no definite stable basic carbonate with a field between that of hydroxide and that of normal carbonate, for by substituting the values of K_H and K_M in the expression given above, we derive a value of P_{tr} of the same order as that observed; whereas the assumption of any basic carbonate (for instance, $MgCO_3 \cdot Mg(OH)_2$ or $3MgCO_3 \cdot Mg(OH)_2 \cdot 3H_2O$), leads to a calculated transition pressure so much larger as to be irreconcilable with that observed.

Summary

The equilibrium in solutions of magnesium carbonate at 25° has been investigated over a range of pressures of carbon dioxide from 1 to 0.0001 atmosphere. The carbonate is stable down to 0.004 atm., below which the hydroxide is stable; no indication of definite basic carbonates was observed. The activity product constant of magnesium carbonate at 25° is taken as 1×10^{-5}; that of magnesium hydroxide similarly as 5×10^{-12}. Interpolated values of the molality of magnesium in the solution saturated with the carbonate at 25° for a series of values of the partial pressure (in atrn.) of carbon dioxide are appended.

THE KETONIC DECOMPOSITION OF BETA-KETO CARBOXYLIC ACIDS

BY KAI JULIUS PEDERSEN

RECEIVED MARCH 21, 1929 PUBLISHED JULY 5, 1929

It is well known that β-keto carboxylic acids, *e.g.*, acetoacetic acid, split off carbon dioxide according to the scheme

$$CH_3COCH_2COOH \longrightarrow CH_3COCH_3 + CO_2$$

and that the cleavage is catalyzed by certain amines. This so-called ketonic decomposition is characteristic of β-keto acids, neither a- nor γ-acids showing any appreciable decomposition. Thus pyruvic and levulinic acids are stable. Unless both the a-hydrogen atoms are substituted, the β-keto acids consist of a mixture of two tautomers, a keto form and an enol form; for instance, in the case of acetoacetic acid

$$CH_3COCH_2COOH \rightleftharpoons CH_3COH{:}CHCOOH$$

Opinions differ as to whether the keto or the enol form is the unstable form. The present work is an attempt to solve this problem. On the suggestion of Professor N. Bjerrum the α,α-dimethylacetoacetic acid, which exists only in the keto form, was investigated. If only the enol form of β-keto acids is unstable, the α,α-disubstituted acid must be stable in aqueous solution.

The kinetics of the ketonic decomposition of β-keto acids and the catalysis by amines have been investigated several times. G. Bredig and his school[1,2,3] studied camphorcarboxylic acid and a-bromocamphorcarboxylic acid

$$C_8H_{14}\left\langle\begin{array}{l}CO\\ |\\ CHCOOH\end{array}\right. \quad \text{and} \quad C_8H_{14}\left\langle\begin{array}{l}CO\\ |\\ CBrCOOH\end{array}\right.$$

While the former has a keto and an enol form, the latter is purely ketonic. It was first shown by Fajans[3] that the latter splits off carbon dioxide and that its decomposition is catalyzed by amines. For camphorcarboxylic acid it has thus been established that the keto form can decompose.

The decomposition of acetoacetic acid has been studied by I,. Pollak,[4] N. O. Engfeldt,[5] E. M. P. Widmark,[6] H. v. Euler[7] and G. Ljunggren.[8]

[8] Ljunggren, "Katalytisk Kolsyreavspjälkning ur Ketokarbonsyror," Dissertation. Lund, 1925.

It has been shown that the rate of decomposition follows the law

$$-\frac{dc}{dt} = k'_m c(1 - \alpha) + k'_i c\alpha \tag{1}$$

where c is the concentration of acetoacetic acid, α its degree of dissociation and k'_m and k'_i are velocity constants for the decomposition of the undissociated acid and the ion. From experiments in buffer solutions it is possible to calculate the dissociation constant of acetoacetic acid (Widmark). Ljunggren's results are given in Table VI at the end of this paper. Widmark and Ljunggren have found that amines only catalyze when the PH of the solution is kept within a limited interval, while the amines are inactive in strong acid and alkaline solutions. This they explain by assuming that either the neutral amine reacts with the undissociated acetoacetic acid or the positive ammonium ion with the' acetoacetate ion. It is impossible to distinguish between these possibilities on the basis of kinetic experiments. Ljunggren has found that only primary amines are good catalysts. Secondary and tertiary amines give only small effects.

A similar reaction, the decomposition of acetone-dicarboxylic acid

$$CO(CH_2COOH)_2 \longrightarrow CO(CH_3)_2 + 2\,CO_2$$

has recently been studied by E. O. Wiig.[9] He determined the velocity of the decomposition in water, aniline and various alcohols and also the effect of catalysts. Wiig does not take into account the dissociation equilibrium of acetone-dicarboxylic acid. This acid is fairly strong. According to Angeli[10] its dissociation constant in aqueous solution is 0.79×10^{-3}. Consequently its aqueous solution contains both undissociated acid and univalent ion, and these will probably decompose with different velocities. It seems to the author that this is the simplest explanation of Wiig's experiments in aqueous hydrochloric acid, where he finds that the velocity constant at first decreases and then remains constant with increasing concentration of hydrochloric acid. He explains the retardation by assuming that hydrogen chloride adds to the keto group, forming a stable compound, but it is simpler to assume that the undissociated acetone-dicarboxylic acid decomposes somewhat more slowly than its univalent ion. Addition of hydrochloric acid to the solution causes a depression of the dissociation until the acid is completely undissociated. On p. 970 Wiig takes into account the hydrogen-ion concentration due to the dissociation of the carbonic acid formed by the reaction in an aqueous solution of acetone-dicarboxylic acid, while he disregards the much greater hydrogen-ion concentration from the acetone-dicarboxylic acid itself.

Experimental Part

The velocity of the ketonic decomposition of α,α-dimethylacetoacetic acid was determined at the temperature 18.00° by means of an apparatus

---

[9] **Wiig,** *J. Phys. Chem.,* 32, 961 (1928).

[10] Angeli, *Gazz. chim. ital.,* II, *22,* 31 (1892).

described by J. N. Brönsted.[11,12] The pressure of carbon dioxide above the solution in the closed apparatus is measured during the reaction. Experiments were made in solutions of hydrochloric acid sufficiently concentrated to make the dimethylacetoacetic acid practically completely undissociated, and in glycolate and acetate buffer solutions, where the dimethylacetoacetic acid is partially dissociated.

Impurities of acetoacetate and monomethylacetoacetate were removed from the ethyl ester of α,α-dimethylacetoacetic acid (Kahlbaum) by shaking for an hour with an equal volume of 25% potassium hydroxide solution.[13] After separation from the aqueous layer and two distillations it boiled at 184–185° (boiling point found by Perkin[14] 184.8–185.0°).

The amount of the ethyl ester used for an experiment (0.001-0.002 mole) was weighed out, an excess of sodium hydroxide added and the mixture was left at room temperature until the next day. Rough determinations of the rate of hydrolysis of the ester had shown that this was sufficient for practically complete hydrolysis. Acid was added, the solution diluted to 100 cc. and poured into the reaction flask in the apparatus.

Experiments in Solutions of Hydrochloric Acid.—The reaction follows the unimolecular law

$$-k_m t = \log c + \text{constant} \tag{2}$$

where k_m is the velocity constant expressed by means of decadic logarithms, t is the time in minutes and c the concentration of dimethylacetoacetic acid at the time t. P denotes the difference, $p_\infty - p$, between the pressure p_∞ above the solution after the reaction is complete and the pressure p at the time t. As P and c are proportional during the reaction, $c = fP$ and Equation 2 may be written

$$-k_m t = \log P + \text{constant}$$

k_m was computed according to this equation by plotting log P against t; f does not enter into the calculations when the reaction follows the unimolecular law. Only when this law does not hold, as in experiments in buffer solutions, is a knowledge of the value of f necessary. f can be calculated from the known concentration of the reacting substance before the experiment (c_0) and the total increase in pressure during the experiment (P_0); $f = c_0/P_0$.

The results of the experiments in hydrochloric acid are given in Table I. Owing to the method of preparation of the solutions they all contain a little ethyl alcohol (<0.02 M) originating from the ester. By comparison of Expts. 1 and 2 with 4, where extra alcohol has been added, it is seen that 0.02 M alcohol can have no detectable effect. Hydrochloric acid,

[11] Brönsted and King, THIS JOURNAL, 47, 2523 (1925).

[12] Brönsted and Duus, Z. *physik.* Chem., 117, 299 (1925).

sodium chloride and glycolic acid all have a small accelerating effect. If we assume that the effects vary linearly with the concentrations of the substances, and that they are independent of one another, we get the following values for the increase in k_m per mole/liter of added substance: hydrochloric acid, 50×10^{-6}; sodium chloride, 37×10^{-6}; undissociated glycolic acid, 25×10^{-6}. By means of these data we find by extrapolation the velocity constant for the decomposition of undissociated dimethylacetoacetic acid in pure water, $k_{m0} = 723 \times 10^{-6}$.

5	.01465	.108	.640	....	752
6	.01576	.108	.040	1.18 M $CH_2OHCOOH$	759

Experiments in Buffer Solutions.—These measurements were made in order (1) to determine the dissociation constant of dimethylacetoacetic acid, (2) to obtain an idea of the velocity of decomposition of the dimethylacetoacetate ion and (3) to examine whether the reaction like the decomposition of the acetoacetic acid itself is catalyzed by amines.

The velocity of decomposition in a buffer solution depends on the degree of dissociation (α) of the dimethylacetoacetic acid at the P_H of the solution. Equation 1 holds as for acetoacetic acid.

Glycolate buffer solutions were chosen for the determination of the dissociation constant of dimethylacetoacetic acid because this constant and that of glycolic acid are of the same order of magnitude. The ratio $L = K_D/K_G$, where K_D and K_G are the concentration dissociation constant of dimethylacetoacetic acid and glycolic acid, is presumably almost independent of the salt concentration even in fairly concentrated solutions, although the dissociation constants themselves are very sensitive to salt. In order to minimize the change in hydrogen-ion concentration due to the disappearance of the dimethylacetoacetic acid, rather concentrated buffer solutions were used. A correction formula was also applied.

It will be shown later that for experiments in glycolate buffer solutions the decomposition of the dimethylacetoacetate ion is negligible compared with that of the undissociated acid, at least when no catalyst is present. Equation 1 reduces to

$$\frac{dP}{Pdt} = -k'_m(1-\alpha) \tag{3}$$

α increases during the decomposition. α_0 denotes its value at the time ∞ when the concentration of dimethylacetoacetic acid is 0. We want to calculate the velocity constant

$$k' = k'_m\,(1 - \alpha_0) \qquad (4)$$

corresponding to this concentration.

From the mass action law we get

$$\frac{a + \alpha c}{b - \alpha c}\,\frac{\alpha}{1 - \alpha} = L$$

where a and b are the stoichiometric or final concentrations of glycolic acid and sodium glycolate, respectively. Hence

$$\alpha = \frac{L(b - \alpha c)}{a + Lb - (L - 1)\alpha c} \text{ and } \alpha_0 = \frac{Lb}{a + Lb} \qquad (5)$$

$$\alpha_0 - \alpha = \frac{L(a + b)\alpha c}{(a + Lb - (L - 1)\alpha c)\,(a + Lb)}$$

We now use as an approximation in the numerator $\alpha = \alpha_0$ and in the denominator c = 0. Using $c = f \times$ P and (5), we get

$$\alpha_0 - \alpha = \frac{L^2b(a + b)fP}{(a + Lb)^3}$$

From (3), (4) and (5) we get

$$-\frac{dP}{Pdt} - k' = k'_m\,(\alpha_0 - \alpha) = \frac{L^2b(a + b)f \times k'_m}{(a + Lb)^3} \times P$$

$$= \frac{L^2b(a + b)f \times k'}{(a + Lb)^2a}\,P = A \times k' \times P$$

where A denotes

$$\frac{L^2(a + b)b \times f}{(a + Lb)^2 \times a}$$

Hence by integration

$$\log_e\left(\frac{1}{P} + A\right) = k't + \text{constant, or}$$

$$\log_{10}\left(\frac{1}{P} + A\right) = kt + \text{constant} \qquad (6)$$

In order to use this formula we require an approximate value of L. We find this by plotting log P against t. We get in this way a curve which deviates only slightly from a straight line. The slope gives an approximate value of $k = k_m(1 - \alpha_0)$. We now calculate L from Equation 5. Knowing L we can calculate A. We finally plot log $(1/P + A)$ against t and find k. The calculation of an experiment has been given in Table II.

In Table III are given the values of k computed in this way for glycolate buffer solutions.

It has been found in the experiments in hydrochloric acid that sodium chloride and undissociated glycolic acid have a small accelerating effect on the decomposition of the undissociated dimethylacetoacetic acid and the magnitude of these effects has been found. From a comparison of Expts. 7 to 10 or 11 and 12 (Table III) we see that sodium glycolate has a

similar effect. Although $1-\alpha_0$ is almost constant within these experiments, k varies much more than can be accounted for by the small effect of the undissociated glycolic acid and the sodium chloride. We first calculate L without taking into account the effect of the sodium glycolate. We denote by * the data in the calculation of which this effect has been neglected.

$$1 - \alpha_0^* = \frac{k}{k_m^*} \qquad L = \frac{a}{b} \times \frac{\alpha_0^*}{1 - \alpha_0^*} \tag{7}$$

where $k_m^* = (723 + 37\,c_{\mathrm{NaCl}} + 25\,a) \times 10^{-6}$.

We assume that the effect of the sodium glycolate on k_m is proportional to its concentration, $k_m = k_m^* + \beta b$. By introduction in (7)

$$L^* = \frac{a}{b} \times \frac{k_m - \beta b - k}{k} = \frac{a}{b}\,\frac{k_m - k}{k} - \beta\,\frac{a}{k}$$

$$L^* = L - \beta \times \frac{a}{k} \tag{8}$$

From this equation we see that we can find β by plotting L^* against a/k. See the diagram. The value of the slope is $-\beta = -155 \times 10^{-6}$. We can now calculate k, $1 - \alpha_0$ and L. The values are given in Table III. The mean value of L is 2.04. Using this value for L and

$$10^6 \times k_m = 723 + 37\, c_{\mathrm{NaCl}} + 25\, a + 155\, b$$

we calculate the k values given in the last column of Table III. They are in good agreement with the experimental values.

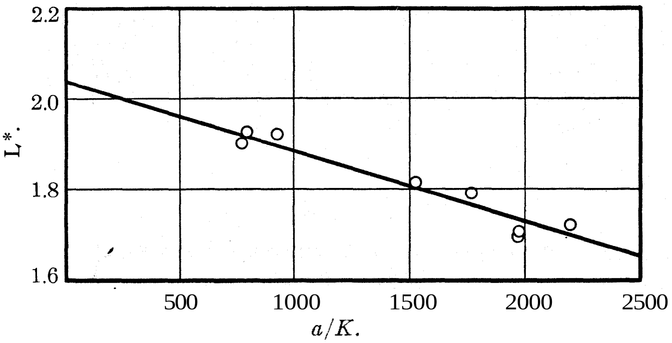

Fig. 1.—Graphical determination of the effect of sodium glycolate on the rate of decomposition of undissociated dimethylacetoacetic acid, Equation 8. The slope is $-\beta = -155 \times 10^{-6}$.

We have now determined the ratio between the dissociation constants of dimethylacetoacetic acid and glycolic acid, L = 2.04 at 18°. The dissociation constant of glycolic acid has been determined by J. Boeseken and H. Kalshoven.[15] They found at 25° the value 1.54×10^{-4} for dilutions from 4 to 512 liter/mole. It is permissible to use the same value at 18°, because the dissociation constants of weak acids in general do not vary much with the temperature. We thus find for dimethylacetoacetic acid the dissociation constant 3.14×10^{-4}.

In order to get an idea of k_i, the velocity of the decomposition of the dimethylacetoacetate ion, some measurements were made in acetate buffer solutions, where the dimethylacetoacetic acid is almost completely dissociated (Table IV). In the calculation of the velocity constant k Equation 6 has been applied. By means of the dissociation constant ratio for dimethylacetoacetic and acetic acid, $L = K_D/K_A = (3.14 \times 10^{-4})/(1.80 \times 10^{-5}) = 17.5$, $1-\alpha_0$ is calculated. If we neglect the effect of the medium (acetic acid and sodium acetate) on the decomposition of the undissociated dimethylacetoacetic acid, we can calculate $k_{m0}\,(1 - \alpha_0)$, the part of k which is due to the decomposition of undissociated dimethylacetoacetic acid. The part of k which is due to the decomposition of the ion is probably smaller than the difference given in the last column of Table IV, because

---

[15] Boeseken and Kalshoven, Rec. *trav. chim.*, 37, 130 (1918).

we have used k_{m0} instead of k_m. Thus the velocity constant for the decomposition of the dimethylacetoacetate ion k_i is smaller than 4×10^{-6}, while that for the undissociated acid is $k_{m0} = 723 \times 10^{-6}$. In the experiments in glycolate buffers, k_i has been neglected. The results will only be slightly different if we use $k_i = 4 \times 10^{-6}$.

TABLE IV

THE VELOCITY OF DECOMPOSITION OF DIMETHYLACETOACETIC ACID IN ACETATE BUFFER SOLUTIONS

No.	Concn of acetic acid	Concn. of sodium acetate	k × 10^6	$1 - \alpha_0$, calcd.	$k_{m0}(1 - \alpha_0)10^6$	Diff.
17	0.300	0.300	44	0.059	42	2

19	.500	.500	46	.059	42	4

The Catalysis by Amines.—In Table V are given two experiments in which the catalysis of an amine, aniline, was examined. The results are only approximate because no correction has been made for the change in α during the reaction. Nevertheless, it is clear from a comparison of the last two columns of Table V that aniline has a very great accelerating effect. In the calculation of α the value found by Bronsted and Duus[12] for the acid strength[16] of the anilinium ion

$$K_{C_6H_5NH_3^+} = \frac{(C_6H_5NH_2)\ (H^+)}{(C_6H_5NH_3^+)} = 2.06 \times 10^{-5}$$

has been used. The ratio $L = K_D/K_{C_6H_5NH_3^+}$, unlike L for glycolic acid, is highly salt sensitive. The α-values calculated in this way are therefore only rough approximations.

TABLE V

THE CATALYTIC EFFECT OF ANILINE ON THE DECOMPOSITION OF DIMETHYLACETOACETIC ACID

Discussion

In Table VI the velocity constants found by Ljunggren for acetoacetic acid are given together with the constants found in the present work for dimethylacetoacetic acid. Ljunggren worked at 37 and 25°. His values have been extrapolated to 18° by means of the formula d log $k/\mathrm{d}(1/T)$ = constant, where T is the absolute temperature. As seen from the table, the undissociated dimethylacetoacetic acid, that is, a pure ketone, at 18° decomposed 4.5 times as quickly as the undissociated acetoacetic acid. At 18° dimethylacetoacetic acid decomposes with the same velocity as

---

[16] J. N. Bronsted, *Rec. trav. chim.*, 42, 718 (1923); *J. Phys. Chem.*, 30, 777 (1926)

acetoacetic acid at about 29°. It has thus been shown that the keto form is unstable. Probably only the keto form decomposes.

TABLE VI

ACETOACETIC AND DIMETHYLACETOACETIC ACID. VELOCITY CONSTANTS FOR THE KETONIC DECOMPOSITION (DECAD. LOG., MIN.$^{-1}$) AND DISSOCIATION CONSTANTS

	Acetoacetic acid (Ljunggren)			Dimethylacetoacetic acid,
	37°	25°	18° (extrap.)	(K. J. P.) 18°
Undissociated acid $k^0_m 10^6$	2080	430	161	723
Ion $k_i \times 10^6$	38.5	8.95	3.6	<4
Dissociation constant	2.04×10^{-4}	2.21×10^{-4}	2.29×10^{-4}	3.14×10^{-4}

Engfeldt[5] has by means of the bromination method of K. H. Meyer[17] determined the amount of ketone and enol in acetoacetic acid dissolved in water. Bromine reacts instantaneously with the enol form while it has no effect on the keto form. The accuracy of the analysis is not great owing to the formation of enol from the ketone during the analysis. Engfeldt therefore considers his results as being only rough approximations. He finds that undissociated acetoacetic acid (free acid + an excess of hydrochloric acid) consists of 18% keto form and 82% enol form. This result is not confirmed by a work which the author is doing on the applicability of the bromination method for the enol determination in aqueous solutions of acetoacetic acid and ester and similar substances. This together with a study of the velocity of the reaction ketone ⟶ enol will be the subject of a later publication. It was found that an aqueous solution of acetoacetic acid contains only very little enol, less than 1%.

As a result of the present work the following hypothesis is suggested. Only the keto form of β-keto carboxylic acids undergoes the ketonic decomposition. The amines which catalyze the reaction form an intermediate compound of unknown constitution with the keto form (enol $\rightleftarrows$ ketone $\rightleftarrows$ ketone-catalyst), thus reducing the concentration of both enol and ketone. The intermediate compound splits off carbon dioxide much more quickly than the free keto form.

The α,α-disubstituted acetoacetic acid is especially suited for the study of the catalysis, the non-occurrence of enol making this case simpler than that of the ordinary acetoacetic acid. A theory of the decomposition and catalysis must take into account that only β-keto acids show the ketonic decomposition with appreciable velocity, and that only the primary amines are good catalysts, while the secondary and tertiary amines have a moderate or almost no effect.

The work is being continued and it is hoped to give a further test of the above hypothesis in a later publication.

In conclusion I wish to thank the Carlsberg Poundation for a grant which has defrayed the expenses of the apparatus. I also wish to express my in-

---

debtedness to Professor N. Bjerrum, whose many valuable suggestions have been of great importance to my work, and to Mr. E. A. Guggenheim for helpful criticism.

Summary

1. The kinetics of the ketonic decomposition of α,α-dimethylacetoacetic acid, $CH_3COC(CH_3)_2COOH \longrightarrow CH_3COCH(CH_3)_2 + CO_2$, have been studied. Experiments were made in hydrochloric acid, glycolate and acetate buffers.
2. The dissociation constant of α,α-dimethylacetoacetic acid has been calculated from the experimental results.
3. It has been shown that the decomposition is catalyzed by amines.
4. From the fact that α,α-dimethylacetoacetic acid is unstable it follows that the keto form of β-keto carboxylic acids is unstable.

EXTRACTION OF COMMERCIAL RARE-EARTH RESIDUES WITH A VIEW TO THE CONCENTRATION OF ILLINIUM

BY ROBERT W. BALL[1] WITH J. ALLEN HARRIS[2]

RECEIVED MARCH 26, 1929 PUBLISHED JULY 5, 1929

Historical

In 1926[3] one of the writers, in conjunction with Professor B. S. Hopkins of the University of Illinois, was able to isolate, although in an impure state, sufficient of Element 61 to be able to identify it by means of x-ray analyses. Since, however, some 700 pounds of original material yielded a concentrate of but a few grams, it would seem to indicate that (a) the element is extremely rare and hence, in order to obtain quantities sufficiently great for purification, enormous amounts of the original material must be worked on, or (b) that while not rare, our method of concentration was inefficient and considerable of the element was lost at different stages of the treatment involved.

Assuming the latter possibility, one of the most likely sources of loss would be inefficiency in extraction of original residues; this possibility is discussed in this paper.

The element has not yet been obtained in a state of purity great enough to permit the mapping of its arc and absorption spectra, so it is impossible

---

[1] Part of this paper was presented as a thesis for the M.A. degree at the University of British Columbia.

[2] National Research Fellow. Paper completed at the Sorbonne, Paris, as part of work under National Research Council Award.

[3] Harris with Hopkins, THIS JOURNAL, 48, 1585 (1926).

to make use of these in following the progress of concentration. Similarly, x-ray analyses are not sensitive when amounts of less than one part per thousand are present. Hence it was decided that the best method for attacking this problem would be from the standpoint of the quantitative determination of total rare-earth content of the original material, by analytical methods.

Introduction

The materials used in the investigation were (1) commercial double sulfates, having the same source as those used in the original concentration of illinium, and (2) commercial hydrated oxides, prepared by the Welsbach Company for the University of Illinois, and kindly loaned to us by Professor Hopkins.

However, although much work has been carried out regarding the extraction of the rare-earth minerals, and several methods have been devised for decomposing the double sulfates, it is probable that all of these methods are selective in their action and it does not appear that a single one of the methods has been studied from a quantitative view-point.

Analysis

Extremely careful analyses were made of the original materials, first by the method outlined by Hillebrand[4] and, second, by a modification of the above method which appeared to give results consistently concordant with the Hillebrand procedure.

The average of these analyses is: (1) double sulfates? 39.40 g. of rare earth as oxide per 100 g. of material; (2) hydrated oxides, 73.05 g. of rare earth as oxide per 100 g. of material.

Part I. Extraction of Double Sulfates

(a) Wet Extraction of Small Amounts.—Two-gram samples of the carefully dried material were moistened with water and then digested with **25** cc. of concd. nitric, hydrochloric and sulfuric acids, respectively, until the volume was reduced to about **5** cc. These were then taken up in **250** cc. of water and, after filtering, the residue was again treated with hot water, filtered and the filtrates combined. After correcting acidity to reduce solubility of the oxalates to a minimum,[5] the rare earths were precipitated as the oxalates, washed, dried and ignited to the oxides. The maximum and minimum of the results, which were never concordant, are as follows

Acid	Nitric	Hydrochloric	Sulfuric
Maximum yield as oxide, %	**15.73**	**29.07**	**39.87**
Minimum yield as oxide, %	**11.26**	**25.35**	**34.35**

These compared to actual content of **39.40%** as oxide indicated that concentrated sulfuric acid is the most efficient of the acids. Although the maximum value is more than the theoretical, the majority of extractions were in the vicinity of **39.0%.**

---

[4] Hillebrand, U. S. Geological Survey Bulletin 700.

[5] Sarver and Brinton, THIS JOURNAL, **49,943** (1927); Neckers with Kremers, *ibid.*, **50, 950 (1928).**

Turning now to alkali extraction, the one recommended, as mentioned previously, is the use of a 50% solution of sodium hydroxide.

Accordingly, two-gram samples were digested for several hours with such a solution. The resulting mixture was taken up in 250 cc. of water and washed by decantation until alkali free; the residue was then digested with nitric acid to dissolve the hydroxides, diluted, filtered and the residue leached with hot water. The combined filtrates were subsequently treated with oxalic acid and the resulting oxalates ignited and weighed as the oxide. In all cases where there was evidence of a basic salt forming, the sample was rejected; maximum yield as oxide, 38.89%; minimum yield as oxide, 37.98%. Thus it may be seen that the alkali extraction gives more consistent results than does the extraction with acids.

(b) Fusion of Small Amounts.—The fluxes chosen were sodium hydroxide and sodium carbonate and the acids used as extractants of the melt were dilute and concentrated hydrochloric, nitric and sulfuric acids.

As in the previous cases, samples of two grams each were used and fused with excess of the flux. After lixiviating with water, the mass was extracted with acid of varying concentration. In the case of the dilute acids the results were never concordant; this no doubt was due to the tendency of the cerium to become basic. The best results were obtained by fuming the melt with concentrated sulfuric acid, and then extracting several times with hot water.

Flux	Sodium hydroxide	Sodium carbonate
Extractant	Concd. sulfuric acid	Concd. sulfuric acid
Rare earth as oxide, %	Av. 39.06	Av. 39.32
Total rare-earth content, 39.40		

In the foregoing determinations, then, it would appear as though extraction by means of sulfuric acid, sodium hydroxide or fusion with sodium hydroxide or sodium carbonate would eliminate possibility of loss of illinium during the initial extractions.

Since, however, the rare-earth worker is usually interested in larger amounts, it was deemed advisable to investigate the efficiency of these reagents on larger amounts of original material, up to 3000 g.

(a) Wet Extractions of Larger Amounts. (1) With Acids.—These gave results too low and so inconsistent as to render their use valueless.

(2) With 50% Sodium Hydroxide Solution.—This method, while giving excellent results on small samples, for larger amounts of material gave a maximum yield of but 18.34% as oxide against the actual content of 39.4%.

(3) Concentrated Sodium Hydroxide Solution.—The method suggested by Professor Urbain and the one used in his laboratory for decomposition of sulfates is a digestion with a saturated solution of sodium hydroxide. Two digestions with this solution gave the following results for amounts in the vicinity of 300 grams: A. % as oxide, 38.88—98.68% efficient; B. % as oxide, 39.20—99.49% efficient.

(4) Digestion with saturated Na_2CO_3 solution.—A. % as oxide, 34.82—88.37% efficient; B. % as oxide, 35.30—89.59% efficient. Hence for wet extractions a concentrated solution of sodium hydroxide is extremely efficient.

(b) Fusion with Sodium Carbonate.—These fusions were carried out in fire-clay crucibles in a gas-fired muffle furnace. Amounts of the commercial double sulfates in the vicinity of one kilogram were mixed with excess of dry sodium carbonate and fused until the mass was thoroughly molten. The temperature was then maintained for about an hour, the furnace allowed to cool and the crucible removed. Great difficulty was experienced in removing the melt from the container—the crucible usually had to be broken. The mass was then extracted and treated as in the case of the small samples. The maximum yield obtained by this method was 37.26 g. of oxide per one hundred grams of original material.

Believing the discrepancy to be due to incomplete removal of the melt from the crucible, a method was devised which is outlined below and which we cannot recommend too highly for large-scale laboratory operations. In addition to being highly efficient, it has the advantage of being a practically continuous process.

TABLE I

RESULTS OBTAINED BY THIS PROCESS

Original residue, g.	872.00	1000.00	1500.00	2000.00	3000.00
Oxides, g.	324.8	392.73	587.40	774.00	1169.99
Oxide per 100 g., g.	37.75	39.27	39.16	38.70	39.00
Efficiency, %	95.81	99.66	99.39	98.22	99.00

In the first and fourth cases the results are low—no doubt due to the fact that in both instances new crucibles were used and hence some of the melt was retained as a glaze during pouring. The last two fusions were carried out as a continuous process to test its possibilities.

Conclusions

The following methods are recommended as being efficient in extracting the rare earths from double sulfate residues.

(1) For Large Amounts.—The dried double sulfates are thoroughly mixed with a large excess of dry commercial sodium carbonate. The mixture is then fired in a muffle until molten and the temperature maintained until reaction is complete. The crucibles are then removed and the molten contents poured into a vessel containing hot water; the still red-hot crucible is quickly recharged and returned to the muffle. The sudden cooling of the melt causes thorough disintegration. When the last pouring has been made the crucibles are cooled somewhat and the addition of dilute sulfuric acid to the container effectively loosens all adhering melt, which may then be added to the solution.

The mixture is allowed to settle and the residue washed thoroughly by decantation until alkali-free. It is then transferred to a large evaporating dish and evaporated to dryness.

The dry residue is now made up to a thin paste with concentrated sulfuric acid and evaporated until there is copious evolution of fumes, in order to convert the rare earths into the soluble acid sulfates. The resulting mass is extracted with water until the last extraction gives no test for the rare earths.

These extracts are combined, diluted and the rare-earth hydroxides precipitated with ammonia, washed thoroughly to remove any sulfate, taken up in as little nitric acid as possible, diluted and precipitated as the oxalates with subsequent ignition to the oxide.

(2) **For Smaller** Amounts.—For amounts below one kilogram the following method is perhaps more adaptable. Moisten the dried residues with as little water as possible and cover with a saturated solution of sodium hydroxide to a depth of at least one inch. Digest on a steam-bath, following by digestion on a hot-plate until the mass is thoroughly disintegrated and the rare earths converted. to the bulky hydroxides. The mass is allowed to cool and any liquor is decanted. The hydroxides are then boiled with water until all alkali has been removed and extracted with dilute nitric acid, heating only sufficiently to aid the solution of the soluble portion. The undissolved residue is filtered off and extracted a second time. The filtrates containing the rare earths as nitrates are combined, precipitated by means of ammonia and after thorough washing treated as formerly.

Either of these methods will reduce to a minimum the possibility of loss of any rare earths and consequently illinium during the extraction of commercial double sulfates and will also yield a product of considerable purity.

Part II. Extraction of Commercial Hydrated Oxides

(a) Acid Extraction.—It is natural to assume that acid extractions of such residues would be the more efficient; consequently alkaline extractions were not used.

In the case of larger amounts, varying between 200 and **312** g., the maximum yields obtained from a great many extractions, covering both digestions with acid and addition of the material to the hot acid with constant stirring, were as follows

Extractant	**Hydrochloric acid**	**Sulfuric acid**	**Nitric acid**
Oxide per 100 g., g.	**60.19**	**70.36**	**68.40**

In all cases the tendency to become basic was very pronounced and had to be carefully guarded against. The best results are obtained by carefully moistening the original material with water, care being necessary as a great deal of heat is liberated. The material is then slaked with water and when concentrated nitric acid is slowly added complete solution takes place. The yield, however, is always low, but if a little hydrogen peroxide is added at this point the results are always concordant and **much** higher.

TABLE II

RESULTS BY THIS METHOD

Original material, g.	**200**	**200**
Oxides, g.	**145.82**	**144.70**
Wt. per 100 g., g.	**72.91**	**72.36**
Efficiency, %	**99.80**	**99.04**

Deep appreciation is hereby expressed to Professor Hopkins for the loan of material for the investigation; to the National Research Council and International Education Board for furnishing funds to allow a continuation of this work in Europe, and also to Professor Georges Urbain of the Sorbonne whose kindly advice and interest was a source of inspiration at all times.

Summary

1. As mentioned in the historical part of this paper, it was feared that there was a possibility of loss of illinium during original extraction of double sulfate residues. As the material used had been extracted with a 50% solution of sodium hydroxide, the foregoing experiments show that there is a possibility of loss of rare earths at this point.

2. A method has been outlined whereby using a sodium hydroxide solution, practically theoretical results—as compared with an accurate quantitative determination—have been obtained for amounts up to 300 g.

3. An equally efficient method for larger amounts, involving fusion with sodium carbonate, has been described.

4. The use of nitric acid and hydrogen peroxide is recommended for the extraction of commercial hydrated oxides. Hence, if the original material is extracted by any of the above methods, all of the rare earths, including illinium, should be found in the extract. All undissolved residues are, however, being investigated.

DICHLORO-AMINE

BY ROBERT M. CHAPIN

RECEIVED MARCH 26, 1929 PUBLISHED JULY 5, 1929

Available evidence for the existence of dichloro-amine, $NHCl_2$, including the most recent,[1] rests upon incidental observations made in the course of work on nitrogen trichloride. The conditions necessary for the formation of the substance remain undefined, while methods for its separation from the two other reaction products are lacking.

The nature of the product obtained through chlorination of an excess of ammonium ions is known to depend upon the reaction of the solution, acidity leading toward nitrogen trichloride and alkalinity toward monochloro-amine. It will be shown here that when the reaction is effected through rapid mixing of sufficiently cool and dilute buffered solutions, with ammonium ions always in excess, the nature of the product is governed solely by the concentration of hydrogen ions. In solutions more alkaline

---

[1] W. A. Noyes, THIS JOURNAL, 42,2173 (1920).

than slightly above PH 8.5 nothing but monochloro-amine was found; below *P*H 4.4 nitrogen trichloride is produced with only a trace of chloro-amine; between PH 4.4 and 8.5 graduated mixtures of the two chloro-amines result. That is, while the shift between nitrogen trichloride and dichloro-amine is sharp near PH 4.4, there is a considerable range over which the two chloro-amines coexist in a ratio ultimately fixed by the hydrogen-ion concentration. Accordingly an acidified solution of monochloro-amine becomes proportionately converted to dichloro-amine on storage.

In the physical properties of odor, volatility from aqueous solution and relative solubility in various immiscible solvents, dichloro-amine is intermediate between nitrogen trichloride and monochloro-amine. Like these two it liberates iodine from an acidified solution of potassium iodide, and may be thus determined when free from both of the others. Removal of contaminating nitrogen trichloride is easily effected with little loss of chloro-amine by shaking out the aqueous solution with successive small proportions of carbon tetrachloride, but no way for removing contaminating monochloro-amine was found other than conversion to dichloro-amine by subjection to a sufficiently low hydrogen-ion concentration.

Mixtures of the two chloro-amines that are free from nitrogen trichloride may be assayed by determining the apparent partition ratio in an appropriate immiscible solvent, either chloroform, carbon tetrachloride or pure ether, and comparing the result with the partition ratios of the two pure substances in that solvent.

Experimental

The solutions of chlorine and of ammonium ions were mixed expeditiously and the products were stored in the dark at room temperature. The buffers employed in the preparations were acetate, phosphate or borate mixtures, which are resistant to chlorine. Hydrogen-ion concentrations were determined colorimetrically by standard methods (Clark) with the indicators methyl red, brom thymol blue, cresol red and thymol blue (alkaline range). Errors from bleaching could be sufficiently avoided by rapid work except that nitrogen trichloride required previous removal by carbon tetrachloride. Any solution to be analyzed for "available chlorine" was pipetted (tip beneath surface) into a flask already charged with a dilute iodine-free mixture of potassium iodide and the necessary excess of hydrochloric acid, with constant swirling. All extractions and subsequent analyses, once started, were put through as expeditiously as possible.

Experiment I.—The ammonium solution, 250 cc., was 0.1 M ammonium acetate brought to the desired *P*H by acid or alkali and in many cases carrying additional buffer. The chlorine solution, 250 cc., had been brought to the same *P*H by calculated addition of buffer to 100 cc. of chlorine water carrying 0.4 to 0.6% chlorine.

After admixture, storage and determination of the *P*H, the whole solution was thoroughly shaken with 10 cc. of carbon tetrachloride in a separatory funnel. A little of the carbon tetrachloride was discarded to rinse the stem of the funnel, then 5 cc. of the remainder was added to acidified potassium iodide'and titrated with 0.01 N sodium thiosulfate. After expulsion of sludge, extraction and titration were repeated until the slightness of the difference between successive results proved the absence of nitrogen trichloride.

Following extraction with carbon tetrachloride, the apparent partition ratio of the chloro-amine in chloroform was determined, 25 to 30 cc. of each liquid being thoroughly shaken together, and 20 cc. of each phase being titrated in acidified potassium iodide solution with 0.01 N thiosulfate. Many of these determinations were made in duplicate.

The results of Expt. 1 are contained in Table I. Owing to the formation of acid in the reaction, the final PH usually fell below the calculated initial PH to a degree dependent upon the nature and proportion of buffer present. There appears a marked difference in the solubility and hence in the nature, of the substances extracted by carbon tetrachloride from Preparations A and B, respectively. The partition ratio in chloroform of Preparation A was not determined because the total available chlorine remaining after the fourth carbon tetrachloride extraction required only **3.8** cc. of 0.01 N thiosulfate per 50 cc.

Experiment 2.—This experiment shows the effect of acidification upon monochloro-amine. The ammonium solution contained 30 cc. of 10% ammonium sulfate and 5 cc. of N sodium hydroxide in 200 cc. The chlorine solution contained 100 cc. of chlorine water and 20 cc. of *N* sodium hydroxide in 200 cc. After admixture and standing for one hour, a predetermined quantity of 0.5 N acetic acid was added and the PH was immediately determined. Other determinations were made after a further interval, as shown in Table I. As in Expt. 1, Preparations A and B on either side of PH 4.4 yielded different substances to extraction by carbon tetrachloride. It is also evident that monochloro-amine held at *PH* 4.4 to **5.3** undergoes extensive conversion to dichloro-amine.

Experiment 3.—The rate of the formation of dichloro-amine from chlorine and ammonium ions at a favorable *PH* was next investigated. Mixtures were made as in Expt. 1 at a calculated initial *PH* of 4.9. The results are contained in Table II. Residual Preparation B after standing for a total of three hours was extracted twice with carbon tetrachloride. The obtained titrations of 9.50 and 9.25 cc of **0** 01 N thiosulfate showed freedom from nitrogen trichloride. Accordingly, the reactions leading to dichloro-amine under the most favorable conditions require at least one to two hours for completion.

TABLE II

INFLUENCE OF TIME UPON FORMATION OF DICHLORO-AMINE IN EXPERIMENT 3

			Partition in CCl_4			Partition in $CHCl_3$		
Prepn.	Time, min.	PH, detd.	CCl_4 phase; titrn.	Aq. phase; titn.	$\frac{CCl_4}{aq.}$	$CHCl_3$ phase; titrn.	Aq. phase; titrn.	$\frac{CHCl_3}{aq.}$
A	2		29.0	42.4	0.68			
	17		26.7	36.3	.74			
	60	4.7	26.0	32.8	.79			
	120		24.3	30.1	.81			
B	15					47.2	26.3	1.79
	60		24.2	28.1	.86	44.6	23.7	1.88
	120	4.6	22.6	26.6	.85	44.0	23.7	1.86

Experiment 4.—Marckwald and Wille[2] found the partition ratio of monochloro-amine between ether and water to be near unity. To determine that of dichloro-amine, portions of Preparation B of Expt. **3** after the two extractions by carbon tetrachloride were shaken with ether, free from peroxide and alcohol, and the partition ratio was determined as before described, except that only 10 cc. of the ether layer was pipetted out, and this was discharged into 10 cc. of carbon tetrachloride underlying the acidified potassium iodide in the flask in order to sink the non-aqueous solvent. Two trials gave partition ratios of **47.5** and **47.0.**

On the assumption that dichloro-amine was the sole product present at *a PH* slightly above *4.4,* the previous experiments indicate the following partition ratios

Monochloro-amine in chloroform	0.25
Dichloro-amine in chloroform	1.88
Dichloro-amine in carbon tetrachloride	0.85
Dichloro-amine in ether	47.3

From the partition ratios of the two pure chloro-amines in chloroform, the percentage of dichloro-amine chlorine in total chloro-amine chlorine

---

[2] Marckwald and Wille, Ber., 56, 1319 (1923).

may accordingly be calculated from the apparent partition ratio, R, of a mixture by the formula

$$44.2 = \frac{4R - 1}{R + 1}$$

Application of this formula gave the results in the last column of Table I.

Experiment 5.—With respect to the determination of the chlorine–nitrogen ratio in the supposed dichloro-amine, the work of Noyes[1] on nitrogen trichloride indicated that transfer of the substance to an immiscible solvent would be the best means for purification from ammonium salts and chloride. For the actual analysis the methods of Marckwald and Wille[2] for monochloro-amine were followed as closely as possible.

Preparations were made as in Expt. 1 but with the chlorine water increased to 150 or 200 cc. After one hour the PH was found to lie between 4.5 and 4.7 and freedom from nitrogen trichloride was proved by two extractions with carbon tetrachloride. Dichloro-amine was then extracted with 125 cc. of peroxide-free ether. The ether extract was transferred to a small separatory funnel and washed four times with 10 to 15 cc. of acetate buffer of PH 4.5, though the last wash was not removed. The second and third washings afforded only opalescences with silver nitrate solution.

From the clear ether layer 50 cc. was pipetted into a 200-cc. volumetric flask containing 35 to 50 cc. of strong aqueous sulfur dioxide, while 10 cc. was pipetted into a glass-stoppered flask charged with acidified potassium iodide and 10 cc. of carbon tetrachloride. The liberated iodine in the latter flask was at once titrated with 0.1 N sodium thiosulfate.

The flask containing sulfur dioxide and ethereal solution was stoppered and frequently shaken for one-half hour; then the ether and evident excess of sulfur dioxide were gently boiled off. Half of the cooled solution was taken for cold precipitation of silver chloride and half for distillation of ammonia into 0.1 N acid. The results in Table III appear adequate to identify the substance as well as to prove the applicability of the assay method for "available chlorine."

TABLE III

ANALYTICAL RESULTS ON DICHLORO-AMINE SOLUTIONS IN EXPT. 5

				Results in g. per 100 cc.			
Prepn.	$Na_2S_2O_3$, titrn.	AgCl, g.	NH_3, titrn.	"Avail. Cl"/2	Total Cl	N	At. ratio, total Cl/N
A	16.19	0.2945	10.10	0.2870	0.2914	0.0566	2.034
B	12.09	.2147	7.50	.2144	.2125	.0420	1.998

Experiments on the germicidal powers of dichloro-amine have been begun in these Laboratories.

Summary

Dichloro-amine is produced by chlorination of excess ammonium ions at PH 4.4 to 8.5, being practically the sole ultimate product at PH 4.5 to

5.0, and, likewise, by corresponding acidification of monochloro-amine solutions. It was identified through its behavior with immiscible solvents and by its chlorine–nitrogen ratio.

THE DETERMINATION OF FERROUS IRON IN SILICATE ROCKS. II. ELECTROMETRIC

BY BYRON A. SOULE

RECEIVED MARCH 30, 1929 PUBLISHED JULY 5, 1929

In a previous article[1] it was shown that the ferrous iron content of silicate rocks can be determined by decomposing the sample with hydrofluoric acid in a pyrex glass flask, diluting with a solution of boric acid and titrating with standardized potassium permanganate. The method has two advantages over that commonly used: (a) the course of decomposition can be watched, and (b) solution and titration are conducted in the same vessel. The most significant disadvantage is that a correction must be applied for the permanganate reduced by dissolved glass constituents.

A consideration of the composition of pyrex glass[2] suggested that arsenic might be the only disturbing element. It was therefore decided to try ceric sulfate as the oxidizing agent, Willard and Young[3] having reported that the titration is not affected by a moderate amount of arsenious acid. The results obtained were satisfactory and led to the development of the method herein advocated.

Materials

Apparatus.—The decomposition flasks were of two sorts: (1) ordinary 250-cc. pyrex glass suction flasks, each having an especially made, well fitting, glass stopper provided with an outlet tube 1 cm. in diameter and bent sharply at the lower end to almost touch the side of the flask; (2) 250-cc. transparent, fused quartz, Erlenmeyer flasks with similar stoppers.

Titrations were conducted with the aid of a bimetallic electrode system similar to that suggested by Furman and Wilson.[4] The resistance used was 240,000 ohms. The electrodes were prepared from pieces of No. 27 B. and S. gage platinum wire and silver wire[5] annealed at 100–105°, then sealed into the ends of glass tubes as usual. About 3 cm. of the platinum and 6 cm. of the silver wire projected. When not in use the anode was kept in a solution of ceric sulfate and the cathode in dilute ammonia water.

[3] Willard and Young, THIS JOURNAL, 50, 1335 (1928).

[4] Furman and Wilson, *ibid.*, 50, 277 (1928).

[5] This work was nearing completion when the article by Brann and Clapp, *ibid.*, 51, 39 (1929), appeared.

Reagents

The ceric sulfate solution was prepared from U. S. P. quality cerium oxalate by a method similar to that of Willard and Young.[6]

The electrolytic iron, especially prepared and carefully preserved under hydrogen in the form of cubes weighing approximately 0.1 g., had been analyzed by several workers and found to contain impurities totaling not over 0.03%.

Carbon dioxide was obtained from a commercial cylinder and passed through chromous chloride to remove any oxygen.[7] The purified gas was tested and found satisfactory.

Water for standard solutions was redistilled first from alkaline permanganate then from sulfuric acid. Just before use all water was boiled and cooled.

All other reagents were carefully tested in order to prove that they would introduce no error.

Weighings.—Standard solutions were weighed directly. All other weighings were by substitution.

Experimental

Standardization of Ceric Sulfate.—A single cube of electrolytic iron was placed in a glass flask filled with carbon dioxide; 10 cc. of sulfuric acid (1 :6) was added and the flask gently warmed. After fifteen to twenty minutes, when the iron had dissolved, the rate of flow of carbon dioxide was increased. Then 100 cc. of water containing 5 g. of boric acid and 5 cc. of hydrofluoric acid (48%) was added, with care that no air should be drawn in during the operation. After the addition of a few drops of concentrated hydrochloric acid the mixture was titrated electrometrically with ceric sulfate.

Four consecutive determinations gave an average iron equivalence of 0.0034685 g. of iron per gram of solution, that is, a normality of 0.04828.

Determination of Ferrous Iron in Magnetite.[8,9]—A 0.3–0.4 g. sample of magnetite[10] was placed in a glass flask filled with carbon dioxide. Next

[6] Willard and Young, THIS JOURNAL, 50, 1322 (1928); 51, 149 (1929).

[7] Moser, *Z. anorg. Chem.*, *110*, 126 (1920).

[8] U. S. Bureau of Standards, Sample No. 29, even though it contains but 12.02% of SiO_2, was selected to illustrate the method proposed because of its status. The FeO content is 24.78% according to the certificate, dated Dec. 1, 1910. This value, apparently contrary to the present practice of the Bureau, is the work of but one analyst, which point together with the early date should be taken into consideration when comparing the figure with averages here reported.

[9] Compare Adam, *J. S. African Chem. Inst.*, *8*, 7 (1925). A copy of this article was obtained after the work here reported had been finished. In agreement with Adam it should be emphasized that HCl + HF + water as a solvent was found far more satisfactory than H_2SO_4 + HF + water, especially, for magnetites. Ores that were dissolved only after long and repeated boiling in the latter mixture were completely decomposed by the former in less than five minutes at a temperature approximating 50°. Combinations of sulfuric acid and hydrochloric acid in various ratios were distinctly less efficient than hydrochloric acid alone.

[10] See U. S. Bureau of Standards Circular No. 26, p. 4, for procedure when drying sample.

10 cc. of hydrochloric acid (35%) and 3 cc. of hydrofluoric acid (48%) were added and the flask gently warmed (40–50°) until no black residue was discernible. This required three to five minutes. Then the rate of flow of carbon dioxide was increased and 100 cc. of water containing 5 g. of boric acid and 5 cc. of sulfuric acid (1:6) was added. The mixture was titrated immediately. Results obtained on three consecutive days are given in Table I.

TABLE I

DETERMINATION OF FEO IN BUREAU OF STANDARDS MAGNETITE (IRON ORE NO. 29)

1 g. of $Ce(SO_4)_2$ soln. $\approx$ 0.0034685 g. FeO. Certificate value of FeO in Fe_3O_4 = 24.78%

	Fe_3O_4, g.	$Ce(SO_4)_2$ soln., g.	FeO, %	
1	0.2776	19.635	24.53	Average, 24.57
	.2806	19.900	24.58	
	.3012	21.355	24.59	
2	.3793	26.832	24.54	Average, 24.56
	.4019	28.445	24.55	
	.3192	22.649	24.60	
	.3852	27.229	24.52	
	.4206	29.824	24.60	
3	.4609	32.613	24.54	Average, 24.54
	.4077	28.859	24.55	
	.3683	26.038	24.52	

Restandardization of Ceric Sulfate.—On the same day that the third set of magnetite samples was analyzed the ceric sulfate was again standardized against electrolytic iron using essentially the method originally employed. The average of results obtained was 0.04827 N by weight. The solution was then compared with a different primary standard, retaining, in so far as possible, a final reaction essentially similar to that originally used. The three steps following were completed in one day.

First, 0.1 N potassium permanganate was standardized against Bureau of Standards sodium oxalate.[11] Next, portions of a sample of ferrous sulfate, selected and tested for uniformity of composition, were transferred to 500-cc. Erlenmeyer flasks filled with carbon dioxide; 200 cc. of water and 10 cc. of sulfuric acid (1:1) were added and the solution was titrated at once with the permanganate just standardized. Determining the equivalence point visually the average of three consecutive results, expressed in ferrous iron content, was 26.63% of FeO. Finally, the ferrous sulfate was titrated with ceric sulfate, using the same reagents as for analysis of magnetite but modifying the procedure to the extent that the reagents were all added at once and the titration was carried out immediately. The average of three consecutive determinations showed an iron content of 26.60% of FeO. Later, the ferrous sulfate was

---

[11] For details of procedure see the certificate or McBride, THIS JOURNAL, 34, 393 (1912).

again analyzed using exactly the same procedure as for magnetite. The results averaged 26.66% of FeO.

In order to detect any effect due to the decomposition flask, samples of magnetite were analyzed by the usual procedure in flasks of transparent fused quartz. The average of three consecutive results was 24.58% of FeO.

As a final variation a silver chloride electrode[12] was substituted for the silver wire. Three more analyses of magnetite gave an average of 24.55% of FeO.

Discussion

Among the sources of error encountered in the determination of ferrous iron those leading to low results are considered to be the more common. In the work under consideration thorough preliminary tests and the experiments with ferrous sulfate would indicate that the reagents were satisfactory and the measures for protecting against atmospheric oxidation adequate. The question of low results due to the current generated during titration by the method of Furman and Wilson can be dismissed after a brief calculation. Assuming a titration period double that required and the maximum instead of the average galvanometer deflection only 1.5×10^{-6} g. of FeO would be oxidized.

Another source of error mentioned especially by Adam[g] is "whether the HCl decomposition takes place without oxidation of a part of the ferrous iron." In the preliminary work experiments were conducted involving variations in amount of hydrochloric acid up to 25 cc. and time of digestion up to 160 minutes. No effect attributable to such variations was found.

Summary

Ferrous iron can be determined quickly and accurately in magnetites and materials of higher silicate content by electrometric titration with ceric sulfate after decomposition in a pyrex glass flask by a mixture of hydrochloric and hydrofluoric acids. Reducing agents derived from the glass have no effect.

CHEMICAL REACTIONS OF DRIED SUBSTANCES. I. AMMONIA AND PHOSPHORUS PENTOXIDE

BY LOUIS HARRIS AND CHARLES BUSHNELL WOOSTER[1]

RECEIVED APRIL 1, 1929 PUBLISHED JULY 5, 1929

It was reported by H. B. Baker[2] that phosphorus pentoxide did not absorb thoroughly dried ammonia. Gutmann[3] was unable to duplicate these results but he failed to describe the purity of the phosphorus pentoxide and the method of introducing it into his apparatus. Baker[4] repeated his own experiments and reaffirmed his claim, suggesting that the presence of metaphosphoric acid would explain the absorption of ammonia observed by Gutmann. Recently, Robertson, Fox and Hiscocks[5] passed dried and purified ammonia through a tube of phosphorus pentoxide and confined it over mercury in contact with the pentoxide. They observed a slight reaction at first, after which no decrease in volume occurred during forty-eight hours.

In several of these investigations the experimental conditions were such that the ammonia might have partly saturated the phosphorus pentoxide before the observations were made. Furthermore, the possible formation of a protective film upon the pentoxide was not excluded. It appeared worth while, therefore, to repeat the experiments, avoiding these sources of uncertainty and taking the additional precautions made possible by modern, high-vacuum technique. The hazard of preliminary saturation of the phosphorus pentoxide may be eliminated by observing the pressure of ammonia before as well as after exposure to it and the possibility of film formation may be tested by exposing the gas to a fresh surface of the pentoxide after reaction with the first sample has ceased.

Baker dried his apparatus by heating the glass nearly to the softening point and simultaneously drawing through it a stream of air dried with sulfuric acid. Ammonia was prepared from ammonium chloride and dried over lime for several days. A thin glass tube containing sublimed phosphorus pentoxide was broken in a reaction chamber containing the dried ammonia and pressure changes were observed on a mercury manometer.

In the present investigation it was considered desirable to dry the apparatus by evacuation at elevated temperatures, to employ phosphorus

pentoxide free from lower oxides[6] and observable quantities of metaphosphoric acid and to use ammonia which, after drying with dissolved sodium, had been triply distilled without further contact with any but dried and outgassed surfaces of pyrex glass and fused quartz.

Experimental Part

Apparatus.—The apparatus consisted essentially of purification trains for the reagents, a storage bulb for the ammonia and storage tubes for the phosphorus pentoxide, a quartz spiral manometer (connected by means of a graded seal) and suitable attachments for evacuating the system. A diagram appears in Fig. 1. The points at which various sections were sealed off during the manipulation are indicated by constrictions. Temporary separation of various parts was accomplished by the use of plunger stopcocks of the Richards type through which were made the connections described later.

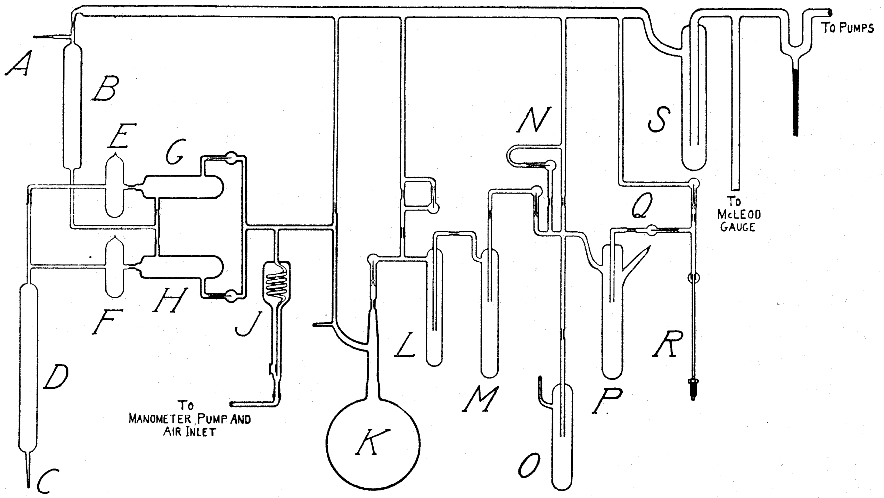

Fig. 1.—Apparatus for studying the reaction between dried ammonia and phosphorus pentoxide.

The iron cores were enclosed in glass sheaths to prevent contact between ammonia and the metal surfaces. A small mirror mounted on the indicator of the quartz manometer reflected the image of a straight filament upon a ground-glass scale placed at a distance of three meters. The manometer was used as a null instrument, balancing the pressures within it by external pressures which were read on a mercury manometer. Readings were accurate and reproducible to one millimeter. This auxiliary equipment is not shown in the diagram.

Method of Drying.—The glass and quartz surfaces were outgassed by evacuating through a liquid-air trap S with a mercury diffusion pump and a high-vacuum type of oil pump fifteen hours a day for five days. During this pumping the apparatus was intermittently heated with a blow torch until a yellow color was imparted to the flame and a high-tension discharge from a high frequency coil (which gives a one-inch spark in air) played upon the hot surfaces. After the third day no discharge from the heated

---

[6] Biltz, *Ber.*, 27, 1257 (1894), observed that the presence of lower oxides caused absorption of the ammonia.

surfaces was observable. At the end of the five-day period the pumps could be disconnected for nine hours without a rise in pressure of more than 3 × 10^{-6} mm. of mercury. The direct leads to the pumps were then sealed off.

Materials.—Several brands of C. P. phosphorus pentoxide were tested for lower oxides and organic matter. The tests used for lower oxides were the mercuric chloride test advocated by Whittaker[7] and the silver nitrate test suggested by Finch and Peto[8] which is claimed to be the more sensitive by Finch and Fraser.[9] Our observations confirm this claim. One brand which was nearly free from these impurities was selected and further purified by sublimation at 800° in a stream of oxygen according to the directions of Finch and Fraser[9] and obtained in the highly pure and voluminous form which they described. Samples of this purified material were placed in the sublimation tubes E, F which were sealed off and evacuated. The surfaces of the storage tubes G, H were then outgassed and dried as described. The fine capillary C which terminated the inlet was broken and a stream of dry air entered through the phosphorus pentoxide protection tube D. The tip A of the second protection tube B was broken to provide an outlet and a slow stream of oxygen, dried by passage through an additional phosphorus pentoxide tube 80 cm. in length, was led through the sublimation train. Upon moderate heating, the pentoxide in the sublimation tubes readily sublimed and collected in the storage tubes as a voluminous deposit of feathery crystals and white powder. This material was apparently free from metaphosphoric acid, since it could be sublimed from one part of the tube to another without leaving any visible residue. The sublimation tubes together with the attached guard tube D were sealed off, the tip A of the second guard tube sealed and the storage tubes evacuated. Thus the storage tubes were protected by a guard tube of phosphorus pentoxide and a liquid-air trap. They were heated as hot as possible without driving out the pentoxide and treated with the discharge until a satisfactory vacuum and outgassing had been achieved, when they were sealed off from the vacuum line. Samples of the material which had collected in the connecting tubes were tested and found to be free from lower oxides.

Commercial anhydrous liquid ammonia was used as a starting material. This had been in contact with sodium in a special steel cylinder for four months. The outlet R of this cylinder was attached to the purification train with de Khotinsky cement. The connecting tubes between the tank and the first stopcock Q were pumped out but could not be heated, so the entering ammonia was redried by condensation at −78° into the first distillation tube, P, which contained metallic sodium. As soon as a sufficient quantity had collected, the lead from the tank was sealed off and the solution of sodium in the liquid ammonia allowed to stand for five hours.

One-third of the ammonia was distilled into a receiver O and discarded after sealing off this receiver. Baths of solid carbon dioxide in alcohol were used as refrigerants in all of the distillations. Hydrogen present in the vapors was now removed by connecting the first distillation tube through a stopcock N to the vacuum pumps. The ammonia was kept at −78° during this process and after the pumping was completed the vacuum connection was sealed off. Connection was then made to the second distillation tube M, one-half of the remaining ammonia distilled into it and this sample twice fractionated, retaining only the middle third at each step. Economy of apparatus and manipulation was achieved by returning the first third of each distillate to the residue and discarding them together.

Before allowing a sample to evaporate from the third distillation tube L into the storage bulb K, connection was made to the vacuum pumps for a short time to ensure

---

[7] Whittaker, J. Chem. *Soc.*, **127, 2221 (1925).**

[8] Finch and Peto, *ibid.*, **121,692 (1922).**

[9] Finch and Fraser, *ibid.*, **129, 117 (1926).**

complete removal of any residual traces of hydrogen. When the vacuum connection had been sealed off and the stopcock leading to the storage bulb opened, a deflection of the quartz manometer J was observed which was found to indicate a pressure of 46.0 mm. (of mercury) within the system. As the ammonia in the third tube was partly frozen to a white solid at this time, this value should correspond to the vapor pressure at the melting point. This pressure is given by Landolt-Börnstein[10] as 44.9 mm., thus providing a check upon the reliability of the manometer. The purified ammonia was allowed to evaporate until the storage bulb was filled to a pressure slightly below atmospheric when the third distillation tube and the stopcock were sealed off.

The Action of Dried Ammonia on Phosphorus Pentoxide.—The volume of the storage bulb, manometer and connecting tubes had been found to be 1124 cc. by allowing dried air to expand into this system from a bulb of known volume. Accordingly, by reading the pressure and noting the temperature of a water-bath surrounding the storage bulb, the amount of ammonia therein (0.742 g.) could be determined. The volumes of the two phosphorus pentoxide storage tubes (neglecting the volume of the pentoxide, itself) was also known and thus the drop in pressure, due to expansion alone, upon connecting these tubes with the bulb could be calculated.

When the stopcock leading to the first pentoxide tube was opened a very rapid drop in pressure occurred which only continued for less than one minute. Thereafter the pressure fell very slowly. During the reaction some of the pentoxide near the ammonia entrance shrank considerably in volume and took on a glassy appearance. In other parts of the tube its appearance was not so markedly changed. Since the tube became heated during the reaction, one hour and fifteen minutes was allowed for cooling and the pressure then determined. Upon standing thirteen hours the pressures dropped 7.4 mm. (of mercury) more. The second pentoxide tube was then connected and a similar effect was observed. The data for these pressure changes appear in Table I. The third column lists the pressures in mm. of mercury before opening the pentoxide tubes, the fourth the new pressures calculated for expansion only, the fifth the new pressures observed, the sixth the drop in pressure due to absorption.

TABLE I

PRESSURE CHANGES DURING RAPID REACTION

Tube no.	Volume, cc.	P_1	P_2 (calcd.)	P_2 (obs.)	P (abs)	Temp., °C.
I	52	713	682	532.5	149.5	21.3
II	47	525.1	505	122.9	382.1	20.3

The system was allowed to stand for two days after these observations were made and the pressure read from time to time. These values, corrected for temperature variations, together with the time intervals are given in Table II.

---

[10] Landolt-Börnstein, "Physikalisch-Chemische Tabellen," Berlin, 1923, Vol. II, p. 1345.

TABLE II

PRESSURE CHANGES SUBSEQUENT TO RAPID REACTION

Pressure, mm.	122.8	119.8	113.9	102.8	92.0
Time, min.	0	85	320	1370	2810

The second pentoxide tube was then heated to 74° in a water-bath but no effect upon the pressure was observed beyond that calculated for expansion. This indicates the occurrence of a true reaction as opposed to mere adsorption.

Finally, dry air was admitted to the system and the two pentoxide tubes were sealed off. These were weighed, broken open, cleaned out with water and reweighed. By subtracting from the total weight of the contents of each tube the weight of ammonia absorbed in that tube as calculated from the pressure drop, the amount of pentoxide originally present was determined. These data appear in Table III, where Col. 2 gives the amounts of phosphorus pentoxide in each tube, Col. 3 the amount of ammonia actually absorbed and Cols. 4 and 5 give the amount calculated upon the assumption that one and two moles of ammonia, respectively, react per mole of pentoxide.

TABLE III

ABSORPTION OF AMMONIA BY PHOSPHORUS PENTOXIDE

Tube no.	P_2O_5, g.	NH_3(obs.), g.	NH_3 (calcd., 1 mole), g.	NH_3 (calcd., 2 moles), g.
I	3.060	0.162	0.366	0.732
II	5.635	.435	.673	1.346

It was noticed that, whereas part of the contents of the pentoxide tubes was glassy in appearance and dissolved but slowly in water, other portions reacted vigorously, indicating the presence of unused pentoxide. The aqueous solutions were tested and the absence of lower oxides in the reaction product was demonstrated.

Conclusions

There is, of course, no known method of establishing the precise degree of dryness actually attained in an investigation of the kind here described. It is the opinion of the authors, however, that the procedure employed was at least equal, and in some respects superior, to that described by the previous investigators.

It is a noteworthy fact that the amount of ammonia absorbed in the period of rapid reaction was insufficient to saturate the available phosphorus pentoxide. This is evident from Table III upon comparing the observed absorption with that calculated even upon the assumption that only one mole of ammonia reacts with one mole of the pentoxide. The actual difference is probably much greater, for the nature of the reaction products obtained by various investigators[11] indicates that at least *two* molecules of the gas are involved in the reaction. This marked retardation of the absorption cannot be ascribed to the removal of residual traces of moisture from the ammonia since a rapid absorption again took place when *a* fresh surface of the pentoxide was exposed. The effect may be explained by assuming the formation of a protective film of the reaction product upon the phosphorus pentoxide. This assumption is compatible with the appearance and character of the reaction product obtained.

No indications of such film formation have been reported by the previous workers and the information which they give is not sufficient to determine to what extent their observations may have been influenced by this effect.[12]

Summary

1. Pure phosphorus pentoxide has been found to absorb appreciable quantities of carefully dried ammonia rapidly.

2. Evidence has been obtained indicating that the reaction product forms a protective film upon the pentoxide which retards further absorption.

CAMBRIDGE, MASSACHUSETTS

---

[11] J. W. Mellor, "A Comprehensive Treatise on Inorganic and Theoretical Chemistry," London, 1928, Vol. VIII, pp. 708–711.

[12] After this paper was submitted for publication our attention was called to an article by H. Tramm [*Z. physik. Chem.*, **105**, 356 (1923)]. He found that phosphorus pentoxide reacted with ammonia dried by Baker's procedure or by dissolving sodium in the liquid ammonia. However, he reported that ammonia dried by passage over sodium wire and then through liquid sodium–potassium alloy did not react with the pentoxide. He did not consider the possible influence of the formation of a protective film upon the pentoxide and it appears from the description that the ammonia was first admitted at low pressure into the pentoxide tube. Under such conditions film formation might occur without a very noticeable heat effect and thus the disappearance of a small amount of ammonia at the beginning of the experiment might have been unnoticed. Since he did not state his criterion for reaction, it seems advisable to reserve judgment upon his experiment until it has been repeated.

A STUDY OF THE PRODUCTS OBTAINED BY THE REDUCING ACTION OF METALS UPON SALTS IN LIQUID AMMONIA SOLUTION. I. INTRODUCTION. II. THE ACTION OF SODIUM UPON ZINC CYANIDE

BY WAYLAND M. BURGESS AND ARTHUR ROSE*

RECEIVED APRIL 15, 1929 PUBLISHED JULY 5, 1929

I. Introduction

When an alkali metal is dissolved in liquid ammonia, it ionizes, forming cations identical with the positive ion of a salt of this metal, and anions consisting of solvated electrons.[2] This solution containing free electrons is a most powerful reducing agent. Many reactions between solutions of this kind and both organic and inorganic compounds have been carried out.[3] A quantitative method for analysis of chlorine in organic compounds has been developed in this way.[4] Many of the reactions, however, have been studied chiefly from a qualitative point of view. A quantitative investigation of reactions of this type and of the products formed is being carried out in this Laboratory. The present series of papers deals with the results obtained with inorganic salts.

The type reactions that may take place between ammonia solutions of the metals and salts have been presented by Kraus and Kurtz.[3j] With the alkali or alkaline earth metals and salts of less positive metals, reaction may occur in which the cation is reduced and precipitated as free metal, or is reduced further and forms a compound, usually insoluble, with the reducing metal. These possibilities were illustrated by Kraus and Kurtz[3j] with numerous reactions. In some cases compounds of unusual composition were postulated as, for example, $NaZn_4$, Ca_7Zn. These formulas were established only from the ratio of reacting materials, and not by analysis. It is the purpose of this investigation to isolate the products formed in reaction between salts and metal solutions, determine their composition by analysis and make a study of their properties.

II. The Action of Sodium upon Zinc Cyanide

Introduction.—Kraus and Kurtz[3j] found that sodium reacts very readily with zinc cyanide in liquid ammonia solution, forming a finely-

divided metallic precipitate, extremely reactive with respect to water and air. From the reaction ratio they proposed the formula $NaZn_4$. Mathewson[5] obtained only the compound $NaZn_{12}$ by the method of thermal analysis. In the present paper the precipitate formed as mentioned above is analyzed and shown to have the composition $NaZn_4$. The results of a study of the reactions between this compound and oxygen, air and water are also presented.

Preparation of the Sodium Zinc Compound.—The apparatus used for the reaction of sodium upon zinc cyanide is shown in Fig. 1. Anhydrous ammonia gas, obtained from a small supply tank of liquid ammonia, to which pieces of sodium had been added, entered the reaction tube, R, through a tube, I, and condensed under a pressure of 10 cm. of mercury as shown by the gage P. Cooling was provided by a bath of liquid ammonia in the Dewar flask D, through which a current of air was bubbled to secure a still lower temperature. After 100 cc. of ammonia had condensed, about 0.5 g. of sodium, freshly cut under petroleum ether, immediately transferred to a weighing bottle filled with dry nitrogen and weighed, was added through the side tube O. Then the calculated amount of Kahlbaum's zinc cyanide was added slowly. Reaction occurred very rapidly and a dense black precipitate quickly settled out. That a gaseous product insoluble in water was not formed was shown in several cases by closing the clamp, G, and opening the clamp, H, for the duration of the reaction.

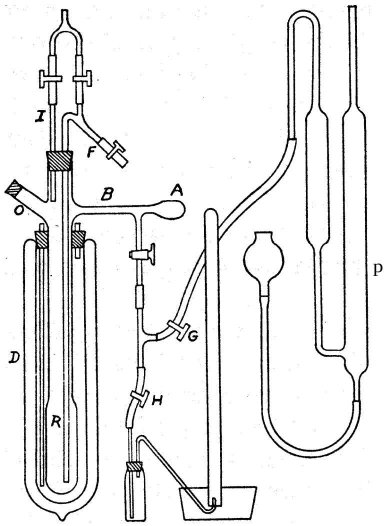

Fig. 1.—Apparatus used for the preparation of $NaZn_4$.

When the reaction was completed, the clear solution was removed and the precipitate washed as follows. With a small pressure on the system, a clamp on tube F was opened and the liquid above the precipitate forced out through tube F. By careful manipulation 90% or more of the liquid could be drawn off without loss of the solid. Fresh ammonia was now condensed and the process repeated. In this way the precipitate was washed seven or eight times. The last trace of ammonia in the reaction tube was allowed to evaporate against a slight pressure.

The product of the reaction was left in the form of a black powdered material. Samples for analysis were obtained by tipping the reaction tube until a suitable quantity had entered the collection tube A. The collection tube was then sealed off at B, evacuated to about 0.01 mm. of mercury and weighed. The sample was then dissolved in 6 *N* hydrochloric acid, using a technique similar to that described by Franklin.[6] The solution was analyzed for zinc and ammonia.

Composition of the Sodium–Zinc Compound.—An aliquot part of the acid solution was analyzed for zinc by precipitating and weighing as $ZnNH_4PO_4$. Another portion was analyzed for ammonia by distillation, after the addition of concentrated sodium

hydroxide and collection of the distillate in 0.1 N HCl. No more than a trace of ammonia was found in any sample. The results of the zinc analyses are given in Table I.

TABLE I

COMPOSITION OF THE SODIUM–ZINC COMPOUND

Calculated for $NaZn_4$: Zn = 91.9%

No.	Sample, g.	$ZnNH_4PO_4$, g.	Zinc, g.	Zinc, %
30	0.2074	0.5155	0.1889	91.1
31	.1295	.3243	.1188	91.8
32a	.0778	.1960	.0718	92.3
32b	.0851	.2144	.0786	92.3
32c	.1479	.3700	.1356	91.7
20	.1058	.2636	.0966	91.3
23	.1046	.2635	.0965	92.3

The first three samples were prepared solely for the zinc analysis, the others were first treated in various ways. All samples, except 32, were prepared by adding zinc cyanide to a sodium solution in the ratio of 1 $Zn(CN)_2$ to 2.25 Na. This ratio, first determined by Kraus and Kurtz,[3j] was checked and found to be correct. In preparing Sample 32 the addition of zinc cyanide was stopped while the solution was still blue, so that a slight excess of sodium was present.

The results establish the formula $NaZn_4$ for the sodium zinc compound. The equation for the reaction is

$$4\ Zn(CN)_2 + 9\ Na = NaZn_4 + 8\ NaCN$$

A slight excess of sodium does not affect the composition of the precipitate. An excess of zinc cyanide, however, does change its composition. Thus by having a 20% excess of zinc cyanide present, the product analyzed once 98.1% of zinc and again, 99.3% of zinc.

Oxidation of the Sodium–Zinc Compound.—Kraus and Kurtz[3j] reported that this compound was very active toward air and water. Attempts were made to establish quantitatively the reactions taking place between $NaZn_4$ and dry oxygen, dry air, moist oxygen and moist air.

In most of the experiments the $NaZn_4$ was first prepared in a small reaction tube, the top of which was sealed before the final evaporation of the ammonia. The side arm of the reaction tube was then sealed to another tube which we shall call the oxidizing system. This system was also joined through stopcocks and glass tubing with an evacuating pump, a closed mercury gage and a buret. The top of the buret was also connected with a source of dry oxygen or air and the bottom was joined by rubber tubing to a leveling pear containing mercury. After the entire system had been evacuated to approximately 0.01 mm. of mercury, a measured volume of gas was allowed to enter from the buret. The process of the oxidation was followed by the decrease in pressure as shown on the mercury gage. The entire system was later calibrated so that the volume of gas in the system corresponding to any gage reading could be calculated. By subtracting the amount of gas in the system from the total amount let in, the volume used up at any stage of the reaction could be obtained. In a few cases the sample was weighed before and after oxidation, to get the weight of oxygen involved.

The oxidation reaction is divided into two distinct stages. At first oxygen is taken up rapidly, with considerable evolution of heat, but no noticeable change in the appearance of the sodium zinc takes place. This primary oxidation is followed by a secondary reaction which proceeds at a very slow rate for a long period of time, accompanied by a change in the color of the substance from black through gray to white.

Dry air acts in the same way as dry oxygen. Moist air or moist oxygen accelerates the oxidation so much that the two stages are not apparent. A higher temperature also speeds up the secondary reaction. The data for these statements are given in Table II.

16	0.5274	...	0.0912	5.700	1.854	3.1

The most remarkable feature of the oxidation experiments is that the $NaZn_4$ rapidly takes up enough oxygen to form sodium monoxide. Then apparently the zinc is slowly oxidized. With moisture both the sodium and part of the zinc react rapidly with oxygen, the heat liberated increasing the speed of the reaction. Tests for peroxides were made on several samples, oxidized in different ways, without obtaining any evidence of their formation. That the amount of oxygen taken up by the sample varied considerably was' due to variation in conditions. For instance, if the oxygen were let in rapidly, considerably more heat was developed and more oxygen absorbed in a given time than when the gas was let in slowly. A further study and standardization of the conditions of oxidation are necessary for more definite conclusions.

The Action of Water and Dilute Acid upon $NaZn_4$.—The reaction between $NaZn_4$ and water, and also dilute acid, was investigated by allowing a small amount of water, or acid, to enter the evacuated collection tube containing a known weight of sample. The hydrogen liberated by the reaction was removed by means of a Toepler pump and analyzed by explosion with air. With water the reaction, even at first, was a slow one, continuing with decreasing rate for some time. Thus during the first week approximately 20 cc. of hydrogen per gram of sample was liberated each day. At the end of a month about 1 cc. of hydrogen per day was formed. With dilute acid the reaction was over in a short time. The total amount of hydrogen liberated is given in Table III.

TABLE III

HYDROGEN LIBERATED BY THE REACTION DURING A PERIOD OF TWO MONTHS

	With water		With 6 *N* HCl	
Expt. no.	18	19	32a	32b
$NaZn_4$, g.	1.1316	1.9280	0.0778	0.1479
Hydrogen, cc. (S. T. P.)	189.0	334.6	27.4	53.1
Hydrogen, g.	0.0170	0.0301	0.0025	0.0048
Equiv. H_2 per mole $NaZn_4$	4.2	4.4	9.0	9.1

The reaction of the sodium in $NaZn_4$ upon water and of the sodium hydroxide formed in this way upon zinc would account for less than half of the hydrogen obtained. Evidently the zinc reacted directly with water to furnish this extra hydrogen.

The hydrogen liberated when the sample was treated with acid is equivalent to the total sodium and zinc present. This result may be taken as additional evidence of the composition of the compound.

Summary

The product formed when zinc cyanide is added to a solution of sodium in liquid ammonia has been shown by analysis to have the composition $NaZn_4$. This compound reacts with oxygen or air in two stages, the speed of the secondary reaction being increased by the presence of moisture or by heating. Reaction of the compound with dilute acid liberates nine equivalents of hydrogen per mole of $NaZn_4$; with water, approximately 4.5 equivalents of hydrogen are liberated in two months.

A STOPCOCK IN WHICH CONTAMINATION BY GREASE IS PREVENTED AND ITS APPLICATION TO A PROBLEM IN GAS TECHNIQUE

By Herman C. Ramsperger[1]

Received April 18, 1929 Published July 5, 1929

Vapors from stopcock grease are always more or less objectionable in high vacuum work, but greased stopcocks have frequently been tolerated when gases under moderate pressure were to be transferred through such a system in roughly controlled amounts. The objection to stopcock grease is more serious when organic vapors are to be handled, for in many cases these vapors are taken up in appreciable amounts by the stopcock grease. This is the case in a problem in reaction velocity which the author wished to undertake, and the apparatus here described was successfully used in that work.

The principle is illustrated by Fig. 1A.

This stopcock is of the hollow plug type. The ground portion is about 4-cm. long. A small groove is ground on the outside of the plug, completely encircling it at about two-thirds of the way down the ground portion as shown at a. Two vertical grooves are etched on the inside of the bore of the stopcock from the top of the ground portion down sufficiently far to reach the circular groove when the plug is in place. They are shown in the cross-sectional diagram, Fig. 1B, at b. They are about 1 mm. wide and probably about 0.1-mm. deep. They are produced by etching with concentrated hydrofluoric acid for about twenty minutes.

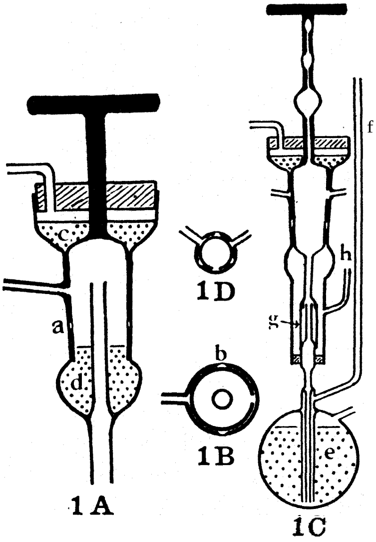

Fig. 1.

The stopcock is assembled as follows. A very small amount of stopcock grease is applied to the lowest edge of the ground portion of the bore and the plug inserted with the hole of the plug in line with the side opening on the bore. If now the system is evacuated, mercury from above the plug at c will flow down the two vertical grooves and into the circular groove. Gas flowing through the stopcock cannot come in contact with the stopcock grease on the lower ground portion, for it is protected between the ground surfaces by the ring of mercury, and from the inside by the mercury at d. To close the stopcock the plug is turned through 180° as shown in Figure 1B. In this process a very small droplet of mercury falls through the hole as the hole passes one of the grooves. It is apparent that the stopcock will not allow gas to pass if the pressure on either side of the stopcock is a few cm. less than the external pressure forcing the mercury into the grooves.

---

[1] National Research Fellow in Chemistry.

The success of such a stopcock depends on the fact that surface tension prevents the mercury from going beyond the edges of the grooves, which it will not do if the surfaces are sufficiently close fitting. If, however, they fit very tightly, the stopcock cannot be turned. The purpose of the grease in the lower portion is to give a slight separation so that the stopcock may be turned easily. It was found that from 40 to 50 cm. difference in pressure was the upper limit for which the mercury would not leak through and the stopcock could yet be turned. It was, therefore, necessary to control the external pressure by placing a rubber stopper over the top of the stopcock, thereby making it possible to control the pressure on the mercury at c. The hole in the stopper through which the handle of the plug passes is greased and remains airtight.

It was convenient in the study of the thermal decomposition of the gas methyl isopropyl di-imide to be able to introduce a measured amount of gas from a supply bulb into the reaction cell, and to measure the pressure in the cell immediately and at intervals during the reaction. In another research it was necessary to introduce into the reaction cell a definite pressure of azomethane gas mixed with varying amounts of some inert gas, and then to follow the decomposition of the azomethane by pressure measurements. If this were attempted using ordinary greased stopcocks the partial pressure of azomethane would change during handling of the gases, due to absorption by the grease.

An application of the above described stopcock was devised for these experiments. It is illustrated in Figs. 1C and 1D.

The body of the stopcock is made as in Fig. 1A except that there are two side tubes and three vertical grooves as indicated in Fig. 1D. When this stopcock is in the closed position (Fig. 1D) it may be used as a McLeod gage, mercury being forced up from the bulb, e. Accuracy over a wide range of pressures is secured by placing bulbs of varying size in the handle of the stopcock. The gage is calibrated by determining the volumes to fixed points on the capillaries between the bulbs, and to a fixed point in the tube below the hollow plug. The one used in the experiments referred to has a total volume of 15.2 cc. and can measure pressures from 0.06 to 30 mm. with an accuracy varying between 0.2 and 2%. The tube, f, leads to a high vacuum. This tube is larger than the capillaries in the handle, so that with the gage evacuated the mercury in the tube, f, rises to a higher level than in the capillary. When the mercury is at one of the fixed points on the capillaries the mercury levels on the tube, f, are taken as the positions of zero pressure.

To allow the stopcock to turn and yet keep the mercury bulb, e, stationary, a rubber tubing connection is made at g. The space surrounding it is evacuated through the tube, h. When the mercury has once been run up through this rubber connection and has filled the rubber tube and the inner glass tube, no gas in the gage comes in contact with rubber tubing.

In using the device for the azomethane research, azomethane was introduced through the left tube. The flow could be controlled readily, since the gas could be made to pass between the ground surfaces to reach the hole. The stopcock was closed and the pressure measured. Azomethane was pumped out of the left tube and an inert gas under pressure was then similarly admitted. The total pressure was then determined. The gases were thoroughly mixed by the compression and expansion during the pressure measurement. The mixed gases were admitted to the reaction cell, which was attached close to the right-side tube. The stopcock was then closed and the pressure read at liberty. At any predetermined time the stopcock was opened for a few seconds and another pressure measurement made. The rate of this reaction could thus be followed, since an increase in pressure at constant volume occurs in the reaction.

It is evident that at no time after the gases were once admitted to the gage did they come in contact with grease. The device is very compact when one considers the number of operations to be performed.

THE THERMAL DECOMPOSITION OF METHYL ISOPROPYL DI-IMIDE: A HOMOGENEOUS UNIMOLECULAR REACTION. THE THERMAL DECOMPOSITION OF HYDRAZOIC ACID AND METHYL AZIDE

BY HERMAN C. RAMSPERGER[1]

RECEIVED APRIL 18, 1929 PUBLISHED JULY 5, 1929

It is important that present theories of unimolecular reaction velocity should be thoroughly tested with a wide variety of reactions. All homogeneous unimolecular gas reactions so far discovered involve rather large molecules. Their reaction rate is too fast to be accounted for without ascribing to some of them as large a number of internal degrees of freedom as can be justified, while others require but few degrees of freedom. The decomposition of nitrogen pentoxide cannot at present be accounted for in this way, but the low-pressure data may still be questionable.

The author had previously found that the two azo compounds, azomethane[2] and azo-isopropane[3] decompose in a homogeneous unimolecular manner. A new azo compound, methyl *iso*propyl di-imide was recently prepared[4] by the author to provide an additional test of unimolecular reaction rate theories. Its decomposition will be shown to be first order at high pressures. However, the rate constant becomes lower at low pressures, as was also the case with azomethane.[5]

A unimolecular reaction involving a smaller molecule with a more limited number of degrees of freedom would provide another valuable test of reaction rate theories. For this reason the decomposition of hydrazoic acid and methyl azide was studied.

The Thermal Decomposition of Methyl Isopropyl Di-imide

Methyl *iso*propyl di-imide was prepared as described in a previous publication.[4] The thermal decomposition was carried out at pressures ranging from 5.8 $\times 10^{-3}$ cm. to **13.12** cm. and at temperatures ranging from 250 to 332°.

Nature of the Reaction Products.—A rough analysis of the products of decomposition in Expt. 34 (Table I) was made. The final pressure in this experiment (and all other experiments with this sample) was **2.18** times the initial pressure at constant volume. We may write equations for the likely reactions analogous to those of the other two azo compounds previously studied. The main reaction products in these cases were nitrogen and a hydrocarbon as shown, for example, in the equation $CH_3N{=\!=}NCH_3 = N_2 + C_2H_6$. In this new mixed azo compound, however, an analogous reaction may yield either a single hydrocarbon or a mixture of hydrocarbons according to whether the two radicals combine at the instant of disruption of the molecule or the separate radicals combine at random later.

The former case gives only butane and nitrogen. In the latter case we may expect combinations between two methyl radicals, between two isopropyl radicals and between methyl and isopropyl radicals. The equations for the two mechanisms are then as follows

$$CH_3N{=\!=}NC_3H_7 = N_2 + C_4H_{10} \qquad \text{(a)}$$

$$CH_3N{=\!=}NC_3H_7 = N_2 + xC_2H_6 + yC_4H_{10} + zC_6H_{14} \qquad \text{(b)}$$

Since the final pressure is greater than twice the initial pressure as would be required by both of these equations, there is a side reaction, as was also the case with the other azo compounds. Analogous side reactions are

$$2CH_3N{=\!=}NC_3H_7 = 2N_2 + C_2H_4 + 2C_3H_8 \qquad \text{(c)}$$

$$CH_3N{=\!=}NC_3H_7 = N_2 + CH_4 + C_3H_6 \qquad \text{(d)}$$

The gas to be analyzed was collected in a 250-cc. flask which had a manometer attached and had a tube sealed to the bottom. Liquid air, carbon dioxide snow and freezing mixtures were placed around this tube. After surrounding the tube with a constant temperature bath, the manometer pressures were read repeatedly until no further change was noted. This usually required only ten or fifteen minutes but a much longer time was usually taken to be sure of a constant reading. . The initial pressure of the gas was 10.98 cm. At −78°, 17.6% of the gas was condensed by means of ether–carbon dioxide mixture. Most of this condensed out between —20 and —50". Liquid air condensed **43.4%.** The vapor pressures of all of the possible reaction products are known at least approximately. Hexane is the only hydrocarbon that should condense out at temperatures above —78". Methane and nitrogen are the only gases that should remain uncondensed with liquid air. Since Reaction b is the only one producing hexane, the main reaction is to be represented by Equation b. If the side reaction c is to account for the final pressure, then 54.1% of the gas should be condensable with liquid air, while if Reaction d occurs only 45.9% of the gas should condense. Since the experimental result is even slightly lower than the latter value, it seems that Reaction d is the probable side reaction. An analysis made by the freezing out of vapors is not expected to be very accurate, but if a choice is to be made among these four reactions, the differences in the pressures expected are sufficiently great for this method to give the correct result. The 17.6% condensed at −78° is somewhat higher than one might expect. Collisions between the larger isopropyl radicals will occur more often than collisions between methyl radicals. If the diameter of an isopropyl radical be taken as 2.5 times that of a methyl radical and all combinations of the radicals are taken to be equally probable, then kinetic theory equations for the number of collisions[6] show that 37.1% of the mixed gases should be hexane and 14% of all of the gas should be condensable. It seems likely that the difference between the latter value and 17.6% may be due to butane and propylene dissolving in the condensed hexane, especially since the partial pressure of the butane is about two-thirds of its saturation pressure for this temperature.

Preparation and Purification.—Methyl isopropyl di-imide was prepared and purified in the manner described in a previous paper by the author.[4] Two different samples were used in this research. Experiments 1 to 30 (Table I) were made with the first sample and Expts. 31 to 47 were made with the second sample. An examination of the rate constants shows that the second sample gave the same rate constants as the first sample. However, the final pressures were about 2.12 times the initial pressure for Sample 1, and 2.18 times the initial pressure for Sample 2. The rate constants were calculated on the basis of the final pressures obtained. It is likely that the first sample contained a small amount of impurity, probably a hydrocarbon of similar boiling point.

Reaction Rate Measurements.—The same pyrex reaction cell, surrounded by mercury vapor boiling under a constant pressure, that was used with the previously studied azo compounds was used here. In addition, a similar apparatus made entirely of quartz was used in Expts. 1, 2, 31, 32 and 33. Experiments at pressures above 3 cm. were made exactly as with azomethane.[2] Experiments at low pressures were made with a combination of stopcock and McLeod gage described in the preceding article.[7] The first reading could be made within several seconds after the McLeod gage was open to the cell, and in only a few of the most rapid experiments was a correction necessary for the decomposition before this reading was made. The McLeod gage was kept closed between readings, and opened for only five to ten seconds before each pressure reading was made. The calculation of the partial pressure of the methyl *iso*propyl di-imide in the reaction cell was somewhat simpler than was the case with the apparatus used in the previous researches.

---

[6] Tolman, "Statistical Mechanics," The Chemical Catalog Co., New York, 1927, p. 71.

[7] Ramsperger, This Journal, 51, 2132 (1929).

Let P be the pressure read on the McLeod gage and *AP* the pressure increase during the preceding time interval. Let V_1 and T_1 be the volume and temperature of the McLeod gage and V_2 and T_2 the volume and temperature of the reaction cell. Then P', the total pressure in the reaction cell just before the reading, is given by $P' = P + \Delta P V_1 T_2/V_2 T_1$. Now the increase in pressure from the previous reading at time t' to the reading at time t divided by ***1.18*** (or ***1.12*** for the first sample) gives the reduction in pressure of the methyl isopropyl di-imide in the cell. If P'_{At} represents the partial pressure of methyl isopropyl di-imide before the reading at t' and $P_{At'}$ represents its partial pressure at the end of the previous reading, we have

$$P'_{At} = P_{At'} - (P_{t'} - P'_t)/1.18 \quad \text{and} \quad P_{At} = P'_{At}\, P_t/P'_t$$

The rate constant is then given by

$$K = \log_{10} \frac{P_{At'}}{P'_{At}} \times \frac{2.303}{t - t'}$$

where t and t' are given in seconds.

Experimental Results.—A summary of all of the experiments is given in Table I.

the experiments made with the empty cell and with those made in the quartz cell, the reaction is homogeneous and not influenced by the walls.

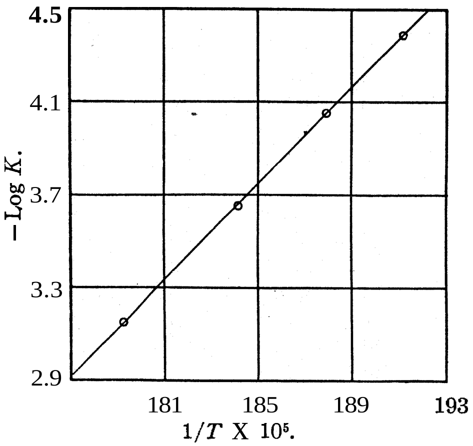

Fig. 1.

It is apparent that within experimental error and reproducibility the decomposition is first order in any given experiment. It is also apparent that the rate constant varies with the initial pressure, being lower for lower initial pressures. It does, however, approach a constant value at the higher pressures and lower temperatures as, for example, at 270 and 285°. Experiments were made at 250, 259.1, 270 and 285" at sufficiently high pressures to approach the value which would be obtained for very high pressures. The log of the rate constants for these experiments is plotted against $1/T$ in Pig. 1. These points should fall on a straight line according to the Arrhenius equation for the temperature coefficient of reaction velocity, namely, $d \ln K/d(1/T) = Q/R$. The line drawn through the points in Pig. 1 is a straight line. Q is found to be 47,480 cal. per mole. The equation for the rate constant is $2.72 \times 10^{15} \times e^{-47480/RT}$. However, the asymptotic values of the rate constants have not quite been reached at the highest pressures studied. We may take roughly $2.80 \times 10^{15} \times e^{-47480/RT}$ as the best value of the rate constant for very high pressures.

This reaction is evidently very similar to that of azomethane, which was shown to be first order at high pressures and to fall off in rate at lower pressures. With methyl isopropyl di-imide the high pressure rate is maintained to somewhat lower pressures than with azomethane. The more complex azo-isopropane showed no dropping in rate at the lowest pressures studied. A collision theory of activation developed by Rice and the author[8] (Theory II) was shown to be in agreement with the experimental data on azomethane.[9] Kassel[10] has also developed a theory (Theory III) which is very similar to Theory II of Rice and the author. Another theory (Theory I) of Rice and the author, which is an extension of the theory of Hinshelwood and Lindemann[11] to low pressures, does not fit the azomethane data. It has also been shown by Kassel[10] and by Rice and the author that several reactions studied by Hinshelwood and his co-workers cannot be accounted for as well on Theory I as on Theory II or III. More recently Rice[12] and Kassel[13] have given quantum treatments based on Theories II and III. The quantum treatments are more difficult to apply and for large molecules are not sufficiently different from the earlier classical theories for experimental data of the usual accuracy to decide between them. There is also no appreciable difference between Theories II and III for a molecule having a large number of degrees of freedom involved in the reaction, as is the case with the azo compounds. I will therefore use Theory II to interpret the decomposition of methyl isopropyl di-imide.

Equation 19 of reference 8 (*cf.* p. 1624) has been integrated graphically, using a value of 33 for n, and values of 543, 573 and 603 for T, corresponding to 270, 300 and 330°. E is 46,900 cal. per mole (from Equation 20 of reference 8). Log K/K_∞ is then calculated for a series of values of β_2/p. The experimental data are plotted as in Fig. 2. The theoretical curves are then found to fit the data if the molecular diameter be taken as 6×10^{-8} cm. The upper theoretical curve is for 270°, the middle curve for 300° and the lower curve for 330°. Most of the experimental points from 270 to 332° fall within the region bounded by the theoretical curves. It may also be observed that low temperature points fall above high temperature points. The small differences between the theoretical curve and experimental points should be ascribed to experimental errors of the indi-

vidual points and to a small possible error in K_∞ as calculated from Equation 1. The agreement is therefore as good as the experimental accuracy would justify.

The author would like to call attention to the significance of this agreement. If, for example, Theory I be applied with the same value for n and for the molecular diameter as used for Theory II, the dotted curve of Fig. 2 is obtained. This curve has the wrong shape and so cannot be made to fit all of the experimental points by changing either the diameter or the number of degrees of freedom. The curves for Theory II have now been shown to fit the low pressure data for the two azo compounds, azomethane and methyl *iso*propyl di-imide. They have also been shown to fit the data for diethyl ether and dimethyl ether.[9] The only other reaction that has been carried to low enough pressures to test theories of reaction velocity is the decomposition of nitrogen pentoxide. Here, however, the data of the various investigators do not agree among themselves, and Loomis and Smith[14] have recently shown that the methods used in these experiments produce very large errors due to absorption and occlusion. Very recently it has been reported that the rate constant of this reaction falls off even at several mm. pressure,[15] so conclusions regarding this reaction must be withheld until the low pressure data are confirmed. It is also significant that all of the various theoretical treatments that are based on the assumption that reaction occurs whenever a definite amount of energy becomes localized in one or at most several degrees of freedom, give the correct shape of curve. Normal molecular diameters are used

and the number of degrees of freedom required is not greater than is allowable in applying these theoretical treatments.

If, however, reliable data on the decomposition of nitrogen pentoxide do not agree with these theories, we may expect to find other unimolecular reactions, especially of inorganic molecules, which will disagree. It is possible that the assumptions made in the derivation of the theories regarding energy transfer both between molecules at collision and between internal degrees of freedom are approximately obeyed in the organic molecules and not in the others.

Data on the three azo compounds studied by the author are collected in Table III. P(cm.) is the pressure range studied, T the temperature range, A and Q are the quantities in the expression for the rate constant at high pressures, $K_\infty = Ae^{-Q/RT}$ and n is the number of degrees of freedom required by Theory II.

TABLE III

COLLECTED DATA FOR THREE AZO COMPOUNDS

Compound	P, cm.	T, °C.	A	Q, cal.	n
$C_2H_6N_2$	0.0259 to 70.79	278 to 327	1.07×10^{16}	51,200	25
$C_4H_{10}N_2$	0.0058 to 13.12	250 to 332	2.80×10^{15}	47,480	33
$C_6H_{14}N_2$	0.025 to 4.60	250 to 290	5.6×10^{13}	40,900	>40

The heat of activation of the new compound is intermediate between that for dimethyl di-imide and di-isopropyl di-imide. If now the decomposition of these azo compounds occurs by the breaking of a single bond, then we may expect the heat of activation of methyl isopropyl di-imide to be very nearly that of di-*iso*propyl di-imide, namely, 40,900 cal. per mole, for the reaction will occur at the weaker isopropyl bond and the interchange of methyl for *iso*propyl should not greatly alter the binding energy of the *iso*propyl bond. If, however, the reaction occurs by the simultaneous rupture of both bonds, then we may expect an intermediate heat of activation, and this is the experimental result. From the fact that the main reaction gives a mixture of hydrocarbons, we conclude that the two radicals are not combined at the instant of reaction but are separately dislodged and combine at random later.

The Thermal Decomposition of Hydrazoic Acid

Anhydrous hydrazoic acid vapor was found to decompose at 290° with measurable velocity. A white solid, probably ammonium azide, was formed and a gas, probably nitrogen, which was not condensable in liquid air was also produced. Only a small increase in pressure accompanied the reaction, so that the rate was followed by determining the percentage of gas not frozen out by liquid air. Three experiments, all at 290° and about 4-cm. pressure, showed that 9 to 11% of the hydrazoic acid was decomposed in twenty-five minutes, When pyrex tubing was placed in the reaction cell in sufficient amount to increase the surface to four times the original surface, three similar experiments showed that 12% was decomposed in eight minutes, 22% in twenty-five minutes and 31% in thirty-four minutes. While no great accuracy can be claimed for these experiments, they show conclusively that the reaction is catalyzed by the walls of the vessel. Since the reaction is not homogeneous it cannot be used to test gas phase reaction theories and so the reaction was not studied further.

The Thermal Decomposition of Methyl Azide

Methyl azide (CH_3N_3) was prepared from sodium azide and methyl sulfate. Five experiments were carried out at 245°. The complete decomposition gave a final pressure of 1.55 times the initial pressure. No analysis of the products of reaction was made but a white solid formed similar to that from hydrazoic acid. The reaction may very likely be the following, $2CH_3N_3 = C_2H_4 + 2HN_3$. The reaction rate so measured by the pressure increase was not influenced by increasing the wall surface and is therefore homogeneous. The reaction rate was first order during a given experiment but the rate constant became much lower at low pressures. A summary of the five experiments is given in Table IV.

TABLE IV

SUMMARY OF EXPERIMENTS

Expt.	5	4	1	3	2
Init. press., cm.	5.75	4.06	3.37	0.226	0.0484
Av. $K \times 10^3$	1.98	1.64	1.50	0.52	0.31

The reaction is somewhat uncertain because of the fact that it may be followed by the decomposition of hydrazoic acid, and the formation of the white solid would lead to inaccuracies at higher pressures. It seems likely, however, that this is really another homogeneous unimolecular reaction the rate of which falls off at low pressures.

The author wishes to take this opportunity to express an appreciation of the interest and encouragement Professor Gilbert N. Lewis has generously given throughout the author's researches on azo compounds made at the University of California and elsewhere.

Summary

The thermal decomposition of methyl *iso*propyl di-imide was studied over a temperature range of 250 to 332° and a pressure range of 0.0058 to 13.12 cm. The reaction has been found to be homogeneous and first order at high pressures, but the rate constant falls off at pressures below several cm. The high-pressure rate constant is given by the expression $K_\infty = 2.80 \times 10^{15} \times e^{-47480/RT}$. Theory II of Rice and the author has been found to fit the data if the molecule be assumed to have 33 degrees of freedom. The significance of this agreement is discussed. All unimolecu-

lar reactions (with the possible exception of nitrogen pentoxide) agree with theories based on the assumption that reaction occurs whenever a definite amount of energy becomes localized in one or, at most, several degrees of freedom.

The thermal decomposition of hydrazoic acid was found to be catalyzed by the pyrex walls of the reaction vessel.

The thermal decomposition of methyl azide was found to be homogeneous and first order during a given experiment but the rate constant becomes lower at lower initial pressures.

SOME THIOPHENE ANALOGS OF DI-, TRI- AND TETRAPHENYLMETHANE COMPOUNDS[1]

By Wesley Minnis

Received October 15, 1928 Published July 5, 1929

In the course of an attempt to extend the results of a previous investigation[2] of free radicals containing the thiophene ring, studies were made of various analogs of di-, tri- and tetraphenylmethane compounds in which one phenyl group was replaced by the thienyl group.

In general, methods of synthesis used in the benzene series were successfully applied. Usually the thiophene analogs were isolated with more difficulty, probably because of the greater reactivity of the thiophene nucleus, which tends toward the formation of by-products. After isolation, decomposition often occurred under conditions which do not similarly affect the phenyl compounds. For example, phenylthienyl ketone dichloride could not be distilled under reduced pressure without decomposition, whereas benzophenone dichloride is readily purified in such manner. The diphenylcarbinol halides have been made and are moderately stable, but attempts to prepare phenylthienylcarbinol halides resulted in deep-seated decomposition. The reduction of diphenylthienylcarbinol gave only a 50% yield of methane as contrasted with the practically quantitative yield of triphenylmethane from its carbinol. Diphenylthienylcarbinol halides were much less stable than the triphenylcarbinol halides, and the same was true of the corresponding free radicals.

The instability of the free radical, diphenylthienylmethyl, was reminiscent of the behavior of phenylthioxanthyl,[3] and it is tentatively suggested

[1] This article is an abstract of Part II of the dissertation submitted to the faculty of the University of Michigan, in partial fulfilment of the requirements for the degree of Doctor of Philosophy. 1922.

[2] Gomberg and Jickling, This Journal, 35, 446 (1913).

[3] Gomberg and Minnis, *ibid.*, 43, 1940 (1921).

that the presence of a bivalent-ring sulfur atom in its structure confers instability upon a free radical.

Of novel interest may be noted the preparation of a **di-triphenylmethyl-dithienyl** by a peculiar side reaction during a Grignard reaction; and of a-naphthylphenylthienylcarbinol, one of the few asymmetric **triarylcar**binols so far described.

Phenylthienyl Ketone **Dichloride,** $C_6H_5CCl_2C_4H_3S$.—Phenylthienyl ketone was prepared by the method described in the literature[4] but with higher yield than heretofore claimed, namely, 87%. A mixture of 19 g. of ketone and 22 g. (5% excess) of phosphorus pentachloride was heated at 60 to 80° for one hour. The phosphorus oxychloride formed in the reaction was distilled under reduced pressure and the partial vacuum maintained for one hour in order to remove excess pentachloride. The residual liquid could not be distilled under 20 mm. pressure without decomposition.

Anal. Calcd. for $C_{11}H_8Cl_2S$: Cl, 29.18. Found: Cl, 29.39.

Phenylthienylcarbinol, $C_6H_5CHOHC_4H_3S$.—The procedure of Montagne[6] for reducing a ketone to the corresponding carbinol by means of zinc dust and sodium alcoholate gave a product with sulfur content 3% under the theoretical. The method of Cohen[6] gave good results. To 5 g. of ketone dissolved in 40 cc. of alcohol and 10 cc. of concd. ammonium hydroxide solution was added 10 g. of aluminum amalgam and the mixture was refluxed for six hours. After cooling and filtration, the filtrate was poured into water, whereupon crystals separated after long standing. Recrystallized from ether, the crystals melted at 57 to 58°. Non-identity with the ketone was proved by a mixed melting point.

Anal. Calcd. for $C_{11}H_{10}OS$: C, 69.43; H, 5.30; S, 16.86. Found: C, 69.29; H, 5.23; S, 17.09. *Mol. wt.* Calcd.: 190. Found (cryoscopic in benzene): 195, 187.

Attempts to prepare the carbinol halides by passing dry hydrogen chloride or hydrogen bromide into solutions of the carbinol produced dark-colored oils which evolved gases while drying in a vacuum desiccator, leaving black lava-like solid residues.

Diphenylthienylcarbinol $(C_6H_5)_2C(OH)C_4H_3S$.—This has been described by Thomas? and Gomberg and Jickling[2] as prepared from benzophenone and the Grignard reagent from iodothiophene. A slightly higher yield was obtained by synthesis from phenylmagnesium bromide and phenylthienyl ketone, and the product melted at 131°, higher than either of the temperatures previously reported. Condensation of benzophenone dichloride with thiophene in carbon disulfide solution by means of aluminum chloride gave a much lower yield.

When boiled with formic acids the carbinol was reduced to the methane.9 About half of the carbinol, however, reacted to form a new compound, m. p. 174°, which gave analytical values corresponding to the methane but had a molecular weight of about double that of the methane.

Diphenylthienylcarbinol Bromide $(C_6H_5)_2CBrC_4H_3S$.—A solution of the carbinol in benzene or a suspension in low-boiling petroleum ether was saturated with dry hy-

drogen bromide. A few lumps of calcium bromide were added to take up the water formed in the reaction. After filtration and evaporation under reduced pressure, crystals of melting point 110 to 111° were obtained. Originally only slightly colored, they quickly turned deep purple, even in a sealed tube in the dark.

Anal. Calcd. for $C_{17}H_{13}BrS$: Br, 24.31. Found: Br, 24.30, 24.09.

Diphenylthienylcarbinol Chloride.[2]—Best results were obtained by suspending the carbinol in petroleum ether with a few lumps of calcium chloride and slowly passing in dry hydrogen chloride to saturation. The solution was evaporated under reduced pressure and the crystals were washed with very small amounts of ice-cold petroleum ether and dried in a current of dry air at room temperature. They melted at 80 to 81° and the yield was 90%. The anilide, $(C_6H_5)_2C_4H_5SCNHC_6H_5$, melts at 118–119°.

After standing for a short time the crystals of the carbinol chloride became colored but no change in the chlorine content could be detected by analysis. No hydrogen chloride was given off when the crystals were held at 65° for twelve hours, or when a benzene solution was held at 65° for twenty-four hours.

Diphenylthienylmethyl.—The free radical was prepared by shaking benzene, bromobenzene or xylene solutions of the chloride or bromide with molecular silver at room temperature. The solutions were immediately colored red. Measurements of the amount of free radical formed by the usual oxygen absorption test[10] gave very erratic results. Depending upon the length of time the sample was left in the apparatus, absorptions ranged from 25 to 200% of the quantity theoretically required for the formation of a peroxide. Determination of the amount of silver chloride formed proved that the metal reacted completely with the halogen.

Attempts to isolate the solid free radical by usual methods gave pink crystals of melting point 157 to 162°, which gave oxygen absorptions of only 20% of the calculated value. The general behavior of this free radical was very much like that of phenylthioxanthyl.[3]

5,5′-Di-triphenylmethyl-2,2′-dithienyl, $(C_6H_5)_3CC_4H_2SC_4H_2SC(C_6H_5)_3$.—Triphenylthienylmethane was made by Weisse[11] from triphenylcarbinol and thiophene with phosphorus pentoxide as condensing agent. An attempt was made to prepare this compound from triphenylchloromethane and the Grignard reagent of iodothiophene, by analogy to the method for making tetraphenylmethane.[12] Besides quantities of triphenylmethyl peroxide and triphenylmethane, a new product was obtained, in 5 to 40% yields, which was not the methane of Weisse. The latter melts at 237°, whereas the new substance melted at 277°, after recrystallizing from ethylene dibromide.

The structure of this new product was established by its synthesis from triphenyliodothienylmethane through the Ullmann condensation, using copper-bronze.

$$2(C_6H_5)_3CC_4H_2SI + Cu \longrightarrow (C_6H_5)_3CC_4H_2SC_4H_2SC(C_6H_5)_3 + CuI_2$$

The 5,5′-positions of the triphenylmethyl groups in the thiophene rings have not been proved, but rest on the assumptions of Weisse for the constitution of the products of his phosphorus pentoxide condensations.

Two grams of triphenyliodothienylmethane was mixed with an equal volume of white sand, placed in a small flask and heated in a sulfuric acid bath to 200°. As the temperature rose further, 2 g. of copper–bronze was gradually added with stirring. When the temperature reached 250°, the flask was removed, cooled and the contents extracted with hot benzene. Concentration of the benzene extract gave a 90% yield of crystals of melting point 277°. Comparison of physical properties, solubilities and

mixed melting point proved the identity of this compound with that from the Grignard condensation. Inasmuch as the latter reaction was carried out in an atmosphere of hydrogen, the formation of the dithienyl required an oxidation at the expense of part of the reacting compounds.

The dithienyl gave no color with concd. sulfuric acid, was markedly insoluble in most solvents in the cold and was moderately soluble in hot carbon tetrachloride, ethyl acetate, naphthalene, nitrobenzene, bromoform, chloroform and benzene.

Anal. Calcd. for $C_{46}H_{34}S_2$: C, 84.88; H, 5.27; S, 9.86. Found: C, 84.85, 84.48; H, 5.62, 5.43; S, 9.81, 9.79. Mol. *wt.* Calcd.: 650. Found:[13] 670 (benzene); 668 (chloroform).

Upon bromination in boiling carbon tetrachloride solution, a dibromo compound, of melting point 287°, was obtained.

Biphenylenethienylcarbinol,  $\begin{matrix} C_6H_4 \\ | \\ C_6H_4 \end{matrix}\!\!>\!C\!<\!\!\begin{matrix} OH \\ \\ C_4H_3S \end{matrix}$.—To the Grignard reagent from iodothiophene and magnesium in ether was added a benzene-ether solution of fluorenone. The light green precipitate which formed was filtered, washed and treated with ice and acetic acid. The crude carbinol was extracted with ether, washed with sodium carbonate solution and water and dried. After evaporation of the solvent, the oil was recrystallized from petroleum ether. Colorless crystals of melting point 81 to 82° were obtained. After long standing they turned green.

Anal. Calcd. for $C_{17}H_{12}OS$: C, 77.24; H, 4.58; S, 12.13. Found: C, 76.89; H, 4.62; S, 12.20.

α-Naphthylphenylthienylcarbinol $(C_{10}H_7)(C_6H_5)(C_4H_3S)COH$.—α-Naphthylphenyl ketone in ethereal solution was treated with thienylmagnesium iodide. The precipitate was washed, iced and steam distilled. The residue from the distillation was recrystallized from a mixture of ether and petroleum ether, giving colorless crystals with a melting point of 131°.

Anal. Calcd, for $C_{21}H_{16}OS$: C, 79.71; H, 5.10; S, 10.14. Found: C, 79.65; H, 4.92; S, 10.20.

Thienylxanthenol,  $O\!<\!\!\begin{matrix} C_6H_4 \\ C_6H_4 \end{matrix}\!\!>\!C\!<\!\!\begin{matrix} OH \\ C_4H_3S \end{matrix}$.—Xanthone was added in small quantities to the ether solution of thienylmagnesium iodide. The reaction was sluggish and required warming. The yellow precipitate was filtered, iced and extracted with ether. Concentration of the extract and recrystallization from ethyl acetate gave a product with melting point of 168 to 169°.

Anal. Calcd. for $C_{17}H_{12}O_2S$: C, 72.83; H, 4.32; S, 11.44. Found: C, 72.78; H, 4.28; S, 11.42.

Thienylxanthenol chloride was made by passing dry hydrogen chloride into a solution of the carbinol in ethyl acetate. Without isolating the chloride, solutions of metal halides in ethyl acetate were added and the following double salts were obtained: $C_{17}H_{11}OSCl \cdot FeCl_3$, bronze plates, m. p. 198°; $C_{17}H_{11}OSCl \cdot HgCl_2$, small red crystals, melting with decomposition at 182 to 198°, varying with the rate of heating; $C_{17}H_{11}OSCl \cdot ZnCl_2$, red crystals, m. p. 225 to 227°.

The author wishes to express his gratitude to Professor M. Gomberg, who suggested and supervised this investigation, and to the National Aniline and Chemical Company for the aid of its Fellowship.

Summary

Various compounds, formally derived from di-, tri- and tetraphenylmethane compounds by replacement of one phenyl group with a thienyl group, have been prepared by synthetic methods analogous to those used in preparing the corresponding phenyl compounds. The thienyl compounds were in general less stable than their phenyl analogs. The free radical, diphenylthienylmethyl, was found to possess the same instability as phenylthioxanthyl.

MONONITRO- AND DINITROTHIOPHENES. II. A STUDY OF VAPOR PRESSURES

BY V. S. BABASINIAN AND J. G. JACKSON

RECEIVED JANUARY 9, 1929 PUBLISHED JULY 5, 1949

Introductory

It is a noteworthy fact that, while the physical properties of thiophene have been made the subject of extensive study, its derivatives have received scanty attention only. Aside from sparse references to crystallographic, microscopic, optical, spectrochemical or physico-chemical studies, the literature makes no mention of the critical constants of the numerous derivatives of thiophene. This scarcity of information is probably explained by the fact that difficulty has often been experienced in the synthesis of thiophene compounds. Throughout the literature one is impressed by the glaring omission of references to percentage yields. In their extensive researches on the thiophene series, Steinkopf and co-workers[1] have recently described improved methods of preparation, but if percentage yield be taken as a measure of efficiency, the results of these workers will in numerous instances be found to leave a great deal to be desired.

During the past three years methods have been developed in this Laboratory for the quantity production of mononitro- and dinitrothiophene. The notable absence in the literature of critical data for the thiophene series has suggested a study of the vapor pressures of these nitro compounds.

Preparation and Purification of Materials.—The compounds employed in this study were synthesized by the methods outlined by one of the authors.[2] Mononitrothiophene was readily purified by steam distillation and by subsequent crystallization

---

[1] (a) Steinkopf and co-workers, *Ann.*, 403, 1–72 (1914); (b) 407, 94–108 (1915); (*c*) **413**, 310–349 (1917); (d) **424**, 1–71 (1921); (e) 428, 123–163 (1922); (f) **430**, 41–161 (1923); (*g*) 437, 14–36 (1924); (h) **448**, 205–222 (1926).

[2] Babasinian, THIS JOURNAL, 50, 2749, 2751 (1928).

from petroleum ether. Repeated crystallization from this solvent produced snow-white needles which melted at 45.5°.[3]

Dinitrothiophene obtained by ordinary methods of crystallization always contains a weighable fraction of an isomer. Prolonged distillation with steam was found to remove the more volatile isomer to a great extent.[4] The residue was then freed from traces of tarry impurities by repeated crystallization from alcohol. The product was almost white and melted at 52°.[5,3a]

Method.—The apparatus employed for the vapor pressure determination was that of Smith and Menzies,[6] as shown in Fig. 1, with modifications as outlined below. Accurate temperature control was obtained by very rapid stirring of a glycerin bath A (shielded by G) by the rotary stirrer B. Temperature readings were made by means of the certified thermometer C. In order to secure greater compactness in the glass system, to eliminate leakage into the reservoirs H and I and to insure increased facility in manipulation, the apparatus of Smith and Menzies was modified as shown in Fig. 1a. In the modified form, V, I, and N remained unchanged except that I, was placed on the vacuum side of Cock N, but the reservoirs H and I were replaced by the special Cock P.[7]

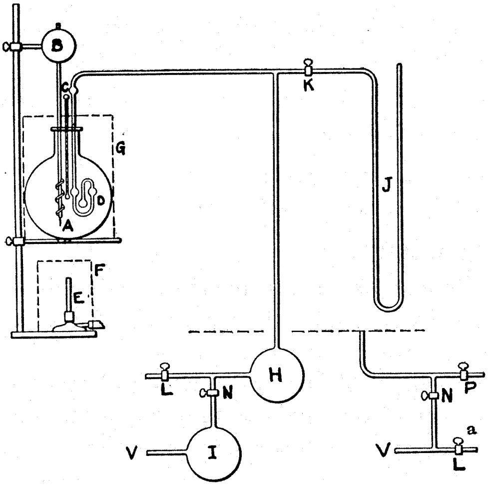

Fig. 1.—Diagram of apparatus.

Each determination required about twenty-four hours. Several readings were made at each temperature in order to insure accuracy. No decomposition was noticed in the case of mononitrothiophene at the maximum temperature of 170° employed with the compound. The liquid dinitrothiophene darkened and bore evidence of carbonization at 250°. At 256° decomposition became so rapid that it was impossible to obtain vapor pressure readings in the manometer J with any hope of accuracy. The vapor slowly attacked the mercury in the manometer at 195°. At 250° the action was more rapid, and at 260° a noticeable quantity of golden yellow flakes condensed on the surface of the mercury.

---

[3] Meyer and Stadler reported 44° as the melting point of mononitrothiophene (a) *Ber.*, **17**, 2649 (1884). Steinkopf obtained a small quantity which melted at 46.5°; (b) ref. 1a, p. 18.

[4] The isomer occurs in such small quantities and is so difficult to purify that no attempt was made to produce it in quantity for vapor pressure studies.

[5] Meyer and Stadler's dinitrothiophene also melted at 52°.

[6] (a) Smith and Menzies, THIS JOURNAL, 32, 1414, 1434, 1448 (1910). This method has been employed by (b) Monroe, *Ind. Eng. Chem.*, 12, 969 (1920), on phthalic anhydride; (c) Nelson and Senseman, *ibid.*, 14, 58 (1922), on naphthalene, anthracene, phenanthrene and anthraquinone; (d) Berliner and May, THIS JOURNAL, 47, 2350 (1925); (e) *ibid.*, 48, 2630 (1926), on nitranilines and mononitrotoluenes.

[7] Cock P was specially constructed by filling the opening in the movable member of an ordinary stopcock with de Khotinsky cement, except for a small pocket at one end, in order that a minute quantity of air could be admitted when desired.

Discussion of Results

According to the Clausius–Clapeyron Equation[8]

$$L = \frac{RT^2}{p}\,\frac{dp}{dt} \tag{1}$$

where p is the corrected vapor pressure in millimeters of mercury, T the absolute temperature, L the molar latent heat of vaporization and R the gas constant. Thus the curve obtained by plotting $\log_{10} p$ against $1/T$ will be a straight line. This was done on a very large scale in the case of each substance. The result is shown in Fig. 2. The deviation of the curves from a straight line below *a* seems to indicate that the observations are not dependable in this region. In Tables I and II the vapor pressures of the substances are given at various temperatures, as ascertained from Fig. 2.

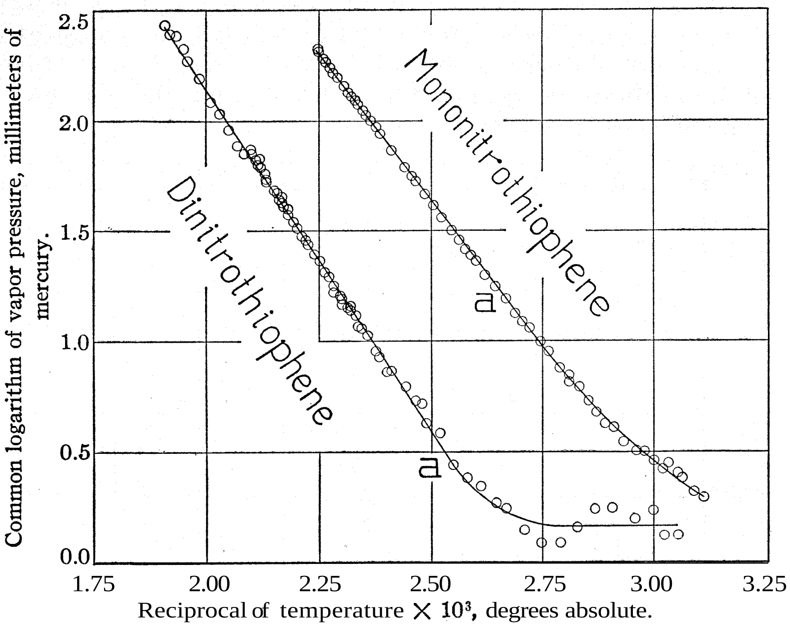

Fig. 2.

V.p., mm.	85.9	100.0	115.6	134.3	154.2	178.2	204.2	233.9	267.3	

By extending the curve for mononitrothiophene in Fig. 2, the theoretical boiling point of that substance was found to be 218.2°, as compared with previously published results of about 224–225°.[3a] The theoretical boiling point of dinitrothiophene was found to be 293.3°, while the value given by Meyer and Stadler[3a] is 290°.

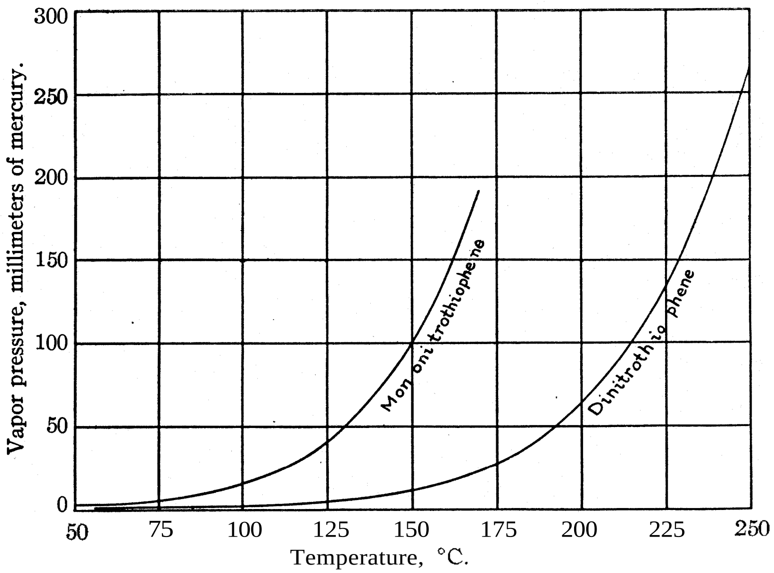

Fig. 3.

From Equation 1 the average value of L, the molar latent heat of vaporization, was found to be 12,300 cal. for mononitrothiophene above 100°, and 14,300 cal. for dinitrothiophene above 110". From these it may be determined by the method of Hildebrand[9] whether the substances are normal liquids, since

$$S = \frac{L}{RT'} \qquad (2)$$

where S is the entropy of vaporization, L the molar latent heat of vaporization and T' the temperature at which the concentration of the vapor is

---

[9] Hildebrand, THIS JOURNAL, 37, 970, 974 (1915).

0.00507 mole per liter. According to the data of Hildebrand,[10] the value of S should be between **13.1** and **13.9** for a normal liquid. The values obtained for **S** were **14.7** for mononitrothiophene and 14.8 for dinitrothiophene, thus indicating that neither is a normal liquid within the range of temperature considered.

Acknowledgment

The authors desire to express their sincere acknowledgment to Professor Warren W. Ewing for numerous helpful suggestions and assistance during the progress of this study.

Summary

A study of the literature showed a marked absence of critical data for the thiophene series.

The vapor pressures of mononitro- and dinitrothiophene were measured, and their theoretical boiling points, molar latent heats of vaporization and entropies of vaporization calculated.

Mononitrothiophene showed no decomposition at the maximum temperature to which it was subjected. Dinitrothiophene was found to decompose above 250° and to attack mercury at much lower temperatures.

ADDITION REACTIONS OF VINYL PHENYL KETONE. I. PHENYLNITROMETHANE

BY CHARLES F. H. ALLEN AND M. PHILBRICK BRIDGESS

RECEIVED JANUARY 17, 1929 PUBLISHED JULY 5, 1929

Vinyl phenyl ketone (I) is the lowest member of the series of unsaturated phenyl ketones having a conjugated system. It should be of interest to compare the properties and reactions of the products derived from it by the addition of certain substances having active hydrogen with those obtained by the addition of the same compounds to a substituted vinyl phenyl ketone, such as benzalacetophenone (II)

$$\underset{\text{I}}{CH_2{=}CHCOC_6H_5} \qquad \underset{\text{II}}{C_6H_5CH{=}CHCOC_6H_5} \qquad \underset{\text{III}}{CH_2ClCH_2COC_6H_5}$$

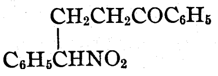
Since it combines very readily with substances[1] that have an active hydrogen atom, it can be used for making saturated ketonic compounds which are unsubstituted in the beta position and which it is difficult to secure in any other manner. It seemed probable that these addition products could be converted into other substances which would be useful in connection with the study of reactions of which the mechanism is at

---

[10] **Ref.** 9, **p.** 975.

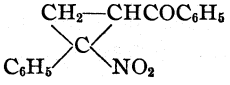
[1] Kohler, *Am. Chem. J.*, **42**, **375** (1909).

present in doubt. Thus, for example, from the addition product of phenylnitromethane (IV) it should be possible to make a nitrocyclopropane derivative (VII) isomeric with the one that is known (VIII), and a comparison of these isomers would be expected to yield valuable information on the mechanism of the peculiar rearrangements of these cyclopropane derivatives.

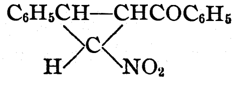


$C_6H_5CH(NO_2)CH_2CH_2COC_6H_5$

IV



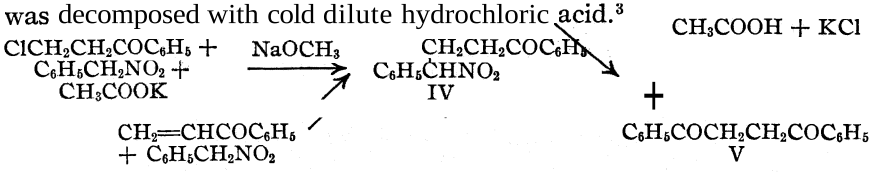
VII



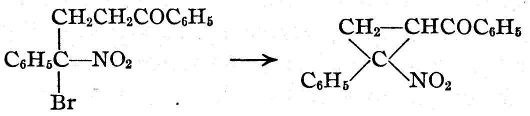
VIII

Unfortunately, the preparation of large amounts of vinyl phenyl ketone is so difficult[2] that it is not a serviceable starting material for any extensive investigations. It occurred to us that it might be possible to substitute the more readily available β-chloropropiophenone (111), and remove from it hydrogen chloride either just prior to use or in the presence of the substance to be added, thus avoiding isolation of the reactive unsaturated ketone. This procedure was, indeed, found to be possible.

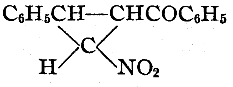
In the presence of alkaline reagents, phenylnitromethane combined with p-chloropropiophenone to give the same saturated y-nitro-ketone (IV) as was obtained with phenyl vinyl ketone. Its structure was proved by the formation of dibenzoylethane (V) when a solution of the sodium derivative was decomposed with cold dilute hydrochloric acid.[3]



On bromination in a solution of sodium methylate, followed by elimination of hydrogen bromide, a tertiary nitrocyclopropanone (VII) was produced.



VI VII



VIII

The behavior of this compound with sodium methylate was of particular interest because the previous investigations[4] showed that if a secondary

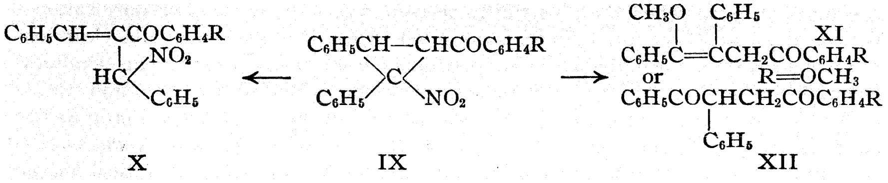
nitro group was present (VIII), the final product was a 1,3-diketone, while with a tertiary nitro group (IX) two types of reaction occurred, one forming an ethylenic compound with the nitro group still present and the other a nitrogen-free 1,4-diketone (or its monomethyl ether).

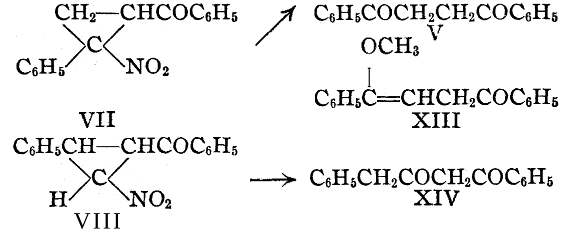


After separation of one of the two theoretically possible isomers of (VII), a lower-melting solid was deposited from the solution; this substance analyzed for an isomer, but was a constant-melting mixture undoubtedly containing some of the cyclopropane first isolated, since mixtures always gave melting points intermediate between those of this solid and the pure cyclopropane. All efforts to separate it into its constituents by fractional crystallization or change of solvents were unsuccessful.

Both this solid and the isomeric cyclopropane derivative reacted with sodium methylate, yielding dibenzoylethane (V) and its methyl ether (XIII).

The formation of dibenzoylethane can only be explained by the opening of the ring between carbon atoms 1 and 2—a new type of reaction between cyclopropane ketones and alkaline reagents. Those studied previously, chiefly by Kohler and his students, if attacked by bases, were always opened in the 1,3- or 2,3-positions. There is nothing novel about the ring being broken in different places by other reagents (*e. g.*, reducing agents have attacked all three possible bonds), but this is the first time that alkaline reagents have been found to react in the 1,2-position.

The isomeric nitrocyclopropanone (VIII)[4a] under similar conditions also opened between the carbon atoms to which the phenyl and benzoyl groups are respectively attached, and the final product is a 1,3-diketone (XIV).



Experimental

The Addition Product with Phenylnitromethane

γ-Nitro-γ-phenylbutyrophenone (IV). A.—Fifteen grams of β-chloropropiophenone[5] and 12 g. of fused potassium acetate were dissolved in 60 cc. of hot methyl

---

[5] Prepared by the method of Hale and Britton, THIS JOURNAL, 41, 844 (1919).

alcohol. Then 12 g. of phenylnitromethane in 20 cc. of alcohol was added and the whole made faintly alkaline to litmus by admitting a 5% solution of sodium methylate, drop by drop. The reddish mixture was refluxed for forty minutes, then acidified with acetic acid and poured into 120 cc. of cold water. After several hours the precipitated addition product was filtered; the average yield of several preparations was 82%—this was true only when the phenylnitromethane was redistilled. For purification it was dissolved in 40 cc. of hot benzene and dried with calcium chloride; the clear solution was decanted, warmed slightly and petroleum ether added to incipient cloudiness. The addition product crystallized in clusters of needles which were filtered and washed until white with a 1:1 mixture of ether and petroleum ether. A second crop was secured by partial evaporation of the mother liquor. Further purification was eflected by a similar treatment or by recrystallization from methyl alcohol. Analytical samples prepared by either method gave the same result.

γ-Nitro-γ-phenylbutyrophenone crystallizes in bunches of needles that melt at 72°. It is very soluble in all the usual organic solvents except petroleum ether. It tends to separate as an oil from solutions containing other substances.

Anal. Calcd. for $C_{16}H_{15}O_3N$: C, 71.4; H, 5.6. Found: C, 71.3; H, 5.7.

We did not try to isolate the vinyl phenyl ketone (except in one instance, to see that it was formed) or determine the extent of its formation quantitatively. Since none of the acetate, which has previously been isolated,[1] was found at any time, the reaction between the chloro ketone and potassium acetate is probably best represented as follows

$$ClCH_2CH_2COC_6H_5 + CH_3COOK = CH_2{=}CHCOC_6H_5 + CH_3COOH + KCl$$

B.—Vinyl phenyl ketone was prepared by the method described by Mannich.[2f] The yellow oil from the steam distillation was dissolved in ether, dried over calcium chloride and the solvent evaporated in a tared flask. This residual oil was used without further purification.

To 3.8 g. of the ketone was added 10 cc. of absolute methyl alcohol; most of it immediately polymerized to a white, insoluble mass. The whole was warmed and the clear solution decanted from the polymer into a clean flask. Two grams of phenylnitromethane was added, then enough dilute sodium methylate to give an alkaline reaction to litmus, and the mixture warmed on the steam-bath for fifteen minutes. It was next acidified with acetic acid; an oil separated and crystallized on cooling. This was purified as described above and identified as the same substance by a comparison of melting points, mixed melting points and solubilities.

Proof of Structure.—One gram of the addition product was dissolved in a slight excess of sodium methylate, 10 cc. of water added and the clear solution filtered into 25 cc. of cold, dilute (1:5) hydrochloric acid. The white precipitate thus formed was filtered and recrystallized from methyl alcohol; yield, 0.7 g., or 80%. It was identified as dibenzoylethane (V) by melting point and mixed melting point with an authentic sample.[6]

Bromination.—The nitro ketone was readily brominated in sodium methylate solution, the bromine replacing the hydrogen on the y-carbon atom. Like many other compounds having a bromine atom and nitro group on the same carbon atom, this substance decomposed just above its melting point.? The reaction is not clean, but the principal product is 2,5-diphenyl-3-bromofuran.

γ-Bromo-γ-nitro-γ-phenylbutyrophenone (VI).—Ten and two-tenths grams of

---

[6] Kindly supplied by Dr. R. E. Lutz.

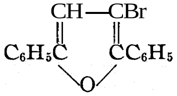
[7] Some of these compounds have been investigated by one of us; the results will appear in a subsequent paper.

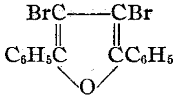
the nitro ketone was added to the sodium methylate solution prepared from 0.8 g. of sodium and 65 cc. of methyl alcohol, the whole being cooled in an ice-bath and well stirred. After ten minutes a slight excess over the theoretical amount of bromine was run in from a dropping funnel, the end of which was drawn out into a fine capillary. A white solid soon separated. The excess bromine was removed by sodium bisulfite solution, and the buff-colored precipitate filtered and thoroughly washed with water and alcohol; yield of crude solid, 94%. It was recrystallized rapidly from glacial acetic acid; prolonged heating resulted in decomposition. It formed long, fine prisms that melted at 146° with gas evolution. It is insoluble in petroleum ether, very slightly soluble in ether and the alcohols, moderately soluble in acetone, ethyl acetate and chloroform, but easily soluble in glacial acetic acid or pyridine; a solution in the latter solvent does not readily lose hydrogen bromide.

Anal. Calcd. for $C_{16}H_{14}O_3NBr$: Br, 22.7. Found: Br, 22.3.

After boiling for fifteen minutes with alcoholic sodium hydroxide and acidifying the solution, a 50% yield of dibenzoylethane resulted; the residue remained as an oil.

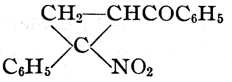
The Bromofurans,



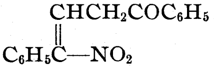


A solution of the bromonitro compound in glacial acetic acid was refluxed for an hour; oxides of nitrogen appeared in the condenser. The black solution was poured into water, the precipitated oil extracted with ether, the extract dried with calcium chloride and the solvent allowed to evaporate spontaneously. The oil left was then dissolved in methyl alcohol; on slow evaporation crystals separated; they melted at 76–77°, and on recrystallization at 77–78°. They were identified as 2,5-diphenyl-3-bromofuran by comparison with a sample at hand. A small amount of another solid was also isolated and identified as 2,5-diphenyl-3,4-dibromofuran, m. p. 88°.[6]

The Nitrocyclopropanones.—The bromo ketone loses hydrogen bromide very slowly in a boiling methyl alcoholic solution of potassium acetate, but prolonged heating gives a good yield of cyclopropane. By derivation, substances formed from (VI) by loss of hydrogen bromide could be cyclopropane derivatives (VII), ethylenic compounds (XV, XVI), or dihydrofuran derivatives (XVII), but since in all such previous instances only the cyclopropane has been formed, it would be expected here. Further, the products neither decolorize bromine nor reduce permanganate, thus excluding the ethylenic compounds (XV, XVI). Also, as furan rings are not sensitive to alkaline reagents, although the substance (XVII) could lose nitrous acid, the product expected would be the known 2,5-diphenylfuran.

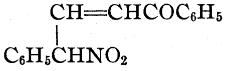


VII



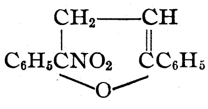
$$\begin{matrix} CHCH_2COC_6H_5 \\ \| \\ C_6H_5C—NO_2 \end{matrix}$$

XV



$$\begin{matrix} CH{=}CHCOC_6H_5 \\ | \\ C_6H_5CHNO_2 \end{matrix}$$

XVI



XVII

1-Phenyl-1-nitro-2-benzoylcyclopropane (X).—Fifteen grams of the bromo compound and an equal weight of fused potassium acetate in 75 cc. of absolute methyl alcohol was refluxed for twenty-two hours. The solution was decanted from the bulk of the potassium bromide and the solvent partially evaporated. An oil separated on cooling, but soon solidified; the crude product was filtered; yield, 90%. It was submitted to fractional crystallization, using different solvents, in an effort to isolate both isomeric forms. Ethyl acetate gave the best separation; most of the high-melting cyclopropane crystallized out first, followed by a mixture of constant melting point. Attempts to separate this into its constituents were unsuccessful. Both the pure nitrocyclopropane and the mixture crystallized in rosets, made up of fine white needles, which dissolved easily in all the usual organic solvents except petroleum ether. The pure substance melts at 131° and the mixture at 80°. The analytical samples were crystallized from methyl alcohol.

Anal. Calcd. for $C_{16}H_{13}O_3N$: C, 71.9; H, 4.9. Found: (131") C, 71.7; H, 5.0; (80°) C, 71.7; H, 5.1.

The melting points of mixtures in several proportions of the pure nitrocyclopropane and the substance of constant melting point all were above that of the latter and below that of the former. Neither solid reduces permanganate nor decolorizes bromine. They may be recrystallized unchanged from acetyl chloride. On addition to concd. sulfuric acid, a bright green color was produced and oxides of nitrogen were evolved. This reaction is to be investigated.

Action of Sodium Methylate.—Five grams of the constant-melting substance was added to 40 cc. of 5% sodium methylate solution; on warming, the solid dissolved and solid sodium nitrite separated from the brown liquid. The latter was decanted into a separatory funnel containing 100 cc. of water and enough ether added to give two layers. The ether layer was separated and the aqueous layer extracted once. The combined ethereal solutions were washed with water, followed in order by solutions of sodium bicarbonate, copper acetate, potassium carbonate and water, and then dried over calcium chloride. On evaporation, **2.4** g. of yellow oil was left; it slowly deposited dibenzoylethane. The original aqueous layer was acidified, extracted with ether and the extract treated similarly. On evaporation it left 1.7 g. of an oil that deposited more dibenzoylethane during the course of a month. The total yield of diketone was 70%. Nothing was obtained from any of the solutions used to wash the ethereal extracts. When the operation was interrupted after five minutes, the first ether extract deposited high-melting nitrocyclopropane as well as dibenzoylethane.

The cyclopropane, m. p. 131°, behaved similarly, on the same treatment; 4.1 *g* of oil was obtained. During the course of three weeks it slowly deposited **55%** of the theoretical amount of dibenzoylethane and 10% of the theoretical amount of the monomethyl ether of that diketone (XIII). This was a very sensitive substance, difficult to recrystallize without hydrolysis to dibenzoylethane. It is very soluble in all the usual solvents; methyl alcohol gave fine, white needles, m. p. 72".

Anal. Calcd. for $C_{17}H_{16}O_2$: C, 81.0; H, 6.4. Found: C, 81.1; H, **6.3.**

On cautious oxidation by permanganate the odor of methyl benzoate could **be** detected; benzoic acid was also identified.

A small portion of the oil was oxidized by permanganate; no benzaldehyde could be detected; the sole solid product was benzoic acid. **A** second portion failed to **give** a solid when treated with semicarbazide in the usual way.

This tertiary nitrocyclopropane is relatively inactive with hydrogen bromide. The mixed solid is turned into the high-melting form (131°) which does not react.

This work has been assisted by a generous grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences.

We are indebted to Professor E. P. Kohler for valuable criticism in **the** preparation of this paper.

Summary

1. It has been shown that β-chloropropiophenone can be used in place of vinyl phenyl ketone in addition reactions. With phenylnitromethane the same γ-nitro ketone is obtained from both substances.

2. The nitro ketone is easily brominated in the gamma position; the bromo ketone is unstable to heat. Hydrogen bromide is eliminated by the use of potassium acetate, and the product is a tertiary nitrocyclopropanone.

3. Sodium methylate reacts with this cyclic nitro compound in such a way that the ultimate product is dibenzoylethane.

TRIARYLMETHYL CARBONATES. CATALYTIC DECOMPOSITION IN THE PRESENCE OF COPPER

BY J. O. HALFORD

RECEIVED JANUARY 31, 1929 PUBLISHED JULY 5, 1929

Triphenylmethyl carbonate has been recorded by Gomberg[1] as an intermediate in the preparation of triphenylmethyl oxide. The carbonate was formed by the action of silver carbonate on triphenylchloromethane in benzene

$$2(C_6H_5)_3CCl + Ag_2CO_3 = [(C_6H_5)_3C]_2CO_3 + 2AgCl \qquad (1)$$

A solution of triphenylmethyl carbonate in boiling xylene produced triphenylmethyl oxide and carbon dioxide under the catalytic influence of finely-divided copper.

$$[(C_6H_5)_3C]_2CO_3 \longrightarrow CO_2 + [(C_6H_5)_3C]_2O \qquad (2)$$

This reaction, similar to the thermal decomposition of metallic carbonates, is consistent with the general properties of the triarylmethyls, whose salts with strong acids, particularly the halides, show many of the reactions of metallic salts. If the analogy is complete, Equation *2* should represent a general reaction of the triarylmethyl carbonates and should be reversible.

With this in mind, three other carbonates, those of diphenyl-α-naphthylmethyl, p-tolyldiphenylmethyl and phenylbiphenylenemethyl, have been prepared and their behavior in the presence of copper powder studied. Although p-tolyldiphenylmethyl carbonate and diphenyl-α-naphthylmethyl carbonate are decomposed catalytically by copper, the oxides have not been obtained in appreciable quantity and it must be concluded that Reaction 2 is not general, but that the catalytic effect of copper is common to the triarylmethyl carbonates. The decomposition of triphenylmethyl carbonate has not been reversed.

Further, the occurrence of a slow catalytic decomposition presents an opportunity to study the mechanism through the interpretation of the rate of reaction. This has been done for the decomposition of triphenylmethyl carbonate.

---

[1] Gomberg, THIS JOURNAL, 35, 200 (1913).

Triphenylmethyl Carbonate.—Ten grams of triphenylchloromethane in 50 cc. of dry benzene was shaken with two to three times the theoretical amount of silver carbonate for twenty-four hours. The silver carbonate had been dried at 140° in a stream of carbon dioxide and analyzed as 99.7% pure. The benzene solution was heated to boiling, filtered and the residue extracted with 50 cc. of boiling benzene. The volume was reduced to 30 cc. at low pressure on the steam-bath. The carbonate crystallized rapidly and was light yellow in color. One recrystallization produced white crystals containing one molecule of benzene of crystallization. The yield is 60–80%; m. p. 200–201° with carbon dioxide evolution.

Anal. The carbon dioxide evolved by heating to 200° was weighed. Calcd. for $C_{45}H_{36}O_3$: CO_2, 7.05. Found: CO_2, 7.00, 7.03.

Part of the benzene was removed by heating for several hours in a vacuum at 90°, the rest by recrystallization from xylene and washing with dry ether; m. p. 208–209° with carbon dioxide evolution.

Anal. Calcd. for $C_{39}H_{30}O_3$: CO_2, 8.06. Found: CO_2, 7.98, 8.12. The first measurement (7.98) was obtained by heating the dry solid, the second (8.12) by titrating the carbonate produced by alkaline hydrolysis. *Mol. wt.* in benzene, calcd., 546. Found: 523, 560, 531, 531; average 536. The solubility in hot benzene is about 55 g. per 100 cc.; in cold benzene, 2 g. per 100 cc.; in hot acetone, 5 g. per 100 cc.; in hot ethyl acetate, 20 g. per 100 cc. Long standing in ethyl acetate slowly produces triphenylcarbinol.

Triphenylmethyl Oxide.—A sample of triphenylmethyl oxide was obtained by the action of mercuric oxide on triphenylchloromethane;~ m. p. 232–233°. Five grams of triphenylmethyl carbonate was heated in boiling xylene for two hours. It crystallized unchanged. The experiment was repeated with the addition of a small quantity of copper powder. The resulting crystals melting at 235–236° were identified with triphenylmethyl oxide by a mixed melting point of 233–234°; yield, 95%. Recrystallization from xylene raised the melting point to 237–238°.

Diphenyl-a-naphthylmethyl Carbonate.—In the preparation of this substance, it is desirable, because of its low solubility, to use 10 cc. of benzene for each gram of diphenyl-a-naphthylchloromethane. The solution of the product in benzene was evaporated under reduced pressure to a thick sirup and crystallized by the addition of ether. Crystallization of the crude carbonate required twenty-four to forty-eight hours. The product at first obtained was dark yellow and contained 20 to 40% of impurities; yield 40–60%. Recrystallization from boiling xylene (20 cc. per gram) produced a white powder melting with carbon dioxide evolution at 228–230°.

Anal. Calcd. for $C_{47}H_{36}O_3$: CO_2, 6.8 Found: CO_2, 6.2, 6.6. Mol. *wt.* in benzene, calcd., 648. Found: 638, 639.

A solution of diphenyl-a-naphthylmethyl carbonate in xylene was boiled for an hour without appreciable carbon dioxide evolution. The addition of copper powder effected complete decomposition in thirty to forty-five minutes. However, no substance was successfully crystallized from the product, showing that diphenyl-α-naphthylmethyl oxide is probably unstable under the conditions of the experiment.

Diphenyl-a-naphthylchloromethane in benzene was kept in contact with mercuric oxide for several days. A 50% yield of diphenyl-a-naphthylcarbinol was obtained. The remainder was precipitated as a gum by petroleum ether and was not successfully crystallized. The occurrence of the carbinol in this quantity suggests the abstraction of hydrogen chloride and subsequent decomposition of half the material, accompanied by hydrolysis of the other half.

***p*-Tolyldiphenylmethyl** Carbonate.—This compound is the most soluble in benzene and xylene of the carbonates prepared. It was obtained as a white powder by adding ether to the oily residue left after removal of the benzene used in the preparation. Four or five cc. of xylene per gram is sufficient for recrystallization; yield, 40–50%. The melting point is 193–195° with carbon dioxide evolution. For analysis the sample was refluxed in a solution of 0.1 *N* sodium hydroxide, barium chloride was added, and excess alkali titrated to phenolphthalein.

Anal. Calcd. for $C_{41}H_{34}O_3$: CO_2, 7.66. Found: CO_2, 7.40, 7.45. *Mol. wt.* in benzene, calcd., 574. Found: 556, 568.

***p*-Tolyldiphenylmethyl Oxide.**—The use of xylene in recrystallizing *p*-tolyldiphenylmethyl carbonate shows its stability at 140°. The introduction of powdered copper into the solution in boiling xylene or toluene resulted in rapid carbon dioxide evolution. A small amount of white powder melting at 180–185° was separated. The reaction of p-tolyldiphenylchloromethane with mercuric oxide produced a 10% yield of white material melting at 205–207°. This latter must be the oxide since it has a high melting point and is readily converted to the carbinol by hydrochloric acid. One part of this substance was mixed with three parts of the material melting at 180–185° and a mixed melting point of 190–195° was obtained, showing that a small quantity of the oxide was produced by decomposition of the carbonate in the presence of copper. Evidently the p-tolyldiphenylmethyl compounds enter, to some extent, into the same reactions as the triphenylmethyl compounds.

The residue from the *p*-tolyldiphenylmethyl oxide preparation by the mercuric oxide method was a yellow oil from which nothing was crystallized. This result is similar to that of Schlenk and Meyer,[2] who attempted to prepare diphenylquinomethane from p-tolyldiphenylchloromethane and pyridine but obtained only a yellow oil from which nothing was crystallized. In this case mercuric oxide may have produced the same result as pyridine.

Phenylbiphenylenemethyl Carbonate.—A solution of phenylbiphenylenechloromethane in benzene slowly turned dark red when kept in contact with silver carbonate. A 10% yield of pink crystalline material was obtained. White crystals melting with carbon dioxide evolution at 218–220° were separated by recrystallization from xylene. Heating in boiling xylene with or without copper for four to five hours failed to produce carbon dioxide evolution. The compound was decomposed by boiling in mesitylene over copper but phenylbiphenylenemethyl oxide was not obtained. This behavior is not surprising in view of the high stability and generally sluggish reactions of the phenylbiphenylenemethyl compounds.

Rate of Carbon Dioxide Evolution by Triphenylmethyl Carbonate

The mechanism of carbon dioxide evolution from triphenylmethyl carbonate in boiling xylene under the influence of powdered copper was studied through the rate of evolution of the gas. Rate measurements on the other carbonates were not made because their decomposition was complicated by side reactions. The triarylmethyl oxide was produced quantitatively only from triphenylmethyl carbonate.

The carbon dioxide evolved in the flask A was carried through the reflux condenser into the receiver B by a stream of dry nitrogen. The nitrogen was passed through soda lime and dried with phosphoric anhydride before entering the apparatus. Xylene was distilled in a small apparatus which

---

[2] Schlenk and Meyer, *Ber.*, 52, 16 (1919).

had been dried in an oven at 110°. The flask **A and** the reflux condenser were dried in the oven before use. Very small amounts of water interfered by hydrolysis of the carbonate. For example, calcium chloride instead of phosphoric anhydride let through enough water in an hour for complete hydrolysis of a gram of the carbonate. The receiver B contained a known amount of standard barium hydroxide whose concentration as a function of time was measured by means of the conductivity cell C. The pipet cell allowed sampling at definite time intervals with sufficient time for measurement. The outlets of the flask and cell were protected by soda lime tubes D. The temperature in the reaction flask was 139° during all the runs and the barium hydroxide in the receiving flask was kept at 25°. At the end of each run the triphenylmethyl oxide produced was separated and in each case was found to represent a 90–95% yield without taking into account the solubility in xylene. The xylene solution was made up each time in the same concentration and approximately the same quantity, **1** g. of carbonate to 24 g. of xylene. The resistance of the barium hydroxide as a function of concentration was found to be expressed accurately by the equation, log $CR^{1.0801}$ = **0.61584.** The

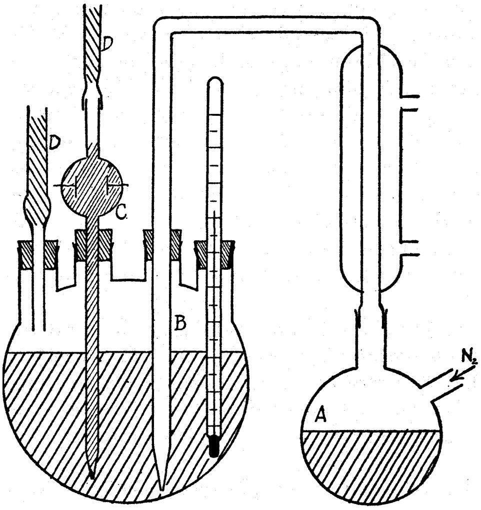

Fig. 1.

50	79.0	3681	1484	.0N
60	79.9	3641	1524	.048
70	81.3	3573	1592	.060

range of concentration was 0.1 to 0.025 *M*. The results of a typical run are given in Table I. The last column gives the unimolecular rate constant in reciprocal minutes. The volume of barium hydroxide was 200 cc.

With a rapidly boiling solution no interference by rate of diffusion was encountered. Some distortion of the rate curve might be expected during the first and more rapid part of the reaction due to lag in carrying over the carbon dioxide. This, however, was negligible since changes of the rate of flow of nitrogen during the reaction were without effect on the results.

In Table II the effect of the amount of copper surface is summarized. The first row gives the weight of copper per gram of triphenylmethyl carbonate; the second, the unimolecular rate constant. The solution in each case contained 1 g. of carbonate in 24 g. of xylene.

TABLE II

EFFECT OF THE EXTENT OF COPPER SURFACE ON THE RATE OF CARBON DIOXIDE EVOLUTION

Cu, grams	3.15	1.57	0.90	0.75	0.38
K	0.047	0.046	0.032	0.025	0.028

Although the fourth and fifth points are in reverse order, it is evident that doubling the copper surface produced only a small increase in the rate.

A series of qualitative experiments failed to discover any substance other than copper powder which would catalyze the reaction. Freshly reduced nickel, platinum and cadmium were without effect. With the possibility of intermediate metallic carbonate formation in mind, stannic oxide, mercuric oxide and cupric oxide were tried. The last two are significant, mercuric oxide because of its use in preparing the triarylmethyl oxides and cupric oxide because of the possibility of an oxide film on the surface of the catalyst. Although negative results are not necessarily significant in catalysis, the reaction is probably the result of a specific property of copper. The reaction was carried out with two samples of copper from different sources, although all rate measurements were made with the same sample to obtain a uniform surface.

Mechanism of the Reaction.—A catalytic reaction at a solid–liquid interface should be unimolecular[3] if it is governed by a rate of diffusion or by adsorption covering only a small fraction of the active surface at any time. In either case the amount reacting in unit time at a given concentration should be proportional to the surface, or nearly so, if the reaction causes adsorption to lag behind equilibrium. Since the rate constant is defined as the quantity reacting in unit time at unit concentration, it follows that the constant should increase in direct proportion to the surface. It must be concluded, then, that in the reaction studied the catalytic

---

[3] Taylor, "Physical Chemistry," D. Van Nostrand Company, Inc., New York, 1924, p. 953.

effect cannot be explained in terms of adsorption covering a small fraction of the active surface. However, if the catalyst is able to produce and maintain an equilibrium concentration of active molecules in the solution, rather than on the surface, the results are explained. If equilibrium were maintained by the catalyst, the constant would be independent of the extent of the surface; but if it is assumed that increasing the surface decreases the lag behind equilibrium, a large increase in the active surface should be attended by a small increase in the rate constant. The experimental results give no indication of the nature of such an intermediate but, since the yield of triphenylmethyl oxide is almost quantitative, it is probably a tautomer or active form of the carbonate itself.

Levi and Haardt[4] obtained a similar result in a measurement of the effect of the surface area of platinum on the rate of decomposition of hydrogen peroxide. Vavon[5] found that the rate of hydrogenation of nitrobenzene in alcohol increased rapidly with the weight of catalyst employed.

Summary

Triphenylmethyl carbonate, diphenyl-α-naphthylmethyl carbonate, *p*-tolyldiphenylmethyl carbonate and phenylbiphenylenemethyl carbonate have been prepared.

The evolution of carbon dioxide in boiling xylene from the first three of the carbonates mentioned has been shown to be catalyzed by copper powder. Phenylbiphenylenemethyl carbonate was not affected by copper, triphenylmethyl carbonate broke down quantitatively to triphenylmethyl oxide and carbon dioxide. Diphenyl-a-naphthylmethyl carbonate decomposed without producing the oxide, and a small quantity of *p*-tolyldiphenylmethyl oxide was obtained from *p*-tolyldiphenylmethyl carbonate.

p-Tolyldiphenylmethyl oxide was also prepared in small quantity from mercuric oxide and *p*-tolyldiphenylchloromethane.

The rate of evolution of carbon dioxide from triphenylmethyl carbonate catalyzed by copper in boiling xylene was measured as a function of the extent of copper surface. The rate constant was unimolecular and the effect of extent of surface precluded explanation in terms of adsorption. An alternative explanation has been given.

CATALYTIC REDUCTION OF ALPHA-DIKETONES AND THEIR DERIVATIVES

BY JOHANNES S. BUCK AND SANFORD S. JENKINS[1]

RECEIVED FEBRUARY 23, 1929 PUBLISHED JULY 5, 1929

In order to obtain certain derivatives of a-diketones the authors investigated the catalytic reduction of benzils. The usual methods given in the literature are difficult and give poor yields. Five benzils were selected as starting materials: benzil made by the oxidation of benzoin with nitric acid;[2] anisil derived from anisoin after the method of Bösler;[3] piperil made from piperoin by oxidation with Fehling's solution;[4] veratril, obtained by oxidizing the crude reaction product of veratric aldehyde and alcoholic potassium cyanide;[5] and, finally, furil, prepared by oxidizing furoin in air.[6]

The catalytic reduction method of Adams[7] was selected, but as it was desired to work with quantities of the order of 0.005-0.01 mole, the apparatus was modified to this end. A second gage was inserted in the line between the reservoir and the bottle (Burgess–Parr Company's apparatus) as shown in the sketch. After the bottle was filled with hydrogen, it was cut off from the reservoir by means of the needle-valve. Under these conditions it functions as its own reservoir, the pressure in the bottle being read on the second gage. Since the capacity of the bottle is about 0.05 that of the tank, a correspondingly small amount of material will give about the same drop in pressure.

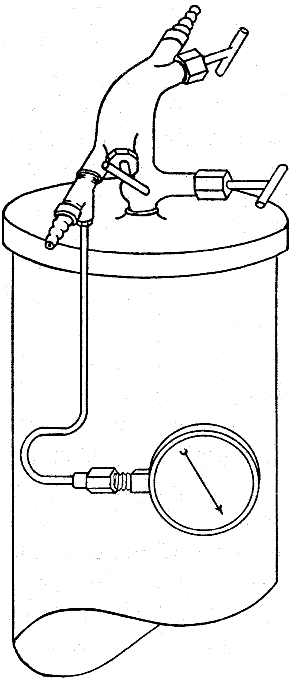

Fig. 1.

It is essential to guard carefully against leaks and to control the temperature within narrow limits. The authors find that benzoin is a very satisfactory material for calibrating the apparatus for one molecule of hydrogen, and benzil for two

[7] Voorhees and Adams, THIS JOURNAL, 44, 1397 (1922).

molecules of hydrogen. Heating the solution very often greatly speeds up the reduction and facilitates the solution of difficultly soluble compounds. The bottle was therefore heated by means of a thin copper cylinder, insulated and wound with resistance wire, current being supplied by a step-down transformer and controlled by a rheostat. It is necessary to calibrate the apparatus for each temperature and the temperature must be held sensibly constant throughout the run.

Benzil is readily reduced to benzoin and to hydrobenzoin. Usually an almost pure product was obtained after one recrystallization. When reduction was carried to completion the hydrobenzoin was obtained practically pure. The following equations represent the reaction

$$\mathrm{RCOCOR + H_2 = RCHOHCOR}$$
$$\mathrm{RCOCOR + 2H_2 = RCHOHCHOHR}$$

The solvent has an important effect on the reduction. Thus anisil reduces best in ethyl acetate, while piperil could only be reduced in pyridine. After many attempts under different conditions the authors failed to reduce veratril, but work is being continued on this compound. Furil readily takes up one molecule of hydrogen, but the action was not investigated beyond this stage as it has been dealt with by Adams.[8]

A number of attempts to dehydrate the hydro compounds to the desoxy compounds by the use of acetic and hydrochloric acids were made. In the case of hydro-anisoin a good yield of desoxyanisoin was obtained, but from hydropiperoin a compound of melting point 114°, not identical with desoxypiperoin, was obtained but not further examined. Hydrobenzoin is known to dehydrate to an anhydride and diphenylacetaldehyde. One case of similar dehydration using sulfuric acid, (hydro-anisoin and isohydro-anisoin)[9] is recorded in the literature. Iso compounds, however, were never obtained in the present research. The desoxy compounds were prepared for this work by reducing the corresponding benzoins by means of tin and alcoholic hydrochloric acid.[10] Desoxybenzoin readily reduced to toluylene hydrate. Desoxyanisoin formed di-p-methoxytoluylene hydrate, and desoxypiperoin reduced with great difficulty to form di-*p*-methylenedioxytoluylene hydrate. Twenty-four runs were made on the desoxypiperoin using various solvents and otherwise modifying conditions; only one run gave the required product in satisfactory yield. The equation $\mathrm{RCH_2COR + H_2 = RCH_2CHOHR}$ represents the process. The toluylene hydrates readily lose water under the action of a mixture of acetic acid and hydrochloric acid to form the corresponding stilbenes, $\mathrm{RCH_2CHOHR = H_2O + RCH{=}CHR}$. Stilbenes so obtained are reduced more or less readily to form the corresponding diphenylethanes.

---

[8] Kaufmann and Adams, THIS JOURNAL, 45,3029 (1923).

[9] Rossel, *Ann.*, 151, 42 **(1869).**

[10] I. Allen, private communication.

It will be seen that in one case the complete series of compounds from anisil to di-p-methoxydiphenylethane can be produced catalytically (acid or platinum oxide) in excellent yield.

The following scheme represents the process (anisil as example). Benzil and piperil are similar, but lack the stage *hydro* to *desoxy compound.*

$$\underset{\text{Anisil}}{\mathrm{CH_3OC_6H_4COCOC_6H_4OCH_3}} \xrightarrow{\mathrm{H_2}} \underset{\text{Anisoin}}{\mathrm{CH_3OC_6H_4COCHOHC_6H_4OCH_3}} \xrightarrow{\mathrm{H_2}}$$

$$\underset{\text{Hydro-anisoin}}{\mathrm{CH_3OC_6H_4CHOHCHOHC_6H_4OCH_3}} \xrightarrow[\mathrm{HAc}]{\mathrm{HCl}} \underset{\text{Desoxyanisoin}}{\mathrm{CH_3OC_6H_4COCH_2C_6H_4OCH_3}} \xrightarrow{\mathrm{H_2}}$$

$$\underset{\text{Dimethoxytoluylene hydrate}}{\mathrm{CH_3OC_6H_4CHOHCH_2C_6H_4OCH_3}} \xrightarrow[\mathrm{HAc}]{\mathrm{HCl}} \underset{\text{Dimethoxystilbene}}{\mathrm{CH_3OC_6H_4CH{=}CHC_6H_4OCH_3}} \xrightarrow{\mathrm{H_2}}$$

$$\underset{\text{Dimethoxydiphenylethane}}{\mathrm{CH_3OC_6H_4CH_2CH_2C_6H_4OCH_3}}$$

The yields obtained in the foregoing reactions are excellent and would be practically quantitative if carried out on a larger scale. Compared with the usual methods of reduction (amalgam, tin and hydrochloric acid, etc.), the catalytic method is much superior, where applicable. It is interesting to note that many compounds usually described as yellow are obtained pure white by the catalytic method.

Experimental

In the following reductions 0.01 mole of substance, 50 cc. of solvent and 0.05 g. of platinum oxide were used. The product was usually identified by a mixed melting-point determination and comparison with an authentic specimen. The melting points of the crude products were usually within one or two degrees of the melting points given in the literature, indicating a high state of purity. Unless otherwise stated 0.01 mole of material was used for the reduction. The yields may be regarded as minimal in view of the small amounts of material used. For convenience the results are tabulated.

TABLE I

TABULATED RESULTS

Starting material	Product	Best solvent	Temp., °C.	Yield, %	M. p. of product, °C.
Benzil	Benzoin	Alcohol	Room	93	134
Anisil	Anisoin	Et. ac.	60	90	109–110
Piperil	Piperoin	Pyridine	60	87	118–120

TABLE I *(Concluded)*

Starting material	Product	Rest solvent	Temp., °C.	Yield, %	M. p. of product, °C.
Desoxybenzoin	Toluylene hydrate	Alcohol	Room	85	63
Desoxyanisoin	Di-*p*-methoxytoluylene hydrate	Acetic acid	Room	85	110.4
Desoxypiperoin	Di-p-methylenedioxytoluylene hydrate	Pyridine	Room	97	154–155
Stilbene	Diphenylethane	Alcohol	Room	86	53
Di-*p*-methoxystilbene	Di-p-methoxydiphenylethane	Et ac.	60	91	125
Di-*p*-methylenedioxystilbene	Di-*p*-methylenedioxydiphenylethane	Acetic acid	60	81	138

Desoxybenzoin, desoxyanisoin and desoxypiperoin (the latter not previously described) were produced by the reduction of the corresponding benzoins with tin and alcoholic hydrochloric acid. Desoxyanisoin may also be prepared by the action of acetic and hydrochloric acids on hydro-anisoin. Desoxypiperoin forms white crystals melting at 114.5° when crystallized from acetic acid. It is sparingly soluble in alcohol and moderately soluble in acetic acid.

Anal. Calcd. for $C_{16}H_{12}O_5$: C, 67.61; H, 4.24. Found: C, 67.48; H, 4.40.

Di-p-methoxytoluylene hydrate was found to melt at 110.4°. It forms white diamond-shaped crystals.

Anal. Calcd. for $C_{16}H_{18}O_3$: C, 74.49; H, 6.97. Found: C, 74.32; H, 6.81.

Wiechell[11] obtained this compound in another way and reports the melting point as 170". As a check, the authors reduced desoxyanisoin with sodium amalgam and acetic acid and found the same melting point of 110". Their specimen, prepared catalytically, gave dimethoxystilbene in 90% yield when heated with acetic and hydrochloric acids.

Di-p-methylenedioxytoluylene hydrate was obtained only once out of 24 runs, and then in a yield of 97%. The compound forms white crystals from alcohol and melts at 154–155°.

Anal. Calcd. for $C_{16}H_{14}O_5$: C, 67.13; H, 4.89. Found: C, 66.95; H, 5.09.

The same compound was obtained in moderate yield by the reduction of desoxypiperoin with sodium amalgam and acetic acid. Prepared by either method, it was convertible into di-p-methylenedioxystilbene in 90% yield.

The stilbenes listed were obtained in 85–90% yield by heating the corresponding toluylene hydrates for ten minutes with a mixture of 80% acetic acid and 20% concentrated hydrochloric acid.

Summary

1. Benzoins are readily produced from benzils by catalytic reduction.
2. Hydrobenzoins are similarly produced from benzils or benzoins.
3. Desoxybenzoins reduce to toluylene hydrates.
4. Stilbenes, conveniently prepared by dehydrating the toluylene hydrates, give on reduction diphenylethanes.
5. Veratril failed to reduce.
6. Desoxypiperoin reduced once out of 24 trials.

---

[11] Wiechell, *Ann.*, 279, 340 (1894).

7. The catalytic method, when applicable, gives excellent yields and is superior to other methods.
8. A convenient method for reducing 0.01 to 0.0025 mole is described.
9. Benzoin is recommended as a standard for calibrating the apparatus for one mole of hydrogen and benzil for two moles.
10. The complete series of reduction products of anisoin may be prepared catalytically.

THE PREPARATION OF ALLOMUCIC ACID AND CERTAIN OF ITS DERIVATIVES

BY C. L. BUTLER AND LEONARD H. CRETCHER

RECEIVED MARCH 1, 1929 PUBLISHED JULY 5, 1929

While engaged in the investigation of certain sugar acids, it was desired to prepare allomucic acid in comparatively large amounts. This is one of the less common dibasic acids in the sugar group and but few of its derivatives have been described. The only published method of preparation is that of Fischer,[1] who obtained the acid by epimerization of mucic acid with excess of pyridine at 140°. The yield was 14%.

The present authors have been able to prepare pure allomucic acid from mucic acid in yield of 33%. This was accomplished under the conditions of epimerization previously employed in this Laboratory for the preparation of d-talonic acid from d-galactonic acid.[2]

It was shown by Fischer[1] that allomucic acid is partially converted into a monolactone on boiling or evaporation of a water solution. Fischer did not isolate this lactone and we were not able to prepare it in crystalline form. A solution of the lactone was used in the present work for the preparation of the mono-amide.

Diethyl allomucate was prepared by the method employed by Malaguti[3] for the esterification of mucic acid, namely, the use of a comparatively large amount of concd. sulfuric acid and alcohol. The yield was 42% of the theoretical. It was found that it was also possible to esterify with alcohol containing 1% of hydrochloric acid. This method gives a better yield (58%) of ester and is somewhat simpler in manipulation. The ester was easily converted into the diamide by addition of concd. ammonia water.

It was shown by Kiliani[4] that *l*-mannosaccharic dilactone reduces

---

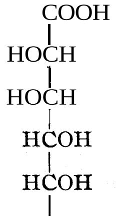
Fehling's solution and that in alkaline solution it rapidly becomes yellow when heated. Very recently,[5] he again studied the properties of this lactone and made the surprising discovery that it adds hydrogen cyanide to give a compound which can be hydrolyzed to a tricarboxylic acid.

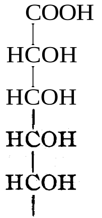
Fischer[6] has reported that d-mannosaccharic dilactone also reduces Fehling's solution. This fact has been confirmed in our laboratory.

Mannosaccharic acid, so far as the authors have been able to learn, is the only dibasic sugar acid possessing these properties. Inspection of the formulas of mannosaccharic and allomucic acids shows that they are



$$\begin{array}{c}\mathrm{COOH}\\ |\\ \mathrm{HOCH}\\ |\\ \mathrm{HOCH}\\ |\\ \mathrm{HCOH}\\ |\\ \mathrm{HCOH}\\ |\\ \mathrm{COOH}\end{array}$$

Mannosaccharic acid



$$\begin{array}{c}\mathrm{COOH}\\ |\\ \mathrm{HCOH}\\ |\\ \mathrm{HCOH}\\ |\\ \mathrm{HCOH}\\ |\\ \mathrm{HCOH}\\ |\\ \mathrm{COOH}\end{array}$$

Allomucic acid

similar in that the two hydroxyl groups adjacent to each of the carboxyl groups are in the cisposition.

This is not true of any other of the dibasic sugar acids. If this configuration is responsible in any way for the properties of mannosaccharic acid, it might be expected that similar properties would be observed in the case of allomucic acid. However, tests failed to confirm this prediction. Allomucic acid was found to be non-reducing, both when tested with Fehling's reagent immediately after solution and when tested after boiling an aqueous solution for one-half hour to convert to lactone. It remained colorless when boiled with 10% sodium hydroxide. Moreover, while mannosaccharic acid readily forms the dilactone, allomucic acid apparently forms only a monolactone under ordinary conditions.

Experimental

Preparation of Allomucic Acid.—One hundred g. of mucic acid, 1000 cc. of water and 100 g. of pyridine were placed in a 2-liter round-bottomed flask and the mixture was heated to boiling. The flask was then tightly closed with a rubber stopper which was wired in position. The flask was wrapped with cloth and heated for 115 hours on a steam-bath. One hundred and fifty g. of crystallized barium hydroxide dissolved in hot water was then added. This precipitated the barium salts of mucic and allomucic acids. The mixture was vacuum distilled until practically all of the pyridine was removed. After cooling, the crude barium salt was filtered off, washed with water and dried. The yield was 160 g. The salt was suspended in 1500 cc. of hot water and the calculated amount of sulfuric acid (based on the amount of barium found by analysis) was added. The mixture was heated, with stirring, on a steam-bath for two hours.

[5] Kiliani, Ber., 61, 1155 (1928).

[6] Fischer, *ibid.*, 24, 539 (1891).

It was then filtered and the residue, which consisted of a mixture of barium sulfate and unchanged mucic acid, removed by filtration and washed with a little hot water. After treatment with decolorizing carbon, the filtrate was obtained as a pale yellow liquid. It was then concentrated under reduced pressure to 500 cc. and allowed to stand overnight in the ice box. The mucic acid which crystallized was removed by filtration. The filtrate was evaporated to half its volume under reduced pressure, at about 60°, and allowed to stand in the ice box overnight. The crystalline material, which still contained a small amount of mucic acid, was filtered off and treated with ten times its weight of boiling water. The mixture was filtered hot. Crude allomucic acid separated from the filtrate on cooling. The main bulk of mother liquor was again evaporated to half its volume and cooled. The crystalline acids were filtered off and treated with ten times their weight of boiling water as before. After filtration of the mixture, the filtrate deposited further crystals of crude allomucic-acid. This process was repeated with the original mother liquor until only a small amount of dark colored sirup remained. The several fractions of crude allomucic acid were washed with a little 95% alcohol and recrystallized to constant melting point. The total yield was **33** g. which melted at 167–168° with effervescence. The melting point as determined by Fischer[1] was 166–171°. The higher melting point of 172–173° reported by Patterson and Fulton[7] was found on rapid heating.

Allomucic **Mono-amide.**—Twenty grams of allomucic acid was dissolved in 300 cc. of water and boiled for forty minutes. The solution was allowed to stand overnight and was then filtered from a small amount of allomucic acid. The filtrate was evaporated under reduced pressure until most of the acid had crystallized out. After filtering, the solution was again evaporated until about **25 g.** of a sirupy mixture of acid and lactone was obtained. This was cooled in ice and treated with **30** cc. of concentrated ammonia water. After standing for about five hours, the solution was carefully neutralized with cold, concentrated hydrochloric acid, using Congo Red as indicator. On standing overnight a mixture of crystals of ammonium chloride and allomucic mono-amide was obtained. The former was removed by washing with water. The yield of practically pure amide melting at 175–175.5° was **2** g. Two additional crystallizations from water raised the melting point only **0.5'.** An additional gram of amide was obtained on concentrating the mother liquor.

Anal. **Calcd.** for $C_6H_{11}O_7N$: N, **6.69; 4.78 cc.** of **0.1** *N* NaOH, Found: N, **6.66; 0.1000 g.** required **4.77** cc. of **0.1** *N* NaOH.

Diethyl Allomucate.—This ester was prepared according to the method employed by Malaguti[4] in preparing diethylmucate. The yield was **42%.** It was also prepared as follows: **3.4** g. of allomucic acid was placed in a flask with **20** cc. of 1% hydrochloric acid in absolute ethyl alcohol. After refluxing for twenty minutes, a clear solution was obtained. Boiling was continued for three and one-half hours. The volume then was reduced about one-third by evaporation and the solution allowed to stand in the ice box overnight. The crystals of diethyl allomucate were filtered off and washed with absolute alcohol. The yield of crude product was **3.3** g. On recrystallization from alcohol 2.5 g. (58% of the theoretical) of pure ester was obtained, melting point **137–138°.** On evaporation of the mother liquor and washing, an additional **0.6** g. of crude material melting at about **130°** was obtained. The melting point of the second crop did not change after one recrystallization from alcohol.

ture with 3 cc. of concd. ammonia water. The ester dissolved and the diamide separated out almost immediately. It was washed thoroughly with water and alcohol and dried. The yield was 0.27 g., 75% of the theoretical. The substance is practically insoluble in water, ethyl alcohol and ether. It commenced to discolor at 185° and gradually darkened as the temperature was raised. It melted at 209°, with effervescence.

Anal. Calcd. for $C_6H_{12}O_6N_2$: N, 13.46. Found: N, 13.50, 13.38 (Kjeldahl).

Summary

1. An improved method for the preparation of allomucic acid is described.
2. Methods for the preparation of several new derivatives of the acid are presented.
3. A comparison is made of some of the properties of allomucic and mannosaccharic acids.

THE MOLECULAR WEIGHT OF EDESTIN

BY THE SVEDBERG AND ALFRED J. STAMM[1]

RECEIVED MARCH 6, 1929 PUBLISHED JULY 5, 1929

The proteins that have thus far been subjected to the ultracentrifuge analysis in this Laboratory in order to determine their molecular weights as well as other physical characteristics have been water soluble[2] with the exception of serum globulin.[2f] This protein required only relatively small salt concentrations to hold it in solution. There are a number of other proteins of the globulin class that are soluble only in strong salt solutions. It was thus the authors' desire to see if the previously developed methods of study were completely applicable to the study of proteins dissolved in strong salt solutions.

The protein edestin, belonging to the vegetable globulin class, was chosen for this work so as to add another type of protein to the list of those studied. Edestin seemed especially suitable because of the ease with which it can be isolated and because of its definite crystalline structure, which is a strong indication of its homogeneity.

Preparation of Material.—Coarsely ground hemp seed (600 g.) was directly subjected to digestion and extraction with a mixture of 2000 cc. of 10% sodium chloride solution and 400 cc. of 2.1% disodium phos-

phate.[3] After standing for twelve hours at room temperature the material was heated for two hours at 40° and then filtered through a filter cloth. The filtrate was clarified in a bucket centrifuge. Three volumes of water were added to each volume of the filtrate, causing precipitation of the extracted edestin. This was allowed to stand overnight in an ice box. The supernatant liquid was removed from the precipitate in the bucket centrifuge. After washing the precipitate several times by decantation with a dilute sodium chloride solution, the precipitate was dissolved in 10% sodium chloride. The reprecipitation and solution was repeated three times. The stock edestin was kept in an ice box in a precipitated form under dilute sodium chloride. A few drops of toluene were added to the solutions in the course of the preparation and to the stock precipitate and stock solutions to prevent bacterial action.

Due to the decreased solubility of edestin at low temperatures, as well as the decreased solubility of the phosphate buffers used, the stock solutions made up from the above precipitated edestin were dialyzed and kept at room temperature (about 18°). The course of the experiments showed that this had no deleterious effect.

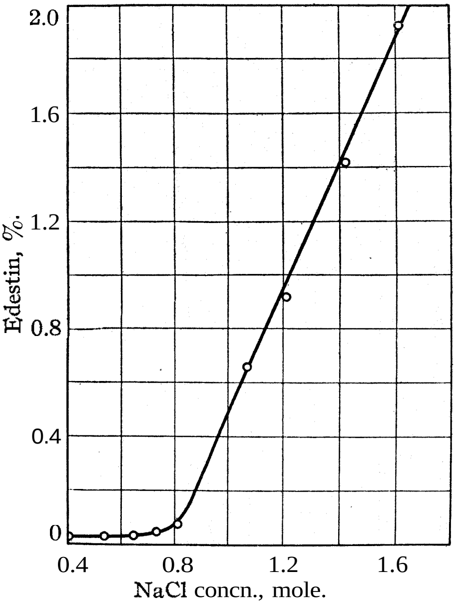

Fig. 1.

Solubility and Isoelectric Point.—Though edestin has perhaps been studied more than any other protein of this class, practically none of its physical characteristics are known with any degree of accuracy. Two different values have been obtained for the isoelectric point. Rona and Michaelis[4] found it to be at a PH 6.9 in phosphate buffers, and Michaelis and Mendelssohn[5] found it to be at PH 5.6 in acetate buffers. Because of this discrepancy, it seemed advisable to determine the isoelectric point from solubility measurements under the conditions used in this research, and at the same time to get the solubility information that would be of value in connection with the ultracentrifuge analysis.

---

[3] The grinding of the hemp seed was kindly done for us in an experimental mill at the laboratory of Upsala Ångkvarn.

[4] Rona and Michaelis, Biochem. *Z.*, 28, 193 (1910).

[5] Michaelis and Mendelssohn, *ibid.*, 65, 1 (1914).

Three sets of solubility measurements were made. In each case the concentrations were determined by evaporating 2 cc. of the solvent and 2 cc. of the solution, and drying to constant weight in an oven at 105°. The solutions were allowed to stand in contact with an excess of edestin for several hours at room temperature (about 18°) and they were then clarified in a bucket centrifuge before pipetting off the samples for analysis. Figure 1 gives the solubility of edestin in different concentrations of sodium chloride solution. The solubility is small up to 0.8 M sodium chloride, but above this concentration the solubility increases rapidly. Figure 2 gives the changes in solubility of edestin in phosphate buffer solutions with the change in PH of the solvent. Curve A is for the phosphate buffer alone and Curve B for the phosphate buffer together with sodium chloride. Curve A gives a minimum solubility isoelectric point at PH 5.5 and B gives it at PH 5.4. A solution of edestin, in a previously boiled sodium chloride solution (PH 5.8), after twelve days' dialysis against the solvent, gave a PH of 5.5. As the sodium chloride has practically a negligible buffering action, the PH of the solution should be practically at the isoelectric point. These three values are in very good agreement and also check the value of the isoelectric point given by Michaelis and Mendelssohn.

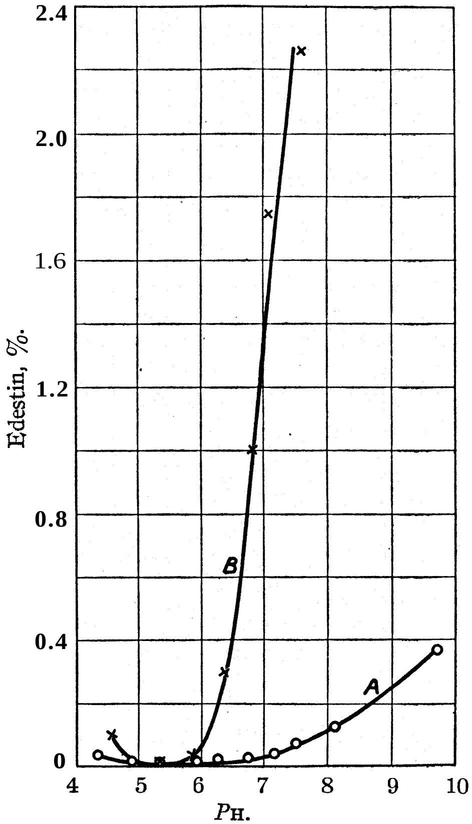

Fig. 2.—A, in phosphate buffer, total concn. 0.15 M; B, in phosphate buffer, total concn., 0.15 M + 0.735 M NaCl.

The solubility curves show that the solubility of edestin in buffered solutions is very small near the isoelectric point. The measurements to follow, that were made at the isoelectric point, have hence been made on unbuffered sodium chloride solutions. Measurements on solutions containing no sodium chloride could only be made at the higher PH values.

Specific Volume.—The partial specific volume of the protein was determined pycnometrically at 19.8°. Measurements were made on three different solutions of edestin of different *Ph* value and different concentration, as shown in Table I. Each of the solutions was dialyzed against

0.56

TABLE I

PARTIAL SPECIFIC VOLUME OF EDESTIN IN DIFFERENT SOLVENTS AT 19.8°

Edestin concn., %		**1.19**	*0.58*
Solvent	1.24 M NaCl	0.735 M NaCl *0.15* M Na_2HPO_4 *0.06* M KH_2PO_4	0.62 M NaCl *0.0375* M Na_2HPO_4 *0.026* M NaOH
Ph of soln.	*5.5*	*6.7*	**11.3**
Part. sp. vol.	*0.744*	*0.743*	*0.745*

the solvent for twelve days at room temperature (16 to 18°). The outer liquid was changed twice a day. The dialysis was conducted under a bell jar to minimize evaporation from the solvent. The table shows that the partial specific volume is not affected by the *Ph* of the solution over the range tested. These values agree, within the range of experimental error, with the partial specific volume of egg albumin, hemoglobin, serum albumin, serum globulin, phycocyan and phycoerythrin, as determined in this Laboratory.

Light Absorption.—The light absorption of cdestin solutions was determined with the Judd–Lewis spectrophotometer. The specific extinction coefficient, $\epsilon/c = 1/cd \log I_0/I$ (where c is the concentration in per cent., d the thickness of the solution, I_0 the intensity of the light beam after passing through the solvent and I the intensity of light after passing through the same thickness of solution), is plotted against the wave length of the light (see Fig. 3). Measurements were made upon 0.110 and 0.055% solutions of edestin in 1.24 M NaCl, *Ph* 5.5; 0.198, 0.099 and 0.0495% solutions of edestin 0.735 **M** in NaCl, 0.15 M in Na_2HPO_4 and 0.06 M in KH_2PO_4, *Ph* 6.7; a 0.090% solution of edestin 0.15 M in Na_2HPO_4, 0.0036 M in KH_2PO_4 and 0.0052 M in NaOH, *Ph* 9.7; a fresh 0.053% solution of edestin 0.62 M in NaCl, 0.0375 M in Na_2HPO_4 and 0.025 M in NaOH, *Ph* 11.3; a similar solution to the latter made up from a solution five days old containing originally 0.58% of edestin; and a 0.089% solution of edestin 0.206 M in NaCl and 0.0167 M in HCl, *Ph* 1.S. All of these solutions gave practically

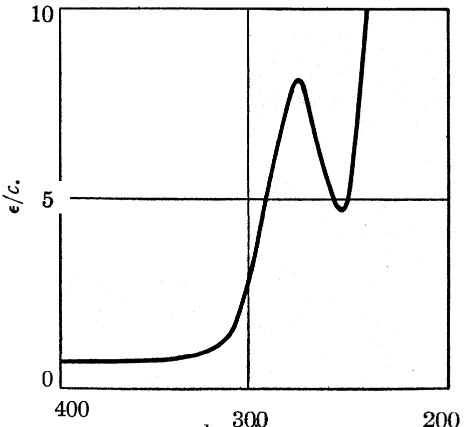

Fig. 3.

identical curves so only the average value is plotted. The absorption showed a maximum at 276$\mu\mu$, and a minimum at 254$\mu\mu$.

Determination of the Molecular Weight

Sedimentation Velocity Method.—The apparatus and the method have been so completely described in previous publications[2c,d,e,f,6] that no attempt will be made to repeat the description here. The modifications described by Svedberg and Sjögren[2f] were effective in this work. As the maximum light absorption of edestin is similar to that for the other proteins studied, the same optical system and the same chlorine and bromine filters were used.

The molecular weight is given by the relation

$$M = \frac{RTs}{D(1 - V\rho)}$$

where R is the gas constant, T the absolute temperature, *s* the specific sedimentation velocity or $1/\omega^2x\cdot dx/dt$, D the diffusion constant, V the partial specific volume of the protein, p the density of the solvent, *x* the distance from the axis of rotation, w the angular velocity and *t* the time.

Table II gives the results of a typical run made with an edestin solution at the isoelectric point. The constancy of the values for the specific

[6] The Svedberg, "Colloid Chemistry," 2nd ed., Chemical Catalog Co., Inc., New York, 1928.

sedimentation velocity s and the diffusion constant D indicates that the cdestin is mono-disperse and that the solvent shows no time function effect upon the systems. The edestin further settled so as to give clear buffer at the top of the cell, thus showing that there was no non-centrifugible material present with a light absorption between 250 and $290\mu\mu$, the wave lengths of the light entering the cell.

Figure 4 gives the concentration curves from which the data of Table II were obtained. The curves have been corrected for the sector shape of the cell and the variation of the centrifugal force with distance from the center of rotation. The dotted curves for each represent the theoretical diffusion curves of a substance of only one molecular species when subjected to the same experimental conditions. The deviations obtained are well within the range of experimental error.

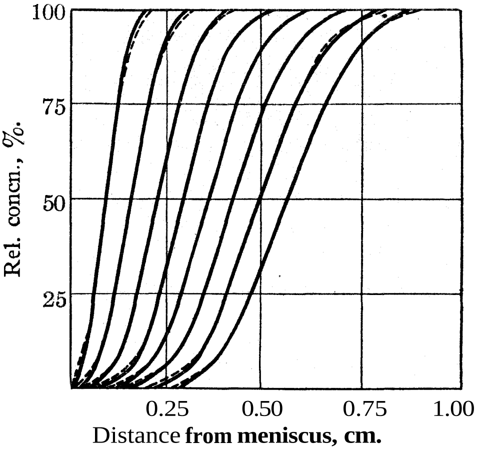

Fig. 4.

Table III gives a summary of all of the sedimentation velocity runs. The effect of varying only the edestin concentration was determined for two different solvents. The specific sedimentation velocities and the diffusion constants show no regular shift between the concentrations of 1.16 and 0.193% in 1.24 M NaCl, P_H 5.5. The resulting molecular weight values are constant within experimental error over this range. The same is true in the solutions at P_H 6.7 from a concentration of 1.38% edestin to a concentration of 0.155%. At the concentration of 0.108 there is an appreciable change in the specific sedimentation velocity and diffusion constant, indicating a change in the molecular dispersion of the edestin. Dissociation has very likely taken place in this dilute solution. The abnormal specific sedimentation velocity and the continuous shift in the apparent diffusion constant from 3.1 at the start of the run to 11.3 at the end of the run indicate the heterogeneity of the system. The molecules of different molecular weight settling at different speeds caused a spreading or blurring at the sedimentation boundary, which according to the methods of calculation is included with the true diffusion. Though such runs as this cannot be quantitatively analyzed and the true molecular weights calculated, they show very nicely in a qualitative way what has happened to the solution.

The molecular weights calculated from the data of all of the runs at

[a] Extrapolated values (see Fig. 5).

PH 5.5 and PH 6.7, with the exception of the one above cited where dissociation took place, are in very good agreement. The average molecular weight of 215,000 is almost exactly the same as that of phycoerythrin obtained by Svedberg and Lewis. This molecular weight is considerably larger than any of the estimates that have been made from analytical data; Cohn[7] gives 29,000 as the minimal molecular weight of edestin. Osborne[8] gives 7250 as the minimal molecular weight from the acid combining capacity and chemical composition. Estimates by the osmotic pressure methods cannot be made as in the case of several of the other proteins, because high electrolyte concentrations are necessary to hold the edestin in solution and they would exert a far greater pressure than the edestin itself.

In order to compare the specific sedimentation velocity and the diffusion constant in the different solvents, the experimentally determined values have been converted to a basis of sedimentation and diffusion in pure water. The specific sedimentation velocity depends inversely upon the viscosity of the solvent and directly upon the difference in density between the particle and the solvent. The experimental values have thus been multiplied by the relative viscosity of the solvent and the ratio between the density differences in water and in the solvent. As the diffusion depends inversely upon the viscosity, it has been multiplied by the relative viscosity. The values of s on the water basis for the solutions at P_H 5.5 and 6.7 show a maximum deviation of 5%, and a mean deviation of 2% from the average value. The values of D show a maximum deviation of 7% and a mean deviation of 4% from the average.

The percentage of non-centrifugible normal light-absorbing material from each run is also included in Table III. These values were obtained from the deviation of the light absorption of the liquid at the top of the cell from that of the pure buffer. For all of the solutions at P_H 5.5 it was very small. In the case of the solution of P_H 6.7 it was somewhat larger and showed a slight increase with a decreased edestin concentration, as has been noted with other proteins.[2f] The fact that the solutions at P_H 6.7 were considerably older at the time the runs were made than those at P_H 5.5 may account for the slight decomposition of the former. In none of these cases, however, is the percentage of non-centrifugible material present sufficient to interfere with the determinations.

The effect of the dilution of the solvent with water is shown by Run 11, Table III. The values of the specific sedimentation velocity, diffusion constant and molecular weight are quite normal. The fact that the concentration of the solvent and its saline composition can be varied over a considerable range without affecting the results indicates the applicability of the sedimentation velocity method to the study of the molecular weights of proteins in strong salt solutions.

[7] Cohn, *Physiol. Rev.*, 5, 360 (1925).

[8] Osborne, THIS JOURNAL, 24, 39 (1902).

Table III also shows the effect of varying the *PH* of the solution. The results show that edestin is stable over a considerable range of Pa on the alkaline side of the isoelectric point. Run 13 shows the results for a sample that was made up three months before the measurements were made. Not only is the molecular weight normal, but the sedimentation curves further show that only 4% of non-centrifugible material of normal light absorption can be present. This is even less than the amount present in the case of several of the runs at *PH* 6.7.

A further increase in the *PH* above *PH* 9.7 shows a definite decomposition or dissociation. Runs 15 and 16 were at a *PH* of 11.3. The former was run at a speed of 23,900 r.p.m. and the latter at 42,500 r.p.m. The specific sedimentation velocities are in good agreement but they are less than half of the normal value. The diffusion constants, which are apparent rather than real because of the heterogeneity of the system, are plotted in Fig. 5 for the different times of sedimentation. In the case of the high-speed run the change of the apparent diffusion with time is greater than for the low-speed run, because of the greater separation of the sedimentation boundaries of the different molecular species present. It is of interest to note that the ratio of the slopes of the two curves after a considerable time of centrifuging approaches the square of the ratio of the centrifugal forces, that is, the *Z* displacements per unit of time approach proportionality to the centrifugal forces applied. This means that with increased time the proportion of the apparent diffusion constant that is caused by true diffusion becomes less and less, and that the spreading of the sedimentation boundaries predominates. When the apparent diffusion curves are extrapolated to zero time the converse should be true for the resulting values. There should be no spreading of the boundaries and the diffusion values should be real, and a sort of average value for the diffusion constants of the various constituents present in the mixture. It will be shown later that this is the case.

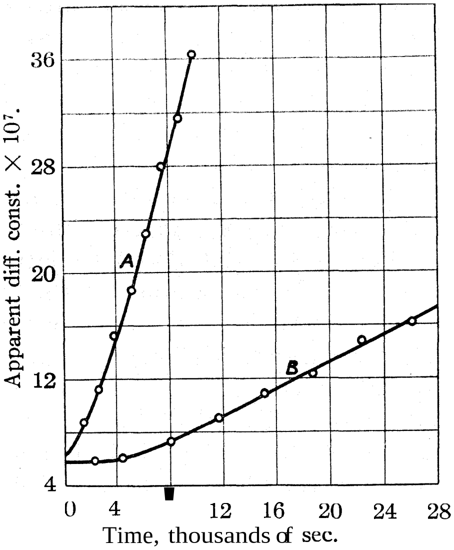

Fig. 5.—A, 42,500 r.p.m.; B, 23,900 r.p.m.

A further analysis of the data of Run 15 is given in Fig. 6. The experimental sedimentation curve E corrected for the sector shape of the cell and the variation of the centrifugal force with distance from the center of rotation is given for the longest time of centrifuging (corresponding to the highest point on Curve A (Fig. 5). The dotted curves A, B and C are the theoretical sedimentation curves for normal edestin, a protein of one-half the normal molecular weight and one of one-third the normal molecular weight, respectively, each of which is subjected to the actual experimental conditions. The specific sedimentation velocities and diffusion constants used for the fractional molecular weight calculations were the actual experimental values obtained for the proteins that have these molecular weights.[2c,d,f] The dotted curve, D, is for the theoretical mixture of 15% A, 30% B and 55% C, respectively. This curve

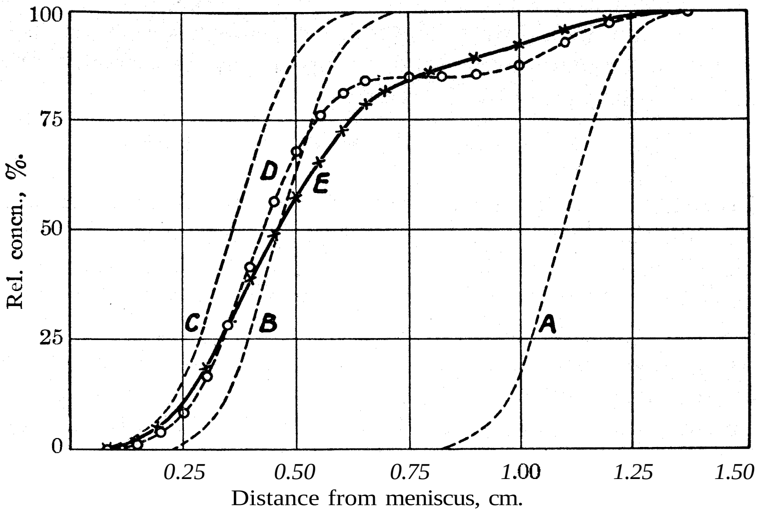

Fig. 6.—*A*, Theoretical curve for normal edestin; B, for *a* protein of $M = 106{,}000$; C, $M = 68{,}000$; *D*, *15%* A, *30%* B, and 55% C; E, actual experimental curve for edestin at $P_H = 11.3$.

shows a fair agreement with the actual experimental curve, E. It is especially good at the ends, the deviation being almost entirely near the inflection point. Similar curves for shorter times of sedimentation showed far better agreement between the observed and the theoretical curves. Such an analysis as this of course cannot prove the molecular constitution of the mixture, for perhaps other combinations will satisfy the experimental conditions as well as this. It serves, however, to show the general nature of the mixture. In the last section of this paper the constitution of this mixture will be shown quite definitely to be that represented here.

Edestin is far less stable on the acid side of the isoelectric point than on the alkaline side. Decomposition takes place both at P_H 3.1 and 1.8. Though the specific sedimentation velocity is almost normal, showing the presence of normal edestin, the diffusion constant is definitely of the apparent diffusion type pictured above. The decomposition, however, is quite different from that on the alkaline side of the isoelectric point, as the decomposition is mostly into material of such a low molecular weight that no sedimentation will take place. This can be seen readily by comparing the percentages of non-centrifugible material present for each of the runs listed in Table III. Slight irregularities in the sedimentation curves for both of these acid runs indicate that there are some centrifugible decomposition products present, as is required by the abnormal diffusion constant. Though these cannot be identified definitely, it seems probable from the curves that a material of one-half of the normal molecular weight is present.

Sedimentation Equilibrium Method.—A few runs were made by the sedimentation equilibrium method as previously described.[2a,b,d,e] The molecular weight is given by the relation

$$M = \frac{2RT \ln (c_2/c_1)}{(1 - V\rho)\omega^2(x_2^2 - x_1^2)}$$

c_1 and c_2 are the concentrations at the distances x_1 and x_2 from the center of rotation and the other symbols have the same significance as previously.

Table IV gives the results of a typical run showing that there is no regular change of molecular weight with height. Table V gives a summary of all of the equilibrium runs. The molecular weights obtained by this method agree quite well with the values obtained by the sedimentation velocity method. An unsuccessful attempt was made to determine the molecular weight of the protein at PH 11.3 by this method.

TABLE IV

RESULTS OF A TYPICAL SEDIMENTATION EQUILIBRIUM RUN MADE UPON AN ISOELECTRIC SOLUTION OF EDESTIN IN 1 24 M SODIUM CHLORIDE SOLUTION

Concentration, 0.58%; PH of solution, 5.5; $V = 0.744$; $\rho = 1.0479$; length of column of solution, 0.59 cm.; thickness of column, 0.2 cm.; distance of outer end of solution from axis of rotation, 5.95 cm.; average speed, 5280 r.p.m.; aperture of lens, F:25; time of exposures 1, 2 and 3 min.; exposures made after 30, 35 and 45 hours of centrifuging.

Distances, cm.		Mean concn. (orig. soln. = 1.00)		No of exposures	Mol. wt.
x_2	21	c_2	c_1		
5.86	5.81	2.09	1.76	6	222,000
5.81	5.76	1.76	1.48	9	223,000
5.76	5.71	1.48	1.29	12	179,000
5.71	5.66	1.29	1.12	12	185,000
5.66	5.61	1.12	0.95	12	216,000
5.61	5.56	0.95	.81	12	212,000
5.56	5.51	.81	.68	12	238,000
5.51	5.46	.68	.58	9	217,000
5.46	5.41	.58	.49	9	234,000
5.41	5.36	.49	.42	9	214,000
				Mean	214,000

The results showed definitely that the edestin had decomposed or dissociated into several molecular species of the order of molecular weight of those predicted by the sedimentation velocity method, but no quantitative results could be obtained because of the complexity of the system and the long time required to obtain equilibrium during which further changes in the protein may have resulted.

TABLE V

Sedimentation Velocity Method as Modified by **Lamm.**—Ole Lamm, working in this Laboratory, has developed a new method for determining the changes in concentration in a sedimenting system based on the measurement of the changes in the refractive index of the system. The theory of the method has been described by Lamm.[9] For a complete description of the method the reader is refered to the above publication and subsequent publications of Lamm to follow. It suffices to state here that the measurements yield directly a function which is proportional to the change in the concentration with changes in height, that is, a first derivative curve. As the results will show, such a function gives the abnormalities due to the presence of several molecular species in the system much more definitely than the simple concentration–height relationship obtained by the old method. A run made by the new method on a 0.487% solution of edestin in 1.24 M sodium chloride (average speed, 24,300 r.p.m.) gave a molecular weight of 222,000, a specific sedimentation velocity of 12.4×10^{-13} and a diffusion constant of 5.30×10^{-7} on a water basis. These values all agree well with the values given in Table III.

In Fig. 7 is plotted the function of the change in concentration with height against the height for a 0.487% solution of edestin at *PH* 11.3 after one and one-half hours' sedimentation. Instead of obtaining the simple one-maximum curve that would result if only one molecular species were present, there are three definite maxima. The three dotted curves

---

[9] Lamm, *Z. physik. Chem.*, 138,313 (1928). The application of the method to the ultracentrifuge was not as yet published at the time of the preparation of this manuscript, but should appear in print soon. The authors are grateful to Lamm for granting them permission to publish their results obtained by the new method before his complete description of the method has appeared in print.

represent the three simple curves whose summation is the experimental curve. From the position and the shape of these three curves the specific sedimentation velocities and the diffusion constants of each of the constituents can be calculated according to the method which Lamm will describe. Table VI gives a summary of the results of this run, obtained from the curves of Fig. 7, as well as from similar curves for different times of centrifuging. Because of the high centrifugal force used the normal edestin is so completely removed from the system in two hours that only two values for the specific sedimentation velocity could be obtained from the data. The small percentage of the normal edestin present, as is shown by the relatively low maxima, made it practically impossible to obtain diffusion data for this constituent. The specific sedimentation velocity for Constituent 1, however, shows definitely that it represents the original normal edestin. Both the specific sedimentation velocities and the diffusion constants for Constituent 2 are very close to the values for serum, globulin and phycocyan,[2d,f] and those for Constituent 3 are very close to the values for hemoglobin and serum albumin.[2e,f] The data thus definitely show that edestin at a PH of 11.3 dissociates into particles having one-half and one-third of the original molecular weight, and that these dissociation products have the same specific sedimentation velocity and diffusion constant as the other proteins that have the same molecular weights. This run by the new method further shows that the proportions of the three constituents present are of the same order of magnitude as in the theoretical calculation of Fig. 6.

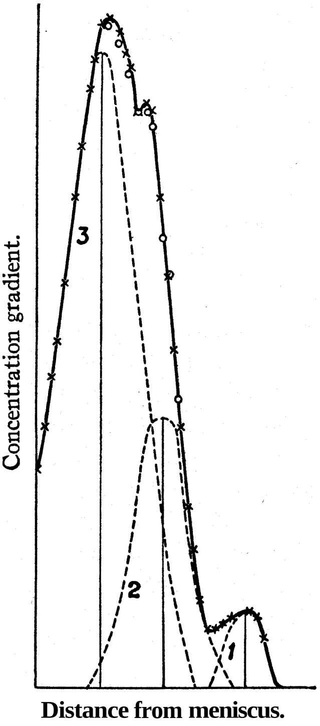

Fig. 7.

This one illustration shows very nicely the possibilities of applying the new method to the study of mixed proteins. Further work along this line is now under way at this Laboratory and should yield more important data regarding the dissociation of proteins.

Discussion of Results

This research has shown quite definitely the applicability without modifications of both the sedimentation velocity and sedimentation equilibrium methods to the study of proteins dissolved in strong salt solutions.

TABLE VI

SUMMARY OF THE RESULTS OBTAINED ON EDESTIN AT P_H 11.3 BY THE NEW METHOD DEVELOPED BY OLE LAMM

Edestin concentration, 0.487%; solvent 0.62 M in NaCl; 0.0375 *M* in Na_2HPO_4; 0.025 M in NaOH; P_H of solution, 11.3; density of solvent, 1.0295; relative viscosity of solvent, 1.0350; thickness of column of solution, 0.60 cm.; average speed, 42,500 r.p.m.; average temperature, 21.2°

	Specific sedimentation velocities at 20°

Molecular weight	....	106,000	62,200

The specific sedimentation velocity values obtained in different solvents can be converted to a basis of sedimentation in water merely by multiplying by the relative viscosity of the solvent and the ratio of the difference in densities between the particle and the solvent, in water and in the solvent under consideration. The diffusion constant values can be converted to a basis of diffusion in pure water by merely multiplying by the relative viscosity of the solvent. The results in Table III show very nicely the constancy of both the specific sedimentation velocity and diffusion constant when corrected to a water basis for all of the solvents except those in which dissociation took place.

The molecular weight of normal edestin is practically the same as that of phycoerythrin. The specific sedimentation velocity and diffusion constant are likewise the same within experimental error. Calculation of the radius of the particle by applying both Stoke's law and Einstein's law shows that the edestin molecules are practically spherical as in the case with phycoerythrin.[2d]

This research gives considerable further evidence in favor of the senior author's theory that the proteins all have molecular weights that are integral multiples of the molecular weight of egg albumin, namely, 34,500.

Normal edestin has a molecular weight very close to six times this value. Every one of the proteins thus far studied in this Laboratory has a molecular weight of either 1, 2, 3 or 6 times that of the egg albumin with the exception of the two hemocyanins, which are such large multiples that it is impossible to determine whether they are integral multiples.

The nature of the dissociation products of edestin at P_H 11.3, obtained by the new method of Lamm, gives perhaps the best single piece of evidence obtained to date of the validity of the theory. Not only are the molecular weights of the dissociation products even multiples, but they are the same multiples as other known proteins and have the same specific sedimentation velocities and diffusion constants. No protein with a molecular weight 4 times that of egg albumin has ever been found. It is of interest to note that there was no evidence of any such multiple molecular weight dissociation product either, or a multiple of 1.5 as might be expected if the dissociation took place in two steps. A more extended research upon the dissociation products of edestin as well as of other proteins outside of their normal P_H stability range will undoubtedly settle this theoretical consideration definitely.

The expenses connected with these experiments have been defrayed by grants from the Nobel Fund of Chemistry and from the foundation "Therese och Johan Anderssons Minne."

Summary

1. The previously developed ultracentrifuge methods for determining the molecular weights of proteins have been shown to be completely applicable to the study of proteins dissolved in strong salt solutions.

2. The normal molecular weight of edestin was found to be 212,000 ± 10,000, the average specific sedimentation velocity 12.8×10^{-13} cm./sec. and the average diffusion constant 5.6×10^{-7} cm.^{2}/sec. both on a water basis at 20°.

3. The edestin concentration showed no effect upon the resulting molecular weight, above a concentration of 0.1%. Below this value definite dissociation or decomposition took place.

4. Edestin was shown to be quite stable and to give a normal molecular weight on the alkaline side of the isoelectric point (P_H 5.5 by solubility measurements) as high as a P_H of 9.7. At a P_H of 11.3 definite dissociation took place. Edestin was found to be quite unstable on the acid side of the isoelectric point, definite*dissociation taking place at P_H 3.1.

5. Employing a new method developed by Ole Lamm at this Laboratory for determining the concentration gradients in the sedimentation systems, the molecular constitution of dissociated edestin at a P_H of 11.3 was definitely determined. Under the conditions of the experiment given,

molecules of one-half and one-third of the normal molecular weight are present together with the normal.

THE FATTY ACIDS ASSOCIATED WITH RICE STARCH

BY LEO LEHRMAN

RECEIVED MARCH 7, 1929 PUBLISHED JULY 5, 1929

It has been shown that in several naturally occurring starches fatty acids are combined with carbohydrate.[1] In the case of corn and rice the fatty acids constitute part of the molecule of one of the components, namely, the α-amylose.[2] The fatty acids liberated by the hydrolysis of corn starch free from extraneous material have been identified and their amounts determined.[1b,3] From a review of the "fat by hydrolysis,"[1b] acid number and iodine number of the fatty acids liberated from corn and rice starch free from extraneous material,[1b] a difference in amounts and possibly in kind is apparent. Therefore, it is important that these fatty acids which are in the rice starch molecule[1] (a-amylose portion) should be determined both qualitatively and quantitatively. This would enable a comparison of these two starches and furnish additional evidence in the understanding of the different behavior of the starches.

In the course of the investigation the probable absence of sterols or other substances that might occur in the starch and be present in the liberated fatty acids was shown. As the fatty acids occurring in the germ are present as glycerides, the aqueous filtrate from the hydrolysis was examined for glycerol; a negative result was obtained. This is added evidence that the fatty acids identified were not present extraneously in the starch.

Experimental Part

Mixed Fatty Acids from Rice Starch.—The rice starch[4] which was used as the starting material had a negligible amount of extractable extraneous material, using petroleum ether as the solvent. In the course of the work a total of twenty pounds was used. The hydrolysis[1b] was carried out using hydrochloric acid and a much more concentrated suspension of the rice starch. Five pounds of the starch yielded a suspension of 3.5 liters; the acid solution was made up by diluting 525 cc. of concentrated hydrochloric acid to 1.5 liters. The filtrate from the hydrolysis, which had a dark brown color, was reserved for the examination for glycerol. The fat by hydrolysis, obtained by

[4] The author wishes to thank Stein, Hall and Co., Inc., New York City, for their kindness in supplying this material.

extracting the dry residue with petroleum ether and then allowing the solvent to evaporate spontaneously, was a light yellow colored solid; five pounds of the original rice starch gave **14.75** g. of mixed fatty acids free from traces of the solvent.

Examination of Filtrate for Glycerol.—In order to concentrate the glycerol if it was present, a distillation of some of the filtrate from the hydrolysis was attempted but there was so much frothing that the process had to be stopped. Two liters was put in a large beaker and evaporated to about **300** cc., a dark brown precipitate being obtained. This was filtered off and the filtrate extracted with chloroform. After the chloroform was distilled off, a black tarry material was left. This was boiled up with a small amount of water, filtered, treated with potassium permanganate in acid solution and tested for formaldehyde.[5] The result was negative.

In order to be sure that the acid present from the hydrolysis had no effect in the subsequent procedure, one liter of the filtrate from the hydrolysis was neutralized with calcium carbonate, extracted with chloroform and the chloroform distilled off. The small amount of tarry material left gave negative results for glycerol.[5]

Isolation and Identification of Saturated Fatty Acid.—The mixed fatty acids were dissolved in alcohol, the solution chilled in an ice–salt mixture until nearly solid, filtered quickly by suction and washed with several portions of cold alcohol. The solid white residue was recrystallized several times from alcohol, when it gave a melting point of 62°.

The phenylhydrazide, made by heating with an excess of phenylhydrazine,[6] was a white crystalline solid, m. p. 110°,[7] which corresponded with that made similarly from pure palmitic acid.

The molecular weight of the acid was determined by dissolving a weighed amount in neutral alcohol and titrating with standard alkali to phenolphthalein, running a blank at the same time.

Anal. Subs., **0.0784, 0.1245: 7.50, 11.86** cc. of $N/25$ NaOH. Calcd. for palmitic acid, $C_{16}H_{32}O_2$: mol. wt. **256.3.** Mol. wt. found: (monobasic acid) **261.3, 262.4.**

Anal. Subs., **0.1252, 0.1163:** CO_2, **0.3446, 0.3206;** H_2O, **0.1387, 0.1295.** Calcd. for palmitic acid, $C_{16}H_{32}O_2$: C, **74.91;** H, **12.59.** Pound: C, **75.06, 75.18; H, 12.40, 12.46.**

From the above data the presence of palmitic acid in the mixed fatty acids is shown.

Identification of Unsaturated Fatty Acids

A. Oxidation.—The mixture of unsaturated fatty acids separated from the saturated fatty acid by means of the magnesium soap alcohol method[3] was a light brown oil.

A portion of this mixture of unsaturated fatty acids was oxidized with potassium permanganate in alkaline solution.[8] It was found that about half of the oil could bc recovered unoxidized, so the oxidation was repeated on this and the product combined with that from the first oxidation. After the hydroxy acids were filtered off, they were washed with water and allowed to dry on the filter paper. In the course of this investigation it was found that the lower hydroxy acid fraction (ether-soluble part) always contained a small amount of the higher hydroxy acid which was difficult to eliminate. This was due to the slight solubility of the higher hydroxy acid in ether, a fact not mentioned previously. In order to make a sharper separation a different solvent was sought and it was found that chloroform on prolonged extraction dissolves the lower hydroxy acid and none of the higher.

[8] Lapworth and Mottram, J. *Chem. Soc., 127,* **1628 (1925).**

After several recrystallizations from chloroform and a final one from ether, a white crystalline solid was obtained, m. p. 124–126". Equal parts of this substance were mixed with dihydroxystearic acid, m. p. 127–128" (obtained from corn starch),[3] ground to a fine powder and the melting point determined (123–124").

Anal. Subs., 0.0619, 0.1072; CO_2, 0.1549, 0,2691; H_2O, 0.0608, 0.1074. Calcd. for dihydroxystearic acid, $C_{18}H_{36}O_4$: C, 68.29, H, 11.47. Found: C, 68.25, 68.44; H, 10.99, 11.21.

The silver salt was prepared9 and the molecular weight determined by igniting a weighed amount in a porcelain crucible and weighing the residue of metallic silver.

Anal. Subs., 0.0365: Ag, 0.0090. Calcd. for dihydroxystearic acid, $C_{18}H_{36}O_4$: mol. wt., 316.3. Found: 330.7.

The above results indicate the presence of oleic acid in the mixture of unsaturated fatty acids.

The residue of the chloroform extraction of the solid hydroxy acids was extracted with hot water and the solution allowed to cool slowly, silky white crystals coming out. These crystals were filtered off, recrystallized from water and dried, giving a melting point of 154–155°.

Anal. Subs., 0.1354, 0.1421: CO_2, 0.3084, 0.3245; H_2O, 0.1239, 0.1314. Calcd. for tetrahydroxystearic acid, $C_{18}H_{36}O_6$: C, 62.02; H, 10.42. Found: C, 62.12, 62.28; H, 10.24, 10.35.

These data indicate the presence of linolic acid in the mixture of unsaturated fatty acids.

The filtrate from the filtration of the insoluble hydroxy acids was now examined for higher hydroxy acids according to the method of Lewkowitsch[10] but the results were negative, thus indicating the absence of acids more unsaturated than linolic.

B. **Bromination.**—A sample of the unsaturated fatty acid mixture was brominated[11] and gave no ether-insoluble bromides, indicating the absence of acids more unsaturated than linolic, which substantiates the results as obtained by oxidation. After evaporation of the ether, the residue was recrystallized several times from petroleum ether, yielding white crystals, m. p. 113°.

Anal. (Carius). Subs., 0.1587, 0.1637; AgBr, 0.1984, 0.2050. Calcd. for tetrabromostearic acid, $C_{18}H_{32}O_2Br_4$: Br, 53.33. Found: Br, 53.18, 53.27.

These data are additional indication of the presence of linolic acid in the mixture of unsaturated fatty acids.

Examination for **Other** Substances,—The result of a sodium fusion on the mixed fatty acids showed the absence of nitrogen, sulfur and halogens. A fusion of another sample of the mixed fatty acids with a mixture of equal parts of sodium carbonate and sodium nitrate showed the absence of phosphorus.

During the alcoholic saponification of the mixed fatty acids necessary in the preparation of the magnesium soaps[3] no unsaponifiable matter was noticed. The Liebermann–Burchard[12] test for phytosterol was also

[12] Ref. 10, p. 270.

negative. The modified Kerr and Sorber[13] method for detecting phytosterol was applied but again the results were negative.

Thus the results given above show the presence of three fatty acids, that is, palmitic, oleic and linolic, and the probable absence of other substances in the fatty acid mixture obtained by extracting the solid material resulting from the hydrolysis of rice starch.

Determination of Iodine Numbers and Amounts of the Fatty Acids.—Having the qualitative data, the amounts of the fatty acids were estimated[3] from the determinations of the iodine numbers[3] of the mixed and unsaturated fatty acids portions.

THE ACETATE OF THE FREE ALDEHYDE FORM OF GLUCOSE

BY M. L. WOLFROM[1]

RECEIVED MARCH 12, 1929 PUBLISHED JULY 5, 1929

The formula of glucose is at present considered to be best represented by the closed chain or lactal type of structure. In the study of the reactivity of the sugars, there has frequently arisen a need for characterizing these compounds as open-chain hydroxy-aldehydes or ketones, capable of showing keto-enol tautomerism. This is particularly true in the study of their behavior in alkaline media, as exemplified by the work of Nef and his students, and by the work being conducted in this Laboratory by Evans and co-workers. Accordingly, we have attempted to isolate a crystalline derivative of the open-chain, free aldehyde form of glucose. We have succeeded in obtaining this as the acetate. This compound may be char-

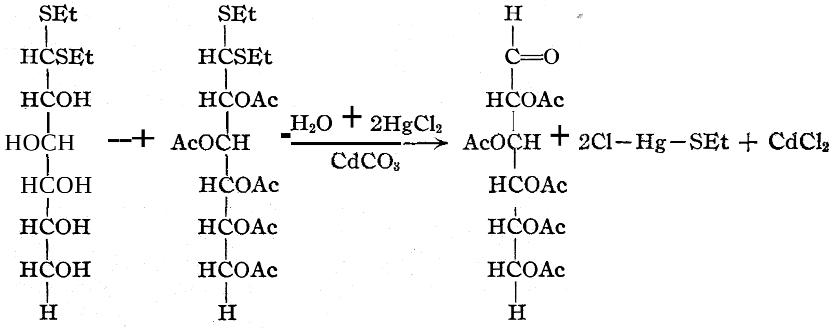
[1] National Research Fellow in Chemistry.

acterized as 2,3,4,5,6-penta-acetyl-*d*-glucose or, using the nomenclature proposed by T. M. Lowry[2] in considering the free aldehyde form as the intermediary in mutarotation, μ-*d*-glucose penta-acetate.

Emil Fischer[3] prepared the thio-acetal of glucose and of other aldoses. He showed that the thio-acetal groups could be removed with mercuric chloride and that the composition of the precipitate formed was Cl-Hg-S-Et. W. Schneider and J. Sepp[4] showed that under proper conditions one thio-acetal group could thus be removed, leaving the a-thio-glucoside. This procedure was improved by E. Pacsu.[5] Schneider and Sepp prepared the acetate of glucose-ethylmercaptal and unsuccessfully attempted to remove the thio-groups. We were unaware of this attempt at the time our experimental work was performed. P. A. Levene and G. M. Meyer[6] methylated glucose-diethylmercaptal and removed the thio-acetal groups with mercuric chloride, obtaining the 2,3,4,5,6-pentamethylglucose. They prepared its dimethyl acetal and extended the work to mannose and galactose.[7] Owing to the great difficulty of obtaining crystalline products in the methylated sugar series, all these compounds were obtained as distilled sirups.

By the employment of definite experimental conditions, we have succeeded in removing the thio-acetal groups from d-glucose-diethylmercaptal penta-acetate without de-acetylation. The steps involved are as follows



The resulting crystalline glucose penta-acetate differs in its characterizing constants from the two α-[8] and β-forms[9] known. It possesses a low optical rotation, as would be expected from its open-chain structure, and gives a definite Schiff aldehyde test. It dissolves in water on slight heating and

reacts with semicarbazide to form a crystalline glucose-semicarbazone penta-acetate.

The free aldehyde form of glucose may be considered one of the important tautomeric phases of this compound. It is perhaps the intermediary in mutarotation phenomena.[2] Certainly it is the form first involved in enolic transformations. H. Kiliani[10] has recently called attention to the unimportance of the position of the oxygen bridge in many of the most important reactions of glucose, the end result being the same regardless of the type of ring assumed. The lactal structure may be considered as a passive tautomeric phase, opening, when required, to form the more reactive free aldehyde phase. Thus, the lactal form may be a device of nature for more nicely regulating the reactivity of the aldose or ketose molecule. The so-called y-ring forms, which are best characterized in the sugar acetate series, are known to possess the property of ease of lactal rupture. Their sensitivity to reagents may then be due to the ease of formation of the open-chain forms, the latter being the true reactive phases.

Further work on this compound and the extension of the reactions to other sugars is in progress.

Experimental

Preparation of Glucose-ethylmercaptal Penta-acetate.—A procedure different from that of W. Schneider and J. Sepp[4b] was employed. Five g. of glucose-ethylmercaptal (m. p. 127°) was dissolved at room temperature in 18 cc. of dry pyridine. The solution was cooled in ice and 36 cc. of acetic anhydride added gradually. A considerable amount of solid was thrown out of solution in a fine state of subdivision. It was kept at 0° with occasional shaking until the solid had redissolved, about ten minutes being required. The solution was allowed to stand overnight and was then gradually poured into a liter of ice water, with stirring. A sirup was formed which crystallized after standing in the ice box for about ten days. This was filtered and washed with cold water, 8.1 g. of product being obtained. This was recrystallized by dissolving in methyl alcohol, adding water to opalescence, nucleating and allowing to stand in the ice box. A sirupy phase was first formed which gradually crystallized in very good condition. Further portions of cold water were then added, a 97% recrystallization yield of pure product being possible.

After one recrystallization, the substance melted at 45–47° and showed $[\alpha]_D^{30} = +11.4°$ (0.4050 g. subs, 10.07 cc. of chloroform soln., $\alpha_D = +0.46°$, 1-dm. tube) in chloroform solution. After four recrystallizations, the m. p. was 45–47' and the rotation in chloroform solution was $[\alpha]_D^{29} = +11.2°$ (1.255 g. subs., 24.88 cc. of chloroform soln., $\alpha = +1.13°$, 2-dm. tube). A rotation in acetylene tetrachloride gave the value $[\alpha]_D^{28} = +17.4°$ (1.250 g. subs., 24.88 cc. of acetylene tetrachloride soln., a $= +1.75°$, 2-dm. tube). W. Schneider and J. Sepp[4b] give the melting point as 42–45° and $[\alpha]_D^{20} = +17.7°$ in acetylene tetrachloride.

2,3,4,5,6-Penta-acetyl-*d*-glucose.—An amount of glucose-ethylmercaptal penta-acetate (m. p. 45–47°) equal to 25.2 g. (1 mol.) was dissolved in 90 cc. of acetone and 45 cc. of water added. The clear solution was held in a 3-necked, round-bottomed flask provided with a reflux condenser and a mercury-sealed mechanical stirrer. An

---

[10] H. Kiliani, *Z. angew. Chem.*, 42, 16 (1929).

excess, 45–50 g., of washed cadmium carbonate was added and under rapid stirring a solution of 49.5 g. (3.6 mols.) of mercuric chloride dissolved in 72 cc. of acetone was gradually added. Stirring was maintained at room temperature for twenty-four hours, with occasional additions of small amounts of fresh cadmium carbonate. At the end of this period the reaction flask was encased in a water-bath, and this rapidly heated to 50° and held at this temperature fifteen minutes, very vigorous mechanical stirring being maintained. The bath was then rapidly heated until refluxing began and the solution was refluxed gently for fifteen minutes. The solution was then filtered from the excess cadmium carbonate and CI-Hg-S-Et precipitate, an excess of fresh cadmium carbonate being placed in the suction flask, and the precipitate washed with acetone. The filtrate was then concentrated to dryness at 30–35° under reduced pressure and in the presence of excess cadmium carbonate. The residue was dried by repeatedly adding acetone and distilling under reduced pressure. The residue was extracted with warm chloroform, filtered, and the chloroform evaporated at room temperature in a vacuum desiccator. The crude product crystallized during the course of this evaporation. This was dissolved in 50 cc. of hot acetone, 25 cc. of alcohol-free ether added and then petroleum ether (40–60°) to opalescence. The substance crystallized out in plates. After standing for several hours in the ice box, the material was filtered, washed with a cold mixture of the same composition as the mother liquor and finally with petroleum ether. The amount of the product was 10.1 g., m. p. 116.5°. A further crop of 1.9 g. was obtained from the filtrate by the addition of more petroleum ether.

After one recrystallization the product melted at 116.5" and gave the value $[\alpha]^{25}_{\mathrm{D}} = +3.3°$ (1.244 g. subs., 24.88 cc. of acetylene tetrachloride soln., a $= +0.33°$, 2-dm. tube) in acetylene tetrachloride. After three recrystallizations performed in the same general way, the melting point was 119.5–120.5° and the polarization value in the same solvent was $[\alpha]^{26}_{\mathrm{D}} = +2.6°$ (0.4985 g. subs., 10.08 cc. of acetylene tetrachloride soln., a: $= +0.14°$, 1.1-dm. tube). After five recrystallizations the melting point was 116–118° and the polarization value in the same solvent was $[\alpha]^{25}_{\mathrm{D}} = +2.7°$ (0.5028 g. subs., 10.05 cc. of acetylene tetrachloride soln., $\alpha = +0.15°$, 1.1-dm. tube). A mixed melting point with pure 8-glucose penta-acetate (m. p. 131°, $[\alpha]^{25}_{\mathrm{D}} = +4.2°$, $CHCl_3$) gave the value 106–109°. In chloroform (U.S.P.) solution the values $[\alpha]^{24}_{\mathrm{D}} = -4.6'$ ($c = 4.997$) and $[\alpha]^{24}_{\mathrm{D}} = -4.8'$ ($c = 4.725$) were obtained. This value changed slowly to dextro, due probably to acetal formation with the ethyl alcohol present in the U.S.P. chloroform. In methyl alcohol the initial rotation was $[\alpha]^{25}_{\mathrm{D}} = +10°$ (c $= 4.980$; $c = 2.013$), changing slowly in the dextro direction. a-Glucose penta-acetate shows the melting point 113° and $[\alpha]^{20}_{\mathrm{D}} = +101.6°$ ($CHCl_3$), while 8-glucose penta-acetate possesses the melting point 132" and $[\alpha]^{20}_{\mathrm{D}} = +3.8°$ ($CHCl_3$).[11]

Anal. Subs., 0.2183: CO_2, 0.3947; H_2O, 0.1124. Subs., 0.2039: CO_2, 0.3697; H_2O, 0.1092. Subs., 0.0993: 12.7 cc. of 0.1 *N* KOH. Calcd. for $C_6H_7O_6(CH_3CO)_5$: C, 49.20; H, 5.69; cc. 0.1 *N* KOH, 12.7. Found: C, 49.31; H, 5.76; C, 49.45; H, 5.99; S, absent.

I am indebted to Professor W. J. McCaughey of the Department of Mineralogy of this University for the following crystallographic description of the compound.

"Crystal, monoclinic, tabular in direction parallel to side (clino) pinacoid. On the flat tabular face emerges an acute bisectrix; the optic angle is small, probably around 40°. On the clinopinacoid, the index of refraction of beta (β) and gamma (y) can be measured. Sometimes when crystalliza-

---

[11] C. S. Hudson, *Scientific* Papers of *the Bureau* of Standards, No. 533, 379 (1926).

tion takes place from dilute solution, the crystals separate in elongated forms showing parallel extinction and negative elongation (elongation || to (a) alpha). With this orientation alpha (a) can be measured. The optical sign of the crystal is negative; the indices are a = 1.460, β = 1.500–, γ = 1.515.

"The vibration direction of beta (β) is inclined to what is taken to be crystallographic axis c by 1–2°. The vibration direction alpha is parallel to crystallographic axis $\bar{b}$. The crystal faces present are basal pinacoid, clinopinacoid, orthopinacoid and an orthodome. When the crystal habit shows growth in the direction of crystallographic axis $\bar{b}$ it appears as square prisms. When the crystal is tabular in the direction of $\bar{b}$ it shows hexagonal outline but the adjacent angles are not 120° as in a truly hexagonal crystal.

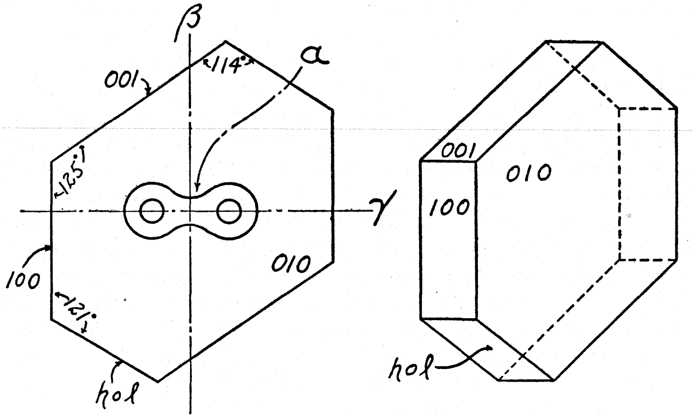

Fig. 1.—Crystalline form of μ-*d*-glucose penta-acetate, tabular habit.

The face having the hexagonal outline is the side or clinopinacoid. The size of the crystals was 0.2 mm.

"p-Glucose penta-acetate consists of needles showing parallel extinction and negative elongation. Indices: low = 1.47; high < 1.50."

The crystals of the new penta-acetate are very soluble in chloroform, soluble in acetone, alcohol and warm water, moderately so in ether and benzene and practically insoluble in petroleum ether (40–60°). The substance gave a positive fuchsin or Schiff aldehyde reaction. The fuchsin solution available gave a negative reaction with vanillin. With benzaldehyde a faint coloration was obtained at one minute and a distinct coloration at one and a half minutes. On dissolving 50–70 mg. of the acetate in about 0.5 cc. of warm acetone, cooling to room temperature, and adding 2.5 cc. of the reagent, a faint coloration was obtained at one and one-half to two minutes, becoming very distinct at five minutes. A blank on the acetone used gave negative results.

d-Glucose-semicarbazone Penta-acetate.—Four and one-half g. (1 mol.) of pure μ-glucose penta-acetate was dissolved in 45 cc. of warm water, cooled to room temperature, and a mixture of 1.1 g. of semicarbazide hydrochloride (0.9 mol.) and 1.8 g. of potassium acetate (1.6 mols) was added in the solid form. In a few minutes the solution became cloudy and an oil was gradually deposited. On standing overnight at room temperature this solidified. This was filtered and washed with cold water, 3.6 g. being obtained. The material was dissolved in methyl alcohol, treated with decolorizing carbon, filtered and water added. On standing at ice-box temperature 1.4 g. of crystals (m. p. 148–150°) in the form of minute elongated prisms was deposited. These were removed by filtration, washed with water and a further crop of 1 3 g (m. p. 148–150°) obtained from the filtrate by further addition of water. On two further recrystallizations the substance melted at 150–151° and on two more (5) melted at 150°.

Anal. Subs , 0.2055: N_2, 18.83 cc. (751.5 mm., 28°). Calcd. for $C_7H_{10}O_6N_3$-$(CH_3CO)_5$: N, 9.40. Found: N, 9.87. Calcd. for 0.2019: 22.6 cc. 0.1 *N* KOH. Found: 22.7 cc. Calcd. for 0.2074: 23.2 cc. 0.1 N KOH: Found: 23.1 cc.

The writer wishes to acknowledge his indebtedness to Professor W. L. Evans for his inspirational counsel and advice.

Summary

1. A new form of d-glucose penta-acetate has been prepared in pure condition.

2. Evidence is given that this compound possesses the open-chain, free aldehyde structure and the suggestion is made that the name μ-*d*-glucose penta-acetate be applied to the substance.

3. The crystalline semicarbazone of this aldehyde has been prepared in pure form.

PREPARATION OF SOME METHYLATED GALLIC ACIDS

BY R. L. SHRINER AND P. MCCUTCHAN

RECEIVED MARCH 13, 1929 PUBLISHED JULY 5, 1929

During the course of a study of some anthocyan pigments it was desired to have samples of certain methylated gallic acids, since these are produced by degradation of the anthocyanidin. The compounds desired were: 3,5-dimethylgallic acid, 3,4-dimethylgallic acid and 3-methylgallic acid. The first of these, syringic acid, is easily prepared by the method of Bogert and Ehrlich,[1] and its properties and derivatives[2] have been thoroughly studied. However, the data available in the literature on the other two methylgallic acids are very meager. The 3,4-dimethylgallic acid has been previously prepared by Zincke and Francke[3] and Her-

Bogert and Ehrlich, THIS JOURNAL, 41,798 (1919).

[2] Bogert and Coyne, *ibid.*, 51, 569 (1929).

[3] Zincke and Francke, *Ann.*, 293, 191 (1896).

zig and Pollak,[4] and 3-methylgallic acid by Vogl.[5] Since the methods used in the present work for the preparation of these last two compounds differed from those previously used and since the properties of the compounds obtained do not agree with those recorded in the literature, it was thought that a brief report of their preparation would be of interest.

Vanillin was the starting material for the preparation of both of these compounds. The 3,4-dimethylgallic acid was obtained as a result of the following series of preparations: Vanillin ⟶ 5-bromovanillin ⟶ 5-bromo-3,4-dimethoxybenzaldehyde ⟶ 5-bromo-3,4-dimethoxybenzoic acid ⟶ 3,4-dimethylgallic acid. The product crystallized from alcohol in long white needles and melted at 184–185°. Zincke and Francke[3] gave no melting point at all, while Herzog and Pollak[4] reported 189–192°. It was free from bromine and gave only a light yellow color with ferric chloride, which indicates the absence of gallic acid and 3-methylgallic acid which might be produced by the action of the alkali in the last step.

The 3-methylgallic acid was prepared from 5-bromovanillin by heating the latter with alkali and copper powder. After careful purification the 3-methylgallic acid was obtained in the form of needles which melted constantly at 131–132°. The previously reported value[8] was 199–200°. Dilute ferric chloride produced a light green color quite distinct from the blue produced by gallic acid itself.

Experimental

5-Bromovanillin.—A solution of 105 g. of bromine in 200 cc. of glacial acetic acid was added to 100 g. of vanillin dissolved in 200 cc. of glacial acetic acid. The bromovanillin separated at once. It was filtered off and recrystallized from 95% alcohol. Colorless cubic crystals which soon turned yellow on standing were obtained; yield, 118 g. or 77.6% of the theoretical. It melted sharply at 163–164°, which agrees with the melting point recorded by Dakin.[6]

5-Bromo-3,4-dimethoxybenzaldehyde.—A solution of 10.5 g. of 5-bromovanillin in 75 cc. of 2.5% sodium hydroxide solution was stirred vigorously and 10 cc. of dimethyl sulfate added. As soon as the solution became acid to litmus another 10 cc. of dimethyl sulfate was added with sufficient alkali to render the solution alkaline. In this manner four more successive portions of dimethyl sulfate were added, keeping the temperature between 45 and 50°. After the addition of the last portion the solution was boiled for two hours and then cooled. The methylated bromovanillin was filtered off and recrystallized from 80% alcohol. Nine g. (80% of the theoretical) of white flocculent crystals was obtained melting at 61–62°. This agrees with the value reported by Jones and Robinson.[7]

5-Bromo-3,4-dimethoxybenzoic acid.—A hot solution of 22 g. of potassium permanganate in 500 cc. of water was added with vigorous stirring to a boiling mixture of 30 g. of 5-bromo-3,4-dimethoxybenzaldehyde and 300 cc. of water containing 35 g. of potassium carbonate. After refluxing for one hour the solution was cooled and filtered.

[6] Dakin, *Am. Chem. J.*, 42, 493 (1909).

[7] Jones and Robinson, *J. Chem. Soc.*, 111, 922 (1917).

The filtrate was acidified, the white precipitate filtered and recrystallized from hot water, yield, 30 g. of white crystals, m. p. 190–192°, which agrees with the melting point reported by Dakin.[6]

3,4-Dimethylgallic acid.—Ten g. of 5-bromo-3,4-dimethoxybenzoic acid, 200 cc. of 8% sodium hydroxide and 2 g. of copper powder were placed in an iron pipe fitted with lead-seated screw caps. The bomb was heated to 200° for one hour. After cooling the contents were acidified with dilute sulfuric acid and extracted with four 100-cc. portions of ether. The ether was distilled and the residue recrystallized from alcohol. Long colorless needles were obtained melting at 184–185°. Recrystallization from hot water or alcohol did not change the melting point. It gave a very light yellow color with ferric chloride; yield, 1.5 g. (20% of the theoretical).

Anal. Subs, 0.1118: CO_2, 0 2228; H_2O, 0 0520. Calcd, for $C_9H_{10}O_5$: C, 54.52. H, 5.09. Found: C, 54.45; H, 5 20.

The acetyl derivative was prepared by acetylation with acetic anhydride and a drop of perchloric acid according to the general method of Conant and Hall[8] The acetate was crystallized from alcohol. Needles melting at 137–138° were obtained

Anal. Subs., 0.0702: CO_2, 0.1415; H_2O, 0.0325. Calcd. for $C_{11}H_{12}O_6$: C, 55.00; H, 5.01. Found: C, 54.98; H, 5.18.

3-Methylgallic Acid.—The simultaneous removal of bromine and oxidation of the aldehyde group of 5-bromovanillin was accomplished by heating 5 g. of the latter with 100 cc. of 8% aqueous sodium hydroxide and 2 g. of copper powder at 200–210° for one hour. The reaction mixture was cooled, acidified with dilute sulfuric acid and extracted with ether. The ether was distilled and the residue treated with sodium bicarbonate solution. The insoluble material, consisting of unreacted 5-bromovanillin and some condensation products, was filtered and the filtrate acidified. The material which separated was recrystallized several times from benzene and melted sharply at 131–132"; yield, 1.0 g. Ferric chloride gives a light green coloration. It was acetylated by the method used above and the diacetate obtained after crystallization from benzene in the form of colorless plates melting at 102–103°.

Anal. Subs., 0.1621: CO_2, 0 3180; H_2O, 0 0654 Calcd. for $C_{12}H_{12}O_7$: C, 53.71; H, 4.52. Found: C, 53.50; H, 4.48.

Summary

The preparation and properties of 3,4-dimethylgallic acid and 3-methylgallic acid are described.

MERCURATION IN ALKALINE SOLUTION. PRELIMINARY PAPER

By A. L. Fox with Frank C. Whitmore

Received March 15, 1929 Published July 5, 1929

Mercuration is ordinarily carried out by means of mercuric acetate in a solution acidified with acetic acid. When 2,3-hydroxynaphthoic acid was mercurated in this way, the mixture was tested with sodium hydroxide to detect any unreacted inorganic mercury. It was found that rapid addition of sodium hydroxide gave a precipitate of mercuric oxide but that slow addition did not do so. After some study it was found that the addition of the base was increasing the speed of mercuration. It was finally found that 2,3-hydroxynaphthoic acid could be mercurated in strongly alkaline solution. This method of mercuration was applied successfully to salicylic acid and to phenol. It failed when applied to *m*-hydroxybenzoic acid, p-hydroxybenzoic acid, a-naphthol, o-nitrophenol, aniline, anthranilic acid, sulfanilic acid, benzenesulfonic acid, 1-naphthoic acid and phthalic acid. It should be noted that traces of mercuration products may have been formed but none could be isolated using the same technique which gave good yields with 2,3-hydroxynaphthoic acid, salicylic acid and phenol.

The mercuration product obtained by this method from phenol corresponded to an anhydro-hydroxymercuriphenol.

Experimental Part

Mercuration of **2,3-Hydroxynaphthoic** Acid in Alkaline Solution.—A solution of 30 g. (0.16 mole) of the acid in 500 cc. of water and 150 cc. (0.9 mole) of 6 N sodium hydroxide was heated to boiling and stirred during the gradual addition of 52 g. (0.16 mole) of mercuric acetate dissolved in 300 cc. of water and 10 cc. (0.15 mole) of acetic acid. As the mercuric acetate solution was added a momentary precipitate of mercuric oxide formed. The mixture was boiled for a few minutes, treated with decolorizing carbon, filtered and treated with a slight excess of sodium chloride and slightly less than enough dilute hydrochloric acid to make the mixture acid. The precipitate was dried. It formed a yellow powder which was probably anhydro-4-hydroxymercuri-3-hydroxy-2-naphthoic acid.

Anal. Calcd. for $C_{11}H_6O_3Hg$: Hg, 51.9. Found: 51.8, 51.4.

The mercuration was repeated with cold dilute solutions with similar results.

Mercuration of Salicylic **Acid.**—This mercuration was carried out in an exactly similar way. From 15 g. of salicylic acid was obtained 27 g. of hydroxymercurisalicylic acid.

Anal. Calcd. for $C_7H_6O_4Hg$: Hg, 56.6. Found: 57.0, 56.8.

Mercuration of **Phenol.**—This process was similar to the other two, 100 g. of phenol yielding 215 g. of anhydro-hydroxymercuriphenol.

Anal. Calcd. for C_6H_4OHg: Hg, 68.6. Found: 68.9.

A similar mercuration of phenol using mercuric chloride instead of the acetate gave the same product

Unsuccessful Attempts at Mercuration in Alkaline Solution. **α-Naphthol** was oxidized immediately by this procedure. Similar results were obtained with aniline.

o-Nitrophenol.—On adding mercuric acetate solution to a boiling alkaline solution of o-nitrophenol a permanent precipitate of mercuric oxide formed. The experiment was discontinued. Similar results were obtained with anthranilic acid, sulfanilic acid, benzenesulfonic acid, 1-naphthoic acid and phthalic acid.

Summary

It has been found that certain organic compounds can be mercurated in alkaline solution while other compounds of very similar structure cannot.

THE MOLECULAR STRUCTURE OF INULIN. ISOLATION OF A NEW ANHYDROFRUCTOSE

BY JAMES COLQUHOUN IRVINE AND JOHN WHITEFORD STEVENSON

RECEIVED MARCH 16, 1929 PUBLISHED JULY 5, 1929

The first researches designed to investigate the molecular structure of inulin with the precision rendered possible by the methylation method were carried out by Irvine and Steele.[1] These authors showed that the polysaccharide although converted by hydrolysis into the normal levorotatory form of fructose is actually based on the unstable dextrorotatory variety of the hexose known as γ-fructose. The research was subsequently extended[2] to include a more detailed examination of dimethyl- and trimethylinulin, together with the dimethyl- and trimethylfructoses obtained, respectively, from these derivatives by hydrolysis.

The collective evidence, although complicated by a number of minor irregularities such as the tendency of trimethylinulin to undergo depolymerization from a levorotatory powder to a dextrorotatory sirup, pointed to the idea that the molecule of inulin is symmetrical in the sense that all of the fructose residues belong to the γ-type and that in each fructose residue three hydroxyl groups occupy the same positions. This view was based on the fact that on hydrolysis trimethylinulin gave a homogeneous trimethyl-7-fructose, and all subsequent speculations on the structure of inulin have been founded on this observation. In the course of the past five years we have, however, accumulated much incidental evidence that the inulin problem is not so simple as at one time appeared, and we have accordingly continued our investigations; in the meantime Haworth has published what is, in effect, a repetition of our earlier work,

[1] Irvine and Steele, J. Chem. *Soc.*, 117, 1474 (1920).

[2] Irvine, Steele and Shannon, *ibid.*, 121, 1060 (1922).

contributing, however, the new observation that our trimethyl-7-fructose is capable of yielding a phenylosazone.[3] Lest the idea should prevail that the molecular structure of inulin is now fully solved, it is advisable to contribute some results which show that such is not the case.

The first indication that the molecular unit of inulin is not homogeneous is found in the results of Irvine and Steele. The sequence of reactions

$$\text{Inulin} \longrightarrow \text{Trimethylinulin} \longrightarrow \text{Trimethyl-}\gamma\text{-fructose}$$

proceeded smoothly, giving good yields at each stage, but the yield of sugar, relative to the weight of trimethylinulin from which it is formed, was invariably of the order of 80%. The loss of 20% is accounted for by the fact that in the purification of the sugar by distillation a small first fraction, consisting of a mobile sirup, was collected. This constituent is now being examined in detail and we have traced its origin to the existence in inulin of at least one component yielding an anhydro-fructose of an unknown type. The new anhydro-sugar can be prepared from inulin in various ways, all of which emphasize its stability. For example, when triacetylinulin is dissolved in chloroform containing fuming nitric acid, the anhydro-ring of most of the fructose residues is opened and from its properties the essential product appears to be a triacetylfructose dinitrate. The reaction is therefore analogous with that studied by Oldham,[4] who converted triacetylglucosan into triacetylglucose-1,6-dinitrate by similar processes. On treating the crude triacetylfructose dinitrate with methyl alcohol, conversion into triacetylmethylfructoside mononitrate took place and a crop of crystals separated which amounted to approximately 20% by weight of the triacetylinulin initially taken. The product, which crystallized in needles melting at 123° and showed $[\alpha]_D + 1.5°$ in chloroform, was a triacetylanhydrofructose. As was to be expected, this acetate of anhydrofructose is devoid of action upon Fehling's solution but, unexpectedly, the anhydro-ring proved to be unusually stable, being opened only by prolonged heating with acids.

On removing the acetyl groups by the action of dimethylamine, the parent anhydrofructose separated in spheroidal crystals melting at 143–145° and showing $[\alpha]_D + 30.17°$ in water. It is significant that although the new anhydro-sugar can be hydrolyzed to give normal fructose in almost quantitative amount, it is much more stable than the known derivatives of γ-fructose. For example, although heating with $N/100$ hydrochloric acid effects the rapid hydrolysis of sucrose and likewise converts about 80% of inulin into fructose, the same reagent has little effect in opening the anhydro-ring of the particular form of anhydrofructose now under consideration. The importance of this observation will be referred to later.

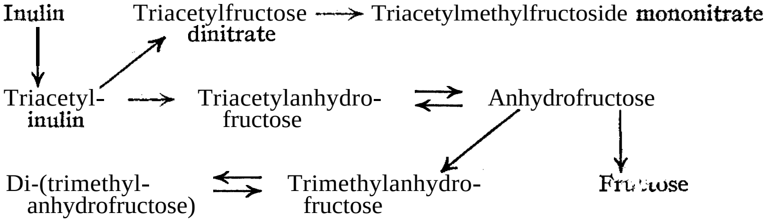
In order to gain an insight into the structure of the anhydrofructose, the compound was subjected to the methylation process, it being found necessary to supplement the methyl sulfate reaction by treatment with silver oxide and methyl iodide. The product proved to be a di-(trimethylanhydrofructose) showing that either the methylation, or more probably the vacuum distillation necessary to isolate the compound, had occasioned polymerization. This is not an abnormal experience in the case of methylated fructoses and, as is usual with polymers of low molecular weight in the inulin series, the rotation was dextrorotatory ($[\alpha]_D + 23.8°$). By employing the general method of diminishing polymerization by heating with methyl alcohol containing hydrogen chloride, the above dimeride was converted into the monomeric form of trimethylanhydrofructose, the structural study of which is now in progress.

The scheme of reactions involved in the research is represented below.



Discussion

In the particular method of preparing the anhydro-fructose now described, the possibility must not be overlooked that the use of a powerful reagent such as nitric acid may cause intramolecular changes in triacetylinulin, thereby forming triacetyl-anhydrofructose as an adventitious product. This possibility is ruled out as, when triacetylinulin is hydrolyzed by acetic acid containing 0.03% of sulfuric acid, the same triacetyl-anhydrofructose can be isolated from the products. Moreover, when inulin is subjected to graded acetolysis by Barnett's method,[5] 18% of the polysaccharide fails to pass into solution and triacetyl-anhydrofructose is obtained from this stable fraction. The accumulated evidence[6] is thus in favor of the idea that inulin is not homogeneous but consists of at least two main components one of which is easily hydrolyzed while the other is relatively resistant to hydrolytic agents. These components fall into two classes present in the approximate ratio of 4:1 and for the time being, it is not safe to claim that more than 80% of the inulin aggregate is based on y-fructose. It is possible that the remainder may also be derived from y-fructose but in such an event the anhydro-ring must occupy a more stable position than in the major component of the polysaccharide; alternatively,

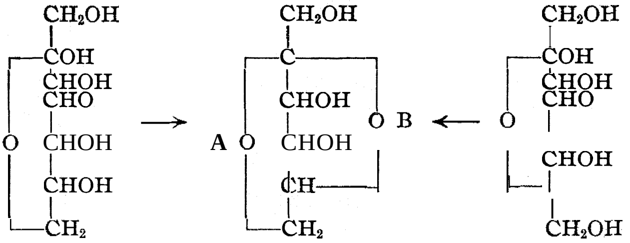
this constituent may be related to normal fructose or to an isomeric form of the ketose hitherto unknown.

It will at once be evident that a serious complication is introduced into the constitutional study of inulin, as the lack of homogeneity now revealed may be due to several causes. For example, inulin may be a polymeride of individual anhydrofructoses differing from each other, or it may be a polymeride of condensed fructose residues in which the structure of some of the C_6 units differs from that of others. This does not exhaust the possibilities, but until our structural examination of triacetyl-anhydrofructose is complete it is premature to develop the situation further or to utilize constitutional formulas in illustration. Obviously the solution of the inulin problem now demands a critical study of the relative stability of oxygen rings in the fructose series and also of methods whereby anhydro-sugars can be referred to their parent type. Thus, the anhydrofructose now under discussion might originate in either normal fructose or in γ-fructose and, in turn, the anhydro-ring may occupy the butylene-oxide or the amylene-oxide position. This is shown below.



Two oxygen-rings (A and B) are present in the anhydride and it is impossible to designate one as the anhydro-ring and the other as the oxygen-ring characteristic of the sugar. Nor is it always possible to identify which ring is opened during hydrolysis and which one is unaffected. Research on this problem is well advanced and the results will be applied in a further discussion on the structure of inulin to be communicated later.

Experimental

Action of Nitric Acid on **Triacetylinulin.**—The inulin employed was obtained from four different sources but no variation was found either in the composition or in the yields of the various products. Pringsheim's method was used for the preparation of inulin triacetate, the crude product being purified by dissolving in hot alcohol and pouring the solution into a large excess of water; all the specimens employed in the subsequent experiments were analyzed and conformed to the following standard: m. p. 97"; $[\alpha]_D = -33.9$" in chloroform and $-37.1°$ in glacial acetic acid (c = 2.6 in each case).

Numerous preliminary trials were necessary in order to ascertain the best conditions under which triacetylinulin is acted on by nitric acid. Using chloroform as the solvent, the addition of nitric acid up to 20% caused an alteration in the rotation from levo to dextro, but the product nevertheless consisted chiefly of unchanged triacetylinulin.

When the acid concentration was raised in successive experiments to 70% the dextrorotation of the liquid increased to the maximum, +48.8°, but the yield of product was then seriously diminished. Ultimately, a 30% solution of nitric acid in chloroform was selected as the most suitable reagent and the course of the reaction was followed polarimetrically, the results showing that the action was complete in thirty minutes, when the rotation had attained the value $[\alpha]_D$ +34°.

Triacetyl-anhydrofructose.—The conditions established above were used as the basis of the preparation of triacetyl-anhydrofructose but it was found advisable to carry out the preparation in successive experiments with small quantities of material. Five grams of well-dried triacetylinulin was dissolved in 70 cc. of chloroform and 30 cc. of fuming nitric acid (sp. gr., 1.55) added. The flask was stoppered and cooled, as heat is developed in the course of the reaction, and, from time to time, phosphorus pentoxide was added to remove traces of water. After thirty minutes the clear solution was poured into a separating funnel containing 200 cc. of water mixed with ice and shaken until all coloring matter had passed into the aqueous layer, the chloroform being then run off and dried over anhydrous sodium sulfate. A small quantity of barium carbonate was added to the filtered liquid, after which the solvent was distilled, fresh chloroform added, the solution again filtered and taken to dryness, the process being completed at 100° under diminished pressure. In this way 4.5 g. of a mobile sirup was obtained showing $[\alpha]_D$ +22° in chloroform for $c = 2.28$. As explained in the introduction, analysis showed this material to be a mixture consisting essentially of triacetylfructose dinitrate and triacetyl-anhydrofructose, the former constituent being convertible into the corresponding triacetylmethylfructoside mononitrate by boiling a 10% solution in methyl alcohol in the presence of barium carbonate.

When the sirup was dissolved in hot absolute alcohol the solution slowly deposited crystals, the weight of which was remarkably uniform in different experiments and amounted to 20% of the sirup taken. After recrystallization from absolute alcohol and drying at 100°, a pure product was obtained, but, considering the origin of the material, it was desirable to carry out a careful analytical survey. Nitrogen and ethoxyl were absent, no double bond was present, and the action of Fehling's solution was negative until after drastic hydrolysis. Analysis showed that the crystals contained half a molecule of combined acetic acid.

Anal. Calcd. for $C_{13}H_{18}O_9$: C, 49.05; H, 5.66; CH_3CO, 47.3. Found: C, 49.15, 48.99; H, 5.86, 5.90; CH_3CO, 46.1.

Difficulty was experienced in confirming the molecular weight. Using the cryoscopic method and employing benzene as a solvent, the mean of four experiments was 438, a value which indicates molecular association. In glacial acetic acid the freezing point depressions were irregular, but the molecular weight averaged 299, thus corresponding with a monomolecular form (calcd. for $C_{12}H_{16}O_8$, 288; for $C_{13}H_{18}O_9$, 318). Triacetylanhydrofructose crystallizes from alcohol in needles melting at 123". The compound, which is readily soluble in organic solvents generally and in hot water, is practically inactive, $[\alpha]_D$ +1.5" in chloroform for $c = 2.272$.

Anhydrofructose.—This preparation was likewise carried out in a succession of small-scale experiments. Five grams of triacetyl-anhydrofructose was added to 25 cc. of dry methyl alcohol containing 5% of dimethylamine. On shaking in the cold for twenty minutes the material passed into solution and the solvent was thereafter removed under diminished pressure, the residue being dried by raising the temperature slowly to 100°. The product consisted of a clear deliquescent glass weighing 2.6 g. and on dissolving in absolute alcohol and adding a few drops of dry ether a crystalline precipitate separated which was washed with ether–alcohol and finally with ether.

The anhydrofructose thus obtained forms transparent spheroidal crystals melting at 143–145°, is highly hygroscopic and fails to reduce Fehling's solution. In water, for $c = 2.32$, $[\alpha]_D = +30.17°$, but it is difficult to guarantee these constants in view of the hygroscopic character of the compound and in consideration of the fact that analysis disclosed the presence of a trace of acetyl.

Anal. Calcd. for $C_6H_{10}O_5$: C, 44.44; H, 6.17; CH_3CO, nil; mol. wt., 162. Found: C, 44.49; H, 6.28; CH_3CO, 1.0; mol. wt. by the freezing-point method in water, 162.

The properties of anhydrofructose are simple. When acetylated under standard conditions it is reconverted almost quantitatively into the original triacetyl-anhydrofructose melting at 123° and showing $[\alpha]_D$ +1.5° in chloroform. The opening of the anhydro-ring of anhydrofructose was effected by heating at 100° a 2.5% solution of the substance in water containing 3% of oxalic acid, a polarimetric record of the reaction showing that the initial specific rotation of +25.7° altered regularly to the constant value −87.7°, so that the figures plotted on a smooth curve. This corresponds to a nearly quantitative conversion into normal fructose and, on working up the product in the usual manner, the sugar crystallized and was thereafter converted into glucose phenylosazone showing the correct constants.

Methylation of Anhydrofructose.—A preliminary methylation, carried out by means of methyl sulfate and sodium hydroxide, gave a partly alkylated product which was extracted with boiling alcohol and recovered. After three subsequent methylations with the same reagents, but using chloroform as the extracting agent, a quantitative yield of a transparent fairly mobile sirup was obtained which, when distilled at 206° (0.35 mm.) showed $n_D = 1.4731$ and gave a methoxyl content of 43.2%. The methylation was accordingly completed by dissolving the sirup in excess of methyl iodide and boiling with dry silver oxide, the extracting agent in this case being ether. The product, isolated in the customary manner, boiled at 166° (0.1 mm.); examination showed that the refractive index remained at 1.4730 but the methoxyl content had increased to the theoretical value.

Anal. Calcd. for $C_9H_{16}O_5$: C, 52.94; H, 7.84; OCH_3, 45.58. Found: C, 52.74; H, 8.14; OCH_3, 45.68.

When again distilled and collected in two equal fractions, the same constants and analytical composition were duplicated, so that the material was a homogeneous pure specimen of trimethylanhydrofructose. The specific rotation in chloroform for c = 2.5 was +23.8°. In view of the high boiling point, the value of the refractive index and the viscosity of the sirup, the compound had evidently undergone polymerization to some extent and, in an attempt to effect depolymerization, a solution was prepared in dry methyl alcohol containing 0.5% of dry hydrogen chloride and heated at the boiling point of the solvent. The specific rotation, initially +33.5°, increased steadily to the constant value +48.7°, which was attained in 150 minutes. After neutralizing with barium carbonate and isolating the product in the usual manner, a low-boiling mobile fraction was obtained which still retained the composition of a trimethyl-anhydrofructose, but the refractive index had altered to 1.4610, a value which corresponds to a monomeric form. Nevertheless, the depolymerization was incomplete, as higher-boiling fractions identical with the original material were also collected. These results show that the action of acid methyl alcohol had effected depolymerization but that, as is frequently the case in the methylated fructose series, molecular association was induced by distillation.

The authors desire to express acknowledgment to the Carnegie Trust for the Universities of Scotland for a Research Scholarship awarded to one of them.

Summary

1. When triacetylinulin is dissolved in chloroform and acted on by nitric acid the greater part of the material is converted into triacetylfructose dinitrate, the esterification being preceded by the opening of the anhydro-linkages.

2. One component of triacetylinulin present to the extent of 20% is resistant to the hydrolytic action and is isolated as triacetyl-anhydrofructose (m. p. 123°; $[\alpha]_D + 1.5°$ in chloroform). The same compound can be obtained in similar yield from other reactions in which triacetylinulin is used as the starting material.

3. Anhydrofructose (m. p. 143–145°; $[\alpha]_D + 30.17°$ in water) has been prepared from the triacetate by the action of dimethylamine. The compound is quantitatively convertible into fructose but is much more stable toward hydrolysts than the known derivatives of γ-fructose.

4. Anhydrofructose has been converted into trimethyl-anhydrofructose, which was isolated in a dimeric form.

5. The main conclusion drawn is that inulin is not related exclusively to a single form of γ-fructose but contains two classes of components in the approximate ratio of 4:1. Of these, one is relatively much more stable toward hydrolysis. The additional complication introduced into the constitutional study of inulin through these results is discussed.

THE VAPOR PHASE OXIDATION OF ISOMERIC OCTANES. II. OCTANES WITH BRANCHED CHAINS

BY J. C. POPE, F. J. DYKSTRA AND GRAHAM EDGAR

RECEIVED MARCH 16, 1929 PUBLISHED JULY 5, 1929

I. Introduction

In Part I of this paper[1] data were presented on the vapor phase oxidation of n-octane, which indicated that under the conditions in question the oxidation proceeds almost entirely according to certain simple reactions. These reactions are: (1) the formation of octaldehyde; (2) the oxidation of octaldehyde to carbon monoxide, water and aldehydes of successively smaller number of carbon atoms; and (3) a side reaction in which octaldehyde is oxidized to carbon dioxide, water and aldehydes of successively smaller number of carbon atoms.

In Part II data are presented on the vapor phase oxidation of five isomeric octanes, 3-methylheptane, 3-ethylhexane, 2-methyl-3-ethylpentane, 2,5-dimethylhexane and 2,2,4-trimethylpentane. These data were ob-

---

[1] Pope, Dykstra and Edgar, THIS JOURNAL, 51, 1875 (1929).

tained in the course of a general survey of the oxidation characteristics of hydrocarbons, and are consequently somewhat fragmentary in nature. In three of the five cases only a single experiment was carried out, and the temperature range covered was not always as great as could be wished. Nevertheless, the data, when taken in conjunction with the much more detailed study of *n*-octane, seem to throw much light on the oxidation characteristics of branched-chain hydrocarbons, about which no information has been available heretofore, and it has been thought wise to publish them in their present form, since circumstances have prevented this Laboratory from carrying out the work more exhaustively.

The data are of especial interest in connection with the behavior of these hydrocarbons as fuels in the internal coinbustion engine, a subject which will be discussed in Part III of this paper.

II. Apparatus and Experimental Methods

(a) General.—The apparatus and experimental procedure were identical with those described in Part I. The runs were made with slowly rising temperature, except in the case of 2,5-dimethylhexane, in which several runs under constant temperature conditions were carried out.

(b) Materials.—The hydrocarbons were synthesized in this Laboratory by methods analogous to those described for the isomeric heptanes,[2,3] with the exception of 2,2,4-trimethylpentane, which was synthesized by the method described by Edgar.[4] The boiling points indicated a fair state of purity and were as follows: 3-methylheptane, 117.5–120.5°; 3-ethylhexane, 116–119°; 2-methyl-3-ethylpentane, 113–116°; 2,5-dimethylhexane, 108–110°; 2,2,4-trimethylpentane, 99.2–99.4°.

III. Experimental Data

(a) General.—The experimental data are expressed graphically in Figs. 1, 2, 3, 4 and 5, in which the oxygen consumed and the carbon oxides formed per mole of octane input are plotted against the temperature. As in the case of n-octane, the temperatures are the average values for the few degrees temperature range during sampling. The oxygen–fuel ratios were not always the theoretical values for complete combustion (12.5 moles O_2 to 1 mole octane), but they were usually not far from this value. The actual values are given in the figures.

(b) Individual Cases.—Before discussing the data it seems desirable to point out certain facts in connection with the behavior of the individual hydrocarbons. It will be recalled that in the case of n-octane, two abrupt changes in the nature of the reaction occurred, each involving luminescence

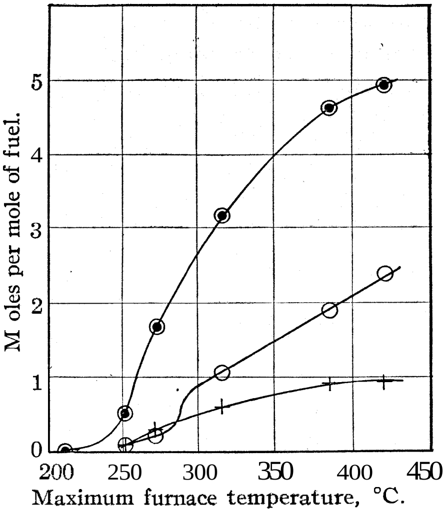
[4] Edgar, *Ind. Eng. Chem.*, 19, 145 (1927).

and strong pulsations in the oxygen and nitrogen flowmeters. The first of these was considered to be due to the incidence of a "chain" reaction involving the oxidation of an aldehyde to carbon monoxide, another aldehyde and water; the second, occurring at much higher temperatures, involved complete oxidation of all products to carbon dioxide and water. For the sake of convenience these phenomena will be referred to as "low temperature disturbance" and "high temperature disturbance," respectively.

In the case of 3-methylheptane and 3-ethylhexane low-temperature disturbances, similar to those of *n*-octane, were observed, occurring between temperature ranges of 280–305 and 285–302°, respectively. In the other three cases the low temperature disturbance was not observed.

The high-temperature disturbance was observed in the cases of 3-ethyl-hexane, 2-methyl-3-ethylpentane and 2,2,4-trimethylpentane, occurring at 510,526 and 560°, respectively. In the other two cases, the temperatures were not carried high enough for such disturbances to occur, but judging from the behavior of many hydrocarbons studied by this Laboratory, this phenomenon would undoubtedly have occurred had the temperatures been carried high enough.



●, O_2 reacted; ○, CO produced; +, CO_2 produced.

Fig. 1.—3-Methylheptane (oxygen/fuel ratio = 9.6/1).

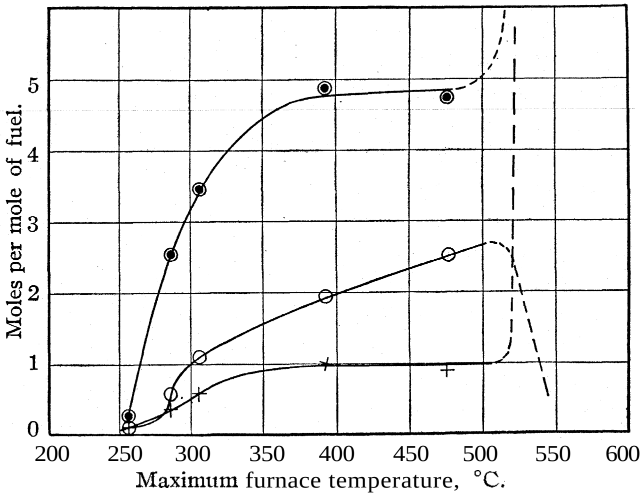
As in the case of n-octane, the low temperature disturbance was accompanied by an increase in the rate of formation of carbon monoxide, and the high-temperature disturbance by complete reaction to carbon dioxide and water.

NOTE.—In the case of 2-methyl-3-ethylpentane an experimental point was obtained at 431° in which very much less oxidation had occurred than at somewhat lower temperatures. A negative temperature coefficient of reaction is frequently observed in reactions of the type studied, but in the case in question the drop in the reaction rate is so pronounced as to suggest experimental error, such as might be caused by a temporary clogging of the fuel feed, or leakage of air into the sampling tube. There was no evidence of such occurrence, but it has been thought advisable to regard this experimental point as of doubtful significance when unverified by other determinations, and the curve has been drawn accordingly.

In the case of 2,5-dimethylhexane, the data refer to a series of constant temperature runs, rather than rising temperature runs, as in the other cases. Judging from the authors' experience with n-octane these data should, however, be reasonably comparable with the others.

IV. Discussion of Data

(a) General.—It might be expected that differences in resistance to oxidation would exist among these hydrocarbons, but no previous data are available to suggest the course of the reaction in such cases. It has been indicated by Stephens,[5] in the case of aromatic hydrocarbons with aliphatic side chains, that the oxidation of such hydrocarbons begins at a secondary carbon atom, but the nature of the hydrocarbons and the experimental conditions were so different from those involved in the present investigation as to make his conclusions of doubtful applicability.



◉, O_2 reacted; ○, CO produced; +, CO_2 produced.

Fig. 2.—3-Ethylhexane (oxygen/fuel ratio = 12.6/1).

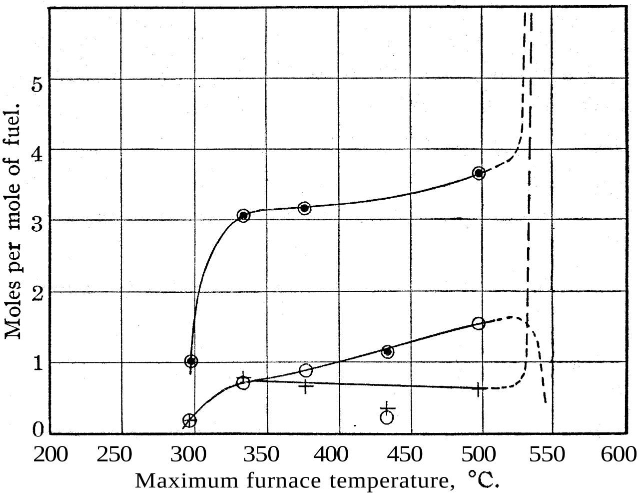
Inspection of Figs. 1, 2, 3, 4 and 5 shows that distinct differences actually exist in the behavior of the different hydrocarbons. With the exception of the data for 2,2,4-trimethylpentane, the various curves show a marked similarity in general nature to those for n-octane (Part I), the oxygen consumpti-on curves, for example, rising rather abruptly at temperatures below 300" and then showing little further rise over a considerable temperature range. The extent to which oxidation proceeds, however, before the reaction slows down, varies greatly among the different hydrocarbons. 2,2,4-Trimethylpentane shows characteristics differing from the others. The significance of these variations will be discussed below.

---

[5] Stephens, **This journal,** 50, 2523 (1928).

Although the data are not as complete as could be wished, it seems desirable to subject them to careful scrutiny in order to determine if possible (1) whether the reaction mechanism is similar to that of n-octane, and (2) the point of initial attack. These two questions will, therefore, be considered in order.

(b) Main Course of Reaction.—In the case of n-octane it was found that the total oxygen consumption per mole of octane input (at temperatures below the high-temperature disturbance) was very nearly equal to the total of one mole (to form an aldehyde), plus the number of moles of carbon monoxide (since the oxidation of an aldehyde to 1 mole of carbon monoxide, water and another aldehyde requires one mole of oxygen), plus 1.5 times the number of moles of carbon dioxide (since the oxidation of an aldehyde to carbon dioxide, water and another aldehyde requires 1.5 moles of oxygen), indicating that no other reactions than those suggested were occurring to an appreciable extent. Calculations on a similar basis for the four isomeric octanes, which are oxidized at low temperatures, give the results in Table I.



◉, O_2 reacted; ○, CO produced; +, CO_2 produced.

Fig. 3.—2-Methyl-3-ethylpentane (oxygen/fuel ratio =11.7511).

The experimental data for oxygen reacted agree reasonably well in most cases with those calculated, suggesting that the mechanism of oxidation is analogous to that of n-octane. The oxygen consumed is usually slightly greater than that calculated, indicating that a small amount of oxygen may have reacted to form olefins (small amounts of gas absorbable in fuming sulfuric acid were found experimentally) or some products other than those involved in the theory, but such reactions cannot be a major factor in the

TABLE I

RESULTS OF CALCULATIONS

Moles of CO	Moles of CO_2	Moles of O_2 consumed	(1 + CO + 1.5 CO_2)	Moles of CO	Moles of CO_2	Moles of O_2 consumed	(1 + CO + 1.5 CO_2)
	3-Methylheptane				2-Methyl-3-ethylpentane

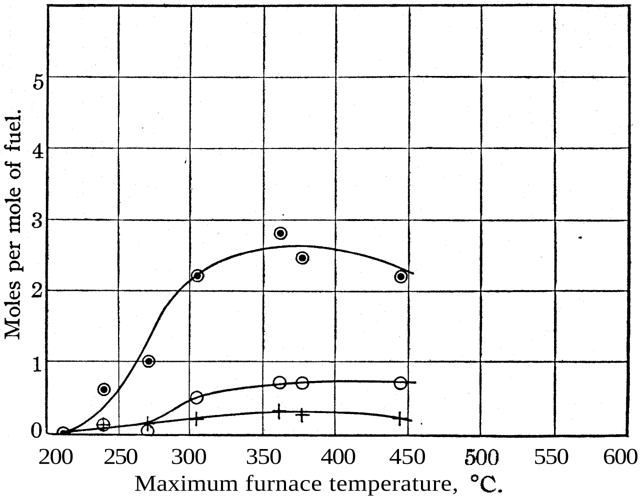
Data for 2,2,4-trimethylpentane are not included since it does not exhibit the low-temperature oxidation phenomena shown by the others.

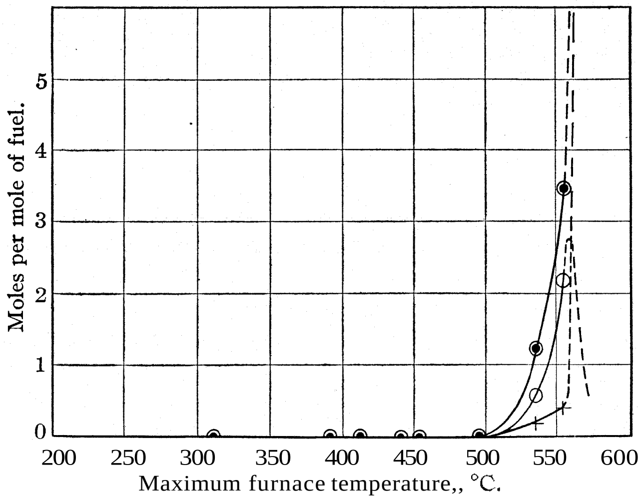
oxidation, since nearly all of the oxygen consumed is accounted for on the hypothesis outlined above. It seems reasonable, therefore, to assume for the four cases cited that, as in the case of n-octane, the primary product of oxidation is an aldehyde; that this aldehyde is further oxidized (a) by a "chain" reaction producing aldehyde, carbon monoxide and water and (b) by a reaction producing aldehyde, carbon dioxide and water; and that these reactions proceed until products are formed which resist further oxidation until temperatures are reached which are high enough for general disintegration to occur, accompanied by complete oxidation to carbon dioxide and water.



◉, O_2 reacted; O, CO produced; +, CO_2 produced.

Fig. 4.—2,5-Dimethyhexane (oxygen/fuel ratio = 9.1/1).

(c) Point of Initial Attack.—The data in the preceding paragraph indicate that the point of initial attack is a methyl group, rather than a secondary or tertiary atom. This view is substantiated by several facts: (1) the over-all similarity of the oxidation curves to that of n-octane and the similar phenomena observed during the reaction; (2) the hydrocarbons containing secondary or tertiary atoms are more resistant to oxidation than those not containing them, and the more highly condensed the structure, the more resistant the hydrocarbons become; **(3)** oxidation of secondary carbon atoms would be expected to result in a rapid degradation of the hydrocarbon into molecules of low molecular weight, which would be oxidized with difficulty even in the form of aldehydes (see Part I). The result of such reactions would be a large consumption of oxygen without production of correspondingly large amounts of carbon oxides, which is contrary to the experimental data. It appears, therefore, that secondary and tertiary atoms are points of strength rather than weakness, and that the initial attack is at a methyl group, as in the case of n-octane. With n-octane, however, only the methyl groups at the ends of the molecule are available for oxidation. In the case of most of the isomeric octanes the initial attack might theoretically be at any one of several points.



◉, O_2 reacted; O, CO produced; +, CO_2 produced.

Fig. 5.—2,2,4-Trimethylpentane (oxygen/fuel ratio = 12.3/1).

Examination of Figs. 1, 2, 3 and 4 gives a clue to the actual point of attack. In the case of 2,5-dimethylhexane, the oxidation does not increase with rising temperature after a total of one atom of carbon has been oxidized away as gas. In the case of 2-methyl-3-ethylpentane the reaction stops similarly when approximately two carbon atoms have been oxidized away. In the case of 3-ethylhexane, the reaction stops when three carbon atoms have been oxidized away. In the case of 3-methylheptane more than three atoms of carbon have been oxidized away at the highest temperature recorded, and the reaction is still increasing with rising temperature. Now the longest unbranched, open-end straight chain of these compounds is one, two, three and four carbon atoms in length, respectively. It seems reasonable, therefore, to interpret the reactions as follows. (I) Oxygen attacks the methyl group at the end of the longest open-end straight chain of the hydrocarbon, forming an aldehyde and water. (2) The aldehyde is oxidized with the formation of an aldehyde of one less carbon atom, water and either carbon monoxide or carbon dioxide. (3) This reaction proceeds until a branch in the hydrocarbon chain occurs, making the oxidation product a ketone instead of an aldehyde. (4) When this stage has been reached the low-temperature oxidation slows down markedly, as it would be expected that a ketone would resist further oxidation more than an aldehyde.

2,2,4-Trimethylpentane has, like 2,5-dimethylhexane, an open-end straight chain of only one carbon atom, and might be expected to behave similarly. Evidently, however, the highly condensed structure renders the hydrocarbon so resistant to oxidation that no reaction occurs at all until such high temperatures are reached that the reaction, once started, goes rapidly to completion, the high-temperature disturbance setting in at once.

(d) Low-Temperature and High-Temperature Disturbances.—As pointed out above, evidence was presented in Part I of this series that the low-temperature disturbance involves the oxidation of an aldehyde to carbon monoxide, an aldehyde of a smaller number of carbon atoms and water, the reaction being undoubtedly of the "chain reaction" type. That similar phenomena occur in the case of two out of five of the isomeric octanes is further evidence that at least in these cases a chain reaction occurs, involving the oxidation of an aldehyde. It is significant that in the three cases in which the phenomenon was not observed it is found that for 2,5-dimethylhexane and 2-methyl-3-ethylpentane less than one mole of oxygen has been consumed in this reaction, and hence it would be expected that the results of this reaction would be less apparent than in the other cases; in the case of 2,2,4-trimethylpentane, no low-temperature reaction occurs at all. In the case of 3-ethylhexane, the disturbance was only slight, and it is not surprising that it was not noticeable in the cases involving still less of the reaction in question.

The high-temperature disturbance presumably occurs when the hydrocarbon itself, or its primary oxidation products, are brought, together with oxygen, to a temperature sufficiently high for the reaction to go semi-explosively to completion. Two questions seem worthy of consideration: (a) does the reaction at the point of the high-temperature disturbance pass through the same steps as occur at lower temperatures, and (b) is some entirely new mechanism involved in the oxidation at this point? It is hardly possible to answer either of these questions definitely from the available data, but a probable answer can be given to the first one. If the oxidation proceeds always through the steps involved in the low-temperature oxidation, it would be expected that the temperature at which the high-temperature disturbance sets in would be determined (a) by the extent to which the primary oxidation has proceeded, (b) by the nature of the oxidation products and (c) by the excess oxygen present. The experimental facts seem to be in accord with this hypothesis. Thus n-octane, mixed with the theoretical quantity of air for complete combustion, does not react completely until a temperature ,of 667° has been reached, which may mean that oxygen has been consumed so readily in forming primary oxidation products that the concentration of oxygen is much reduced, and a very high temperature must be reached before the primary products can undergo semi-explosive reaction. On the other hand, in the case of 2,2,4-trimethylpentane, when oxidation begins at 515°, the concentration of oxygen is higher and the evolution of heat of the initial oxidation brings about the semi-explosive reaction at a lower temperature than is the case with n-octane. The behavior of other isomeric octanes presumably falls between these two cases, the temperature of the high-temperature disturbance depending partly on the oxygen concentration and partly on the nature of the primary oxidation products.

On the hypothesis that the reaction is the direct oxidation of the hydrocarbon, without passing through the low-temperature stage, it is most surprising that a readily oxidized hydrocarbon such as n-octane shows this reaction at a higher temperature than 2,2,4-trimethylpentane. The first hypothesis is therefore favored.

It should be realized, of course, that the actual temperatures at which these reactions occur are undoubtedly influenced by such factors as design of apparatus, oxygen concentration and oxygen–fuel ratio. The actual data given refer only to the particular conditions in question.

The reaction proceeds so rapidly at the point of the high-temperature disturbance that it is impossible to determine whether or not some new mechanism, such as "cracking," or simultaneous attack of the molecule at several points, is involved.

(e) Temperature of Initial Attack.—There is little relation between the temperature of initial attack and the other oxidation characteristics. Thus 2,5-dimethylhexane is attacked at a temperature about equal to that for n-octane, while 2,2,4-trimethylpentane is not attacked at all until very much higher temperatures have been reached. The other isomers are all attacked at slightly higher temperatures than n-octane, a slight trend being observed with increasing condensation of the molecule.

V. Probable Behavior of Other Hydrocarbons

In the first place, it should be emphasized that the conclusions reached in this paper should not be taken as indicating that oxidation of even these particular hydrocarbons must follow the course outlined above under all conditions. Many reactions of oxygen with hydrocarbons are thermodynamically possible, and the reaction under different conditions of oxygen concentration, oxygen–fuel ratio and experimental technique may doubtless follow courses quite different from those observed in this paper. It is particularly probable that the liquid-phase oxidation and the oxidation under static conditions may follow a course distinctly different from those discussed herein. The present data are perhaps of particular interest in connection with the behavior of fuels in the internal combustion engine, in that air and not pure oxygen was employed for the oxidation, and in that the dynamic method employed involves a time of contact more closely related to that of the internal combustion engine than does the static method. It is interesting to speculate on the possible behavior of hydrocarbons other than those studied. It may be reasonably expected that all normal paraffins of intermediate molecular weight will show characteristics similar to n-octane. Certain branched-chain hydrocarbons offer interesting possibilities which may be only guessed at. Thus hydrocarbons, similar to 2,5-dimethylhexane but of higher molecular weight, might conceivably be attacked toward the center of the molecule as well as the end. Highly condensed hydrocarbons such as hexamethylethane, in which the oxidation of an aldehyde could not occur in the manner noted above, might well be extremely resistant to oxidation, and hydrocarbons in which a chain is branched at a quaternary carbon atom also involve possible complications of the general scheme. It would be interesting to have data for such cases. The oxidation of olefins also is a question of much interest. A few preliminary data available in this Laboratory indicate that the oxidation of *α-n*-octene begins at a higher temperature than the oxidation of n-octane, and is otherwise analogous to the case of n-octane, which certainly suggests that the oxidation does not begin at the double bond, but at the opposite end of the hydrocarbon, and follows a course similar to that of the saturated hydrocarbons. It is to be hoped that many more data than those contained in this paper will soon be available, in order to determine many of the points which must remain for the present in doubt.

VI. Summary

1. Data have been presented on the vapor phase oxidation of five branched-chain octanes. Distinct differences exist in the behavior of these hydrocarbons toward oxygen.

2. The data have been interpreted as indicating that in general oxygen first attacks the methyl group at the end of the longest free straight chain

and that it proceeds in a manner analogous to that observed for *n*-octane (Part I) until a branch in the chain occurs, the oxidation slowing down markedly at this point.

3. Certain points of interest bearing on the general problem of hydrocarbon oxidation have been briefly discussed.

THE VAPOR PHASE OXIDATION OF ISOMERIC OCTANES. III. THE EFFECT OF TETRA-ETHYL LEAD AND THE RELATION OF OXIDATION TO ENGINE DETONATION

BY J. C. POPE, F. J. DYKSTRA AND GRAHAM EDGAR

RECEIVED MARCH 16, 1929 PUBLISHED JULY 5, 1929

I. Introduction

The marked effect of tetra-ethyl lead and other "anti-detonants" upon certain characteristics of the combustion of hydrocarbons in the internal combustion engine is a phenomenon which has attracted the attention of numerous investigators. In several cases the oxidation of hydrocarbons in the presence of anti-detonants has been studied, and theories have been propounded connecting the phenomena observed with the behavior of fuels in the internal combustion engine.[1] It cannot be said, however, that these theories have given a complete explanation of the effect of anti-detonants on engine detonation, and no data at all have been presented in explanation of the wide differences in engine behavior of isomeric hydrocarbons.[2] Any data bearing upon these subjects seem, therefore, to be worthy of careful scrutiny.

In Parts I and II of this paper data have been presented upon the vapor phase oxidation of six isomeric octanes and simple interpretations have been given of their behavior. In Part III there are presented data upon the oxidation of n-octane and of n-heptaldehyde in the presence of tetra-ethyl lead. The relation between the data in Parts I, II and III and the detonation tendencies of paraffin hydrocarbons in the internal combustion engine is discussed.

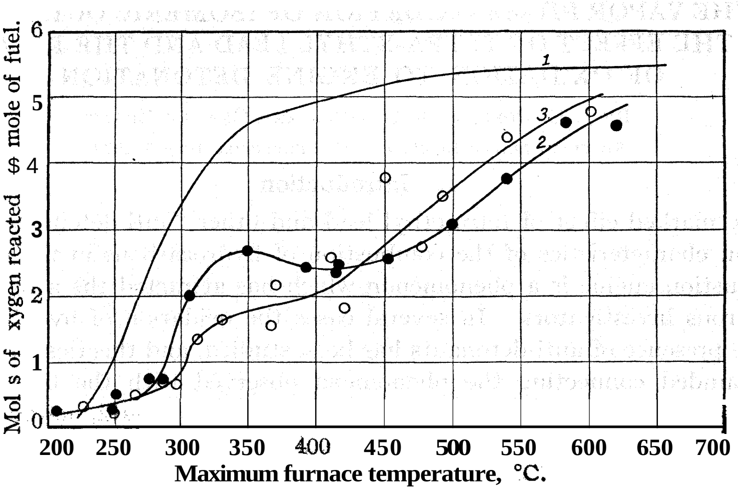
II. Experimental Procedure

The oxidation of n-octane and of n-heptaldehyde in the presence of tetra-ethyl lead was studied in an apparatus and by a procedure identical with that employed with n-octane alone (Part I). Tetra-ethyl lead was added to the fuel and vaporized with it. Runs were carried out with slowly rising temperature and with the temperature stationary. In all cases the gaseous oxidation products were determined and in the latter case some analyses were made of the liquid oxidation products. The details of the methods of analysis, etc., were described in Part I.



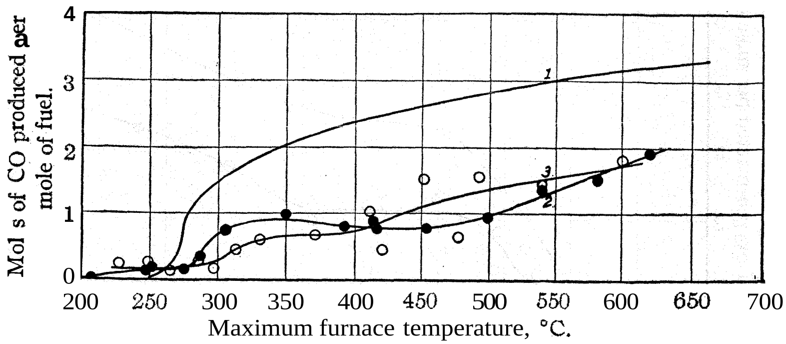
1, *n*-Octane; 2, -●-, n-octane plus 0.3% vol. lead tetra-ethyl; 3, -O-, n-octane plus 1.07% vol. of lead tetra-ethyl.

Fig. 1.—Normal octane (theoretical air/fuel ratio).

III. Experimental Data

Characteristic experimental data from rising temperature runs are expressed graphically in Figs. 1, 2 and 3 for n-octane and in Figs. 4 and 5 for n-heptaldehyde. For the sake of comparison, the corresponding data from Part I for n-octane alone and for n-heptaldehyde alone are included. The data on n-octane with tetra-ethyl lead were obtained in four individual experiments; for n-heptaldehyde the results of three experiments are included.

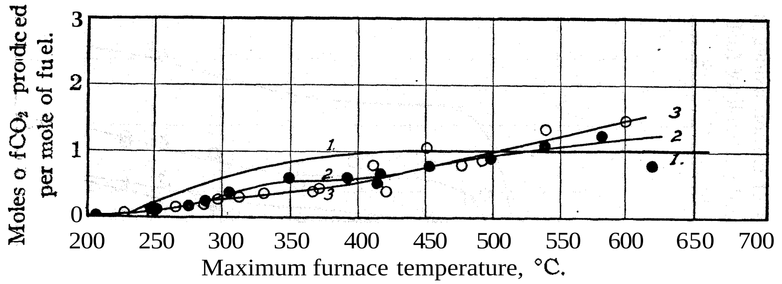
The oxygen consumption and carbon oxides produced are expressed in moles per mole of octane input and the temperatures are the maximum furnace temperature at the average time of sampling. In addition to the data in the figures it may be noted that as usual small amounts of gas absorbable in fuming sulfuric acid were found, in amounts not differing appreciably from those found in the experiments of Parts I and II. The liquid oxidation products contained aldehyde and water in considerable amounts and acid in very small amounts. The data did not differ materially from those found with n-octane in the absence of tetra-ethyl lead. The phenomena accompanying the oxidation were similar in most respects to those observed in Part I. Certain differences will be described below.



1, n-Octane; 2, –O–, n-octane plus 0.3% vol. of lead tetra-ethyl; 3, –O–, n-octane plus 1.07% vol. of lead tetra-ethyl.

Fig. 2.—Normal octane (theoretical air/fuel ratio).

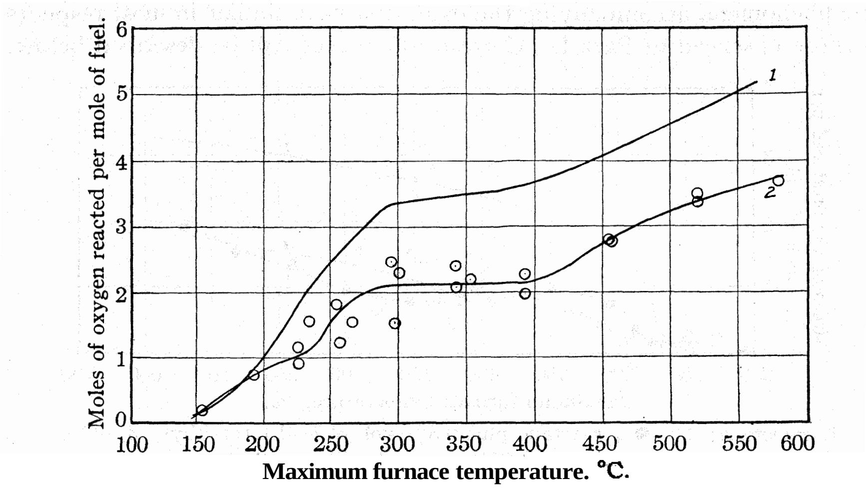
It may be noted that the experimental data in the presence of rather large amounts of tetra-ethyl lead were much more erratic than those observed with the hydrocarbons alone. This is not altogether unexpected, since under the conditions of the experiments tetra-ethyl lead undergoes oxidation, in amount varying with the temperature. The extent of such oxidation, the point at which it occurs in the furnace and the distribution of the products through the furnace undoubtedly vary with the temperature and perhaps between runs, and may account for the somewhat erratic results. The varying effect of tetra-ethyl lead at different temperatures, discussed below, may also be at least partially due to the decomposition phenomena. For the purpose of this paper no distinction is made between tetra-ethyl lead itself and its various decomposition products, as the data



1, n-Octane; 2, —O—, *n*-octane plus 0.3 % vol. of lead tetra-ethyl; 3, —O—, n-octane plus 1.07% vol. of lead tetra-ethyl.

Fig. 3.—Normal octane (theoretical air/fuel ratio).

herein presented do not permit an analysis close enough to determine such distinctions, if they exist.

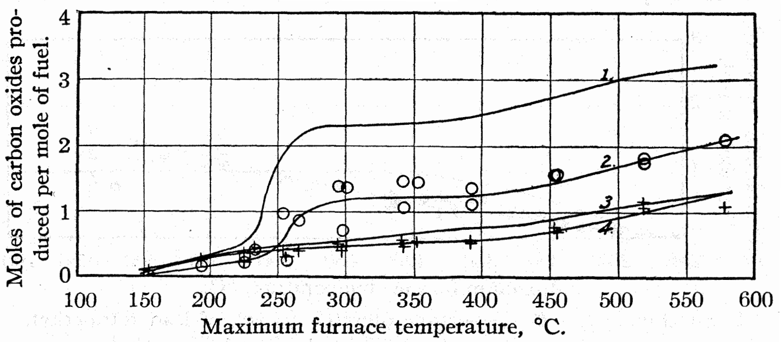


1, n-Heptaldehyde; 2, –O–, *n*-heptaldehyde plus 1% vol. of lead tetra-ethyl.

Fig. 4.—Normal heptaldehyde (theoretical air/fuel ratio).

IV. Discussion of Data

Comparison with the Data in the Absence of Tetra-ethyl Lead.—In Fig. 1 a comparison is made of the oxygen consumption of n-octane at different temperatures with and without tetra-ethyl lead. In Fig. 2 a similar comparison is made of the carbon monoxide produced and in Fig. 3 of the carbon dioxide produced. In Fig. 4 the oxygen consumption data for heptaldehyde with and without tetra-ethyl lead are compared, and in



n-Heptaldehyde: 1, CO produced; 3, CO_2 produced.
n-Heptaldehyde plus 1% vol. lead tetra-ethyl: 2, –O–, CO produced; 4, – + –, CO_2 produced.

Fig. 5.—Normal heptaldehyde (theoretical air/fuel ratio).

Fig. 5 the carbon oxides formed are compared. An analysis of these data follows.

(1) ***n*-Heptaldehyde.**—Data were presented in Part I indicating that aldehydes are intermediate oxidation products of n-octane, and that the carbon oxides formed are the oxidation products of such aldehydes, rather than of n-octane directly. In attempting to determine the exact effect of tetra-ethyl lead it seems therefore desirable to consider first the oxidation of n-heptaldehyde in the presence of tetra-ethyl lead, since in this case only two of the three reactions involved in the oxidation of n-octane are concerned. It is clear from the data in Figs. 4 and 5 that practically the entire effect of tetra-ethyl lead on the oxidation of n-heptaldehyde is upon the reaction producing carbon monoxide. The carbon dioxide formed with tetra-ethyl lead differs from that formed in its absence by little more than the experimental error. The carbon monoxide is, however, greatly reduced in the presence of tetra-ethyl lead, and the data for oxygen consumption differ from those without tetra-ethyl lead by an amount corresponding almost exactly to the reduction in carbon monoxide, since one mole of oxygen is consumed in the production of one mole of carbon monoxide. It would be expected that the reaction involving carbon monoxide would be the one most apt to be affected by tetra-ethyl lead, since it is a "chain" reaction (Part I), and such reactions are usually capable of marked retardation by negative catalysts. Presumably the reaction is normally propagated through the medium of a reaction chain in which "activated molecules" in reacting activate other molecules. Tetra-ethyl lead probably retards the reaction by accepting the surplus energy of such molecules and thus breaking the reaction chain.

The temperature at which the "low temperature disturbance" begins with its accompanying luminescence and pulsations, is distinctly raised by tetra-ethyl lead, (235 to 270°), as would be expected from the fact that the reaction producing this disturbance is suppressed. The range over which the disturbance is noticeable is, however, not measurably affected. It may be noted that at very low temperatures tetra-ethyl lead has very little if any effect upon the oxidation of heptaldehyde, a phenomenon perhaps associated with the fact that tetra-ethyl lead is not decomposed appreciably under the conditions of the experiment in this temperature range. The effect also is diminished at quite high temperatures, which may again be associated with the decomposition phenomena.

(2) n-Octane.+-Octane, according to the view expressed earlier by the authors, differs in its essential oxidation mechanism from n-heptaldehyde only by the initial reaction in which aldehyde is produced from the hydrocarbon. The data in Figs. 1, 2 and 3 are fully in accord with this view. Thus the most striking effect of tetra-ethyl lead is in the suppression of the reaction in which carbon monoxide is formed, a suppression which would be expected from the data on n-heptaldehyde. There is evidence, however, of another effect of tetra-ethyl lead. Thus while oxidation begins at about the same temperature in the presence of tetra-ethyl lead as in its absence, the oxygen consumption rises with increasing temperature somewhat more slowly than can be accounted for by the suppression of the carbon monoxide alone, particularly at low and intermediate temperatures. This suggests that the primary oxidation of n-octane to aldehyde is somewhat retarded and that complete oxidation of the hydrocarbon does not occur in the presence of tetra-ethyl lead until a higher temperature has been reached than is necessary with n-octane alone. The data on carbon dioxide production support this view, since they are slightly lower, at low temperatures, in the presence of tetra-ethyl lead than in its absence, as would be expected if the formation of aldehyde (from which the carbon dioxide is produced) is somewhat retarded. The apparent partial reduction in the primary oxidation of *n*-octane suggests the possibility that this reaction may also be of the chain reaction type, but no further evidence is available.

The effect of tetra-ethyl lead on the low temperature disturbance with n-octane is similar to its effect upon the corresponding disturbance in the case of n-heptaldehyde, in that the temperature at which the disturbance begins is raised (270 to 300°), but with n-octane the disturbance is much less vigorous in the presence of tetra-ethyl lead than in its absence, the luminescent flashes are more frequent and the temperature range over which the disturbance lasts is increased. This seems in accord with the hypothesis that the primary oxidation of n-octane is partially suppressed and the aldehyde oxidation (to carbon monoxide) strongly suppressed. Other facts worth recording in connection with the oxidation are: (1) that, as with *n*-heptaldehyde, the effect of tetra-ethyl lead seems to decrease at high temperatures; (2) that the data were not extended to the temperature of the "high temperature disturbance," so that it cannot be determined whether or not this point is affected by tetra-ethyl lead; and (3) that increasing the concentration of tetra-ethyl lead from 0.31 vol. per cent. to 1.00 vol. per cent. does not produce a corresponding effect on the oxidation phenomena.

V. Relation of Oxidation Phenomena to Engine Detonation

The facts that tetra-ethyl lead effectively suppresses detonation in the internal combustion engine, and that its chief effect upon the oxidation of a hydrocarbon having a high tendency to detonate (n-octane) is the suppression of certain oxidation reactions, suggest a close relationship between the two phenomena. It is interesting in this connection to examine the behavior in the engine of the isomeric octanes whose oxidation characteristics were discussed in Part II. Insufficient amounts of these hydrocarbons were available to enable their tendencies to detonate to be measured on the pure materials; accordingly, they were dissolved in gasoline in the proportion of 10% by volume, and their effect on the tendency of the gasoline to detonate was measured in an engine, employing a technique previously described.[3] The hydrocarbons arranged themselves in the following order, the one having the greatest tendency to detonate being given first: (1) n-octane, (2) 3-methylheptane, (3) 3-ethylhexane, (4) 2-methyl-3-ethylpentane, (5) 2,5-dimethylhexane and (6) 2,2,4-trimethylpentane. Now it has been previously shown (Part II) that the first five of these hydrocarbons have their longest open-end straight chains of eight, four, three, two and one carbon atoms, respectively, and that the length of these chains determines the extent to which the low temperature oxidation can proceed. The sixth hydrocarbon (2,2,4-trimethylpentane) was found to be entirely unoxidized at low temperatures.

We have here, therefore, a striking correlation between engine detonation and oxidation characteristics. This may be recapitulated as follows. (1) A "chain reaction" involving the oxidation of an aldehyde to carbon monoxide, water and another aldehyde has been found to be one of the chief oxidation reactions of the five isomeric hydrocarbons which undergo appreciable oxidation at low temperatures. (2) The extent to which this reaction is capable of proceeding without interruption is determined by the length of the longest open-end straight chain of carbon atoms in the mole-

---

[3] Edgar, J. Soc. *Automotive* Eng., **22,** 41 (1928).

cule, and the oxidation actually slows down when it has proceeded to a point corresponding to the length of such a chain (unless a secondary disturbance sets in before such point is reached). (3) Tetra-ethyl lead sharply retards this reaction (in the one case studied), and apparently reduces somewhat the primary oxidation of the hydrocarbon. (4) The tendency of these hydrocarbons to detonate follows the same order as that of the extent to which this reaction occurs at low temperatures, and the hydrocarbon showing no low temperature oxidation has less tendency to detonate than any of the others. (5) Tetra-ethyl lead reduces the tendency of a fuel to detonate.

Apparently, therefore, both the temperature of initial oxidation and the extent to which such oxidation proceeds are factors involved in the detonation phenomena. If the relationships found for the six octanes are general, it seems reasonable to predict that as far as the paraffin hydrocarbons are concerned: (a) for normal hydrocarbons the tendency to detonate will increase with increasing molecular weight (this is known to be in accord with experiment); (b) branched-chain hydrocarbons which undergo oxidation at low temperatures will have a tendency to detonate increasing with the length of the longest open-end carbon chain; (c) hydrocarbons resistant to low temperature oxidation will have little tendency to detonate (*e.g.*, 2,2,4-trimethylpentane). These will probably have highly condensed structures. It must be admitted that the data on which these conclusions are based are not as complete as could be wished, but they appear to give quite clear indications of the phenomena to be expected with different paraffin hydrocarbons.

VI. Mechanism of Detonation

It is much more difficult to suggest a satisfactory mechanism of engine detonation. So many factors involved in the combustion of fuels in an engine are widely different from those in the laboratory experiments that too close an analogy can hardly be expected. We know little concerning the chemical changes involved in the combustion of fuel in an engine except that Lovell, Coleman and Boyd[4] have shown that the combustion is more rapid when an engine is detonating than during normal operation. In an engine the air–fuel mixture is first compressed to about five atmospheres in a hot cylinder. It is then ignited with a spark and the mixture burns either with or without the development of detonation. It is probable that temperatures of 400–500° are reached during the compression stroke before the spark is fired. It is quite conceivable that when readily oxidized hydrocarbons are used as fuel appreciable oxidation may occur during the compression stroke, and that the rate of burn of the mixture after the charge is fired (and the tendency to detonate) may depend upon the extent of such

---

[4] Lovell, Coleman and Boyd, *Ind. Eng. Chem.*, **19**, 373 (1927).

preliminary oxidation. It is also possible that the rate of burn of a charge fired by a spark may depend upon factors similar to those which govern the low temperature oxidation. The problem is extremely complicated and the authors do not feel that the data presented in this paper give by any means the complete account of engine detonation. Nevertheless, they represent an interesting correlation of laboratory data with engine operation, and are presented with the hope that they may contribute to clearing up at least certain phases of this important problem.

VII. Summary

1. Experimental data have been presented on the vapor phase oxidation of n-octane and n-heptaldehyde in the presence of tetra-ethyl lead.
2. The effect of tetra-ethyl lead seems to be chiefly that of slowing down the oxidation of aldehydes to carbon monoxide, water and other aldehydes.
3. The data, combined with those of Parts I and II, are discussed in comparison with the behavior of the hydrocarbons as fuel in the internal combustion engine, and certain correlations are pointed out.

THE ACTION OF PHENYL ISOCYANATE ON URETHANS, UREAS AND THIOUREAS

BY HANS LAKRA[1] AND F. B. DAINS

RECEIVED MARCH 22, 1929 PUBLISHED JULY 5, 1929

Phenyl isocyanate, which was first obtained by A. W. Hofmann,[2] is characterized by its ability to form addition products with the N=C double bonding. Thus with alcohols urethans, $C_6H_5NHCOOR$, are formed while with ammonia and with primary and secondary amines, substituted ureas result. The presence of aryl groups in the secondary amines often tends to slow up or even in some cases to prevent the expected addition, $RR'NH + C_6H_5NCO = C_6H_5NHCONRR'$.

Since the nature of the hydrocarbon (aryl) group has been found to affect the course of the reaction, it seemed worth while to study the reactivity of phenyl isocyanate toward the group $RNH(NH_2)$ when it was linked with a CO or CS complex, in order to determine their influence upon the expected additions.

In the present investigation the compounds chosen were urethans, ureas and thioureas where the primary reaction might be expected to yield (a)

---

[1] From a dissertation presented by Hans Lakra to the Faculty of the Graduate School of the University of Kansas, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Hofmann, Ann., 74, 9 (1850); *Ber.*, 3, 655 (1870).

with urethans, allophanic esters, $C_6H_5NHCONHCOOR$; with ureas, biurets, $C_6H_5NHCONHCONH_2$, and with thioureas, monothiobiurets, $C_6H_5NHCONHCSNH_2$, or their substitution products where an H had been replaced by aryl or alkyl groups.

Such addition products were isolated in a number of cases; in others only the dissociation products of the initial compound. Any simple formulation of the results was rendered difficult in many instances by the fact that one of the dissociation products was isocyanic acid, which could then condense with itself to form isocyanuric acid or with amino compounds, yielding ureas or biurets. Higher temperatures favored this latter type of reaction.[3]

Experimental

Phenyl Isocyanate and **Urethan.**—Molecular proportions of the two reagents were heated at 140–160° for six hours.[4] From the reaction product were isolated: (1) phenyl allophanic ester, $C_6H_5NHCONHCOOC_2H_5$; (2) phenylurethan, $C_6H_5NHCOOC_2H_5$; (3) phenylisocyanuric acid, $C_6H_5H_2C_3O_3N_3$; and (4) phenylcarbethoxybiuret, $C_6H_5NHCONHCONHCOOC_2H_5$. No. 1 is formed by direct addition; Nos. 2 and 3 by dissociation of the urethan into HNCO and alcohol and subsequent addition of alcohol or the dimer $(HNCO)_2$ to the isocyanate, while in No. 4 the phenylisocyanate and alcohol add to $(HNCO)_2$. No evidence was obtained as to the intermediate possible formation of allophanic ester which with the isocyanate would yield the carbethoxybiuret.

Phenyl Isocyanate and **Phenylurethan.**—Heated at 150° a little carbanilide is formed.[5] At temperatures from 200–250° this is the main product. While the phenylurethan would account for part of the carbanilide, the increased amount would indicate that the ethyl alcohol from the urethan loses a mole of water which then reacts with additional isocyanate to form diphenylurea.[6]

Phenyl Isocyanate and **Ethylurethan,** $C_2H_5NHCOOC_2H_5$.—The mixture was heated at 175° for six hours. The only product isolated was diphenylurea. No ethylphenylurea or diethylurea was detected due to the volatility of the dissociation products, ethylamine and ethyl isocyanate.

Phenyl Isocyanate and **Allophanic** Ester.—The two compounds failed to react at 125°. At 160° unchanged allophanic ester, carbanilide and isocyanuric acid were isolated.

Anal. Calcd. for $C_3H_3N_3O_3$: N, 32.55. Found: N, 32.13.

Heated at 170–178° an additional product, phenylisocyanuric acid was obtained.

Anal. Calcd. for $C_9H_7N_3O_3$: N, 20.48. Found: N, 20.10.

Allophanic ester alone slowly decomposes at 160°, yielding ammonia and isocyanuric acid. The carbanilide is due to the intermediate formation of phenylurea ($C_6H_5NCO + NH_3$) and the phenylisocyanuric acid is formed as indicated in the case of urethan.

Phenyl Isocyanate and Urea.—After heating at water-bath temperature for seven hours, there was isolated a little diphenylurea, and unchanged urea, but the main

---

[3] This work harmonizes with the results on "Urea Dearrangement," Davis and Underwood, THIS JOURNAL, 44, 2595 (1922); Davis and Blanchard, *ibid.*, **45,** 1816 (1923).

[4] Dains, Greider and Kidwell, *ibid.*, **41,** 1008 (1919).

[5] Schiff, *Ber.*, **3,** 249 (1870).

[6] Dains, THIS JOURNAL, 21, 180 (1899).

product was α-monophenylbiuret, $C_6H_5NHCONHCONH_2$, formed by simple addition. This, after recrystallization from hot water and from dilute alcohol, melted at 156–157°.[7]

Anal. Calcd. for $C_8H_9N_3O_2$: N, 23.48. Found: N, 23.60, 23.27.

Phenyl Isocyanate and Urea at **120°** for Four Hours.—In this case the following products were isolated and identified: ammonia, unchanged urea, **biuret,**[8] diphenylurea, monophenylurea, phenylisocyanuric acid[B] and isocyanuric acid.

The results are in harmony with what might be predicted from a mixture containing phenyl isocyanate, urea, ammonia and isocyanicacid ($NH_2CONH_2 \rightleftarrows NH_3 + HNCO$).

$$2C_6H_5NCO + 2NH_3 = 2C_6H_5NHCONH_2 = (C_6H_5NH)_2CO + NH_2CONH_2$$
$$NH_2CONH_2 + HNCO = NH(CONH_2)_2$$
$$3HNCO = C_3H_3N_3O_3$$
$$C_6H_5NCO + 2HNCO = C_6H_5H_2C_3N_3O_3$$

Results When Heated at **140°** for Seven Hours.—The main product was carbanilide. No biuret or monophenylurea was isolated.

Acyl Substituted **Ureas.**—Phenyl isocyanate and acetylurea failed to react at water-bath temperature, but heated at 130 or 160° for five hours, the same products were obtained, *viz.,* α-acetyl-β-phenylurea and isocyanuric acid. The results could be due either to the action of the isocyanate upon acetamide, ($CH_3CONHCONH_2 \rightleftarrows CH_3CONH_2 + HNCO$), or addition to the acetylurea, as follows: $CH_3CON(CONHC_6H_5)CONH_2$ and then loss of HNCO.

The fact that no phenylisocyanuric acid was detected is in favor of this latter formulation.

In the same way benzoylurea and the isocyanate yielded at 150° benzoylphenylurea, which at 210° slowly dissociated into phenylisocyanate and benzamide (m. p. 128").

Phenyl Isocyanate and **Monophenylurea.**—Kuhn and Henschel digested the above mixture[10] at 120° and reported the formation of 1,5-diphenylbiuret and traces of a higher-melting product. On repeating their work but only heating at 100° for four hours, there was obtained diphenylurea, 1,5-diphenylbiuret,[11] m. p. 210°, and monophenylbiuret, m. p. 156–157°, confirmed by a mixed melting point with a known sample of monophenylbiuret.

The result would seem to indicate that the isocyanate can add to the phenylurea at two points; first at Position 3, yielding the 1,5-diphenylbiuret, and at Position 1, giving the isomeric biuret, $C_6H_5NHCON(C_6H_5)CONH_2$. This dissociates into diphenylurea and isocyanic acid, which then adds to the unchanged phenylurea. The same products would be formed if it were assumed that some of the phenylurea dissociated, $C_6H_5NHCONH_2 = C_6H_5NH_2 + HNCO$, but this seems a question at 100°.

The fact that phenylurea when boiled for several hours with water yields aniline can well be regarded as a simple case of hydrolysis.[12]

Disubstituted **Ureas.**—Carbanilide and phenyl isocyanate at 150° gave 1,3,5-triphenylbiuret (m. p. 147°).[13] Above its melting point the biuret is unstable, breaking down into carbanilide and the isocyanate.

[13] Hofmann, *Ber.,* 4,250 (1871); Kuhn and Henschel, *Ber.,* **21,** 504 (1888).

Anal. Calcd. for $C_{20}H_{17}N_3O_2$: N, 12.68. Found: N, 16.34.

Methylphenylurea and phenyl isocyanate failed to react at 100° but at 135–140° carbanilide alone was obtained, the probable intermediate 1,3-diphenyl-5-methylbiuret not being stable at this temperature.

Phenylacetylurea does not combine with the isocyanate at 150°, but at 200° diphenylurea is the main product. The acetylurea dissociates at this temperature into phenylisocyanate and acetamide; loss of a mole of water converts the isocyanate into diphenylurea.

Phenyl Isocyanate and Thiourea

1-Phenyl-4-thiobiuret, $C_6H_5NHCONHCSNH_2$.—This was formed in good yield when the two substances were heated at water-bath temperature for five hours. The residue was washed with dry ether and recrystallized from alcohol. It then melted at 186°.

Anal. Calcd. for $C_8H_9N_3OS$: N, 21.55. Found: N, 21.78, 21.67.

Its constitution was proved by the fact that on desulfurization with lead hydroxide in alcohol solution, α-monophenylbiuret was obtained. At 110" the thiourea and isocyanate yielded the same biuret mixed with carbanilide, the amount of which increased with rising temperature.

1-Phenyl-4-methylthiobiuret, $C_6H_5NHCONHC(CH_3){=}NH$.—When the thiobiuret was heated with methyl iodide in a sealed tube in the water-bath, the hydrogen iodide salt was formed. Alkali precipitated from its water solution the free base, which when crystallized from alcohol melted at 147–8°.

Anal. Calcd. for $C_9H_{11}N_3OS$: N, 20.10. Pound: N, 20.00, 20.19.

Mono- and Di-substituted **Thioureas.**—In no case was it possible to isolate addition products from the mono- and disubstituted thioureas. The sole products identified were diphenylurea and mustard oils. Thus allylthiourea and phenylthiourea reacted slowly at water-bath temperature, completely at 110–120°, yielding carbanilide and allyl- or phenylisothiocyanate, while allylphenylthiourea or diphenylthiourea at 120–130° gave quantitatively diphenylurea and allyl- or phenylisothiocyanate.[14]

Addition of Phenyl Isocyanate to the Isothiourea Ethers

Methylthiocarbonyldiphenyldiurea, $C_6H_5NHCON{=}C(SCH_3)NHCONHC_6H_5$.—The methyl iodide addition product of thiourea (22 g.) was dissolved in as little water as possible. To this was added phenyl isocyanate (24 g.) and a concentrated solution of potassium hydroxide (5–6 g.). On shaking a viscous mass was formed which slowly solidified. Purified from alcohol, it melted at 142°.

Anal. Calcd. for $C_{16}H_{16}N_4O_2S$: N, 17.07. Found: N, 16.82, 16.78. Mol. *wt.* in acetic acid: calcd., 328. Found: 289.

The same compound (m. p. 142") was obtained from 1-phenyl-4-methylthiobiuret and the isocyanate.

The thio-ether was warmed for a few minutes with one mole of alcoholic potassium hydroxide, hoping thus to obtain the carbonyldiphenyldiurea. Instead the ether broke down into mercaptan, aniline and a product soluble in alkali which proved to be phenylisocyanuric acid.

Anal. Calcd. for $C_9H_7N_3O_3$: N, 20.48. Found: N, 20.19.

When the thio-ether was treated with potassium sulfhydrate, mercaptan was

---

[14] Goldschmidt and Meissler, Ber., 23,273 (1890).

eliminated with the formation of thiocarbonyldiphenyldiurea, $CS(NHCONHC_6H_5)_2$; m. p. 202°.[15]

The Ethyl Ether of Thiocarbonyldiphenyl-diurea, $C_6H_5NHCONHC(SC_2H_5){=}NCONHC_6H_5$.—This was prepared from γ-ethylthiourea and phenyl isocyanate. Crystallized from 50% alcohol it melted at 145°.

Anal. Calcd. for $C_{17}H_{16}N_4O_2S$: N, 16.37. Found: N, 16.87.

Phenyl Isocyanate and the Methyl Ether of **Phenylthiourea.**—The two compounds united with the development of heat and gave 1,5-diphenyl-4-methylthiobiuret, $C_6H_5NHCON{=}C(SCH_3)NHC_6H_5$, melting at 108°.

Anal. Calcd. for $C_{15}H_{15}N_3OS$: N, 14.73. Found: N, 14.94.

The methyl thio-ether when treated with KSH yielded the corresponding 1,5-diphenyl-mono-thiobiuret, $C_6H_5NHCONHCSNHC_6H_5$, melting at 161°.

As shown by Johnson[16] and confirmed by our work, γ-methylthiourea combined with only one mole of phenyl mustard oil, yielding 1-phenyl-2-thio-4-methylthiobiuret (m. p. 122").

These thio-ethers exhibit an interesting analogy to the corresponding oxygen isourea ethers in that both types add one mole of phenyl isothiocyanate and two moles of the phenyl isocyanate."

Phenyl Isocyanate and the Ethyl Ether of Diphenylthiourea, $C_6H_5NHC(SC_2H_5)NC_6H_5$.—While no action was observed at 100°, two varying sets of results were obtained at higher temperatures. Thus the isocyanate (24 g.) and the thio-ether (52 g.) heated at 160–170° for three hours gave diphenylurea, phenyl mustard oil and triphenylcyanuric acid (m. p. 270°). Evidently in this case a portion of the isocyanate had condensed to the cyanuric acid and it is possible that the expected addition product, $C_6H_5NHCONC_6H_5C(SC_2H_5)NC_6H_5$, has broken down into carbanilide, phenyl mustard oil and ethylene, although this latter was not identified.

After heating in a sealed tube at 200°, the tube opened with pressure and the issuing gases had the odor of mercaptan. The reaction product consisted of diphenylurea and a thick oil soluble in ether which after distillation in a vacuum and crystallization from alcohol melted at 162°. It gave no test for sulfur and gave figures on analysis corresponding to carbodiphenylimide, $(C_6H_5N)_2C$.

Anal. Calcd. for $C_{13}H_{10}N_2$: N, 14.43. Found: N, 14.28.

No mustard oil or triphenylcyanuric acid was found. Evidently at 200° much of the thio-ether dissociated directly into mercaptan and carbodi-imide, a reaction which has been previously observed.

Guanidine Carbonate and Phenyl Isocyanate

The Diphenylamide of Guanidine Dicarboxylic Acid, $HN{=}C(NHCONHC_6H_5)_2$.—Michael[18] had obtained this compound by the action of the isocyanate on the guanidine carbonate and sodium ethylate. It was found that potassium hydroxide could be used with good results instead of the ethylate in concd. water solution. It melted at 174°.

Anal. Calcd. for $C_{15}H_{15}N_5O_2$: N, 23.57. Found: N, 23.82.

Action on Hydrolysis.—The diamide when refluxed for thirty minutes with 15% isodium hydroxide solution gave ammonia, aniline, diphenylurea and isocyanuric acid.

---

[15] Unpublished investigation by John F. Olin, who has found that KSH hydrolyzes isothiourea ethers to the corresponding thio carbonylcompounds.

[18] Michael, J. *prakt. Chem.*, [2] *49*, 42 (1904).

Anal. Calcd. for $C_3H_3N_3O_3$: N, 32.56. Found: N, 32.40.

When heated alone at 190–200° for three hours, ammonia, diphenylurea and isocyanuric acid were identified as decomposition products.

The observation was confirmed that guanidine unites with only one mole of phenyl isothiocyanate.[19] Its behavior in this respect is analogous to the isourea and isothiourea ethers.

Summary

1. Direct addition products of phenyl isocyanate were obtained with the following: urethan, urea, mono- and diphenylurea, thiourea and all isothiourea ethers containing a free NH grouping.

2. In all other cases, the results obtained were due (a) either to addition and subsequent breaking down of the addition product or (b) dissociation at the elevated temperature of the urethan, urea, etc., as

$$C_6H_5NHCONH_2 \rightleftharpoons C_6H_5NCO + NH_3 \rightleftharpoons C_6H_5NH_2 + HNCO$$
$$NH_2CONH_2 \rightleftharpoons NH_3 + HNCO$$
$$C_6H_5NHCOOC_2H_5 \rightleftharpoons C_6H_5NCO + HOC_2H_5$$

and the re-uniting of phenyl isocyanate and these fission products in various ways. This is illustrated especially by the formation of isocyanuric acid and its derivatives.

3. Thiourea ethers, isothiourea ethers and guanidine unite with **two** moles of phenyl isocyanate but with only one mole of phenyl isothiocyanate.

RELATIONS BETWEEN ROTATORY POWER AND STRUCTURE IN THE SUGAR GROUP. XIX. IMPROVEMENTS IN THE PREPARATION OF ALDONIC ACIDS[1]

BY C. S. HUDSON AND H. S. ISBELL

RECEIVED MARCH 25, 1929 PUBLISHED JULY 5, 1929

Introduction

It is customary to prepare an aldonic acid by the oxidation of the corresponding aldose with bromine water. The reaction is a slow one because of the retarding influence of the hydrobromic acid that is produced during its course.[2] If the aldose is not a monosaccharide it may be partly hydrolyzed by the hydrobromic acid, with a resulting poor yield of the desired acid. Thus Fischer and Meyer's[3] oxidations of lactose and maltose to their

---

respective aldobionic acids by bromine water gave yields of only about 30% and Kunz and Hudson[4] obtained similar yields in oxidizing neolactose. In these cases the isolation of the aldobionic acid was rendered difficult by the presence of gluconic and galactonic acids resulting from hydrolysis. Recently Goebel[5] has used the iodine oxidation in alkaline solution to produce aldobionic acids in nearly quantitative yield. The method obviously avoids any hydrolysis by acids and should be very suitable in researches where small quantities of sugars are to be oxidized. In larger scale preparations,[6] however, the cost of the iodine and barium iodide becomes important and for this reason we have sought to modify the plan of the bromine oxidation with the aim of making it a nearly quantitative reaction suitable for large-scale preparations. The modification which has brought success is a simple one, namely, the addition of a salt of a weak acid to the sugar solution. This acts as a buffer and keeps the hydrogen-ion concentration at a low acidity because the hydrobromic acid is neutralized by the salt and is replaced by the weak acid. The maintaining of the acidity of the solution at a low value results in the reduction of the acid hydrolysis of compound sugars to a negligible amount, and in an important increase in the speed of the oxidation. The choice of a suitable buffering salt was made on the basis that its acid and basic constituents would not interfere with the isolation of the aldonic acid. The benzoates of barium and calcium have met these requirements very well. The details of the recommended procedure will be shown by the following examples of typical preparations.

Preparation of Calcium **Gluconate.**—Six cc. of bromine (0.12 mole) was added to an ice-cold solution of 18 g. (0.1 mole) of anhydrous glucose and 60 g. (0.15 mole) of barium benzoate in 750 cc. of water. The bromine rapidly dissolved when the solution was shaken and crystals of benzoic acid soon formed. Although a faint but definite Fehling's test for reducing substances was obtained when light was not excluded, a Fehling's test of the mixture after it had stood for thirty-six hours at room temperature (20–25°) in darkness was negative, indicating the oxidation of all of the sugar. The excess bromine was removed by a stream of air and the barium was precipitated quantitatively with sulfuric acid, about 60 cc. of 5 N H_2SO_4 being required. The barium sulfate was filtered off by suction, after the addition of about 10 g. of active carbon. The hydrobromic acid was removed quantitatively by the use of lead carbonate (27 g.) followed by silver benzoate (5 g.). A more rapid removal is obtained if silver carbonate (28 g.) is used in place of lead carbonate. Soluble silver and lead salts were then removed as sulfides and the filtrate was concentrated to 200 cc. under reduced pressure. The slight quantity of dissolved benzoic acid was largely removed by several extractions

[4] Kunz and Hudson, THIS JOURNAL, 48, 2435 (1926).

[5] Goebel, *J. Biol.* Chem., 72, 801 (1927).

[6] Stoll and Kussmal, U. S. Patent 1,648,368, Nov. 8, 1927, describe a method for the preparation of aldonic acids in good yields from the corresponding sugars by chlorine oxidation in the presence of a bromide or iodide. The method is excellent for the commercial preparation of the acids but the conditions must be carefully controlled; consequently the method is not particularly desirable for general laboratory preparations.

with chloroform. The resulting aqueous solution of gluconic acid was colorless and did not reduce Fehling's solution. It was neutralized with calcium carbonate and concentrated to about 75 cc. The addition of ten volumes of 95% alcohol precipitated granular calcium gluconate, which weighed 21.5 g. after drying at 80°. The crude product was recrystallized by solution in 100 cc. of boiling water, addition of 2 g. of active carbon, filtration, concentration of the filtrate to 50 cc. and the addition of a small quantity of alcohol. After standing overnight in an ice box the crystals were separated, washed with 50% alcohol and dried; yield, 20.2 g. The mother liquor yielded only 0.25 g. The total yield of the recrystallized product was thus 96% of the theoretical. The specific rotation of the calcium gluconate in about 3% aqueous solution was $[\alpha]_D^{20} = +8.5$.

Preparation of the Cadmium Xylonate–Cadmium Bromide Double **Salt.**[7]—Six cc. of bromine (0.12 mole) was added to an ice-cold solution of 15 g. of d-xylose (0.1 mole) and 60 g. of barium benzoate in 1500 cc. of water and the oxidation conducted in the dark at 20–25°. The solution gave a negative Fehling test after thirty-six hours. The excess bromine and the barium were removed as described for the gluconate preparation and the dissolved benzoic acid was extracted with chloroform. The solution was then boiled with 28.5 g. of cadmium carbonate to neutral reaction, filtered and concentrated to a thin sirup under reduced pressure. Addition of a little alcohol and crystallization overnight in the ice box yielded 29.1 g. of the double salt, after washing with alcohol and drying at 80°. The mother liquor yielded 3 2 g. of crystals and the total yield was 90% of the theoretical. The specific rotation of the double salt in 1.5% aqueous solution was $[\alpha]_D^{20} = +8.8$. The only previous record seems to be that by C. A. Browne,[8] who found +7.4.

Preparation of Calcium **Lactobionate.**—Six cc. of bromine (0.12 mole) was added to an ice-cold solution of 36 g. of a-lactose monohydrate (0.1 mole) and 60 g. of barium benzoate (0.15 mole) in 1500 cc. of water and the oxidation conducted in the dark at 20–25°. The solution gave a negative Fehling test in from thirty-six to forty-eight hours. Free bromine and barium were removed as described for the gluconatc preparation and the hydrobromic acid was removed by stirring the solution with lead carbonate (27 g.), filtering off the lead bromide and removing the last traces of dissolved bromide with silver benzoate (5 g.).[9] The filtrate then showed no reaction with silver nitrate. Lead and silver were then removed as sulfides and benzoic acid was largely removed by several extractions with chloroform, finally blowing out the dissolved chloroform with air. The resulting solution contains no sugar by the Fehling test, is colorless and represents a nearly pure solution of lactobionic acid.

The substance may be further purified through its basic calcium salt. The addition of 37 g. of calcium hydroxide to the hot solution of lactobionic acid results in the slow formation of a fine white precipitate. After eighteen hours' standing at room temperature the precipitate was filtered off and washed three times with cold water saturated with calcium hydroxide. This precipitate was then suspended in 100 cc. of water, neutralized with carbon dioxide and the bicarbonate decomposed by passing air through the warmed solution. The filtrate was concentrated to 50 cc. on the water-bath by a current of air, transferred to a mortar and rubbed with 250 cc. of 95% alcohol. The precipitated gummy mass of neutral calcium lactobionate soon became granular on further rubbing. It was triturated successively with 50-cc. portions of 80%, 95% and absolute alcohol, collected on a filter and dried at 80"; yield, 34.5 g. The precipitation

---

[7] Rertrand, *Bull. soc. chim.*, 5, 554 (1891).

[8] C. A. Browne, "Inaugural Dissertation," Göttingen, 1901, p. 21.

[9] The hydrobromic acid may be more rapidly removed by using litharge in place of lead carbonate or by omitting lead entirely and using 28 g. of silver carbonate.

of lactobionic acid as its basic calcium salt by calcium hydroxide is not quite quantitative and it was possible by concentrating the mother liquor and adding alcohol to obtain about 3 g. more of an impure salt which reduced Fehling's solution slightly. Redissolving this in a little water and reprecipitating with alcohol purifies it. Three such purifications yielded 2.1 g. which contained no sugars. The total yield of neutral calcium lactobionate was thus 36.6 g. or 95.7% of the theoretical. The result shows that the procedure of bromine oxidation can be applied to compound reducing aldoses in a way that avoids hydrolysis and gives a nearly quantitative yield of the corresponding compound aldonic acid or its salts.

Hydrolysis of Lactobionic Acid to Galactose and Gluconic Acid.—It will be recalled that Fischer and Meyer[3] first carried out this hydrolysis and by it proved that lactose is a galactosidoglucose rather than a glucosidegalactose. So far as we are aware, the preparation has never been repeated though the beautiful reasoning from which the conclusion is deduced should appeal so strongly to students that the preparation might well be included in laboratory instruction. Doubtless the difficulties which Fischer records in preparing pure lactobionic acid have deterred others from repeating the work. It is believed that the directions which are now supplied improve the method to such an extent that it may be used generally by students.

A solution of 9 g. of calcium lactobionate in 100 cc. of 7.5% sulfuric acid was heated for three hours on the steam-bath and then neutralized with calcium carbonate (8 g.). The yellow solution was decolorized with carbon, filtered and concentrated under reduced pressure to 30 cc. The gradual addition of 70 cc. of hot methyl alcohol precipitated most of the calcium gluconate as a heavy sirup, the galactose remaining in solution. The liquid was decanted and the sirup was extracted thrice with 50 cc. of hot methyl alcohol. The alcoholic solutions were combined, purified with 1 g. of active carbon, filtered and evaporated to a sirup on a hot-plate by a current of air. Galactose crystallized from this sirup on standing overnight. It may be preferable to start crystallization by nucleation. The crystals were washed with 50% cold alcohol and dried at 65°; yield, 2.5 g. The mother liquor was concentrated to a sirup, which was dissolved in 50 cc. of hot methyl alcohol. A small quantity of insoluble material was filtered off and added to the calcium gluconate fraction. The alcoholic solution was concentrated as before and from it was obtained, after nucleation, 0.95 g. of crystalline galactose. The total yield of galactose was 3.45 g. or 80% of the theoretical. After one recrystallization from 10 cc. of hot water, the sugar showed a melting point of 165° and $[\alpha]^{20}_{D} = 79.7$ in aqueous solution.

The amorphous calcium gluconate was dissolved in 15 cc. of hot water and crystallized from the cooled solution by the addition of alcohol just short of cloudiness (about 5 cc.) and scratching the container. After standing overnight in an ice box the crystals were filtered off, washed with a little cold water and dried at 65°; yield, 4.8 g. The mother liquor yielded only 0.1 g. of crystals; total yield, about 95% of the theoretical. After one recrystallization and drying at 65° the salt showed $[\alpha]^{20}_{D} = +8.2$ in aqueous solution.

Summary

It is found that the use of a buffering salt of an organic acid, such as barium or calcium benzoate, during the oxidation of aldoses by bromine water, greatly increases the speed of the reaction, due to the maintaining

of a relatively low hydrogen-ion concentration and permits the oxidation of compound reducing aldoses, such as lactose, without complications from hydrolysis. The reaction mixture should be kept in the dark for best results. The yields of aldonic acid are nearly quantitative. In the case of lactose it is possible to oxidize it to nearly pure lactobionic acid, which can then be hydrolyzed to galactose and gluconic acid, both of which can be obtained in high yield. It is believed that the new directions make the method of bromine oxidation of aldoses much more precise and suitable for a wide range of preparations. Examples of the oxidation of glucose, xylose and lactose are given. It is suggested that the improved directions may be found suitable for laboratory instruction in sugar chemistry as well as for research.

HALOGEN-SUBSTITUTED AROMATIC PINACOLS AND THE FORMATION OF KETYL RADICALS, $R_2(IMgO)C—$

BY M. GOMBERG AND JOHN C. BAILAR, JR.[1]

RECEIVED MARCH 27, 1929 PUBLISHED JULY 5, 1929

It has been shown that aromatic ketones may be reduced to pinacols by a binary system consisting of a mixture of magnesium iodide and magnesium in anhydrous solvents[2]

$$2R_2CO \xrightarrow[Mg]{MgI_2} R_2(IMgO)C—C(OMgI)R_2 \xrightarrow{H_2O} R_2(HO)C—C(OH)R_2 + 2Mg(OH)I \quad (1)$$

We now find that this method can be applied to the preparation even of some of the halogenated pinacols with considerable success.

The decisive color effects given by some of our pinacols afforded an opportunity to test, by the application of Beer's law, the hypothesis that halomagnesium pinacolates dissociate into ketyls

$$R_2(IMgO)C—C(OMgI)R_2 \rightleftharpoons 2R_2(IMgO)C— \quad (2)$$

In the field of the pinacolin rearrangement, various investigators have reported upon the relative migratory tendency of bromophenyl and phenyl groups[3], and upon that of phenyl and biphenyl groups.[4] We have now studied the relative migratory tendencies of bromophenyl and biphenyl groups, in order to compare the actual findings with the predictions.

Preparation of the Halogen-Substituted Pinacols.—For preparative purposes, best results are obtained with tolerably concentrated solutions

---

[4] Ref. 2, p. 251.

of the ketones and magnesium iodide, and with the metal in the form of powder; the reduction is complete in a few hours, especially when the mixture is heated. However, for the study of the mechanism of the reaction, a modified procedure has been used in order to obtain further evidence whether the amount of magnesium consumed by the reduction fulfils the conditions of the hypothesis (Equation 1), and also in order to determine to what extent the halogen in the ketone molecule is detached from the benzene nucleus. Obviously, if no such halogen be split off, then for each equivalent of metallic magnesium consumed one equivalent of hydroxide ion should be formed on hydrolysis of the glycolate, and one mole of the ketone should be reduced to pinacol. On the other hand, if, in addition to reduction of the CO group, some halogen in the ring is removed, the amount of magnesium dissolved will be larger, and will be equivalent to the sum of the hydroxide ion and halide ion detached from the nucleus.

These measurements were carried out in the following manner. Somewhat more than 0.01 of a gram atom of iodine and an excess of magnesium powder were allowed to react in anhydrous ether, and the colorless solution was filtered into a 100-cc. graduate. Ordinarily most of the ether was boiled off and the solution was diluted to a known volume with dry benzene, retaining just enough ether to keep the magnesium iodide in solution. Two cc. of the solution was pipetted out and titrated for halide and the amount of the halide in the remaining solution was calculated. To this solution was added 0.01 of a gram molecule of the ketone and a weighed amount of magnesium shavings; the graduate was stoppered and shaken until the reaction was certain to have become complete. When the magnesium shavings remaining had settled, most of the liquid was pipetted off and quickly poured into water containing a known amount of standard sulfuric acid. The water layer was diluted to 500 cc. Of this, 100 cc. was titrated with sodium hydroxide and 25 cc. with silver nitrate. Simple calculation indicates how many equivalents of hydroxide ion have been produced by the hydrolysis of the pinacolate, and possibly other organomagnesium compounds, and how many equivalents of halide have been liberated from the ring. The magnesium shavings were filtered from the remaining liquid, quickly washed with ether, alcohol and water, then dried and weighed. The benzene layer was dried and allowed to evaporate. The product was macerated with petroleum ether or with alcohol in order to remove any unchanged ketone, and the pinacol remaining weighed.

It has been found that while *m*- and p-halogenated ketones are reduced to the corresponding pinacols, in the o-substituted ketones the halogen in the nucleus is also attacked by the magnesium. The reduction of the halogen-substituted ketones proceeds much more slowly than in the case of the ketones that Gomberg and Bachmann reduced. Instead of a few minutes, some of the bromobenzophenones are not completely reduced, even after shaking for several hours.

Gomberg and Bachmann reported that magnesium bromide can be substituted for the iodide in this reaction; the only difference is in the speed of the reduction. In the case of the halogenated benzophenones this does not seem to be the case. The conditions were varied widely in regard to concentration, time and temperature, but in every instance the ketone was recovered unchanged. This failure of magnesium bromide to react may be due to the extreme insolubility of the double compounds formed between the ketones and magnesium bromide.

Sym.-**4,4′-dibromobenzopinacol.**—This was prepared from 4-bromobenzophenone in accordance with the general directions. One one-hundredth of a mole of ketone gave rise to 0.009 equivalents (0.0045 mole) of the pinacol and 0.0093 equivalents of $(OH)^-$, and there was consumed 0.0095 equivalent of magnesium. No ring halogen was taken out by the metallic magnesium. In nearly all of the experiments, as in this one, slightly more than the theoretical quantity of magnesium was consumed. This discrepancy is explained if the formation of magnesium oxide, by the air left in the reaction vessel, is considered. When working with larger amounts and magnesium powder, the yield of pure product was 94%; and the crystals of the pinacol melted at 178°, as given by Montagne.

Sym.-**3,3′-dibromobenzopinacol.**—*m*-Bromobenzophenone gave with magnesium iodide a white double compound that did not completely dissolve until after three days. It was found that from 0.01 mole of ketone, 0.01 equivalent of pinacol had been produced, 0.0104 equivalents of magnesium had been used up, and no bromine had been removed from the benzene ring in the ketone molecule.

In another experiment 5.2 g. of the ketone was reduced in 60 cc. of solution in a few hours. The pinacol melted sharply at 147°, as Koopal has previously found. The yield of pure product was 85%.

Reduction of 2-Bromo- and of 2-Chlorobenzophenones by the Binary System.—The bromine atom of 2-bromobenzophenone is so labile that it may be removed almost completely from the molecule by the action of the magnesium and magnesium iodide mixture, although magnesium alone has no effect, even upon boiling for several days. It was never possible to get more than a very small amount of pinacol; this melted at 160–165°, as compared with 168° as given by Koopal.

A mixture of magnesium and magnesium bromide gave equally unsatisfactory results. In one experiment the vessel was heated to 70° for a week. The solution became pink but when the mixture was hydrolyzed it was found that no reduction had taken place, but that 17.5% of the ketone had been destroyed through loss of nucleus bromine.

2-Chlorobenzophenone behaves like its bromo-analog and repeated experiments indicated that a large amount of chlorine had been removed from the benzene nucleus.

This result with the o-halogeno-benzophenones is in harmony with other instances of lability of halogen atoms ortho to the carbonyl group. In addition to the well-known Ullmann syntheses from o-chlorobenzoic acid, one may mention the experience of Montagne and van Charante,[5] of Simonis and Kirschten[6] and of Zal'kind and Schmidt.[7]

---

[5] Montagne and van Charante, *Rec. trav. chim.*, 31,300 (1912).

[6] Simonis and Kirschten, *Ber.*, 45, 567 (1912).

[7] Zal'kind and Schmidt, *J. Russ. Phys.-Chem. Soc.*, 46,681 (1914).

4,4′,4″,4‴-Tetrabromobenzopinacol.—Magnesium iodide and 4,4′-dibromobenzophenone form a yellow double compound. After six hours' shaking with metallic magnesium the precipitate was completely dissolved and the solution was clear bright red; after ten hours more it was hydrolyzed. The pinacol melted at 179–180°, as Montagne[8] has reported. The yield of pure product was 94%.

The quantitative relationships involved are normal. From the reaction with 0.01 mole of ketone there was obtained 0.0091 equivalent of pinacol and 0.0091 equivalent of magnesium were used **up.** No bromide ion was present in the aqueous solution.

3,3′-Dibromobenzophenone.—To the Grignard reagent from 20 g. of *m*-dibromobenzene and 2 g. of magnesium was added an ether solution of 15.4 g. of *m*-bromocyanobenzene. The solution was refluxed for several hours and then hydrolyzed. After three recrystallizations from alcohol, the ketone melted sharply at 140°.[9] The yield of pure material was 13.7 g. or 46%. From the mother liquors was obtained a small amount of a substance consisting of very fine needles, m. p. 172°, doubtless the diketone, *m*-$BrC_6H_4COC_6H_4COC_6H_4Br$-*m*, (CO:CO = 1:3).

Anal. Calcd. for $C_{13}H_8OBr_2$: Br, 47.06. Found: Br, 47.20. *Mol. wt.* in benzene. Calcd.: 340. Found: 341. *Anal.* of diketone. Calcd. for $C_{20}H_{12}O_2Br_2$: Br, 36.04. Found: Br, 35.70.

3,3′,3″,3‴-Tetrabromobenzopinacol.—In the process of reduction the solution assumed a bright red color and after five days the double compound, ketone + MgI_2, had completely dissolved. The pinacolate was hydrolyzed in the usual way; it was found that no halogen had been removed from the ketone molecule and that the calculated amount of magnesium was used up. The pinacol was exceedingly difficult to purify and only 40% of the crystalline product could be obtained pure. After recrystallization from a mixture of alcohol and chloroform, it melted at 152–156°.

Anal. Calcd. for $C_{26}H_{18}O_2Br_4$: Br, 46.92. Found: Br, 46.99. *Mol. wt.* in benzene. Calcd.: 682. Found: 658.

3,4′-Dibromobenzophenone.—A mixture of 20 g. of 3-bromobenzoyl chloride, 50 cc. of bromobenzene and 14 g. of aluminum chloride was heated on the steam-bath for three days. The ketone was recrystallized from alcohol and then from benzene; the yield was 49%; m. p. 132°.[10]

For the purpose of verifying the constitution, the same ketone was prepared by the Grignard reaction, from *p*-dibromobenzene and m-bromocyanobenzene. After successive recrystallizations from benzene, acetone and alcohol, pure ketone was obtained, m. p. 130–131°. Mixed with the product obtained by the method of Friedel and Crafts, it melted at the same temperature. Here again a small amount of the diketone, *m*-$BrC_6H_4COC_6H_4COC_6H_4Br$-*m*, was formed (CO:CO = 1:4); m. p. 217–220°.

Anal. Calcd. for $C_{13}H_8OBr_2$: Br, 47.06. Found: Br, 47.09. *Mol. wt.* in benzene. Calcd.: 340. Found: 343. *Anal.* of diketone. Calcd. for $C_{20}H_{12}O_2Br_2$: Br, 36.04. Found: Br, 36.47.

Sym.-**3,3′,4,″4‴-Tetrabromobenzopinacol.**—The reduction of 3,4′-dibromobenzophenone proved to be a very difficult problem, although the **4,4′-dibromo-** and the 3,3′-dibromobenzophenones offered no difficulty. **A** solution of a large excess of magnesium iodide, from 8 g. of iodine and an excess of magnesium powder, in 50 cc. of ether was diluted to 100 cc. with benzene and 1 g. of the ketone was added. The vessel was tightly stoppered and the solution was heated to 75° for four days. At the end

of the first day a pink color had developed—this gradually darkened to deep red. Although the reduction had proceeded to the extent of 76%, only about 35% of the material could be obtained crystalline; m. p. 160–163°. No bromine was detached from the ketone.

Anal. Calcd. for $C_{26}H_{18}O_2Br_4$: Br, 46.92. Found: Br, 47.17. Mol. *wt.* in benzene. Calcd.: 682. Pound: 686.

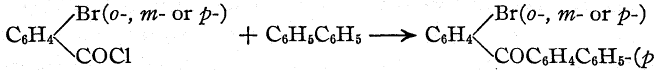
4-Chloro-4'-bromobenzophenone.—This ketone was prepared from 4-bromobenzoyl chloride, chlorobenzene and aluminum chloride. After recrystallization from alcohol and then from benzene it melted at 150°. The yield of pure product was 60%. The identical ketone was also prepared from 4-chlorobenzoyl chloride and bromobenzene.

Anal. Calcd. for $C_{13}H_8OBrCl$: Br, 27.07; Cl, 12.01. Found: Br, 27.46; Cl, 11.85. Mol. *wt.* in benzene. Calcd.: 295.5. Found: 289.

Sym.-**4,4'-dichloro-4'',4'''-dibromobenzopinacol.**—With magnesium shavings the reduction is somewhat slow, but after eight hours' shaking with magnesium powder the yield of the pinacol is quantitative. The halogen in the benzene nucleus is not affected by the metallic magnesium. The pinacol is crystallized from ether or acetone and melts at 169°.

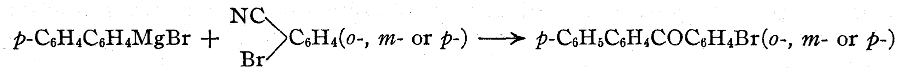
Anal. Calcd. for $C_{26}H_{18}O_2Br_2Cl_2$: Br, 26.98; Cl, 11.97. Found: Br, 26.52; Cl, 12.26. Mol. *wt.* in benzene. Calcd.: 593. Found: 633.

4-Bromo-4'-phenylbenzophenone, 3-Bromo-4'-phenylbenzophenone **and** 2-Bromo-**4'-phenylbenzophenone.**—These three ketones were prepared according to the reaction



$$C_6H_4{<}\begin{matrix}Br(o\text{-}, m\text{- or } p\text{-})\\ COCl\end{matrix} + C_6H_5C_6H_5 \longrightarrow C_6H_4{<}\begin{matrix}Br(o\text{-}, m\text{- or } p\text{-})\\ COC_6H_4C_6H_5\text{-}(p)\end{matrix}$$

The acid chloride from 20 g. of the corresponding bromobenzoic acid was dissolved in 150 cc. of carbon disulfide, 20 g. of biphenyl was added, and then 16 g. of aluminum chloride, in small portions. The mixture was warmed on the steam-bath for three days. After hydrolysis, the unchanged biphenyl was removed by distillation under reduced pressure. The ketones may then also be distilled under reduced pressure, though their boiling points are very high (near 300° at 15–18 mm.), or they may be purified by crystallization from alcohol or benzene. The yields were *o*-bromo-, 65; m-, 75 and *p*-, 55%. In order to verify the structure of the ketones they were prepared also from *p*-biphenylmagnesium bromide and the corresponding bromocyanide



$$p\text{-}C_6H_4C_6H_4MgBr + \begin{matrix}NC\\ Br\end{matrix}{>}C_6H_4(o\text{-}, m\text{- or } p\text{-}) \longrightarrow p\text{-}C_6H_5C_6H_4COC_6H_4Br(o\text{-}, m\text{- or } p\text{-})$$

The materials prepared by the two different methods melted at the same temperature in every case and mixed melting points showed no depression. The melting points, analyses and molecular weights are:

Ketone, $C_9H_{13}OBr$	M. p., °C.	Bromine Calcd.	Bromine Found	Mol. wt. Calcd.	Mol. wt. Found

Sym.-**4,4'-Dibromo-4'',4'''-Diphenylbenzopinacol.**—4-Bromo-4'-phenylbenzophenone, subjected to the action of the binary system, gave a light green solution of the ketyl. No bromine had been removed from the ketone molecule. The loss in weight of the magnesium and the amount of pinacol corresponded each to 0.009 equivalent. The pinacol melts at 158–159°.

Anal. Calcd. for $C_{38}H_{28}O_2Br_2$: Br, 23.67. Found: Br, 23.56. *Mol. wt.* in benzene. Calcd.: 676. Found: 652,

Sym.-**3,3′-Dibromo-4″,4‴-Diphenylbenzopinacol.**—This was obtained by reduction of the 3-bromo-4'-phenylbenzophenone in a solution containing largely benzene and but little ether. The yield of pinacol was 64%; m. p. 175°.

Anal. Calcd. for $C_{38}H_{28}O_2Br_2$: Br, 23.67. Found: Br, 23.63. *Mol. wt.* in benzene. Calcd.: 676. Found: 662.

Reduction of 2-Bromo-4'-Phenylbenzophenone.—This ketone, which contains a bromine atom ortho to the carbonyl group, offered the same difficulties as the 2-bromo- and 2-chlorobenzophenones. Bromine was removed from the ketone and no pinacol could be isolated.

Colorimetric Study of the Iodomagnesium Pinacolates

The iodomagnesium pinacolates are colorless in the solid state but when dissolved impart color to the solution. In this respect they behave very much like so many of the hexa-arylethanes, and, like the latter, they are assumed to dissociate with the production of free radicals; in this case the ketyls of the type $R_2C(OMgI)$, Equation 2. Unfortunately, it has not proved possible to isolate the pinacolates in such a degree of purity that molecular weight determinations could serve as definite proof of their dissociation. We have therefore sought to determine whether the color of solutions of pinacolates is intensified on dilution. Such deviation from Beer's law has, in many cases, furnished the only means of detecting changes on dilution, that is, dissociation into free radicals. Four iodomagnesium pinacolates, namely, those prepared from benzophenone, 4-bromobenzophenone, 4-chloro-4'-bromobenzophenone and 4-bromo-4'-phenylbenzophenone, have been studied from the point of view of Beer's law. The solutions of all of these pinacolates are red.

We have used the colorimeter previously described,[11] but so modified for the present purposes that, instead of solid pinacolates, the reduction solutions of the ketones could be introduced directly into the colorimeter. The ketone was reduced by means of the binary system in a Drechsel bottle; one arm of this was then connected with appropriate stopcocks to a hydrogen pressure tank and the other led to a filtering tube, from which the pinacolate solution could be discharged into each of the two comparator tubes and into the reservoir.

The iodomagnesium pinacolates are extremely sensitive to traces of air and great care was necessary in order to avoid decolorization of the solution. The entire system was repeatedly evacuated and filled with hydrogen. During the course of the experiment the apparatus was always kept under a positive pressure of hydrogen. All rubber connections were made of the best material available and were coated at the joints

[11] Gomberg and Sullivan, THIS JOURNAL. 44, 1825 (1922).

with paraffin or de Khotinsky cement. In some of the earlier experiments the filtering funnel was fitted with hardened filter paper instead of the alundum disk, as in the latter experiments, but it was found that the traces of air adsorbed by the paper were sufficient to decolorize a dilute solution of the pinacolate. The hydrogen was purified by passing over a red-hot copper spiral and through concentrated sulfuric acid. The solvent used for diluting the solutions was freed from dissolved air by bubbling pure hydrogen through it. Part of the pinacolate solution was forced through the filter tube into that arm (B) of the colorimeter where dilutions were to be made, the remainder into the reservoir. The liquid in the reservoir could then be raised into the second arm (A) of the colorimeter by pressure of hydrogen until the depth of color appeared the same in the two colorimeter tubes. Solvent was then forced into the colorimeter tube B and, when equilibrium had been established, the

depth of color in the two tubes was again compared and another dilution was made. The average of four or more readings is recorded in the table, the individual readings agreeing within one mm.

The results of typical experiments on each of the ketones studied are shown graphically in Fig. 1. They show unmistakably that in three of the four cases increase of color occurs. Consequently, the pinacolates dissociate on dilution, producing iodomagnesium ketyls.

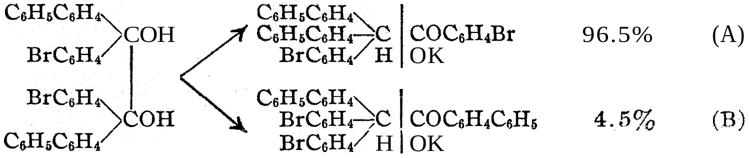
Fig. 1.

Comparative Migratory Tendencies of the Phenyl, p-Biphenyl, p-Bromophenyl and m-Bromophenyl Groups.—Montagne[3] has compared the migratory tendencies of the p-bromophenyl and the phenyl groups by rearranging the appropriate pinacol, and has found that 42 to 43% of the rearrangement is due to the migration of the p-bromophenyl group and 57 to 58% to that of the unsubstituted phenyl group. This work has been repeated and Montagne's results have been checked; our results have shown 41% of the migration due to the bromophenyl group and 59% to the phenyl group. Koopal has compared the migratory tendencies of the phenyl and the m-bromophenyl groups and has reported that only the substituted group migrates. This result has also been substantiated. Gomberg and Bachmann have shown that in the rearrangement of 4,4′-*sym.*-diphenylbenzopinacol, 92% of the migration is due to the *p*-phenylphenyl group and 8% to the unsubstituted group. Taking the migratory tendency of the phenyl group as 1, we may arrange the other groups as follows: p-bromophenyl, 0.695; m-bromophenyl, 0; p-phenyl-phenyl, 11.5. From these one may predict that the migratory tendencies of the *p*-bromophenyl and p-phenyl-phenyl groups should be in the relation of 1:16.5. Also, in a pinacol with a m-bromophenyl and p-phenyl-phenyl group, the latter group exclusively will migrate in the pinacolin rearrangement. Our actual results gave for the first case, 21.5 instead of 16.5; for the second, complete corroboration.

Rearrangement **of** ***Sym.*-4,4'-Dibromo-4'',4'''-Diphenylbenzopinacol.**—Two grams



of the pinacol was dissolved in a mixture of 40 cc. of benzene, 10 cc. of acetic acid and 20 cc. of acetyl chloride, and the solution was boiled gently for eight hours. The liquid was evaporated and the crystalline residue of the pinacolins was boiled twelve hours with alcoholic potassium hydroxide. After removal of the triarylmethane compound, the resulting acids were separated from each other by converting the phenylbenzoic acid into the insoluble barium salt. We obtained 0.038 g. of this salt (which is equivalent to 0.028 g. of the phenylbenzoic acid) and 0.589 g. of bromobenzoic acid. This corresponds to 4.5 and 96.5%, respectively. The migratory tendencies are as 1:21.5. The pinacolin (A), recrystallized from glacial acetic acid, melts at 227°.

Anal. Calcd. for $C_{38}H_{26}OBr_2$: Br, 24.32. Found: Br, 23.97. *Mol. wt.* in benzene. Calcd.: 658. Found: 637.

The methane compound that was obtained by the splitting of the pinacolin was recrystallized from glacial acetic acid and melts at 186°. Since this substance has not been described, it was synthesized from biphenyl-p-magnesium bromide and the methyl ester of *p*-bromobenzoic acid. The 4,4'-diphenyl-4''-bromotriphenylcarbinol that resulted melted at 248–250°; reduced by means of zinc and glacial acetic acid, it gave the methane, which after purification melted at 186°. Rearrangement of the pinacol by acetic acid and iodine gave the same pinacolin.

Anal. of Carbinol. Calcd. for $C_{31}O_{23}OBr$: Br, 16.29. Found: Br, 16.03. ***Anal.*** of Methane. Calcd. for $C_{31}H_{23}Br$: Br, 16.84. Found: Br, 17.20. ***Mot.*** wt. in benzene. Calcd.: 475. Found: 497.

Rearrangement **of** ***Sym.*-3,3'-Dibromo-4'',4''-Diphenylbenzopinacol.**—This rearrangement was carried out with 2 g. of pinacol in the same way as that of the 4,4'-dibromo-4'',4'''-diphenylbenzopinacol. The pinacolin gave only 0.002 g. of *m*-bromobenzoic acid, which is practically negligible. Thus the rearrangement is due entirely to the migration of the *p*-phenyl-phenyl group. The pinacolin, recrystallized from glacial acetic acid, melts at 202–203'.

Anal. Calcd. for $C_{38}H_{26}OBr_2$: Br, 24.32. Found: Br, 24.14. ***Mol. wt.*** in benzene. Calcd.: 658. Found: 652.

The constitution of the methane compound as 4,4'-diphenyl-3''-bromotriphenylmethane was verified by preparing it from the m-bromobenzoic ester exactly as was described for the b-bromomethane. The carbinol melted at 304° and the methane at 143°.

Anal. of Carbinol. Calcd. for $C_{31}H_{23}OBr$: Br, 16.29. Found: Br, 16.58. ***Anal.*** of Methane. Calcd. for $C_{31}H_{23}Br$: Br, 16.84. Found: Br, 16.70. ***Mol.*** wt. in benzene. Calcd.: 475. Found: 469.

This investigation has been carried out with the aid of a fellowship donated by the University of Michigan. We wish to express our gratitude for the aid so received.

Summary

1. It has been shown that the method suggested by Gomberg and Bachmann can be applied to the preparation of many halogeno-benzopinacols, especially those from ketones containing bromine or chlorine atoms meta or para to the CO group. When the halogen atom is in the ortho position, however, the magnesium of the reducing mixture tends to remove the halogen atom from the ketone molecule and no pinacol is formed.

2. By a study of the iodomagnesium pinacolates from the point of view of Beer's law, the existence of the equilibrium pinacolate   ketyl, has been demonstrated.

3. The relative migratory tendencies of the p-bromophenyl, *m*-bromophenyl and p-phenyl-phenyl groups have been determined by rearrangement of the appropriate pinacols to pinacolins. The results obtained are in good agreement with those obtained by previous investigators on different examples.

REDUCTION OF AROMATIC 1,2-DIKETONES BY THE BINARY SYSTEM MAGNESIUM IODIDE (OR BROMIDE) + MAGNESIUM

BY M. GOMBERG AND F. J. VAN NATTA[1]

RECEIVED MARCH 27, 1929 PUBLISHED JULY 5, 1929

Benzil is reduced by the binary system[2] to the unsaturated glycolate, iodomagnesium-stilbene–diolate, $C_6H_5(IMgO)C{=}C(OMgI)C_6H_5$, which when hydrolyzed gives benzoin. We have now extended this reaction to various benzils and find that it may be applied even to halogen-substituted diketones without danger of removing the halogen. Many of the reactions of the new unsaturated glycolates are analogous to those of the parent substance. More definite evidence, however, has now been obtained in regard to the reaction between the diketones and MgI_2 alone. It was reported that benzil liberates iodine from MgI_2, presumably in accordance with the reaction

$$RCOCOR + 2MgI_2 \rightleftharpoons R(IMgO)C{=}C(OMgI)R + I_2 \qquad (1)$$

About 5% of the calculated amount of iodine was found to be set free but most careful search failed to reveal benzoin in the hydrolyzed reaction product. Experience with substituted, more reactive, benzils here described has now definitely proved the correctness of that hypothesis.

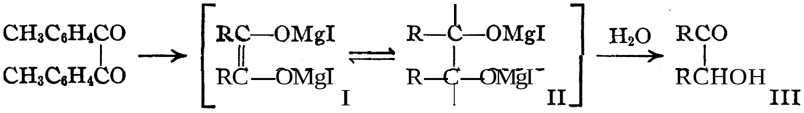
---

[1] The material here presented is part of a dissertation submitted by F. J. Van Natta to the Faculty of the University of Michigan in partial fulfilment of the requirements for the degree of Doctor of Philosophy, 1928.

[2] Gomberg and Bachmann, THIS JOURNAL, 49,2584 (1927).

When a diketone is added to the binary system, there is consequently liberation of some iodine from the magnesium iodide, with simultaneous formation of an equivalent amount of the unsaturated iodomagnesium glycolate. As reduction proceeds through the presence of the metallic magnesium, the red solution becomes still deeper in color, notwithstanding the fact that the iodine is being taken up by the metal. Later in the process the solution commences to lighten. While the reduction of benzil itself gave an almost colorless solution of the glycolate, the solutions which resulted on the reduction of substituted benzils are usually quite intensely colored. The loss in weight of metallic magnesium convinced us that all of the ketone had been reduced; quinhydrone formation between glycolate and unreduced ketone is, consequently, excluded. This persistence of color we are inclined to interpret by the supposition that we have here a partial opening of the double bond in the unsaturated glycolate, forming a single bond with the production of two trivalent carbon atoms. I $\rightleftharpoons$ II.[3] Those glycolates especially which contain methoxyphenyl and biphenyl groups give deep colors—an indication of the extent to which C^{III} is produced. This behavior is in harmony with the extensive formation of free radicals from those hexa-arylethanes, tetra-arylhydrazines and tetra-aryldicyano-ethanes[4] which contain either anisyl or biphenyl groups.

Reduction of *p*-Tolil by the Binary System



$$\begin{array}{c}CH_3C_6H_4CO\\ |\\ CH_3C_6H_4CO\end{array} \longrightarrow \left[\begin{array}{c}RC—OMgI\\ \|\\ RC—OMgI\end{array}_{\text{I}} \rightleftharpoons \begin{array}{c}|\\ R—C—OMgI\\ |\\ R—C—OMgI^-\\ |\end{array}_{\text{II}}\right] \xrightarrow{H_2O} \begin{array}{c}RCO\\ |\\ RCHOH\end{array}_{\text{III}}$$

The solution of magnesium iodide was prepared from 2.5 g. (0.02 atom) of iodine and 0.5 g. of magnesium powder in a mixture of 25 cc. of ether and 20 cc. of benzene; it was filtered from the excess of magnesium into a 70-cc. test-tube. To this solution was added 1.19 g. (0.005 mole) of tolil, and a weighed magnesium rod was inserted, followed by the addition of 20 cc. of benzene. The tube was tightly corked and placed on the shaking machine. In the course of several days the solution underwent the color changes deep red, light red and light brown. The transparent brown solution at this stage is very sensitive toward oxygen, the surface becoming opaque when exposed to air for an instant. The magnesium rod was removed, washed with benzene and reweighed. The solution was quickly decomposed with water, the precipitated magnesium hydroxide dissolved in standard sulfuric acid and the excess of acid titrated with standard alkali.

Anal. Loss in wt. of Mg, calcd.: 0.1216. Found: 0.1268. $Mg(OH)_2$ (in equivalents), calcd.: 0.01 equiv. Found: 0.0101 equiv.

The ether–benzene solution, which contained the hydrolyzed reduction product,

---

[3] Schlenk and Weickel, *Ber.*, 44, 1189 (1911); Ingold and Marshall, *J. Chem. Soc.*, 129, 3081 (1926).

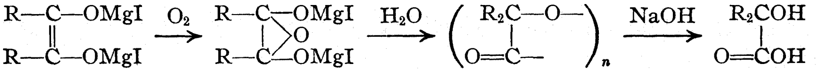
[4] Löwenbein and Gagarin, *Ber.*, 58, 2643 (1925); Blicke, THIS JOURNAL, 47, 1477 (1925).

was dried over sodium sulfate and evaporated spontaneously. The 1.15 g. of crystalline product consisted mainly of toluoin in admixture with a small amount of tolil. By fractional crystallization from hot alcohol the two products may be separated, but not quantitatively. For the estimation of the relative amounts of toluoin and tolil, the mixture in alcohol was boiled with excess of Fehling's solution and the amount of cuprous oxide, due to reduction by the toluoin, was determined. One mole of toluoin reduces two moles of cupric hydroxide. The reduction mixture from the 1.19 g. of tolil was in this manner found to consist of 77% of toluoin and 23% of tolil. In a separate experiment when hydrolysis was accomplished by means of boiled water and in a stream of nitrogen, the yield of toluoin was over 90%.

Reaction with Iodine and with Bromine.—The completely reduced solution of the glycolate, prepared as before from 1.19 g. of tolil, was treated with an equivalent amount of solid iodine and allowed to stand for two weeks. The reaction mixture was decomposed with dilute sulfuric acid and the free iodine titrated with sodium thiosulfate; about 52% of the iodine originally added was still present as such. Analysis by Fehling's solution showed the formation of an amount of tolil equivalent to the amount of iodine consumed. Evidently the reaction (Equation 1) reaches equilibrium when 48% of the glycolate has been oxidized.

With bromine the bromomagnesium glycolate reacted far more readily than with iodine, the end reaction being readily recognized and reached in a few minutes. The yield of tolil was over 90%.

Reaction with Dried Air



. The reduction of 1.19 g. of tolil was carried out in a corked Drechsel bottle. A slow stream of dried air was then passed through this solution, which soon became opaque; a large amount of free iodine separated. The mixture was hydrolyzed and worked up as with benzil. There were obtained 0.33 g. of the insoluble polymer, which accounts for 28% of glycolate oxidized, 0.54 g. of tolil and 0.32 g. of toluoin, which accounts for further 45% glycolate oxidized and for 27% glycolate which remained unaffected by the oxygen. The polymer shows no indication of melting below 360". On hydrolysis in the cold by aqueous potassium hydroxide it yields *p*-tolilic acid, m. p. 133–135°.[5]

p,p'-Dimethylstilbenediol-dibenzoate.—To a solution of the glycolate, from 2.38 g. of tolil, there was added 6 g. of benzoyl chloride and the mixture was allowed to stand for a short time. It was then decomposed with water and the product isolated in the usual manner. Crystallization of the crude ester from hot alcohol produced colorless needles of the dibenzoate; m. p. 135"; yield, 59%.

Anal. Calcd. for $C_{30}H_{24}O_4$: C, 80.36; H, 5.36. Found: C, 80.14; H, 5.43. Mol. *wt.* in benzene, calcd.: 448. Found: 442.

Reaction of Tolil with Magnesium Iodide Alone (Equation I).—To a filtered solution of 3.8 g. of magnesium iodide was added 1.19 g. of tolil. The resulting garnet-colored solution soon became turbid; within a half hour the tube was opaque. After standing in the dark for a month, the reaction mixture was decomposed with water. Titration with sodium thiosulfate showed the presence of 42% of the theoretical amount of iodine and analysis of the organic material showed that an equivalent amount of toluoin was produced.

Reduction by Magnesium Bromide and Magnesium.—To an ether solution of

---

[5] Gattermann, Ann., 347, 364 (1906).

magnesium bromide[6] in a 70-cc. test-tube was added 4.76 g. of tolil and 20 cc. of benzene. A deep yellow solution resulted with no trace of insoluble double compound. No bromine is liberated, in contrast to the liberation of iodine from the reaction between magnesium iodide and tolil. A weighed magnesium rod was inserted and the tube was corked. Soon a deep brown coloration formed around the ends of the magnesium rod; after several hours the entire solution had become very deep brown. The reduction was apparently complete after twenty hours' shaking. The amount of magnesium used up in the reduction and that of the magnesium hydroxide formed on hydrolysis of the glycolate agreed satisfactorily with the calculated values. A yield of 82% of pure toluoin was obtained.

Reduction of p-Anisil

Anisil, 1.35 g., was added to a solution of magnesium iodide and immediately there formed, as an oil, an orange double compound. A weighed magnesium rod was then inserted and the tube stoppered. In the course of two days the solution became very deep red, and finally red in color, the double compound having disappeared. It was not possible to obtain a completely colorless solution even after three weeks, the final color being garnet-red.

The magnesium rod had lost 0.1249 g. (calcd. loss, 0.1216 g.) and the theoretical amount of magnesium hydroxide was formed on hydrolysis of the glycolate. By analysis with Fehling's solution, 62% of the theoretical amount of anisoin was shown to be present; the low yield is attributed to the fact that the reduction product, being extremely sensitive toward oxygen, is reoxidized in air to anisil.

With magnesium bromide solution, anisil forms a deep yellow insoluble addition compound; due presumably to the insolubility of this compound, it was not possible to reduce anisil in the cold by the system, $MgBr_2 + Mg$, even on prolonged contact of the reactants.

Reactions of the Glycolate.—After twelve days' reaction with the theoretical amount of iodine, equilibrium (Equation 1) was reached, and the reaction had proceeded to the extent of 63%. Also, when anisil was treated with magnesium iodide in ether solution, there was liberation of iodine with formation of glycolate to the extent of about 20%.

Air was passed into a solution of the glycolate for three days; much iodine was liberated. From the hydrolyzed reaction mixture there was isolated the polymerized acid anhydride, 31%, a cream-colored insoluble substance, infusible below 360". Hydrolysis of this material by alkalies produced anisilic acid; m. p. 175".

Reduction of *p,p'*-Dichlorobenzil

The crude benzoin, prepared by the condensation of *p*-chlorobenzaldehyde by means of potassium cyanide, showed no tendency toward crystallization even after extraction of the benzene solution with sodium bisulfite and subsequent evaporation of the benzene. Consequently, the mixture was oxidized directly by means of nitric acid diluted with acetic acid. After purification and recrystallization of the crude benzil from glacial acetic acid, pure *p,p'*-dichlorobenzil was obtained; m. p. 195–196°.

Reduction by Magnesium Iodide and Magnesium.—To a solution of magnesium iodide was added 1.40 g. of the benzil and a weighed magnesium rod. Iodine was liberated and during the course of two days' shaking the color of the solution changed from deep brown to light cherry-red; the magnesium rod had lost in weight the theoretical amount. The mixture was hydrolyzed, the organic solvent was evaporated, and the dichlorobenzoin and benzil were separated from each other by means of cold

---

[6] Gomberg and Bachmann, THIS JOURNAL, 49, 245 (1927).

alcohol, the former being very much more soluble than the latter; in this way 9% of the benzil and **91%** of the benzoin were isolated. After recrystallization from dilute alcohol, the dichlorobenzoin melted at **85–87".** Hantzsch[7] reports the m. p., 88°.

Careful tests of the original aqueous washings from the reaction mixture failed to show the presence of any chloride ion. The nuclear chlorine atoms in the para position to the C=O group do not, then, react with metallic magnesium under the conditions of this experiment.

Attempts were made to reduce this benzil at room temperature by means of the system, $MgBr_2 + Mg$, but owing to the slight solubility of the benzil + $MgBr_2$ double compound, there was no reduction, and over **90%** of the benzil originally taken was recovered unchanged.

Reactions of the Glycolate.—With the theoretical amount of iodine after two weeks' shaking in the cold, the mixture was found to consist of equal parts of dichlorobenzil and of benzoin.

After two days' passage of air through a solution of it, the glycolate yielded **52%** of the white, insoluble anhydride of dichlorobenzilic acid polymer, **26%** dichlorobenzoin and **22%** of the benzil. The amorphous polymer decomposes at 320–340°; it gives a brilliant carmine color with concentrated sulfuric acid, identical with that shown by pure dichlorobenzilic acid.

p,p'-Dichlorostilbene-diol-dibenzoate.—After two recrystallizations from a mixture of benzene and alcohol, the product melted at 200–202°.

Anal. Calcd. for $C_{28}H_{18}O_4Cl_2$: Cl, **14.52.** Found: **Cl, 14.63.** *Mol. wt.,* calcd.: **489.** Found: **499.**

Reduction with Magnesium Iodide Alone.—The equilibrium: dichlorobenzil + $MgI_2 \rightleftharpoons$ glycolate + I_2, was attained when 62% of the benzil had reacted and formed the unsaturated glycolate.

Reduction of a-Naphthil

a-Naphthoin, $C_{10}H_7COCH(OH)C_{10}H_7$.—This product may be prepared by either of two methods: from a-naphthaldehyde, using potassium cyanide as a catalyst; or from a-naphthoic acid by reduction with magnesium iodide and magnesium powder in ether–benzene solution.[8] The solution, composed of **26.5** g. of a-naphthaldehyde, **10** g. of potassium cyanide, **100** cc. of alcohol and **50** cc. of water. was refluxed on the steam-bath for three hours; 5 g. more of potassium cyanide was added and the heating continued for eight hours. The solution was diluted with water and the organic material extracted with benzene. The benzene was evaporated and the residue, an oil, was redissolved in ether; on slow evaporation of the solvent, **3.4** g. of crystalline a-naphthoin was deposited. After recrystallization from hot alcohol, it melted at 138–139°.

Anal. Calcd. for $C_{22}H_{16}O_2$: C, 84.02; H, **5.13.** Found: **C, 84.51;** H, **5.14.**

The oil obtained on evaporation of the ether washings was oxidized to naphthil by copper sulfate in pyridine,[9] and **3.4** *g.* of naphthil was obtained as yellow prisms; m. p. 188–189°.

[9] Clarke and Dreger, "Organic Syntheses," John Wiley and Sons, Inc., New York, **1926,** Vol. **VI,** p. **6.**

The combined amount of naphthoin and naphthil obtained represented a yield of 26%, calculated on the amount of aldehyde taken.

The preparation of naphthoin from the acid is preferable to that from the aldehyde, as the acid is more accessible and the yield of naphthoin is somewhat larger.

The a-naphthil has previously been described by Stolle[10] who obtained it by the thermal decomposition of azo-dinaphthoyl, but in poor yield, owing to numerous side reactions. Quite recently Schlenk[11] described another method for the preparation of this substance. Our product agrees in its properties with those reported by these investigators.

The qninoxaline of a-naphthil, prepared by heating the diketone with *o*-phenylenediamine hydrochloride in pyridine, melts at 203–204°; color reaction with sulfuric acid, deep indigo-blue.

α-Naphthilic Acid $(C_{10}H_7)_2C(OH)CO_2H$.—This acid was prepared in good yield from a-naphthil by means of cold alcoholic potash in absolute ether solution.[12] It was recrystallized from benzene and petroleum ether; needle-like prisms, m. p., 137–138°, with decomposition. With concentrated sulfuric acid, naphthylic acid gives only a very slight brown color, while other benzilic acids produce brilliant colors.

Anal. Calcd. for $C_{22}H_{16}O_3$: C, 80 49; H, 4.88. Found: C, 80.76; H, 4.95. *Mol. wt.*, calcd.: 328. Found: by the ebullioscopic method, 330: by ignition of the Ag salt, 328.

Reduction of **α-Naphthil** by Magnesium Iodide and Magnesium.—The reduction was completed within three days. During this time, the mixture, originally deep red, became opaque, but the color finally lightened to a yellow. The magnesium rod had lost 97.6% of the theoretical amount. In order to minimize oxidation, the benzene solution was decomposed with boiled water in a stream of carbon dioxide and then the yield of pure a-naphthoin was 91%.

When dried air was allowed to pass for some time through a solution of the glycolate and the solution hydrolyzed, there was complete absence of the usual formation of the polymer-anhydride. Instead, there was formed naphthilic acid to the extent of 40%.

Reduction of *p,p'*-Diphenylbenzil

***p,p'*-Diphenylbenzoin,** $(C_6H_5C_6H_4)(HO)HCCO(C_6H_4C_6H_5)$.—A solution of 8 g. of *p*-phenylbenzaldehyde and 3 g. of potassium cyanide in 80 cc. of alcohol and 40 cc. of water was refluxed for two hours. A thick precipitate of the benzoin formed within fifteen minutes. The yield of the purified product was 95%. The diphenylbenzoin is soluble, 1 g. in about 115 cc. of cold benzene or ethyl acetate; it is quite soluble in hot pyridine, glacial acetic acid and xylene, and from these it may be obtained as a white powder; m. p. 168–170°.

Anal. Calcd. for $C_{26}H_{20}O_2$: C, 85.71; H, 5.50. Found: C, 85.42; H, 5.50. *Mol. wt.*, calcd.: 364. Found: 375.

***p,p'*-Diphenylbenzil,** $(C_6H_5C_6H_4)COCO(C_6H_4C_6H_5)$.—This was obtained by oxidizing the benzoin by means of copper sulfate in dilute pyridine. The yield of the diketone was 95%. The diphenylbenzil is very soluble in hot benzene and glacial acetic acid, but only slightly soluble in the cold solvents; light yellow needles, m. p. 141–142°. The quinoxaline, cream-colored iridescent needles, melts at 209–210°.

Anal. (of the benzil). Calcd. for $C_{26}H_{18}O_2$: C, 86.19; H, 4.97. Found: C, 86.03; H, 5.04. *Mol. wt.*, calcd.: 362. Found: 374.

[10] Stolle, *Rer.*, 45, 281 (1912).

[11] Schlenk and Bergmann, *Ann.*, **463,** 20 (1928).

[12] *Cf.* Schonberg and Keller, *Ber.*, 56, 1638 (1923).

In order to verify further the structure of our benzil, the latter was allowed to react with an excess of phenylmagnesium bromide, and *p,p'*-diphenylbenzopinacol was obtained; m. p., 197–199°.[13]

Reduction by Magnesium Iodide and Magnesium.—The loss in weight of magnesium was 99.2% of the theoretical. On hydrolysis of the glycolate, the corresponding benzoin was obtained in a yield of 88%, and was identical with the product obtained from *p*-phenylbenzaldehyde by means of the benzoin condensation.

The reaction between the iodomagnesium glycolate and iodine attained equilibrium when 47% of the theoretical amount of the halogen had reacted. By the action of dried air on a solution of the glycolate, the polymer of the diphenylbenzilic acid anhydride was formed to the extent of 35%. This polymer, decomposition point 250°, was hydrolyzed with difficulty by hot aqueous potassium hydroxide, ultimately yielding the corresponding *p,p'*-diphenylbenzilic acid, m. p., 185–188°; Schlenk reports 178–181°.[14] The polymer, like the acid, produces a brilliant green color with concentrated sulfuric acid.

p,p'-Diphenylstilbene-diol-dibenzoate.—Benzoyl chloride reacts vigorously with glycolate. The dibenzoate so formed behaves as though it were composed of a mixture of the two possible stereoisomers, *cis* and *trans;* when heated it passes through two points of fusion, 180 and 203°, with intermediate solidification. If this mixture of the isomers is fused by heating to 210° and then recrystallized from benzene, the colorless needles obtained melt sharply at 200–203°, indicating the presence of the more stable isomer alone. The lower-melting isomer could not be isolated in the pure state.

Reduction with Magnesium Iodide Alone.—In the case of this benzil, also, we obtained free iodine from the reaction between the benzil and magnesium iodide. Equilibrium was reached when about one-third of the benzil had been transformed to the glycolate.

Reduction of p-Phenylbenzil

p-Phenylbenzil, $(C_6H_5C_6H_4)COCO(C_6H_5)$.—This unsymmetrical benzil was prepared by the oxidation of benzyl-p-biphenyl ketone[15] in the cold with potassium permanganate in aqueous pyridine solution, with a yield of 64%. After recrystallization from hot alcohol the light yellow plates melted at 105°.

Anal. Calcd. for $C_{20}H_{14}O_2$: C, 83.92; H, 4.90. Found: *C,* 84.17; H, 5.05. ***Mol. wt.,*** calcd.: 286. Found: 293.

The structure of this benzil was further verified by its rearrangement to *p*-phenylbenzilic acid, which Schlenk[14] had prepared in another manner.

Reduction by the Binary Systems.—In the reduction by $MgI_2 + Mg$, practically the theoretical amount of magnesium was used up, and an equivalent amount of magnesium hydroxide was formed on hydrolysis. From the benzene solution there was obtained a good yield of the *p*-phenylbenzoin, but with a rather low melting point. A more easily purified product was obtained on reduction by the system $MgBr_2 + Mg$; the originally transparent yellow solution became deep brown, then finally orange. The crude benzoin, recrystallized from hot alcohol, was obtained as a pure white powder; m. p. 148–151°.

Anal. Calcd. for $C_{20}H_{16}O_2$: C, 83.33; H, 5.56. Found: C, 83.39; H, 5.61. ***Mol.*** wt., calcd.: 288. Found: 297.

It has not been established which isomer of the two possible benzoins this compound actually is.

Summary

The unsaturated halogeno-magnesium glycolates obtained by reduction of various aromatic diketones have been prepared and their reactions studied. Several new benzils and benzoins necessary for this work have been prepared and described.

It has been found that magnesium iodide alone, even in the absence of metallic magnesium, has a decided reducing action on the diketone; the amount of glycolate formed is dependent upon the equilibrium: diketone $+ \mathrm{MgI_2} \rightleftharpoons$ glycolate $+ \mathrm{I_2}$. The amount of iodine thus set free is from 16 to 50% of the theoretical.

The characteristic color changes during and at the end of the reduction process suggest the probability of the existence in the unsaturated glycolates of molecules containing each two trivalent carbon atoms $\mathrm{R—(XMgO)}\underset{|}{\mathrm{C}}—\underset{|}{\mathrm{C}}\mathrm{(OMgX)R}$.

THE SYNTHESIS OF SOME ALKYLXANTHINES[1,2]

BY D. W. MACCORQUODALE

RECEIVED APRIL 1, 1929 PUBLISHED JULY 5.1929

In view of the valuable therapeutic properties of the naturally occurring xanthine bases theophylline, theobromine and caffeine, it seems desirable that a study be made of the relation between the pharmacological action and the nature of the alkyl groups attached to the xanthine nucleus. This work was undertaken at the suggestion of the late Dr. A. S. Loevenhart in order to make available some of the homologs of these alkaloids for such a study.

A consideration of the various syntheses devised for the preparation of compounds of this type finally led to the selection of a series of reactions worked out by Emil Pischer during his researches on the purines and used by him for the preparation of caffeine.

Potassium urate when heated with phosphorus oxychloride yields 8-hydroxy-2,6-dichloropurine (I) which in turn is converted into trichloropurine when heated with a large excess of the same reagent.

The chlorine atom at position eight being much more firmly attached than those in the other positions, does not react with sodium ethoxide,

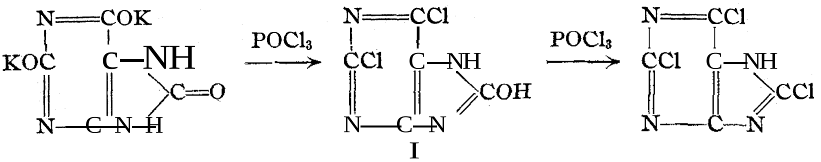
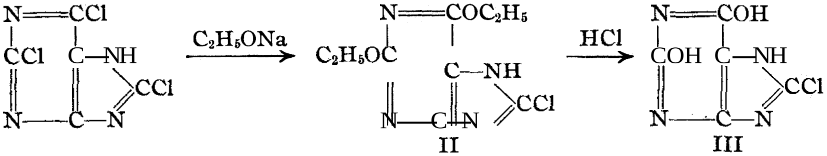
[1] This paper is constructed from a thesis submitted to the Graduate School of the University of Wisconsin in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry.

[2] Read before the Regional Meeting of the American Chemical Society at Minneapolis on June 19, 1928.



while the others are readily replaced by ethoxyl groups forming 2,6-diethoxy-8-chloropurine (II). The ethoxyl groups are easily replaced by hydroxyl groups by heating the compound with concentrated hydrochloric acid.



The 8-chloroxanthine (III) thus obtained is dissolved in aqueous potassium hydroxide solution and heated with two moles of alkyl iodide to form the 3,7-dialkyl-8-chloroxanthine, which can be reduced to the 3,7-dialkylxanthine or can be further alkylated to the 1,3,7-trialkyl-8-chloroxanthine, which upon reduction yields the 1,3,7-trialkylxanthine. It was found that the 1,3,7-trialkyl-8-chloroxanthine cannot be readily obtained in one operation from the 8-chloroxanthine, for even when a considerable excess of the alkylating agents is used the yield of trialkylchloroxanthine is small and the yield of dialkylchloroxanthine relatively large. This is in agreement with the work of Biltz and Peukert,[3] who found that the ethylation of 3-ethyl-8-chloroxanthine produced 3,7-diethyl-8-chloroxanthine, but they did not attempt to ethylate this compound further. Other evidence to show that xanthine and its substitution products are most readily alkylated in the 3- and 7-positions is found in the work of Fischer, who showed that theobromine is formed by the methylation of xanthine,[4] that the methylation of 3-methylxanthine also produces theobromine[5] and that chlorotheobromine can be obtained by the methylation of 3-methyl-8-chloroxanthine.[6]

By the ethylation of 8-chloroxanthine (III) a compound was obtained which analysis showed to be a diethylchloroxanthine. That it was the 3,7-isomer which would be expected was shown by its reduction to 3,7-diethylxanthine,[3] but its melting point (207°) did not agree with that of the 3,7-diethyl-8-chloroxanthine obtained by Biltz and Peukert, who give its melting point as 238°. They proved the structure of their compound by hydrolyzing it with alkali and obtaining 3,7-diethyluric acid,

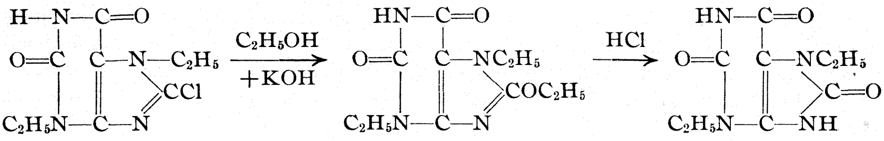
[5] Fischer and Ach, Ber., 31, 1987 (1898).

[6] Ref. 5, p. 1984.

which had previously been prepared by Biltz and Sedlatschek.[7] We attempted to hydrolyze our compound both by boiling with normal potassium hydroxide solution and by heating to 125–130° with concentrated hydrochloric acid for five hours; in both cases the substance was recovered unchanged.

The diethylchloroxanthine was finally converted into 3,7-diethyluric acid (IV) by treatment with potassium hydroxide in absolute alcohol solution. 3,7-Diethyl-8-ethoxyxanthine was thus obtained and this compound; upon heating with concentrated hydrochloric acid, readily yielded the 3,7-diethyluric acid prepared by Biltz and Sedlatschek.



IV

Contrary to statements of these authors it was found that this compound suffers decomposition at its melting point and so it proved unsuited for identification of the diethylchloroxanthine. This was accomplished, however, by methylation of the diethyl-8-chloroxanthine, treatment of the methyldiethyl-8-chloroxanthine with alcoholic potassium hydroxide to form methyldiethyl-8-ethoxyxanthine, and hydrolysis of this with concentrated hydrochloric acid to form a compound identical with the 1-methyl-3,7-diethyluric acid of Biltz and Sedlatschek,[7] thus proving the structure of the 3,7-diethyl-8-chloroxanthine, and also of each of the intermediate compounds.

By application of these methods the ethyl and normal butyl analogs of theobromine and caffeine were obtained as well as a number of other new purine derivatives.

Experimental Part

2,6-Dichloro-8-hydroxypurine.—This was prepared by Fischer's[8] method, the yields varying from 42 to 48% of the theoretical. It was partly purified by boiling with three times its weight of concentrated nitric acid, further purification being found unnecessary for the preparation of trichloropurine.

Trichloropurine.—This was prepared as described by Fischer[9] and yields of 46 to 50% of the theoretical were obtained.

2,6-Diethoxy-8-chloropurine.—The method described by Fischer[10] was followed except that it was found unnecessary to heat the reactants in a sealed vessel. The reaction takes place readily when a hot solution of trichloropurine in absolute alcohol is added slowly to a boiling alcoholic solution of sodium ethoxide under a reflux condenser; yield, 64–73% of the theoretical.

[7] Biltz and Sedlatschek, *Ber.*, 57, 179 (1924).

[8] Fischer and Ach, *ibid.*, 30, 2209 (1897).

[9] Fischer, *ibid.*, 30, 2221 (1897).

[10] Fischer, *ibid.*, 30, 2234 (1897).

8-Chloroxanthine.—This was prepared exactly as described by Fischer,[10] the yield of crude product being 91% of the theoretical. It was purified by crystallization of the ammonium salt from dilute ammonia solution and subsequent decomposition of the salt with hydrochloric acid.

3,7-Diethyl-8-chloroxanthine.—Five grams of 8-chloroxanthine was dissolved in 68.5 cc. (2.25 molecular equivalents) of 0.917 *N* potassium hydroxide solution and shaken in a closed vessel with 9.4 g. (2.25 molecular equivalents) of pure ethyl iodide for one and one-half hours at 90–95". The light yellow, crystalline product was filtered off, washed with water and then treated with very dilute potassium hydroxide solution whereupon it readily passed into solution, leaving practically no residue. In the cases of those runs in which larger proportions of alkali and ethyl iodide were used a small amount of alkali-insoluble material was obtained which proved to be triethylchloroxanthine but its amount was never very great. Upon addition of a slight excess of dilute hydrochloric acid to the filtrate the product was precipitated as a white crystalline solid which was filtered off, washed with cold water and dried at 110°. The yield was 1.6–2.0 g. For the analysis it was crystallized from a large volume of hot water and dried at 110°.

Anal. Calcd. for $C_9H_{11}O_2N_4Cl$: Cl, 14.62. Found: Cl, 14.40, 14.23.

The compound dissolves in hot alcohol, benzene, ethyl acetate and acetone, and separates in white needles on cooling. It is very soluble in chloroform. It is difficultly soluble in hot water and the solution on cooling deposits beautiful white needles. After one such crystallization the substance melted at 201–202° (207° corrected) and a recrystallization did not raise the melting point. Biltz and Peukert give the melting point of this substance as 238° but this is evidently a typographical error and probably 208" is intended. Upon reduction with hydriodic acid and phosphonium iodide it yields 3,7-diethylxanthine melting at 183°.

3,7-Diethyl-8-ethoxyxanthine.—One gram of 3,7-diethyl-8-chloroxanthine was heated for two hours under reflux with 15 cc. of a 10% solution of potassium hydroxide in absolute alcohol. A precipitate of potassium chloride began to separate soon after the heating was started. The alcoholic solution was evaporated to about 3 cc. and then was diluted with 20 cc. of water. The solution was acidified with hydrochloric acid and the voluminous white precipitate filtered off, washed with water and dried at 110°; yield, 0.93 g. After being recrystallized from alcohol the melting point was 207° (212° corrected). The analysis for nitrogen was by the Kjeldahl method.

Anal. Calcd. for $C_{11}H_{16}O_3N_4$: N, 22.22. Found: N, 22.12, 22.39.

The 3,7-diethyl-8-ethoxyxanthine is easily soluble in benzene, chloroform, acetone and glacial acetic acid. It dissolves sparingly in ether. Strong acids and dilute alkali solutions dissolve it easily. In hot water it dissolves only very slightly and separates again on cooling in fine, short, white needles. It is readily soluble in hot alcohol–water mixtures and these solutions on cooling deposit long, closely matted, hair-like needles.

3,7-Diethyluric Acid.—One tenth of a gram of 3,7-diethyl-8-ethoxyxanthine was dissolved in 2 cc. of concentrated hydrochloric acid (sp. gr. 1.19) and heated on the water-bath for twenty minutes. White crystals began to separate from the clear solution almost immediately. A little water was added and after the mixture had been cooled to 5° the product was filtered off and washed with a little cold water. The crystals were dissolved in 5 cc. of hot water to which had been added a drop of concentrated hydrochloric acid and 2 cc. of 95% alcohol. The solution was filtered and upon cooling and standing the diethyluric acid separated in small white crystals which were filtered off, washed with water and dried in the oven at 110°. The melting point was 360–365° (371–376° corrected) with decomposition. Biltz and Sedlatschek give the melting point as 350–355° without decomposition.

1-Methyl-3,7-diethyl-8-chloroxanthine.—Two grams of 3,7-diethyl-8-chloroxanthine was dissolved in 100 cc. of 0.917 N potassium hydroxide solution and 2 g. (excess) of pure methyl iodide was added. This was sealed in a pyrex bomb tube and shaken at 80–85° for two and one-half hours. When cool the crystalline product was filtered off and washed with very dilute potassium hydroxide solution to remove any unchanged diethylchloroxanthine and free iodine. After washing with water and drying at 105° it weighed 1.78 g. For the analysis it was recrystallized from 50% alcohol, from which it separated in beautiful white needles which melted at 113° (114.5° corrected).

Anal. Calcd. for $C_{10}H_{13}O_2N_4Cl$: Cl, 13.82. Found: Cl, 13.97, 13.73.

The compound is insoluble in water and in alkali but dissolves readily in strong hydrochloric acid. It dissolves in acetone, chloroform, benzene, ether and glacial acetic acid.

1-Methyl-3,7-diethyl-8-ethoxyxanthine.—Seven-tenths of a gram of 1-methyl-3,7-diethyl-8-chloroxanthine was heated under a reflux condenser with a 10% solution of potassium hydroxide in absolute alcohol for forty minutes. Potassium chloride separated rapidly during the heating. Most of the alcohol was removed by evaporation and the solution was acidified with dilute acetic acid. The voluminous white product was filtered off, washed with water and dried; yield 0.43 g. It was recrystallized from 50% alcohol; m. p. 111° (112° corrected).

Anal. Calcd. for $C_{12}H_{18}O_3N_4$: N, 21.05. Found: N, 20.68.

The compound is insoluble in water and in alkali but dissolves readily in strong hydrochloric acid. It is readily soluble in alcohol, ether, benzene, acetone and chloroform.

1-Methyl-3,7-diethyluric Acid.—Fifty milligrams of 1-methyl-3,7-diethyl-8-ethoxyxanthine was dissolved in 3 cc. of concentrated hydrochloric acid and heated on the water-bath for fifteen minutes, the solution being allowed to evaporate to dryness at the end of this period. The white crystalline residue was dissolved in 1.5 cc. of boiling 95% alcohol and chilled to −10°. The white crystalline product was filtered off and washed with a few drops of alcohol. It melted sharply without decomposition at 258° (266° corrected). Biltz and Sedlatschek obtained this compound by heating 1-methyl-3,7,9-triethyluric acid with hydrochloric acid and found it to have a melting point of 257–258°.

1,3,7-Triethyl-8-chloroxanthine.—Four grams of 3,7-diethyl-8-chloroxanthine was dissolved in 18.4 cc. of 0.895 N potassium hydroxide and 5.0 g. of pure ethyl iodide added. The mixture was shaken in a closed vessel at 90–95° for two hours. The solid product was filtered off and leached with very dilute potassium hydroxide solution and then washed with water. The air-dried product weighed 2.05 g. Upon acidification of the potassium hydroxide solution with hydrochloric acid, 0.48 g. of unchanged diethylchloroxanthine was obtained. The product was recrystallized from 50% alcohol; m. p. 79–80°.

Anal. Calcd. for $C_{11}H_{15}O_2N_4Cl$: Cl, 13.10. Found: Cl, 12.89, 12.81.

The triethyl-8-chloroxanthine is insoluble in water and alkali but dissolves readily in hydrochloric acid. It is also soluble in alcohol, ether, acetone, benzene, chloroform and glacial acetic acid.

1,3,7-Triethylxanthine.—Four grams of pure 1,3,7-triethyl-8-chloroxanthine was dissolved in 20 cc. of fuming hydriodic acid (sp. gr. 1.96) and heated on the water-bath with the occasional addition of small amounts of finely pulverized phosphonium iodide. When iodine was no longer liberated the reduction was over. This required about eight hours. The solution was evaporated on the water-bath until only a thick paste of crystals of the hydriodide of triethylxanthine remained. The crystals were dissolved in 15 cc. of water and dilute ammonium hydroxide solution added to liberate the base. The solution was chilled and the white crystalline product filtered off, washed and dried in the air; wt. 3.05 g. From the mother liquor a small crop of crystals was obtained upon concentration. The compound was purified by recrystallization from dilute alcohol; m. p. 113°.

Triethylxanthine was first obtained by Scarlat[11] by means of Traube's synthesis. He gives the melting point as 115°. Like caffeine it has no acid properties but acts as a weak base. It is difficultly solpble in water but dissolves readily in strong hydrochloric acid. It also dissolves in alcohol, ether, acetone, benzene, chloroform and glacial acetic acid. It can be volatilized undecomposed at atmospheric pressure.

3,7-Dibutyl-8-chloroxanthine.—The butylation of 8-chloroxanthine was found to proceed in exactly the same manner as the ethylation, that is, upon shaking the chloroxanthine with an excess of alkali and butyl iodide at 130°, the main product obtained was a dibutylchloroxanthine, only a very small amount of the tributyl derivative being formed. For the preparation of 3,7-dibutyl-8-chloroxanthine, 10.0 g. of 8-chloroxanthine was dissolved in 126 cc. of 0.895 N potassium hydroxide and 20.8 g. of pure *n*-butyl iodide was added. This was shaken in a closed vessel for two hours at 130°. The solid product was filtered from the well-cooled reaction mixture and purified in the manner described for 3,7-diethyl-8-chloroxanthine. The yield of crude product was 7.9 g. After recrystallization from 60% alcohol the melting point was 142.5 (145° corrected).

Anal. Calcd. for $C_{13}H_{19}O_2N_4Cl$: Cl, 11.87. Found: Cl, 11.86.

The 3,7-dibutyl-8-chloroxanthine is very slightly soluble in boiling water and separates in crystals on cooling. It dissolves readily in dilute alkali and in strong hydrochloric acid. It is readily soluble in alcohol, acetone, benzene, chloroform and glacial acetic acid, and somewhat less readily soluble in ether.

3,7-Dibutylxanthine.—This was prepared by the reduction of 3,7-dibutyl-8-chloroxanthine in a manner precisely the same as that described for the preparation of triethylxanthine. From 1 g. of 3,7-dibutyl-8-chloroxanthine 0.83 g. of dibutylxanthine was obtained which after recrystallization from dilute alcohol had a melting point of 124–125° (127° corrected).

Anal. Calcd. for $C_{13}H_{20}O_2N_4$: N, 21.20. Found: N, 21.11, 21.24.

The 3,7-dibutylxanthine is very sparingly soluble in boiling water, from which it crystallizes on cooling. Dilute alkali and strong hydrochloric acid dissolve it readily. It dissolves with ease in alcohol, acetone, benzene, chloroform and glacial acetic acid, and a little less readily in ether.

1,3,7-Tributyl-8-chloroxanthine.—Six grams of 3,7-dibutyl-8-chloroxanthine was dissolved in 28.2 cc. (25% excess) of 0.895 N potassium hydroxide solution and 4.7 g. (25% excess) of pure n-butyl iodide added. The mixture was shaken in a closed vessel at 125–130° for two hours. When the vessel was allowed to cool the product remained as a viscous brown oil. The reaction mixture was shaken with 20 cc. of pure redistilled benzene to dissolve the oil and the benzene solution was shaken three times with 5% potassium hydroxide solution. From this alkaline solution there was recovered 0.4 g. of dibutylchloroxanthine by acidification with dilute hydrochloric acid. The benzene solution was washed three times with water and then dried over anhydrous sodium sulfate. The benzene solution was filtered into a small distilling flask and the solvent distilled off, the last traces being removed at 10-mm. pressure and the temperature of the boiling water-bath. The flask was then heated strongly, the pressure being maintained at 10 mm., and the product began to distil at 232° (uncorrected), about 80%

---

[11] Scarlat, Bull. Sciences *Bucarest,* 13, 155–159 (1903).

of it distilling before the temperature reached 240°. The distillate was light yellow in color and weighed 4.2 g.

Anal. Calcd. for $C_{17}H_{27}O_2N_4Cl$: Cl, 9.99. Found: Cl, 9.92, 9.98.

The 1,3,7-tributyl-8-chloroxanthine is a viscous oil, soluble in alcohol, ether and benzene. An unsuccessful attempt was made to form the hydrochloride salt by precipitation from dry ether and benzene solutions with dry hydrogen chloride.

1,3,7-Tributylxanthine.—This compound, which is the butyl analog of caffeine, was prepared by the reduction of 1,3,7-tributyl-8-chloroxanthine with fuming hydriodic acid and phosphonium iodide in the manner already described. The free base was obtained as a colorless oil which solidified when chilled with ice and salt. It was filtered off and washed with water, and after drying thoroughly was dissolved in 155 cc. of absolute alcohol and the solution was saturated with dry hydrogen chloride gas. Then 30 cc. of dry ether was added and the solution cooled to 0° whereupon the hydrochloride of tributylxanthine separated almost completely in white crystals which were filtered off and washed with dry ether. The yield was 2.20 g. from 3.30 g. of tributylchloroxanthine. The salt was recrystallized from an alcohol—ether solution (1:2) saturated with hydrogen chloride and after being washed with dry ether was dried in a vacuum desiccator over calcium chloride and solid caustic potash. The melting point was 131–134°.

Anal. Calcd. for $C_{17}H_{29}O_2N_4Cl$: Cl, 9.94. Found: Cl, 9.75, 9.51.

The free base was liberated from the salt by dissolving the latter in a few cc. of 95% alcohol and adding dilute ammonium hydroxide solution. Upon chilling the solution in ice and salt the tributylxanthine separated as a colorless oil which gradually crystallized and was filtered off and washed with dilute alcohol. It was recrystallized again from alcohol, being obtained as pure white crystals which melted at 4142°.

Anal. Calcd. for $C_{17}H_{28}O_2N_4$: N, 17.56. Found: N, 17.56.

The 1,3,7-tributylxanthine is a white crystalline solid which is practically insoluble in water and alkali. It dissolves readily in strong acids, forming salts which are hydrolyzed upon dilution. It can be volatilized at atmospheric pressure without decomposition. It dissolves easily in the common organic solvents such as alcohol, ether, acetone, benzene, chloroform and glacial acetic acid.

To Dr. Homer Adkins, under whose supervision this work was carried out, the author wishes to express his thanks for many valuable suggestions made during the course of this investigation.

Summary

1. The ethyl and the n-butyl analogs of caffeine and theobromine have been prepared, the latter for the first time and the former by a method not heretofore used for the preparation of these compounds.

2. A number of other new derivatives of xanthine have been synthesized and described.

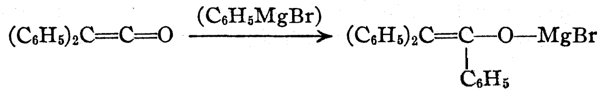
THE FORCED REACTION OF PHENYL ISOCYANATE, PHENYL ISOTHIOCYANATE AND BENZOPHENONE-ANIL WITH PHENYLMAGNESIUM BROMIDE. AN UNUSUAL TYPE OF 1,4-ADDITION TO A CONJUGATED SYSTEM THAT IS PART ALIPHATIC AND PART AROMATIC

BY HENRY GILMAN, J. E. KIRBY AND C. R. KINNEY

RECEIVED APRIL 5, 1929 PUBLISHED JULY 5, 1929

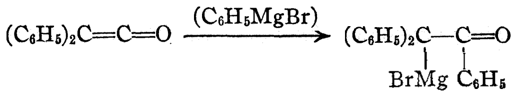
Introduction

In a study of compounds having terminal cumulated unsaturated groups, Gilman and Heckert[1] showed that phenylmagnesium bromide added to diphenylketene in the following manner



$$(C_6H_5)_2C{=}C{=}O \xrightarrow{(C_6H_5MgBr)} (C_6H_5)_2C{=}\underset{C_6H_5}{\underset{|}{C}}{-}O{-}MgBr \qquad (I)$$

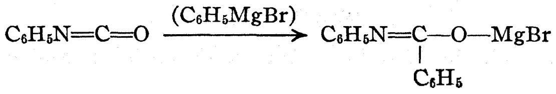
and not as follows



$$(C_6H_5)_2C{=}C{=}O \xrightarrow{(C_6H_5MgBr)} (C_6H_5)_2\underset{BrMg}{\underset{|}{C}}{-}\underset{C_6H_5}{\underset{|}{C}}{=}O \qquad (II)$$

The mode of addition represented by Reaction II is that which was currently in vogue at that time, inasmuch as the addition reactions of ketenes were then assumed to take place through a preliminary addition to the ethylenic linkage. Subsequently the earlier explanations for many addition reactions were altered to conform with that mechanism which postulates prior addition to the carbonyl group.[2]

Because of the marked similarity in many respects between ketenes and isocyanates, it might have been predicted that phenylmagnesium bromide would add to the terminal —C=O group and not to the —N=C group of phenyl isocyanate, in the following manner



$$C_6H_5N{=}C{=}O \xrightarrow{(C_6H_5MgBr)} C_6H_5N{=}\underset{C_6H_5}{\underset{|}{C}}{-}O{-}MgBr \qquad (III)$$

This reaction was studied by Gilman and Kinney[3] and although they did not get unequivocal proof for the type of addition postulated in Reaction III, they did show that addition could not have taken place at the —N=C linkage. By analogy with the reaction of the related phenylisothiocyanate, $C_6H_5N{=}C{=}S$, and by the established relative inertness of the —OMgX grouping,[4] they showed that Reaction III was undoubtedly

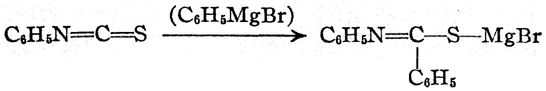
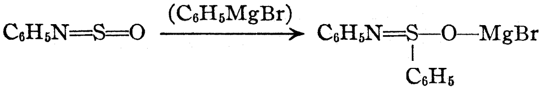
[4] Gilman and Schulze, *Rec. trav. chim.* 47,752 (1928).

correct. Gilman and Kinney[3] showed very definitely that phenylmagnesium bromide reacts with phenyl isothiocyanate as follows



$$C_6H_5N{=}C{=}S \xrightarrow{(C_6H_5MgBr)} C_6H_5N{=}\underset{\displaystyle C_6H_5}{\underset{|}{C}}{-}S{-}MgBr \qquad \text{(IV)}$$

Subsequently Gilman and Morris[5] showed that the following reaction very probably occurs between phenylmagnesium bromide and thionylaniline



$$C_6H_5N{=}S{=}O \xrightarrow{(C_6H_5MgBr)} C_6H_5N{=}\underset{\displaystyle C_6H_5}{\underset{|}{S}}{-}O{-}MgBr \qquad \text{(V)}$$

There are two marked similarities between these several reactions. First, in each case addition takes place at the ultimate unsaturated group of these types having terminal cumulated unsaturated groups. Second, the reaction stops at this unsaturated group even with a liberal excess of phenylmagnesium bromide and extended refluxing at the low temperatures given by ether as a medium. This is hardly unexpected with ketenes inasmuch as such subsequent addition would involve addition to an ethylenic linkage, and Gilman and co-workers[6] have made a good case for the non-addition of the Grignard reagent to an ethylenic linkage. We are not so certain of the —N═S group in thionylaniline, but if such a grouping has anything in common with a related —N═O group, then it is to be expected that the —N═S group should add phenylmagnesium bromide.[7]

We can speak with greater assurance and definiteness on the —N═C linkage in phenyl isocyanate and phenyl isothiocyanate. It is known that organomagnesium halides add to the —N═C— group. Accordingly, it is reasonable to expect when phenyl isocyanate (or phenyl isothiocyanate) is refluxed for an extended time and at elevated temperatures with an excess of phenylmagnesium bromide, that subsequent to addition to the terminal —C═O (or —C═S) group, a second molecule of Grignard reagent should add to the —N═C— linkage; this explains the primary objective of this paper.

When phenylisocyanate was refluxed in an ether–toluene mixture (70–80°) with a liberal excess (5 or 6 equivalents) of phenylmagnesium bromide for about eight hours, the chief product obtained (in yields

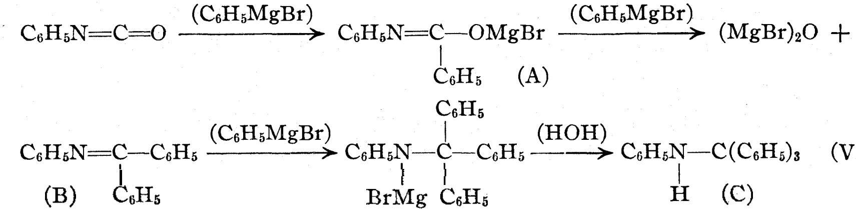
---

[5] Gilman and Morris, This Journal, 48,2399 (1926). See Footnote 6 in the paper by G. and M. on the reaction between RMgX compounds and aliphatic diazo compounds and diazo-imides.

[6] One of the more recent references to the non-addition of RMgX compounds to an ethylenic linkage is Gilman and McGlumphy, *Rec. trav. chim.*, 47, 418 (1928). This paper contains references to earlier studies.

[7] See Gilman and McCracken, This Journal, 49,1052 (1927), and 51,821 (1929), for the reaction of the Grignard reagent with nitroso and nitro compounds.

reaching 44%) was a compound melting at 144°. The ultimate analysis and molecular weight determination showed the compound to have a molecular formula agreeing with triphenylmethylaniline. It is easy to understand, from the following reactions, how triphenylmethylaniline might have formed



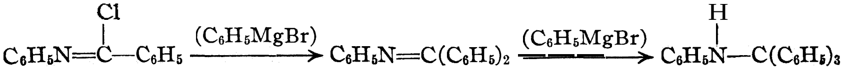
$$C_6H_5N{=}C{=}O \xrightarrow{(C_6H_5MgBr)} C_6H_5N{=}\underset{\substack{|\\ C_6H_5}}{C}{-}OMgBr\ \text{(A)} \xrightarrow{(C_6H_5MgBr)} (MgBr)_2O +$$

$$\text{(B)}\ C_6H_5N{=}\underset{\substack{|\\ C_6H_5}}{C}{-}C_6H_5 \xrightarrow{(C_6H_5MgBr)} C_6H_5\underset{\substack{|\\ BrMg}}{N}{-}\overset{\substack{C_6H_5\\ |}}{\underset{\substack{|\\ C_6H_5}}{C}}{-}C_6H_5 \xrightarrow{(HOH)} C_6H_5\underset{\substack{|\\ H}}{N}{-}C(C_6H_5)_3\ \text{(C)} \quad \text{(VI)}$$

The same product would result if prior to or simultaneous with replacement of the —OMgBr group by C_6H_5— the phenylmagnesium bromide had added to the —N=C— group in Compound (A).

The possible formation of triphenylmethylaniline, Compound (C), was rendered more reasonable when it was found that the 144° compound was obtained in equally high yields from the forced reaction not only with phenyl isocyanate but also with phenyl isothiocyanate and benzophenone-anil (Compound (B)). The formation of the same compound from the three different reactants proved that the terminal oxygen and sulfur, respectively, were replaced by two phenyl groups, and made it altogether reasonable that benzophenone-anil was an intermediate compound.

However, despite the fact that the melting point of our compound was near that of triphenylmethylaniline (147°) and that every reasonable prediction led to the expected formation of triphenylmethylaniline from the three compounds studied, the 144° compound certainly was not triphenylmethylaniline. Furthermore, the expected triphenylmethylaniline could not have been, in all probability, an intermediate. This was shown in an experiment in which triphenylmethylaniline was refluxed in an ether–toluene mixture for ten hours with five equivalents of phenylmagnesium bromide. Practically all of the triphenylmethylaniline was recovered unchanged. Our confusion was increased when we later found that Busch and Fleischmann[8a] obtained some triphenylmethylaniline from the reaction between benzanilideimidechloride and phenylmagnesium bromide. The formation of triphenylmethylaniline in their reaction is readily understandable[8b] from the following



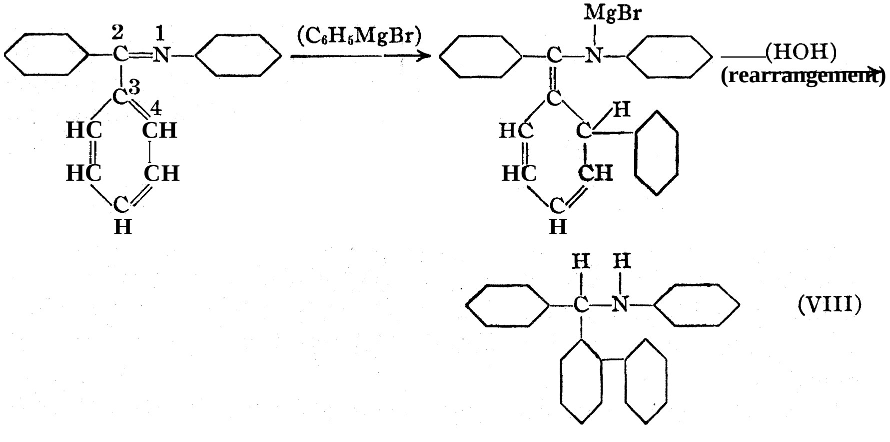
$$C_6H_5N{=}\overset{\substack{Cl\\ |}}{C}{-}C_6H_5 \xrightarrow{(C_6H_5MgBr)} C_6H_5N{=}C(C_6H_5)_2 \xrightarrow{(C_6H_5MgBr)} C_6H_5\overset{\substack{H\\ |}}{N}{-}C(C_6H_5)_3 \quad \text{(VII)}$$

---

[8] (a) Busch and Fleischmann, *Ber.*, **43**, 2553 (1910). (b) The triphenylmethylaniline which they obtained might have come from reactions other than those illustrated in Reaction VII. For example, there may have been addition to the —N=C linkage prior to or simultaneous with replacement of the chlorine by a phenyl group.

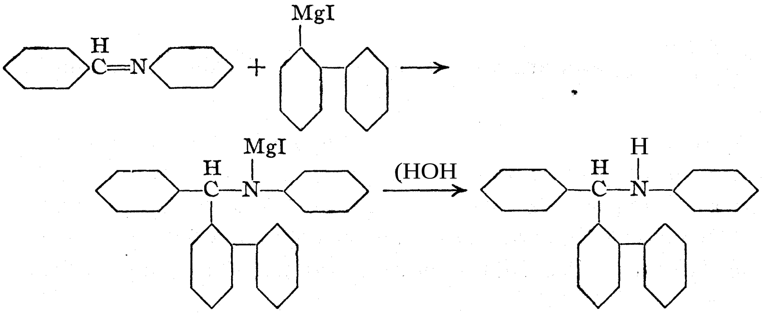
It is interesting to recall their observation that they were unable to repeat this experiment. Also, their major reaction product was benzophenone-anil (Compound (B)). Although triphenylmethylaniline was not isolated in our several experiments, it would be unwise to say that it was not present, because the forced conditions of the reaction gave oily products which were not altogether tractable.

Triphenylmethylaniline hydrolyzes with ease to triphenylcarbinol and aniline. The 144° compound when hydrolyzed gave phenylfluorene, 
, and aniline. It was next shown that under our conditions of hydrolysis, triphenylcarbinol did not go over to phenylfluorene. The identification of phenylfluorene as a product of hydrolysis of the 144° compound was of help in suggesting several possible formulas for the 144° compound. Some critical experiments showed the impossibility of all but one of these formulas. We finally showed that the 144° compound must be *o*-**phenylbenzohydrylaniline,** 
. The idea for this compound came with the thought that inasmuch as addition of phenylmagnesium bromide probably did not take place at the —N=C— linkage (as evidenced by the absence of triphenylmethylaniline), 1,4-addition might have taken place with the conjugated system formed by the —N=C— group and **a** so-called ethylenic linkage in one of the phenyl groups attached to carbon, as follows



(VIII)

So far as we[7] know, a reaction of this type has not been reported with any class of compounds. A great deal of our present knowledge on the mode of 1,4-addition to conjugated systems rests on the excellent and thorough studies of Kohler and co-workers. Their studies were carried out, in the main, with organomagnesium halides. The rearrangement postulated in Reaction VIII may or may not be correct; that remains to be determined. However, there is no doubt concerning the structure of our o-phenylbenzohydrylaniline. It was synthesized as follows



(IX)

Over and against this method for the proof of structure of the *o*-phenylbenzohydrylaniline, a question may properly be raised on the choice of an anil (in this case, benzalaniline) in establishing the structure of a compound which was formed in a so-called abnormal manner from an anil (namely, benzophenone-anil). But benzophenone-anil is not benzalaniline, and we have shown that benzalaniline behaves normally even under forced conditions with phenylmagnesium bromide. Of course, there remains the possibility of abnormal reactions with *o*-biphenylmagnesium iodide. We know of no such abnormal reactions, but to remove all doubt the o-phenylbenzohydrylaniline should be synthesized by a reaction not involving RMgX compounds; this we propose to do.

Additional evidence is necessary for the support of Reactions VIII and IX. When the intermediate addition compound of the forced reaction between phenyl isocyanate and phenylmagnesium bromide, namely, Compound (D), is treated with diethyl sulfate, the —NMgBr grouping should be converted to an —NC_2H_5 grouping. Diethyl sulfate and related compounds have been shown to be eminently satisfactory reagents for the characterization of the —NMgX group? The product of this reaction with diethyl sulfate should be identical with that obtained from our o-phenylbenzohydrylaniline and diethyl sulfate. So far such identity is confined to the fact that the two products are oils, a fact which is without significance. However, the amines of this study have a marked tendency to form apparently intractable oils which crystallize slowly and with difficulty.

---

[9] A leading reference is that of Gilman and Heck, This Journal, 50, 2223 (1928).

That the 144° compound contains a secondary amine grouping **is** shown by the Liebermann nitroso reaction for secondary amines, the Zerewitinoff method for active hydrogen and the formation of aniline as a product of hydrolysis.

As further indicative evidence for the correctness of Reaction VIII and, in particular, for Compound (D), we should state that the reaction mixture assumes a brilliant deep red color which fades appreciably on hydrolysis. This is what one might expect in view of the quinoid structure postulated for Compound (D).

If we grant the correctness of the reactions as postulated, there remains the desirability of proposing an explanation for this unusual type of 1,4-addition to a conjugated system. The most satisfactory explanation that we offer at this time involves the phenomenon of steric hindrance. We do so with full knowledge of the traditional weakness of such an explanation for some reactions. Quite recently Gilman and Heck[10] have shown that although some reactions of organomagnesium halides can be very satisfactorily explained on this basis, other reactions of a kind that might merit such an explanation cannot be correlated with the phenomenon of steric hindrance. From the studies reported at this time we know that one equivalent of phenylmagnesium bromide reacts very smoothly with phenyl isocyanate and phenyl isothiocyanate to give benzanilide and thiobenzanilide, respectively, and that the reaction apparently stops at this stage with an excess of phenylmagnesium bromide and extended refluxing in an *ether* solution.[3] We also know that benzophenone-anil reacts decidedly slowly, if at all, under the same conditions. This resistance to addition of phenylmagnesium bromide to this particular —N=C group (a resistance which we attribute at this time to steric influences) is so marked that when the reaction is forced at an elevated temperature, 1,4-addition takes place with the unique conjugated system designated in Reaction VIII.

It should be possible to find an answer to this question with subsequent studies on different anils and other related compounds with a variety of Grignard reagents and other compounds. Until at least several such studies have been completed it would be wise to defer suggestive theoretical considerations on the structure of benzene and the mechanism of substitution reactions of benzene.

The Experimental Part contains brief descriptions of some of the pertinent reactions carried out in connection with other possible structures that were considered prior to the identification of our 144° compound as *o*-phenylbenzohydrylaniline.

The authors wish to thank N. J. Beaber and A. P. Hewlett for some preliminary work and for valuable suggestions.

---

[10] Gilman and Heck, *Ber.*, **62**, 1379 (1929).

Experimental Part

Preparation of o-Phenylbenzohydrylaniline from Phenylmagnesium Bromide. (1) Phenyl Isocyanate.—A vigorous reaction took place with the slow addition of **16** g. (**0.134** mole) of phenyl isocyanate in ether to **0.6** mole of phenylmagnesium bromide. When addition was complete, most of the ether was removed by distillation; toluene was added and the mixture was refluxed (internal temperature 70–80°) with stirring for six to eight hours. After hydrolysis by ice and hydrochloric acid, the ether–toluene layer was separated and steam distilled to remove toluene, diphenyl and other steam-distillable products. The non-volatile, sticky, reddish-brown paste that remained as a residue from the steam distillation was extracted with warm alcohol. The alcohol extractions on cooling usually deposited an oil. In some cases crystallization could be induced by rubbing with a glass stirring rod. When a little of the material solidified, it proved very effective in seeding other solutions. The compound was obtained as a yellowish powder melting between **139** and **142°**. It is sparingly soluble in alcohol, and a good solvent for crystallization is a mixture of **65%** alcohol and **35%** toluene. When recrystallized from this mixture, the compound is obtained as glistening yellow crystals melting at 143–144°. The yield from phenyl isocyanate was generally about 30%, but in some cases yields as high as 44% were obtained.

(2) Phenyl Isothiocyanate.—From **25.5** g. (**0.189** mole) of phenyl isothiocyanate and **0.8** mole of phenylmagnesium bromide refluxed for ten hours at 70–75° in an ether–toluene mixture, there was obtained **28.6** g. or a **45%** yield of the *o*-phenylbenzohydrylaniline. In the course of hydrolysis, hydrogen sulfide was evolved. The evolution of hydrogen sulfide is indicative of the formation of $(MgBr)_2S$ (or its equivalent) in accordance with Reaction VI.

(3) **Benzophenone-anil.**—From **19.3** g. (**0.075** mole) of benzophenone-anil and **0.3** mole of phenylmagnesium bromide refluxed for ten hours at 90–105° in an ether–toluene mixture, there was obtained **10.6** g. or a **42%** yield of the o-phenylbenzohydrylaniline. The reaction mixture prior to hydrolysis was deep purple in color. In some experiments hydrolysis was also effected by means of iced ammoniacal ammonium chloride.

Analysis and Properties of *o*-Phenylbenzohydryl-aniline.—Calcd. for $C_{25}H_{21}N$: C, **89.55**; H, **6.27**. Found: C, **89.38**, **89.75**; H, **6.87**, **6.53**. Mol. *wt.* Calcd., **335**. Found (in boiling acetone), **317**, **300** and **301**.

Hydrochloride.—The hydrochloride melting at 182.5° was obtained by adding hydrogen chloride to the amine dissolved in anhydrous ether. The free amine may be recovered from the salt by gently warming with dilute alcoholic potash. Analysis. Two samples of the hydrochloride were titrated with a standard solution of potassium hydroxide (and then back-titrated with a standard solution of hydrochloric acid). Calcd. molecular weight, **335**. Found: **337** and **335.9**.

Active Hydrogen by Zerewitinoff Analysis.—Two determinations by heating in xylene and amyl ether at 70° for fifteen minutes gave **0.7** and **0.69** active hydrogen. A third analysis under the same conditions with the exception of a fifty-minute period of heating at 70° gave **0.72** active hydrogen.[11] In these experiments the compound was dissolved in xylene and the methylmagnesium iodide was prepared in amyl ether. When, however, the determination was carried out with n-butyl ether as the solvent (both for the amine and the methylmagnesium iodide), the values obtained were **0.97** and **1.03** active hydrogen.[12]

---

[11] Analyses by R. E. Fothergill.

[12] Analyses by R. J. VanderWal. It is interesting to note that triphenylmethylaniline in butyl ether reacts very slowly (eight hours at **70°** for completion) with methylmagnesium iodide in butyl ether to give **1.00** and **1.01** active hydrogen. This is one of a number of striking illustrations of what appear to be cases of steric hindrance. Others

With xylene as a solvent for the amine and n-butyl ether as a solvent for the Grignard reagent, the value was 0.75 active hydrogen.[12]

Splitting Reactions. (1) **Concd.** Hydrochloric Acid.—When 5 0 g. of the amine was heated in a sealed tube with 75 cc. of concd. hydrochloric acid for three hours at 145°, there were obtained 3.6 g. (a 99.6% yield) of 9-phenylfluorene and aniline. That triphenylcarbinol was not an intermediate product of this hydrolysis was shown by a parallel experiment in which triphenylcarbinol was heated under like conditions. The product in this case was triphenylmethane.

(2) Alcoholic Hydrochloric Acid.—9-Phenylfluorene was also obtained when 5 g. of the amine was refluxed for seventeen hours with a mixture of 150 cc. of 95% alcohol and 50 cc. of concd. hydrochloric acid. Under corresponding conditions triphenylmethylaniline gave triphenylmethane. **Also,** triphenylcarbinol when refluxed under corresponding conditions for twenty-four hours gave a 96.8% yield of triphenylmethane.

(3) Acetyl Chloride and Acetic Anhydride.—In an attempt to acetylate the amine by means of acetic anhydride, an apparently intractable tar was obtained. In a subsequent experiment 9-phenylfluorene was obtained after refluxing 5 g. of the amine with a mixture of 25 cc. of acetyl chloride and 50 cc. of acetic anhydride.

The identity of every solid described in this study was confirmed by a mixed melting point determination with an authentic specimen. Synthetic 9-phenylfluorene was prepared by two different methods: first, by refluxing 10 g. of triphenylchloromethane in benzene for five hours with one g. of mossy zinc; and, second, by heating triphenylcarbinol with sirupy (85%) phosphoric acid.[13]

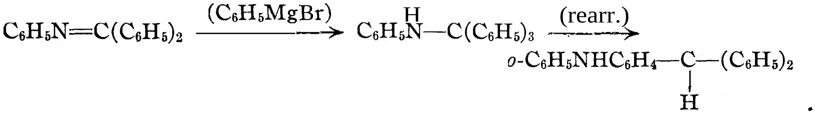
Miscellaneous.—The amine (3.9 g.) was recovered unaltered after refluxing for twelve hours in xylene. Its hydrochloride, when dry distilled, underwent considerable decomposition but gave a small quantity of 9-phenylfluorene in the distillate.

When 2 g. of the amine was refluxed for several hours with benzoyl chloride and pyridine and then worked up in the customary manner it gave a nitrogen containing compound which melted at 155–156°. However, we had no success in hydrolyzing this as yet unidentified compound to benzoic acid and the amine by means of alcoholic potash.

After refluxing 5 g. of the amine for twenty hours with 100 cc. of 20% alcoholic potash. 4.5 g. of the amine was recovered unchanged.

The yellowish color of the amine obtained from phenyl isocyanate, phenyl isothiocyanate and benzophenone-anil suggested at one time that the amine might be quinoidal in nature. Accordingly, some reduction experiments were carried out. Neither sodium and alcohol nor zinc and glacial acetic acid appeared to affect the amine. It was not until the amine was finally synthesized from benzalaniline and o-biphenylmagnesium iodide that we discovered the amine to be without color, or rather of a grayish-white color.

It was believed, for a time, that the amine melting at 144° was o-phenylaminotriphenylmethane, formed possibly by the rearrangement of triphenylmethylaniline, as follows



$$C_6H_5N{=}C(C_6H_5)_2 \xrightarrow{(C_6H_5MgBr)} C_6H_5\overset{H}{N}{-}C(C_6H_5)_3 \xrightarrow{(rearr.)} o\text{-}C_6H_5NHC_6H_4{-}\underset{\underset{H}{|}}{C}{-}(C_6H_5)_2 \quad (X)$$

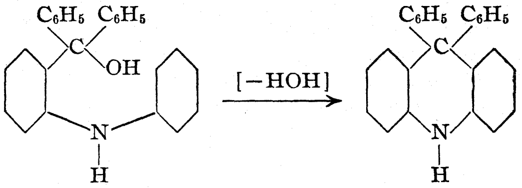
This prompted some oxidation experiments with the hope of converting the supposed

---

will be reported later by R. J. VanderWal. The values of triphenylmethylaniline in xylene are lower (0.81 and 0.92) after heating for fifteen hours at 70°.

[13] Kliegl, *Ber.,* 38, 287 (1905).

o-phenylaminotriphenylmethane to the known *o*-phenylaminotriphenylcarbinol, *o*-$C_6H_5NHC_6H_5—C(OH)—(C_6H_5)_2$. Mild treatment with nitric acid did not affect the amine, and gentle warming with nitric acid of sp. gr. 1.33 gave an intractable tar. Failing in this we thought we might achieve the same result by reducing the known *o*-phenylaminotriphenylcarbinol to o-phenylaminotriphenylmethane. However, we were equally unsuccessful in this, for when o-phenylaminotriphenylcarbinol was treated with alcohol and sulfuric acid,[14] formic acid,[15] glacial acetic acid and zinc dust or hydriodic acid and zinc dust, a sparingly soluble compound melting at 244–245° was obtained, and not our 144° amine. The 244–245° compound is the diphenyldihydroacridine of Baeyer and Villiger[16]



(XI)

Zinc dust and alkali, and catalytic reduction with the platinum catalyst of Adams were without effect on the o-phenylaminotriphenylcarbinol.

Triphenylmethylaniline and Phenylmagnesium Bromide.—After refluxing 5 g. (0.015 mole) of triphenylmethylaniline with 0.075 mole of phenylmagnesium bromide in an ether–toluene mixture at 100° for ten hours, 4 g. or 80% of the amine was recovered.

Benzalaniline and Phenylmagnesium Bromide.—A 48.5% yield of benzohydrylaniline, $(C_6H_5)_2CHNHC_6H_5$, was obtained after refluxing 18 g. (0.1 mole) of benzalaniline and 0.3 mole of phenylmagnesium bromide in an ether–toluene mixture for eight hours. No other product was isolated. In a comparable experiment with 14 g. (0.077 mole) of benzaniline, 0.1 mole of phenylmagnesium bromide and refluxing at 106° for eleven hours, the yield of benzohydrylaniline was 65%. This amine was identified as the hydrochloride melting at 194–195° and the nitrate melting at 158.5°.[17]

Some orienting experiments with benzanilide, $C_6H_5NHCOC_6H_5$, benzophenone-oxime, $(C_6H_5)_2C{=}NOH$, and benzophenone-oxime-o-methyl ether, $(C_6H_5)_2C{=}NOCH_3$, with phenylmagnesium bromide under forced conditions have not as yet yielded any of the expected o-phenylbenzohydrylaniline. The high recovery (69%) of benzophenone-oxime methyl ether might have been predicted from related experiments of Busch and Hobein[18] with oxime-ethers.

Preparation of o-Biphenylmagnesium Iodide.—The 2-nitrodiphenyl was prepared according to the directions of Bell, Kenyon and Robinson,[19] and then reduced to 2-aminodiphenyl by the method of Scarborough and Waters.[20]

Forty-three and one-half g. (0.21 mole) of 2-aminodiphenvl hydrochloride was diazotized in iced dilute hydrochloric acid by means of a solution of 14.5-g. (0.21 mole) of sodium nitrite. Then 100 g. of potassium iodide in 150 cc. of water was added slowly with continuous stirring. A heavy paste separated and after standing for

one and one-half hours the mixture was warmed gently to expel nitrogen; a few crystals of sodium thiosulfate were added to remove free iodine and the almost black oil was extracted with toluene. The toluene solution was washed with water, dried over calcium chloride and then distilled in a vacuum. The yield of *o*-iododiphenyl boiling at 158° (6 mm.) was 30.4 g. or 51.7%; d_{25}^{25}, 1.6038. The iodide was strongly resistant to nitric acid decomposition in the Carius analysis.

Anal. Calcd. for $C_{12}H_9I$: I, 45.3. Found: I, 44.6.

There was no difficulty in getting a Grignard reagent from 21.1 g. of the o-iododiphenyl and 1.82 g. of magnesium turnings. The reaction was started with the activated $12^3/_4\%$ copper–magnesium alloy of Gilman, Peterson and Schulze.[21] The Grignard reagent gave the color test of Gilman and Schulze,[22] and when an aliquot was treated with carbon dioxide in the customary manner[z3] o-diphenylcarboxylic acid[2*] was obtained.

Preparation of *o*-Phenylbenzohydrylaniline from Benzalaniline and o-Biphenylmagnesium Iodide.—A toluene solution of 13.6 g. (0.075 mole) of benzalaniline was added to the 0.075 mole of Grignard reagent. Since there was no evidence of reaction the ether was partially replaced by toluene until the boiling point of the mixture was 95°. Immediately on increasing the reaction temperature, a deep red color set in. This was the only evidence of reaction, although refluxing was continued for eight hours. Occasional color tests[22] were made during the heating and in every case a deep green color was obtained. It was discovered on hydrolysis that this green color might not have been due to any unused Grignard reagent. After hydrolysis, about 0.5 g. of solid was removed by filtration from the deep red toluene layer. All of the hydrolysis mixture was steam distilled without separating the layers. The acid hydrolysis mixture immediately assumed a deep green color when steam was passed into it. Some benzaldehyde distilled over: this may have been due to unaltered benzalaniline. The residual heavy, deep green tar was taken up in 250 cc. of an alcohol–toluene mixture containing about 25% of toluene. On standing for three to four hours, crystals started to separate. After about twenty-four hours the crystals were filtered off and washed thrice with alcohol. The yield was 9 g. or 35.8% of o-phenylbenzohydrylaniline, and very probably more of the amine was formed as it is a compound that is affected (at least colorimetrically) by atmospheric exposure in a way to impede crystallization. The compound showed no depression in a mixed melting point determination with the amine obtained from phenyl isocyanate and phenylmagnesium bromide.

Summary

The forced reaction of phenyl isocyanate, phenyl isothiocyanate and benzophenone-anil with an excess of phenylmagnesium bromide gives o-phenylbenzohydrylaniline. The formation of this amine is unique in the sense that it undoubtedly takes place as a result of a 1,4-addition to the —C=N group in the side chain and one of the so-called ethylenic linkages in a benzene ring.

AMINO ALCOHOLS. I. PHENYLPROPANOLAMINE AND PARA-TOLYLPROPANOLAMINE

BY WALTER H. HARTUNG AND J. C. MUNCH

RECEIVED APRIL 5, 1929 PUBLISHED JULY 5, 1929

The encouraging results from the pharmacodynamic investigations of ephedrine, particularly those of Chen,[1] have stimulated the interest of chemists in this compound as well as in its homologs and analogs.[2]

Since Smith[3] isolated *nor-d-ψ*-ephedrine from ephedra species and in view of the fact that (3,4-dihydroxyphenol)-ethanolamine has in many respects a physiological activity not unlike that of (3-4-dihydroxyphenyl)-ethanolmethylamine, or adrenaline,[4] it appeared that arylalkanolamines of the general types $ArCHOHCHRNH_2$ merited further study and investigation.

Various methods are recorded for the synthesis of compounds of this class. Phenylethanolamine has been prepared in low yields by reducing o-amino-acetophenone[5] or mandelonitrile[6] with sodium amalgam; Alles claimed better results from phenylnitro-ethanol.[2c] Phenylpropanolamine has been made by reducing a-aminopropiophenone with sodium or its amalgam;? by reducing phenylnitro-ethanol with zinc dust and acetic acid;[8] from isonitrosopropiophenone by catalytic means with palladinized gum arabic, but from 5.7 g. of isonitroso ketone in a solution of 85 cc. of alcohol, 57 cc. of water and 7.1 cc. of 30% hydrochloric acid, only 1.4 g. of phenylpropanolamine was isolated.[9] A method of more general application was developed by Tiffeneau and Lévy[10] who used the scheme

$$C_6H_5CHOHCN\ (or\ C_6H_5CHOH{\cdot}CONH_2) \xrightarrow{RMgX} C_6H_5CHOHCOR \xrightarrow{H_2NOH}$$

$$C_6H_5CHOHC({=}NOH)R \xrightarrow{H_2} C_6H_5CHOHCHRNH_2$$

the reduction of the alcohol-oxime being accomplished by means of sodium. This is a valuable method and by means of it various phenylalkanolamines, up to and including phenylhexanolamine, were made. However, the ultimate yields were not very large.

In order to facilitate a more complete study of various arylalkanolamines, a search was first made for a more satisfactory method of making them, which centered itself on finding a suitable means for reducing isonitroso ketones, since the work of Slater[11] indicated that these intermediates could be prepared pure and in good yields. The process finally adopted has been described by one of us.[12] The isonitroso ketone was dissolved in absolute acohol containing three equivalents of hydrogen chloride and shaken with palladinized charcoal in an atmosphere of hydrogen until saturated, whereby the ketonic group was reduced to a secondary alcohol and the oximino to a primary amine; the product was isolated as its hydrochloride, practically pure and in very good yield, by removing the catalyst, concentrating the alcoholic solution and diluting with excess ether. In the absence of hydrogen chloride the reduction was incomplete and the product was not the desired amino alcohol. Two compounds, phenylpropanolamine and p-tolylpropanolamine, have been prepared in this manner; others are under way and will be reported later.

Phenylpropanolamine has been known, but p-tolylpropanolamine, isomeric with ephedrine, is new. Pharmacologically both compounds produce effects paralleling those of ephedrine; they exert as great an effect on the blood pressure of an anesthetized dog as does the natural alkaloid and are also effective when administered orally. Their mydriatic action was found to be greater than that of either ephedrine or phenylethanolamine. Phenylethanolamine has no action when given by mouth.'' Both compounds had a potentiating effect when epinephrine was subsequently administered; that is, the effect of epinephrine was greatly increased.

The toxicity of phenylpropanolamine and p-tolylpropanolamine compared with that of natural ephedrine and phenylethanolamine[14] given by Alles (ref. 2c) and Miller and Piness (ref. 13) is shown in the table.

It is seen that the phenyl derivative is less toxic and the tolyl more toxic than ephedrine. The pharmacological investigation is being continued and the results will be published later elsewhere.

Procedure

The isonitrosopropiophenone and *p*-tolyl-α-oximino-ethyl ketone were prepared from freshly distilled butyl nitrite and propiophenone and *p*-

Phenylethanolamine	...	......	30	1000

methylpropiophenone, respectively; these were reduced as described above. The pure amino alcohols did not reduce Fehling's solution but formed with it a crystalline precipitate.[15] The incompletely hydrogenated product, however, did reduce Fehling's solution, and this fact as well as the measure of the hydrogen absorbed could be used in determining the completeness of the catalytic reduction. This test is based on the observation that the oximino group is more easily reduced than the carbonyl, the remarks of Hunnius and Rabe to the contrary notwithstanding; and it is well established that in alkaline solution α-amino ketones are readily oxidized to pyrazine derivatives.[16] Thus amino-acetone, in ammonia solution, is oxidized by mercuric chloride to dimethylpyrazine;[17] *p*-methyl-α-amino-acetophenone to 2,5-di-*p*-tolylpyrazine;[18] and α-aminopropiophenone is oxidized with methyl iodide to 3,6-diphenyl-2,5-dimethylpyrazine.[19]

Deamination by means of nitrous acid resulted in the formation of the original aryl alkyl ketones, identified as their semicarbazones. This is in harmony with the findings of Tiffeneau and Lévy,[20] who treated bases of the type $ArCHOHCHRNH_2$ with nitrous acid and obtained ketones of the type $ArCOCH_2R$. However, a peculiarity observed in connection with these deaminations was that unless the resulting product was first distilled, no semicarbazone could be isolated.

Experimental

Propiophenone and *p*-tolylethyl ketone were prepared by the regular Friedel–Crafts reaction of propionyl chloride on benzene and toluene, respectively.

Isonitrosopropiophenone was prepared from propiophenone and butyl nitrite. Slater[11] used methyl nitrite, a gas; butyl nitrite, a liquid, was found more convenient. In a 1-liter 3-necked, round-bottomed flask, fitted with stirrer, reflux and delivery tube for hydrogen chloride, was placed a solution of 80 g. of propiophenone (0.6 mole) in 400 cc. of ether; hydrogen chloride was passed through the stirred solution at the rate of 2–3 bubbles per second, stirring and addition of acid being continued throughout the reaction; then freshly distilled butyl nitrite, b. p. 75–81°, was added through the

reflux condenser in 2–3-cc. portions until a total of 61.8 g. (0.6 mole) was added. After addition of the first portion the reaction mixture slowly became a yellow-brown and after several more minutes a light yellow color, after which a second oortion was added; now the color change took place more rapidly, whereupon a third portion was added, etc. The mixture gradually warmed up and the ether began to reflux gently. The total time required for the addition of the nitrite was about ninety minutes. Stirring and bubbling of hydrogen chloride were continued for another fifteen minutes and the mixture then was allowed to stand overnight, during which time it became quite dark. The next day the ethereal solution was slowly stirred into dilute sodium hydroxide containing pieces of ice and the ethereal layer was repeatedly extracted with cold alkali until no more product was obtained. The alkaline extracts were slowly stirred into concentrated hydrochloric acid containing sufficient ice to keep the reacting mixture cold. In this manner white crystals of isonitrosopropiophenone were obtained; these were recrystallized from toluene and melted at 106.0–106.5°;[21] yield, 71 g., or 72.5% of the theoretical. When treated with hydroxylamine (hydrochloride) in alkaline solution for several hours it formed, on acidifying, a voluminous precipitate which was recrystallized from alcohol and melted at 230.5–231.0'; this agrees with the melting point given for phenylmethylglyoxime by Gudeman and Borsche[22] who prepared it from $C_6H_5C(=NOH)COCH_3$.

***p*-Tolyl-α-oximino-ethyl** ketone was prepared after the manner described for isonitrosopropiophenone, except that 88.8 g. of *p*-tolylethyl ketone (0.6 mole) was substituted for the propiophenone; yield, 78.5 g. of the twice recrystallized isonitroso ketone, or 74% of the theoretical. The crystals, from toluene, were white flakes and melted at 125°.

Anal. Calcd. for $C_{10}H_{11}O_2N$: N, 7.91. Found: (Kjeldahl) N, 7.90.

***p*-Tolylmethylglyoxime,** prepared as was the phenyl homolog, decomposed at 230° (uncorr.), as recorded by Gudeman and Borsche.[22]

Phenylpropanolamine.—With catalyst prepared as previously described[12] from 0 5 g. of palladium chloride and 3 g of charcoal, it was possible to reduce two portions of 9.8 g. of isonitrosopropiophenone (0.06 mole), dissolved in 150 cc. of absolute alcohol containing 7.0 g. of hydrogen chloride, to phenylpropanolamine in from 145 to 190 minutes with yields of the isolated hydrochloride from 9.4 g. to 11.0 g., or 84 to 98% of the theoretical. After recrystallization from absolute alcohol the salt melted at 191°, which is the value given by Calliesz[7] and Eberhardt.[7]

The free base was obtained by treating an aqueous solution of the hydrochloride with alkali; on cooling, the liberated amino alcohol solidified and after recrystallization from water melted at 103°, which agrees with the melting point given by Hunnius and Rabe.[9]

When isonitrosopropiophenone was reduced in the absence of hydrogen chloride, the reduction proceeded very slowly and not to completion: *e.* g , 3.3 g. of isonitroso ketone in 75 cc. of absolute alcohol absorbed in six hours 1280 cc. of hydrogen (calculated for reduction to phenylpropanolamine, 1350 cc.), but from the product there was isolated only 1.3 g. of material which melted at 108–110°; when this was mixed with known phenylpropanolamine, the melting point ranged from 70 to 80°. This product was not identified.

***p*-Tolylpropanolamine** was obtained as the hydrochloride by reducing the *p*-tolyl-α-oximino-ethyl ketone under the conditions described for phenylpropanolamine. The hydrochloride, after recrystallization from absolute alcohol, melted at 205°.

---

[21] The melting point given in Beilstein's "Handbuch," 4th ed., Vol. VII, p. 678, varies from 108 to 115°.

[22] Gudeman and Borsche, *Ber.*, 40, 740 (1907).

Anal. Calcd. for $C_{10}H_{15}ON \cdot HCl$: Cl, **17.59;** N, **6.95.** Found: Cl (as AgCl), **17.49, 17.62; N** (Kjeldahl), **7.04.**

The free base, isolated as was phenylpropanolamine, melted at **112°.**

Anal. Calcd. for $C_{10}H_{15}ON$: N, 8.48. Found: N (Kjeldahl), **8.53, 8.63.**

Deamination.—A solution was prepared of **6** g. of *p*-tolylpropanolamine hydrochloride **(0.03** mole) in **200** cc. of water and **15** cc. of acetic acid; it was cooled to **7°** and to it was slowly added a solution of **6.2** g. of sodium nitrite **(0.09** mole) in **35** cc. of water; the mixture was allowed to stand at room temperature for twenty-four hours, was neutralized with sodium carbonate and extracted with ether. From about one-third of the extract the ether was allowed to evaporate spontaneously and the residue was treated in the regular way to form semicarbazone; there was no evidence of its formation. The remainder of the ethereal solution was dried and distilled. The high-boiling product formed a semicarbazone melting at 191°; mixed with known semicarbazone of *p*-tolylethyl ketone there was no change in the melting point.

Phenylpropanolamine was deaminated under similar conditions. From a fourth of the ethereal extract the ether was evaporated on the steam-bath; the residue formed no semicarbazone. From a second fourth the ether was evaporated, the residue heated to boiling but not distilled and treated to form semicarbazone; after standing for ten days a very small yield of crystals was obtained, insufficient to recrystallize. The remainder of the ethereal solution was distilled; that boiling at 210–220° formed a semicarbazone that melted at **177.5°,** the semicarbazone of propiophenone.

Thus it appears that the deaminated product must be distilled before it will form a semicarbazone.

Summary

1. Phenylpropanolamine and p-tolylpropanolamine have been prepared by reducing the appropriate isonitroso ketones catalytically.
2. The method appears to be of general application and is being extended.
3. The two compounds discussed show physiological activity paralleling that of ephedrine. Further pharmacological studies are being made.

THE ALIPHATIC DIOLEFINS. II. THE PREPARATION AND SOME PHYSICAL CONSTANTS OF Δ-1,5-HEXADIENE

BY FRANK CORTESE[1]

RECEIVED APRIL 10, 1929 PUBLISHED JULY 5, 1929

In connection with some previous work on Δ-1,5-hexadiene,[2] it was noticed that great confusion existed among the physical constants recorded in the literature. Accordingly, the hydrocarbon was made from two different sources and the following accurate concordant constants were determined: . boiling point, dt/dp, melting point, density and refractive index.

---

[1] Research Associate, Massachusetts Institute of Technology.

[2] Cortese, *Ber.*, 62, **504 (1929).**

Δ-1,5-Hexadiene, or diallyl, has been made by the following methods: by the action of sodium,[3] or sodium–tin alloy,[4] on allyl iodide; by the dry distillation of allyl mercuric iodide[5,6]; from allyl bromide, sodium and a few drops of alcohol (anhydrous ether was also a catalyst); from allyl iodide, zinc and a little formic ether[7] or ether;[8] from allyl iodide, aluminum and ether;[9] from 1,2,3-tribromopropane, magnesium and ether.[10] Almost all workers mention that the existing methods give poor yields and *a* poor quality of product. Undoubtedly this is due to the fact that specific directions are not given, for one worker will get a very low yield with a method which gave a good yield to another worker.

We have adopted the convenient method of causing allyl bromide to react with magnesium in the presence of ether.[11] This is an abnormal Grignard reaction, the magnesium seemingly acting as a coupling agent.[12]

Experimental Part

Preparation of Δ-1,5-Hexadiene from Allyl Bromide.—The allyl bromide was made from allyl alcohol and 48% hydrobromic acid as described in a previous paper[13] from this Laboratory.

Seventy-five grams of magnesium turnings is covered with 150 cc. of dry ether in a 2-liter flask. Six hundred grams of allyl bromide is run in as fast as possible, without stirring. It is best to add about 5 g. and wait until the reaction starts and subsides. The rate of reflux will determine the rate of addition. When the reaction stops, 50 cc. of ether is added and all is refluxed gently for five hours. The mixture of diallyl, unchanged bromide and ether is distilled from an oil-bath whose temperature is gradually raised to 250°. The distillate is dried with sodium and added to *25* g. of magnesium turnings in a one-liter flask. Fifty cc. of ether is added and a small crystal of iodine. If the reaction does not start spontaneously, a *micro burner* is used to induce it. When the reaction subsides, refluxing is continued gently for three hours. After cooling, one cc. is pipetted out and a little magnesium added to it. If there is still a reaction after standing for a few hours, fresh metal is added to the main hatch and the refluxing continued. When the indicated test is negative, all is distilled from an oil-bath, gradually raised to 140°. The distillate is shaken with ordinary concentrated hydrochloric acid[14] with cooling under the tap. The layers are separated and the process is repeated five times. Each time a volume of acid equal to that of the hydrocarbon residue is used. Finally, it is washed once with 10% sodium hydroxide and once with water. After a

preliminary short shaking with calcium chloride, it is dried over sodium. The amount of this crude hydrocarbon is 70–75% of the theoretical based on the allyl bromide. The rest of the yield is taken up by by-products, a yellowish oil covering the magnesium bromide etherate and a copious evolution of gas when water is added to this etherate residue. These were not investigated. The yield, boiling between 59–60°, is 68%. There are no low- or high-boiling fractions. The yield boiling between 59.4 and 59.6° at 760 mm. is 36%.

From **Allyl** Chloride.—Exactly analogous procedures were used. The crude yield was 68%. The yield boiling between 59 and 60° was 55%, and the yield boiling between 59.4 and 59.6° was only 27%.

Purification.—The two samples of Δ-1,5-hexadiene were each distilled four times from fresh sodium, through a Widmer[15] column. **A** distillation curve was made each time and the appropriate cut taken from the flat portion of the curve. The final samples boiled constantly, 30 cc. from the allyl bromide run and 55 cc. from the allyl chloride run. They were halogen free as shown by sodium fusion-silver nitrate tests.

[a] By Dr. E. L. Skau, National Research Fellow.

The determinations of the melting point and freezing point were kindly made by Dr. E. L. Skau[16] in a special apparatus. His remarks were as follows: "Good heating curves were obtained on Sample A, although a cooling curve was not run. On Sample B cooling curves were run which were checked within 0.1° by heating curves. Both cooling and heating curves were reproducible within themselves within 0.04°. The shape of the curves obtained indicated that Sample **A** was purer than Sample B. From the amount of water and gas observed, when the samples were vacuum distilled, and from the shape of the curves, it was also concluded that the true density of diallyl had probably been determined to at least ±0.0003.

"The methods used and the interpretation of the heating curve as a criterion of purity will be discussed in a forthcoming paper."

[15] Widmer, *Helv. Chim. Acta*, 7, 59 (1924).

[16] National Research Fellow.

The writer also reached the conclusion that Sample A was the purer one from the distillation characteristics of A and B.

Pure diallyl does not have a sharp odor, as sometimes claimed. It has a very penetrating, highly "unsaturated," nauseating odor, inducing anesthesia easily. It has a sweet taste when highly diluted with water. It must be kept in a sealed bottle as it is very volatile. Ordinary samples develop a sharp odor and deposit a yellow oil on standing; purified material in sealed tubes evidently keeps indefinitely. It can be conveniently identified by the preparation of the cyclic, crystalline, neutral, monosulfuric acid ester of hexane-2,5-diol, which melts at 90° corr.[2]

Summary

1. Detailed directions are given for the preparation of Δ-1,5-hexadiene from allyl halides and magnesium in ether.

2, The boiling point, dt/dp, melting point, density and refractive index of Δ-1,5-hexadiene have been accurately determined.

SYNTHESIS OF EPHEDRINE AND STRUCTURALLY SIMILAR COMPOUNDS. III. A NEW SYNTHESIS OF ORTHO-DIKETONES

BY HAROLD W. COLES, RICHARD H. F. MANSKE AND TREAT B. JOHNSON

RECEIVED APRIL 12, 1929 PUBLISHED JULY 5, 1929

The synthesis of ephedrine described in Papers I and II[1,2] necessitated the preparation of considerable quantities of 1-phenylpropane-1,2-dione. This substance has been prepared by the decomposition of isonitrosoethylphenyl ketone by means of dilute sulfuric acid[3] or by means of amyl nitrite.[4] In the first case decomposition is slow and in the second case by-products are formed in large amount so that the yield of diketone in either case is small. In view of the great stability of this oxime it is not surprising that the carbonyl group with which the hydroxylamine is associated displays sufficient affinity to combine readily with primary amines—a reaction upon which the synthesis of ephedrine depends.[5] The formation of a crystalline hydrate of benzoylformaldehyde is another

[5] The authors desire to call attention to two errors which occur in the first paper; *ethylbenzyl* (line 18, p. 581) should read *ethylphenyl,* and *specially* (line 2, p. 582) should read *spatially.*

illustration of this reactivity. The dialkyl isonitroso ketones are readily convertible to diketones by means of formaldehyde, but thus far the authors are not aware of a case in which alkylaryl isonitroso ketones can be similarly decomposed. The ease of oxidation of dialkylmalonates to the corresponding mesoxalates by interaction with oxides of nitrogen is well known.[6] Gilman and Johnson[7] have recently developed further the utility of this change and have shown that nitrogen tetroxide serves as the most practical reagent for accomplishing this oxidation. The success of this work suggested the possibility of using this oxide for the oxidation of the methylene group of ethylphenyl ketone. Fortunately the reactivity conferred on the methylene carbon atom by the phenyl and carbonyl groups is sufficient not only to provide a point of attack for the nitrogen tetroxide but also to lend sufficient stability to the resulting diketone to prevent complete disintegration by the further action of the oxidant, although it has not been possible to prevent the formation of benzoic acid in considerable quantities. The yield of pure diketone, though leaving much to be desired, is still greater than that by any other feasible method, and in point of time and attention required, the authors greatly prefer this method.

Ketonic aldehydes are oxidized with great facility and their preparation by this method has not been accomplished. Obviously hydroxy ketones do not lend themselves to the reaction. The authors are inclined to believe from present evidence that isonitroso ketones are intermediate products in the reaction, although a thorough search in the case of ethylphenyl ketone yielded no oxime. It would appear that the oxime presents less stability to nitrogen tetroxide than does the ketone. In one instance, a-hydrindone, the isonitroso ketone is more resistant to the action of the oxide than the unchanged ketone, so that the former is conveniently prepared by the action of nitrogen tetroxide on the latter. In fact, isonitroso-a-hydrindone exhibits considerable stability toward nitrogen tetroxide and when reaction does ensue deep-seated changes result and no diketo-hydrindone could be isolated from the reaction product. Thus far no synthesis of this interesting diketone has been accomplished. Hot dilute acids resinify the oxime, whereas sodium bisulfite[8] forms a resinous mixture as final product. The action of aqueous formaldehyde is unusual in that the oxime is readily soluble in the commercial 35% solution; on cooling the unchanged compound crystallizes out.

A second case of abnormality in cyclic ketones is that of α-ketotetrahydronaphthalene. Here the action of a small amount of nitrogen tetroxide induces rapid and complete decomposition. The product of the

[8] Müller and Pechmann, Ber., 22,2557 (1898).

reaction consisted of comparatively insoluble resins from which neither unchanged ketone, diketone nor isonitrosoketone could be isolated.

The examples given in the experimental section suffice to show that the reaction here discussed is sufficiently general to serve as a useful method of preparing alkylaryl diketones,

Experimental Part

1-Phenyl-1,2-propanedione.—A mixture of ethylphenyl ketone (134 g.), finely powdered anhydrous calcium chloride (35 g.) and alcoholic hydrogen chloride (1 cc.), contained in a flask provided with an efficient mechanical stirrer, an inlet tube for the entry of the nitrogen tetroxide and an exit tube to accommodate the evolved gases, is treated with a stream of nitrogen tetroxide, the temperature being maintained at 60°. It is advisable to stir vigorously and introduce about 60 g. of the gas from a weighed tube in the course of three to four hours. Although there is considerable unchanged ketone in the reaction mixture at this stage, it is advisable to interrupt the reaction, since a point is reached where the rate of decomposition of diketone is nearly equal to the rate of its formation.

The reaction mixture is cooled somewhat and taken up in ether. The ethereal solution is washed with water, then exhaustively with aqueous sodium bicarbonate and finally with water. The ether is distilled from the solution and the residue distilled under reduced pressure. Distillation is continued until the residue begins to decompose. The distillate is treated with an equal volume of alcohol and vigorously shaken with 60 cc. of a saturated aqueous solution of sodium bisulfite. In the course of a few minutes, a colorless crystalline solid separates and the mixture gradually becomes pasty, the yellow color fading almost completely. The mixture is then cooled, filtered with suction and the solid washed with alcohol and finally with a little ether.

The bisulfite compound is conveniently decomposed by treatment with a warm solution of sodium carbonate. After cooling the diketone is extracted with ether, the solvent distilled and the diketone distilled in a rapid current of steam. The diketone is recovered from the steam distillate by extraction with ether and after drying and removal of solvent is distilled under reduced pressure. The yield of pure product boiling at 126–128° at 20 mm. is 26 to 28 g.

The filtrate from the bisulfite compound may be worked up for the recovery of unchanged ethylphenyl ketone by addition of water and extraction with ether. The amount recovered varies from 60 to 70 g.

Other Diketones.—Without further modification the above procedure was applied to the synthesis of a number of other diketones. Those listed below were used in the synthesis of substituted ephedrines, and the authors regard the successful isolation of the expected ephedrines as sufficient evidence of identity of the diketones: 1-phenyl-1,2-butanedione, b. p. 130–132° at 20 mm.; 1-*p*-ethylphenyl-1,2-propanedione, b. p. 138–140° at 20 mm.; 1-(2,5-dimethylphenyl)-1,2-propanedione, b. p. 140–144° at 20 mm.

The yields in all cases varied between 30 and 40%. The corresponding substituted benzoic acid was isolated in considerable quantities. It is interesting to note that the *p*-ethyl derivative is devoid of the piercing unpleasant odor characteristic of the other diketones. Its odor is strongly reminiscent of anisaldehyde, although slightly more aromatic.

Isonitroso-α-hydrindone.—A solution of 52.8 g. of α-hydrindone in 50 g. of dry benzene containing a few drops of alcoholic hydrogen chloride was cooled in ice and treated with a stream of nitrogen tetroxide until the green color persisted for about one minute after stopping the entry of the gas. An equal volume of petroleum ether was cautiously added, the cooled mixture filtered and the oxime washed first with a mixture of benzene and petroleum ether and then with the latter. The yield was 25 g. After one recrystallization it melted at 210° (corr.) alone or admixed with an authentic specimen.[9] The mother liquor yielded 25 g. of unchanged a-hydrindone when it was washed with dilute alkali, dried and distilled under reduced pressure.

This is the fifth communication submitted during the tenure by one of us of the Eli Lilly and Company Fellowship.[10] The authors desire to express their appreciation not only to the executive staff of this company for the privilege thus enjoyed, but also to the members of the technical staff for their generous cooperation.

Summary

1. A new synthesis of alkylaryl diketones which promises to be quite general is described.

2. The synthesis of a cyclic *o*-diketone was not accomplished.

TETRA-ARYLDIARSYLS. I[1]

BY F. F. BLICKE AND F. D. SMITH[2]

RECEIVED APRIL 26, 1929 PUBLISHED JULY 5, 1929

In view of the fact that tetra-arylhydrazines[3] and hexa-arylethanes[4] dissociate spontaneously into diarylnitrogen radicals and triarylmethyls, respectively, it seemed possible that tetra-aryldiarsyls might behave in a similar manner

$$\begin{aligned} R_2As{-}AsR_2 &\rightleftharpoons 2R_2As{-} \\ R_2N{-}NR_2 &\rightleftharpoons 2R_2N{-} \\ R_3C{-}CR_3 &\rightleftharpoons 2R_3C{-} \end{aligned}$$

Several investigators have studied tetraphenyldiarsyl with regard to its tendency to dissociate into diphenylarsyl. Schlenk[5] determined the molecular weight of the substance in boiling benzene but found no evidence of dissociation. According to Porter and Borgstrom,[6] as well as Borgstrom and Dewar,[7] molecular weight determinations in naphthalene by the cryo-

scopic method indicate that tetraphenyldiarsyl is associated rather than dissociated.

It seemed to us that more favorable results might be obtained in the case of tetra-p-anisyl-, tetra-α-naphthyl- and tetrabiphenyldiarsyl; at least it has been found that the anisyl, naphthyl and biphenyl nuclei further dissociation in the hexa-arylethane group.[8]

We decided to investigate these tetra-aryldiarsyls and had intended to prepare them by reduction[9] of the tetra-arylarsyl oxides, since satisfactory methods of preparation for these oxides have been developed.[10] However, a much simpler procedure was found. The tetra-arylarsyl oxides are converted readily by the action of hydrogen chloride into the diarylarsyl chlorides and the latter react with sodium iodide to form the corresponding iodides. Interaction of the latter with metals, at ordinary temperature, yields the tetra-aryldiarsyls. For example, the halogen is removed quantitatively if diphenylarsyl iodide, dissolved in bromobenzene,[11] is shaken vigorously with mercury for twenty minutes. Such a solution, in less than thirty seconds, absorbs almost exactly the quantity of oxygen[12] calculated for the formation of a peroxide, $(C_6H_5)_2As\text{-}O\text{-}O\text{-}As(C_6H_5)_2$ and decolorizes instantly a carbon tetrachloride solution of iodine.

In fact, the solution obtained after removal of the halogen from diphenylarsyl iodide is strikingly similar in behavior toward oxygen and iodine to that obtained when triphenylmethyl chloride, dissolved in bromobenzene, is treated with mercury; however, in the former case the solution is colorless, in the latter it is yellow.

In order to obtain tetraphenyldiarsyl in the solid state, diphenylarsyl iodide was dissolved either in benzene or absolute ether and, after removal of the halogen by mercury, the solution was filtered and the solvent removed under diminished pressure. During these operations precaution must be taken to prevent oxygen from coming in contact with the material. The crystalline diarsyl, when dissolved in bromobenzene, absorbs the amount of oxygen calculated for peroxide formation.

The behavior of tetraphenyldiarsyl and other tetra-aryldiarsyls described in this paper indicates that these compounds dissociate to some

---

[8] In the tetra-arylhydrazine series, according to Wieland, tetra-*p*-anisylhydrazine dissociates to a greater extent than tetraphenylhydrazine but tetrabiphenylhydrazine undergoes less dissociation than the phenyl analog.

[9] Michaelis and Schulte, Ber., **15,** 1952 (1882).

[10] Blicke and Smith, THIS JOURNAL, **51,** 1558 (1929).

[11] This solvent was chosen because of its comparatively low vapor pressure, an essential feature if the solution is to be used subsequently for an oxygen-absorption determination. As far as the removal of halogen and formation of the diarsyl is concerned, other solvents such as ether or benzene serve equally well.

[12] The apparatus devised by Gomberg and Schoepfle, THIS JOURNAL, 39, 1661 (1917), for oxygen absorption was employed.

extent into diarylarsyls, that is, divalent arsenic radicals. Molecular weight determinations of the various diarsyls are now being carried out in the hope that the dissociation, in some cases at least, is of such a magnitude that it can be detected by this method.

The behavior of other diarylarsyl iodides with mercury is described in the experimental part of this paper.

A further study of tetra-aryldiarsyls is in progress in this Laboratory and the action of metals on diarylstibinyl halides and on diarylbismuthyl halides is being investigated.

Experimental Part

Diphenylarsyl iodide, dissolved in bromobenzene, ether or benzene, reacts very rapidly at ordinary temperature with mercury, slower with molecular silver and zinc powder and very slowly, if at all, with magnesium powder or magnesium ribbon. In one instance $^1/_{200}$ mole of diphenylarsyl iodide, 6 g. of mercury and **15** *cc.* of bromobenzene were placed in the absorption bottle and the mixture was shaken continuously by hand. The amount of oxygen which had reacted after twenty minutes was **56** cc.; after thirty minutes, 59 cc. No further amount of oxygen was absorbed after an hour. The calculated quantity of oxygen required for peroxide formation is **56** *cc.*

A mixture prepared from 6 g. of mercury, 0.6 g. of iodine and **15** cc. of bromobenzene was rotated for four hours in a sealed tube. The mixture did not absorb oxygen; neither did diphenylarsyl iodide dissolved in bromobenzene absorb the gas.

It was found by analysis[13] of the mercury halide formed that mercury removes the halogen rapidly from di-*p*-tolyl-, di-*p*-anisyl-, di-α-naphthyl- and dibiphenylarsyl iodide.

Bromobenzene solutions obtained by shaking diphenyl-, di-p-tolyl- and di-p-anisyl iodide, respectively, with mercury, after complete removal of the iodine, absorb at once the calculated quantity of oxygen with the evolution of a considerable amount of heat. If the solution which has absorbed oxygen is allowed to remain in contact with the gas for a long period of time, a further *slow* absorption takes place due, probably, to the decomposition of the peroxide into secondary products which react with oxygen. **A** similar behavior is characteristic of triarylmethyl peroxides. In the case of solutions obtained from di-a-naphthyl- and dibiphenylarsyl iodide there was an immediate absorption of oxygen in excess of that required for the formation of a peroxide, the absorption varying from 125–130% of the calculated amount. At present we are unable to account for this phenomenon.

Relation between the Quantity **of** Oxygen Absorbed and the **Amount of** Halogen Removed.—Two sets of sealed tubes were rotated for definite periods of time. Each tube of the one set contained $^1/_{200}$ mole of diphenylarsyl iodide, **15** cc. of bromobenzene and **3.0** g. of molecular silver **(80–100** mesh). Each tube of the second set contained one-fifth of the above quantities of material. At intervals one tube from each set was removed from the rotating apparatus. The tube which contained the larger quantities was used for oxygen absorption; the contents of the other tube were poured on a filter, the residue of silver and silver iodide was washed several times with boiling xylene and then with acetone. The mixture was removed from the filter and the silver dissolved with hot, dilute nitric acid. The silver iodide was filtered and weighed.

A comparison of Line 4 with Line 3 shows that the percentage of oxygen absorbed is comparable, within the limit of experimental error, to the

---

[13] The analytical procedure of Kohn, *Z. anorg. Chem.*, 59, 108 (1908), was used but the iodine was determined volumetrically by the Volhard method.

percentage of silver iodide formed. The actual amount of oxygen absorbed, Line 2, is practically the same as that calculated, Line 5, from the quantity of silver iodide.

Abs. calcd. from AgI, cc.	12	25	40	52

It was found that diphenylarsyl iodide and triphenylmethyl bromide react instantly, when dissolved in bromobenzene, to form a deep red solution. The tendency for reaction is so great that when the two compounds are mixed in the solid state a red color develops at the points of contact. The solution absorbs oxygen rapidly. Undoubtedly the two compounds react in accordance with the following equation

$$(C_6H_5)_2AsI + (C_6H_5)_3CBr = (C_6H_5)_2AsBr + (C_6H_5)_3CI;\ (C_6H_5)_3CI \rightleftharpoons (C_6H_5)_3C- + I$$

However, the volume of oxygen absorbed (50 cc.) is greatly in excess of that calculated (28 cc.) for the amount of triphenylmethyl which could be produced. Other diarylarsyl iodides behave in an entirely analogous manner with triphenylmethyl bromide,

No color was developed when a mixture of diphenylarsyl bromide and triphenylmethyl bromide was dissolved in bromobenzene, and the solution did not absorb oxygen. No oxygen was absorbed by a mixture of diphenylarsyl bromide, iodine and bromobenzene.

A mixture of $^1/_{200}$ mole of diphenylarsyl iodide, 3 g. of silver and 15 cc. of bromobenzene was rotated for two days. The mixture absorbed 56 cc. of oxygen or 100% of the calculated amount. A similar mixture, except that $^1/_{200}$ mole of triphenylmethyl bromide was used in place of the arsyl iodide, absorbed under similar conditions 52 cc. of oxygen or 93% of the calculated amount. One four-hundredth mole of diphenylarsyl iodide, $^1/_{400}$ mole of triphenylmethyl bromide, 3 g. of silver and 15 cc. of bromobenzene were rotated for two days; the mixture absorbed 73 cc. of oxygen or 130% of the calculated amount.

Preparation and Properties of Tetraphenyldiarsyl.[14]—One-hundredth mole of diphenylarsyl iodide, 12 g. of mercury and 60 cc. of dry benzene[15] were put into a bottle which had been filled previously with dry, oxygen-free nitrogen. The bottle was stoppered tightly and then shaken by fastening it to the rim of a slowly revolving wheel. After the halogen had been removed the mixture was filtered into an apparatus similar to that used for the isolation of triarylmethyls.[16] The bulb of the apparatus was placed in a cone-shaped coil made from lead pipe, steam was passed through the latter

---

[14] This procedure applies also to the preparation of tetra-*p*-tolyldiarsyl and tetra-p-anisyldiarsyl.

[15] The benzene had been saturated with dry, oxygen-free nitrogen and was preserved over sodium. Ether may be used in place of benzene as a solvent:

[16] Gomberg and Cone, *Ber.*, 37, 2033 (1904).

and most of the solvent in the bulb was removed under diminished pressure.[17] The greater portion of the diarsyl separates as a colorless, crystalline precipitate. The contents of the bulb were treated with 20 cc. of dry, oxygen-free ether and the liquid poured out of the apparatus. The precipitate was dried by applying suction to the bulb and maintaining the latter at a temperature of 70–80° for three hours to insure complete removal of the solvent. The apparatus was then filled with nitrogen and the diarsyl transferred to a small test-tube in a stream of the gas.[18] The compound melted at 120–125°.[19]

In several instances oxygen absorptions were made with the tetraphenyldiarsyl isolated from ether. It was found that 0.5440 g. of the diarsyl, dissolved in bromobenzene, absorbed after one minute 26 cc. (calculated amount, 26.5 cc.). In a second experiment 0.5005 g. of the material was dissolved in ethylene bromide. The solution absorbed 25 cc. (calculated amount, 24 cc.).

Potassium permanganate dissolved in acetone was added to tetraphenyldiarsyl dissolved in the same solvent. The diarsyl decolorized instantly the amount of permanganate required theoretically to convert the substance into diphenylarsinic acid, although the latter was not isolated. Tetraphenylarsyl oxide and diphenylarsyl iodide also decolorized immediately an acetone solution of potassium permanganate.

Tetraphenyldiarsyl, tetraphenylarsyl oxide and diphenylarsyl iodide all decolorized instantly iodine dissolved in carbon tetrachloride. In the case of the tetraphenyldiarsyl the exact amount of iodine was added which was necessary for the formation of the diphenylarsyl iodide. A black, gummy precipitate formed which was, no doubt, a periodide. The solution was decanted from the precipitate and after removal of the solvent the black, viscous residue was covered with water and treated with sulfur dioxide. A yellow, crystalline substance was obtained which, after recrystallization from alcohol, melted at 42–43°. This material was diphenylarsyl iodide.

That a solution of tetraphenyldiarsyl is stable toward light, at least in the presence of mercury salts, is shown by the following experiment: 1.78 g. ($^1/_{200}$ mole) of diphenylarsyl iodide, 6 g. of mercury and 15 cc. of bromobenzene were rotated for eighteen hours. The tube which contained the material was then placed outdoors for nineteen days. The contents of the tube absorbed the calculated amount of oxygen, that is, 56 cc.

Summary

It has been shown that a number of tetra-aryldiarsyls can be prepared readily, from the interaction of a diarylarsyl iodide and mercury.

Because of the extremely great reactivity of these compounds toward oxygen, and other reagents, it seems that their behavior can be explained best by the assumption that the tetra-aryldiarsyls dissociate spontaneously into diarylarsyls, that is, divalent arsenic radicals.

ANN ARBOR, MICHIGAN

---

[17] If all of the solvent was removed, the diarsyl obtained was somewhat gummy.

[18] The diarsyls are so extremely reactive toward oxygen that it was found advisable to remove the compound from the apparatus in a large, specially designed box which was filled with dry carbon dioxide. All operations which involved exposure of the diarylarsyl, such as the preparation of pellets for molecular weight determinations, were carried out in this box.

[19] Michaelis and Schulte, ref. 9, state that the compound melts at 135°; Borgstrom and Dewar, ref. 7, recorded the melting point as 130.5° (corr.).

NOTES

A Note on the Use of Aniline in the Preparation of Amino Acids.—A standard method of isolating certain amino acids is to precipitate them from the alcoholic solutions of their hydrochlorides with pyridine. Cox, *J. Biol. Chem.*, 78, 475 (1928), used aniline in preparing d-arginine monohydrochloride. A consideration of the basic ionization constants of glycine, alanine and aniline indicated that aniline should precipitate these amino acids from their hydrochlorides, Experiment justified this prediction. Glycine can be prepared by the method of Clarke and Taylor, "Organic Syntheses," 4, 31 (1925), using aniline instead of pyridine. Alanine has been prepared by mixing acetaldehyde (1 mole), aqueous ammonium chloride (2 moles), and sodium cyanide (1 mole), and hydrolyzing by concentrated hydrochloric acid. This solution is then evaporated under reduced pressure to a thick paste, treated with absolute methanol (10 moles), filtered to remove solid chlorides and treated with aniline (1.3 moles). The yield of recrystallized alanine is 50% of the theoretical amount.

α-Amino-*iso*butyric and a-amino-n-valeric acids can be easily prepared in a similar manner.

β,β-Dinaphthyl Sulfide as a By-product in the Preparation of β-Naphthoic Nitrile. Reduction of the Sulfone with Sodium Cyanide.—Colver and Noyes,[1] while working on the synthesis of anthracene from naphthalene, found that the hydrolysis of the crude nitrile of β-naphthoic acid by boiling with a 30% solution of sodium hydroxide "left an unsaponifiable residue which is a reddish colored liquid at the temperature of the hot water-bath, but solidifies to a dirty red solid upon cooling. It is heavier than water, easily soluble in benzene but much more difficultly soluble in alcohol and ether." Other properties of the substance were not ascertained and no further investigation was made by them as to its identity.

Several years ago, during the course of an investigation on the preparation of certain ketones derived from β-naphthoic acid, a considerable amount of this unsaponifiable residue was accumulated and an investigation was undertaken to identify the material. It was distilled with steam, first in a concentrated alkaline solution and then in a concentrated acid solution; the non-volatile residue was separated from the water, dried and then distilled under reduced pressure. The distillate was a

---

[1] Colver and Noyes, THIS JOURNAL, 43, 901 (1921).

greenish-yellow liquid which on cooling became a light yellow solid. On standing exposed to the air the surface of the material turned red; crystallization from benzene removed the impurity responsible for the red color; a second recrystallization from benzene and washing with petroleum ether gave colorless, glistening, crystalline flakes, m. p. 151°; further recrystallizations from benzene and from ethyl alcohol did not change the melting point.

Anal. Calcd. for $C_{20}H_{14}S$: C, 83.86; H, 4.93; S, 11.2. Found: C, 84.06; H, 4.88; S, 11.7.

The melting point and the analysis indicated that the compound at hand was β,β-dinaphthyl sulfide.[2] Further evidence as to its identity was obtained by the melting point remaining unchanged on mixing with a sample of pure dinaphthyl sulfide prepared by heating the lead salt of β-thionaphthol; when oxidized in acetic acid solution with potassium dichromate and sulfuric acid, β,β-dinaphthyl sulfone, m. p. 177°, was obtained.[3]

These results show that the unsaponifiable portion of crude β-naphthoic nitrile, prepared by the fusion of sodium β-naphthalene sulfonate and sodium cyanide, consists mostly of β,β-dinaphthyl sulfide; this sulfide is probably formed by the reduction of β,β-dinaphthyl sulfone

$$(C_{10}H_7)_2SO_2 + 2NaCN \longrightarrow (C_{10}H_7)_2S + 2NaCNO$$

This sulfone is formed in small quantities when naphthalene is sulfonated at 180°,[4] and is present as an impurity in the sodium naphthalene sulfonate which was used as the starting product for the synthesis of the nitrile.

A New Series of Sulfonephthaleins.—In a recent article under the above title Harden and Drake, THIS JOURNAL, **51,** 562–566 (1929), a number of new compounds suitable for use as indicators for determining hydrogen-ion concentration were announced. Dr. I. M. Kolthoff, of the University of Minnesota, has kindly directed our attention to the fact that one of these compounds, tetrabromophenoltetrabromosulfonephthalein, has distinct advantages over brom phenol blue as an indicator. The new indicator shows a color change from yellow to blue, just as do brom cresol green and brom thymol blue, but without the interfering dichromatism.

NEW BOOKS

Polar Molecules. BY P. DEBYE, Ph.D., Professor of Physics and Director of the Physical Institute, Leipzig, Germany. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York, 1929. 172 pp. 33 figs. 15 X 23.5 cm. Price, $3.50.

During the past four years most papers dealing with dielectric constants have contained a reference somewhere in their first two or three pages to the chapter written by Professor Debye for one of the great German physical handbooks. Now one may expect to see this replaced by a reference to the present book, which makes available in English and in convenient form the most authoritative work on the theory of dielectrics. By this the reviewer does not mean to imply that the book is a mere translation or even a revision of the massive chapter which contains the foundation of so much recent dielectric investigation. It is, rather, a new work. The theory of dielectrics founded on the classical mechanics is presented and treated in the light of the recent extensive experimental investigations. The methods of calculating electric moments are considered and the relation of the moment of the molecule to its structure is shown by material taken from the recent literature. A chapter devoted to the constitution of simple polar molecules attacks the problem by means of the potential energy of the structure as calculated by Heisenberg and Hund. The chapter on anomalous dispersion for radio frequencies has the advantage over the earlier treatment that there is now available somewhat more experimental material to which the theory may be applied. Under electrical saturation effects, a problem of great interest to the physical chemist, that of the dielectric constant of ionic solutions, is treated with a reserve that is necessitated by the discordancy of the experimental results. The last four of the ten chapters are given over to recent developments in fundamental theory, as may be gathered from a list of the principal sub-headings: the thermodynamic potential and the quantum states, the dielectric constant and the Stark effect, geometrical optics and classical mechanics, wave optics and wave mechanics, the energy levels of a rotating diatomic molecule, the dielectric constant of polar gases, probabilities of transition, the wave function of polar molecules disturbed by a periodic field, infra-red dispersion of a polar gas.

The book is written from the point of view of the physicist but touches upon many questions of interest to the chemist, who, although he may find much of it rather hard reading because of the difficulty inherent in the subject, cannot fail to be impressed by the admirable clarity of thought so characteristic of the author and by the value of this penetrating survey of dielectric behavior by the man who has done so much to develop the field.

CHARLES P. SMYTH

Technische Gase, **ihre** Herstellung und ihre **Verwendung.** (Industrial Gases, their Preparation and Uses). DR. FRANZ MUHLERT, Gottingen, and DR. KURT DREWS, Berlin. S. Hirzel, Leipzig, Germany, 1928. viii + 416 pp. 196 figs. 15 × 22.5 cm. Price, unbound, M. 22; bound, M. 24.

The book aims to give a broad survey of the field of industrial gases, showing the relation of the various gas industries to one another and to chemical and metallurgical industries. The authors have been extremely successful in presenting in concise form the fundamental chemical aspects, the engineering developments and the operating features pertaining to the manufacture of a host of industrial gaseous compounds and mixtures of these gases. The technology of the various combustible gases derived from wood, peat, "brown" coal, bituminous coal, anthracite coal, coke and oil is described in considerable detail for many processes. The book is profusely illustrated with flow diagrams of processes and photographs of equipment. Tables correlating the chemical compositions and other characteristics of the various fuels and gases are included. The treatment of the gas prior to its use, to include its purification, transportation and distribution, is described in considerable detail, reflecting the importance of this enterprise in Germany, where coke oven gas is being transported to distant cities. There is also included a compilation of statistics on the present magnitude of the combustible gas industry in Germany and the costs of gas by the various processes.

D. C. BARDWELL

Messungen elektromotorischer **Kräfte** galvanischer Ketten mit **wässerigen Elektrolyten.** (Measurements of the Electromotive Forces of Galvanic Cells with Aqueous Electrolytes.) Edited by CARL DRUCKER. Second supplementary volume. No. 10 of the Abhandlungen der Deutschen Bunsen-Gesellschaft. Verlag Chemie, G. m. b. H., Berlin W 10, Germany, 1929. viii + 234 pp. 17 × 24.5 cm. Price, M. 24.

The first supplementary volume of this compilation of electromotive-force measurements appeared in 1915. The present volume covers the literature from 1914 to the end of 1927.

The method of presentation of the earlier volumes is followed here. The book is divided into three parts. In Part I, under each element is given a chronological bibliography of the literature dealing with the electromotive force of galvanic cells containing this element. In Part II, under each element is given in chronological order a list of the electromotive-force data obtained with each cell measured. In Part III, the normal potentials calculated from these measurements are given, taking the potential of the hydrogen electrode as zero. These are listed first under the head of the various elements and second according to increasing (positive) potentials. Then follows an index according to authors of the articles cited. Finally a convenient summary of the most important normal potentials is provided on a separate card.

This careful and concise collection of electromotive-force data is a valuable one indeed, particularly in conjunction with the earlier volumes of the series.

It is of interest that the contributions from THIS JOURNAL listed in this volume far exceed in number those from any other journal.

ARTHUR B. LAMB

A Textbook of Organic Chemistry. BY JOSEPH SCUDDER CHAMBERLAIN, Ph.D., Professor of Organic Chemistry, Massachusetts Agricultural College. Second edition, revised. P. Blakiston's Son and Co., 1012 Walnut Street, Philadelphia, 1928. xxx + 901 pp. 15 × 22 cm. Price, $4.00.

In this second edition of his organic chemistry textbook, Professor Chamberlain has made some additions to the descriptive matter of the earlier publication, and has introduced two new and rather useful features, first, the placing of appropriate study questions at the end of each chapter and, second, an emphasis on the importance of literature study by introducing throughout the book numerous references to standard methods of preparation for the more common types of organic compounds. A number appearing beside a compound in the text refers the reader to the appendix, in which is given usually more than one reference to well-known laboratory guides and handbooks.

It is suitable for a first course in organic chemistry, although it covers rather more ground than is usually considered appropriate for a beginner. On the other hand, the number (901) of pages is somewhat misleading in that considerable space is devoted to thorough discussion of many of the simpler reactions. In fact this is one of the few criticisms that might be directed at the text. The subject matter is clearly and simply stated; numerous formulations—possibly too numerous in places—make for ease of reading and understanding on the part of the student.

The book as a whole appears to the reviewer to possess real merit; it should find a deserved place among the better American organic chemistry texts.

A. J. HILL

Enzyme Actions and Properties. By ERNST WALDSCHMIDT-LEITZ, Institute of Biochemistry, Prague. Translated and extended by Robert P. Walton. John **Wiley** and Sons, Inc., New York, 1929. xviii + *255* **pp.** 12 figs. **15.5 × 23.5 cm.** Price, $4.00.

So voluminous is the literature of enzyme research published during the past decade by the Willstatter school that it is a convenience to have its main results concisely collected. This Waldschmidt-Leitz has done, giving his summary the form of a general treatise on enzymes. The book is divided (using the terminology which it employs) into a General Section including development of the ferment concept, enzymes as colloids, and as electrolytes, enzymic kinetics, enzymic reaction systems, specificity, and procedures in preparative work; and a Special Section dealing with esterases, proteases and peptidases, aminoacylases, carbohydrases, catalases, peroxidases, oxidases, and fermentation enzymes. Since all this is covered in 241 pages of text, it is plain that detailed treatments of these numerous and comprehensive topics are not to be expected. Doubtless also any detailed attempt at comparative evaluation of the several chapters would be subject to large personal equation according to the individual viewpoint of the critic. In the judgment of the present reviewer, the treatment is reasonably well balanced as between topics, but on most topics is not well balanced in the selection of material. The author's predilection for the work and views of his own school has been permitted seriously to bias what is offered as a general view of the subject, and, while according to the title page the translator has extended the original text, this seems to have been done rather unevenly, so that many if not most of the chapters show an extremely partial presentation of the topics which they profess to cover. Thus, the admirable work of T. B. Osborne upon malt amylase is not even mentioned, nor do we find any reference to the very extensive work of Falk upon the lipases and esterases, nor to any of the recent American work upon the purification and chemical nature of pepsin. It seems especially unfortunate that the long preface, while plausibly written, is as badly biased as the body of the text, and its claims (as often happens) have already been reflected in more than one review. Those who read the book expecting the oriented view which the preface promised will (depending upon their background of acquaintance with enzymes) either be misled or disillusioned. The experienced and critical reader may conveniently make use of this handy little volume as a summary of the views and findings of the recent Munich school. The importance of certain of their findings will be gladly and gratefully acknowledged by all investigators of enzyme problems.

THE CRYSTAL STRUCTURE OF TRICALCIUM ALUMINATE

BY F. A. STEELE[1] AND WHEELER P. DAVEY

RECEIVED JULY 5, 1928 PUBLISHED AUGUST 7, 1929

It was predicted a number of years ago on theoretical grounds that many of the complex minerals, such as those of the polysilicic acids, would be found to contain molecules of the component oxides rather than complex ionic groups.[1a] $K_2O{\cdot}Al_2O_3(SiO_2)_6$ was cited as an example. So far, no data have been published which support this view, and, so far as the present authors know, no compounds of this type have been examined by x-ray methods. It was with the hope of obtaining data on this type of compound that this research was undertaken. Tricalcium aluminate ($3CaO{\cdot}Al_2O_3$) was chosen for analysis because it was known to be optically isotropic, thus showing that the crystals have cubic symmetry, and because of its relatively simple composition and its lack of ability to exist in other than the solid state. It is said to melt incongruently at 1535°, giving a melt of the two oxides with an excess of CaO. No method is known by which crystals of tricalcium aluminate can be grown of such size as to permit of goniometric measurements. This has necessitated the use of a very general method of application of the theory of space-groups to the powder method of x-ray crystal analysis. It turns out that tricalcium aluminate does not show the new type of structure originally sought. Instead, it is "mixed ionic," *i. e.*, the metallic elements and the oxygen all enter the compound as separate crystallographic entities. It is with the determination of this type of structure and with the sort of chemical combination which it discloses that this paper has to do.

Preparation of $3CaO{\cdot}Al_2O_3$.—A mixture of CaO and Al_2O_3 of high purity in the molecular ratio of three to one was very thoroughly mixed and ground in an agate mortar. It was then heated for about twenty minutes in a small platinum boat which was directly heated in the air by an electric current to 1350–1450°. Temperatures were measured by an optical pyrometer and were found to be substantially uniform over the

---

[1] The material here presented was used by the junior author in partial fulfilment of the requirements for the Ph.D. degree at The Pennsylvania State College, June, 1928.

[1a] Langmuir, THIS JOURNAL, 38, 2241 (1916).

portion of the boat used. The substance does not fuse at these temperatures but sinters into a light, friable lump. The cycle of grinding and heating was repeated from two to eight times for each sample. Little improvement in the material could be noted after the third cycle. The temperature was not critical within the above limits.

X-Ray Diffraction Data.—X-ray diffraction patterns of the powdered substance, made on the General Electric apparatus, using molybdenum K-alpha radiation, showed strong lines characteristic of a body-centered cube, $a = 3.812$ Å., superimposed upon a weak pattern of CaO and numerous additional faint lines. Since $3CaO{\cdot}Al_2O_3$ is known from optical data to have cubic symmetry,[2] it seemed likely that the body-centered cubic lines mentioned above were due to this substance. It remained to account for the extra lines.

The optical properties of the four compounds of CaO and Al_2O_3 which have been described in the literature[2] ($3CaO{\cdot}Al_2O_3$, $5CaO{\cdot}3Al_2O_3$, $CaO{\cdot}Al_2O_3$ and $3CaO{\cdot}5Al_2O_3$) are given in the "International Critical Tables." Using these data as a basis of identification, the petrographic microscope revealed the presence of large amounts of $3CaO{\cdot}Al_2O_3$, together with smaller amounts of $3CaO{\cdot}5Al_2O_3$ and CaO. $5CaO{\cdot}3Al_2O_3$ and $CaO{\cdot}Al_2O_3$ were absent. Another batch of the material was prepared with about equal molar proportions of the two oxides. The petrographic microscope showed that it contained a much greater proportion of $3CaO{\cdot}5Al_2O_3$. The x-ray diffraction pattern showed a much greater relative intensity of all but three of the lines which had not been accounted for in the previous diffraction patterns. These three lines correspond to interplanar spacings of 3.1 Å., 2.20 Å. and 1.79 Å. These spacings may be derived from a cube whose side is twice that corresponding to the body-centered cubic pattern. These data were taken as conclusive evidence that the body-centered cubic lines, and the three additional faint lines, were due to $3CaO{\cdot}Al_2O_3$ and that the other faint lines were due to CaO and $3CaO{\cdot}5Al_2O_3$.

The interpretation of the crystal structure of tricalcium aluminate, therefore, resolves itself into a search for those structures which can quantitatively account for the body-centered cubic pattern and for the three faint lines mentioned above. The first step is the determination of the number of "molecules" per unit crystal cell.

The Number of Molecules per Unit Cell.—Since tricalcium aluminate is available only in a finely divided and relatively impure condition, a precision measurement of its density is not possible. An approximation sufficiently close for the determination of the number of molecules per unit cell was made, however, by observing the behavior of the substance in liquids of various densities. The observations were made by filling a

---

fine capillary tube with a suspension of the powder in a mixture of methylene iodide and mesitylene of previously determined density. A petrographic microscope was mounted with its optical axis horizontal, and the tube containing the suspension was mounted vertically on the microscope stage. With a liquid whose density was 2.89 most of the tricalcium aluminate particles moved downward, and those of $3CaO{\cdot}5Al_2O_3$ moved upward. A partial separation of the two was obtained by centrifuging the suspension. Complete separation could not be obtained because of the mechanical union between particles due to the sintering process. The relatively pure $3CaO{\cdot}Al_2O_3$ thus obtained was dried and used in subsequent determinations. This powder was found to fall in a liquid of density 2.94 and to rise in one of density 3.07. In a liquid of density 3.005 the particles went up and down in about equal numbers. The density of $3CaO{\cdot}Al_2O_3$ is therefore between 2.94 and 3.07 and is probably very close to 3.00. The number of molecules per unit cube ($a = 3.812$ Å.) is given by the density and molecular weight as 0.373 ± 0.004. This is very nearly equal to $^3/_8$. No other common fraction whose numerator and denominator are small integers comes within the precision of the data. Since the number of "molecules" in a unit cell must be a whole number, it is evident that the edge of the unit cell must be a multiple of 3.812 Å. A cube of twice these dimensions (*i. e.*, $a = 7.624$ Å.) would contain three "molecules." A smaller cell cannot possibly contain a whole number of "molecules" without conflicting with the x-ray data. Furthermore, there are no data from the diffraction patterns which require that it be larger. This means that for crystallographic purposes the formula of tricalcium aluminate should be $9CaO{\cdot}3Al_2O_3$. The three faint lines mentioned above might be accounted for quantitatively within the precision of the data by assuming that they are caused by first-order diffraction from 2 1 1, second-order diffraction from 1 1 1 and third-order diffraction from 1 1 0, respectively. It will appear later that all three can be accounted for in this way.

The Crystal Structure.—Since the body-centered cubic pattern from the tricalcium aluminate is on the basis of a cube of one-half the dimensions of the unit cell, it must be considered to be essentially an accidental result of the atomic arrangement within the unit cell and, as such, it imposes no symmetry limitations upon the cell as a whole. Since no crystals large enough for symmetry observations or Laue photographs could be made, none of the usual methods for establishing the space-group is available. This means that every possible arrangement of the atoms consistent with cubic symmetry must be considered as a possibility until it is shown to be in conflict with known facts or data.

The procedure used in writing down the possible arrangements was essentially the same as that used by Wyckoff in his treatment of calcite[3]

---

[3] Wyckoff, *Am. J. Sci.*, **50**, **317** (1920).

except that the process is greatly complicated by the fact that all cubic space-groups must be considered and that there are many more atoms to place in the unit cell. In considering the possible combinations of groups of equivalent points occupied by a given kind of atom, it is obviously necessary to consider only those numbers which represent groups. of equivalent points in cubic symmetry, namely, 1, 2, 3, 4, 6, 8, 12 and 16. Furthermore, those which do not have variable parameters, namely, 1, 2 and 3, need not be considered more than once. Bearing these limitations in mind, the possible combinations for the six Al ions are found to be 6 all alike, 4 of one kind and one each of two others, 4 of one kind and 2 of another, 3 of one kind and 3 of another, and **3** of one kind, 2 of another and one of another. These combinations may be expressed more conveniently by merely writing the possible numbers totaling 6, bearing in mind the limitations mentioned above. The possible combinations for Al are, then, 6, 4–1–1, 4–2, 3–3 and 3–2–1. This code will be followed in the subsequent discussion. Reference to the summary table[4] of equivalent points in the various space-groups of the cubic system shows that all of these are possible except the last. The 3–2–1 combination is impossible because there is no one space-group which contains arrangements of both *2* and 3 equivalent points'.

A similar treatment of the nine positions required for the Ca ions leads to the combinations 8–1, 6–3, 4–3–1–1 and 4–4–1. Each combination for Al must now be considered with each combination for Ca, and the space-groups compatible with both are written down. As may be seen in Table I, the entire list includes only five space-groups. This whole process is then repeated for the possible combinations for the 18 oxygen ions. The results are listed in Table II. Although there are only five space-groups involved, there are so many combinations possible within each space-group that the total number of possible arrangements is very large. For instance, if Ca is taken at 8c and 1a,[5] and Al at 6a, there are over **30** configurations of O possible. Since Al may also be at 6b, 6c or 6d, this number is increased four-fold. Placing Ca at 8c and 1b again

TABLE I

SPACE-GROUPS POSSIBLE FOR VARIOUS ARRANGEMENTS OF CA AND AL

Combinations for calcium	Aluminum at 6–0	Aluminum at 4–1–1	Aluminum at 4–2	Aluminum at 3–3
8–1	$T_h^1 O^1 O_h^1$	none	none	$T_h^1 O^1 O_h^1$
6–3	$T^1 T_h^1 T_d^1$, $O^1 O_h^1$	$T^1 T_d^1$	none	none

doubles this figure. Such a systematic procedure involves a number of duplications, but it was followed rigidly to lessen the chances of error. The total number of possibilities tabulated was about 1500.

TABLE II

SPACE-GROUPS POSSIBLE FOR VARIOUS ARRANGEMENTS OF O WITH COMBINATIONS OF CA AND AL ALREADY FOUND POSSIBLE

Combinations for oxygen	6–8–1	6–6–3	6–4–3–1–1	6–4–4–1	8–3–3–1	4–4–3–3–1
12–6	$T_h^1O^1O_h^1$	$T^1T_h^1T_d^1$ $O^1O_h^1$	$T^1T_d^1$	$T^1T_d^1$	$T_h^1O^1O_h^1$	$T^1T_d^1$
12–4–1–1	none	$T^1T_d^1$	none	none	none	none
12–33	$T_h^1O^1O_h^1$	none	none	$T^1T_d^1$	none	none
8–8–1–1	none	$T_h^1O^1O_h^1$	none	none	none	none
8–6–3–1	$T_h^1O^1O_h^1$	$T_h^1O^1O_h^1$	none	none	none	none
6–6–6	$T_h^1O_h^1O^1$	$T^1T_h^1T_d^1$, $O^1O_h^1$	$T^1T_d^1$	$T^1T_d^1$	$T_h^1O^1O_h^1$	$T^1T_d^1$
6–6–3–3	$T_h^1O^1O_h^1$	none	none	$T^1T_d^1$	none	none
6–4–4–3–1	none	$T^1T_d^1$	none	$T^1T_d^1$	none	none
6–6–4–1–1	none	$T^1T_d^1$	none	none	none	none

There were no possibilities with O at 16–2, 16–1–1, 12–4–2, 8–8–2, 8–6–4, 8–6–2–2, 8–4–4–2, 8–4–4–1–1, 6–6–4–2 or 6–4–3–3–1–1.

It was found possible to eliminate most of these possibilities by a consideration of the packing-sizes of the ions involved and the space available in the unit cell. Ionic dimensions have been published by Bragg[6] and by one of the present authors.[7] According to Bragg the ionic radii are Ca = 2.1 Å., Al = 1.45 Å. and O = 0.6 Å. According to Davey they are Ca = 1.4, Al = 0.9 and O = 1.0 Å. Davey's values were used in this work for two reasons: first, that they give the distance from Al to O in Al_2O_3 as 1.9, in agreement with the published data of Bragg, and second, that they give a smaller total distance for Ca + O and for Ca + Al, so that they tended to retain certain of the possibilities which would have been thrown out on the basis of Bragg's values. Thus any error introduced by our limited knowledge of the packing dimensions of ions was clearly on the safe side. The procedure of finding whether or not space was available in a given configuration was greatly facilitated by drawing each of the arrangements of equivalent positions involved on tracing cloth. In this way any combination of arrangements could be superimposed and viewed against a bright light. In this manner the ions placed along any one dimension of the cube could be picked out readily.

As an example of this procedure, consider the structure in which Ca is at 8c and 1a, Al at 3a and 3b and O at 6a and 12d. This places $^1/_2$ Ca, 1 O and $^1/_2$ Al along half the cube edge. This requires a space of 1.4 + 2.0 + 0.9 = 4.3 Å. where only 3.8 Å. are available. The structure is obviously an impossibility if the ions have anything like the packing

---

[6] Bragg, *Phil.* Mag., 40,236 (1920).

[7] Davey, *Phys.* ***Rev.,*** 22, 716 (1923); *Chem.* ***Rev.,***2, 349 (1926); *Gen. Elec.* ***Rev.,*** 29,274 (1926).

radii assigned to them above. In making these eliminations, the packing dimensions assumed for the ions were not regarded as strictly inflexible. No structure was eliminated unless the available distance involved was exceeded by at least 10%. This procedure eliminated all but about 40 of the original 1500 possible structures. It remained to eliminate as many of these as possible on the basis of x-ray evidence. Among the 40 arrangements allowed by the ionic dimensions were a number of duplications, but these were carried through as a check. In general, however, each of these structures actually represents a number of possibilities which cannot be distinguished experimentally because of the similar dimensions and scattering power of Al and O ions. In the present state of our knowledge of diffracting power, we are hardly justified in distinguishing between Alf^{++} and O^{--} on x-ray data alone. It was therefore assumed that interchanging places between the 6 Al ions and 6 of the O ions has no effect on the diffracting power of the crystal planes. Were this assumption not made, the number of structures to receive individual examination would be much larger than forty.

After it had been decided that the unit cell must have a length of 7.624 Å., repeated attempts were made to detect a first-order diffraction from the 1 0 0 planes for d = 7.624 Å. These attempts gave uniformly negative results. This fact served to eliminate a considerable number of otherwise possible structures without an intensity calculation. In accordance with the general practice, the diffracting power of a plane was taken as proportional to the total number of electrons in the ions which were situated in that plane. The diffracting powers of 1 0 0 planes were calculated for all the forty structures. Those whose 2 0 0 planes were obviously too thinly populated with electrons to cut out the first order from d_{100} = 7.624 Å. were discarded. However, because of the lack of definite knowledge of the correct basis for calculating diffracting powers, no structures were discarded on this basis unless the 2 0 0 planes had less than three-fourths the electron population of the 1 0 0 planes. Repeated attempts to find experimental evidence of a second-order diffraction from d_{100} = 7.624 Å. gave negative results. A few additional structures were therefore eliminated because it was inherent in the structure that the ions were distributed in the space between the 1 0 0 and 2 0 0 planes in such a way as unavoidably to produce such a second-order diffraction.

When all possible eliminations had been made by simple inspection of 1 0 0 planes, there remained only 18 structures, of which 9 were duplicates of the other 9. For instance, the structure having Ca at 8c and 1a, Al at 6d and O at 6b and 12d, may be transformed into the structure having Ca at 8c and 1b, Al at 6a and O at 6c and 12e by merely changing the origin of coordinates from a corner of the unit cube to its body-center. From this point on the duplicates were combined, leaving 9 structures for which intensity calculations must be made. In those cases where two arrangements differed only in having one variable parameter more or less (for instance, 12e and 12n), only the more general arrangement was considered. Similarly, the combination of 6b and 6c was used instead of the special case represented by 12f.

In making the intensity calculation the customary assumption was made that the amplitude of the radiation scattered by a given plane is proportional to the electron population of that plane. This population was determined in the usual manner on the basis of $O^{--} = 10$, $Al^{+++} = 10$ and $Ca^{++} = 18$. The resultant amplitude from a given form was taken as the vector sum of the amplitude from the individual coöperating planes. This was determined by the graphical addition of vectors in the same manner as the addition of alternating currents which have a known phase difference.[8] The intensity of the resultant beam was calculated from the formula[9,10]

$$I = R^2 j \left(\frac{d}{n}\right)^m$$

where R is the resultant amplitude, j is the number of families of planes of the form, n is the order of diffraction and d is the fundamental spacing of the form, taking the edge of the unit cube as unity, and regarding the unit cell as being simple cubic. These calculations showed clearly that six of the nine structures are quite incompatible with the x-ray data. For example, the structure with Ca at Sc and la, Al (or O) at 3a and 3b,

---

[8] In this connection see A. Schuster, "The Theory of Optics," Chap. 1, Edw. Arnold, London, **1909, 1919,** or any standard book on alternating currents.

[9] Because of our inexact knowledge of diffracting power this equation can be used only to show qualitatively the relative intensities of diffraction. The simpler the plane form to which it is applied the more reliable are the results. It may be used quite successfully for the 1 0 0 planes—and seems to apply for the 1 1 0 planes. For the 1 1 1 planes the packing radii of the ions are so large in comparison with the interplanar spacing that the calculated results can only be depended upon to show that a line is present or absent in the diffraction pattern. There is a tendency to make the diffracted beam of orders higher than the first abnormally weak. For this reason the formula shows whether the second and fourth orders of 1 1 1 are present and whether the first and third orders are absent, but it does not give the relative intensity of the second and fourth orders.

It is well known that certain crystals act as though the resultant amplitude of the diffraction beam depends upon the square-root of the electron population. For this reason attempts were made to repeat the above calculations on this basis. In no case where this was tried were we able to retain a structure which had been rejected in the original calculations.

[10] Bragg uses $m = 2.0$; Wyckoff uses $m = 2.35$; McKeehan uses $m = 3.0$. None of these seem to be entirely satisfactory. Our Table III was calculated using $m = 2$, merely for the sake of convenience in making the large number of calculations required. It is clear that Table III could have been made to show greater apparent agreement by using a different value for m but it does not follow that such a change would have increased the probability of the correctness of our ultimate solution.

O (or Al) at 6d and O at 12d gave a calculated intensity of 380 for the first order of $d_{100} = 7.624$, and 257 for the fourth order, even when such parameters were used as to give the weakest possible first order and the strongest possible fourth order. Since experimentally the first order is absent and the fourth order is strong, this structure is in direct conflict with the experimental data and must be discarded. Similar calculations on the 1 0 0 planes for the rest of the 9 structures eliminated all but three.

In the case of the three remaining structures it was necessary to make intensity calculations for the first four orders of the 1 0 0, 1 1 0 and 1 1 1 planes. These calculations were made for a large number of different values for the variable parameters which were allowed by the space available for the ions, and by the symmetry requirements of the atomic arrangements. The best fit in intensities was found in the structure illustrated in Fig. 1, in which Ca is at 8c and 1a, Al at 3a and 3b and O at 6d and 12f.[11] The calculated intensities are shown in Table III. It will be noted that they indicate the presence of the three faint lines mentioned at the beginning of this article.

TABLE III

CALCULATED AND OBSERVED INTENSITIES FOR THE MOST PROBABLE ARRANGEMENT

Line	Calculated intensity	Observed intensity
100 1st order ($d_{100} = 7.624$)	75	Absent
100 2nd order	0.1	Absent
100 3rd order	14.1	Absent
100 4th order	1750	Strong
110 1st order	26	Absent
110 2nd order	1420	Very, very strong
110 3rd order	80	Very faint
110 4th order	1500	Weak
111 1st order	163[a]	Absent
111 2nd order	1067[a]	Weak
111 3rd order	69[a]	Absent
111 4th order	552[a]	Faint
211 1st order	4754[a]	Weak
211 2nd order	735[a]	Very strong

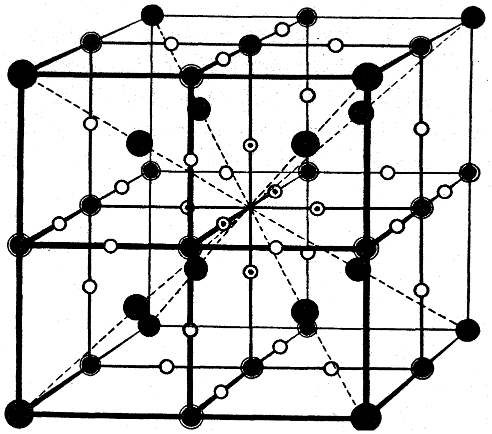
[a] Note statements in the text as to the weight to be put on numerical results for these planes.

As was mentioned previously, it is not possible to distinguish with certainty between Al and O ions on the basis either of dimensions or of diffracting power. The assignment of certain of the positions in Fig. 1 to Al and of other positions to O was made on the basis of electrostatic considerations. For instance, in Fig. 1 the x-ray data would permit Al to be at 6d and six of the eighteen O at 3a and 3b. However, since there

---

[11] The presence of Al at 3a and 3b leaves room for O at 6b and 6c only at a point half-way between 3a and 3b. This changes 6b and 6c into the special case of **12f.**

are O ions at 12f, we would then have five O ions in a row along a direction parallel to the edge of the cube ($d_{100} = 7.624$ Å.). Such an arrangement is highly improbable from electrostatic considerations. Similarly, the Al might have been placed at 6b (or 6c) with the O at 3a, 3b and 6c (or 6b). This also places five O in direct contact with one another, and is therefore a highly improbable structure. Furthermore, there is some theoretical basis for expecting that Al would have a somewhat greater equivalent scattering power than O, especially in the higher orders and from forms of small spacing. If this be true, the Al at 3a and 3b would cause a fainter 1 1 1 second-order diffraction than the calculated value given in Table III. This would give a still better match with the experimental data.



●, Ca; ◉, Al; O, O at 12f; ⊙, O at 6d.

Fig. 1.

It has already been stated that, although the theory of space-groups permits a variable parameter for 12f, the dimensions of Al and O ions fix this parameter in Fig. 1 at $u = 0.25$. Arrangements 6d and 8c have variable parameters. The best intensity match is obtained when u for Ca at 8c = 0.24 and u for O at 6d = 0.31. Intensity calculations show that these parameters are not particularly critical, especially in the case of O at 6d, which may well be somewhat closer to Al at 3a.

The two other structures which were mentioned as possibilities both have Ca at 8c and 1a. One has 6a, 6b, 6c and 6d for Al and O, while the other has them at 6a, 6b, $6b_2$ and 6d. These two structures are closely related, since 6c may be derived from 6b by a single rotation of 90°. While the calculated intensities of these two structures are somewhat less satisfactory than those of the one shown in Fig. 1, the degree of reliability of the laws of scattering with complex crystals is so uncertain that they must be considered as possible structures. In any case, the same general chemical conclusions can be drawn from all three structures.

Chemical Significance **of** the Structure.—It is obvious that there is no particular grouping of ions in any of the three structures of which Fig. 1 is typical. There is no indication of those groups which might have been expected to be present, such as CaO, AlO_3, Al_2O_3, Al_2O_6, etc. The entire structure is built up of Ca, Al and O ions as units. The ionic nature of the compound is evident from its crystal structure. Figure 1 shows **that** the O at 12f are in every case midway between two Al at 3a and 3b, and that each O at 6d is equidistant from four Ca at 8c. Similarly, every Al at 3a is equidistant from each of four O at 12f; every Al at 3b is equidistant from four O at 12f; every Ca at 8c is practically (within 4%) equidistant from six O at 12f, and every Ca at 1a is equidistant from twenty-four O at 12f. Every Al at 3a is equidistant from four Ca at 1a and is equidistant from eight Ca at 8c. Every Al at 3b is equidistant from two Ca at 1a and is also equidistant from eight Ca at 8c. Similarly, every Ca at 1a is equidistant from six Al at 3b and every Ca at 8c is practically equidistant from 3 Al at 3a and from 3 Al at 3b.

Tricalcium aluminate certainly has no grouping which would justify its name. From its crystal structure it would appear to be a mixed oxide and not a salt in any sense of the word. It is distinctly different from solid solutions or mix-crystals, which are either isomorphous substances or simple replacements of one kind of atoms by another kind. In this latter case the structure of one or the other is retained with usually only a change in the lattice dimensions. In the case of tricalcium aluminate the original structure of neither oxide is retained. The structure of tricalcium aluminate is also distinctly different from that of crystals containing complex ions. The complex ionogens whose structures have been determined support the Wernerian conception of secondary valence. $NiCl_2 \cdot 6NH_3$,[12] $K_2Zn(CN)_4$,[13] K_2PtCl_4,[14] $NaClO_3$,[15] etc., are examples of this type of compound. In each of these the complex ion has been found to act crystallographically as a unit, thus confirming the evidence, already strong, from solutions. Tricalcium aluminate, on the other hand, shows the Ca, Al and O to act as crystallographic entities, each surrounded as symmetrically as possible by the other two. In terms of the most probable of the three structures discussed above (see Pig. 1), all six Al ions lie at the intersections of a physical three-dimensional lattice work in such a way as to put an O midway between each pair of Al. This lattice work uses up 12 of the O, so that the lattice work contains two O for every Al. Figure 1 shows, however, that there are no AlO_2 groups existing as physical entities in the crystal. The crystallographic effect might be described as a sort of rectangular sponge of Al and O in the interstices of which are the Ca and the rest of the O ions.

The type of crystal structure reported in this paper for tricalcium aluminate therefore belongs to the fifth type of chemical combination, listed below, *viz.*, (I) ionic compounds (NaCl) (Bragg) in which the crystal is built up of simple ions of an electrolyte; (2) electron-sharing compounds (Al_2O_3) (Bragg) in which the crystal is built up of neutral

---

molecules; (3) geometrical compounds (Cu_3Au) ($CuAu_3$) (Bain) in which definite proportions are an accident of symmetry in homogeneous atomic dispersions; (4) Wernerian compounds ($CaCl_2I$) (Wyckoff) (K_2PtCl_4) (Dickinson) in which the crystal is built up of both simple and complex ions; (5) mixed ionic compounds ($3CaO \cdot Al_2O_3$).

There remains to be discovered a sixth type,[1] namely, the molecular compound in which molecules of the constituents crystallize together without losing their original identity. As in the case of Type 3, it may be expected that this will be an accidental effect of the symmetry of a homogeneous molecular dispersion of one substance in the other.

Acknowledgments.—It is a pleasure to express our appreciation to the General Electric Company, Schenectady, N. Y., the Calumet Baking Powder Company, Chicago, Ill., and to the Aluminum Company of America, New Kensington, Pa., for placing at our disposal facilities without which this research would have been exceedingly difficult, if not impossible; and to Dr. E. A. Harrington, who first showed that the x-ray diffraction pattern of an impure tricalcium aluminate contained lines corresponding to those from a body-centered cube.

Summary

1. The most probable crystal structure of tricalcium aluminate has been determined and the alternate possibilities stated.

2. The structure of tricalcium aluminate has been shown to be mixed ionic.

THE THEORETICAL EVALUATION OF THE ENTROPIES OF AQUEOUS IONS

BY WENDELL M. LATIMER AND CHARLES KASPER

RECEIVED AUGUST 13, 1928 PUBLISHED AUGUST 7, 1929

It has been suggested by Latimer and Buffington[1] that the entropy change, AS, for the process

$$\text{Ion (gas)} = \text{Ion (aq.)}$$

is a function of the charge, e, on the ion, and the radius, r, of the ion cavity in the water solution; AS = $f(e^2/r)$. This relation was noted from an inspection of the experimental values of the entropies of solution and was stated in the form of an empirical equation. The theoretical evaluation of this function will be considered in this article.

The total entropy of hydration may be considered as due to two effects: $\Delta S_{(1)}$, the entropy change arising from the polarizability of the medium,

---

[1] Latimer and Buffington, THIS JOURNAL, 48, 2297 (1926).

and $\Delta S_{(2)}$, the entropy change due to the compression of the water, arising from the electrostatic attraction of the water molecules.

The first effect can be obtained by considering the temperature coefficient of the free energy of the process of charging the ion in the gas and water phases. For this free energy, we have the expression first set forth by Born[2] and Fajans[3] and later developed in the works of Hückel,[4] Zwicky[5] and Webb.[6]

The original Born work, which of late has been supported (in so far as the dielectric constant is concerned) by Latimer,[7] Scatchard[8] and Bjerrum,[9] takes the ordinary dielectric constant to be operative. Hückel advanced the idea that the effective dielectric constant must be less than that of pure water in accounting for the course of the activity–coefficient curve. Webb actually succeeded in calculating such an effective dielectric constant, but, unfortunately, the method which involves the selection of an effective moment, and the application of the Langevin theory to water as a normal liquid is open to serious question, especially in the case of entropies.

It is interesting, nevertheless, to see what result the old picture gives us. Thus, using the Born expression

$$\Delta F_{(1)} = -\frac{e^2}{2r}\left(1 - \frac{1}{D}\right) \tag{1}$$

and by differentiation

$$\Delta S_{(1)} = \frac{e^2}{2rD^2}\left(\frac{\mathrm{d}D}{\mathrm{d}T}\right)_P = \frac{-\Delta F_{(1)}}{D^2}\left(\frac{\mathrm{d}D}{\mathrm{d}T}\right)_P\left(\frac{1}{1-\frac{1}{D}}\right) \tag{2}$$

From Kockel,[10] for 25°, the dielectric constant of water is 78; its temperature coefficient is equal to —0.4. Placing these values in Equation 2 we obtain $\Delta S_{(1)} = 6.3 \times 10^{-5}\, \Delta F_{(1)}$ cal. per degree per mole. The magnitude of this quantity is about half that found experimentally for the total entropy of hydration. However, we cannot attach much significance to the numerical result as the temperature coefficient of the dielectric constant of pure water may not be even of the same order of magnitude as that for water under the enormous electrical field about the ion. the calculations which we are to make it appears that $\Delta S_{(1)}$ must in reality be small in comparison with the other effect. This failure of Equation 2 will be considered in a later paragraph.

The second entropy change accompanying hydration, that is, the change of entropy of the water with pressure, is given by the thermodynamic expression $dS = -(dV/dT)_P dP$. For a differential unit of volume the entropy change is obtained by integrating this expression with respect to the pressure. The total entropy change about the ion is then given by integrating over the total volume of the water outside the ion cavity. Expressing volume as a function of the radius, we obtain

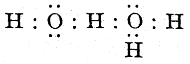
$$\Delta S_{(2)} = -\int_r^\infty \int_1^P \frac{1}{V^0}\left(\frac{dV}{dT}\right)_P dP\; 4\pi r^2 dr \qquad (3)$$

From considerations similar to those of Lorentz for the force density in a polarizable medium in an electric field, Zwicky[5] has developed an expression for the pressure at a distance, r, from a charge, e. The value of this expression depends upon the polarization of the medium by the field. For small fields the polarization is proportional to the field strength and the expression becomes

$$P = \frac{(3 + 2D)\,(D - 1)}{40\pi D^2}\,\frac{e^2}{r^4} \qquad (4)$$

The deviation of the actual pressure at very high values from that given by this expression, due to the electrical saturation of the water, is a matter of some conjecture. The dielectric constant of water may be considered as the sum of three effects: (1) the electronic displacement—this factor is given by the classical relation between the index of refraction and the dielectric constant; (2) the ionic displacements, that is, the stretching of the molecule with respect to hydrogen and hydroxide ions; **(3)** the orientation of the water molecules in the electric field due to their permanent electrical moment. The value of $D_{(1)}$ is about **3** and it has been generally assumed that $D_{(3)}$ is very much larger than $D_{(2)}$ so that the problem may be treated by the methods developed by Langevin.[11] Now, although liquids undoubtedly do exist normally (or under special conditions) in the form of dipoles, we doubt very much whether this is true with associated liquids. Furthermore, it is well known that the theory does not give the correct temperature variation.

Latimer and Rodebush[12] in their discussion of associated liquids have suggested that the association is through "hydrogen bonds," e. g.,



$$\mathrm{H:\underset{\cdot\cdot}{\overset{\cdot\cdot}{O}}:H:\underset{\underset{H}{\cdot\cdot}}{\overset{\overset{H}{\cdot\cdot}}{O}}:H}$$

[12] Latimer and Rodebush, THIS JOURNAL, 42,1419 (1920).

and that the high dielectric is due to the displacement of the hydrogen held between the oxygen by forces which may, as an approximation, be proportional to the displacement over a considerable distance.

On the basis of either picture, a saturation effect is obtained at high field strengths. With the Langevin theory this would correspond to all of the dipoles being lined up. The other view corresponds to the complete break of the water molecule into hydroxyl and hydrogen ions and this is, of course, what actually happens with ions of sufficiently high field strength, *i. e.*, the ion is hydrolyzed.

However, considering the uncertain nature of these theories, we do not feel justified in attempting to calculate a saturation limit for water. Moreover, we are inclined to believe that the electrical polarization can be taken approximately proportional to the field strength to greater values of the latter than has generally been assumed. For this reason we will use Equation 4, which should hold as a rough approximate for the larger ions. For water at 25° this gives

$$P = 375{,}000\,\frac{e^2}{\text{[illegible]}}\ \text{kg/cm.}^2 \qquad (5)$$

where e is the charge in Faradays (i.e., valence) on the ion and r is expressed in Angstroms.

Large Positive Ions.—To integrate Equation **3** it is necessary to know the coefficient of expansion of water as a function of pressure. This has been determined by Bridgman[13] up to 1000 atmospheres. In order to avoid the problem of extrapolating his data to enormously higher pressures, we shall first consider the case of the larger ions. Using his average value for the coefficient $\frac{1}{V^0}\left(\frac{\mathrm{d}V}{\mathrm{d}T}\right)$ as 3.2×10^{-4}, we obtain upon integrating Equation **3,** employing also Equation 5

$$\Delta S_{(2)} = -22\,\frac{e^2}{\text{[illegible]}}\ \text{cal. per degree per mole} \qquad (6)$$

To evaluate this entropy change for any ion, we must know the radius of the ion cavity in the water solution. To obtain this we will employ the Born expression, Equation 1, and the experimental values for the free energy of solution, although in doing this we realize that the Born expression is not exact, since it does not include changes in thermal energy and the compression of the water, both quantities, however, being comparatively small, less than 10% for large ions.[14] It must be kept in

---

[13] Bridgman, *Proc. Am. Acad. Arts Sci.*, *48*, 300 (1913).

[14] See Webb, ref. 6. Bjerrum, ref. 9, has also considered specific effects which he has treated from the standpoint of the free energy of solution of the discharged ion or corresponding rare gas. The Born expression, since it does not consider the thermal energy, is for a sort of hypothetical absolute zero and therefore is both ΔF and ΔH for the process considered.

It should also be noted that the close agreement of the radius of the ion cavity with mind, moreover, that the dielectric constant in this expression is the "effective" value, but since it is the quantity $(1 - 1/D)$ which is involved, the value of the radius is changed but slightly unless the dielectric constant becomes extremely small, a condition which certainly is not the case for the large ions.

To obtain the free energy values, a revision has been made in energy values calculated by Latimer,[7] *i. e.*, the ΔE values have been converted to ΔF. Account has also been taken, of the association of sodium and potassium into Na_2 and K_2. The values obtained agree approximately with the calculations of Webb.[6]

The experimental entropies of the ions in terms of the entropy of H^+ as zero are those given by Latimer and Buffington.[1] These relative values have been converted to absolute entropies using Eastman's[15] value for chloride ion in 0.01 M solution, 28.0 at 15°. Estimating $\bar{c}_p$ as -12.0,[16] we obtain for the hypothetical 1 M solution at 25° $S_{Cl^-} = 18.3$.

The entropies have then been calculated for the concentration corresponding to the molal gas volume at 25° and 1 atmosphere, *i. e.*, $^1/_{24.4}$ M, to eliminate any entropy change arising from a change in volume upon solution. Finally, ΔS of solution of the gas ion is obtained by subtracting the entropy of the ion as a monatomic gas as given by the Sackur equation.[17]

The data employed and the results are summarized in Table I.

the old values of Bragg for the radius of the positive ions in crystals is entirely accidental and that the latter are actually considerably smaller (about 0.7 Å.). See Pauling, THIS JOURNAL, 49, 765 (1927).

It is, of course, more reasonable to expect that the size of the ion cavity in water would be somewhat greater, and the really important fact remains that the relative size of the positive ions in crystals and in solutions is approximately the same. It may also be that the Born expression gives the radius as the distance from the center of the ion to the center of the water dipole, *i. e.*, the radius of the ion plus the radius of an oxygen ion.

[15] Eastman, THIS JOURNAL, 50, 292 (1928).

[16] Based on the work of Randall and Rossini, unpublished.

[17] See Lewis, Gibson and Latimer, THIS JOURNAL, 44, 1008 (1922).

A comparison of the last two columns of Table I shows an excellent agreement between the experimental entropies of solution and those calculated from Equation 3. If these calculations are correct, we must conclude that the entropy of hydration results largely from the change of ,entropy of the water about the ion due to compression, and that $\Delta S_{(1)}$, the dielectric effect, is small. This may be interpreted as meaning that there is but small entropy change in the orientation of electric dipoles, but a large effect in the loss of thermal energy of the compressed (or tied up) water molecules. This is, of course, just the opposite to the magnitude of these two effects in the free energy of hydration.

The reasons for the failure of Equation 2 are not entirely clear. In addition to the uncertainty regarding the temperature coefficient of the dielectric constant of water under high electric fields, it may also be pointed out that the validity of the equation assumes the constancy with temperature of the radius of the ion cavity. Moreover, it must be kept in mind that the Born expression gives a sort of hypothetical free energy (cf. note, ref. 14) which agrees closely with the experimental value only because the magnitude of the entropy factor is small in comparison.

For the large ions Equations 6 and 1 may be combined to give

$$\Delta S = 1.35 \times 10^{-4} \Delta F \text{ cal./deg.} \tag{7}$$

This is the approximate straight-line relation pointed out by Latimer and Buffington.[1]

Small Ions.—Equation 6, when applied to the smaller ions or to the large ions of higher valence, leads to values which are too high, indicating that at very high pressures the coefficient of expansion of water must be very much smaller. This effect may be noted for Ba^{++} listed in Table I. The theorem proposed by G. N. Lewis[18] that at infinite pressure the entropy of a substance is zero (**i.**e., the integral $\int_1^\infty \left(\frac{dV}{dT}\right)_P dP$ must be equal to the entropy of water at 25°) might be used to extrapolate the coefficient to high pressures. However, the uncertainty in the shape of the curve appears to render it inadvisable to attempt these calculations at this time.

Large Negative Ions.—The entropies of solution of the negative ions have not been included in Table I because of the uncertainties regarding the electron affinities of these ions. If the values for entropies were of somewhat higher accuracy, the calculation might be reversed and Equation 7 used to calculate ΔF of solution and from this the electron affinities. However, it does seem worth while to show that the electron affinities of chloride, bromide and iodide, as calculated from the crystal lattice energies,[19]

---

[18] G. N. Lewis, Z. *physik.* Chem., 130, 532 (1927).

[19] Or the values of Angerer and Müller from absorption spectra of the alkali halides, which are in approximate agreement. See Franck and Jordan, "Anregung von Quantensprungen durch Stosse," Springer, Berlin, 1926.

lead to calculated entropy values in approximate agreement with the experimental. The data are summarized in Table II. The entropies of chloride, bromide and iodide are also from the paper by Latimer and Buffington, but instead of taking the values in agreement with the halogen acids, these values have been averaged with those obtained from the silver, thallous and lead salts. The resultant change is, however, small.

TABLE II

SUMMARY OF DATA

	$^1/_2$ X? = $X_{(g)}$ ΔF	+ $^1/_2 X_2$ $E^-_{(g)}$ = $X^-_{(aq.)}$ ΔF	Electron affinity	A F of soln.	S, 1 M X^- $S_{H^+} = 0$	Absolute S 1/24.4 M X^-	S of $X^-_{(g)}$	$-\Delta S$	
								Exp.	Eq. 3
Cl⁻	32	−132	86	78	16.5	24.7	36.4	11.7	10.8
Br⁻	18	−126	86	58	21.8	30.0	38.8	8.8	8.1
I⁻	21	−112	79	54	26.5	34.7	40.2	5.5	7.5

The agreement between the calculated and experimental entropies of solution is probably within the accuracy with which the latter are known and may be considered as substantiating the electron affinities. At the same time, the reasonableness of the result further confirms our theoretical calculation of the entropies of hydration.

These calculations constitute an independent check upon the theory which considers the properties of solutions of strong electrolytes as due to the effect of an electrostatic charge located at the center of a cavity in the dielectric medium. The results seem especially significant in view of the fundamental nature of the ionic entropies and the fact that both the relative and absolute entropies are singularly free from large experimental uncertainties.

Summary

Calculations have been made which indicate that the entropy of hydration of aqueous ions arises largely from the enormous pressures developed about the ion and the resulting decrease in the entropy of the water due to compression.

The entropies of solution of the halide ions are shown to be in agreement with the estimated electron affinities of these elements.

THE HEAT CAPACITY OF OXYGEN FROM 12°K. TO ITS BOILING POINT AND ITS HEAT OF VAPORIZATION. THE ENTROPY FROM SPECTROSCOPIC DATA

BY W. F. GIAUQUE AND H. L. JOHNSTON

RECEIVED FEBRUARY 11, 1929 PUBLISHED AUGUST 7, 1929

The investigation reported in this paper concerns the entropy of oxygen. Aside from its importance as an element, oxygen is particularly interesting in that its three known crystalline forms, as well as the liquid and the gaseous states, are strongly paramagnetic. The main interest lies in the magnetic behavior of the gaseous state and that of the crystalline state stable below 23.66°K. The fact that the gas has a positive magnetic susceptibility indicates a multiplicity in the quantum states which would lead to a considerable effect in the entropy. The paramagnetism of the solid state suggests the possibility that the application of the third law of thermodynamics in the ordinary manner to the calorimetric data of oxygen may not include a contribution to the entropy[1] arising from a random distribution of magnetons in the solid state. It may be said in advance that this latter effect does not contribute appreciably to the entropy of solid oxygen at the temperatures of liquid hydrogen. This is in rather sharp distinction to the case of $Gd_2(SO_4)_3 \cdot 8H_2O$, where the experimental data show[1c] that the magnetons are contributing over eight cal. per deg. per mole to the entropy of this substance at a temperature of 1.3°K.

The experimental procedure is based upon a calorimetric investigation of the various forms of oxygen from a temperature of 11.75°K. to the gaseous state at the boiling point. From the measurements the entropy of oxygen was calculated and found to be in agreement with that calculated from spectroscopic data. The purpose necessitated the attainment of high accuracy in the calorimetric measurements.

Preparation and Purification of the Oxygen

The oxygen was prepared by electrolysis of a sodium hydroxide solution in an electrolytic cell which operated on a current of four hundred amperes. Although generated in a commercial cell, there was little reason to expect impurities other than hydrogen and ozone since the electrolyte in the cell had been in service for a number of years (sufficient to bring about the removal of objectional impurities, if any) and was protected from contact with the air. From the generator the oxygen was carried under pressure to the purifying train. Special high vacuum stopcocks were employed and these were greased with rubber stopcock grease previously saturated with oxygen gas at 150°. Before use the entire purifying train was tested and found to hold a vacuum of 10^{-5} mm. of mercury. Adsorbed gases were removed by warming and sparking the glass

line a number of times and by evacuating it over a period of several days. Finally, a continuous stream of oxygen gas was passed through the line for several hours before any was collected. The train consisted of a tower of potassium hydroxide sticks to remove moisture, a long column of oxidized copper turnings heated to 400° in an electric furnace to remove hydrogen, two more towers of potassium hydroxide sticks, a tube filled with amalgamated copper turnings to decompose ozone (the potassium hydroxide and the copper oxide are also catalytic agents in the decomposition of ozone), two meters of tubing packed alternately with plugs of glass wool and of phosphorus pentoxide, and several bulbs, for use in fractionally distilling the liquid. We relied on the fractionation as the most reliable portion of the process for the removal of the final traces of impurity. The liquid oxygen was subjected to four steps in the fractionation. In each step only the middle portion was saved. About **600** cc. of liquid oxygen initially collected was reduced to a little over **100** cc. of final product which was distilled into the calorimeter. Before heat capacity measurements were begun, the oxygen in the calorimeter, frozen by the aid of liquid hydrogen, was evacuated with a mercury vapor pump for an hour or so to remove any last trace of hydrogen. Kahlbaum's phosphorus pentoxide was employed and Baker and Adamson's C. P. potassium hydroxide as reagents.

This method of purification is substantially that followed by Baxter and Starkweather[2] in their precise density determinations. We are using their value for the density of oxygen. We made no analysis of the oxygen; however, the shape of the heat capacity curve below the melting point and the sharpness of the melting point temperatures showed qualitatively that the oxygen was very pure. Oxygen was prepared on five different occasions. The various preparations of oxygen will be referred to by the designations I, II, III, IV and V.

Experimental Procedure

The experimental procedure in measuring heat capacities and in working up the data corresponded in the main to that of Giauque and Wiebe[3] in their measurements on the halogen acids and we employed the same gold calorimeter, II, and other portions of the same apparatus employed by them. The essential features of the method consisted in introducing a measured amount of heat electrically to the substance contained in the vacuum-jacketed calorimeter and measuring the temperature rise on a sensitive gold resistance thermometer calibrated at frequent intervals against a standard thermocouple soldered to the bottom of the calorimeter. The methods differed in certain important respects from those of Giauque and Wiebe. We will briefly outline some of these changes.

Timing.—To replace stop-watch and hand control of the electrical energy input circuits, a timing mechanism[4] that opened and closed the circuits electrically in response to time signals was designed. The time signals were obtained through the courtesy of the Astronomy Department of the University of California. By calibration it was shown that the heating intervals were thus timed within a maximum limit of error of 3×10^{-3} seconds in an absolute sense, which affected the final heat capacity values in the most unfavorable circumstances by only one part per hundred thousand. Measurements were made with sidereal time but this was corrected to solar time by the equation 1 solar second = **1.002738** sidereal seconds.

Amount of Material Present in the Calorimeter.—The apparatus for measuring the amount of material present in the calorimeter during heat capacity measurements is shown in Fig. 1. The measuring bulb **A** is made from a five-liter pyrex round-bottomed flask and is supported in the hemispherical casting B. The internal diameter of B is a half inch larger than the external diameter of **A** and the intervening space is filled with a cast of Woods metal, C, poured when **A** was clamped in position. To the top and bottom of **A** are fused the small-diameter glass tubes D and E which bear etched scales marking volume intervals of 0.1 cc. The volume included between these two scales was determined by two calibrations which gave agreement to 0.13 cc. The calibrations were made by weighing mercury. The usual precautions in exact volume calibration were taken and the small volume effect due to distortion of the bulb by mercury pressure was evaluated. After calibration the lower end, E, was fused to a glass tube extending to the bottom of the six-liter cast-iron mercury reservoir F. This whole apparatus was immersed in a 25° thermostat which maintained a temperature constant to 0.01°.

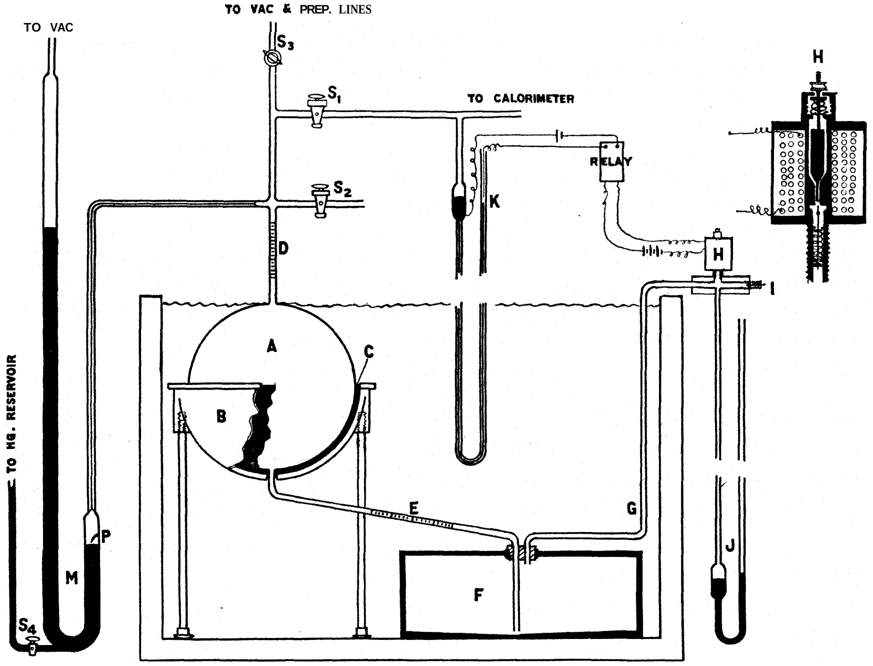

Fig. 1.

When the heat capacity measurements were completed and it was desired to measure the amount of substance present in the calorimeter, pressure was applied through the bicycle valve I to force mercury into Bulb **A**. A portion of the substance in the calorimeter was then vaporized by supplying heat and gas was collected in the bulb **A**. At the same time pressure was released in F by action of the electromagnetic valve H, whose action is described more fully in the next title, so that the mercury returned to the reservoir and the gas collected in **A** at atmospheric pressure. When **A** was almost filled with gas, as evidenced by the mercury height in the capillary manometer J, which was calibrated against an empirical scale, the vaporization was stopped and S_1 was closed. Further pressure was released in F by hand manipulation of the valves and the mercury meniscus was brought into the lower scale E. The pressure was then read on the constant dead-space, large-diameter manometer M which was enclosed in an air-jacketed case and was connected to A through capillary tubing to diminish volume external to the thermostat. The pressure was read with the aid of a standard meter scale and a Société Génévoise Cathetometer. This process was repeated until all of the material in the calorimeter was vaporized. It ordinarily required about eighteen repetitions to complete the measurement. These measurements included a small amount of gas in the line external to the thermostat. Although neither volume nor temperature of this portion of the gas was known to the same accuracy as that enclosed in the thermostat, the amount was small compared to that in A; moreover, it was largely canceled out since ordinarily gas at nearly the same pressure occupied this space both before A was filled with gas and after. The final of the 18-odd measurements included gas in the entire line volume, including the calorimeter. The calorimeter was warmed up to room temperature before this final measurement and it was usually possible to arrange that this should be a measurement of gas at low pressure so that the uncertainty of this volume introduced a negligible uncertainty into the total amount.

The following equation was employed for calculating the amount of gas from the PVT relationship.

$$\text{Amount in moles} = V{\cdot}P{\cdot}\frac{d}{M}\cdot\frac{1}{1+kT}\cdot[1+\alpha\,(1-P)]$$

where V = volume in liters, P = pressure in international atmospheres, d = density of the gas per liter at standard conditions, M = molecular weight, k = mean coefficient of thermal expansion for the range from 0 to 25°, T = temperature in °C. and α = the coefficient of deviation from Boyle's Law per atmosphere. In deriving P from the measured pressure, corrections were applied as given in "International Critical Tables,"[5] for temperature of mercury and of the standard meter scale and for capillary depression as measured by meniscus height. The gravitational acceleration was taken as 979.973 cm./sec.^{2} as given by Sternwarte[6] for this locality. The values used for the remaining constants employed in this equation are as follows: d = 1.42898,[2] k = 0.003672,[7] $\alpha = -0.00087$.[8] Any error in these constants will, of course, affect all of the heat capacity determinations alike. However, the uncertainty in these constants is so small that error from this source may be neglected.

Measurements of Heat of Vaporization

The heat of vaporization was measured by what corresponds to Method II in the paper of Giauque and Wiebe. The absorption bulb of their measurements was necessarily replaced in this work by the measuring bulb A described under the previous heading and the heating interval was chosen of such a length as not quite to fill the bulb.

[7] We used the value employed by Baxter and Starkweather. This is close to the value (0.003674) obtained by Jolly, *Pogg. Ann.*, Jubelband, 96 (1874).

[8] Batuecas, Maverick and Schlatter, *J. chim. phys.*, 22, 131 (1925).

The automatic pressure control by the electromagnetic valve H maintained a pressure constant to about 0.1 mm. of mercury during the measurement. This resulted in constancy of temperature and consequently of resistance in the combined resistance thermometer heater by which the energy was supplied to the calorimeter. A very constant energy current was thus maintained and it was possible to read this factor with great accuracy in the course of the measurements. The construction of H is shown more clearly in the inset to the right of the diagram of Fig. 1. The basic ideas in the construction of this valve and in the electrical set-up are due to Smith.[9] When the pressure registered in the line leading from the calorimeter exceeds a certain predetermined value, an electrical circuit is completed through contact of the mercury with a platinum wire at K. Through a relay this energizes the magnet at H whose armature depresses the stem of a bicycle valve and releases air pressure from the reservoir F. This causes mercury to flow from A and lowers the line pressure. With proper adjustment at H, the regulator can be made very sensitive. The contact at K was adjustable and by this device heats of vaporization could be measured at any desired pressure. However, in this research, all measurements were made at a pressure of 760 mm. of mercury.

Attainment of Low Temperature.—Low temperatures were obtained by liquefaction of hydrogen and subsequent evaporation at low pressures in the manner of Giauque and Wiebe[10] but between the calorimetric apparatus and the vacuum pump of 150 cubic feet displacement mentioned in their article, a battery of three large Nelson oil vacuum pumps connected in parallel was included. These had a total displacement of 12 cubic feet per minute and were capable of producing a vacuum of better than 10^{-3} mm. of mercury in a non-gassing system. With their aid, a maximum temperature lowering to 10.7°K. was produced, although no heat capacity measurements were begun below about 11.7°K. The accuracy of the low temperature measurements was improved by breaking the vacuum in the space surrounding the calorimeter while cooling down, by use of helium gas at low pressure in preference to hydrogen gas. The helium was adsorbed to a much smaller degree than was the hydrogen and it was thus possible to regain a high vacuum in a much shorter interval following the cooling and to operate with a greatly reduced heat leak during the early measurements.

Temperature Scale.—The temperature intervals in the heat capacity measurements were determined from readings of a gold resistance thermometer wound on the exterior surface of the calorimeter and calibrated at short intervals in the course of heat capacity measurements by comparison with a standard copper constantan thermocouple W soldered to the bottom of the calorimeter. The method of treating the calibration data was that described by Giauque and Wiebe. The temperature scale for thermocouple W was fixed in terms of the hydrogen gas thermometer by Giauque, Buffington and Schulze,[11] and in terms of the hydrogen vapor pressure thermometer by Giauque, Johnston and Kelley,[12] for which it was the direct standard of comparison. These authors also found it in agreement with the oxygen vapor pressure thermometer. In the course of the heat capacity measurements, it was again compared with the oxygen vapor pressure thermometer and found to be in agreement and at the end of the measurements it was compared a second time with the hydrogen vapor pressure thermometer and found in agreement. The temperatures given by thermocouple W are believed to be correct to within 0.05". All fixed temperature points recorded in the data that follow, such as transition points, melting points and boiling and vapor pressure points, are based directly on the temperature readings of thermocouple W. The readings taken from the resistance

[12] Giauque, Johnston and Kelley, ibid., 49, 2367 (1927).

thermometer should represent the temperature intervals correctly to within 0.001 to 0.003' since over a short interval the absolute error of calibration should not vary appreciably and since the resistance readings are reproducible to 0.001 ohm, which corresponds to 0.001° over nearly the entire temperature range above 35°K. At lower temperatures, errors in the temperature interval may be larger and may approximate 0.01 to 0.05' at the very lowest temperatures, where dR/dT rapidly diminishes. Two different resistance thermometers of nearly similar character and dimensions were employed in the course of the measurements.

Corrections to the Experimental Data. - In addition to corrections involving only physical constants of the substances measured, the following experimental corrections were applied because of conditions peculiar to the method and apparatus.

(a) A correction amounting normally to about 0.2 of 1% of the total heat input was applied for heat generated in a resistance of 55,000 ohms shunted across the thermometer heater terminals for purposes of measuring the potential drop. This correction could be applied with high accuracy.

(b) A correction was applied for heat generated in a pair of No. 40 copper leads one inch in length bridging the vacuum space surrounding the calorimeter and connecting the gold resistance thermometer ends with the so-called thermometer terminals which were in thermal contact with the surrounding jacket. It was assumed that half the heat generated in this pair of leads went to the calorimeter and that half was conducted to the surrounding jacket. This entire correction amounts to only about 0.02 of 1% of the total energy.

(c) A correction amounting to 0.2 of 1% at liquid-air temperatures and increasing several fold at lower temperatures was applied for heat interchange between the calorimeter and its surroundings during the heating period. This correction was obtained from measurements of warming rates before and after each run and could be applied with an error not over from 10 to 20% of the correction.

(d) A supplementary correction was applied to make allowance for the temperature head of the resistance thermometer from radiation and conduction during resistance measurements. This correction was evaluated through the application of Newton's Law of Heat Transfer combined with certain assumptions involved in the geometry of the apparatus. It affected the specific heats by less than 0.05 of 1% over the greater portion of the temperature range investigated, and introduced an uncertainty of 0.01 or 0.02% into the final data.

(e) Correction was applied for heat spent in vaporizing material into the 70-odd cc. of line volume adjacent to the calorimeter. This correction was effective over about the last thirty degrees of the heat capacity range investigated. It amounted to about 1% of the total energy input for the heat capacity measurement at the highest temperature, but its importance dwindled rapidly for the measurements at lower temperatures.

The correction itself might be in error by as much as 10%. In applying this correction we used the data of Cath,[13] in agreement with our own[12] for oxygen. Allowance was made for the vapor space within the calorimeter, for which we employed the densities of liquid oxygen given by Mattias and Onnes.[14]

(f) A correction amounting to from 10% to 15% of the total energy supplied was necessary to take account of the heat capacity of the empty calorimeter. This was evaluated from heat capacity measurements carried out on the empty calorimeter with the same care as those carried out on the substances investigated. The heat capacity of the empty calorimeter was determined in three separate series of measurements carried out, respectively, before, during and after the period covered by the measurements. A smooth curve fitted the experimental values to within 0.1 of 1% with almost no exceptions.

In measuring heats of transition, fusion and vaporization the heat interchange correction corresponding to corrections (c) and (d) was applied graphically by plotting, respectively, temperatures of calorimeter and of surrounding jacket against time elapsing during the measurement. From the area between the two curves thus obtained and with the further employment of an empirical heat interchange factor experimentally determined as a function of temperature difference between calorimeter and surroundings, the correction was applied. In one or two instances the magnitude of this correction exceeded 1%. More often it was about 0.2 or 0.3 of 1%. This correction introduced an uncertainty of about 10% of its value.

Probable Errors

Heat Capacity Measurements.—The expression for obtaining the heat capacities from the experimental data takes the form

$$C_p \text{ (at } T) = \frac{\left(\frac{\epsilon \cdot I \cdot t}{\Delta T} \cdot W\right) - C_c}{A}$$

where ϵ = voltage across heater terminals during heat input, I = amperes through heater during heat input, t = the time of heat input in seconds, W = factor for converting joules to calories. This factor is taken from "International Critical Tables."[5]

We express our results in terms of the 15° calories: C_c = heat capacity of the empty calorimeter, A = amount of material present in the calorimeter. By means of a White double potentiometer, ϵ was known to within 0.05 of 1% and I to within 0.02%.

The factor "t" is known with very high accuracy. In the most un-

---

[13] **Cath,** *Comm. Phys. Lab. Univ. Leiden,* 152d (1918).

[14] Mattias and Onnes, *ibid.,* 117 (1911).

favorable circumstances, its limit of error has been mentioned as of about 0.001 of 1%.

AT is determined from resistance measurements made with the White potentiometer. As the temperature interval was usually between 4 and 5°, 0.05 of 1% appears a reasonable limit of error in this factor. To this must be added a possible error of 0.1 of 1% for uncertainty of temperature scale on the resistance thermometer. It should be mentioned that this latter error will have little effect on the entropy since if the temperature coefficient of resistance is too high in some temperature region, it must be too low by a corresponding amount in some adjacent temperature region.

The correction for heat capacity of the calorimeter has been discussed under the heading correction (f). The uncertainty present in this factor may introduce an error of from 0.01 to 0.03 of 1% in the final values of C_p.

Error in the amount of material present in the calorimeter is introduced by each of three factors, pressure, volume and temperature of the gas. Prom a consideration of these combined factors, the amount of gas measured cannot be in error by more than 0.03 of 1% for an individual measurement and must average to a somewhat smaller limit over the eighteen-odd measurements involved in obtaining A.

The limits of error present in these factors combined with those introduced in the corrections (a), (b), (c), (d) and (e) thus cannot introduce a greater maximum error than about 0.4 of 1% into individual specific heat points and that only for the highly improbable assumption that all errors are present at a maximum and in the same sign. The probable error should not exceed half of this figure. As a matter of fact C_p values obtained with this apparatus rarely deviate from a smooth curve drawn through the points by over 0.1 of 1% in the region above 35°K.; 0.2 of 1% appears to be a reasonable limit to the error of the smooth curves through our data. The statements here made apply only for the temperature region above 35°K. Below that temperature the inaccuracy increases, due in part to the increase in the relative importance of the various correction factors, to the smaller heat capacities but principally to the decreasing dR/dT of the resistance thermometer. At 20°K. the values for C_p may be as much as 0.7 of 1% in error and at 12° the errors of measurement may be as high as 5%.

Heats of Transition, Fusion and Vaporization.—The heats of transition and fusion contain about the same probable error as do the specific heats. The heats of vaporization are somewhat more accurate, however, due to a smaller contribution from several factors that introduce the major inaccuracies. The more important of these favorable influences are the small, almost negligible, AT; the nearly constant energy current, **I;** the smaller correction for extraneous heat capacity and the smaller inaccuracy remaining in the heat interchange correction. The mean of the several determinations of heats of vaporization is believed to be correct to within 0.1 of 1%.

Heat Capacity Data.--pour series of measurements were carried out to determine the heat capacities of solid and liquid oxygen. Each was carried out with a different lot of oxygen and the preparation numbers corresponding to these four lots will serve to describe the series. Series

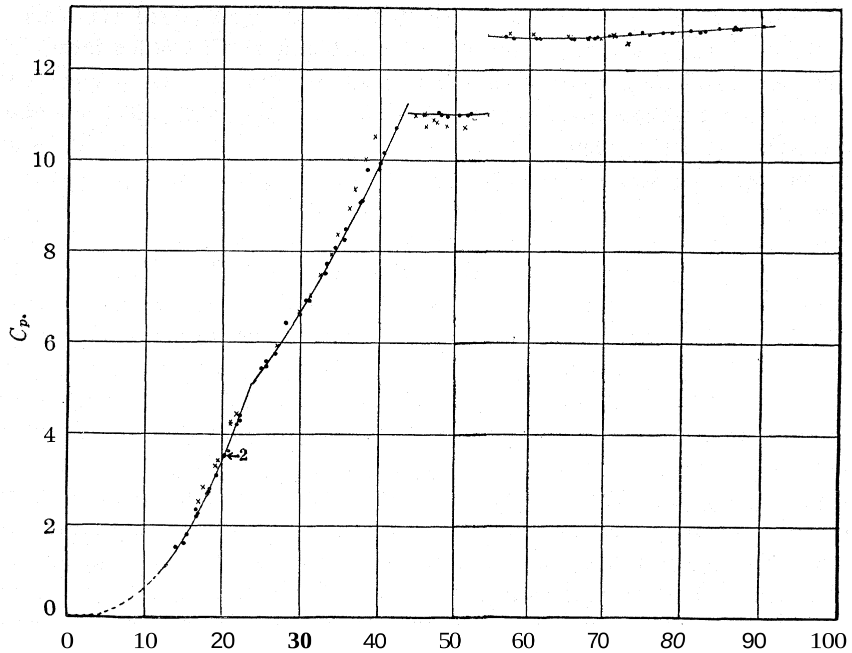
I was carried out only for liquid oxygen; Series IV only for solid as a short circuit developed during the heat of fusion determinations. Series II and V covered both solid and liquid. Series V covered the extremes of the temperature interval investigated, as its measurements extended from 11.75°K. to 91.64°K. The individual results are tabulated in Table I. Column 1 gives the series number, Col. 2 the mean absolute temperature, Col. 3 the temperature interval covered and Col. 4 the heat capacity in calories per mole per degree.



Temperature, °K. ●, This Research; X, Eucken.

Fig. 2.—Heat capacity in calories per mole of oxygen.

These data are reproduced graphically in Fig. 2, where the dark circles represent the values obtained in the individual measurements. The various series of measurements are in good agreement for liquid oxygen as only six of the twenty-four measurements secured over that range lie off the smooth curve by more than 0.1 of 1%. The largest deviation is 0.3 of 1%. This curve is believed to represent the correct heat capacity for liquid oxygen to within 0.2 of 1%. The initial downward slope of the curve with a subsequent upward trend may indicate the presence of an equilibrium between polymerized and unpolymerized molecules with small heat of dissociation as predicted by Lewis.[15] This comment

---

[15] Lewis, THIS JOURNAL, **46**, 2027 (1924).

is in keeping with the minimum observed in the heat capacity data for water; see, for example, the data given by Barnes.[16]

The same degree of accuracy cannot be claimed for the curves representing the heat capacities of solid oxygen as for the liquid since the various series do not lead to quite the same close agreement, particularly for the two forms stable at lower temperatures. We cannot reconcile this small disagreement with what is believed to be the normal accuracy of the experimental method, particularly since repeated measurements made in determining the heat capacity of the empty calorimeter—an essentially more difficult measurement for the attainment of accuracy—and the various measurements for the liquid and for other substances all yielded individual values in good agreement with the respective curves. We suspect that the somewhat poorer agreement for solid oxygen may be due to some characteristics in its behavior observed by Wahl,[17] who found that liquid oxygen becomes viscous close to its freezing point and readily supercools to a glass interfused with crystals of the solid modification stable just below the melting point. When cooled to the transition (at 43.76°K. by our measurements), Wahl reports that the crystal modification stable below that temperature is formed almost instantaneously from the supercooled glass. This crystal form cracks badly and appears to have a considerably greater density than the higher temperature form. The latter property would lead to poorer thermal conductivity within the calorimeter and would increase the difficulties attendant on the attainment of accuracy. The former property might result in slight differences in physical composition in various instances. The comparative sharpness of transition and melting points discussed in the next section precludes the possibility of our having had more than traces of a physical form other than the respective pure crystals. Lest we convey an exaggerated impression of the irregularities in heat capacity to which we are referring, it should be mentioned that the individual measurements for the various solid modifications seldom were off the curves drawn by more than a very few tenths of one per cent., but the number of points that deviated over wider limits and the average deviations as well were considerably larger than for the other measurements. Due to the large number of points obtained, the curve for Solid I (43.76°K. to the melting point) is believed to be correct to within 0.3 of 1%, that for Solid II (23.66°K. to 43.76°K.) to within 0.5 of 1%, and that for Solid III (below 23.66°K.) to within 1% at its upper extremity but increases in uncertainty with temperature lowering and may be in error by 5% at the lowest temperature the measurements attained. In drawing the curves low weight has been given to certain measurements for which experimental

---

[16] *Barnes, Trans. Roy. Soc. London, 199,* 149 (1902).

[17] Wahl, *Proc. Roy. Soc. London,* **88,** 61 (1913).

conditions were less favorable, as shown by entries in the data books, and no weight has been given to two points obtained in Series I for Solid II which we could not substantiate in the later series when special care was given to those particular temperatures.

The graph includes the results of Eucken[18] shown by crosses. For Solid III Eucken is higher than our curve by amounts ranging from 6 to 14%, with an average deviation of 10%. Eucken's results are in agreement with ours for Solid II up to about 34°K. Above this temperature they deviate sharply and at 39°K. are about 9% above the curve. For Solid I Eucken obtains values lower than ours by about 2% on the average. For liquid oxygen the values of Eucken begin about 0.4 of 1% higher and approach the curve. His last point at about **73°K.** is 1% lower than the curve. It seems probable that much of the discrepancy between Eucken's measurements and this investigation is due to his temperature scale between the liquid hydrogen and liquid air regions. It can be noticed that his measurements for Solid I are low and those for Solid II are high. This would be in accord with the fact that he recorded 42.5°K. for the I–II transition against the value of 43.76 ± 0.05°K. This transition temperature is very easily measured.

Melting and Transition Temperature.—The melting point was determined in one series of measurements with Preparation IV. The transition temperatures were both determined with Preparation III.

In determining the melting point the oxygen was first cooled below 40°K. and then warmed through the transition (Solid II to Solid I) in order to avoid the presence of supercooled liquid so far as possible. After warming into the melting point, twelve measurements were taken over a period of sixty-five hours and with different proportions of solid melted. The thermocouple showed an extreme difference of 0.05° and the resistance thermometer, which is essentially the more reproducible of the two, showed a maximum change of 0.015". From these measurements the melting point was selected as 54.39 ± 0.05°K.

In determining the temperature of the higher transition seven measurements were taken over a period of eight hours. The thermocouple showed an extreme variation of 0.04" and the resistance thermometer a variation of 0.015". From these measurements the value 43.76 ± 0.05°K. was obtained.

The lower transition temperature was studied over a period of five hours. Due to the low heat capacities of the portions of the apparatus, the low heat of transition and the difficulty of maintaining adequate constancy in the temperature of the surroundings at this temperature the same constancy of results could not be expected as for the higher temperatures. Both thermocouple and resistance thermometer showed a temperature

variation of 0.1° among the eleven measurements carried out, in the course of which the percentage of oxygen transformed was increased from about 15% to about 65%. The value was 23.66 ± 0.1°K.

[a] The value in parentheses was given no weight in arriving at this value.

[b] This is a mean of 24 determinations varying from 1629.9 to 1638.5. 0.2 of 1% (3.3 calories) is claimed as the limit of error for the mean. We have corrected Dana's values to the "International Critical Tables" value for the mechanical equivalent of heat and to Baxter and Starkweather's value for the density of oxygen to correspond to the present work.

[c] Eucken states that on account of his experimental procedure, his heat of vaporization probably corresponds to a pressure higher than atmospheric.

Entropy from the Heat Capacity Data.—We have calculated the entropy of oxygen gas at the boiling point of oxygen, making use of the heat capacity data. In making the extrapolation below 11.75°K. the Debye function with $\beta\nu = 90.9$ has been used. It has been assumed that the oxygen molecule is acting as a unit at these low temperatures. The extrapolated entropy of 0.32 entropy units is very unlikely to contribute an appreciable error. Lewis and Gibson[z9] made a similar calculation from the data of Eucken.[18] In Table V is summarized the entropy contribution of the various $\int C_p d \ln T$'s and ΔH's, both from our own data and from those of Eucken. The temperatures recorded in the first column are the present transition, melting and boiling point values. The entropy

Entropy of actual gas at boiling point	40.57 ± 0.1 E.U.		40.27

In order to make a comparison of this entropy value with that calculated from spectroscopic data, which is the primary purpose of this paper, it is necessary that the experimental value given above be corrected to the hypothetical perfect gas state. This may be done with the aid of Berthelot's equation and the thermodynamic equations involving the successive processes of expansion of the actual gas to zero pressure and of compression of perfect gas from zero pressure to one atmosphere. These lead to a net correction of $27T_c^3P/32T^3P_c$, as shown by Giauque and Wiebe.[3] With the aid of the critical data of Onnes, Dorsman and Holst,[30] namely, T, = 154.3°K. and P_c = 49.7 atmospheres, +0.17 entropy units is obtained as the value of this correction for oxygen gas at its boiling point. Hence the entropy of the hypothetical perfect oxygen gas at 90.13°K. is 40.74 E.U.

Entropy from Spectroscopic Data.—Dieke and Babcock[31] have obtained measurements of the fine structure of the atmospheric absorption bands of oxygen. Recently Mulliken[32] has given an interpretation which is satisfactory for the strong bands in this absorption and more recently Giauque and Johnston[33] have extended Mulliken's interpretation to include the weak A' band as well and so obtained a complete interpretation of the atmospheric bands. In the light of Mulliken's interpretation, the normal state of the molecule in oxygen gas is what is described by spectroscopists as a triplet *s* level. This means that the molecules in oxygen gas are differentiated into three forms of small energy difference characterized by the coupling between the angular momentum of electron spin

---

of the two unbalanced electrons in the oxygen molecule and the angular momentum of the rotating molecule. This coupling may be represented by drawing the momenta vectors oriented with respect to one another in parallel position, in anti-parallel position and in a position approximately at right angles. The molecules are further differentiated with respect to vibrational states with $n = {}^1/_2, {}^3/_2, {}^5/_2, \ldots\ldots$ The energy difference between the lowest state, the ${}^1/_2$ state, and the next higher state, the ${}^3/_2$ state, is sufficiently large (1554 wave numbers)[34] that at the boiling point of oxygen the number of molecules in the ${}^3/_2$ state is entirely negligible as shown by application of the Boltzmann factor. A still further differentiation of the oxygen molecules results from the quantized distribution of rotational energy among the various molecules. Characteristic of a homopolar molecule whose atoms have no nuclear spin, the alternately quantized rotation states are missing in oxygen, as in the diatomic helium molecule. This statement is supported by the quantum interpretation necessary to explain the Schumann bands of oxygen and by the interpretations of the atmospheric bands referred to above. The rotation states containing even-numbered units of angular momentum are missing and those present correspond to $j_k = 1, 3, 5, \ldots$ where j_k here is identical with the number of units of momentum possessed due to rotation of the molecule.

A further differentiation results due to the presence of isotopic molecules composed of an atom of oxygen of mass 16 combined with an atom of oxygen of mass 18 as shown by the interpretation[33] of the weak A' band. However, the very low intensities of the lines of the weak A' band when compared quantitatively with the intensities of the corresponding lines of the strong A band show that this isotope molecule is present in such a small amount as to have a negligible influence on the entropy.

The utilization of the energy levels of molecules, as obtained from spectroscopic data, in the calculation of entropy has been discussed by Giauque and Wiebe.[3] The equation

$$S_{\mathrm{E+R+V}} = R\left[\ln \Sigma_{e,n,m} p_{e,n,m} e^{-\epsilon_{e,n,m}/kT} + \frac{1}{kT}\,\frac{\Sigma_{e,n,m} p_{e,n,m}\epsilon_{e,n,m} e^{-\epsilon_{e,n,m}/kT}}{\Sigma_{e,n,m} p_{e,n,m} e^{-\epsilon_{e,n,m}/kT}}\right]$$

permits the calculation of the entropy due to all energy absorption other than that of translation. $\epsilon_{e,n,m}$ represents the energy of a certain state fixed with respect to the electronic configuration, the molecular vibration and molecular rotation; $p_{e,n,m}$ represents the corresponding *a priori* probability, or statistical weight of such a state, and $\Sigma_{e,n,m}$ indicates that terms within the summation sign are summed over all electronic, vibrational and rotational states of the molecule until it is apparent that further terms will add no appreciable contribution to the summation;

---

[34] *Cf.* Birge, *Bull. Nat. Research* **Council, 11, 332 (1926).**

k represents the Boltzmann constant and e the base of the natural logarithms.

To the above entropy must be added the entropy due to the translation as given by the Sackur equation[35]

$$S_T = \frac{3}{2}R \ln M + \frac{3}{2}R \ln T + R \ln V + S_1$$

where R is the gas constant, T is the temperature on the absolute scale, M the molecular weight and V the molal volume in cc. $S_1 = 11.06$ cal. per degree per mole.

For the summations indicated above values were obtained from the data of Dieke and Babcock[31] for the energies corresponding to the first twenty-six rotation states in the normal oxygen molecule. Only odd-numbered values of j_k are present as explained previously. In keeping with the nomenclature of Mulliken,[32] F_1, F_2 and F_3 represent the three kinds of molecules resulting from differences in coupling between the angular momentum due to rotation of the molecule as a whole and the angular momentum due to spin of the electrons. F_1 represents the coupling with spin parallel to rotation, F_2 the coupling with spin approximately at right angles to the rotation vector and F_3 the coupling with spin antiparallel to rotation. j represents the total resultant angular momentum of the molecule and is given by the vector sum of j_k and s. Here s equals 1 and results from spin of the two unpaired electrons each electron contributing $^1/_2$ unit of angular momentum. The *a priori* probabilities necessary for use in the entropy equation given above are obtained from the values of j here listed by the relationship $p_{e,m,n} = 2j + 1$, as given by the wave mechanics. The energies for the molecules possessed of the F_2 coupling are derived by the use of the energy equation given by Dieke and Babcock,[31] with the constants derived from their P_1 and R_1 branches. The energies for molecules of corresponding j_k with F_1 or F_3 couplings were calculated from the F_2 energies by subtracting the approximate energy differences which exist between the F_2 and the F_1 or F_3 states. Several of these differences are tabulated by Mulliken and they have been smoothed out and extrapolated to higher j_k states by a graphical method.

[35] (a) Sackur, Ann. *Physik*, 36, 598 (1911); (b) Tetrode, *ibid.*, **38,** 434 (1912); (c) Ehrenfest and Trkal, *Proc.* Acad. *Sci., Amsterdam,* 23, 162 (1920).

In Table VI we show the values obtained for the sums which appear in the entropy equation for T = 90.13°K. The sums are not affected within the numbers of decimals used by the inclusion of higher j_k states.

It is interesting to note that the oxygen molecules are quite unevenly distributed between the F_1, F_2 and F_3 states at the boiling point of oxygen gas. The distribution is 42.3% of F_1, 32.1% of F_2 and 25.6% of F_3. This uneven distribution is almost entirely due to the differences in the *a priori* probabilities. These differences are more pronounced for the low rotation states. The energies of the various states are nearly identical. We have calculated the contributions to these sums from the next higher vibration state and found them negligible for this temperature. Putting these sums into the entropy equation

$$S_{E+R+V} = 10.29 \text{ entropy units}$$

Combining this value with the 30.39 entropy units found for the contribution due to translation of the molecules as calculated with the Sackur[35a] equation for a monatomic gas, we find for the entropy of the hypothetical perfect oxygen gas at 1 atmosphere pressure and 90.13° K. the value 40.68 cal./deg. mole. The result of a similar calculation for a temperature of 298.1°K. is given in Table VII.

TABLE VII

SUMS IN THE ENTROPY EQUATION FOR OXYGEN

T = 298.1°K.

e	$\Sigma_{n,m} p_{n,m} e^{(-\epsilon_{n,m}/kT)}$	$1/kT\Sigma_{n,m} \epsilon_{n,m} p_{n,m} e^{(-\epsilon_{n,m}/kT)}$
n = 1/2, F_1	83.831	77.959
n = 1/2, F_2	72.882	72.628
n = 1/2, F_3	63.155	67.363
	219.868	217.950
n = 3/2, $\Sigma_{e,n,m}$	0.125	1.055
n = 5/2, $\Sigma_{e,n,m}$	.000	0.001
$\Sigma_{e,n,m}$	219.993	219.006

This leads to a value of $S_{298.1}$ = 49.03 E.U.

It will be of interest to compare the above method of calculating the rotational entropy with that proposed by Tetrode,[35b] who derived the equation $S_R = R \ln IT + S_2$ for the rotational entropy of a rigid molecule, where I is the moment of inertia in g.cm.^{2} and S_2 = 177.68. The above formula was derived for infinite temperature but for practical purposes holds quite well at ordinary temperatures. However, while this formula correctly represents the entropy of the molecular situation assumed by Tetrode, it fails to consider a number of factors which are now recognized as important in molecular behavior. Two of these are encountered in the case of the oxygen molecule. First, the triplet multiplicity of the various states of the oxygen molecule leads to an increase in the entropy of R ln 3 for the limiting case and by a slightly smaller amount at ordinary temperatures. Second, the homopolar character of the molecule combined with the non-spinning character of the oxygen nuclei results in the exclusion of alternate rotation states. This leads to a smaller entropy by R ln 2 for the limiting case. The net result of the above is that the rotational entropy of the oxygen molecule would be given approximately by

$$S_R = R \ln IT + R \ln \frac{3}{2} + S_2$$

The theoretical and experimental values are given in Table VIII. The "spectroscopic" values are those derived by the summation method.

TABLE VIII

COMPARISON OF SPECTROSCOPIC AND THIRD LAW VALUES OF THE ENTROPY OF OXYGEN

	T, °K.	90.13	298.1
	Spectroscopic, cal. per deg. per mole	40.68	49.03
Third law	Actual gas	40.57 ± 0.1	....
	Corrected to ideal state	40.7	49.1

The third law value given for 298.S°K. was obtained by adding the 0.17 E.U. correction for gas imperfection estimated by means of Berthelot's equation and the spectroscopic difference to the value obtained for the actual gas at the boiling point. The entropy was also calculated by utilizing the thermodynamic equation $\mathrm{d}P/\mathrm{d}T = \Delta S/\Delta V$ and vapor pressure measurements in place of the direct entropy of vaporization. The vapor pressure equation of Cath[13]

$$\log_{10} P(\text{atmos.}) = -\frac{419.31}{T} + 5.2365 - 0.00648T$$

was taken to represent the data. Later measurements[12] agree very closely with this equation. This was combined with Berthelot's equation, for which the constants have been given previously. For convenience the calculation was carried out at 71.40°K., where the vapor pressure of oxygen is 6.046 cm. and the molal volume of the liquid is 25.9 cc. from the work of Mattias and Onnes.[14]

The entropy of vaporization at this temperature and pressure was found to be 24.58 E.U., to which must be added a correction of 0.03 E.U. for gas imperfection of the Berthelot gas at this temperature and pressure. The entropy of the liquid at 71.40°K. was found to be 19.50 E.U. The entropy change accompanying the compression of ideal gas from 6.046 cm. to one atmosphere is −5.03 E.U. The increase in entropy on heating ideal gas from 71.40°K. to the boiling point at 90.13°K. is 1.62 E.U. when we assume a C_p of $^7/_2R$, which should be nearly correct. Then at 90.13°K., $S_{O_2} = 19.50 + 24.58 + 0.03 - 5.03 + 1.62 = 40.70$ E.U.

This value, which might be expected to contain a possible error of several tenths of an entropy unit, happens to be in excellent agreement with the theoretical value 40.68 E.U. and the more direct experimental value 40.74 E.U. This may be taken as a substantiation of the use of Berthelot's equation to represent gas imperfection.

Eucken, Karwat and Fried[36,37] have given the value $S_{298.1} = 49.04 \pm 0.2$ E.U. for oxygen.

This latter value is in excellent agreement with the theoretical value, although rather fortuitously so, as may be seen from the comparison made in Table V. In making the above calculation, Eucken, Karwat and Fried used the value 1629 obtained from an average of the available data rather than the value 1599 used by Lewis and Gibson in computing the entropy of vaporization given in Table V. Their selected value is identical with our experimental value.

It is well worth noting that the extended Tetrode equation leads to values which are practically identical with those calculated by the more reliable summation method. The value obtained at 90.13 is high by 0.02 E.U. while that at 298.1°K. is in exact agreement. While this close agreement is partially due to the fortuitous canceling of several effects it is to be expected that the Tetrode equation properly extended where necessary will usually give values correct to within a few hundredths of an entropy unit per mole at ordinary temperatures.

It is suggested that entropy values deduced from reliable spectroscopic data are preferable as a basis for thermodynamic calculations to the less accurate values obtained from heat capacity measurements and the third law. The values of the entropy obtained from spectroscopic data are for the ideal state of a gas, which is also the state of reference used in tabulating thermodynamic data.

The Paramagnetism of Solid Oxygen.—The magnetic susceptibility of solid oxygen has been investigated by Onnes and Perrier.[38] The susceptibility of the crystalline form stable below the boiling point of hydrogen has a very small positive temperature coefficient and appears to be approaching the absolute zero with a temperature coefficient of zero. From this some conclusions may be drawn as to the change in entropy with magnetic field strength. We have the thermodynamic equation[39]

$$\left(\frac{\partial S}{\partial \mathfrak{H}}\right)_{P,T} = \mathfrak{H}\left(\frac{\partial x}{\partial T}\right)_{P,\mathfrak{H}}$$

from which it is evident that a zero temperature coefficient of susceptibility corresponds to no change in entropy as the magnetic field strength is increased. While this in itself is not proof that the contribution to the

entropy due to the magnetic system of the oxygen molecule is practically zero in this particular solid state, it is the condition imposed by the third law of thermodynamics for zero entropy in such systems. However, the agreement of the entropy calculated from our calorimetric measurements with that obtained from spectroscopic data shows that the magnetons in solid oxygen have little randomness at the temperatures of liquid hydrogen. It is therefore concluded that the magnetons have coupled with each other into what may be considered as a magneton crystal within the molecular crystal lattice of oxygen. The strong paramagnetism of solid oxygen must be regarded as due to what corresponds to a Paschen–Back effect in the solid—that is, a destruction of the coupling by the applied field as is observed in the case of some gaseous ions. This does not mean that the magneton crystal has been largely broken down by the fields of about 16,000 gauss which have been used for the susceptibility determinations, since the intensity of magnetization obtained is only 0.25% of the saturation value for two Bohr magnetons.

The small positive susceptibility obtained for many substances, and which has little temperature coefficient, may be due to the initial effect of the coupling breakdown which a sufficiently strong field could produce.

We wish to thank Mr. J. O. Clayton for assistance in making many of the measurements.

Summary

The heat capacities of the three crystalline forms of solid oxygen and of the liquid have been measured from 11.75°K. to the boiling point. The curves through the data are believed to represent the heat capacity of liquid oxygen to within 0.2 of 1%; of Solid I to within 0.3 of 1%; of Solid II to within 0.5 of 1%. For Solid III the inaccuracy of the curve may be somewhat larger, ranging from 1% at the upper extremity (23.66°K.) to possibly 5% at 12°K.

The transition temperatures were determined to be 23.66 ± 0.10°K. and 43.76 ± 0.05°K., respectively. The melting point was found to be 54.39 ± 0.05°K. and the boiling point 90.13 * 0.05°K.

Calorimetric measurements were made of the heats of transition, fusion and vaporization. Arranged in order of the transition at 23.66°, the transition at 43.76°, fusion and vaporization, these values are 22.42 ± 0.1, 177.6 * 0.5, 106.3 ± 0.3 and 1628.8 ± 1.6 calories per mole, respectively.

The entropy of oxygen gas at 90.13°K. and 1 atmosphere was calculated from the above data and the third law of thermodynamics, and found to be 40.57 ± 0.1 calories per degree per mole. Corrected to the ideal state with the aid of Berthelot's equation, a correction which amounted to +0.17 cal./degree/mole, this value was compared with that calculated by the accurate "summation" method from the molecular spectra of

oxygen gas. The two values are in almost exact agreement, showing that the triplet character of the oxygen molecule due to the unbalanced angular momentum of its two spinning electrons has contributed approximately R ln 3 to the entropy of gaseous oxygen, and also that the absence of alternate rotation levels in the oxygen molecule due to its homopolar nature results in an entropy of R ln 2 less than would be the case for a polar molecule of the same moment of inertia.

The entropy of oxygen gas at 298.1°K. was calculated by the "summation" method from the spectral data and found to be 49.03 calories per mole per degree. We believe that this is the best value for use in thermodynamic calculations.

It is also shown that the magnetons in the crystalline form of oxygen stable below 23.66°K. are not contributing appreciably to the entropy and must, therefore, be coupled in a non-random manner into what may be regarded as a magneton crystal within the ordinary molecular crystal lattice.

It is shown that the existing magnetic susceptibility data on solid oxygen are in agreement with the requirement of the third law of thermodynamics for zero entropy in magnetic systems, namely, that the temperature coefficient of the magnetic susceptibility should approach zero as the absolute zero of temperature is approached.

It is concluded that the large positive susceptibility of solid oxygen is due to the initial effect of a coupling breakdown induced by the applied field in analogy to the Paschen–Back effect in gaseous ions.

The general agreement of the various physical facts concerning the oxygen molecule in relation to the entropy and particularly the close agreement of the entropy as obtained by the two methods support our confidence that the third law of thermodynamics is an exact law.

GERMANIUM. XXX. HALOGEN SUBSTITUTION PRODUCTS OF MONOGERMANE[1]

BY L. M. DENNIS AND P. R. JUDY

RECEIVED FEBRUARY 14, 1929 PUBLISHED AUGUST 7, 1929

Most of the possible halogen substitution products of methane and monosilane (SiH_4) of the types RHX_3, RH_2X_2 and RH_3X, have been prepared.[2] The purpose of the present investigation was the preparation and study of some of the analogous compounds of germanium.

---

[1] This article is based upon part of the thesis presented to the Faculty of the Graduate School of Cornell University by P. R. Judy in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] See Landolt-Börnstein, "Physikalisch-chemiseheTabellen," 1923, Vol. I, p. 356.

Monochloromonogermane, GeH_3Cl, and Dichloromonogermane, GeH_2Cl_2.—These were prepared by the action of hydrogen chloride on monogermane in the presence of a catalyst.

Apparatus.—The apparatus was patterned after that of Laubengayer and Corey[3] and is shown in Fig. **1**. Stock's[4] modification of his mercury float valve was used. The bulb B_1, which is used as the reaction chamber, has a capacity of about **500** cc. and there is attached to the bottom of the bulb a tube 14 mm. wide and about **15** cm. long which is closed at the lower end. **A** tube **7** mm. in diameter and about 6 cm. long, open at its further end, is fused at right angles to the upper tube of the bulb at C. Just before beginning an experiment, a short tube of the same diameter, closed at one end and containing about **0.1** gram of anhydrous aluminum chloride, is fused to the open end of this side tube and the aluminum chloride is then sublimed into the bulb B_1, whereupon the side tube is sealed off at the point marked C. Three smaller bulbs, B_2, B_3 and B_4, attached to the line as shown, are used for the fractionation of the gases. K is a manometer for measuring gas pressures and E is a bulb for the weighing of separate samples. The space between the stopcocks S_2 and S_4, which would be full of air after D is detached and again attached to the chain, can be exhausted through the stopcock S_3. The volumes of various portions of the apparatus are calibrated by the use of the Hempel buret F in the manner described by Laubengayer and Corey. H is a calibrated tube which is used for measuring the volumes of liquids and determining their melting points. The bulbs B_5 and B_6 are storage bulbs of about one liter capacity which carry at the bottom short tubes and small bulbs for the application of the cooling baths.

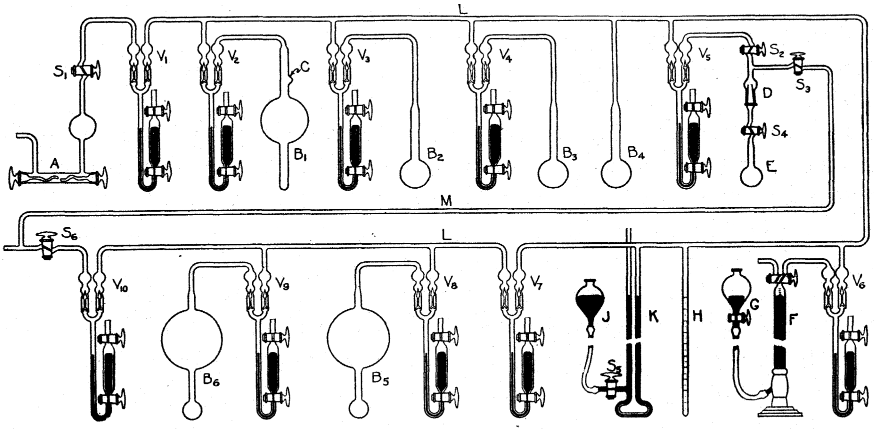

Fig. 1.

Before beginning an experiment the whole apparatus was freed from moisture by drawing through it air that had been purified by passage through soda lime, concentrated sulfuric acid and finally phosphorus pentoxide contained in the tube **A.**

Manipulation.—The monogermane that was used was a portion of the large sample of this gas that was prepared in **1923** for the study of the hydrides[5] of germanium, Determinations of the densities of two samples of this gas from different gas-holders gave

3.396 and 3 405, showing that the gas was quite pure and that it is very stable at room temperature over long periods of time. The gas was introduced through the stopcock S_6 into the bulbs B_5 and B_6.

Hydrogen chloride entirely free from air was introduced into the buret[3] F over mercury, where it could be measured.

The bulb B_1 was now evacuated, the catalyst was cautiously sublimed into it and the side tube was sealed by fusion at C. The change in the volume of the bulb which was thus caused was so small that recalibration of this part of the apparatus was unnecessary.

A known volume of monogermane, which was measured in the calibrated portion of the apparatus, was condensed in B_2 by means of liquid air. An amount of hydrogen chloride somewhat less than the theoretical volume required for the formation of monochloromonogermane was then drawn over into B_2 and condensed. The mixture of the two gases was then transferred to the reaction bulb, B_1, by cooling the tube attached to the bottom of the latter with liquid air and removing the refrigerant from around the bulb B_2. The valve V_2 was then closed.

Upon removing the liquid air from around the tube of B_1, the two liquids vaporized and reaction began at once. The application of heat was unnecessary. Equilibrium was reached in about thirty minutes.

After the reaction was complete, all gases other than hydrogen were frozen by liquid air and the hydrogen was measured.

In every experiment more hydrogen was evolved than corresponded to the formation of GeH_3Cl alone. Some dichloromonogermane was always simultaneously produced.

Fractionation.—After the hydrogen had been removed from the apparatus by the pump, the volatile residue in B_1 was transferred to B_2 to remove it from the catalyst. Unchanged monogermane (b. p. −90°) was distilled off at from −135 to −120° and condensed in B_4. Its volume was measured and it was then transferred to the storage bulbs. Hydrogen chloride (b. p. −83°) was then distilled off at from −120 to −90°, measured and removed.

The first slight rise in the manometer above −90° was at about −83°, at which temperature monochloromonogermane begins to come off. This was distilled over at −78°, and a quite pure product was usually obtained.

Dichloromonogermane began to come over at about −61° and distilled quite rapidly at −52°. Sharp separation of the two products was therefore possible on careful fractionation with the vacuum apparatus. The yield of the two compounds in the last experiment, after familiarity with the manipulation had been attained, was GeH_3Cl, 48%, and GeH_2Cl_2, 14%, of the GeH_4 that had reacted.

Analysis.—In the analysis of the corresponding compounds of silicon, Stock made use of the reaction with sodium hydroxide, in which hydrogen is quantitatively evolved. For example

$$SiH_3Cl + 3\ NaOH = Na_2SiO_3 + NaCl + 3\ H_2$$

This procedure was tried with the germanium compounds but when these were brought into contact with a solution of sodium hydroxide, germanium monoxide, not the dioxide, was formed, and the hydrogen set free was always considerably less than is called for in the equations

$$GeH_3Cl + H_2O = GeO + HCl + 2\ H_2$$
$$GeH_2Cl_2 + H_2O = GeO + 2\ HCl + H_2$$

Secondary reactions apparently take place, for even after prolonged treatment with sodium hydroxide, the odor of hydrides or chlorinated compounds of germanium could be detected.

The method of analysis that was finally adopted was to bring a known weight of the sample into the bulb E, close stopcock S_4, detach the bulb from D, cool E and then run into the bulb through the neck, first a dilute solution of potassium hydroxide, and then hydrogen peroxide. After decomposition of the sample and solution of the products were complete, the solution was acidified with nitric acid, the chlorine was precipitated by silver nitrate and after removal of the excess of silver from the filtrate, germanium was precipitated as the disulfide. The results of the analyses did not agree closely with the theoretical because of the unstable character of the compounds. They sufficed, however, to establish the identity of the monochloromonogermane and the dichloromonogermane and gave a ratio Ge:Cl of 1:1.03 in the first-named compound, and of 1:2.04 in the latter.

Properties of Dichloromonogermane and **Monochloromonogermane.**—Both substances are mobile, colorless liquids of peculiar, nauseating odor.

TABLE I

DICHLOROMONOGERMANE

Boiling point, 69.5°; melting point, −68'; density as liquid at −68°, 1.90; mol. wt., av. of four detns., 145.2; calcd., 145.54.

T, °C.	−54.7	−41.8	−31.5	−23.2	−11.5	−9.7	−3.5	0.4
P, mm.	1.3	2.1	5.9	9.3	19.3	21.6	30.6	36.9

P, mm.	41.1	58.1	72.2	110.0	142.1	176.3	214.2	258.2
T. °C.	44.3	48.5	53.5	58.0	61.6	65.3	68.7	71.2
P, mm.	304.9	358.8	431.2	511.7	588.2	660.6	739.4	802.3

The general equation derived from the above data is

$$\text{Log}_{10} P_{\text{mm.}} = -1742.7 \times \frac{1}{T} + 7.969$$

TABLE II

MONOCHLOROMONOGERMANE

Boiling point, 28°; melting point, −52°; density as liquid at −52°, 1.75; mol. wt., av. of seven detns., 110.92; calcd., 111.08.

T, °C.	−52	−44.2	−38.5	−32.8	−31.2	−24.6	−20.7
P, mm.	11.3	18.5	27.9	39.5	45.4	70.0	88.9
T, °C.	−14.8	− 9.4	− 5.0	2.1	5.5	8.8	
P, mm.	118.8	150.9	185.1	257.5	298.6	345.2	
T, °C.	11.9	16.3	20.7	24.6	27.6	29.5	
P, mm.	392.9	469.9	559.0	646.9	724.4	786.9	

The general equation derived from the above data is

$$\text{Log}_{10} P_{\text{mm.}} = -1527.4 \times \frac{1}{T} + 7.961$$

Both compounds fume when exposed to moist air, the walls of the container becoming coated with a film which is at first white and then becomes yellow, finally deepening to an orange tint. Considerable heat is liberated during this reaction. Water rapidly hydrolyzes the compounds and hydrogen is evolved. Absolute alcohol precipitates a white substance which dissolves to a yellow solution when an equal volume of water is added. Solutions of fixed alkali hydroxides precipitate an orange-colored compound, considerable hydrogen being set free. An alcoholic solution of potassium hydroxide yields a pale yellow precipitate, no hydrogen being evolved until water is added to the mixture.

Hydrogen chloride in the presence of aluminum chloride converts monochloromonogermane into dichloromonogermane with liberation of hydrogen. The dichloro compound does not further react with hydrogen chloride.

Ammonia acts instantly on both compounds, forming non-volatile, colored substances which decompose with explosive violence when heated in air.

Monochloromonogermane slowly breaks down at room temperature

$$2\ GeH_3Cl = GeH_4 + 2\ HCl + Ge$$

Dichloromonogermane decomposes much more rapidly. Among the products that are formed there were detected Ge, $GeCl_2$, GeH_4, HCl, GeH_3Cl, $GeCl_4$ and traces of hydrogen.

Monobromomonogermane, **GeH_3Br,** and Dibromomonogermane, **GeH_2Br_2.**—The method of preparation of these compounds was essentially the same as for the chlorine substitution products, hydrogen bromide replacing hydrogen chloride and aluminum bromide being used as the catalyst.

Reaction between the monogermane and the hydrogen bromide took place as soon as they were brought together, considerable heat being evolved. When reaction was complete, the bulb was surrounded by liquid air and the hydrogen was pumped off. The excess of monogermane was then removed at about —120". The separation of the bromination products by fractionation of the residue was difficult because of the instability of the compounds. This tendency to dissociate, even at quite low temperatures, rendered it impossible to obtain closely agreeing analytical results.

Properties of Dibromomonogermane and **Monobromomonogermane.**—Both compounds are colorless, mobile liquids of nauseating odor.

TABLE III

DIBROMOMONOGERMANE

Boiling point, 89°; melting point, −15°; density as liquid at 0°, 2.80

T, °C.	−26.6	− 5.6	0.6	5.9	15.5	21.7	27.4
P, mm.	1.2	3.7	6.5	9.6	15.7	28.3	36.1
T, °C.	34.1	35.2	38.9	43.2	49.5	57.2	
P, mm.	55.4	62.7	79.5	102.4	146.6	215.8	
T, °C.	63.9	69.2	75.3	79.2	81.1	82.3	
P, mm.	304.1	409.2	519.4	633.0	733.3	814.8	

The following general equation, derived from the above data, is accurate up to a temperature of 50°. At higher temperatures the pressure does not agree with the calculated values because of dissociation of the compound.

$$\text{Log}_{10} P_{\text{mm.}} = -2461.9 \times \frac{1}{T} + 9.798$$

TABLE IV

MONOBROMOMONOGERMANE

Boiling point, 52°; melting point, −32°; density as liquid at 29.5°, 2.34; mol. wt., 155.4; calcd., 155.54.

T, °C.	−44.6	−27.3	−16.4	−7.8	−3.3	4.8	10.9	15.4
***P*, mm.**	8.1	22.2	43.0	59.2	73.8	107.7	145.4	176.6
T, °C.	19.1	24.5	29.4	35.2	40.5	45.3	49.0	52.5
P, mm.	212.9	265.1	321.9	401.4	496.3	592.6	687.5	776.1

The general equation derived from the above data is:

$$\text{Log}_{10} P_{\text{mm.}} = -1614.7 \times \frac{1}{T} + 7.851$$

The chemical behavior of the monobromo- and dibromomonogermane is quite similar to that of the corresponding chlorine compounds.

Mono-iodomonogermane, CH_3I, and Di-iodomonogermane, CH_2I_2.—The iodine derivatives of methane are not very stable. Iodoform sublimes at 110° and begins to dissociate at this temperature. Tri-iodomonosilane boils at about 220° and begins to decompose at 150°. Tri-iodomonogermane was found to be unstable[6] above 0°. It was therefore to be expected that GeH_3I and GeH_2I_2 would, if their syntheses were successful, prove to be considerably less stable than the corresponding bromine and chlorine compounds of germanium.

In the preceding experiments it was found that monogermane reacts quietly upon hydrogen chloride in the presence of a catalyst with only slight rise of temperature, whereas with hydrogen bromide the reaction is vigorous and considerable heat is evolved. When equal volumes of monogermane and hydrogen iodide were mixed and were brought into a bulb containing aluminum bromide, the two gases reacted energetically and the bulb became quite hot near the reaction zone. A gas was evolved and drops of a colorless liquid formed on the catalyst. This liquid almost immediately turned yellow and soon changed to a solid. After three hours, the hydrogen that had been liberated was pumped off, and the unattacked monogermane was removed at −78°. Attempts to isolate GeH_3I and GeH_2I_2 by careful distillation in the vacuum apparatus were unsuccessful, and although evidence of the formation of those two compounds in the first stages of the reaction was obtained, it appeared that they then reacted with the hydrogen iodide to yield GeI_2 as the final product.

---

[6] Brewer and Dennis, J. *Phys. Chem.*, 31, 1526 (1927).

$$\begin{aligned} GeH_3I + HI &= GeH_2I_2 + H_2 \\ GeH_2I_2 + HI &= GeHI_3 + H_2 \\ GeHI_3 &= GeI_2 + HI \end{aligned}$$

The formation of germanium di-iodide was established by first pumping off the hydrogen, monogermane and hydrogen iodide from the reaction bulb and then adding an excess of hydriodic acid to the yellow residue in the bulb. This dissolved the substance and the filtered solution deposited, on cooling, yellow, feathery crystals[6] of GeI_2. Some GeI_4 was also present, this being formed by the dissociation of some of the di-iodide

$$2\,GeI_2 = GeI_4 + Ge$$

The end-products of the reaction between monogermane and hydrogen iodide therefore appear to be germanium di-iodide, hydrogen and some germanium tetra-iodide.

Summary

This article deals with the preparation and properties of monochloromonogermane, dichloromonogermane, monobromomonogermane and dibromomonogermane. Evidence was obtained that indicated the formation of the corresponding iodo compounds which, however, could not be isolated because of their instability.

POLARIZATION IN STANDARD CELLS

BY WENDELL S. NIEDERHAUSER AND GEORGE A. HULETT

RECEIVED MARCH 1, 1929 PUBLISHED AUGUST 7, 1929

Introduction

Experimental studies of the effects of withdrawing current from standard cells[1] have shown these cells to be subject to a considerable degree of polarization, even at relatively low currents. It has also appeared that the polarization is roughly proportional to the strength of current, and that the cells recover quite satisfactorily following polarization, provided it has not been too prolonged. The passage of a current in the reverse direction through the cells also causes polarization, which, from the published results, appears to be somewhat more severe and of longer duration than that produced by discharging.[1e,f]

In all of the work mentioned above the cell has been considered as a

single unit and the results refer to the total polarization. This is, of course, the sum of the polarizations of the individual electrodes, quantities which may be widely different. Jaeger, in a theoretical treatment of the polarization of such cells,[2] deals with the cases of the individual electrodes and mentions some experimental work done by Lindeck in which measurements were made of these separate effects. That a more complete report of Lindeck's work does not appear to have been published is regrettable, inasmuch as the results of the one experiment mentioned by Jaeger are in direct contradiction to those which are here presented. No other work on these single effects in standard cells has been found in the literature.

This paper presents the results of a study of the polarization of the individual limbs of the saturated, unsaturated and acid cadmium cells, and of the zinc cell at very low currents. Both the effects of discharging and of charging the cells are studied, and the results are interpreted in terms of the processes which take place at the separate electrodes during and after the passage of the current. No attempt is made to apply a theoretical treatment, such as that proposed by Jaeger, to the results, since the factors entering into such a treatment (ionic mobilities, rates of diffusion, and rates of solution and of crystallization of the salts present) are too uncertain to admit of accurate use.

General Experimental Methods

Preparation of Materials.—Mercury was purified by treatment with nitric acid followed by distillation under diminished air pressure.[3]

Cadmium amalgam (10%) was prepared by dissolving the weighed amount of Kahlbaum's purest, electrolytically prepared, stick cadmium in mercury on a steam-bath. Zinc amalgam (7%) was prepared in a similar manner.

Cadmium sulfate and zinc sulfate were recrystallized from solutions of the purest salts obtainable commercially.

The mercurous sulfate was prepared electrolytically in a 1.6 sulfuric acid solution (1.15 density), using a current density of 1 ampere per square decimeter of anode surface, according to the methods of Wolff[4] and Hulett.[5] The product varied from a fairly dark gray, finely divided material containing much mercury, to a pure white, somewhat coarser substance, according to the efficiency with which the anode surface of electrolyte was renewed by stirring during the preparation. The white material, the average grain size of which was about *25* microns, gave the most normal values when placed in cells and was used in most of the cells made in this work. A gray product having an average grain size of about 10 microns gave nearly identical cell values and was also employed in some of the work.

The saturated cadmium sulfate and zinc sulfate solutions were prepared by shaking an excess of the purified crystals with conductivity water in a thermostat at 25.0°. For unsaturated cells the electrolyte was prepared by dissolving the amount of the crystalline cadmium sulfate required to give a 43.06% solution (on the basis of the

anhydrous salt) in conductivity water in a stoppered bottle. Cells containing such a solution have a temperature coefficient of approximately zero.[6] The electrolyte for the acid cells was prepared by saturating a 0.1 *M* solution of sulfuric acid with cadmium sulfate.

In preparing the paste, the mercurous sulfate was filtered, with suction, in a Gooch crucible and washed several times with the electrolyte to be used in the cell. About one-third its volume of finely ground crystals (of zinc sulfate or cadmium sulfate as the case might be) was then added and the whole made up to a thin paste with the proper electrolyte.[7]

Cells.—The cells were the customary H-form, the internal diameter of the limbs being 10 mm. and that of the cross-arm somewhat less. Some special forms of cells used in the polarization studies will be described later. All cells were carefully cleaned and the platinum terminals amalgamated before filling. The materials were introduced by means of pipets, after which the cells were hermetically sealed. They were allowed to age for at least a month at constant temperature before use.

Constant-Temperature Bath.—The cells were kept in a constant-temperature bath as described in a previous paper by one of the present authors? A high grade mineral oil[9] was used as a bath liquid. The 25.00" point, at which the bath was maintained, was determined by means of a calibrated platinum resistance thermometer. Under the most favorable conditions the control of temperature could be maintained to ±0.002°.

Reference Standards.—Through the cooperation and kindness of the Bureau of Standards, a series of comparisons was run, during the course of this work, between the cells used as a basis of reference in this Laboratory and the Standards maintained by the Bureau in Washington. The Princeton reference group now consists of 15 cells, all of which are from fourteen to twenty-five years old, and have shown very constant values throughout their history. The mean value of the group has been established to an accuracy of I microvolt, on the present basis of the Bureau of Standards.

Measurement of E.m.f.—The electromotive force measurements reported in this work were made with a 5-dial Wolff potentiometer having a resistance of 15,000 ohms and a range from 0.00001 to 1.5 volts. The working current for the potentiometer was obtained from a two-cell standard battery[10] and was controlled by means of a manganin coil resistance box adjustable to 0.1 ohm. As a null instrument a high sensitivity moving coil galvanometer (Leeds and Northrup Co.) was used. The sensitivity of this instrument was such that, with the method of measurement described below, a deflection of 10 mm. or more (on the scale at a distance of one meter) was usually obtained for a change in potentiometer setting of 10 microvolts. This made the estimation of cell voltages to one microvolt relatively easy. For the elimination of parasitic electromotive forces in the circuit, reversing switches were placed in the working

[7] In this and subsequent operations, no attempt was made to prevent access of air to the materials, as suggested by (a) Vosburgh, THIS JOURNAL, 47, 1258 (1925); and (b) Eppley, *Trans. Am. Electrockem. Soc.*, **53**, 149 (1928). Evidence will be presented in a later paper [THIS JOURNAL, **51**, 2345 (1929)] to show that the high initial values of neutral cells, attributed by them to oxidation of the Hg_2SO_4 of the paste during its preparation, may be partially explained on another basis. Further experiments designed to test more directly the importance of Vosburgh's and Eppley's methods are being conducted in this Laboratory.

battery circuit and the unknown e.m.f. circuit, so that these could be simultaneously reversed and, from the difference in galvanometer deflection obtained, a zero correction applied. The whole measuring outfit, including the baths in which the cells were kept, was carefully shielded against the effects of external e.m.f.'s.[11]

The method of measurement used was the differential method, employed at the Bureau of Standards.[12] Each cell to be measured was placed in opposition to a chosen cell whose e.m.f. had been previously established by a similar comparison with the cells of the reference group, and the difference in e.m.f. between these two cells determined. The potential of the unknown cell could then be calculated. Corrections for parasitic e.m.f.'s were made on every reading and with proper care final readings could be duplicated over and over without variation.

Measurement of Internal Resistances of Cells.—The measurement of the internal resistances of the cells, required in this work, presented some difficulty, as it was necessary that the method employed should not cause polarization. A modification of the capacity bridge method of Nernst and Haagn[13] was found most satisfactory. The introduction of a vacuum tube amplifier in the telephone circuit permitted an interchange of the microphone hummer, used as a source of audio frequency current, with the telephones, and the elimination of one condenser. Such a bridge is better balanced than the Nernst–Haagn arrangement. It was found to give a sharp sound minimum and was capable of adjustment well within the 0.5% accuracy required for our work.

To see whether such a measurement was injurious to a cell, potential measurements were made on several cells simultaneously with the resistance measurements. A change of about 10 microvolts could be detected while the resistance measurements were being made but this disappeared immediately upon the removal of the bridge connections. The resistances of most of the cells used were between 300 and **500** ohms.

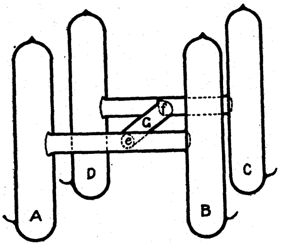

Fig. 1.—Four-legged cell used in polarization studies.

Methods of Study of the Polarization of the Separate Electrodes of Cells.—In order to determine how the polarization was distributed between the separate electrodes of the cell, a special form of cell vessel was devised (Fig. **1**). The mid-points of the cross-arms of two H-type cell vessels, AB and CD, were joined by a third cross-arm, ***G***. Limbs **A** and C were made cadmium amalgam-cadmium sulfate electrodes, while B and D were mercury–mercurous sulfate poles.

When a current was passed through one of the cell combinations thus made, say AB, the other electrodes, C and D, were entirely unaffected and could be used as reference electrodes to test the polarization of the working electrodes. Since **A** and C were of identical construction, the potential existing between them when the cell was on open circuit was very nearly, or exactly, zero. During the polarization of **A,** therefore, the potential difference measured from **A** to C (with a small zero correction if necessary) represented the total change in potential between the point e within the cell and the (external) terminal at A due to the passage of current. This total change in potential, ΔE_{Ta}, is the sum of two quantities, ΔE_{Ra}, which is the e.m.f. required to produce the flow of current through the resistance, R_a, between these two points, and ΔE_{Pa}, which is the polarization of the electrode.

---

[11] White, THIS JOURNAL, **36, 2011 (1914).**

[12] Wolff and Waters, Bull. Bur. *Standards, 4,* **1 (1907).**

[13] Nernst and Haagn, *Z. **Elektrochem.***, 2, **493 *(1896).***

The current flowing through the cell may be obtained by measuring the potential difference, E_x, across a known resistance, R_x, in the external circuit. ΔE_{Ra} may then be calculated from Ohm's Law, and we obtain

$$\Delta E_{Pa} = \Delta E_{Ta} - \Delta E_{Ra} = \Delta E_{Ta} - \frac{E_x}{R_x} \times R_a$$

We may use the subscript, a, in the above equation to designate the amalgam limb of the cell. For the polarization of the mercury limb, ΔE_{Pm}, and of the cell as a whole, ΔE_{Pc}, similar relationships may be derived. The accuracy of the whole method was tested by comparing ΔE_{Pc} with the sum of ΔE_{Pa} and ΔE_{Pm}, each obtained from independent measurements. The agreement was exact at low currents, and never varied by more than 0.5% (due to leakage at the junction e) at the higher currents.

The determination of the resistances of the single limbs of the four-legged cells was accomplished by measuring the resistance across each of the six possible combinations of the four terminals of the cells (Fig. 1). The values thus obtained could be represented as sums of the resistances of the separate limbs of the cells (including in each case the resistance of the connecting cross-arm as far as the junctions e and f, respectively) and the cross-arm, G, connecting the two complete cells. The six equations representing these sums offered solutions for the resistances of the separate limbs. The results of different determinations agreed with each other to better than 0.5%. (There is a slight uncertainty at the junctions e and f, of course.)

In making the potential measurements called for in the above equations, the procedure was as follows. The e.m.f.'s of the two cells, AB and CD (Fig. 1), were first measured by the usual method. The potential differences between the amalgam limbs, A–C, and between the mercury limbs, B–D, were also measured. These latter were always zero or very small initially. The circuit connecting the cell AB across a high resistance[14] so as to discharge it, or in opposition to a larger e.m.f. (2 volts from a lead accumulator) with an appropriate high resistance in series, so as to charge the cell, was now closed. Experience having shown that the potential at the mercury limb was most affected by the passage of the current, special attention was paid to this quantity and readings of the change in it were taken as quickly as possible after closing the circuit and at frequent inter-

---

[14] The high resistances required to secure the low currents used in this work were specially constructed by the International Resistor Company of Philadelphia, Pa. They consisted of a thin metallic coating on glass wires, insulated and mounted in sealed glass tubes. While these had appreciable temperature coefficients, and were not entirely unaffected by atmospheric conditions, they were much cheaper than coil resistances of the same denominations (0.1 to 10 megohms), and by placing them inside the thermostat they could be kept quite constant in value. Their values were checked from time to time to insure constancy, For all work below 100,000 ohms manganin coil resistances were used.

vals thereafter for at least one-half hour. Between these readings the change in potential at the amalgam limb and the total potentials of the polarized cell and of the unpolarized cell, CD, were also measured. A convenient arrangement of switches facilitated the change from one set of connections to another in making these readings. The unpolarized cell was, as expected, entirely unaffected by the passage of current through the other element. The recovery of the cell after opening the circuit was also observed. A second experiment was not started on a given cell until it had recovered from the effects of the last previous experiment. Inasmuch as the effect of charging was found to be more severe than the effect of discharging the cells, experiments on the polarization due to charging were never run on a given cell until all of the discharge measurements had been made.

A typical set of data from an experiment in which a cell was charged at the rate of 1.7 micro-amperes for thirty minutes is given below.

TYPICAL EXPERIMENTAL DATA

Cell U_3. $R_M = 193$ ohms. $R_A = 192$ ohms. $R_C = 385$ ohms. $R_X = 0.583 \times 10^6$ ohms.

Time, min.	B-D mmv.	A-C mmv.	CD volts	AB volts	E_x, volts[a]
0	− 12	0	1.018080	1.018068	.....

30.0	985	334	......	......	.....

[a] E_x changes as the polarization of AB changes. The percentage change in E_x is negligible, however, in the calculations for which it is used, and in its effect upon the magnitude of polarization of the cell.

From the above data, we calculated $\mathbf{I} = 1.729 \times 10^{-6}$ amperes; $\Delta E_{Rm} = 334$ mmv.; $\Delta E_{Ra} = 332$ mmv.; $\Delta E_{Rc} = 666$ mmv.

For the mercury electrode we obtain from the above data the following:

TABLE I

COURSE OF POLARIZATION OF MERCURY ELECTRODE WHILE CHARGING CELL U_3 AT A CURRENT OF 1.7 MICRO-AMPERES

Time, min.	0	0.5	1.0	2.0	5.0	10.0	15.0	30.0
ΔE_{Tm}, mmv.	0	662	712	776	874	928	952	997
ΔE_{Pm}, mmv.	0	328	378	442	540	594	618	663

For the amalgam electrode, on the other hand, $\Delta E_{Pa} = 0$ to 2 mmv. throughout the course of the experiment. The polarization is, therefore, practically entirely in the mercury limb.

The recovery observations (Table II) are given for the mercury limb only, as the recovery of the amalgam limb was practically immediate. Here, of course, the potential measurements represent polarization with no calculation other than a zero correction of 12 mmv.

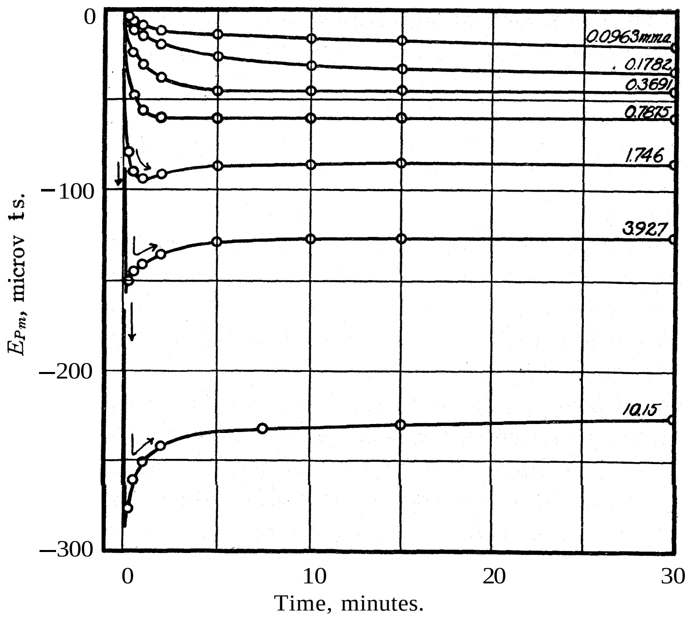
TABLE II

COURSE OF RECOVERY OP MERCURY ELECTRODE OR CELL U_3 AFTER THIRTY MINUTES' CHARGING AT 1.7 MICRO-AMPERES

Time, min.	0	1	2	5	10	15	30	60	120
R–D, mmv.	...	330	300	250	210	189	147	107	70
ΔE_{Pm}, mmv.	663[a]	342	312	262	222	201	159	119	82

[a] This value is obtained from Table I.

Observations on this cell were discontinued at the end of two hours. A week later the e.m.f. was still about 5 mmv. high.



Pig. 2.—Polarization in mercury limb at different discharging currents.

Results

Behavior of Mercury Limb during Discharge.—The course of polarization with time of discharge at the mercury electrode of a cell is shown for different currents in Fig. 2. The true polarizations, ΔE_{Pm}, of the electrode are plotted as ordinates with times as abscissas. The cell from which the data represented by these curves were obtained was a neutral unsaturated cadmium cell. The curves obtained for neutral saturated cadmium cells and zinc cells were entirely analogous to those here shown. The *magnitude* of the polarization at any given current differed from cell to cell, but the types of curves obtained as one increased the current were similar to those here shown throughout a number of studies of cells of each type.

It should be aoted that at low currents the polarization increases with time, but at a diminishing rate. Although cells were observed at currents of 0.1 micro-ampere for as long as fifty hours, they did not reach a steady state. It is to be assumed, however, that such a state would eventually be reached. As the rate of withdrawal of current is increased, the initial change in potential is more rapid, and a steady state is then reached in a very few minutes. A further increase in the current drawn produces a large initial polarization, followed by a period of apparent recovery, rapid at first and then more gradual. In some cases this recovery reached a maximum, after which the polarization again increased along a curve similar to that obtained at lower currents, while in other cases the recovery continued over a long period of time, apparently approaching a steady state.

Saturated cadmium cells made up with an acid electrolyte differed slightly in behavior from the cells above described. With a given sample of mercurous sulfate, acid cells required a current density nearly ten times as great as neutral cells to produce a polarization of given magnitude. They reached a steady state far more quickly than neutral cells. At 20 mma., for example, an acid cell became constant in e.m.f. in less than thirty seconds after the circuit was closed. The recovery effect, noted above, did not appear in an acid cell until a fifty-fold increase in current density was made.

Behavior of Mercury Limb **during** Charge.—The course of polarization at the mercury electrode of the same cell during charge is shown in Fig. **3.** The effect is, of course, opposite in direction to the effect of discharge. The slopes of the curves are greater at corresponding currents than for the discharge of the same cells, and a steady state is not reached as quickly as on discharge. The recovery tendency, noted in the discharge curves, is less pronounced, and soon gives way to the "normal" polarization effect. The results obtained on charging neutral saturated cadmium cells and zinc cells were strictly analogous to those obtained for the unsaturated cell as given in Fig. **3.** For the acid cells the differences in behavior from that of neutral cells noted in the experiments on discharging were found again to hold when the cells were charged.

Polarization over Longer Times.—A saturated cadmium cell was allowed to discharge for eleven days at a rate of 1.75 mma. Figure 4, Curve I, shows that the recovery tendency persisted throughout this time, and that the electrode recovered from an initial polarization of 2600 mmv. to within 300 mmv. of its value on open circuit. When the cirucit was then opened, the cell quickly recovered from the effects of polarization, and in less than nineteen hours the cathode had reached a value 20 mmv. higher than it had before the experiment was started. It maintained this value for three days, when the circuit was again closed, giving the curve shown as Curve II in the same figure. It will be noticed that the initial drop is now only 600 mmv., while the recovery seems to approach the same value as before. After sixty-five hours the circuit was opened. Recovery was complete (to the value 20 mmv. above the initial value of the cell) in ninety minutes and the circuit was then closed again. The initial drop was now only 300 mmv. and the curve quickly took up a continuation of Curve II. Eleven days of rest on open circuit followed, and, on again discharging at the same current, an initial polarization of 1400 mmv. was obtained. It is apparent that, although no change in the e.m.f. of the

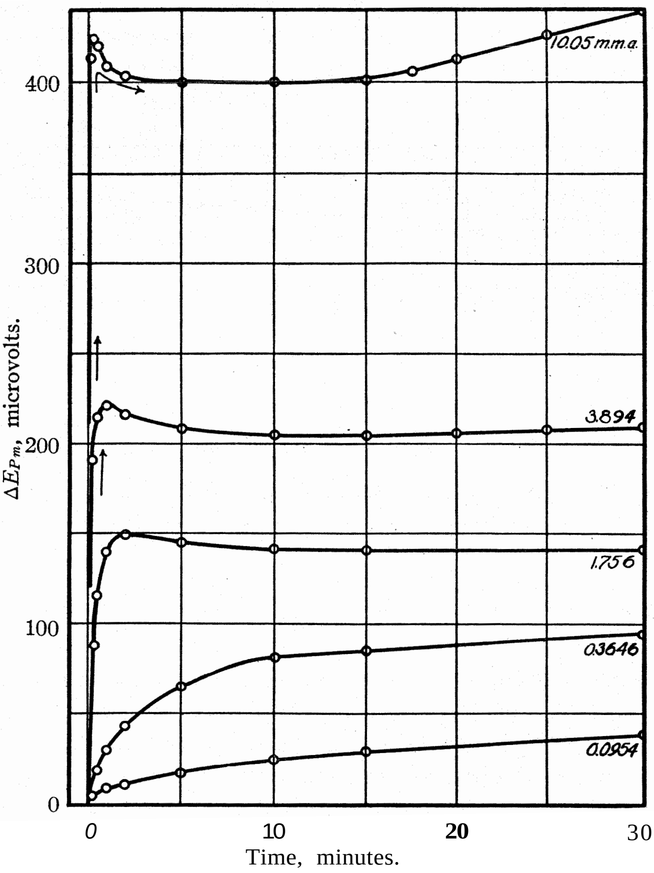


Fig. 3.—Polarization in mercury limb at different charging currents.

electrode took place during these periods of rest on open circuit, some process was going on which caused a decided increase in the *initial* polarization when the cell was later used to deliver current.

Inasmuch as the long time polarization of the cell had produced such a marked change in its behavior at the higher current, the question arose as to how its polarization at a much lower current would now compare with that previously observed for the cell. It was found that the polarization at a current of 0.1 micro-ampere was now 46 mmv., whereas it had formerly amounted to 168 mmv. at the same current.

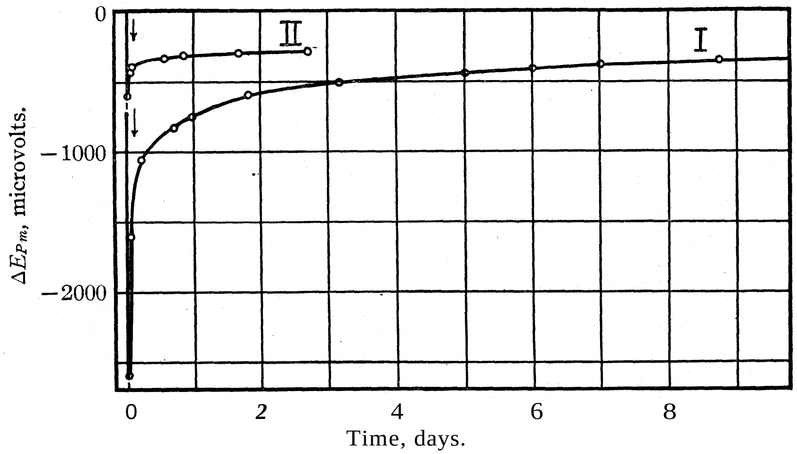

Fig. 4.—Effect of continued discharge at 1.75 micro-amperes upon mercury electrode.

The increase of 20 mmv. in the e.m.f. of the cell above described when allowed to rest after such a long time of polarization is interesting. Some old cells, particularly cells whose e.m.f. had shown a marked decrease, exhibited this effect, the increase in some cases being as great as 100 mmv. It usually disappeared within a few days after the circuit was opened.

Effect of Age of Cells upon their Polarization.—The discharge polarization of a cell was measured at a current of 10 micro-amperes six hours after it had been set up and placed in the bath. The recovery effect observed in older cells was also present in this cell, and its polarization was nearly as great at this time as it was found to be a month later, after the cell had been "aged" somewhat. Several cells built during the early spring of 1927, however, and tested with regard to their polarization in May and June of that year, were found to show an initial polarization nearly 30% higher at a given current when again measured ten months later. The characteristics of the polarization curve are the same, therefore, for new cells as for old ones, but the magnitude of polarization increases somewhat with the age of the cells.

Discharge of a Cell without Solid Depolarizer.—In order to see whether or not the presence of the solid mercurous sulfate had anything to do with the nature of the polarization curve, a cell was made in which the cathode limb contained a saturated solution of mercurous sulfate and cadmium sulfate with no solid salt. This cell was discharged at a rate of 10 mma. The recovery tendency was entirely absent. From an initial value of 313 mmv. the polarization increased in thirty minutes to 6003 mmv. When the circuit was opened the cell recovered to its initial value, though somewhat more slowly than *a* cell set up with the usual paste.

Internal Resistance of a Cell during Polarization.—The measurements of ΔE_{Tm}, from which the true polarization, ΔE_{Pm}, is obtained, include the ΔE_{Rm} term which is due to the internal resistance of the cell. A change in the internal resistance of the cell during the passage of current might, therefore, account for the recovery effect observed.[15]

To test this point the internal resistance of a cell was measured before and during polarization. The resistance during the passage of current was found to be the same, to within 0.1%, as it had been on open circuit. While these resistance measurements were being made, the polarization of the mercury limb of the cell decreased by an amount which, at the current drawn, would have necessitated a decrease in resistance greater than the total resistance of the cell if due to this cause. A change in the internal resistance of the cell is, therefore, excluded from any explanation of the recovery effect observed during the passage of current.

Recovery of the Mercury Electrode following Polarization.—The general nature of the recovery curve following the discharge of cells has been studied by other workers.[1] For the purpose of comparing the recovery following charge with that following discharge, however, results are here presented (Fig. 5) which show the recovery of the mercury electrode of a cell, (A) after sixty-five hours of discharge at 1.75 mma., and (B) after three and one-half hours' charge at 1.77 mma. The charge curve was the last obtained and the cell had rested for a month immediately beforehand. It is noted that three and one-half hours of charging produced a polarization six times as great as sixty-five hours of discharging at the same current. The recovery was, quite naturally, more rapid after discharge; but, although the effects of discharge disappeared one and one-half hours after the circuit was opened, the polarization following charge persisted for over two weeks. Similar observations were made on a large number of cells. Acid in the cells shortened the time required for recovery, both from discharge and from charge.

---

[15] Changes in the resistance at the surfaces of the electrodes in certain electrolytic cells during the passage of current have been observed previously: (a) Burgess, *Trans. Am. Elertrochem. Soc., 7,* 51 *(1905);* (b) Holler, Bur. *Standards Sci. Papers, 20,* **153** *(1925).*

Polarization and Recovery of the Anodes of the Cells.—During the experiments on polarization of the mercury limb of the cell, observations were also made of the polarization of the amalgam limb. These observations showed, in general, that the polarization of the amalgam limb at a given current density was only 1/40 that of the mercury limb, and that the recovery tendency observed during polarization of the mercury limb was not present at these currents in the amalgam limb. The true polarization at these low currents was so small that it was, in many cases, of the same order as the uncertainty in determining ΔE_{Ra}.

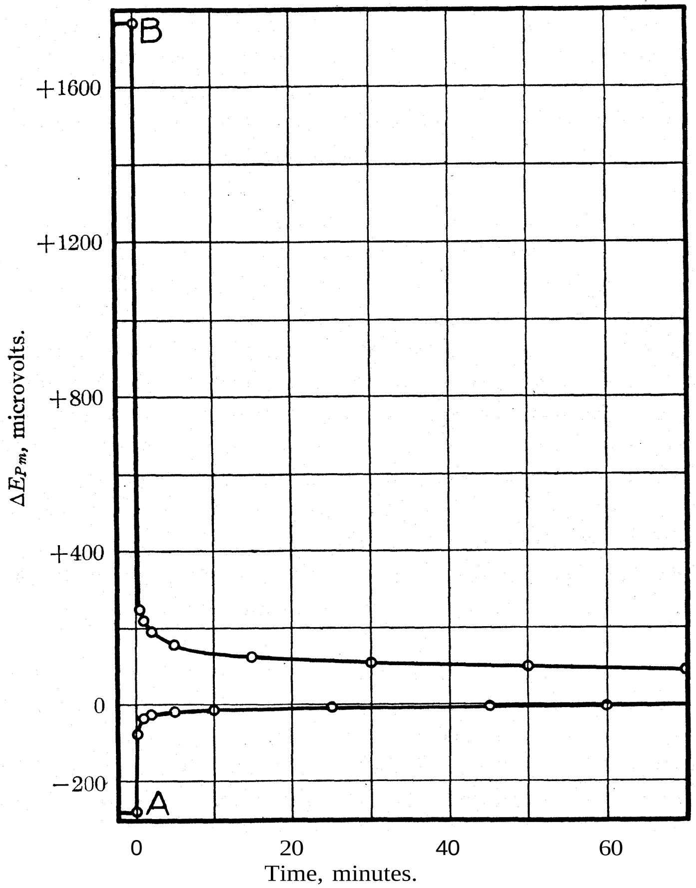

Fig. 5.—Recovery of mercury electrode from polarization: A, after 65 hours' discharging at 1.75 micro-amperes; B, after 35 hours' charging at 1.77 micro-amperes.

In order to compare the effects of charging and of discharging on the amalgam limb, therefore, a current of 15 mma. was passed through two amalgam limbs of a four-legged cell and the polarization and recovery of each limb (one of which had thus been charged and the other discharged) were observed by reference to the unpolarized mercury electrodes. The observations made during polarization are recorded in Table III.

TABLE III

COMPARISON OF EFFECTS OF CHARGE AND DISCHARGE ON AMALGAM LIMB OF A CELL

$I = 15$ micro-amperes

Time, minute.;		0	1	3	5	10	25	75	90
ΔE_{Ta}, mmv.	Discharge	0	−3838	−3841	−3844	−3848	−3856	−3874	−3879
	Charge	0	+4212	+4212	+4212	+4213	+4211	+4210	+4211

It is seen that the polarization of the amalgam electrode during charge is constant throughout at this current, while the polarization of the discharged electrode gradually increases. Calculation of ΔE_{Ra} gives for the discharged limb −3804 mmv. and for the charged limb +4216 mmv. with an uncertainty of 20 mmv. in each case. A calculation of ΔE_{Pa} is seen to be practically meaningless under these conditions.

During recovery on open circuit, however, the potential measurements give us the true polarization of the electrodes directly. The recovery of these limbs is shown in Table IV.

TABLE IV

RECOVERY OF AMALGAM LIMBS OR CELL FOLLOWING THE POLARIZATION SHOWN IN TABLE III

Time, minutes		0	1	5	15	30	75	4 hrs.	8 hrs.
ΔE_{Pa}, mmv.	After discharge	−75[a]	−42	−36	−30	−26	−19	−9	−2
	After charge	?	+2	0	0	0	0	0	0

[a] This value is obtained from Table III and is only approximate.

We observe from Tables III and IV that the polarization of the amalgam limb of the saturated cell is greater when it is being discharged than when it is being charged. Similar results were obtained from observations on the anodes of an unsaturated cadmium cell and of a zinc cell.

Discussion of Results

From the foregoing experiments it is seen that:

1. Neutral saturated and unsaturated cadmium cells and zinc cells are very similar in their behavior during the passage of current through them.
2. Most of the polarization in these cells is found in the mercury limbs.
3. At the mercury electrode the effect of charging is the more severe, while at the amalgam electrode discharging the cell causes the greater polarization.
4. A recovery effect, present only in the mercury limb of the cell, appears when the polarization occurs at the higher currents and tends to decrease the polarization of the cell.

5. This effect persists over long periods of time and produces marked changes in the subsequent behavior of the cell during polarization.

6. The magnitude of the initial polarization increases somewhat with the age of a cell.

7. Removal of the solid mercurous sulfate causes the disappearance of the recovery effect.

8. The presence of acid diminishes the magnitude of polarization and prevents the appearance of the recovery effect until greater currents are used than are required for its appearance in neutral cells.

9. No noticeable change in the resistance of a cell is found accompanying polarization.

10. The effects of polarization produced at the mercury electrode by discharging currents disappear more rapidly when the cell is left on open circuit than those of charging, while the converse is found to be the case at the amalgam electrode.

The neutral saturated cadmium cell will be used in the following discussion of the processes which occur during and following the passage of current through the cell. What is said of it may be applied equally well to the case of the zinc cell, and the additional considerations needed to explain the action of unsaturated and acid cadmium cells will be indicated.

In the mercury limb of the saturated cadmium cell we have a paste composed of crystals of mercurous sulfate and cadmium sulfate, and a saturated solution of these salts lying on a mercury surface. In the solution in contact with the mercury there are Cd^{++} ions, Hg_2^{++} ions, a few Hg^{++} ions, SO_4^{--} ions and the ions of water. When a current is passed through the cell so as to discharge it, positive ions from the solution are discharged into the mercury. We may expect that the ions discharged are principally the mercurous ions. Some cadmium ions are probably discharged, the metal going into solution in the mercury to form a very dilute amalgam. It is doubtful if hydrogen ions are discharged in any appreciable amount. The polarization of the electrode on discharge is due, then, to the removal of mercurous ions and cadmium ions from the solution immediately above the electrode and to the formation of an amalgam in the electrode. These are both concentration polarization effects.

In the solution the migration of positive ions toward the electrode tends to compensate for this type of polarization, as does the process of convection which sets in because of the diminished density of the solution immediately above the mercury surface. Also, cadmium sulfate and mercurous sulfate crystals in this region go into solution to make up the deficiency in concentration. At a given current a steady state would eventually be reached, at which the rate of depolarization due to the above processes would exactly equal the rate of polarization.

When a charging current is passed through the cell, mercury passes from the liquid metallic state into the ionic state in solution. This increases the concentration of mercurous ions in the solution, and results again in concentration polarization in the electrolyte. There is an additional complication in this case, however, because of the possibility of mercurous ions in the vicinity of the electrode being oxidized by the electrolytic action to the mercuric state. The accumulation of mercuric ions in such a neutral sulfate solution would result in the deposition of basic mercuric sulfate in the solid state.[16] There is no change in the composition of the mercury electrode during charging. The depolarizing processes here are those of electrolytic migration and of crystallization of both the mercurous sulfate and basic mercuric sulfate, and we would again expect a steady state to be reached between the polarizing and depolarizing actions.

When the circuit is opened, recovery begins. Diffusion, convection and solution or crystallization of the solid salts present act to restore saturation equilibrium in the electrolyte. Cadmium, which may have been deposited in the mercury during discharge, is removed by electrolytic displacement, and basic mercuric sulfate which was formed during charging redissolves, the mercuric ions being reduced by the mercury and deposited as mercurous sulfate.

The above discussion indicates that the electrolytic actions at the mercury electrode of the standard cell are not strictly reversible, and observed differences between the rates of polarization and recovery of this electrode when the cell is charged from those when it is discharged are easily understood from this point of view.

But this discussion does not indicate any explanation for the recovery effect observed during the polarization of a cell. The simple processes described above can only give a polarization curve which starts at a rapid rate and gradually slows down to a steady state that continues until one of the reacting substances is exhausted. No simple depolarizing process can explain the anomalous nature of the experimental curves, for such processes act only to reestablish a condition of equilibrium with the polarizing process. They cannot of themselves overbalance the polarizing action.

The recovery effect must be due to an independent change in the rate of one of the polarizing or depolarizing processes. A study of these various effects shows that the rates of most of them are dependent, either directly or indirectly, upon the strength of the current passing and, since this was practically constant, these rates could undergo no such change.

---

[16] Smith, ref. 1f, observed the formation of this "green salt" during the charging of a cell, and Wolff, ref. 4, found "a basic salt containing mercuric compounds" formed when the electrolytic preparation of mercurous sulfate was attempted in a neutral solution of cadmium sulfate.

The rates of crystallization and of solution of the mercurous sulfate, however, while dependent upon the degree of unsaturation or supersaturation of the solution, and, therefore, indirectly upon the strength of current, are also a function of the state of the surface of the crystal. The fact that a cell from which the solid paste was omitted did not show the recovery effect lends support to the view that it is to this place we must look for an explanation.

If a crystal is well developed, as those of the paste must tend to become during long contact with their saturated solution, the removal or deposition of ions at its surface will take place more slowly than if the surface is irregular and imperfect. It is possible that at low currents the degree of unsaturation or of supersaturation of the solution in the vicinity of the mercurous sulfate crystals is such that solution or deposition takes place fairly uniformly over the whole crystal surface, without changing in any marked degree the nature of that surface. The polarization curve at such currents is perfectly normal. At higher currents, however, the degree of unsaturation or of supersaturation is much greater, and the solution or deposition of the ions at the crystal surfaces at the outset may produce a roughened surface which then has a greater rate of solution or crystallization than the original surface. The depolarizing power of such crystals is thus increased and the observed "recovery" takes place. This increase continues until a maximum is reached in the rate of interchange at the crystal surface and we may then have either a steady state in the polarization curve, or, if the other polarizing and depolarizing effects have not yet reached a state of equilibrium, the polarization may again increase until such a state is reached. When the cell is allowed to stand on open circuit, normal saturation equilibrium is first established, at which polarization disappears. The process of rebuilding the crystal face goes on, however, and as this progresses the magnitude of the initial polarization to be found on passing current through the cell is increased. The increase in the magnitude of polarization with the age of a cell would also be accounted for by this gradual building up of more perfect crystal surfaces.

Such changes in the rates of solution and crystallization of the mercurous sulfate do not explain the apparent increase in the equilibrium e.m.f. of the cells on open circuit after discharge. It is possible that this effect, which was observed principally in old cells that had fallen to low values, may be due to the removal, during polarization, of a thin film of basic mercurous sulfate which had been deposited on the crystals and prevented them from showing their normal solubility. Its removal gave the normal salt a chance to dissolve, and the value of the cell was temporarily increased after the circuit was opened. As the cell stood on open circuit, the coating of the basic salt was again formed and the value of the cell decreased.

No entirely satisfactory explanation has been found of the role of acid in decreasing the polarization of cells at a given current and preventing the appearance of the recovery effect at currents at which it appears in neutral cells. It seems that acid greatly accelerates the interchanges at the surface of the crystals, but just how such an effect operates is not clear.

That no difference was observed in the action of the mercury limbs of unsaturated cells from those of saturated cells indicates that the cadmium sulfate crystals mixed into the paste in order to maintain saturation of the solution in the one case do not play an important role in the polarization and depolarization of this limb.

In the amalgam limb of the cell we have a saturated solution of cadmium sulfate, with an excess of crystals, in contact with a two-phase cadmium amalgam. Cadmium ions go into solution from the amalgam during discharge and are deposited in metallic form in the amalgam during charge. The relative changes in cadmium-ion concentration in the electrolyte due to these actions are far smaller than the corresponding changes in mercurous-ion concentration at the other electrode, and it is natural, therefore, that the polarization at the amalgam electrode should be the less severe. Except for the possibility of some mercury from the amalgam passing into the ionic state during discharge, the electrolytic actions here appear to be perfectly reversible. The persistence of polarization following discharge, over the almost immediate recovery following charge, at this electrode, may be due to the presence of such ions in the solution, or to the fact that convection aids in the reestablishment of saturation equilibrium in the electrolyte in the latter case while in the former we are dependent upon diffusion alone.

Polarization during the Measurement of Cell Potentials.—In the measurement of cell potentials by the deflection method, currents as great as 10^{-8} amperes are occasionally drawn. The smallest current used in the polarization studies above described was 10^{-7} amperes, but a number of cells showed a polarization of 10 microvolts or more at this current. If the linear relationship between current and polarization holds at this current, it appears that some cells must be polarized to the extent of a microvolt or more during measurements that endeavor to determine their values to a single microvolt.

That such polarization does actually occur is indicated by the fact that the sensitivity of the galvanometer to a change of 10 microvolts in the potentiometer setting was always at least 10% lower when cells were being measured than that found when neutral resistances of the same magnitudes were substituted for them. In some cases this loss in galvanometer sensitivity was as great as 80% of its normal value. Such an extreme loss in galvanometer sensitivity is usually attributed to a high internal resistance in the cell. Calculation shows, however, that the resistance of such cells would have to be of the order of *2000* ohms, while their actual resistances were found by measurement to be less than 600 ohms in every case. There is no apparent reason for the high polarization shown by these cells. They were identical in construction, and in many cases had been made at the same time and of the same materials as cells that were less affected by the passage of current.

In actual practice the errors introduced by such polarization are very small and, to a certain extent, cancel one another in the course of a measurement. As a test of their effect a White potentiometer[17] having a range of 10,000 microvolts and adjustable to 1 microvolt was placed beside the Wolff instrument and alternate measurements of a number of cells were taken on the two instruments. In the case of the two cells which had been found to be most subject to polarization, the readings of the two instruments differed by 1 microvolt in the expected direction. In all other cases the agreement was exact. The use of an instrument of the White type is to be recommended, however, when measurements of high accuracy are undertaken.

Summary

The polarization of the separate electrodes of various types of standard cells under the influence of small charging and discharging currents has been studied experimentally, and the results interpreted in terms of the various polarizing and depolarizing actions which operate in the cells during and after a flow of current through them.

An interesting secondary effect of polarization has been found in the mercury limbs of cells, which causes an apparent recovery from polarization to take place during the passage of current. This recovery has been attributed to an increase in the rates of solution and of crystallization at the surfaces of the mercurous sulfate crystals.

It has been shown that cells are subject to polarization at the small currents that flow through them during measurements which undertake to estimate their potentials to microvolts by a deflection method. The actual error introduced because of such polarization is usually negligible.

HYSTERESIS IN STANDARD CELLS

BY WENDELL S. NIEDERHAUSER AND GEORGE A. HULETT

RECEIVED MARCH 1, 1929 PUBLISHED AUGUST 7, 1929

Introduction

The theory has been advanced by Vosburgh[1] that the hysteresis observed when standard cells are subjected to a lowering of temperature is due to an excess of mercuric ions in the electrolyte. He considers that the equilibrium

$$Hg_2^{++} \rightleftharpoons Hg + Hg^{++}$$

which operates at the mercury surface in such cells is displaced to the right when the temperature of a cell is raised. The reverse reaction, which occurs on cooling, is a heterogeneous reaction and would be expected to take place more slowly than the dissociation caused by heating. Until the excess of mercuric ion thus present in a cell after cooling has been removed, the electromotive force is abnormally high.

On the basis of this theory he endeavored to account for earlier observations relating to hysteresis. The fact that cells containing *a* fine-grained sample of mercurous sulfate show less hysteresis than those containing a coarser material[2] he attributed to the smaller amount of solution in immediate contact with the mercury surface, and the reduced velocity of diffusion of mercuric ions to this surface in cells of the former type, making it possible for the mercury to maintain equilibrium with the solution at all times. The decrease in hysteresis caused by the presence of acid in a cell[2c,3] was considered to be due to a catalytic effect of the acid upon the above reaction. The increase in hysteresis with the age of a cell[3] could not be explained.

The temperature coefficient of the saturated cadmium cell is negative.[2b] A simple hysteresis on cooling the cell would be expected to appear as a low e.m.f., gradually rising toward the equilibrium value. The usual observation, however, is a rapid increase in e.m.f. to a value above that predicted by the temperature formula, followed by a slow decrease to equilibrium. The former type of hysteresis has been observed[4,2c] and associated with the use of large crystals of cadmium sulfate in the cells. It is obvious that we are dealing with two distinct effects and must turn to a

study of the sources of each of these effects if we would understand them more fully.[5]

This paper reports the results of an experimental study of the hysteresis shown by the separate electrodes of the cadmium cell. The results are not in agreement with Vosburgh's theory, and a more satisfactory explanation is presented for the observed facts.

Experimental Methods and Results

Apparatus and Materials.—The "adjustable cells"[6] used in studies of the cathode equilibrium in standard cells were a convenient form of cell for use in studying hysteresis in the separate limbs of cells. The anode and cathode half-cells of which these were made could be subjected separately to any desired temperature change, and tested under the new condition by measuring their potentials in opposition to another half-cell which had been brought to equilibrium previously at the new temperature.

The materials used in the construction of cells were those described in a previous paper.[7] The thermostats were maintained at 25 and 35°, respectively, with an accuracy of ±0.02°. E.m.f.'s were measured by the methods previously described,[7] with reference to standards maintained constantly at 25.00°. The effects of both heating and cooling the separate limbs of the cells were studied.

Hysteresis at the Anode.—Anode half-cells were transferred from the 25° bath to the 35° bath. A cathode half-cell which was kept in the 35° bath was used as a test electrode and the e.m.f.'s of the cells formed by combining this with the various anodes were measured at frequent intervals. In every case their values became constant within fifteen minutes after the change in temperature, and were in good agreement with the values calculated by use of the Wolff formula. After one hour the anodes were returned to the 25° bath and placed in opposition to cathodes which had been kept in this bath, and against which they had been tested previously. The results of measurements on two anodes, S_1, which contained large crystals of cadmium sulfate (average size about 2 mm.) and S_2, in which finely ground crystals were used, are given in Table I. The values are given as differences in microvolts from their former values at 25°.

---

[5] F. E. Smith, *Phil. Mag.*, 19, 250 (1910), found an additional type of hysteresis that occurred in the amalgam when it was subjected to sudden temperature changes of 50° or more. He considered this to be due to a slow establishment of equilibrium between the liquid and solid phases of the amalgam. A more detailed theoretical investigation of this case, based upon the theory of solid solutions, was presented by S. W. J. Smith, *Phil. Mag.*, 20, 206 (1910). In the present work, which deals with manifestations of hysteresis likely to be met in the actual use of cells, we are not concerned with hysteresis of this type.

TABLE I

HYSTERESIS IN ANODE LIMBS OF CELLS AFTER A SUDDEN CHANGE IN TEMPERATURE FROM 35 TO 25°

Time, minutes		10	15	20	25	30	35	40	50	65	85
Diff. from normal value at 25°, mmv.	S_1	−445	−345	−245	−195	−150	−115	−95	−57	−30	−14
	S_2	−2	0	0	0	0	0	0	0	0	0

The effect of large crystals of cadmium sulfate, first described by Wold, is shown by these results.

It was also found that placing a cell in the 35" bath for as short a time as three minutes caused hysteresis nearly as great as that shown above, when the cell was again cooled to 25°.

Hysteresis at the Cathode.—A similar method of study was applied to the cathode limbs of cells. Because of the practically complete absence of hysteresis in the anode limbs of cells containing finely-ground cadmium sulfate crystals, it was also possible to consider that hysteresis in such cells was located entirely in the cathodes. Some typical results are given in Table II, showing the hysteresis in the cathode limbs of cells containing a paste composed of different sized crystals of mercurous sulfate mixed with finely-powdered crystals of cadmium sulfate. The cells had been kept for one hour in the 35° bath and had attained constant values at that temperature, in practical agreement with the Wolff formula, well within that time. The average grain size of the mercurous sulfate used in the cells is indicated in each case.

TABLE II

HYSTERESIS IN CATHODE LIMBS OF CELLS AFTER A SUDDEN CHANGE IN TEMPERATURE FROM 35 TO 25°

Time, hours	Differences in mmv. from normal value at 25°			
	S_5 − 10μ	S_7 − 25μ	X_{53} − 50μ	X_{51} − 150μ[a]
1	+82	+90	+298	+936
5	63	77	197	842
10	55	70	169	774
24	44	58	117	655
48	38	47	79	482
72	35	41	68	333

[a] The large crystals used in cells X_{51} and X_{53} were obtained by recrystallization from a hot acid solution.

The relationship between the size of mercurous sulfate crystals and hysteresis in the cathode limb[2] is confirmed. It is also noted that the disappearance of hysteresis in this limb is very much slower than that in the anode limb.

Here again, placing the cells in the 35" bath for three minutes caused hysteresis, nearly as great as that shown above, when the cells were returned to 25°.

Effect of Temperature Changes on Cathodes Containing No Solid Mercurous Sulfate.—Cathode half-cells were constructed in which the electrolyte was a solution saturated with mercurous sulfate and cadmium sulfate at 25°, but which contained no solid mercurous sulfate."

The effect of temperature changes upon these elements was studied in the manner previously described. There was absolutely no hysteresis observed, either on heating or cooling. They reached constant values at 35° as quickly as temperature equilibrium was attained and showed a similar rapid return to their previous values at 25" when cooled to this temperature. The potential of the cell formed by this element and a normal anode half-cell at 35° was not that predicted for the normal cell by the Wolff formula. The formula predicts a decrease in potential of 563 mmv. on raising the temperature of the cell from 25 to 35°. This cell showed *a* decrease of 4120 mmv. Obviously the temperature coefficient of such a limb is very much different from one that contains solid salt.

Discussion

F. E. Smith[5] has shown that the temperature coefficient of the anode limb of the saturated cadmium cell is —0.00035 volt per degree, and that of the cathode limb is \$0.00031 volt per degree, making the over-all-temperature coefficient of the cell —0.00004 volt per degree, in agreement with the Wolff formula. The hysteresis shown in each limb of the cell corresponds then, to a slow continuous adjustment of that limb to equilibrium at the new temperature, and the anomalous nature of the hysteresis shown by the cell as a whole is due to the more rapid adjustment of the anode limb to the new temperature, leaving the cathode effect predominant.

In the anode limb the size of the cadmium sulfate crystals is found to determine the magnitude of hysteresis. The only function of these crystals is to maintain saturation in the solution. The solubility of cadmium sulfate increases with temperature, and a denser solution is formed at the surfaces of the crystals when the temperature is raised. Convection currents immediately carry this solution downward to the amalgam surface, where a layer of the saturated solution soon forms. Equilibrium at the electrode is thus quickly established. On cooling the cell, cadmium sulfate must crystallize from the solution and it can do this only at the surfaces of the crystals already present. It must reach these surfaces of the crystals already present. It must reach these surfaces by diffusion. In large-crystal cells the distances through which diffusion must take place are greater, and the available surface is less than in cells containing small crystals. The rate at which a state of supersaturation is relieved by crystallization of the excess solute is slower in the former case, and the

---

[8] The solution was prepared by rotating a saturated solution of cadmium sulfate with solid mercurous sulfate and mercury (ref. 6). Solid cadmium sulfate was added to cells built with this solution so that saturation with respect to this salt would be maintained in the experiments which followed.

longer time required for such cells to reach equilibrium upon lowering the temperature is thus explained.

A similar explanation appears to be the most reasonable one to apply to the cathode limb. The abnormal temperature coefficient shown by a cathode that contained no solid mercurous sulfate indicates that an important role of this substance in the cell is to maintain saturation of the solution at the mercury surface at varying temperatures. The extremely long time taken for the disappearance of hysteresis in this limb in some cases is surprising. The high viscosity of the electrolyte is undoubtedly a factor in preventing a more rapid establishment of equilibrium.[9]

Vosburgh has entirely overlooked the change in solubility of mercurous sulfate with temperature in his consideration of hysteresis. The fact that cells containing no solid mercurous sulfate showed immediate responses to temperature changes is out of accord with this theory, which would predict a maximum of hysteresis in such cells.

The effect of acid in diminishing hysteresis is, from the point of view here presented, the same as its effect in diminishing polarization and accelerating the disappearance of polarization in cells.[7] It appears to increase the rates of crystallization and solution at the crystal surfaces.

The increase in magnitude of hysteresis with the age of cells, which Vosburgh was unable to explain, may be attributed to the same cause as the increase in polarization with the age of cells. We have considered that the surfaces of the crystals become more and more nearly perfect during long contact with their saturated solution. They then show a lower rate of solution or of crystallization than the imperfect crystals first placed in the cells. As the rate of crystallization is thus decreased with age, the hysteresis, which depends upon it, increases.

A study of the effect of temperature upon the solubility of mercurous sulfate in saturated cadmium sulfate solution, and of the mercurous–mercuric ion equilibrium in these solutions in contact with mercury, is now in progress. The results of this work will serve as a final test of the theories advanced to explain hysteresis in cells.

High Initial Values of Cells

Wolff[2b] observed that cells which showed abnormal hysteresis had also shown high initial values, which dropped rapidly during the first month after their construction and finally became nearly normal. He considered that this was because the cells were constructed in a laboratory where the temperature was different from that of the thermostats in which they were subsequently placed. But thermostats are usually maintained, except under

---

[9] Menzies and Potter, THIS JOURNAL, 34, 1452 (1912), have shown that supersaturation may continue over very long periods of time in a viscous solution of H_3AsO_4, even though the solution is being stirred and a large number of nuclei are present to induce crystallization. The present case seems to be analogous to theirs.

special circumstances, at temperatures above room temperature, and we have seen that a change to higher temperatures is not attended by marked hysteresis. Wolff's explanation therefore, does not appear probable.

Vosburgh[10] considered that the high initial values were due to oxidation of the mercurous sulfate during the preparation of the paste and its introduction into the cells, the excess of mercuric salt being only slowly reduced at the mercury surface. He set up cells with great care to prevent access of air to the paste. The records of these cells, as well as those of cells set up without taking such precautions, are given in his papers. The cells made with protection from air are, on the whole, better than those made without such protection, yet some of the latter cells (Nos. 169 and 170) are quite as good as those of the protected group. The cells of the unprotected group which showed the most abnormal values were made from a different sample of mercurous sulfate than those of the protected group. It appears that there are factors other than the possible oxidation of the mercurous sulfate which must be considered in accounting for the high initial values of cells.

The fact noted in the hysteresis experiments that raising the temperature of a cell to 35° for as short a time as three minutes caused hysteresis effects when the cell was again returned to 25° suggested that a very short period of overheating during the construction of cells might cause them to show high initial values. As the temperature of the hand is usually above 30°, such overheating could come from simply holding the cells in the hand. Experimental evidence for this was obtained by warming old cells in the hand for several minutes and then returning them to the 25° bath from which they had been taken. In every case a large increase in e.m.f. was observed, which persisted for several weeks.

New cells were built, therefore, taking great care to avoid warming them above 25" at any time. The laboratory temperature was about 22° and the cells were cooled to 15° just before sealing. For the manipulations in the flame, during the sealing of these cells, they were held by means of a clamp fixed on the cross-arm, and an asbestos guard was used to protect the lower parts of the cells from the heat of the flame. No attempt was made to exclude oxygen from the cells, although the operations connected with the preparation and introduction of the paste were carried on as rapidly as possible.

Table III shows the values of cells made in this way compared with those of cells made by the old methods, in which the lower parts of the cells were supported in the fingers while sealing them. All of these cells were made from the same materials. The mercurous sulfate was a white electrolytic product, the average grain size of which was about 25 microns. Cells 55 and 56 were the first two cells set up in the new way, About a

---

[10] **Vosburgh, THIS** JOURNAL, 47, 1225 (1925); 49, 78 (1927).

month later the next four cells, 57-60, were built. Of these four, 57 and 59 were sealed in the new way, while 58 and 60 received the same treatment throughout except for the sealing, which was done in the old way. The values of four other cells, 41-44, which were set up several months earlier and were not measured until they were a day old, are also included for comparison. The values of the cells of each group agreed with each other within a few microvolts, and are averaged in the table.

TABLE III

COMPARISON OF CELLS BUILT WITH AND WITHOUT CARE TO AVOID HEATING ABOVE 25° DURING CONSTRUCTION[a]

	E m f at 25 00°[b]			
Age of cells	55 and 56	57 and 59	58 and 60	41-44
15 minutes	1.018060	1.018036	1.018218	......
30 minutes	1.018068	1.018048	1.018206	......
75 minutes	1.018074	1.018058	1.018188	......
4 hours	1.018076	1.018071	1.018164	......
1 day	......	1.018072	1.018128	1.018121
2 days	1,018069	1.018070	1.018106	......
3 days	......	......	......	1.018099
5 days	......	1.018067	1.018089	......
1 week	1.018070	1.108070	1.018085	1.018084
2 weeks	1.018072	1 018074	1 018084	1.018080
1 month	0.018075	......	......	1.018080
2 months	......	......	......	1.018079

[a] Where blank spaces appear in the above table no readings were taken.

[b] The value of the Weston normal cell at this temperature, according to the Wolff formula, is 1.018074 volts.

The effect of such heating is clearly shown to account for the high initial values of these cells. It is interesting to note that cells made by the new method reached values within a few microvolts of the defined value in less than four hours, and, although they have varied slightly from time to time, they have been very close to that value ever since.

Summary

An experimental study has been made of the adjustment of the individual limbs of standard cells to temperature changes.

A new theory is suggested to explain hysteresis, which is based upon the rate of establishment of saturation equilibrium between the solution and the solid salts present in the cells.

The high values of new cells, which decrease during the first month or so, have been shown to be due, at least in part, to hysteresis which results from overheating them in the course of construction. A method of avoiding this trouble has given excellent results in the construction of cells which reached normal values within a few hours after they were built.

A STUDY OF THE SYSTEM SODIUM BICARBONATE–POTASSIUM BICARBONATE–WATER

BY N. E. OGLESBY

RECEIVED MARCH 7, 1929 PUBLISHED AUGUST 7, 1929

I. Introduction and Survey of Previous Work

Although studies have been made of the systems sodium bicarbonate–ammonium bicarbonate–water,[1] of sodium bicarbonate–sodium carbonate–water,[2] of potassium carbonate–sodium carbonate–water, including a very thorough investigation of the solid phases,[3] and of potassium bicarbonate–potassium carbonate–water,[4] no real investigation of the system sodium bicarbonate–potassium bicarbonate–water has been found in the literature.

The writer first became interested in this system during 1920, when it was suggested by Mr. W. D. Mount, Consulting Engineer of Lynchburg, Virginia, that he determine the practicability of developing commercially a process of obtaining soda ash as a by-product in the purification of potassium salts from Nebraska brines. A search of the literature at that time failed to disclose any study of the system sodium bicarbonate–potassium bicarbonate–water but the relative solubilities of sodium carbonate, potassium carbonate, sodium bicarbonate and potassium bicarbonate indicated that carbonating a saturated brine to convert the carbonates to bicarbonates, thereby precipitating the less soluble sodium bicarbonate, and then fractionally crystallizing the salts in solution, might offer a practical means of separating the salts commercially.

Dibbits has shown that solutions of sodium bicarbonate and of potassium bicarbonate lose appreciable quantities of carbon dioxide at even comparatively low temperatures, and that definite solubilities of the bicarbonates will only be found with definite partial pressures of carbon dioxide.[1,2,5] Since many investigators failed to consider loss of carbon dioxide from bicarbonate solutions, the solubility data given in the literature for pure $NaHCO_3$ and $KHCO_3$ are not always consistent. Of the references given, Fedotieff,[1] McCoy and Test,[2] Hill and Kill[4] and Dibbits[5] have taken into consideration the loss of carbon dioxide.

Since definite solubilities of the bicarbonates will be obtained only with

a definite partial pressure of carbon dioxide, and since practical application of the present study to the separation of sodium and potassium carbonates would be by passing a stream of carbon dioxide through the carbonates, it was decided to study the system $NaHCO_3$–$KHCO_3$–H_2O under the fixed condition that the partial pressure of carbon dioxide plus the partial pressure of water is equal to one atmosphere in the same way that Fedotieff[1] studied $NaHCO_3$–NH_4HCO_3–H_2O.

II. Theoretical Considerations

Since the restriction has been made that the partial pressure of carbon dioxide plus the partial pressure of water is equal to one atmosphere, carbon dioxide is not a component in the system. The components, therefore, can be considered as sodium bicarbonate, potassium bicarbonate and water. In the presence of one vapor and one liquid phase, three solid phases are required to make the system invariant. In the experimental work it has been found that at 20, 25 and 30° neither sodium bicarbonate nor potassium bicarbonate exists as a hydrate. Also, it has been found that at these temperatures solid solutions and double salts do not exist in equilibrium with solutions of any concentrations. Since only two solid phases have been found to separate from the solutions at these three temperatures, a quintuple point does not exist between the temperatures taken and the system cannot, therefore, become invariant between these temperatures. If the temperature is held constant, the system is fixed when the two phases sodium bicarbonate and potassium bicarbonate are present.

III. Apparatus and Procedure

The thermostat used was provided with a special shaker. The thermometer was graduated in tenths of a degree and was calibrated by the Bureau of Standards. Ordinary 300-cc. Erlenmeyer flasks were used to hold the solution and solids which were to be brought to equilibrium. These flasks were closed with two-holed rubber stoppers. A glass tube passed through one hole of the rubber stopper to well down into the solution in the flask, and when the flask was placed on the shaker in the thermostat, this glass tube was connected to a combination trap and carbon dioxide distributor by means of a light rubber tube. For the greater part of the run this glass dip-tube was raised above the solution. A second glass tube, about three inches in length, was placed in the second hole of the rubber stopper, flush with the bottom of the stopper and extending about two inches above the top of the stopper to prevent the possible entry of water from the thermostat. The combination trap and carbon dioxide distributor was connected to a cylinder of compressed carbon dioxide by means of a rubber tube.

In the earlier runs at 25° carbon dioxide was allowed to bubble through the solution for a considerable part of the run while the temperature was maintained at about 0.1" above the desired equilibrium temperature. It was later found that all the points determined with this procedure gave low solubility values, due to the temperature depression caused by bubbling carbon dioxide through the solution. It was also found, however, that unless carbon dioxide was bubbled through the solution for an appreciable time, considerable time would be required to convert the small amount of carbonate present to bicarbonate. The final procedure was to bubble carbon dioxide through the solutions for from two to four hours prior to starting the accurate temperature control, while holding the temperature 0.5 to 1° above the desired equilibrium temperature. In order to determine whether or not carbonates had been removed from the solutions, a small portion of the solution was, in some cases, removed from the flask and tested with phenolphthalein, which reacts approximately neutral to bicarbonate solution. The dip-tubes extending into the solution were then raised above the surface of the liquid, the carbon dioxide outlets on the Erlenmeyer flasks were capped and a slow stream of carbon dioxide was allowed to escape through a vent attached to the rubber tube leading to one of the Erlenmeyer flasks. By this method a pressure of carbon dioxide equal to the atmospheric pressure was maintained within the flasks, but carbon dioxide was not allowed to pass freely over the solution so as to cause a temperature depression. When the dip-tubes had been raised and the outlets capped, the temperature was adjusted to the equilibrium temperature and shaking continued to the first sampling period.

After the samples were taken, the air that had entered the Erlenmeyer flasks was displaced with carbon dioxide, the carbon dioxide outlets were again capped and carbon dioxide again was allowed to escape from the vent until the next sampling period.

For analysis of the solution and identification of the solid phases, the following determinations were in general made: (1) determination of the density of the solution at the equilibrium temperature by means of a pycnometer which had been standardized with distilled water at the equilibrium temperature; *(2)* determination of the total alkali in the solution by the titration of a 10-cc. sample with approximately normal hydrochloric acid, using methyl orange as an indicator; **(3)** determination of potassium present in the solution by means of the perchloric acid method; (4) determination of the total alkali bicarbonate in the solid phase which had been quickly washed and sucked fairly dry in a Buchner filter and then dried between folds of filter paper, or which had been whizzed until dry in a basket-type centrifuge; **(5)** determination of the ratio of sodium bicarbonate to potassium bicarbonate in the solid phase by heating the washed solid to a constant weight as carbonates and determining potassium by the perchloric acid method.

Due to the fact that the work had to be carried out in an atmosphere of carbon dioxide, an effort was made to shorten the runs as much as possible. Actually, much time was lost by trying to obtain consistent values after very short times (three or four hours) in the thermostat. Although the titration checks were fairly close (0.1 cc.) for an interval of about one hour, it was found that still better checks could be obtained. It would appear that the final rate at which equilibrium is obtained in the apparatus used is fairly slow, although equilibrium is approached very closely within a comparatively short time. Slight but consistent variations in the analyses established the greater certainty of the values obtained in longer runs. Equilibrium was considered to have been established when titrations separated by a two- or three-hour interval checked within 0.05 cc.

All pipets used in sampling were calibrated for delivery at each equilibrium temperature and the proper corrections for this delivery were made in the calculations.

IV. Materials

Merck's C. P. sodium bicarbonate was purified by dissolving in warm distilled water and recrystallizing with a stream of carbon dioxide passing through the solution.

The potassium bicarbonate employed was also a Merck product and was labeled "U. S. P. IX—Highest Purity—C. P." Before use it was dissolved in warm water and recrystallized with a stream of carbon dioxide passing through the solution.

V. Probable Errors in the Procedure

The temperature was maintained constant to 0.01" at 19.97°, to 0.03° at 25° and to 0.04° at 30.01". The maximum variation at 30° would affect the solubility of pure sodium bicarbonate, or of pure potassium bicarbonate, by about 1 part in 2000 and is therefore negligible.

In the analysis of the samples taken there was in no case a difference of over 0.1 cc. between check titrations. For most of the points at 19.97° and at 30.01°, the difference did not exceed 0.05 cc. In many cases the difference was not over 0.03 cc. Check potassium determinations did not differ more than 1 part in 350, except in one or two cases. Potassium checks of 1 in 1000 were not unusual and for most of the points variations not to exceed 1 part in 700 can be assumed.

The density determination was one of the most consistently reproducible determinations made. It is true that solutions of the bicarbonates tend to lose carbon dioxide, but the transfer to the pycnometer could be made quickly and the pycnometer sealed. The pycnometer was always brought to within 0.2" of the equilibrium temperature before being filled. The density determinations invariably checked in the third decimal place, while checks of 3 in the fourth decimal place were not unusual.

All of the above errors may, of course, be slightly increased by errors in taking the samples. Care was exercised, however, in keeping the pipets clean and in sampling, so that such errors were reduced to a minimum. It must be admitted that any difference method of analysis in which the combined errors may possibly all be thrown on that material present in the smallest percentage may result in comparatively large errors in the values found for the latter material. However, such a difference method of analysis is more accurate than the indirect determination of sodium and potassium bicarbonates by titrating, weighing as carbonates and solving a simultaneous equation for the quantities of sodium and potassium bicarbonates present. With the balance and compensation of errors that is obtained by plotting a curve from the data obtained, values read from the curve should be considerably more accurate than the maximum probable error for a single point.

At 25" the determinations of potassium by the perchloric acid method were made according to the procedure recommended by Scott,[6] with one exception. The procedure of Smith[7] was followed in all determinations at 19.97 and at 30.01°. In one case at 25° the two methods were run in

---

[6] Scott, "Standard Methods of Chemical Analysis," D. Van Nostrand Co., New York, 1920.

[7] Smith, THIS JOURNAL, 47, 780 (1925).

parallel. A weight of 2.0771 g. of $KClO_4$ was obtained by the method of Scott and a weight of 2.0742 g. by the method of Smith. This is a variation of about 1 in 700, with the method of Smith giving a slightly lower value. In general, the procedure of Scott gave as good checks as the procedure of Smith, but the latter is decidedly smoother from the standpoint of manipulation and probably gives more accurate results, as claimed by Smith.

VI. Experimental Details and Tabulation of Results

A. Study of the System at a Temperature of 19.91 ± **0.01°.**—The work at approximately 20° was carried out after the procedure at 25° had been well developed and checked. For some reason solutions at 19.97°, fairly high in potassium, gave in two successive runs points which did not fit all of the curves, the deviations being comparatively large in some cases. The slowness with which equilibrium appeared to be reached suggested the possibility of solid solutions.

Analyses of the solid phases from runs which were continued considerably longer than usual established definitely that no solid solution or double salt existed along that portion of the curve where erratic results were obtained in the shorter runs. The longer runs with concentrations lying

TABLE I

DATA OBTAINED (EXCLUDING THE ERRATIC VALUES IN TWO RUNS)

1	1.0625	9.55	0.00	8.72	0.00	$NaHCO_3$
2	1.0954	8.15	7.46	7.05	6.45	$NaHCO_3$
3	1.1309	7.03	15.60	5.73	12.72	$NaHCO_3$
4	1.1519	6.55	20.52	5.16	16.15	$NaHCO_3$[a]
5	1.1637	6.33	23.31	4.88	17.98	$NaHCO_3$[a]
6	1.1803	6.11	27.34	4.58	20.48	$NaHCO_3$[a]
7	1.1968	6.07	31.54	4.41	22.93	$NaHCO_3$–$KHCO_3$
8	1.1965	5.97	31.36	4.34	22.84	$NaHCO_3$–$KHCO_3$[b]
9	1.1897	3.85	32.05	2.84	23.58	$KHCO_3$
10	1.1830	1.86	32.74	1.38	24.32	$KHCO_3$
11	1.1777	0.00	33.30	0.00	24.98	$KHCO_3$[a]

[a] The solid phase was identified by analysis for all points except 11. Since hydrates of $KHCO_3$ had been found not to exist at Points 7, 8, 9 and 10, analysis of the solid at Point 11, other than *a* microscopic examination, was not considered necessary. Results of solid phase analyses are given for Points 4, 5 and 6, since it was in this area that solid solutions were suspected. A 0.6647-g. sample of solid from 4 that had been quickly washed and sucked fairly dry in a Buchner filter did not give a weighable quantity of $KClO_4$. Solid phases centrifuged but not washed from 5 and 6 gave the following analyses: 5, $NaHCO_3$, 99.25%; $KHCO_3$, 0.75%; 6, $NaHCO_3$, 98.99%; $KHCO_3$, 1.01 In the solid phase from both 5 and 6 a few minute crystals of $KHCO_3$ that formed during centrifuging could be identified with the microscope.

[b] With the aid of a reading glass and a small pair of tweezers a mechanical separation of the two solid phases was made. One analyzed 95.89% $KHCO_3$ and the other 94.80% $NaHCO_3$.

along the curve where erratic results had been previously obtained gave values which fitted closely into a smooth curve with the other points. No explanation can be offered for the comparative slowness with which equilibrium was reached.

B. Study of the System at a Temperature of 25 ± **0.03**°.—The work at *25"* was carried out first and it was during these runs that the technique was improved. While the values obtained at 25° are hardly, as a whole, as accurate as the values obtained on the 19.97" curves, and on the 30.01° curves, nevertheless, a very accurate check was made of the solubility of the pure sodium and potassium bicarbonates and of the solution composition at the break in the curve where both sodium and potassium bicarbonates are present as solid phases. Also, in plotting the values on the curve slightly greater weight was given to the later results.

TABLE 11

DATA OBTAINED AT 25 ± 0.03°

No.	Density	G. per 100 g of H_2O		G per 100 g of soln.		Solid phases
		$NaHCO_3$	$KHCO_3$	$NaHCO_3$	$KHCO_3$	
1	1.0648	10.31	0.00	9.34	0.00	$NaHCO_3$
2	1.0857	9.36	4.82	8 20	4.23	$NaHCO_3$
3	1.1035	8 72	8 98	7 41	7.63	$NaHCO_3$
4	1.1282	7.83	14.85	6.38	12.10	$NaHCO_3$
5	1.1547	7.21	21.12	5.62	16.46	$NaHCO_3$
6	1.1746	6 8 8	26.03	5.18	19.59	$NaHCO_3$
7	1.1732	6.81	25.69	5.14	19.39	$NaHCO_3$
8	1.1903	6.76	29.92	4.94	21.89	$NaHCO_3$
9	1 2087	6.58	34.59	4.66	24.50	$NaHCO_3$–$KHCO_3$[a]
10	1.2087	6.50	34.42	4.61	24.43	$NaHCO_3$–$KHCO_3$[b]
11	1.2042	5.24	34.95	3.74	24.93	$KHCO_3$
12	1.1998	3.77	35.08	2.72	25.27	$KHCO_3$
13	1.1977	3.32	35.48	2 39	25.56	$KHCO_3$
14	1.1927	1.55	35 93	1.12	26.13	$KHCO_3$
15	1.1884	0.00	36.57	0.00	2678	$KHCO_3$
16	1.1882	0.00	36 56	0.00	26.77	$KHCO_3$[a]
17	1.1879	0.00	36.58	0.00	26.78	$KHCO_3$[a]

[a] The solid phases were not analyzed in these runs, since they were all check runs and the solid phases were identified by the other runs at these same points. Runs 16 and 17 were made because it was realized that 15 did not check the values given in the literature to within the experimental errors.

[b] A rough mechanical separation of the two solid phases was made. One part analyzed 93.63% $NaHCO_3$ and 6.37% $KHCO_3$; the other, 95.86% $KHCO_3$ and 4.14% $NaHCO_3$.

C. Study of the System at a Temperature of **30.01** ± **0.04**°.—Due to the impossibility of keeping the room temperature within over 4 to 7° of the bath temperature, there was a tendency for crystals to separate out in the pipets. It was found advisable to warm the pipets slightly and then bring them to approximately the solution temperature by sucking up some of the solution, discarding it and then taking the sample. This same procedure was used in calibrating the pipets. This procedure in sampling is considered rapid and satisfactory.

All except two points on the curves were determined after the desirability of long runs was established, and from this standpoint the values for 30.01 ± 0.04° may be slightly superior to those on the 25° curves and some points on the 19.97° curves.

TABLE III

DATA OBTAINED

No.	Density	G. per 100 g. of H_2O $NaHCO_3$	G. per 100 g. of H_2O $KHCO_3$	G per 100 g. of soln. $NaHCO_3$	G per 100 g. of soln. $KHCO_3$	Solid phases
1	1.0673	11.05	0.00	9.95	0.00	$NaHCO_3$
2	1.0973	9.61	7.22	8.22	6.18	$NaHCO_3$
3	1.1196	8.90	12.39	7.34	10.22	$NaHCO_3$
4	1.1543	8.02	20.69	6.23	16.08	$NaHCO_3$
5	1.1887	7.48	29.26	5.47	21.40	$NaHCO_3$
6	1.2189	7.01	37.61	4.85	26.01	$NaHCO_3$–$KHCO_3$[a]
7	1.2189	6.97	37.64	4.82	26.03	$NaHCO_3$–$KHCO_3$[b]
8	1.2145	5.13	38.22	3.58	26.66	$KHCO_3$
9	1.2077	2.92	38.90	2.06	27.43	$KHCO_3$
10	1.1986	0.00	39.91	0.00	28.52	$KHCO_3$
11	1.1988	0.00	39.95	0.00	28.52	$KHCO_3$[a]
12	1.1990	0.00	39.92	0.00	28.53	$KHCO_3$[a]

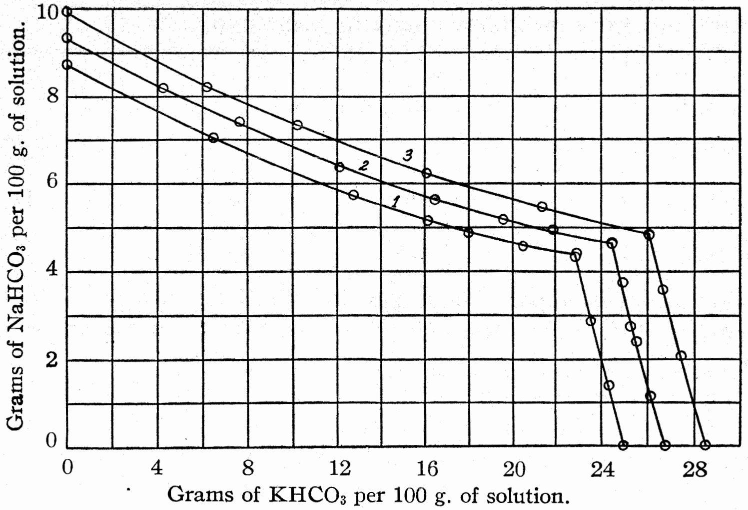
[a] Analysis of the solid phase was not made since these were check runs. Runs 11 and 12 were made after it was realized that the values found in 10 did not check to values found in the literature to within the experimental errors.

[b] A rough mechanical separation of the two solid phases was made. One gave an analysis of 91.74% $NaHCO_3$ and 8.26% $KHCO_3$. The other gave an analysis of 92.55% $KHCO_3$ and 7.45% $NaHCO_3$.

VII. Graphical Representation of Results

The triangular coordinate method of graphically representing results for ternary systems is particularly well adapted to those systems which show more than two solubility curves. Also, in general, lines drawn through the composition of the solution and the composition of the original complex can be made to give very definite indications of the composition of the solid phase.

In the present study an accurate knowledge of the exact composition of the original complex was somewhat difficult to obtain, (1) because the two salts used have a decided tendency to lose carbon dioxide and often contain appreciable quantities of carbonate, and (2) because bubbling carbon dioxide through the solution removed some water. In view of these facts, and the fact that there appeared to be only two solubility curves in the system at the temperatures chosen, it was felt that it would be more advisable to plot the weight of sodium bicarbonate against the weight of potassium bicarbonate while holding the weight of water or weight of solution constant. Curves constructed in this way can be plotted on a scale that makes them suitable for reading off interpolated values.

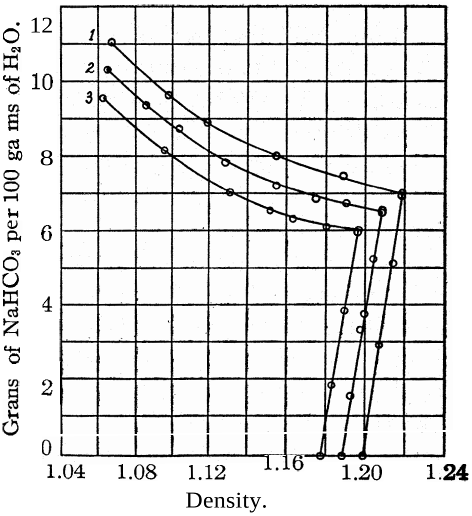


1, 19.97 ± 0.01°C.; 2, 25 ± 0.03°C.; 3, 30.01 ± 0.04°C.

Fig. 1.

Figures 1 and 2 are shown as illustrations of the curves plotted. Figure 1 shows the weight in grams of $NaHCO_3$ per 100 g. of solution plotted against the weight in grams of $KHCO_3$ per 100 g. of solution. Figure 2 shows the weight in grams of $NaHCO_3$ per 100 g. of water plotted against the density of the solution.

Various other smooth curves were plotted from the data obtained but are not considered worth reproducing as they can be readily made up from the tables. It may be of interest to note that when the grams of $KHCO_3$ per 100 g. of water are plotted against the density of the solution, points for the three temperatures all fall on approximately the same curve so long as $NaHCO_3$ is the solid phase.



1, 19.97 ± 0.01°C.; 2, 25 ± 0.03°C.; 3, 30.01 ± 0.04°C.

Fig. 2.

VIII. Comparison of Solubilities Found for Sodium Bicarbonate and Potassium Bicarbonate with Those Given in the Literature

The values found for the solubilities in water of pure sodium bicarbonate and pure potassium bicarbonate may be compared with values previously reported by other investigators, to whose work references have already been made.

TABLE IV

SODIUM BICARBONATP SOLUBILITY IN GRAMS PER 100 GRAMS OF WATER

	20°	25°	30"
Dibbits	9.6	10.35	11.1
Fedotieff	..	...	11.02
Tables I, II, III	9.55	10.31	11.05

McCoy and Test report 98.7 g. per liter for the solubility of sodium bicarbonate at 25°. The values given in Table II are equivalent to 99.4 g. per liter.

On the whole the values found check the better values given in the literature very closely. This is particularly true for values given by Fedotieff for 30°. Fedotieff did his work with the partial pressure of carbon dioxide plus the partial pressure of water vapor equal to the atmospheric pressure, and the values found in the two cases should check very closely.

TABLE V

POTASSIUM BICARBONATE—SOLUBILITY IN GRAMS PER 100 GRAMS OF WATER

	20°	25°	30°
Dibbits	33.2	36.1	39.0
Tables I, II, III	33.3	36.57	39.92

Hill and Hill find the solubility of potassium bicarbonate at 25° to be 26.55 g. per 100 g. of saturated solution, while the solubility given in Table II is 26.78 g. per 100 g. of saturated solution.

It is evident that the values found for the solubility of potassium bicarbonate are higher than the values given in the literature. However the results found, particularly those for 25 ± 0.03" and for 30.01 ± 0.04°, have been thoroughly checked and it has been found that they can be consistently duplicated with carefully calibrated volumetric apparatus, acid standardized at different times and chemicals crystallized separately from different packages. The values reported are consistently reproducible and, therefore, are offered as correct for the conditions under which the study was made.

A study of the work of Dibbits indicates that he made every effort to secure accuracy. Certain criticisms of his technique, however, may be made. Most important of these criticisms is the fact that he used a water-bath for temperature control and states, that, to avoid supersaturation, care was taken that the temperature should rise somewhat rather than drop. This procedure would certainly tend to give low results. According to Dibbits, loss of carbon dioxide at 30° might make a difference of about 0.3 in the values found. Such a difference would not account for the 0.92 variation between the value of Dibbits and that given in Table III. However, Dibbits' calculations of the extent to which loss of carbon dioxide might change the results probably did not represent equilibrium, and, therefore, may have indicated a smaller variation than would have been found at equilibrium.

The value obtained by Hill and Hill for the solubility of potassium bicarbonate at 25° is in good agreement with that of Dibbits, the value of Hill and Hill being equivalent to 36.15 g. per 100 g. of water. The value given in Table II, solubility of potassium bicarbonate in grams per 100 g. of solution, is 0.23 higher than the value of Hill and Hill. Such a variation is well outside of the experimental errors of the work recorded in this paper and, therefore, is significant. That the results found for sodium bicarbonate check the better values in the literature, while the results found for potassium bicarbonate are higher than the better values in the literature, is in agreement with the observation of Dibbits that the partial pressure of carbon dioxide is considerably higher over solutions of potassium bicarbonate than over solutions of sodium bicarbonate.

From the above comparison of results with the results of other investigators, it is indicated that the partial pressure of carbon dioxide over saturated solutions of potassium bicarbonate slightly exceeds the partial pressure of carbon dioxide maintained in the flasks during the experiments. Under such conditions, there would be present in the solutions a small amount of potassium carbonate. The carbonate content was not, however, sufficient to cause the solutions to react alkaline to phenolphthalein.

Even if the solubilities for potassium bicarbonate found in this study are higher than the results in the literature, because of the presence of a small amount of potassium carbonate, the results may be accepted as those that would be obtained when mixed solutions of the carbonates of sodium and potassium are treated at atmospheric pressure with a stream of carbon dioxide gas so as to convert the carbonates to bicarbonates and thereby effect a partial separation by precipitating one of the pure bicarbonates (usually sodium bicarbonate).

IX. Summary

1. The ternary system $NaHCO_3$–$KHCO_3$–H_2O has been studied at temperatures of 19.97 ± 0.01, 25 ± 0.03 and 30.01 ± 0.04° under the fixed condition that the sum of the partial pressures of carbon dioxide and of water vapor is equal to the atmospheric pressure.

2. The only solid phases that exist at these temperatures are $NaHCO_3$ and $KHCO_3$. The absence of hydrates, of solid solutions and of double salts at these temperatures has been definitely established.

3. The values found for the solubility of sodium bicarbonate check very closely the best values given in the literature.

4. The values found for the solubility of potassium bicarbonate, especially at 25 and at 30°, are higher than the best values found in the literature.

5. The composition of the solutions found in the ternary system, and the absence of complicating double salts and solid solutions, indicate that the present study might be of value in the commercial separation of sodium and potassium carbonates.

THE DETERMINATION OF THE SOLUBILITY OF SLIGHTLY SOLUBLE LIQUIDS IN WATER AND THE SOLUBILITIES OF THE DICHLORO-ETHANES AND -PROPANES

BY PAUL GROSS

RECEIVED MARCH 9, 1929 PUBLISHED AUGUST 7, 1929

In order to make some measurements of the salting out effect of salts in water on the slightly soluble dichloro-ethanes and propanes, it became necessary to develop a method for determining their solubility in water and salt solutions. As this method is capable of considerable precision and as Hill[1] has pointed out that the methods for determining the solubility of liquids in liquids are in general very unsatisfactory, it is described here, together with the results of some solubility determinations made by its use.

The principle of the method is to prepare saturated solutions of the substance in water by shaking in a thermostat in the usual way. These solutions are then analyzed by the use of a liquid interferometer. The interferometer scale is calibrated by dissolving weighed amounts of the substance in weighed quantities of water.

Experimental

The instrument available was a Zeiss portable water interferometer with a glass comparison chamber **40** mm in length with two cells, in one of which a sample of the solution to be analyzed was placed and in the other the comparison or reference liquid. The general procedure and precautions to be observed in the use of the interferometer have been described in *a* number of places,[2] so it is unnecessary to repeat them here.

The scale readings on the compensator drum of the interferometer are not directly proportional to the number of interference bands it is necessary to shift to return the displaced upper bands to zero setting. The relation of bands shifted to scale divisions for different parts of the range of the instrument (which has a total of **3000** scale di-

---

[1] Hill, THIS JOURNAL, 45, **1143 (1923).**

[2] See, for example, **L.** H. Adams, *ibid.*, 37, **1181 (1915).**

visions) was therefore found. From these, using the procedure described by Gans and Bose,[3] the following equation was obtained

$$S = R - 0.00003762\ R^2 \qquad (1)$$

where R is the observed scale reading and S is the reading which would be observed if the scale readings were directly proportional to the number of bands shifted.

Standard solutions of the substance being investigated were prepared by dissolving weighed amounts of it in 500 or 1000 g. of water. These were made by dropping a vial with a ground-in stopper containing the liquid into the weighed sample of water contained in a bottle with a well ground-in glass stopper. The stopper of the vial was loosened, the vial dropped in and its stopper after it. The bottle was then stoppered as quickly as possible. The weight of the water in the bottle was so chosen that the free space in the bottle after the vial and liquid were in was not more than 10 cc. in the case of the bottles holding 1000 cc.. and 5 cc. in the case of those holding 500 cc. By making this space small, appreciable loss of the liquid as vapor was thus avoided. These bottles were placed on a shaker and shaken until no more droplets of the liquid remained undissolved. This was quite easy to determine as these substances are heavier than water and have high refractive indices, so that even minute drops are readily visible. When solution was complete the scale reading R was found for a sample of the solution placed in the interferometer. Blank experiments made by shaking an empty vial in these bottles with 500 g. of water showed that no appreciable solution of the glass had taken place. The proper quantities of liquid to be used in making up the standard solutions can be found by a trial determination using about 0.2 g. of the substance per 1000 g. of water and from the value for the saturated solution made as described later.

From the observed readings R for these solutions the values of S were calculated by means of Equation 1. The values of S so obtained, when plotted, were found to be a linear function of the concentrations expressed as grams per 1000 g. of solution. This is illustrated by the data of Table I for 1,1-dichloro-ethane in water. The values of C are the concentrations in grams per 1000 g. of solution. The values of C' are those calculated from the equation

$$C' = 0.00507\ S \qquad (2)$$

where S is obtained as above.

TABLE I

DATA FOR 1,1-DICHLORO-ETHANE

S	C	C'	ΔC	% error
158	0.773	0.801	−0.028	3.5
345	1.711	1.750	− .039	2.2
475	2.443	2.408	+ .035	1.4
633	3.209	3.209	+ .000	0.0

Average error, 1.8%.

The direct proportionality of C and S was also established in another way, as follows. The saturated solutions of the substance were prepared by shaking 10–20 cc. of the liquid with about 500 g. of water in thin-walled cylindrical flasks in a large water thermostat regulated to 25 ± 0.01°.

---

[3] Gans and Bose, *Z. Instrumentenkunde,* 36, 137 (1916).

Samples were withdrawn and analyzed at intervals of several hours until constant readings on the interferometer were obtained. About five hours was usually sufficient to effect equilibrium. However, the shaking in all cases was continued for at least twenty-four hours, and in most cases forty-eight hours elapsed before the final samples for the solubility values were taken. The readings for the saturated solutions were very reproducible. After equilibrium had been attained, one or more samples weighing several hundred grams were siphoned out of the shaking flask in the thermostat and run beneath the surface (to prevent loss by vaporization) of a weighed amount of water contained in a weighed flask with a ground-in stopper. The flask was then stoppered and weighed, and thus the weight of the saturated solution added was found. From this the dilution of this solution as a fraction of the saturated solution was calculated. The interferometer readings for these solutions were then determined. As an illustration of the accuracy with which the direct proportionality between readings and the concentrations figured as fractions of the saturated solution holds, some data for 1,1-dichloro-ethane are given in Table II.

TABLE II

DATA FOR 1,1-DICHLORO-ETHANE

Fraction of saturated solution	1.000	0.6901	0.4187
S, observed	993	685	414
S, calculated	...	685	416

From the data of Table II and Equation 2 the value of the solubility is calculated to be 5.035 g. per 1000 g. of solution and 5.06 g. per 1000 g. of water.

The substances used were purified from the best obtainable commercial samples by fractional distillation, using an all-glass still with a column 150 cm. long of the type previously described.[4] Temperatures were determined on thermometers standardized by the Bureau of Standards and pressures were read on a precision barometer.

1,1-Dichloro-ethane.—A fraction of 414 g. boiling between 57.0 and 57.1" was used. I. C. T. gives 57.3".

1,2-Dichloro-ethane.—A fraction containing 637 g. boiling from 83.6 to 83.8" was used. Timmermans[5] gives 83 69–83.71°.

1,2-Dichloropropane.—The commercial sample containing 1000 g. was fractionated three times and the constant-boiling fraction weighing 257 g. from the third fractionation was used. It boiled from 94.4 to 96.6". I. C. T. gives 96.8".

1,3-Dichloropropane.—A fraction of 507 g. boiling from 120.5 to 120.6' was used. Freund[6] gives a boiling point of 119.5° at 740 mm. This would correspond to a corrected boiling point of 120.3" if we assume that the value of *C* in Crafts' correction rule is $C = 0\,000100$, the same as the value given by Crafts for propylene bromide.

---

[5] Timmermans, *Bull soc. chim. belg*, 24, *244* (1910).

[6] Freund, *Monatsh.*, 2, 639 (1881).

The value 125° given in I. C. T., Vol. I, p. 183, is evidently too high by at least 3°. It is apparently the value of Herzfelder[7] for a sample of 1,3-dichloropropane which, as Herzfelder himself states, contained iodine. The other values in the literature all agree in placing the boiling point at about 120 to 120.5°.

Carbon Tetrachloride.—This was a sample of Kahlbaum's "sulphur-free reagent for analytical use." It was used without further purification. The results for this substance are only preliminary.

The two remaining isomers of dichloropropane had originally been prepared and it was proposed also to measure their solubility. On trial it was found that they were hydrolyzed by water, as shown by the failure to ohtain constant saturation values. This was confirmed by testing for chlorides, which were shown to be present. In the case of each of the five substances used above, hydrolysis was carefully tested for and found absent.

The solubility data are given in Table III. The estimated errors of these solubility values are as follows: for 1,2-dichloro-ethane, 1%; for 1,1-dichloro-ethane, 2.0%; for the dichloropropanes, 2.5%. The error for the carbon tetrachloride is about 5%, as in this case the limit of the sensitivity of the interferometer with the 40-mm. chamber available was approached. This value must therefore be regarded as only preliminary. It is planned to repeat the measurements for this substance with a purer sample and with a longer (80-mm.) liquid chamber.

The sensitivity of the method can be appreciated when it is realized that an error of 2.0% in the solubility value of 1,1-dichloro-ethane represents an error of 0.01% on the total composition of the solution.

TABLE III

SOLUBILITY DATA

	Solubility in water at 25°, g. per 100 g. of H_2O	Moles per 1000 g. of H_2O
1,1-Dichloro-ethane	0.506	0.0511
1,2-Dichloro-ethane	.865	.0874
1,2-Dichloropropane	.280	.0248
1,3-Dichloropropane	.273	.0243
Carbon tetrachloride	.077	.0050

Rex[8] gives values for the solubility of three of these substances in water at 20 and 30°. From these the following values for the solubility in grams per 100 g. of water at 25° were interpolated: for 1,1-dichloro-ethane, 0.545; for 1,2-dichloro-ethane, 0.881; for carbon tetrachloride, 0.082. These values are consistently higher than those given above but this seems probable in view of the method used by Rex, which was to measure in a capillary the volume of liquid before and after saturating a known amount of water with it and determining the solubility from the difference in volume. Apparently no allowance was made for possible loss of the liquid which may have adhered to the walls of the larger vessel, containing the water,

---

[7] Herzfelder, *Ber.*, 26, 2434 (1893).

[8] Rex, *Z. physik. Chem.*, 55, 365 (1906).

to which the capillary was sealed. This loss would result in a larger apparent solubility.

The method as outlined has also been used to determine the solubility of these substances in salt solutions, in particular in 0.5 *M* potassium chloride and 0.5 *M* magnesium sulfate. The procedure is in all particulars the same as for water. A large volume of the salt solution of the desired concentration is made up and used throughout for dilutions, standard solutions, comparison solutions in the interferometer, etc., in the place of distilled water. In general, there appears to be no reason why the method should not be applicable to solubility measurements in practically any colorless aqueous solutions for any type of substance. Measurements of solubilities in non-aqueous solvents are also possible but these would in many cases involve difficulties inherent in the construction of the interferometer itself, which is primarily designed for aqueous solutions.[9]

In conclusion I take this opportunity to thank Professor Peter Debye for placing facilities at my disposal at the Physikalisches Institut, Leipzig, with which part of the work was done, and for valuable suggestions and advice.

Summary

1. A method for the determination of the solubility of difficultly soluble liquids in water and aqueous solutions is described.

2. The solubilities of 1,1-dichloro-ethane, 1,2-dichloro-ethane, 1,2-dichloropropane and 1,3-dichloropropane are given. A preliminary value for the solubility of carbon tetrachloride is also given.

THE ACTIVATION OF OXYGEN BY ELECTRON IMPACT

BY ROBERT H. DALTON

RECEIVED MARCH 11, 1929 PUBLISHED AUGUST 7, 1929

Introduction

The purpose of this research was to study the chemical behavior of oxygen activated by electron impact and to measure the energy necessary for its activation. The general plan was to use an apparatus similar to that employed by Glockler, Baxter and Dalton[1] in the study of the reaction between copper oxide and active hydrogen.

The oxygen was introduced at pressures of 0.05–0.4 mm. of mercury into a four-electrode tube connected with a liquid-air trap and a Pirani pressure gage. A four-electrode tube was used in order that the energy loss of the

---

[9] In this connection see Cohen and Bruins, Proc. Acad. *Sci. Amsterdam,* 24, 114 (1921).

[1] Glockler, Baxter and Dalton, THIS JOURNAL, 49, 58 (1927).

electrons might be studied by making current-potential curves as done by Franck[2] and others. With this arrangement it was possible to follow the course of any reaction which involved a change in the number of molecules or produced a substance condensable in liquid air. It was, of course, not possible to use gases which would undergo reaction when exposed to the hot filament. Several reactions were tried; the one finally studied was that of the activated oxygen with solid carbon to form carbon dioxide.

Materials and Apparatus.--The oxygen was obtained by heating mercuric oxide which was contained in a bulb attached to the apparatus. The mercuric oxide had been previously prepared in the apparatus by boiling mercury for some time with well-dried tank oxygen.

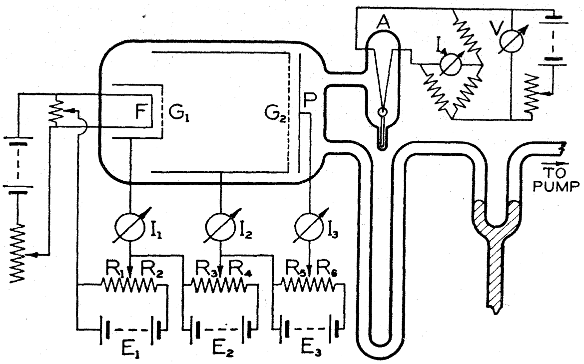

Fig. 1.

The carbon was present in the form of lampblack deposited on the end of grid G_2 with a smoky gas–oxygen flame, except in the case of a preliminary experiment in which graphite previously ignited *in vacuo* was used. The lampblack was deposited only on the end of the grid away from the filament, in order to avoid so far as possible any thermal reaction.

The apparatus used is shown diagrammatically in Fig. 1. Within the tube all metal parts are of platinum except for the short lengths of tungsten wire used to bring the leads through the glass. Attempts to protect the tungsten wires from the action of oxygen by plating them with gold were unsuccessful. The source of electrons is the calcium oxide coated filament F, operating on a potential drop of about 2 volts. Around this is a cylindrical electrode, G_1, with a circular grid of 50-mesh gauze 0.1 cm. from the filament. The next electrode is also cylindrical and has in the end a circular grid, G_2, of the same mesh as G_1. The distance from G_1 to G_2 is about 4 cm. One millimeter behind G_2 is the plate P.

The electrical connections are shown in the diagram; I_1, I_2, I_3 and I_4 are galvanometers. The potential P between filament F and grid G_1 is established by means of a storage battery and resistance in parallel. It is calculated by the expression

$$P = \frac{R_1}{R_1 + R_2}(E_1 - I_1R_2)$$

---

[2] For a complete discussion of these methods see Franck and Jordan, "Anregung von Quantensprüngen durch Stosse," Springer, Leipzig, 1927.

Here R_1 and R_2 are the resistances indicated in the diagram, E_1 is the potential of the battery and I_1 is the current between the filament and the first electrode.

A connecting tube leads from the apparatus to the Pirani gage A, which consists of a fine platinum wire about 18 cm. long and 0.003 cm. in diameter. In the original experiments the wire was sealed in a straight glass tube 0.5 cm. in diameter. This form, while quite sensitive, was undesirable since when heated the wire became slack so that its position with respect to the walls, and hence the heat conductivity and apparent pressure, were variable. These difficulties were avoided by the arrangement shown in Fig. 1 in which the wire is stretched and centered by a small weight sliding in a glass tube. To maintain the walls at constant temperature the tube containing the wire was placed in a thermos bottle filled with water. The slight heating due to the Pirani wire did not raise the temperature of the water appreciably. The connections are shown in the figure and are those recommended by Campbell.[3] The Pirani wire is in one arm of a Wheatstone bridge the other three resistances of which are fixed. The voltage, V, necessary to balance the bridge is then a measure of the pressure. Over the pressure ranges for which the instrument was used (0.01 to 0.3 mm.) the pressure is a nearly linear function of $V^2 - V_0^2$, where V_0 is the voltage to balance the bridge when the pressure is negligible. If absolute pressure measurements are desired, the gage must be calibrated against a McLeod gage with each gas used.

Another connecting tube leads from the apparatus to a liquid-air trap, a mercury cut-off, devices for introducing various gases, a McLeod gage, another mercury cut-off and the pumps.

To prevent changes in pressure due to changes in temperature the electron tube was surrounded by a water jacket through which a stream of tap water was passed.

Procedure.—In general the current, potential and rate of reaction measurements were not taken simultaneously owing to the large number of instruments to be read. In making the rate of reaction runs the apparatus was pumped out to about 10^{-5} mm., the filament lighted and the trap at the tube immersed in liquid air. The gas was introduced, pressures being read both on the McLeod gage and the Pirani gage. The mercury cut-off at the tube was then closed and the rate of pressure change determined with various accelerating voltages between the filament and the first grid. These rates were followed by measuring the rate of deflection of the galvanometer I_4 when the bridge was balanced. Using a sensitive galvanometer changes of pressure of 10^{-5} mm. caused deflections of 1 cm.

In making the current-potential runs the method of Franck[2] was used. The oxygen was admitted as above and the plate current was measured with various accelerating potentials between the filament and the first grid, G_1. In most of the experiments a slight accelerating field of about 0.1 volt was maintained between G_1 and G_2 and a retarding field of 2.5 volts between G_2 and the plate, P.

A great deal of difficulty was encountered in obtaining sufficient electron emission to produce measurable chemical effects. In some cases the emission of a filament in oxygen gas was less than one-hundredth of its value in hydrogen.

Results of the Current-Potential Experiments.—The results of the current-potential measurements will be presented first. Fig. 2 shows a curve obtained with oxygen at 0.4-mm. pressure and is the graph of Expt. 1. The accelerating voltages (uncorrected, even for I_1) between the filament and the grid G are plotted as abscissas and the plate currents in arbitrary units as ordinates. Two breaks in the curve are apparent, a small one at about 9 volts (uncorrected) and a very pronounced one at about 12.5 volts

[3] Campbell, *Proc. Phys. Soc. London,* **33, 287** *(1921).*

(uncorrected). All of the curves in which the oxygen pressure was greater than 0.1 mm. show these two breaks but their relative magnitude varies. At high pressure the second predominates markedly, but as the pressure becomes lower it diminishes in magnitude and finally at the lowest pressures investigated has disappeared entirely, as may be seen in Fig. 3, which is the graph of Expt. 8 made at 0.05 mm.

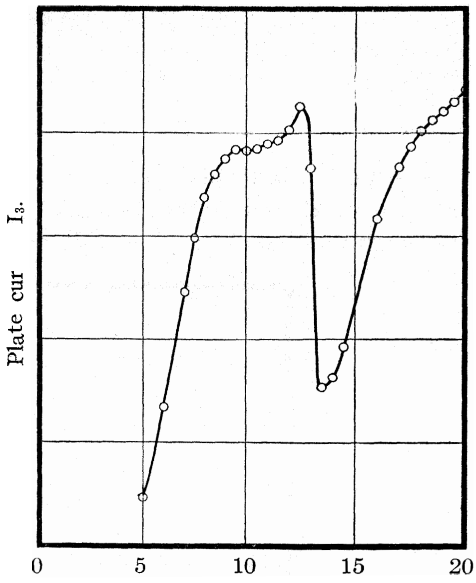

Fig. 2.

The results of all the current potential runs are summarized in Table I. The first line gives the experiment number; the second, the pressure of oxygen in millimeters of mercury; and the third and fourth give the values of the potential in volts (corrected) at which the first and second breaks occur.

The corrected voltages were obtained as follows. The true potential of the grid was determined by the equation given earlier. This is, however, not a true measure of the energy of the electrons since some energy is required to remove the electrons from the filament. This initial velocity correction was determined by taking the voltage at the foot of the curve obtained by plotting the values of the total emission against the voltage, in the region from 0 to 3 volts. The average of three determinations gave 0.9 volt for this correction. Subtracting this value from the applied potential gives for practical purposes the maximum voltage of the electrons and is spoken of as the corrected voltage. The maximum value is of interest rather than the average, which is about a volt lower, since the critical voltage is taken as the point where the cur-

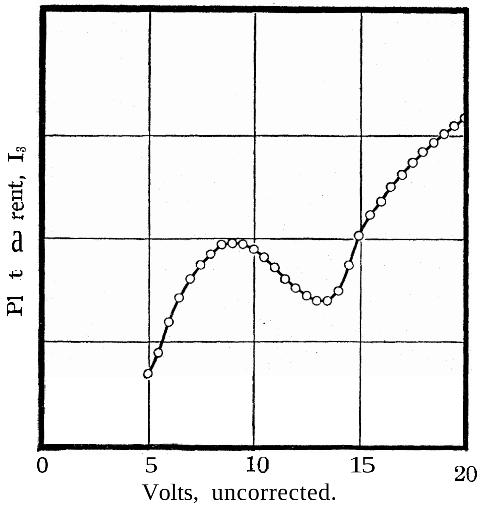

Fig. 3.

rent first starts to change, which is the point at which the fastest electrons just attain the critical voltage.

TABLE I

RESULTS OF CURRENT POTENTIAL RUNS

Experiment	1	2	3	4	5	6	7	8	9	
Pressure	0.40	0.32	0.28	0.22	0.18	0.11	0.08	0.05	0.05	
First break	8.1	7.8	7.5	7.9	7.9	7.6	8.2	7.9	8.2	Mean **7.9**
Second break	10.7	10.7	10.2	10.5	10.5	10.8	Not measurable			Mean 10.6

Results **of the** Rate Experiments.—The experiments on the rate of reaction proved definitely that bombardment with electrons having energies in the neighborhood of the previously-determined critical potentials produced an active form of oxygen capable of reacting with carbon to form carbon dioxide. However, it is not possible to fix accurately the potential at which reaction begins. This is due mainly to the poor emission of the filament in oxygen, which means that the rate of reaction is so low that it cannot be determined accurately. In order to obtain sufficient emission to work with, the filament must be large and must run at as high a temperature as possible. As a result of this the electron distribution is poor and the curves instead of breaking sharply when the critical potential is reached, bend gradually over a considerable voltage range. The fact that the oxygen molecule shows an affinity toward electrons also spoils the electron distribution. Another difficulty arose from the fact that when the filament was lighted a pressure decrease began although no accelerating potential was applied. Attempts to remove this zero rate by running for some time with high oxygen pressure and by cooling the tube failed, but since this zero

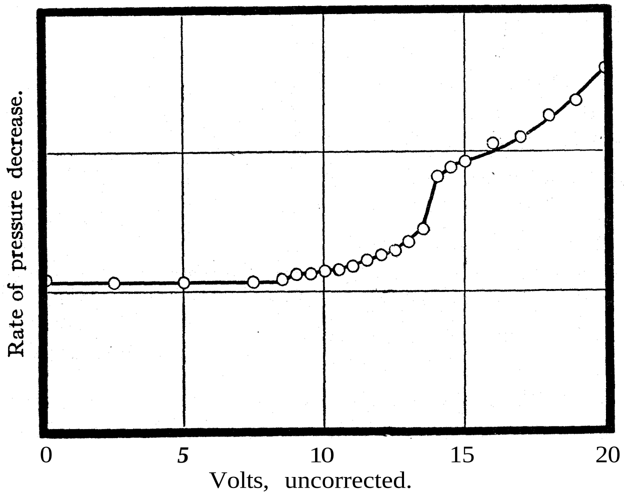

Fig. 4.

rate proved to be fairly constant it was possible to study the superimposed electronic effect.

Figure 4 shows a graph of Run 10 made at a pressure of 0.3 mm. The accelerating voltages (uncorrected) between the filament and G_1 are plotted as abscissas and the rate of pressure decrease in arbitrary units as ordinates. In this case two breaks are clearly present, one at 8.5 volts (uncorrected) and the second at 13 volts (uncorrected). This is in fair agreement with the current-potential data, as will be seen by referring to Fig. 2. In fact, Expt. 10 was made immediately following Expt. 1, keeping everything as nearly the same as possible.

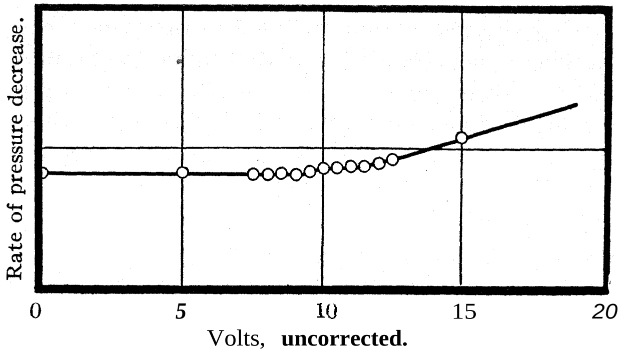

Fig. 5.

Here just as in the current-potential work if we go to low pressures the second break disappears. This is shown in Fig. 5, which is a graph of Run 15 made at 0.11-mm. pressure.

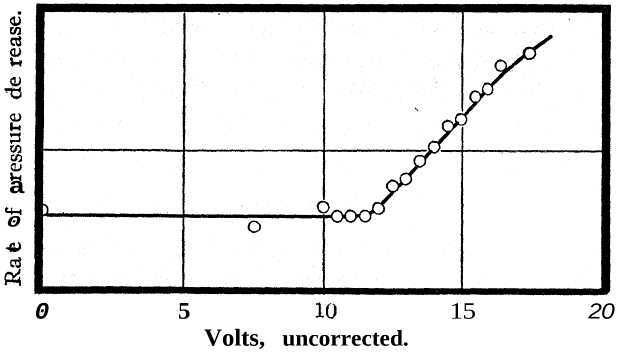

Fig. 6.

Experiments at intermediate pressures show in general only one break, which occurs at about the average of the two critical potentials determined in the current potential experiments. An illustration of this case is given in Fig. 6, which is a graph of Expt. 12 in which the oxygen pressure is 0.22

mm. The data from the most reliable reaction rate experiments are summarized in Table II. The first line gives the experiment number, the second the pressure of oxygen in millimeters of mercury, and the third and fourth give the voltages (corrected) at which breaks in the rate of reaction curves occur.

Table II

Reaction Rate Data

Experiment	10	11	12	13	14	15
Pressure	0.30	0.24	0.22	0.22	0.12	0.11
First break	7	9.3	9.1	9.2	<8.30	7.5
Second break	10.8	..	..	..	..	..

The earlier experiments are not included in the table since the readings were not taken near enough together to determine the point where a break occurs and since a more crude form of apparatus was then in use. They are not, however, in disagreement with the above results.

Considering the results of all the experiments it appears that at both the critical potentials observed an active form of oxygen is produced which reacts with the carbon.

The Reaction Product.—It is natural to suppose that the product of the reaction is carbon dioxide, since carbon monoxide will not be frozen out by liquid air at these pressures. The following experiments substantiated this supposition. The product from a number of runs was allowed to accumulate in the liquid-air trap, the residual oxygen was pumped out, the mercury cut-off at the pumps closed and the liquid air removed. A series of pressure readings was then made on the McLeod gage with the mercury at different heights. The product behaved as a perfect gas up to pressures of 18 cm. and so cannot have been water vapor. There was no permanent change in pressure on lighting the filament, which eliminates ozone as a possibility. Finally, some of the product was collected in a small side tube, cooled in liquid air, sealed off, and opened under barium hydroxide solution. A small quantity of a white precipitate of barium carbonate was obtained. l'hus the product must consist at least in a large part of carbon dioxide.

Discussion

It is interesting to compare the values of the critical potentials found with the known energy levels of oxygen. The band spectra of oxygen have been only partially worked out. There are electronic levels at about 1.7 volts and at 6 volts.[4] It is thought that the convergence limit of the oscillational states of the 6-volt electronic level corresponds to the energy for dissociation into two normal atoms. This gives about 7 volts for the work of dissociation of the normal molecule. Above 6 volts there are no levels given till ionization into O_2^+ between 14 and 15 volts. Thus spectroscopi-

---

[4] Birge, *Bull. Nat.* Res. Council, 57, 244 (1926).

cally there are no energy levels yet given in the neighborhood of 7.9 or 10.6, though it is probable that such exist.

The work of various investigators on the determination of the critical potentials of oxygen by electron impact methods is not in good agreement. For the first critical potential, values varying from 7.9 to 0.2 volts have been reported.[5] However, the later work, which is probably more reliable, gives values close to 8 volts. A second critical potential is found by most observers at about 15.5 volts and is accepted as the ionization potential.[6]

Thus the first potential found in the present work is in good agreement with previous values and is apparently a resonance potential of the oxygen molecule. The second potential and its peculiar dependence on the pressure cannot be interpreted with any certainty, but some possibilities may be considered. Perhaps the simplest explanation is that we are dealing with a previously unrecorded critical potential of the molecule, but this would give no reason for such a marked dependence on the pressure. Or it might be that the second potential represented dissociation of the molecule into a normal and an excited atom. Since dissociation to normal atoms requires 7 volts, that leaves 3.6 volts for the atomic excitation. It seems probable from the study of the auroral lines that there is an atomic level in this region. Another explanation might be that the second break is due to carbon dioxide, which is reported as having a resonance potential at *10.0* volts.[7] This would account for the variation with the pressure since at low oxygen pressures the carbon dioxide would diffuse rapidly to the liquid-air trap while at higher pressures its removal would be retarded. This hypothesis would also account for the fact that previous potential work in oxygen has not in general revealed a critical point at *10.6* volts. It would require, on the other hand, that inelastic collisions of electrons with carbon dioxide be much more efficient than those with oxygen.

The author wishes to express his thanks to Professor Tolman, to Dr. Baxter, and especially to Dr. Glockler, for their assistance in this research; also to the Carnegie Institution of Washington for financial aid received through a grant made to Professor A. A. Noyes.

Summary

The critical potentials of oxygen gas have been determined at various pressures. In addition to the value of 7.9 volts which has been found by previous experimenters, a second critical value was found at *10.G* volts. The latter appears distinctly only at pressures above *0.1* mm., but becomes very pronounced at pressures of *0.2* to 0.4 mm.

The reactivity toward carbon of oxygen gas excited by electron impact was studied. There was no reaction below 7.9 volts, but between 7.9 and 10.6 volts a reaction commenced and increased in rapidity up to the highest potentials investigated. The product of the reaction is carbon dioxide, at least in large part.

THE HEATS OF DISSOCIATION OF THE MOLECULES, CH, NH, OH AND HF

BY DONALD STATLER VILLARS

RECEIVED MARCH 22, 1929 PUBLISHED AUGUST 7, 1929

In an investigation on the dissociation energetics of the molecule of hydrogen cyanide, it was necessary to make an estimate of the heats of dissociation of its different possible decomposition products. Although it sounds strange to the chemist to speak of the molecules, CH, NH and OH, still their existence is definitely proved by the observation of band spectra[1] which are ascribed to them. The molecules, unsaturated chemically, are most probably extremely reactive, but we should not consider them unstable, in the sense that they have a tendency to decompose. The knowledge of the heats of dissociation of these molecules has great theoretical importance in studying the dissociation of other compounds, as well as hydrogen cyanide.

In order to calculate these heats, I have made use of two empirical principles discovered by band spectroscopists. First, Kuhn[2] has shown that the restoring force constant, C, in the equation for the vibration of a harmonic oscillator is approximately proportional to the heat of dissociation of the molecule.

$$C \equiv \mu\omega_0^2 = kD \qquad (1)$$

ω_0 is the frequency of vibration for infinitely small displacement and is determined experimentally by the difference between the first and second vibrational energy levels of the molecule as measured from its band spectrum; μ is the resultant mass and equals $m_1m_2/(m_1 + m_2)$ for a diatomic molecule. Second, Mecke[3] has shown that molecular constants vary with the atomic number in much the same manner as other physical and chemical constants. The method of estimation, then, is to determine

k in (1) and to calculate D from this, making use of ω_0, obtained already or interpolated by applying Mecke's principle.

Birge[4] gives the following values of ω_0 which he calculated for the molecules CH, OH and HF: ω_0'' HF, 3962 cm.$^{-1}$; OH, 3570 cm.$^{-1}$; CH, 2797 cm.$^{-1}$. Interpolating for ω_0 of NH gives 3188 cm.$^{-1}$. Figure 1 shows that all of the points lie on a perfectly straight line.

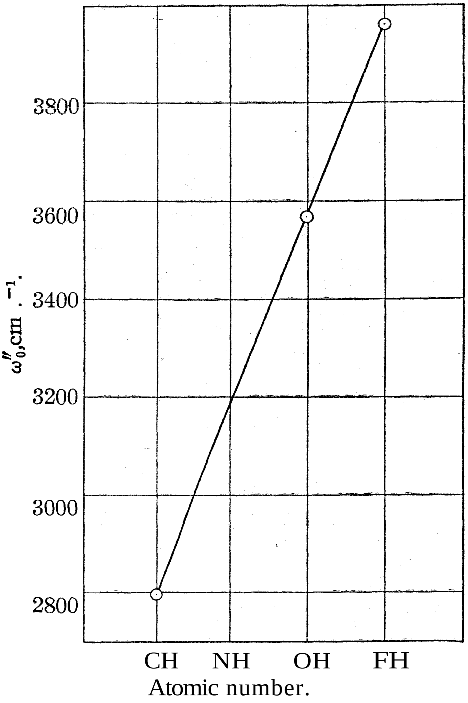

Fig. 1.

The next step made in the approximation process is to tabulate C and D (see Equation 1) for several different molecules and to calculate therefrom the proportionality constant, k. This is given in Table I, the values in parentheses being the results of estimation. It will be immediately evident that k varies also with the atomic number for the similar molecules, H_2, HCl, HBr. Plotting k against atomic number in Fig. 2, we may interpolate and get the values given in parentheses under k. Knowing k and ω_0, one may immediately calculate D and this, too, is given in Table I. If this interpolation is justified, it can be seen that the error involved in our value of D is at most not over 3%.

We can compare these calculated heats of dissociation with some quasi-experimental ones which may be obtained from the work of Ellis.[5] According to him, the bonding power (C in the above notation) of the C–H

TABLE I

HEAT OF DISSOCIATION

Molecule	μ	ω_0, cm.$^{-1}$	D Volts	Kilocal.	k
Cl_2	17.73	555	2.5	58.5	9.36×10^4
Br_2	39.95	326	2.0	45.2	9.42
I_2	63.45	214	1.5	35.2	8.14
N_2	7.00	2345	9.5	219.0	17.6
NO	7.46	1892	7.3	169.0	15.86
CO	6.85	2150	11.2	268.0	12.3
CN	6.47	2060	9.5	219.0	12.1
H_2	0.50	4264	4.4	101.0	9.10
CH	.923	2797	(3.55)	(82.0)	(8.81)
NH	.933	3188	(4.65)	(108.3)	(8.76)
OH	.942	3570	(5.98)	(138.0)	(8.71)
HF	.950	3962	..	(172.0)	(8.68)
HCl	.972	2941	4.4	101.7	8.29
HBr	.976	2559	..	81.7	7.82

linkage is 23% greater in hexane (heat of dissociation, 97 kilocal.) than in the CH molecule. If C is proportional to the heat of dissociation, D, then

$$\frac{C_1}{C_2} = 1.23 = \frac{k_1 D_1}{k_2 D_2} = \frac{97}{D_{\mathrm{CH}}} \qquad (2)$$

where the subscripts 1 and 2 refer to hexane and CH, respectively. If we neglect the fact that k_1 (9.15) is different from k_2 (8.81 according to Table I) we can calculate D_{CH}

$$D_{\mathrm{CH}} = 79 \text{ kilocal.}$$

which agrees very well with the value 82 kilocal. obtained above. To say that the ratio $k_1/k_2 = 1$ is, of course, inconsistent with our other method of calculation and any results obtained in this manner can only indicate the order of magnitude. Likewise, an application of Equation 2 with the same assumption concerning the ratio k_1/k_2 gives us a value for the heat of dissociation of Cl_3C–H. Using Ellis' data for ω_0, this is found to be 105 kilocal., which agrees with his observed value of 108 kilocal.

Mlis also obtained values for the linkage heat of the N–H bond. In aniline he reports it as being 113 (±15%) kilocal. He compared this spectroscopic value with a chemical value obtained by dividing the "atomic" heat of formation (referred to the gaseous atoms) of ammonia by three. He found 101 kilocal. but this should be **93** if we accept the new value[6] for the heat of dissociation of nitrogen, $D_{N_2} = 9.5$ volts or 219 kilocal. This checks well the value obtained from Equation 2 (*i.* e., 91.4 kilocal.)

$$\frac{3440^2 \times 0.989}{3188^2 \times 0.933} = \frac{k_a\, 113}{k_{\mathrm{NH}}\, D_{\mathrm{NH}}}$$

$$D_{\mathrm{NH}} = 91.4 \text{ kilocal. or } 4.0 \text{ volts if } k_a/k_{\mathrm{NH}} = 1$$

---

[6] Mulliken, Phys. Rev., 32,761 (1928); Birge, Nature, 122,842 (1928).

Here $k_a = 10.36$ and the discrepancy may be ascribed to its difference from k_{NH}.

In view of the above discussion concerning the empirical variation of k with atomic number, it seems best to choose as values 'for D those given in Table I.

The heat of dissociation of CN has already been calculated to be 9.5 volts[7] (1 volt = 23 kilocal.). Recent work has indicated that it is probable that one of the products of this dissociation is an excited atom.[6] If it is a characteristic of odd molecules that their normal states will dissociate, resulting in an excited atom, while their next excited molecular states dissociate into normal atoms,[8] then some doubt is thrown on the meaning of our above value for D_{CH}, as it must represent only an upper limit for the heat of dissociation into *normal* atoms. As yet there has been no evidence advanced that this is true for the hydride molecules under consideration.[9] However, even were this true, we still have obtained the *actual* energy necessary to break up the molecule, a quantity which has very interesting theoretical implications.

Our value for the heat of dissociation of OH agrees in order of magnitude with other existent data. If the "atomic" heat of formation of water is 238.8 kilocal., then the heat of dissociation of water into H and OH is $238.8 - 138 = 100.8$. Senftleben and Rehren[10] estimate it to be less than 112 kilocal. Bonhoeffer and Reichardtu obtain a value in agreement with theirs. Bates and Taylor[12] find that the efficiency of excited mercury (113 kilocal.) is much less in its dissociation of water vapor than in its action on other molecules. An explanation, accessory to that advanced by Bates and Taylor, might be that the amount of energy available from the mercury is in excess of that necessary to dissociate the water molecule by 12 kilocal, and that we have here a resonance phenomenon such as is observed elsewhere in collisions of the second kind.[13]

Summary

Data from band spectra have been interpolated by Mecke's method and the magnitude of the heat of dissociation of the molecules, CH, NH, OH and HF was calculated to be, respectively, 82.0, 108.3, 138.0 and 172 kilocalories.

A NEW DIFFERENTIAL PRESSURE GAGE

BY A. R. OLSON AND L. L. HIRST

RECEIVED MARCH 26, 1929 PUBLISHED AUGUST 7, 1929

In a recent investigation we found it necessary to follow the speed of a very slow gas reaction by means of the pressure change produced in the reacting mixture. In this investigation it was desirable to work at about atmospheric pressure. The differential gage devised by Frank,[1] in which he combined the circuit developed by Gunn[2] with a condenser, one plate of which was mounted on the thin glass diaphragm of a reaction chamber, would have been satisfactory. This circuit, however, is complicated and very sensitive to small battery variations, since it depends upon current measurements.

Within the past ten years piezo-electric quartz crystals have been introduced into radio circuits to hold the frequency constant.[3] By combining such a crystal-controlled oscillator with a resonance circuit which utilized a condenser mounted on a glass diaphragm, we were able to construct a gage which combined the advantages of simplicity and accuracy.

The wiring diagram of the oscillation and resonance circuits[4] is shown in Fig. 1. We used a 301 A Cunningham tube operated with a 6-volt filament battery and a 150-volt plate battery. Q is quartz plate which has frequencies of 1080 and 1211 K. C. The inductance L_1 has 25 turns of No. 14 copper wire wound on an 11-cm. bakelite cylinder. L_2 in the resonance circuit consists of 80 turns of No. 16 wire wound on an 8.5-cm. bakelite cylinder. It is tapped at every turn to facilitate adjustment. C_1 is a standard $1500\mu\mu$ variable condenser; C_2 is a small parallel plate condenser which is shown in detail in Fig. 2. The diaphragm D is a No. 0 cover glass about two inches in diameter, to which the lower condenser plate is attached by shellac. The cover glass was attached to the tube by sealing wax. In case an all-glass system is needed, the diaphragm can be blown from the tube itself. The upper plate is rigidly fixed to the top of the gage by an adjusting screw. The distance between plates is about 0.3 mm.

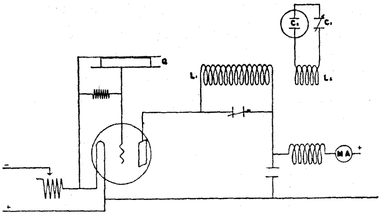

Fig. 1.

When circuit is oscillating, the plate current is about 15 m.a., as shown by the meter MA, Fig. 1. When resonance is established in the gage circuit, the plate current increases very sharply by about 10 m.a. To adjust the apparatus, the oscillator is set going, C_1 is fixed at a rather large value ($1000\mu\mu$ to $2000\mu\mu$) and L_2 is varied until resonance is obtained. No further adjustments are necessary. For accurate work

it is desirable to thermostat the whole circuit to prevent capacity changes, etc., during the measurements.

To use the gage, fill one side with the reacting mixture, and the other side with an inert gas. A small leveling bulb will help to adjust the pressure until the diaphragm is in its undisplaced position. Then start the oscillator and increase C_1 until the sharp increase in the plate current is obtained. Decrease C_1 again until oscillation is restored and repeat the operation. Since the frequency of the oscillator is constant and since the inductances L_1 and L_2 are fixed, the total capacity in the resonance circuit is fixed But $1/C = 1/C_1 + 1/C_2 =$ a constant. Therefore $dC_1/dC_2 = -C_1^2/C_2^2$, or the ratio of the changes of capacity is directly proportional to the square of the ratio of their absolute values. For the condition as outlined above, a small change in C_2 corresponds to a large change in C_1. In our work the gage was reproducible to one division of our standard condenser, which corresponded to 3×10^{-4} mm. mercury pressure. This does not represent the limit of reproducibility of the electrical circuit, for when C_2 was replaced by a small fixed condenser, C_1 readings checked within such limits that we could estimate fractions of a subdivision, *i. e.*, tenths of a division.

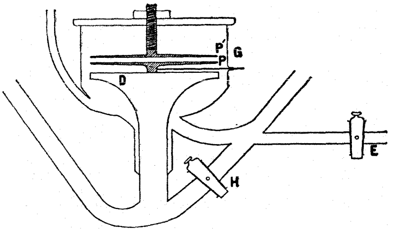

Fig. 2.

To calibrate the apparatus various methods can be used. Thus both sides can be filled with an inert gas and then the pressure on one side can be changed a given amount by changing the leveling bulb, or the whole apparatus may be evacuated and a liquid with a known pressure introduced on one side. The details of such a calibration can be seen from the following data

Press above D, cm. of Hg	**24 5**	**24 5**	$17\ 1 \times 10^{-3}$	$17\ 1 \times 10^{-3}$	$17\ 1 \times 10^{-3}$	17.1×10^{-3}
Press. below D, cm of Hg	**24 5**	**24 5**	$17\ 1 \times 10^{-3}$	$17\ 1 \times 10^{-3}$	$14\ 6 \times 10^{-3}$	$14\ 6 \times 10^{-3}$
C_1	**1026 8**	**1026 9**	**1028 8**	**1028 8**	**1007 7**	**1007.8**

A change of pressure on both sides of D from 24.5 cm. to 2 X 10^{-3} cm. produced a change in C_1 of only two divisions. If the pressure on one side is kept constant, and the pressure on the other side of D is changed, C_1 changes approximately one division for each thousandth millimeter change of pressure. If C_1 were adjusted so as to resonate at $2000\mu\mu$, the change in C_1 would be about four times as much.

Summary

A new simple and accurate differential pressure gage has been devised which will permit the study of very slow reactions at any pressure even when an all-glass gage is needed.

SOME APPLICATIONS OF ELECTRIC MOMENTS TO ELECTRONIC THEORIES OF VALENCE

BY CHARLES P. SMYTH

RECEIVED MARCH 29, 1929 PUBLISHED AUGUST 7, 1929

As most of the electronic theories of valence in their application to organic compounds involve the idea of polarity as a controlling factor, it would seem logical to use the measure of molecular polarity, that is, the electric moment of the molecule, as a means of examining the validity of the theories. In the hands of many workers with these theories, the signs of positive and negative charges and the circles or dots representing electrons have gradually lost all physical significance and become mere symbols of chemical behavior. To attempt to apply principles of electrostatics to test these molecular formulas would be idle. However, hypotheses which have been developed on the basis of physical laws lend themselves to examination in the light of the electric moments of the molecules to which they are applied, provided that the molecules are not too complex.[1] It is not generally possible to accept or reject unreservedly an hypothesis on the basis of the electric moment of the molecule of a single substance or even of three or four substances, although strong evidence pro or con may be obtained. One may, however, set definite physical limitations upon the polarities supposed by the hypotheses and, at the same time, consider the limitations of the electric moment as a criterion by which these hypotheses may be judged.

In view of the uncertainty and the rapidity of change in the hypotheses of atomic structure and our ignorance of the fundamental nature of the chemical bond, it is impossible to assign definite electronic arrangements to the atoms in a molecule. It is generally believed, however, that a single chemical bond involves a pair of electrons and the electrostatic effect of their charges is represented by picturing certain locations between the linked atomic nuclei as occupied by the electrons. The consideration of these locations makes possible the discussion of the distribution of the electricity in the molecule.

In an electrically symmetrical molecule the center of gravity of the electrons coincides with the electrical center of gravity of the positive charges and the molecule has no electric moment. If the electrostatically effective position of an electron is displaced through a distance d, an electric doublet is created and the molecule now possesses an electric moment equal to the electronic charge, $4.774 \times 10^{-10} \times d$. The symmetrical tetrahedral structure commonly ascribed to methane should have

---

[1] For an explanation of electric moment and its relation to molecular structure, see Smyth, *Phil. Mag.*, 47, 530 (1924); THIS JOURNAL, 46, 2151 (1924).

no electric moment, but it is highly improbable that the unsymmetrical pyramidal structure attributed by Henri to methane should not possess a moment.[2] The relation of the theory of a pyramidal carbon atom to the electric moments of tetra-substituted methane molecules has been discussed by Weissenberg[3] and by Ebert and von Hartel.[4] As Sänger[5] has found zero electric moment for the methane molecule, the usually accepted picture of a symmetrical structure appears justified.

The theory of alternating polarities has received much adverse criticisni on chemical grounds and the supposed physical evidence of alternation given by melting points, heats of combustion, etc., has been shown to afford no proof of any intramolecular alternation of polarity.[6] The theory as proposed by Cuy[7] requires that, even in the paraffins, the carbons of the chain should be alternately positive and negative. The difference in polarity between the two carbons in ethane should give rise to an electric doublet, but no moment is found for the ethane molecule? Although, because of the alternation and consequent canceling of the polarities, there should be no building up of large moments in the higher members of the series, there should certainly be moments in the molecules of many and differences should exist between adjacent members. n-Hexane and n-heptane have been shown to be without moment,[9] as have also the other isomers of heptane and one octane. If any alternation in polarity occurred, it would be impossible that all of these molecules should be electrically symmetrical. Further evidence against an alternation in polarity is given by the absence of any difference in moment among the higher members of other homologous series to be considered presently.

The differences between the polarizations of the isomers of heptane were shown by Smyth and Stoops to be so small that the largest difference would, if due to but one pair of electrons, correspond to a displacement of the effective position of the charges of less than 3×10^{-11} cm. from a symmetrical location, that is, approximately 0.002 of the distance between the carbon nuclei in the chain. This distance was calculated as an upper limit for the displacement. Actually, such differences in polarization as were observed might easily occur without any lack of electric symmetry in the molecules. Hydrocarbon molecules may be resolved into various

alkyl radicals to which it is customary to assign varying degrees of electronegativity, Thus Lucas, Simpson and Carter[10] state that, in propane, due to the fact that hydrogen exerts a stronger pull on electrons than methyl does, the electron pairs joining the central carbon to hydrogens are presumably not so firmly held by the carbon so that the polarities of all the carbon–hydrogen unions in propane are not the same, hydrogen joined to the secondary carbon being more negative than hydrogen joined to a primary carbon. If the carbon linkages are tetrahedrally arranged, this difference in the polarities would make the molecule electrically unsymmetrical. A greater effect should be produced at the central carbon of n-heptane, as the two propyl groups attached to it are supposed to be less electronegative than the methyl groups on the central carbon of propane, but n-heptane is found to possess no detectable moment. It is unnecessary to make any assumption of tetrahedral linkages in order to conclude that the differently distributed groups in the isomers of heptane would give rise to electrical unsymmetry if their supposedly different electronegativities actually involved appreciably different displacements of their bonding electron pairs. The previously given calculation shows how small these displacements must be, if they exist at all. The electrical behavior of the paraffins thus gives no support to the hypothesis that the alkyl groups possess electronegativities which vary with the distance of the binding electron pair from the α-carbon.

It would appear, however, that the attachment of very strongly electronegative groups to the alkyl radicals should cause greater electron displacements and accentuate the differences between the radicals. When the hydroxyl is attached to an alkyl radical to form an alcohol, a strong electric moment results. In considering the dielectric constants of methyl, ethyl and propyl alcohols, Thomson[11] has pointed out that the intense electric field due to the principal moment of the molecule might be expected to give rise by induction on the rest of the molecule to moments of the same sign as the original moment, thus increasing the moment of the molecule as a whole. The increase in the moment of the molecule due to these small moments resulting from electronic displacement would be greater, the greater the length of the carbon chain. What appeared to be evidence of such a small increase with increasing length of the carbon chain was obtained by the writer[1] in calculating the moments of several alcohols and in other series as well, but it now seems probable that, at least in the alcohols and ketones, the apparent small increase in moment with increasing size of the molecule was due to error caused by molecular association. The strong molecular association of the alcohols and water makes their moments difficult to determine with accuracy, but the most recent values

lie within 0.15×10^{-18} of 1.7×10^{-18} and show no regular variation with increase in the length of the chain.[12] It is evident that there are no very great differences among the displacements of the bonding electron pairs in the different alkyl groups in the alcohols.

More satisfactory conclusions may be drawn from the moments of the halides, which are less affected by. molecular association and are not complicated by the presence of two doublets in the molecule as is the case with the alcohols.

In the molecules of these halides the negative end of the electric doublet is toward the halogen. Consequently, the more electronegative the group attached to the halogen, that is, the more strongly it draws the binding electron pair toward itself, the shorter is the distance between the centers of gravity of the positive and negative electricity and the smaller the moment. This works out quite satisfactorily for hydrogen, methyl and ethyl chlorides, in which the moment increases as the supposed electronegativity decreases. The difference between ethyl chloride and butyl chloride is no greater than the combined probable errors in the values. An accurate value for methyl bromide is lacking, but approximate values calculated by Höjendahl[13] show that the moment of methyl bromide is about 0.25×10^{-18} lower than that of ethyl bromide. The supposed differences in electronegativity of the bromides and iodides, as in the case of the chlorides, accord well with the increase in moment from hydrogen to ethyl. Beyond this, however, no difference is apparent in the

chlorides and bromides, data for the iodides being lacking. The moments of chlorobenzene and bromobenzene are much higher than those of the corresponding hydrogen halides, although the phenyl group is supposed to be more electronegative than hydrogen. The supposedly different electronegativities are thus only partially successful in explaining the differences in moment. It is evident that some effect is transmitted through the first two carbons of a chain, although the effect upon the second is small and, beyond the second, no effect is apparent in the electric moment.

It is of interest to contrast this transmission of an electrical effect through a chain with the effect of the chain upon the ionization constants of unsubstituted and halogenated fatty acids as quoted by Lowry[14] and by Kharasch and Darkis and shown in Table II.

TABLE II

IONIZATION CONSTANTS OF FATTY ACIDS ($\times 10^5$)

		α			β			γ			δ		
		Cl	Br	I	Cl	Br	I	Cl	Br	I	Cl	Br	I
HCOOH	21.4												
CH_3COOH	1.8	155	156	75									
CH_3CH_2COOH	1.4	147	108	90	8.6	9.8	9.0						
$CH_3(CH_2)_2COOH$	1.5	139	106		8.9								
$CH_3(CH_2)_3COOH$	1.6							3 0	2.6	**2.3**			
$CH_3(CH_2)_4COOH$	1.46										1.9	1.9	1.7

The constants for the unsubstituted acids in the second column of Table II show that, as in the case of the electric moments of the halides, lengthening of the hydrocarbon chain beyond two has little effect. The values for the halogenated acids are somewhat conflicting but, after a great drop in the effect upon the ionization when the halogen is moved from the first to the second carbon, the effect continues to diminish as the distance of the halogen from the carboxyl increases and is still noticeable in the δ-halogenated acid, where it has to be transmitted through five carbons and an oxygen. Yet, in the alkyl halides, no electronic shifts produced by halogen more than two carbons away can be detected by means of electric moments.

Wolf and Lederle[15] have found that the electric moments of a number of ketones, including methylhexyl ketone and methylnonyl ketone, differ from the value for acetone by no more than the experimental error. Their results give no evidence of any change in moment with increasing length of the hydrocarbon chain. There is thus no measurable electrostatic effect transmitted beyond the first carbons attached to the carbonyl group and no sign of any alternating polarity in the chains.

Electronic theories of valence have been applied very frequently to the double bond and, by many investigators, the bond between two carbon

---

[15] Wolf and Lederle, *Physik. Z.*, **29**, 948 (1928).

atoms has been regarded as polar, one pair of electrons being shared between the two carbons and one of the carbons containing one more pair of electrons than the other. Smyth and Zahn[8] have found the electric moment of the ethylene molecule to be zero and have therefore concluded that no more than a small proportion of the ethylene molecules, if any, can he polar. It was further concluded that a molecule in which a single unpaired electron was held by each carbon should possess a moment and therefore could not exist in any considerable quantity in the ethylene. This conclusion is supported by the recent discovery of Vaidyanathan[16] that ethylene is diamagnetic instead of paramagnetic as previously supposed. The zero moment found experimentally for ethylene does not disprove the theory of Lowry[17] and of Carothers[6] that a very small fraction of the molecules containing a double bond are polar at the bond and that it is this small fraction which is active. The small moment, 0.37×10^{-18}, found for α-butylene may be due to the difference in the electronegativities of the hydrogen on one side of the doubly-bonded carbons and the ethyl on the other side as the electrons of the double bond are shown by the high refraction associated with them to be mobile and more easily displaceable than those in a single C–C bond.[18] The moment may, however, as suggested by Smyth and Zahn, be due to small electronic shifts induced in the ethyl group by the force field around the double bond.

If the double bond consisted essentially of a single electron pair held between the atoms and a second pair held by one atom or the other, as supposed in most theories of a polar double bond, the difference in freedom of rotation between singly and doubly linked atoms mould not be explained. This well-recognized difficulty, which has been discussed by Sidgwick,[19] is, of course, obvious in the problem of geometrical isomerism. The comparative rigidity of the double bond is brought out strikingly by the results of Errera for the moments of the acetylene dihalide molecules given in Table I, where the absence of moment in the trans-compound fits in admirably with the conventional representation of the double bond as formed by the sharing of an edge between two carbon tetrahedra. The doublets at the other imaginary tetrahedral apices thus brought into one plane would cancel one another in the trans-compounds so that the moments of the molecules would be zero. Any freedom of rotation about the band would tend to produce electrical dissymmetry and a resultant moment, as found in ethylene chloride, bromide and glycol, for which large moments have been calculated approximately.[18] One might wonder

why the cis-compounds with the two halogen doublets reenforcing each other on the same side of the molecule do not have larger moments than the alkyl halides where there is only one halogen doublet. As was found in the chloromethanes and the dihalogenated benzenes,[20] the two halogen atoms repel each other, widening the angle between the axes of their doublets and decreasing the resultant moment of the molecule as a whole. The repulsion and consequent widening of the angle should be greater, the larger the halogen atoms, and it is evident that the moment is increasingly reduced on passing from chlorine to bromine to iodine. Purely geometrical considerations show that, when the two halogens are attached to the same tetrahedral carbon, the angle between their doublets is greater and the resultant moment less, as evidenced in the value for $CH_2{=}CCl_2$.

The rigidity of the doublet bond between carbon atoms is maintained in the structure proposed by Kharasch and Darkis[6] in which two pairs of electrons are shared between the two carbons, one pair being close to the carbon to which the less electronegative groups are attached and a definite polarity being postulated. This is neither proved nor disproved by the moments in Table II, but the zero moment found for ethylene shows the absence of any detectable polarity in this simple molecule, while the postulates of Kharasch and Darkis would lead us to expect a marked polarity. There appears to be no physical foundation for the postulate of Kharasch and Darkis that "the relative position of the second pair of valence electrons of the double bond depends upon the nature of radical attached to it in such a way that they are always on the carbon atom opposite to that carrying the most electronegative radicals." The more electronegative radicals draw their binding electron pairs farther away from the carbon to which they are attached, thus increasing the effective nuclear charge of this carbon. The increased charge should tend to shift any other adjacent electrons toward this carbon and thus increase very slightly the effective nuclear charge of the carbon away from which they have shifted. A mechanism of this general character is commonly assumed to explain the transmission of an effect through a chain. The short distance through which such an effect can be detected electrostatically has been pointed out. The postulate of Kharasch and Darkis requires that the electrons be forced away from the carbon with the higher effective nuclear charge toward that with the lower charge. However effective such a postulate may be in explaining chemical behavior, it appears electrostatically unsound.

When the results of Errera, Smyth and Morgan and Höjendahl[21] for the moments of substituted benzenes were found to be consistent with

---

[20] Smyth, *Phil. Mag.*, 47, 530 (1924); Smyth and Morgan, THIS JOURNAL, 49, 1030 (1927); Errera, (8) Table I.

[21] Hojendahl, Nature, 117, 892 (1926).

the hypothesis of a benzene ring forming a plane hexagonal structure, it was thought that the relative electronegativities of radicals could be determined not only by comparing the electric moments of analogous compounds containing the different radicals but also by measuring the moments of molecules in which any two groups to be compared were placed opposite one another in the para-position.[20] Williams[22] has recently constructed a list showing the moments produced by the attachment of each of nine common radicals to the benzene ring. When two groups are in the para-positions, the resultant moment should be the difference of the two separate moments, the signs of the moments being taken into account. Although this relation has been found to hold approximately for many of the simple groups, marked deviations occur frequently when more complex groups are attached.[22,13] Particularly in the ortho- and meta-positions, the groups may attract or repel one another quite apart from their action through the carbons of the ring and the resulting effect upon the moment of the molecule is commonly much greater than any to be expected from electronic shifts in the carbon ring. The repulsive effects of this kind, which have been discussed by Smyth and Morgan[20] for the substituted benzenes, are similar to those occurring in the acetylene dihalides. Because of these large changes external to the ring, it seems useless at present to attempt to treat the possible small electronic displacements and polarities occurring within the ring.

Our consideration of electric moments has shown that alkyl groups do not differ sufficiently in electronegativity to cause any detectable electrical dissymmetry in saturated hydrocarbons. When a halogen atom is attached to a carbon chain, only the first two carbons are apparently affected electrostatically, the β-carbon but slightly. It may be supposed that the shifts of electron pairs induced by the strongly electronegative halogen, or, putting it in other terms, by the large doublet at the end of the chain, are too small, in the carbons beyond the first two, to have any measurable electrostatic effect. On the other hand, the ionization constants of the halogenated fatty acids in Table II show that the effect of a halogen is transmitted through five carbons and an oxygen. Moreover, the assumption of polarities arising from the different electronegativities of radicals appears to be useful in explaining and predicting chemical behavior. It is difficult to believe that polarities as small as they must be, if they exist at all, in the chains of the alkyl groups or in a symmetrically located double bond can have powerful directive influence or greatly affect chemical activity or degree of ionization. The moments of any doublets existing must be so small that they would exert considerable forces only at very short distances and, at these distances, the interatomic forces which vary inversely as a high power of the distance should be so large that one might

---

[22] Williams, *Physik. Z.*, **29**, **683** **(1928).**

expect the effect of the forces due to the possible minute polarities to be negligible in comparison. In a molecule there is a possibility of a great variety of energy levels, many of which may differ from one another too little to give rise to measurable differences in polarity between molecules in which these levels are differently occupied. Too little is known of these levels in simple atoms to permit of intelligent reasoning in regard to complex compounds, but one cannot but wonder if the effects transmitted through long chains and the varied chemical behavior attributed to variation in polarity are not due to changes and differences in the energy levels occupied by the valence electrons. Polarity may occur, but ordinarily as an accompanying result rather than as a determining factor in chemical behavior. Although pronounced polarity is doubtless a factor in chemical behavior, a large portion of the polarities assigned by the various electronic theories of valence must be regarded not as a physical fact but merely as a pragmatic representation of chemical behavior.

Summary

Electric moments are used as a test of those electronic theories of valence which require polarity in the molecule. The absence of electric moment in methane, ethane and the higher paraffins shows that there is no measurable alternating polarity in the hydrocarbon chain or inherent dissymmetry in the electron linkages of alkyl radicals. The absence of variation in the moments of the higher ketones and alkyl halides leads to the same conclusion and shows that in these carbon chains no measurable polarity is transmitted through more than two atoms.

The ethylene double bond has no measurable polarity, but when different radicals are attached on opposite sides of the bond polarity may occur. The absence of rotation about the double bond is evidenced by the difference in moment between the cis and the *trans* isomers of the acetylene dihalides.

It is suggested that the directive influences and effects upon chemical activity commonly attributed to differences in polarity may be due rather to differences in the energy levels occupied by the valence electrons, which may or may not give rise to measurable polarity.

THE PREPARATION OF ANHYDROUS HYDROGEN IODIDE[1]

BY ROBERT T. DILLON[2] AND WILLIAM G. YOUNG[2]

RECEIVED APRIL 3, 1929 PUBLISHED AUGUST 7, 1929

Introduction

In order to prepare chloroform solutions of anhydrous hydrogen iodide needed in the synthesis of 2-butene it was necessary to develop a process by which the desired gas could be obtained readily in large quantity.

Anhydrous hydrogen iodide has been prepared by the following methods: (a) passing hydrogen and iodine over platinum,[3] (b) heating iodine and colophony (resin),[4] (c) dropping water upon iodine and phosphorus, and (d) dropping hydriodic acid upon phosphorus pentoxide.[5]

For the purpose desired these methods have certain disadvantages, as follows: Method (a) is time-consuming and gives a product containing iodine unless a large excess of hydrogen is used or unless the product is liquefied and the hydrogen iodide distilled from the iodine; in Method (b) decomposition products of resin are likely contaminants of the hydrogen iodide; in Method (c) a considerable amount of phosphorus is reduced to phosphine, which is carried along in the gas stream, presumably in the form of phosphonium iodide, and explosions are liable to occur, especially at the beginning of the experiment; in Method (d), a small amount of phosphine is formed.

On the other hand, the different methods have certain advantages, as follows: by Method (a) hydrogen iodide of high purity may be prepared since both the hydrogen and iodine can without difficulty be freed of impurities, and by Methods (b), (c) and (d) a rapid evolution of hydrogen iodide may be obtained. Method (c) is the one usually employed for quantity production when a pure product is not needed, probably because the apparatus is comparatively simple, whereas Method (a) is used when a very pure product is desired. Method (b), apparently, is not generally recognized since it is mentioned only in standard reference works. It possesses obvious advantages as a rapid laboratory or lecture demonstra-

tion preparation. This method was not considered by us because of the probable difficulties involved in removing the volatile decomposition products. Method (d) was tried out and an apparatus developed by the use of which pure anhydrous hydrogen iodide could be obtained rapidly in large quantities. This last is superior to Method (c) both as regards the purity of the product and the rate of production.

Apparatus and Method

Approximately 150 g. of concentrated hydriodic acid, sp. gr. 1.7, was placed in a dropping funnel, B (see figure) and was allowed to drop upon 200 g. of phosphorus pentoxide contained in a 0.5-l. conical flask, C, closed by a wired-on rubber stopper. A slight air pressure insured a steady flow of the acid into the generating flask. The evolved hydrogen iodide, containing traces of iodine, water and phosphine, was purified by passage through an all-glass apparatus. A glass tube, D, filled with phosphorus pentoxide removed mist produced by the vigorous reaction in the generating flask. Iodine and a part of the phosphonium iodide were taken out by a saturated solution of calcium iodide[6] at 0° contained in the bubbler, F. Water was absorbed by phosphorus pentoxide in the tube, G, and small amounts of phosphonium iodide were removed by passage through H, maintained at −25° to −30° by a cooling bath of ice and concentrated hydrochloric acid. The purified hydrogen iodide may be used as desired.

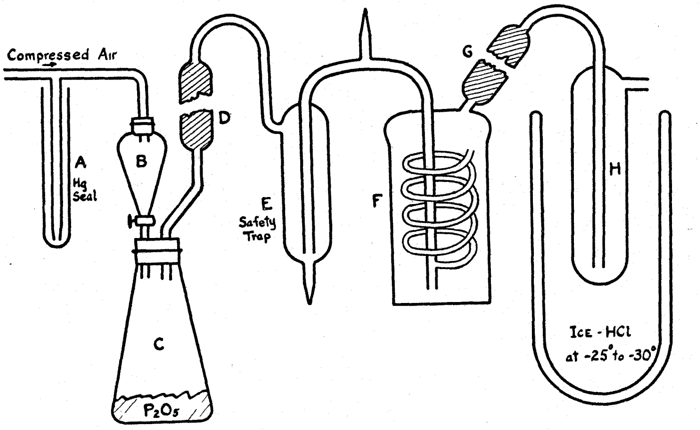

Fig. 1.

The calcium iodide solution, prepared by dissolving 200 g. of the salt in 100 g. of water, removed iodine completely. However, since anhydrous hydrogen iodide in the gaseous state and in solution, for example, in chloroform, is easily oxidized by air and rapidly decomposes when exposed to light, it was necessary to fill the apparatus with nitrogen for the first run and to protect it from light. This latter precaution is of vital importance for obtaining an iodine-free product because even weak, diffused daylight brings about decomposition. Between runs, in spite of these precautions, traces of iodine developed and for this reason it was necessary to discard the gas evolved at the beginning of each run. This formation of free iodine may have resulted in part from the presence of some air introduced while the phosphorus pentoxide supply was being replenished, even though the precaution was taken of passing a rapid stream of nitrogen through the flask before it was connected to the apparatus. Not more than 2 g. of phosphonium iodide crystallized out during the preparation of 650 g. of anhydrous hydrogen iodide. Its solubility in the calcium iodide solution is practically nil since the amount at the end of successive runs increased in proportion to the total hydrogen iodide produced. During each run there was formed in the generating flask a small amount of reddish powder, an intermediate reduction product of the phosphorus pentoxide, which was not investigated.

A saturated aqueous solution of hydrogen iodide prepared by this method gave a negative test for phosphate with ammonium molybdate.

The authors wish to express their appreciation to Professor Howard J. Lucas for his helpful suggestions in the work.

Summary

The description of a method and apparatus is given for the rapid formation of pure anhydrous hydrogen iodide. This is generated by dropping concentrated hydriodic acid upon phosphorus pentoxide and purified by bubbling through saturated calcium iodide, drying with phosphorus pentoxide and cooling to $-30°$.

THE ELECTRONIC INTERPRETATION OF OXIDATION AND REDUCTION

BY WILLIAM ALBERT NOYES

RECEIVED APRIL 11, 1929 PUBLISHED AUGUST 7, 1929

In several papers the attempt has been made to reconcile the positive–negative theory of valence, formerly advocated by myself, Stieglitz, Falk and Nelson, Fry, L. W. Jones and others,[1] with the theories of G. N. Lewis, Kossel and Langmuir, on the basis of the following principles.

1. Nearly all reactions occurring at ordinary temperatures are ionic in character.[2] For electrolytes this is identical with the positive–negative theory and is universally accepted. For other compounds this principle implies that the pair of electrons forming a covalence remains with one or the other of two atoms which separate as they prepare to enter into new combinations.[3]

2. There is a sharp difference between completely polar valences, in which one atom gains and the other loses an electron, and covalences, in which a pair of electrons is shared by two atoms. At the symposium of the Faraday Society in Cambridge, in 1923, I said "The difference

[2] Noyes, *Chem. News*, 90, 228 (1904); THIS JOURNAL, 45, 2959 (1923).

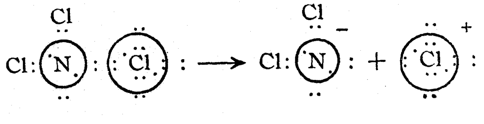
[3] For the hypothesis that a covalence consists of a pair of electrons rotating in opposite directions and including two nuclei within their orbits, see Robert Müller, "Der Aufbau der chemischen Verbindungen (Molekülbau)," Sammlung chem., chem.-tech. Vorträge, Bd. 30 (1928) and Noyes, *Proc. Nat. Acad. Sci.*, 13, 377 (1927).

between polar and non-polar valences is one of degree and not one of kind."[4] In making the statement I had in mind the ionization of weak acids and of tautomeric compounds and of carbon compounds which take part in condensations. It now seems to me better to make the distinction used here and to call covalences which more or less easily separate into positive and negative parts "potentially polar."[5] The distinction is chiefly one of nomenclature.

3. Covalences may be "potentially polar" for three reasons: (a) because one of the atoms has a larger kernel charge than the other and, therefore, a stronger attraction for the pair of electrons. The halogens, with a kernel charge of 7, nearly always retain the pair of electrons when they separate from a carbon atom, which has a kernel charge of 4. Hydrogen, with a nuclear charge of 1, leaves the pair with almost any atom from which it separates. There is no good evidence that it retains the pair and becomes a negative ion, except in separating from a metallic hydride.

(b) Because neighboring atoms in the molecule have a large kernel charge. The bromine of bromo-acetoacetic ester, $CH_3COCHBrCO_2C_2H_5$, is affected in such a manner that it leaves the pair of electrons with the carbon atom and separates in the positive form, $:\overset{\cdot\cdot}{\underset{\cdot\cdot}{\mathrm{Br}}}$, titrating with sodium thiosulfate as equivalent to two atoms of free bromine.[6] Hydrogen atoms attached to a carbon atom adjacent to a carboxyl or aldehyde group or to a carbon atom bearing an hydroxyl group, readily become hydrogen ions. This accounts for many condensation reactions and for the reactivity of alcohols in comparison with hydrocarbons.

(c) Because one of the atoms has a larger number of electrons in the kernel than the other and, for this reason, has less attraction for its valence electrons. The chlorine atoms of nitrogen trichloride give up their pairs of electrons to the nitrogen when the compound is decomposed by hydrochloric acid,[7] in spite of the kernel charge of 5 on the nitrogen atom and of 7 on the chlorine atom, because there are only *2* electrons in the kernel of the nitrogen atom and 10 in the kernel of the chlorine



Phosphorus trichloride, on the other hand, hydrolyzes to phosphorous acid and hydrochloric acid because there are 10 electrons in the kernels

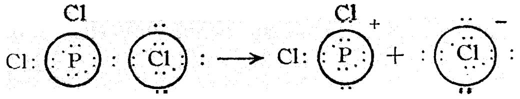
of both phosphorus and chlorine, while the kernel charge of phosphorus is 5 and that of chlorine is 7:



4. In compounds containing only covalences, the number of covalences plus the number of unshared electrons is equal to the number of valence electrons for each atom.

5. In ions, whether simple or complex, there is always some atom which has completed its octet by uniting with a larger or smaller number of electrons than is called for by 4.

6. Atoms may be doubly united either by a doubled covalence or by one covalence and one polar union.

Adherents of the positive–negative theory in its earlier form defined oxidation as the loss and reduction as the gain of electrons. A consideration of the electronic mechanisms in the light of the principles given, leads us to distinguish three types of oxidation.

1. Transfer of an Electron.—When sodium is oxidized by chlorine, the electrons of two sodium atoms are transferred to a molecule of chlorine, giving two chloride ions. When sodium reacts with water, each sodium atom gives its electron to a hydrogen ion, which is the real oxidizing agent. The hydrogen ions are reduced to free hydrogen.

When aluminum dissolves in a solution of sodium hydroxide, there is a similar exchange of electrons between the aluminum and the hydrogen ions of the solution, though the latter are present in small numbers. The fact that the hydroxyl ions unite with the aluminum with a covalence, giving an amphoteric hydroxide and reducing the hydroxyl-ion concentration, is probably an important factor in the phenomenon.

The oxidation of *o*- or *p*-cresol, with evolution of hydrogen,[8] when they are fused with potassium hydroxide, is best explained in a similar manner. The semipolar oxygen atom of the cresylate ion, $CH_3C_6H_4{:}\overset{\cdot\cdot}{\underset{\cdot\cdot}{O}}{:}^-$, enhances the tendency of the hydrogen atoms of the methyl group in the ortho or para position to assume the ionic form, as the hydrogen atoms in the ortho and para positions do in the Kolbe and Reimer–Tiemann syntheses. The hydrogen ions, in this case, do not escape as positive ions, however, but take the electrons from the carbon atom of the methyl group and unite with hydrogen ions of the water, forming free hydrogen. This is essentially the explanation given by Professor Fry, for a similar reaction, at the Columbus symposium.

2. Oxidation by Positive **Hydroxyl.**—This explanation has been given[9]

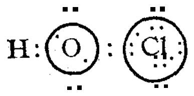
---

[8] Barth, *Ann*, **154, 359** (1870).

[9] Noyes, Bull. *soc. chim.*, 35,437 (1924).

for the oxidation of trimethylamine to trimethylamine oxide by hydrogen peroxide. Hydrogen peroxide separates into a positive hydroxyl, $H:\overset{\cdot\cdot}{O}{}^{+}$, and a negative hydroxyl, $:\underset{\cdot\cdot}{\overset{\cdot\cdot}{O}}:^{-}H$, in the same way that a molecule of chlorine separates into positive chlorine, $:\overset{\cdot\cdot}{Cl}{}^{+}$, and negative chlorine, $:\overset{\cdot\cdot}{Cl}:^{-}$, in reacting with water. This positive hydroxyl can add itself to the two free electrons of the trimethylamine, oxidizing the electrically neutral nitrogen atom to the ionic form,  $CH_3:\overset{CH_3}{\underset{CH_3}{\underset{\cdot\cdot}{\overset{\cdot\cdot}{N}}}}:{}^{+}\underset{\cdot\cdot}{\overset{\cdot\cdot}{O}}:H$. If hydroxyl ions, which have a strong affinity for hydrogen ions, are present, the hydrogen will unite with these, leaving a semipolar union between the oxygen and the nitrogen,  $CH_3:\overset{CH_3}{\underset{CH_3}{\underset{\cdot\cdot}{\overset{\cdot\cdot}{N}}}}:{}^{+}\underset{\cdot\cdot}{\overset{\cdot\cdot}{O}}:^{-}$. If a chloride or bromide ion is present, this does not happen.[10]

The intermolecular oxidation of three moles of hypochlorous acid to chloric acid and hydrochloric acid is most easily explained by a consideration of the close balance in the attraction of the oxygen and chlorine atoms for the pair of electrons forming the covalence between them:



. The chlorine atom with a kernel charge of 7, and 10 electrons in its kernel, has almost the same attraction for the pair of covalence electrons as the oxygen atom has, with a kernel charge of 6 and only two electrons in its kernel.

It has been shown[11] that hypochlorous acid gives the four ions H^{+}, ClO^{-}, HO^{-} and Cl^{+}. Because of the balance between the oxygen and chlorine, two other ions are probable; a positive hydroxyl ion, $H:\underset{\cdot\cdot}{\overset{\cdot\cdot}{O}}{}^{+}$, and the negative chloride ion, $:\underset{\cdot\cdot}{\overset{\cdot\cdot}{Cl}}:^{-}$. By the union of the positive hydroxyl with a mole of hypochlorous acid, the compound $H:\underset{\cdot\cdot}{\overset{\cdot\cdot}{O}}:\underset{\cdot\cdot}{\overset{\cdot\cdot}{Cl}}{}^{+}:\underset{\cdot\cdot}{O}:H$ is formed. The chlorine atom of this compound is positive because the sum of the covalences and unshared electrons is only 6. The loss of a hydrogen atom as an ion leaves a semipolar union between the chlorine and oxygen, $H:\underset{\cdot\cdot}{\overset{\cdot\cdot}{O}}:\underset{\cdot\cdot}{\overset{\cdot\cdot}{Cl}}{}^{+}:\underset{\cdot\cdot}{O}:^{-}$. The hydrogen ion, on the other hand, balances the chloride ion left when the hypochlorous acid separates into positive hydroxyl and negative chlorine. A repetition of this process gives chloric acid.

---

[10] Noyes, THIS JOURNAL, 47, 3025 (1925).

[11] Noyes and Wilson, *ibid.*, 44, 1630 (1922).

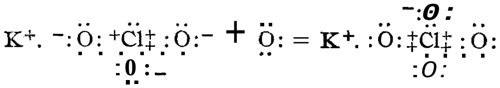
Because of the accumulation of semipolar oxygen atoms, chloric acid has a high ionization constant while that of hypochlorous acid is very small.

F. Foerster[12] nearly thirty years ago gave the following ionic interpretation for the formation of chloric acid

$$ClO^- + 2HOCl = ClO_3^- + 2H^+ + 2Cl^-$$

It will be seen that this is equivalent to the electronic interpretation here given, but less detailed.

3. Oxidation by Semipolar Oxygen Atoms.—When potassium chlorate is kept at its melting point, in the absence of a catalyst, it may be largely converted to potassium perchlorate. This may be explained by supposing the transfer of an electrically neutral oxygen atom from one mole of the potassium chlorate to another



$$K^+.\ ^-{:}\ddot{O}{:}\underset{:\ddot{O}:^-}{{}^+\ddot{Cl}{\ddagger}}{:}\ddot{O}{:}^- + \ddot{O}{:} = K^+.\ {:}\ddot{O}{:}\overset{^-:O:}{\underset{:O:}{{\ddagger}\ddot{Cl}{\ddagger}}}{:}\ddot{O}{:}$$

The oxidation of alcohols by nitric acid, potassium permanganate and other agents which contain semipolar oxygen atoms is probably of this type.

The presence of oxygen in a carbon compound enhances the tendency of the hydrogen atoms attached to the same or to an adjacent carbon atom to separate as positive hydrogen ions. It is well known, of course, that the hydrogen of a primary or secondary alcohol or of an aldehyde group is easily replaced by hydroxyl. In the simplest case, methyl alcohol separates into $H{:}\underset{H}{C}{:}{}^-O{:}H$ and H^+. An electrically neutral oxygen atom would engage the pair of electrons of the carbon atom, but the added oxygen atom would now be negative, $H{:}\overset{:\ddot{O}:^-}{\underset{H}{C}}{:}O{:}H$ and would take up the hydrogen ion. In the compound which results, $H{:}\overset{:\ddot{O}:H}{\underset{H}{C}}{:}O{:}H$, the balance of the affinity of the carbon for the hydroxyl and of the oxygen for the hydrogen, which causes these to separate as water, leaving a double union between the carbon and the oxygen, is well known. That the carbon is doubly united with the oxygen in aldehydes, ketones and acids has been shown by Sugden.[13]

Theoretically any semipolar oxygen atom may separate with its six

valence electrons without disturbing the electronic balance of the atom from which it separates.

Summary

There seem to be at least three types of oxidation reactions.

1. Oxidation by the transfer of an electron from one atom to another.
2. Addition of a positive hydroxyl group, $H:\ddot{O}+$, to an unshared pair of electrons, either of a negative ion or of an electrically neutral molecule. In the latter case a hydrogen ion separates and a semipolar union is formed.
3. Separation of a semipolar oxygen atom in an electrically neutral condition followed by its union with an unshared pair of electrons. The oxygen atom may either remain in the semipolar condition in the new compound or may take up a hydrogen ion and form an hydroxyl group.

TERNARY SYSTEMS. VIII. POTASSIUM CARBONATE, POTASSIUM SULFATE AND WATER AT 25°

BY ARTHUR E. HILL AND SAMUEL MOSKOWITZ

RECEIVED APRIL 15, 1929 PUBLISHED AUGUST 7, 1929

The solubilities of potassium carbonate and potassium sulfate in water have been studied by Blasdale* and more recently by de Ropp,[2] in both cases as part of a study of a four-component system. The two papers give data for the solubilities, however, at the isothermally invariant points only; the solubilities at intermediate concentrations having been determined in this Laboratory, the results are communicated to complete the picture.

Anhydrous potassium carbonate (Kahlbaum's "zur Analyse") and potassium sulfate (purified by recrystallization) were taken in weighed amounts and agitated with measured amounts of water at 25 ± 0.05" until equilibrium was attained, three days being found to be a sufficient time. The saturated solution was analyzed for carbonate by titration against acid, using methyl orange as indicator, with correction for the effect of the sulfate on the end-point. Water was determined as loss by evaporation from platinum dishes. Sulfate was determined only when the amounts had become small, in Line 6 by precipitation as barium sulfate from an acid solution, and in Lines 7, 8 and 9 turbidimetrically. Direct weighing of small pipetted samples gave values for the density of the solution.

TABLE I

SYSTEM K_2SO_4–K_2CO_3 H_2O AT 25°

No.	Original complex K_2SO_4, wt %	Original complex K_2CO_3, wt. %	Saturated solution K_2SO_4, wt. %	Saturated solution K_2CO_3, wt. %	Density	Solid phase
1	..	..	10.7	..	1.083	K_2SO_4
2	21.8	4.6	6.5	6.5	1.103	K_2SO_4
3	17.2	8.3	4.9	8.4	1.122	K_2SO_4
4	17.1	14.1	2.8	16.4	1.170	K_2SO_4
5	13.7	20.4	1.5	23.2	1.230	K_2SO_4
6	14.6	30.1	0.3	35.0	1.348	K_2SO_4
7	8.1	41.5	.08	45.1	1.465	K_2SO_4
8	16.6	40.6	.03	48.6	1.506	
9	8.4	51.6	.03	52.8	1.557	K_2SO_4 +
	2.1	54.8				$K_2CO_3 \cdot 3/2H_2O$
10	..	..	..	52.8	1.557	$K_2CO_3 \cdot 3/2H_2O$

It appears from the table, and also from the figure, that the solubility of the potassium sulfate is reduced to less than 0.1% when the solution is still far from saturation with respect to carbonate, and to 0.03% at the saturation point. It is striking that the solubility is so greatly lessened by the presence of potassium carbonate; so great a salting-out effect upon a reasonably soluble salt is not common.

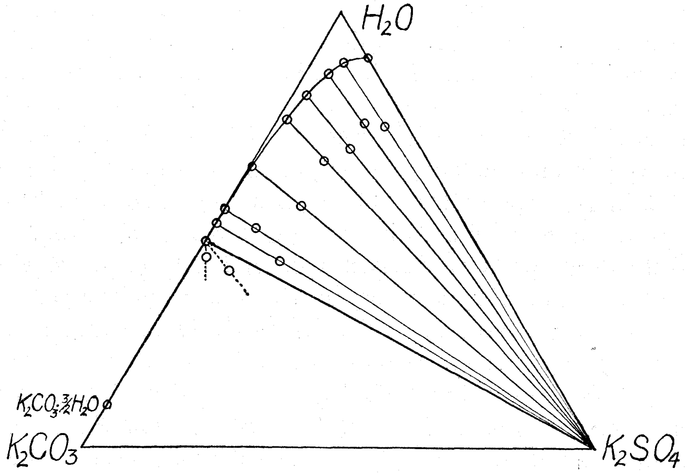

Fig. 1.—25° Isotherms for K_2CO_3–K_2SO_4–H_2O.

Especial attention was paid to the question of possible solid solution of the two salts, since the corresponding sodium salts form the well-known solid solution Glaserite. Algebraic extrapolations of the tie lines from saturated solution through original complex all fell somewhat short of the point representing 100% K_2SO_4, by a matter of several tenths of 1% up to over 1%. Two crystallization experiments, however, from solution rich in carbonate gave solids which analyzed at 99.89 and 99.91% of K_2SO_4, respectively, after correction for the small amount of adhering solution; from this we conclude that the direction of the tie lines was influenced by a small systematic error in the analytical work and that solid solution does not occur in the system at 25° to a measurable extent.

Summary

The solubility of potassium carbonate and potassium sulfate in the ternary system with water at 25° has been measured. Solid solution has not been found to occur.

A GENERAL METHOD OF MEASURING THE PARTIAL PRESSURE OF MERCURY AT ROOM TEMPERATURES

BY L. L. HIRST AND A. R. OLSON

RECEIVED APRIL 15, 1929 PUBLISHED AUGUST 7, 1929

Two methods of determining the activities of amalgam constituents have been used. In the first of these methods the calculation is based on measurements of the electromotive forces of concentration cells. This method has been used successfully in investigating a number of amalgams. In some cases, however, a serious difficulty is encountered. Thus with cesium and barium amalgams, no liquid is known which dissolves enough of the salt to make the liquid sufficiently conducting, and which at the same time is unreactive enough so that no side reactions occur with the metal. In the second method, vapor pressures of amalgams have been measured at high temperatures. The data so obtained must be extrapolated to 25° in order to be used in connection with other data. Because of these difficulties, we have devised a general method of obtaining the partial pressures of mercury over any amalgam at room temperatures.

When light from a mercury arc under properly controlled conditions falls on mercury vapor, the resonance line 2536 Å. is absorbed according to the equation $I = I_0e^{-\alpha pd}$, in which I is the intensity of the transmitted light, I_0 is the intensity of the incident light and a, p and d are the absorption coefficient, the pressure of mercury and the thickness of the absorbing gas layer. If a were a constant, we could determine p directly by measuring the quantity I/I_0. However, it has been shown by Hughes and Thomas[1] that a is not a constant even when a mercury resonance lamp is substituted for the mercury arc. a is also affected by the pressure of foreign gas even though these gases themselves have a negligible absorption for this line. Fortunately it was possible to determine p without evaluating a.

---

[1] Hughes and Thomas, *Phys. Rev.*, **30**, 466 (1927).

In the work of Olson and Meyers[2] it was shown that if mercury resonance radiation falls on a mixture of hydrogen, ethylene and mercury vapor, a reaction occurs which results in a pressure decrease. It was further shown that this reaction was sensitive only to the resonance line (somewhat broadened due to the presence of gases). This reaction, therefore, can be used to measure the amount of mercury resonance light falling on it in a given time.

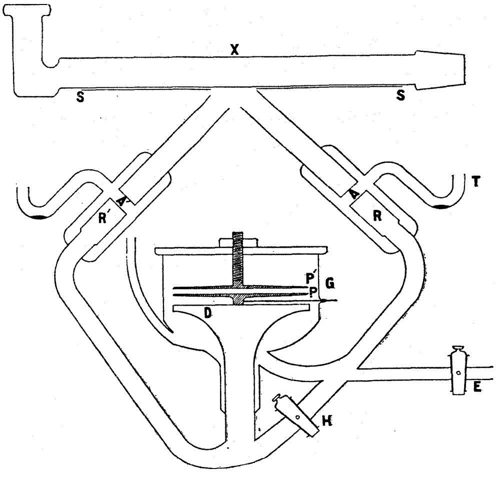

Fig. 1.

The experimental arrangement of our apparatus is shown in Fig. 1. Light from the mercury arc X was passed through the absorption cells A,A' and then into the reaction chambers R,R'. The shield S was used to limit the region of the arc from which light could come. The arc was water cooled and subjected to a magnetic field in the usual way. The absorption chambers were connected to side tubes TT' in which mercury or amalgam could be placed and kept at any desired temperature, and also to the vacuum line so that they could be evacuated or specific gases at known pressures admitted. The reaction chambers were connected to the vacuum line through the stopcocks H and E. They were also connected to the two sides of the differential pressure gage which we have already described.[3] During these experiments the above apparatus with the exception of the arc and the side tube T' was kept in a water thermostat at a temperature of **26.0 ± 0.02"**.

The reaction chambers were filled with a mixture of **93** mole % of hydrogen and 7 mole % of ethylene and saturated with mercury vapor. Stopcocks H and E were then closed. Pure mercury was placed in the side tubes TT' together with **10** cm. of hydrogen. The temperature of the mercury in T' varied from liquid air temperatures to the thermostat temperature. Light from the arc was then permitted to pass through the absorption cell **A,** and the time required to produce a given pressure change in R was noted. The light was next passed through **A'** for a long enough time to produce the same pressure change in R'. This was repeated a number of times and the average rate for each side was calculated. The average rate was necessary in order to minimize the error due to fluctuations in the arc. The change of composition of the reacting mixture was small, for the gage was sensitive to small pressure changes. Even if it had been large, it would have introduced no error for the change was the same in both R and R'. The temperature of T' was then changed, and the above process repeated. The rate of reaction in R decreased with time due to a gradual blackening of the lamp walls, and so the average rates in R' were corrected by the factors necessary to make the rates in R constant. The following table will serve to show how the experimental data were treated,

Olson and Hit, *ibid.*, 51, **2378** (1929).

TABLE I

TREATMENT OF EXPERIMENTAL DATA

R at 26°, rate div./min.	10	9	9.7	9.6	9.8	9.0	9.0	8.6	9.4
R' at 0°, rate div./min.	26.0	24.0	26.5	26.0	25.5	24.5	25.5	26.5	26.0
R at 26°, rate div./min.	8.9	9.0	8.6	8.2	9.2	9.8	Av.	9.2	
R' at 0°, rate div./min.	250	24.5	25.0	25.0	25.5	..	Av.	25.4	

Standard rate for R = 12.3. Therefore corrected rate for R' = (12.3/9.2) X 25.4 = 34.0.

Table II lists all of the corrected average rates.

TABLE II

CORRECTED AVERAGE RATES

Temp., °C.	88	273.1	277.9	282.8	287.0	291.1	299.1
Av. rate div./min.	43.0	34.0	31.3	27.0	21.6	16.9	12.3
Press. Hg, cm. X 10^5	0	1.98	3.20	4.92	7.36	10.72	20.1

The vapor pressures of mercury in the last line of Table II were calculated by the equation of Randall and Langford[4] for the free energy of mercury. In Fig. 2 we have plotted the average rate against the mercury pressure in the absorption cell A'.

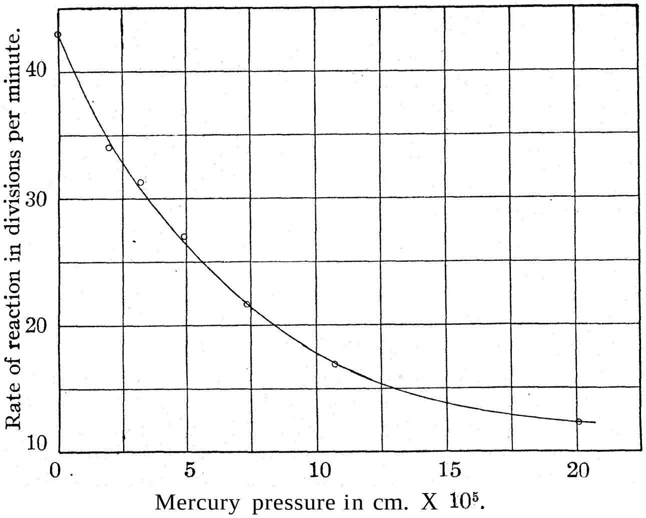

Fig. 2.

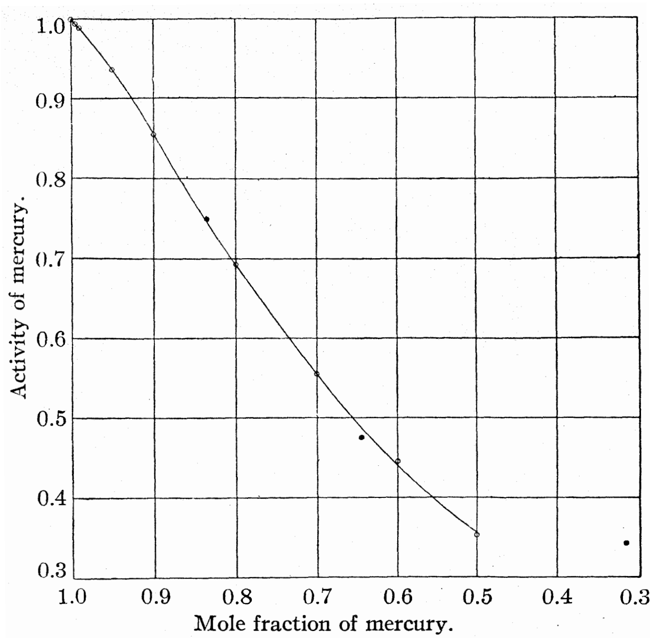
Thallium amalgams were then substituted for pure mercury in T', and kept at the temperature of the thermostat. The rate of change of pressure with time was determined as before. The amalgams were analyzed by the method of Richards and Daniels.[5] The pressure of mercury corresponding to each rate was then obtained from the curve in Fig. 2. From

---

[4] Randall and Langford, unpublished work.

[5] Richards and Daniels, THIS JOURNAL, 41, 1731 (1919).

these pressures and the pressure of pure mercury at 26°, the activities of the mercury in the amalgams were calculated. Table III summarizes these measurements and calculations. The activity of mercury is plotted in Fig. **3,** together with the activity calculated from the electromotive force



○, Richards and Daniels; ●, Hirst and Olson.

Fig. 3.

measurements of Richards and Daniels.[6] It is to be noted that the most concentrated amalgam is a solid.

TABLE III

VAPOR PRESSURE AND ACTIVITIES OF THALLIUM AMALGAMS AT 26°

N_1	1.000	0.835	0.644	0.316
Av. rate	12.3	13.6	18.3	22 5
Press. Hg, cm. × 10^5	20.1	15.15	9.6	6.9
Activity	1.000	0.755	0.477	0.344

It was mentioned above that hydrogen was admitted to the absorption cells. This was necessary in order to make the breadth of the absorption line of mercury about equal to that of the mercury in the reaction chambers. The pressure of hydrogen necessary to do this was determined by measuring the reaction rates for a given pressure of mercury and variable pressures of hydrogen in the absorption cell. Figure 4 shows the depen-

---

[6] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923, p. 270.

dence of the rate on the hydrogen pressure. A slow rate corresponds to a large absorption in the cell. This is the condition for high sensitivity with respect to mercury pressure in the absorption cell. The curve is practically horizontal at 10-cm. pressure; a further increase of hydrogen pressure would slow up the establishment of equilibrium and a decrease would make the method less sensitive to changes in mercury pressure.

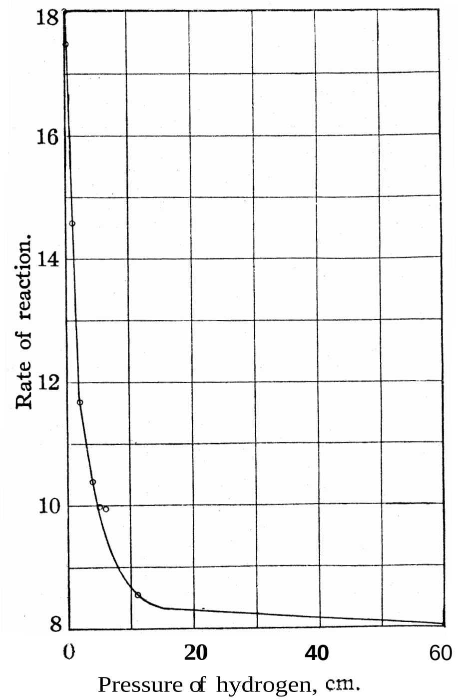


Fig. 4.

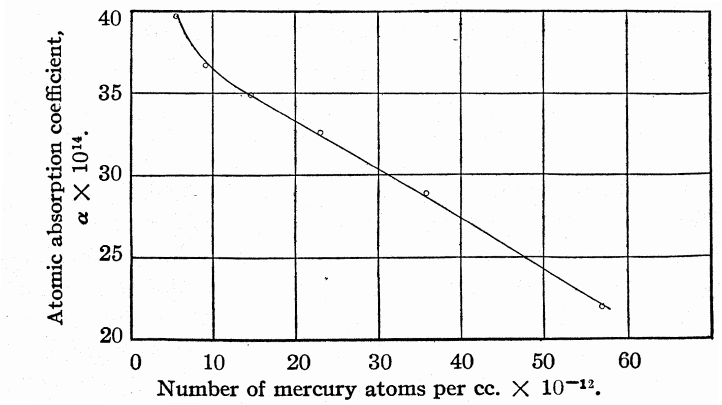

Fig. 5.

From the known pressures and rates as plotted in Fig. 2, it is possible to calculate an average atomic absorption coefficient form ercury at various pressures when subjected to a pressure of 10 cm. of hydrogen. This calculation has been made and the results are plotted in Fig. 5. The absorption coefficient shows the same type of variation that was noted by Hughes and Thomas[1] for pure mercury under its own vapor pressure.

Conclusion

The vapor pressures of mercury over thallium amalgams at 26° have been determined. From these the activities have been calculated and shown to agree reasonably well with those calculated from the electromotive force measurements of Richards and Daniels. The broadening of the absorption line of mercury by hydrogen for its own resonance light has been studied, and the change in the atomic absorption coefficient of mercury in the presence of hydrogen for its resonance line has been determined.

STUDIES RELATING TO METHYL TIN DERIVATIVES. I. INTRODUCTION. II. ACTION OF ZINC ON TRIMETHYL TIN BROMIDE. III. TRIMETHYL TIN PHENOLATE. IV. DECAMETHYLSTANNOBUTANE

BY CHARLES A. KRAUS AND ARTHUR M. NEAL

RECEIVED APRIL 18, 1929 PUBLISHED AUGUST 7, 1929

I. Introduction

The heavier elements of the fourth group are, in many respects, analogous to carbon. Various hydrides of these elements have been prepared and their properties have been found to correspond fairly closely with those of corresponding carbon compounds. The stability of the hydrides decreases with increasing atomic number, so that their study is not generally practicable. We have but few radicals of these elements corresponding to methyl, ethyl, phenyl, etc.

However, if the hydrogen atoms attached to an element, such as tin, are substituted by alkyl or aryl groups, radicals are obtained whose properties correspond closely to those of similar carbon radicals. Thus the group $(C_6H_5)_3Sn$, or triphenylstannyl, bears a close physical and chemical resemblance to triphenylmethyl, $(C_6H_5)_3C$. In the case of most carbon compounds, the tendency of two unsaturated carbon atoms to combine with each other is so great that stable coupling occurs and the group becomes inactive. On the other hand, in the case of the corresponding tin compounds, the coupling is relatively weak and the groups exhibit marked reactivity.

while-such compounds as sodium methyl, sodium ethyl, etc., have been obtained, their reactivity is so great that they are not generally usable for synthetic purposes. This difficulty, in the case of carbon compounds, has been largely overcome through the use of the Grignard reagent, in which an alkyl or aryl group is coupled to magnesium. In the case of tin, compounds of the type $NaSnR_3$ or Na_2SnR_2 are readily obtained and they are convenient reagents for introducing the organic tin groups into various compounds. The alkali metal salts mentioned serve very much the same purpose in the chemistry of tin that the Grignard reagent does in the chemistry of carbon.

Compounds such as sodium trimethyl tin, $NaSnR_3$, are readily soluble in liquid ammonia and in this solvent they react conveniently with many other substances, particularly halogenated compounds. Kraus and Greer[1] have described a number of syntheses in which sodium trimethyl tin was used. In the present investigation the use of the same reagent has been extended to the preparation of various compounds. A considerable number of incidental problems developed which it was found necessary to study and an account of these will be given in the sequel.

II. Action of Zinc on Trimethyl Tin Bromide

Frankland[2] reported that triethyl tin is formed by the action of zinc on triethyl tin chloride in aqueous solution. With a view to utilizing a similar reaction in the preparation of trimethyl tin, the action of zinc on trimethyl tin bromide was investigated. It was found that while reaction takes place between trimethyl tin bromide and zinc, no trimethyl tin is formed. Instead, there are produced tetramethyl tin, trimethyl tin hydroxide and metallic tin.

Procedure.—Trimethyl tin bromide was prepared by adding an equivalent quantity of bromine to tetramethyl tin in the cold,[3] the product being purified by fractional distillation. About 40 grams of this bromide, dissolved in 100 cc. of water, was sealed in a tube with freshly polished strips of zinc. The tube was fitted with a stopcock through which it was evacuated. It was then placed in a bath of boiling water for several days. Initially a red solid was precipitated on the surface of the zinc, but on continued

---

[1] Kraus and Greer, THIS JOURNAL, 47, **2568 (1925).**

[2] Frankland, **Ann.** *Chem. Pharm.,* **85,329 (1853).**

[3] This method of preparing the various halogenated derivatives of tetramethyl tin has since been abandoned in this Laboratory. Mr. Stafford has shown that by heating mixtures of tetramethyl tin with stannic chloride in appropriate proportions, the monochloride, dichloride or trichloride may be obtained at will in practically pure condition. The two liquids are mixed in the cold and the mixture is later heated in a sealed tube until the reaction is complete. The same method has been employed by Mr. Eatough in preparing halogenated derivatives of tetraphenyl tin. This method of preparation is advantageous since there is no loss of organic groups and substantially pure products are obtained. Since writing the above, the same method has been described by K. *A.* Kozeschkow, *Ber.,* 62, **996 (1929).**

heating this disappeared and a volatile yellow oil appeared and settled in the bottom of the tube.

After separating the oil from the supernatant liquid by means of a separatory funnel, it was fractionally distilled. Toward the end of this process needle-like crystals appeared and similar crystals also appeared in the original tube on standing. These crystals volatilized readily, when gently heated, indicating that they were trimethyl tin hydroxide.

The Products of Reaction.—The vapor density of the purified oil was determined and its molecular weight calculated. Using a bulb having a volume of 256 cc., the following data were obtained: 0.1945, 0.1575, 0.2031 g. of subs. at 78.5, 64.2, 81.2-mm. pressure and 26.9, 29.0, 27.2° correspond to the mean molecular weights 181.0, 180.4, 182.6; mol. wt. of $(CH_3)_4Sn$, 178.8.

The boiling point of the liquid was found to be 77.5° (uncorr.); the boiling point of tetramethyl tin is 78.0°. The vapor pressure of the liquid corresponded closely with that of tetramethyl tin. Thus at 0 and 27.7°, the vapor pressure of the liquid was found to be 3.5 and 12.0 mm., respectively, as against 3.6 and 11.6 for tetramethyl tin at the same temperatures.

The strips of zinc were removed from the reaction tube and carefully washed. They were found to be covered with a metallic coating, which was scraped off, dissolved in hydrochloric acid and tested with hydrogen sulfide. A yellow precipitate was formed, indicating the presence of tin.

The action of zinc on trimethyl tin bromide differs from that on triethyl tin bromide. While in the latter case triethyl tin is formed, in the former a complex reaction occurs, the chief product being tetramethyl tin. At the same time, trimethyl tin hydroxide and metallic tin are formed in appreciable quantity.

III. Trimethyl Stannyl Phenolate, $C_6H_5OSn(CH_3)_3$

Preparation.—The phenolate of trimethyl tin is readily prepared by the action of trimethyl tin bromide on sodium phenolate in liquid ammonia. Reaction occurs according to the equation

$$C_6H_5ONa + (CH_3)_3SnBr = C_6H_5OSn(CH_3)_3 + NaBr$$

Sodium phenolate is best prepared by adding phenol, in small portions, to a solution of sodium in liquid ammonia. On adding trimethyl tin bromide to the resulting solution of sodium phenolate, trimethyl tin phenolate is immediately precipitated. The product of the reaction was extracted with ether and, after distilling off the excess solvent, the phenolate was distilled under a pressure of 8 mm. at 109°. Under normal pressure, the liquid boils at 223–224° with some decomposition. It is stable in air in the pure condition but becomes colored on exposure to sunlight. It remains liquid at the temperature of boiling ammonia.

Analysis.—The tin content of the compound was determined by the Carius method. Subs., 0.4015, 0.5213: SnO_2, 0.2381, 0.3111. Calcd. for $C_6H_5OSn(CH_3)_3$: Sn, 46.2. Found: Sn, 46.68, 47.00.

Molecular Weight.—The molecular weight was determined by the freezing point method in benzene in the usual manner. Solvent, 37.03, 37.03 g.; solute, 1.389, 1.927; Δt, 0.718, 1.476°; mol. wt. found, 261.1, 267.7; mol. wt. calcd. for $C_6H_5OSn(CH_3)_3$, 257.

Characterization.—When trimethyl tin phenolate is treated with two equivalents of sodium in liquid ammonia, the following reaction occurs

$$(CH_3)_3SnOC_6H_5 + 2Na = NaSn(CH_3)_3 + C_6H_5ONa$$

The resulting solution is colored slightly yellow due to the sodium trimethyl tin. On adding ethyl bromide to the solution, phenetole and ethyl trimethyl tin are formed. The odor characteristic of phenetole was noticeable but it was not found possible to separate it from the associated tin compound. Accordingly, a solution of trimethyl tin phenolate was treated with one atom of sodium, in which case reaction proceeds as follows

$$2(CH_3)_3SnOC_6H_5 + 2Na = [(CH_3)_3Sn]_2 + 2NaOC_6H_5$$

The precipitated trimethyl tin was allowed to settle, the supernatant liquid was siphoned off and the trimethyl tin was repeatedly washed with fresh ammonia. The insoluble product left behind in the reaction tube melted at 23–25°, which agrees with the melting point of trimethyl tin. On brominating this material, trimethyl tin bromide was identified.

The washings containing sodium phenolate were neutralized with acid and treated with bromine water. A heavy white precipitate was formed, which is characteristic of phenol. On extracting an aqueous solution of the hydrolyzed product with ether and removing excess solvent, an oily liquid was obtained having the odor of phenol.

IV. Decamethylstannobutane

Kraus and Greer have prepared methylated tin derivatives containing chains of three and five tin atoms, corresponding to the general formula $(CH_3)_n + {}_2Sn_n$. In order to complete this series, the corresponding butane was synthesized.

Preparation.—The method of Kraus and Greer was employed, disodium tetramethylstanno-ethane being first prepared by treating two moles of dimethyl tin dibromide with six moles of sodium. Reaction takes place according to the equation

$$2(CH_3)_2SnBr_2 + 6Na = 4NaBr + Na(CH_3)_2Sn{-}Sn(CH_3)_2Na$$

The butane was then prepared by treating the ammonia solution of the above stannide with two moles of trimethyl tin bromide. Reaction proceeds according to the equation

$$Na(CH_3)_2Sn{-}Sn(CH_3)_2Na + 2(CH_3)_3SnBr = \\ (CH_3)_3Sn{-}Sn(CH_3)_2{-}Sn(CH_3)_2{-}Sn(CH_3)_3 + 2NaBr$$

Reaction takes place readily with separation of the stannobutane in liquid form. After evaporation of the ammonia, the liquid was dissolved in ether, the resulting solution was filtered and the ether removed with a pump.

Analysis.—The final product of reaction was analyzed for tin by the Carius method. Subs., 0.2443, 0.1110: SnO_2, 0.2357, 0.1066. Calcd. for $(CH_3)_{10}Sn_4$: Sn, 75.96. Found: Sn, 76.00, 75.65.

Molecular Weight.—The molecular weight of the compound was determined in benzene by the freezing point method. Solvent, 21 90, 21.90 g.; solute, 0.7371, 0.1098 g.; *At*, 0.276, 0.040°; mol. wt. found, 610,627; mol. wt. calcd. for $(CH_3)_{10}Sn_4$, 625.

Properties.—The pure compound is a colorless liquid which is somewhat viscous. It oxidizes readily with the formation of a white solid.

With this compound, the complete series of derivatives up to and including the pentane have been synthesized. The synthesis of the butane further confirms the mechanism of the reduction reactions of the dimethyl tin halides suggested by Kraus and Greer.[4]

Summary

1. The action of zinc on trimethyl tin bromide in aqueous solution has been studied. The chief product of reduction is tetramethyl tin. Some trimethyl tin hydroxide and metallic tin are alsa formed.

THE MEASUREMENT OF THE CONDUCTANCE OF ELECTROLYTES.

II. IMPROVEMENTS IN THE OSCILLATOR AND DETECTOR

BY GRINNELL JONES AND GILES M BOLLINGER

RECEIVED MAY 4, 1929 PUBLISHED AUGUST 7, 1929

The new form of alternating current bridge described in the first paper of this series[1] has been used in the study of the principles of design of cells for the measurement of the conductance of solutions. Although in most respects this bridge has met our most exacting requirements, a few improvements in the accessories of the bridge have been made which it seems desirable to describe without waiting until the results on cell design can be published.

Modification of the Oscillator to Give Low Voltages.—During the work on cells it became evident that it would be advantageous to reduce the voltage used considerably below the values (2 to 5 volts) which had been used in the study of the bridge itself and in the study of resistance boxes, in order to reduce the heating effect of the current on the cells and to study polarization and the variation of resistance with voltage which has been reported by others.[2]

The vacuum tube oscillator as originally built and described in the first paper of this series contained an output coil having 140 turns and when this coil was as close as possible to the oscillating coil, gave a maximum voltage of 5.2 volts at 2280 cycles, 4.3 volts at 1090 cycles and 2.3 volts at 500 cycles, when used to measure 10,000 ohms in the bridge. When measuring lower resistances, the voltage was somewhat less. The voltage could be diminished continuously down to about 0.2 volt by moving the output coil along its axis away from the oscillating coil to a distance of six inches, thus diminishing the inductive coupling. To reduce the voltage still more by moving the coil still farther away from the controlling coil did not seem to be wise because this would reduce the influence of the controlling coil without at the same time reducing the influence of outside disturbing factors such as electric light circuits and nearby electric motors. An attempt to reduce the voltage by the use of

---

[1] Grinnell Jones and R. C. Josephs, THIS JOURNAL, 50, 1049 (1928).

[2] W. A. Taylor and S. F. Acree, ibid., 38, 2416 (1916); C. A. Kraus and H. C. Parker, ibid., 44, 2438 (1922).

taps on the output coil proved to be unsatisfactory and was abandoned. When a tap is used, the unused turns in the coil are thus appended in an unsymmetrical manner to one end of the effective part of the output coil. The unbalanced capacitance between this appended portion and the grounded shield makes it difficult to make a proper ground balance. We, therefore, built two additional output coils, one of 36 turns and one of 12 turns, each shielded by a grounded toroidal coil as described in the first paper, and mounted so as to be movable on their common axis, making it possible to vary the closeness of the coupling with the oscillating coil. The coils not in use are completely disconnected from the circuit. As thus modified our oscillator can be adjusted so as to give any desired voltage from the maximum stated above down to 0.01 volt. Above 0.3 volt these voltages can be measured by means of a thermal voltmeter. Below 0.3 volt the voltages can be estimated with sufficient accuracy for our purposes from the position of the output coil with reference to the oscillating coil. Additional condensers of smaller capacitance than those originally provided were added to the oscillator so that by their use the frequency could be adjusted up to 5000 cycles.

We found that when using very low voltages across the bridge the sensitiveness was no longer adequate for our purpose. When measuring 1000 ohms with 4 volts, the setting of the bridge could be definitely determined to within 0.001 ohm or to one part in a million, but when the voltage was below 0.4 volt it was no longer possible to maintain a sensitiveness of 0.001%, which is the precision we desired. The best remedy seemed to be an improvement in the amplifier.

Improvements in the Amplifier.—The transformers in our two-stage amplifier, which had a step-up turns ratio of 3.5:1, were built by the General Radio Company for use in radio receiving sets and were the best commercially available at the time the bridge was originally built. Recent advances in the science of radio indicated that a substantial improvement in the performance of our amplifier could be obtained by replacing these old transformers by others of superior design.

It has been pointed out by Lord Rayleigh[3] that the telephone to be used as a detector in an alternating current bridge will have the maximum sensitiveness if it is designed so that the impedance of the telephone equals the impedance of the bridge. It is an obvious extension of this principle that when an amplifier is used between the bridge and telephone it is an advantage to have the impedance of the primary in the transformer of the amplifier match the impedance of the bridge and to have the impedance of the secondary of the transformer match the impedance of the vacuum tube which serves as its load. Since the impedance of the bridge varies with the resistance being measured and the impedance

---

[3] *Lord* **Rayleigh,** *Proc. Roy. Soc. London,* 49,203 (1891).

of the primary in the transformer with a fixed inductance varies with the frequency being used, the ideal transformer would have a primary inductance which is adjustable to the most suitable value for every measurement, and a secondary which is adjustable to maintain the best step-up turns ratio.

But there are other considerations in the design or selection of transformers for this purpose. The closer the coupling between the primary and secondary, the more nearly will the effective amplification factor equal the ratio of the number of turns of winding in the secondary to that in the primary. It is also desirable to have a high step-up turns ratio, but if the turns ratio is made too great, the effective amplification factor in the transformer becomes greatly dependent on the frequency, having a sharp maximum at the natural frequency of oscillation of the secondary as determined by the inductance and distributed capacitance of the secondary and its load. The greater the resistance being measured, the sharper is the maximum of the effective amplification at the natural frequency of the oscillation of the secondary.

In the design of transformers for audio frequency amplifiers in radio receiving sets it is important that the amplification factor be as nearly as possible independent of the frequency throughout the audio frequency range to avoid distortion of music. This requirement limits the step-up ratio that can be used for this purpose. To avoid distortion, it is desirable to have the coupling between the primary and secondary as nearly perfect as possible. In recent years iron of higher permeability has become available for the core of transformers, which improves the coupling so that the step-up ratio can be increased to 6:1 without distortion, whereas a step-up ratio of 3.5 was the maximum that could be used without distortion until the better iron became available. Since we never use more than one frequency at a time it is not essential for our purposes that the effective amplification factor should be independent of the frequency and, therefore, it is possible to use greater step-up ratios.

It did not seem practicable to build a transformer which would have a primary adjustable to the most suitable inductance for each measurement and a secondary adjustable to maintain the most suitable step-up ratio and at the same time maintain a close coupling between the primary and secondary. Nor could we find available by purchase any audio frequency transformers with as low a primary inductance and as high a step-up ratio as was shown by some preliminary experiments to be desirable for our purpose. However, this difficulty was overcome through the kindness of Mr. Melville Eastham of the General Radio Company, who gave orders to have one of their standard transformers modified at the factory to serve our needs. Their transformer, Type 284,S24, which has 15,500 turns in the secondary, was modified by bringing out a tap on the primary at 400 turns (Tap I), and a tap at 1000 turns (Tap II) in addition to the original full primary winding of 2500 turns (Tap III), thus making available primary inductances of 0.3, 1.8 and 12.0 henrys, and turns ratios of 39:1 and 15.5:1 and 6.2:1, according to the tap used. In this way some adjustability is secured.

Then, through the kindness of Professor R. F. Field, who made available to us the facilities of the Cruft Laboratory and aided us by helpful suggestions, we were able to determine the actual effective amplification factor of our new modified transformer at 20 different frequencies covering the range 400 to 20,000 cycles and with various resistances covering the range 0 to 100,000 ohms in series with the primary of the transformer, using each of the three taps on the primary winding. These data are not published in full because they are applicable only to a particular instrument and are, therefore, not of general interest, but are shown graphically in Fig. 1. Extracts from these data are given in Table I to illustrate the advantages which can be gained by having a transformer which is well designed for the purpose and has taps giving some adjustability. The first column gives the resistance being measured in the bridge, R; the second column gives the corresponding effective resistance in series with the primary of the transformer, which is $(1000 + R)/2$ in our bridge with fixed ratio arms of 1000 ohms each. The body of the table gives the corresponding effective amplification factor (electromotive force at the terminals of the secondary divided by the electromotive force applied across the resistance given in the second column and the primary in series) as determined at the frequencies shown and with the taps indicated in the heading. Under the I in the heading are given the data obtained when using the first tap with 400 turns in the primary and a turns ratio of 39:1, and an inductance of 0.3 henrys; under II are the data obtained when using the second tap with 1000 turns and a turns ratio of 15.5:1 and an inductance of 1.8 henrys, and under III are the data with 2500 turns in the primary and a turns ratio of 6.2:1 and an inductance of 12.0 henrys. The figures given in parentheses are obtained by interpolation from

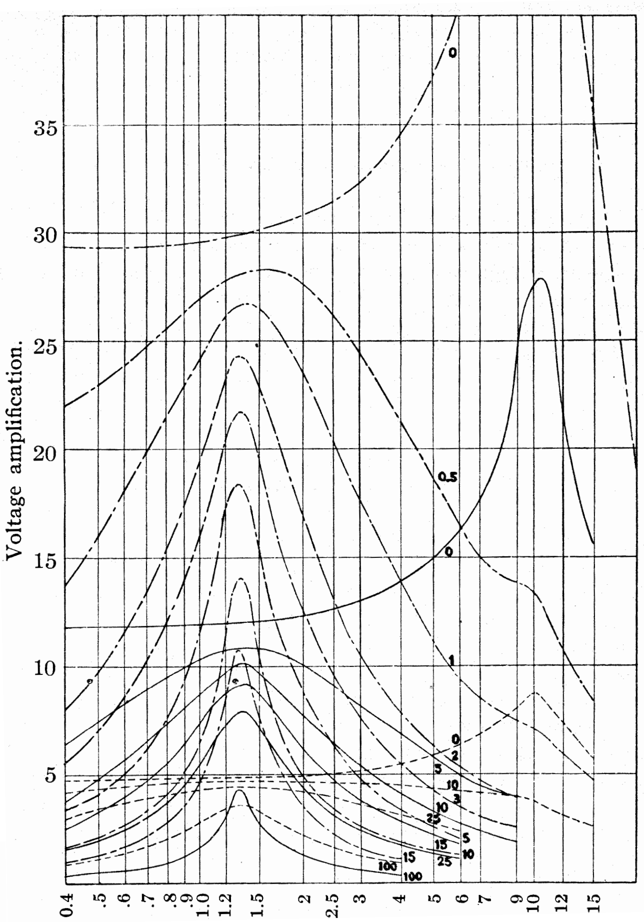
curves. The tap which should be chosen at any given resistance and frequency is shown by italicizing the highest amplification. The great improvement over the original transformer, which had a turns ratio of only 3.5 to 1, and the advantage of having several taps are quite apparent from this table and the curves of Fig. 1. Thus, for example, when measuring 1000 ohms at 1200 cycles, the lower tap (I) gives an amplification factor of 26.1, which is more than five times the amplification factor of 4.7 given by Tap III, whereas when measuring 19,000 ohms at 5000 cycles, Tap III gives an amplification factor three times as great as Tap I. In



Frequency in kilocycles, logarithmic scale.

— — — —, Tap I; ————, Tap II; - - - - - - -, Tap III.

The numbers in the figure indicate the resistance in kilohms placed in series with the primary winding.

Fig. 1.—Voltage amplification of special transformer.

the curves drawn from the complete data (Fig. 1) the natural frequency of the secondary is indicated by the maxima appearing at 1300 cycles.[4]

The selection of the most suitable tap depends both on the frequency being used and on the resistance being measured and cannot be stated in any simple manner; it can be inferred from the curves. Thus, for example, inspection of Fig. 1 shows that the curves for Tap I and for Tap II with 5000 ohms in series (which is the effective value when the resistance being measured in our bridge is 9000 ohms) cross each other at 920 cycles and again at 1800 cycles, which means that the two taps give equal amplification factors (of about 10 at 920 cycles and about 11 at 1800 cycles) with 9000 ohms in the bridge, whereas when using frequencies within this range Tap I is superior, and when using frequencies less than 920 or greater than 1800, Tap II gives the higher amplification factor.

In general, Tap I is to be preferred when measuring low resistances (3000 ohms or below) with any frequency between 500 and 3000 cycles, and can be used to advantage even when measuring high resistances if the frequency is near the natural oscillation frequency of 1300 cycles. Tap III is not to be preferred when measuring any resistance below 9000 at any frequency below 5000. When measuring high resistances, the choice between the three taps depends on the frequency. Thus, for example, when measuring 19,000 ohms in the bridge (equivalent to 10,000 ohms in series with the transformer), Tap III is best below 450 cycles, Tap II between 450 and 1150 cycles; Tap I is best in the range 1150 to 1550 cycles, which is near the natural oscillation frequency of 1300; Tap II again becomes the best in the range 1550 to 3500 and Tap III at all frequencies above 3500 cycles. It is possible to build a transformer so that it will have its natural oscillation at any frequency that may be desired.

By employing a primary winding with still fewer turns and hence a higher turns ratio than is given by Tap I—say, for example, 200 turns and a turns ratio of 78—a correspondingly greater amplification would be obtained at 1300 cycles, but calculations indicate that the curves would drop so sharply on either side of this optimum frequency when the primary was placed in series with a resistance greater than 500 ohms (the lowest limit in our bridge with fixed ratio arms of 1000 ohms each) that the advantage of a gain in the amplification factor would be offset by the narrowness of the range of frequencies over which it would be apparent.

The old transformer, originally used between the first and second stages of the amplifier was replaced by a new transformer, General Radio Type 285H, which was not on the market when the amplifier was originally built. This was an improvement because the step-up ratio was 6:1 instead of 3.5:1 and because the quality of iron is better than that in the old transformer.

The effect of these improvements was an increase of at least ten-fold in the sensitiveness of the bridge when measuring 1000 ohms with 1090 cycles and about three-fold

---

[4] With little or no additional series resistance in the primary circuit a maximum appears for each tap at about 10,000 cycles. The frequency at which this maximum occurs is determined by the natural frequency of the secondary and the coefficient of coupling of the transformer. The maximum voltage rise at this point depends upon the losses in the transformer and is also greatly reduced by any resistance in series with the primary. The greatest amplification factor which we found with our transformer was nearly twice the turns ratio. In the case of Tap I the amplification factor rose to a maximum value of 70 (not shown in the figure). The high increase in amplification at this point is not available for practical use because it occurs at the extreme limit of the audible range and because it disappears as soon as any appreciable resistance is placed in the primary circuit.

when measuring 30,000 ohms. The effective amplification factor of our two-stage amplifier with these improvements varies greatly with the resistance being measured and the frequency being used, but may be estimated to be of the order of magnitude of 10^3 to 10^4.

The Use of a Wave Filter.—These changes in the amplifier brought in their train two disadvantages which were especially evident when working with low voltages. The increased efficiency of the amplifier not only magnified the desired signal but also magnified all of the disturbances, such as the so-called "tube noises," sixty-cycle hum from the electric light circuit, sparks at the commutators of motors, and at the relay control of thermostat heater, all of which were audible in the telephones. The main signal was weakened by lowering the voltage of the oscillator without any corresponding weakening of these noises, so that they became more disturbing. Fortunately the remedy was easy by using so-called wave filters. By placing a variable inductor and a variable condenser both in parallel with the telephone and then adjusting the inductance and capacitance until the relation $LC\omega^2 = 1$ is satisfied, the disturbing noises are greatly reduced with very little weakening of the desired signal in the telephone. The variable inductor was a special instrument made for us by the General Radio Company. It consisted of a coil of 2500 turns of No. 28 enamel-covered wire and a sliding E-shaped laminated iron core. The center tongue could be inserted inside the coil and the outer tongues came close to the coil on the outside. By varying the position of the core with reference to the coil, the inductance could be varied from 0.12 to 1.7 henrys. The sliding core was provided with a pointer and a calibrated scale. For a variable condenser we used a General Radio decade box with dial switches giving capacitances from 0.01 to 1.0 microfarad. With the inductor set at 0.225 henry, capacitances of 0.5 μf, 0.1 μf and 0.02 μf are suitable for 500, 1090 and 2280 cycles, respectively.

Errors at Low Voltage Due to Mutual Inductance.—The other difficulty which followed the improvement in the amplifier was the observation that when using low voltage across the bridge, the setting of the bridge at balance could be varied by merely reversing the lead wires from the amplifier to the midpoint of the bridge. We had tried this experiment on several occasions in the past without finding the effect but these experiments had been made with comparatively high voltages. We now found by experiment that with the oscillator placed about five feet from the bridge the percentage effect of reversing the amplifier lead wires (1) decreased as the voltage across the bridge was increased and became negligible (*i. e.*, less than 0.001%) when 4 volts were applied at the ends of the bridge; (2) increased with the resistance being measured in the bridge; (3) was greatest when the tap at 400 turns on the primary in the first transformer of the amplifier was in use, and least when the full

2500 primary turns were used; (4) decreased with increase in frequency; (5) could be varied by rotating the oscillator on a vertical axis and a position of minimum effect could be found; (6) could be varied by rotating the amplifier and telephones. At its worst, the effect of reversing the amplifier leads was a change of 0.45% in the bridge setting. Moreover, it was noticed that a feeble note could be heard in the telephones when the amplifier was entirely disconnected from the bridge if the oscillator was operating.[5] The note was more intense when the wave filter was connected to the telephone than when it was removed. This note was at the frequency of the oscillator and stopped when the oscillator stopped and, therefore, must have been due to a direct transfer of energy from the oscillator to the coils in the transformers of the amplifier and to the coils in the telephone and wave filter through their mutual inductance.[6] That meant that as a result of this mutual inductance between oscillator and detector there was an induced alternating electromotive force at the ends of the lead wires from the amplifier. If the bridge were at true balance so that the potential between the midpoints was exactly zero and then the lead wires were connected to the bridge, a note would be heard in the telephone, and in order to get silence in the telephone, the bridge setting would have to be changed sufficiently to give a potential between the midpoints equal in magnitude and opposite in phase to the potential induced in the amplifier. On reversing the lead wires, the bridge setting would have to be changed in the opposite direction from its true setting in order to obtain a silence in the telephones. The difference in bridge setting before and after reversing the lead wires is thus twice the error caused by the mutual inductance between oscillator and detector and the average setting would be correct. The induced electromotive force at the end of the amplifier lead wires is independent of the voltage applied to the bridge because it depends upon the variable magnetic field of the oscillating coil and is not appreciably influenced by the choice or position of the output coil. The induced electromotive force at the end of the amplifier lead wires is so small that when 4 volts is applied across the bridge it has a negligible effect, but can become appreciable as the applied voltage is lowered.

Fortunately there is a simple and effective remedy for this error by moving the oscillator to a considerable distance. When the oscillator was moved to a distance of 35 feet from the bridge, the effect of reversing

---

[5] J. L. R. Morgan and O. M. Lammert, THIS JOURNAL, 48, 1231–1232 (1926), have observed a similar effect when using a Vreeland oscillator and have suggested the proper remedy of moving it to a safe distance. They say nothing about the variation of this error with the voltage used and do not suggest the use of an oscillator with a lower external field than the Vreeland oscillator.

[6] The oscillator was enclosed in a grounded metallic box and, therefore, the effect could not have been due to a variable electrostatic field.

the lead wires disappeared entirely and no note could be heard in the telephones when the amplifier was disconnected from the bridge.

Having found that the influence of the variable magnetic field of the oscillator on the detector became significant when using low voltages, it was necessary to reexamine the possibility of error due to the effect of this field on the bridge itself at the lower voltages. This was tested by changing the lead wires from the resistance box to the rest of the bridge, by reversing the lead wires from the oscillator to the bridge and by moving the oscillator. Thus, for example, measuring 30,000 ohms with 4 volts and 1090 cycles with the oscillator at a distance of five feet from the bridge, the error due to mutual inductance between the oscillator and the bridge itself was only 0.0003%. This error is negligible and, together with other similar experiments not reported in detail, confirms the conclusions drawn in the earlier work with this bridge at relatively high voltages. When the voltage was reduced to 0.01 volt without changing any of the other conditions given above, the error was 0.3%. Numerous other experiments were made to determine the influence of frequency, resistance being measured and type of resistance box, but these experiments need not be discussed in detail since the removal of the oscillator to a safe distance is a complete and perfect remedy.

If the available room does not permit moving the oscillator to a safe distance, reliable results can be obtained by taking the mean of the four readings obtained by reversing the lead wires from both the amplifier and the oscillator to the bridge. This is analogous to the usual practice of eliminating error due to thermoelectric effects in direct current measurements by means of reversing switches. Effective magnetic shielding of the oscillator is so difficult as to be hardly practicable, but the oscillator may be improved so as to reduce its outside electromagnetic field.

Grateful acknowledgment is made for an appropriation from the Milton Fund for the expenses of this research.

Summary

1. When measuring the conductance of solutions it is desirable to use a low voltage in the bridge. A modification of the oscillator to give low and controllable voltages is described.

2. The use of low voltages in the bridge diminishes the sensitiveness. The best remedy is to improve the amplifier. The principles of design of the transformer for a vacuum-tube amplifier are discussed and means of increasing the sensitiveness described.

3. The use of a wave filter in parallel with the telephone is recommended.

4. The mutual inductance between the oscillator and detector and between oscillator and bridge may cause an error in the measurement

of the conductance of solutions when low voltages are being used and means for the discovery and elimination of this error are explained.

THE PREPARATION OF ANTIMONY-FREE ARSENIOUS OXIDE AND THE ESTIMATION OF MINUTE AMOUNTS OF ANTIMONY IN ARSENIOUS OXIDE

BY C. W. FOULK AND P. G. HORTON

RECEIVED MAY 15, 1929 PUBLISHED AUGUST 7, 1929

In the preparation of arsenious oxide of a high degree of purity, antimonous oxide is, by far, the most troublesome of the impurities to remove. Chapin[1] seems to be the first to call attention to the importance of this impurity and has given a method for removing it. He points out that it is impossible to accomplish this by the usual methods of purification such as recrystallization and sublimation; indeed, he states that it is entirely possible after recrystallization and sublimation to end with a "purified" arsenious oxide more impure than the original material. On the other hand a number of careful workers have regarded these methods as sufficient. Washburn,[2] in his investigation of the theory and practice of the iodimetric determination of arsenic acid, purified arsenious oxide by recrystallization from hot water and by sublimation. Baxter and Coffin[3] in their work on the revision of the atomic weight of arsenic say, "commercial C. P. arsenious oxide was recrystallized three times from dilute hydrochloric acid solution and after being rinsed with water and centrifugally drained, it was converted into arsenic acid by means of nitric and hydrochloric acid in a porcelain dish," and "arsenious oxide was twice resublimed in a current of dry air and then once recrystallized from dilute hydrochloric acid solution."

In the present investigation Chapin's work was repeated and his method found to be all he claimed for it, but inadequate if the product is to be used in atomic weight determinations or other precise work. The following proposed method is shorter and is believed to effect not only the complete removal of antimony but to a very large extent that of all other impurities as well.

Briefly stated the new method consists in converting arsenious oxide into arsenious chloride which is then repeatedly shaken out in a separatory funnel with concentrated hydrochloric acid to remove antimony. The arsenious chloride is next hydrolyzed with water to give arsenious oxide

[3] Baxter and Coffin, *ibid.*, 31, 297 (1909).

again, which then may be subjected to the usual methods of purification such as recrystallization and sublimation.

Preparation of Arsenious Chloride.—Arsenious chloride is usually prepared by distilling a hydrochloric acid solution of arsenious oxide in a current of hydrogen chloride gas. This distillation method has been used by a large number of workers for the detection and estimation of arsenic and has been most recently studied by Roark and McDonald,[4] who give it as an effective means of separating arsenious chloride from antimony, lead, copper, zinc, iron and calcium. The present writers find, however, that unless the arsenious chloride is redistilled several times, it still contains traces of antimony.

The apparatus used for the preparation of the arsenious chloride consists of a one-liter pyrex distilling flask connected to an ordinary condenser. The condenser is provided with an adapter reaching nearly to the bottom of a 700-cc. Erlenmeyer flask used as a receiver and kept cool with ice.

In a typical experiment a solution of 150 g. of arsenious oxide in 350 cc. of concentrated hydrochloric acid was distilled in a current of hydrogen chloride gas from a suitable generator.[5] The distillate consists of two layers, oily arsenious chloride and hydrochloric acid. As distillation proceeds the distilling flask is recharged from time to time wth arsenious oxide until the desired amount of arsenious chloride is obtained.

Removal of Antimony from the Arsenious Chloride.—It was discovered that antimonous chloride is much more soluble in concentrated hydrochloric acid than in arsenious chloride and hence can easily be removed from the arsenious chloride by repeatedly shaking with portions of concentrated hydrochloric acid and subsequent separation of the two layers. So great is the difference in the solubility of antimonous chloride in the two layers that the shaking out with only a few portions of acid will remove completely a considerable amount of antimonous chloride. The procedure is as follows.

To the oily arsenious chloride in a separatory funnel is added two-thirds of its volume of concentrated hydrochloric acid and the separatory funnel shaken one minute. (The arsenious chloride layer will be diminished in volume about 10% due to its solubility in the acid.) The lower layer is now carefully drawn off and the shaking out process repeated with a fresh portion of acid until the acid layer shows no antimony by the following test.

Test for Antimony.—In order to test the acid layer for antimony it is

---

[4] Roark and McDonald, *J. Ind. Eng. Chem.*, 8, 327 (1916).

[5] The hydrogen chloride generator used in this work was of the type developed by Sweeney, THIS JOURNAL, 39, 2186–2188 (1917). However, if preferred, the concentration can be kept up just as effectively by frequent additions of concentrated hydrochloric acid direct to the distilling flask.

transferred to the distilling apparatus and heated only as long as any oily arsenious chloride which it holds in solution distils over. The residue in the distilling flask is then transferred to a beaker and treated, while still hot, with hydrogen sulfide. All of the arsenic remaining in the acid is precipitated as yellow arsenious sulfide, leaving antimony in solution. The precipitate is filtered off using a double filter paper, on account of the action of the strong acid, and the filtrate diluted with three times its volume of water and again saturated with hydrogen sulfide. Under these conditions, antimony, if present, will come down as orange antimonous sulfide. In the detection of small amounts of antimony, however, the solution should be allowed to stand for a day or two after passing in hydrogen sulfide, for sometimes an orange-colored turbidity may later develop into a distinct precipitate.

The advantage of this method lies in the fact that the antimony can be removed from very large amounts of arsenious oxide, thus permitting the detection of less than 0.001%. Furthermore, when the amount of antimony is very small a fairly good quantitative determination can be made by comparing the precipitated sulfide with a series of similarly prepared precipitates of known amounts of antimony. The following is a typical experiment with the method.

By means of a dilute standard solution, **3.7** mg. of antimonous chloride was added to 300 g. of arsenious chloride, free from antimony. This is at the rate of one part of antimony in 150,000 of the chloride or in 160,000 of the oxide. The arsenious chloride was then shaken once with two-thirds of its volume of concentrated hydrochloric acid. The acid was then distilled until no more oily drops of arsenious chloride could be seen passing over.[6] The residual acid in the distilling flask was next treated with hydrogen sulfide as described above and after removing the sulfide of arsenic the solution was diluted and again saturated with hydrogen sulfide. An orange-colored precipitate was obtained slightly less in bulk than that from 3.7 mg. of antimony trichloride precipitated in the same way, that is, by saturating its concentrated hydrochloric acid solution with hydrogen sulfide, diluting and again passing hydrogen sulfide into it.

Arsenious Oxide by Hydrolysis of the Chloride.—Having obtained antimony-free arsenious chloride, the final step of converting it into the oxide is accomplished simply by allowing the chloride to run slowly from a separatory funnel into a large beaker of boiling water with vigorous stirring. On cooling, arsenious oxide separates as a fine white solid and after being filtered and washed free from acid it can be further purified if desired by recrystallization and sublimation.

---

[6] The usual situation will be the detection of antimony in arsenious oxide in which case, if only a trace of antimony is suspected, 100 *g.* of the oxide is converted into the chloride by the method described above and the residual acid solution in the distillation flask is then examined for antimony.

Summary

A rapid and simple method for the preparation of antimony-free arsenious oxide has been described, and also an application of this method to the qualitative detection and rough quantitative estimation of minute amounts of antimony in arsenious oxide.

COLUMBUS, OHIO

NOTE

An Inexpensive Pyrex Conductivity Cell.—Because of its small thermal expansion and its chemical resistance, pyrex glass is most suitable for the construction of conductivity cells, hydrogen electrodes and similar apparatus. Unfortunately there is considerable difficulty in making satisfactory seals of platinum to pyrex. The writer recently required a conductivity cell which would be gas tight at five atmospheres' pressure and withstand the action of solutions of sulfur dioxide, so that a pyrex cell seemed advisable if it could be constructed. The makers of pyrex were not able to recommend any suitable method of construction but eventually by making use of the suggestions of Housekeeper[1] a suitable cell was made. As the cell is easily and cheaply made and as the construction may be readily modified for other uses, it is described herewith.

The essential point in the construction is that platinum foil, if *sufficiently* thin, may be fused firmly onto the surface of any glass. The cell used by the writer was in the form of a tube about one centimeter in inside diameter with electrodes about six by twenty millimeters spaced about ten centimeters apart. The platinum foil used was a piece recovered as salvage from a platinum resistance furnace and was in the form of a ribbon 6 mm. wide by 0.7×10^{-3} mm. thick. Somewhat heavier foil would probably be satisfactory but was not tried. A piece of this foil was cut approximately as shown at A and the 1-cm. pyrex tube had a three-millimeter side tube attached, as shown at B. The piece of foil was then put in so that the narrow tail extended into the side tube while the wider portion was bent around the inside of the large tube as shown by the dotted line in B and C. The wide tube was then heated to softening and the foil gently pressed into contact with the softened glass, a heavy piece of platinum wire being used to do the pressing. After this portion of the foil had been attached, the side tube was heated at the junction with the large one until it fell in on the foil. A gentle pinch with the tongs when the glass was soft ensured a tight joint. Enough of the tail projected

beyond the seal to make contact with mercury in the side tube, which could be lengthened and bent in any convenient way. All work was done in an ordinary blast lamp using gas and air. The foil adheres firmly to the large tube and forms an electrode which is definitely fixed. No difficulty was found when the platinum black was deposited and the cell with two such electrodes was used repeatedly at temperatures between 0 and 115° without change in constant. The lead-in seal was definitely gas tight. Although a cell of this kind might be rather difficult to make with electrodes of large area, this difficulty is readily avoided since the modern vacuum tube amplifier renders large electrodes unnecessary. The total weight of the electrode in this case was only about four milligrams, a point not without interest where cost is concerned.

THE CHEMISTRY OF LIGNIN. III. THE DESTRUCTIVE DISTILLATION OF LIGNIN FROM CORN COBS

BY MAX PHILLIPS

RECEIVED JULY 12, 1928 PUBLISHED AUGUST 7, 1929

During the past few years a number of papers have appeared on the destructive distillation of lignin. All of the work thus far published has been confined to the lignin isolated from wood. Heuser and Skioldebrand[1] destructively distilled lignin isolated from spruce sawdust by the method of Willstatter and Zechmeister.[2] Their results calculated on the ash-free lignin were as follows: carbon residue, 50.64%; oil, 13.00%; acetone, 0.19%; methanol, 0.90%; acetic acid, 1.09%.

Hagglund[3] distilled lignin isolated from pine wood by the hydrochloric acid method of Willstatter and Zechmeister and obtained 45% carbon residue, 9.6% oil, 0.10% acetone, 0.67% methanol and 0.64% acetic acid.

Fischer and Schrader[4] distilled Willstatter lignin and obtained 13.2% aqueous distillate, 12.5% oil, 57.2% carbon residue and 17.0% gas (obtained by difference). It was found that 16.4% of the oil dissolved in sodium carbonate and 33.9% in sodium hydroxide solution.

[4] Fischer and Schrader, *Abhand. Kohle,* 5, 106 (1920).

Tropsch[5] destructively distilled commercial Willstatter lignin under reduced pressure (1–2 mm.) and obtained **14.2%** aqueous distillate, 10.2% oil and **53.8%** carbon residue. The oil contained 37.5% phenolic compounds.

Pictet and Gaulis[6] distilled under reduced pressure commercial Willstatter lignin isolated from fir. They obtained 15% oil, 21% aqueous distillate and 52% carbon residue. No examination of the aqueous distillate was made. The oil was extracted with 10% sodium hydroxide, in which 89% dissolved. In the alkali-soluble fraction eugenol was identified. The alkali-insoluble fraction was separated by means of liquid sulfur dioxide into saturated and unsaturated hydrocarbons. In the fraction containing the saturated hydrocarbons melene was identified.

The present paper contains results on the destructive distillation of lignin from corn cobs. The lignin used in the destructive distillation experiments was prepared by three different methods: the alkali method, the fuming hydrochloric acid method of Willstatter and the 72% sulfuric acid method. The results obtained tend to support the claim that the lignin fraction obtained from corn cobs by the alkali method is quite different in composition from that obtained by either the Willstätter or the 72% sulfuric acid method. While some differences in the results were noted also in the lignin prepared by the two last mentioned methods, the principal difference was between the alkali lignin on the one hand and the Willstatter and **72%** sulfuric acid lignins on the other.

The results recorded in the literature on the destructive distillation of lignin are limited entirely to lignin isolated from wood by the Willstatter method, and in comparing those results with that recorded in this paper on the lignin isolated from corn cobs by the same method, it is observed that the values, with exception of that recorded for the yield of acetone, are of the same general order of magnitude. The yield of acetone was much higher in the case of lignin isolated from corn cobs than that recorded in the literature on lignin from wood (compare Tables I and II). Whether this may be attributed to an essential difference in the composition of the lignins from the two sources, or is due to some impurity present, it is difficult to state, considering our present fragmentary knowledge of the chemistry of lignin.

Experimental

Preparation of Lignin by the Alkali Method.—The corn cobs were treated with six times their weight of 2% sodium hydroxide solution and heated in an autoclave for eight hours under 25 pounds' pressure. The alkaline liquors were then drained off, the cobs were washed with a stream of water and the wash water was added to the alkaline liquor. This liquor was filtered and then made acid with an excess of either 50% sulfuric

acid or with concentrated hydrochloric acid. This was heated to boiling and boiled for half an hour, allowed to cool to room temperature, then centrifuged in a basket centrifuge and finally dried at 100°. The yield amounted to from 4 to 5% of the weight of the cobs taken. The lignin thus obtained was free from cellulose and when distilled with 12% HCl, according to the Official A. O. A. C. Method,[7] gave a precipitate with phloroglucinol corresponding to 2.45% pentosans as calculated by the Krober formula.

A methoxyl determination was made according to the Kirpal and Buhn[8] modification of the Zeisel[9] method. The iodine was, however, determined gravimetrically as silver iodide instead of volumetrically as recommended by Kirpal and Buhn.

Anal. Subs., 0.4682, 0.6678 (calcd. on ash-free basis): AgI, 0.5075, 0.7223. Found: OCH_3, 14.31, 14.28.

Preparation of Lignin by the Fuming Hydrochloric Acid Method.—The procedure recommended by Willstätter and Kalb[10] was followed, except that a longer period was allowed for the hydrochloric acid to act upon the corn cobs. Corn cobs (200 g.) ground to pass through a 20-mesh sieve were mixed with four liters of fuming hydrochloric acid (d = 1.21 at 15°) and allowed to stand at room temperature for twenty-four hours. The flask containing the reaction mixture was shaken from time to time. To the reaction mixture 1300 g. of crushed ice was added and it was allowed to stand for another twenty-four hours. It was then diluted further with six liters of water, filtered on a Buchner funnel using a woolen filter cloth in place of filter paper, and washed with water until the wash water no longer gave a test for the chlorine ion with silver nitrate. The product, which was almost black in color, was dried at 100°; yield, 23.5–25% calculated on the weight of the cobs used. It contained 1.05% of ash.

A methoxyl determination made on this material gave the following results: Subs., 0.3088, 0.3236 (calcd. on ash-free basis): AgI, 0.1988, 0.2123. Found: OCH_3, 8.50, 8.66.

Preparation of Lignin by the 72% Sulfuric Acid Method.—Corn cobs, ground to pass through a 20-mesh sieve were mixed with four liters of 72% sulfuric acid and allowed to stand at room temperature for thirty-six hours. The reaction mixture was shaken from time to time. At the end of the thirty-six hour period a sample of the reaction product was examined microscopically in parallel polarized light with crossed nicols and was found to be free from doubly refractive substances.[11] The reaction product was diluted with four times its volume of water, heated to boiling and maintained at this temperature for one hour. The product was filtered off and washed with hot water until free from sulfuric acid. It was dried at 100°. The yield amounted to 19% of the weight of the cobs. It contained 1.10% of ash.

A methoxyl determination made on this material gave the following results. Subs., 0.3083, 0.3111 (calcd. on ash-free basis): AgI, 0.2242, 0.2253. Found: OCH_3, 9.61, 9.57.

Apparatus Used.—The destructive distillation experiments were conducted in a copper retort which was heated in a bath consisting of a eutectic mixture of sodium-potassium nitrate. The retort was connected to a weighed distilling flask which served as a

[11] The microscopic examinations were made by Mr. George L. Kennan of the Microchemical Laboratory of the Food, Drug and Insecticide Administration.

condenser and receiver. The distilling flask was cooled with water and connected in series to another receiver which was cooled with ice.

Experimental Procedure and Analysis.—In each experiment 50 g. of lignin was used. After several preliminary tests it was determined that 380–400° was the optimum temperature for carrying out the destructive distillations, which usually required about four hours to complete. The distillate was collected in a weighed receiver and its weight determined. The result thus obtained is recorded in Table I, under the heading "Total Distillate." The oily portion was separated mechanically from the aqueous distillate and weighed, and the weight of the aqueous distillate obtained by difference. The amount of gaseous substances produced was obtained by deducting the combined weight of "Total Distillate" and non-volatile carbon residue left in the retort from the weight of the original lignin.

The aqueous distillate was purified with activated charcoal (Darco) as recommended by Stritar and Zeidler,[12] filtered into a 200- or 250-cc. volumetric flask and made up to the mark. The percentage of methanol in this solution was determined by the method of Stritar and Zeidler.[12] The acetone was determined by the Messinger[13] method, which was carried out as follows: twenty cc. of the solution to be analyzed was measured into a 300-cc. glass-stoppered Erlenmeyer flask. To this was added 20 cc. of N sodium hydroxide solution and an excess (about 50%) of $N/10$ iodine solution. This was well shaken, allowed to stand for one hour and **20.3** cc. of N hydrochloric acid added; the excess of iodine was determined by titration against $N/10$ sodium thiosulfate solution.

The organic acids in the aqueous distillate were determined either by titration against $N/10$ sodium hydroxide solution or, when the color of the solution did not permit direct titration, by boiling an aliquot of the aqueous distillate with an excess of barium carbonate for about one hour under the reflux condenser, filtering off the unused barium carbonate and determining the barium in the filtrate gravimetrically as barium sulfate. In either case the results were calculated as acetic acid. The results obtained are recorded in Table I.

It will be observed from Table I that the results are quite different in the case of alkali lignin than that of the lignin isolated by either the Willstatter or 72% sulfuric acid method. The yields of aqueous distillate and oil were much higher, whereas the yields of carbon residues were lower in the experiments with alkali lignin than with lignin prepared by the other two methods. In this connection it may also be stated that the carbon residues from alkali lignin were light and spongy, whereas those from the other two preparations were generally obtained either in the form of hard lumps or as a black powder.

As regards the composition of the aqueous distillate, it will be observed from Table I that a higher methanol yield but lower acetone and acetic acid yields were obtained from alkali lignin than from Willstatter and 72% sulfuric acid lignin. The higher methanol yield from alkali lignin is undoubtedly due to its higher methoxyl content. The low yield of acetic acid obtained from alkali lignin may be explained by the fact that in preparing lignin by this method deacetylation occurs. This has been shown by Pringsheim and Magnus[14] and confirmed repeatedly in this

Laboratory. The writer has always obtained negative results when making acetyl determinations by the Perkin[15] method upon alkali lignin isolated from corn cobs.

The yields of acetone obtained from alkali lignin are of the same general order of magnitude as that reported on Willstatter lignin from wood by Heuser and Skioldebrand[1] and by Hägglund.[3] However, the acetone yields from the lignin prepared from cobs by the Willstatter and by the 72% sulfuric acid methods were much higher than those recorded in the literature.

For purpose of comparison, the data reported in the literature on the destructive distillation of lignin are recorded in Table II.

The oil obtained in the four distillation experiments with alkali lignin (24.6 g.) was dissolved in ether and successively extracted with 5% sodium bicarbonate solution and 5% potassium hydroxide solution. The ether solution which had thus been extracted was dried over anhydrous calcium chloride, the ether was removed by evaporation and the residue was weighed. The result thus obtained is recorded in Table III under "Hydrocarbons and Inert Compounds." The potassium hydroxide and so-

TABLE III

ANALYSIS OF OIL

	Percentage of oil by weight
Acids	8.6
Phenols	84.0
Hydrocarbons and neutral compounds	7.2

The phenolic portion of the oil was repeatedly fractionated. After several fractionations it was resolved into three fractions: 204–208°, 208–225° and 225–240°. Fraction 204–208° gave an orange color with ferric chloride solution. A picrate prepared according to the directions given in Mulliken, Vol. 1, page 91, melted at 85°. This fraction, therefore, consisted principally of guaiacol. It amounted to 2.3% of the weight of lignin distilled. Fraction 208–225° was not identified. Fraction 225–240° gave a greenish-blue coloration with ferric chloride solution. An alcoholic solution of it gave a blue color with ferric chloride. A benzoyl derivative prepared from this fraction melted at 70.5°. This fraction, therefore, contained eugenol.

Summary

Lignin prepared from corn cobs by the alkali method, the fuming hydrochloric acid method of Willstatter and by the 72% sulfuric acid method, was subjected to destructive distillation under ordinary atmospheric pressure and at a temperature of 380 to 400°. From the alkali lignin the following results, representing the average of four experiments (calculated on the basis of ash-free, dry lignin) were obtained: aqueous distillate, 15.5%; water-insoluble oily distillate, 17.7%; carbon residue

(calculated on the quantity of lignin used), 52.2%; gas, 13.5% (by difference); acetone, **0.13%**; methanol, 1.9%; water-soluble acids (calculated as acetic acid), **0.05%.** The oily distillate analyzed as follows: (The results are expressed as per cent. by weight of the oil) acids, 8.6%; phenols (fraction soluble in 5% KOH solution and insoluble in 5% $NaHCO_3$ solution), 84.0%, hydrocarbons and neutral compounds, 7.2%. In the phenolic portion of the oil guaiacol and eugenol were identified.

In the case of the Willstatter lignin and the lignin prepared by the 72% sulfuric acid method, the percentage of aqueous distillate was about the same as that obtained from alkali lignin, whereas the oily distillate was only about one-half. The percentages of carbon residues obtained from the Willstatter lignin and from the 72% sulfuric acid lignin were considerably greater than that obtained from alkali lignin. The percentages of acetone and acetic acid obtained were considerably greater in the case of the Willstatter and the 72% sulfuric acid lignin than in the alkali lignin, whereas, the percentage of methanol was less. This higher percentage of methanol is probably due, in part, to the greater methoxyl content of alkali lignin than that of Willstatter and 72% sulfuric acid lignin. A possible explanation for the lower yield of acetic acid obtained from alkali lignin is presented.

NEW CONDENSATIONS OF KETONES WITH PHENOLS. III. CONDENSATION PRODUCTS OF MESITYL OXIDE AND MONOHYDROXYBENZENES

BY JOSEPH B. NIEDERL[1]

RECEIVED AUGUST 17, 1928 PUBLISHED AUGUST 7, 1929

Introduction

In continuation of the studies of the condensation possibilities of ketones with phenols, as begun with the condensation system phorone–cresols,[2] the condensation systems of mesityl oxide with monohydroxybenzenes were investigated. The discussion of the results of these investigations is the purpose of this communication.

Theoretical Part

By treating a molar mixture of mesityl oxide and a monohydroxybenzene with concentrated sulfuric acid in the cold, condensation products are ob-

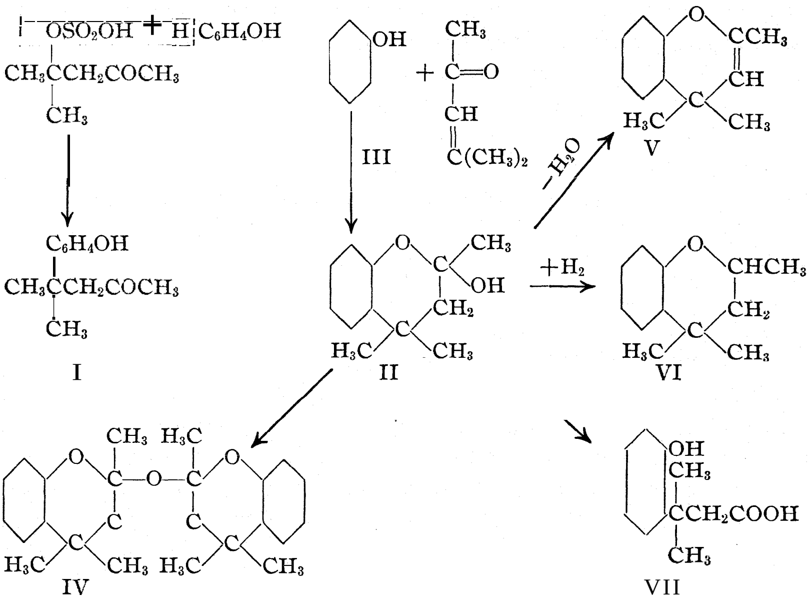
tained which appear to be chromanols (II) and dichromanyl ethers (IV) and their formation may be interpreted either (as illustrated in the chart) that from the mesityl oxide sulfuric acid (I) the phenyl-substituted isobutyl methyl ketone (I) is formed, which then changes into the isomeric chromanol (II), a behavior which is in harmony with observations made on structurally related substances,[3] or that their formation may have taken place in the form of a direct addition (III). In most cases, however, the reaction did not end with the formation of the chromanols, but dehydration occurred and the dichromanyl ethers (IV) resulted.

Both the chromanols (II) (they are really semi-acetals) and the dichromanyl ethers (IV) (di-acetals) are very stable toward alkali but are quite sensitive toward acids, as indicated by the formation of colored decomposition products.*



On reduction (with hydriodic acid or zinc and hydrochloric acid) they are reduced to the corresponding chromanes (VI), while on distillation they lose one mole of water and form the corresponding chromenes (V), a behavior which is in accordance with similar phenomena observed on structurally related chromanols.[5]

The oxidation with chromic acid anhydride in glacial acetic acid yielded phenyl-substituted *iso*valeric acids (VII), the formation of which may also be regarded as a further support of the assigned formulas.

Experimental Part

For the preparation of practically all the condensation products to be described later the following process was used. To a molar mixture or solution of the monohydroxybenzene and mesityl oxide, one mole of concentrated sulfuric acid was added in small amounts. The temperature throughout the addition was kept at 0° to avoid objectionable tar formation. The mixture turned dark red. The flask containing the reaction mixture was then closed with a stopper having a calcium chloride drying tube attached, to prevent any absorption of moisture. To eliminate any further possibility of a violent after-reaction, the flask was kept in a water-bath the temperature of which was maintained at 15 to 20°.

On standing for a week the reaction mixture became solid, or at least semi-solid, indicating positive condensation. When no condensation took place (as in the case of ethers and esters), the material remained a mobile liquid, or in the same state as it had been originally.

Now cold water was added to the reaction mixture in excess, in order to extract the sulfuric acid and the phenylsulfonic acids that may have been formed in the reaction as by-products. After repeated washings of the reaction material with cold water, it was finally heated on a water-bath and treated with a large excess of hot water with constant stirring, in order to make the extraction of water-soluble products complete. At the temperature of the boiling water-bath the material usually melted. After cooling the water was decanted off. This operation was repeated until the wash water remained clear. At this stage the reaction product has the appearance of a dark, solid or semi-solid, gummy mass.

In the next step the solubility of the condensation product in 10% aqueous sodium hydroxide solution is tested. If it is soluble, the entire material is dissolved in hot 10% aqueous sodium hydroxide solution and filtered quickly while hot. The filtrate is then cooled to 0° or lower and ice-cold, dilute (5%) sulfuric acid added in small amounts. Since these condensation products are very sensitive toward acids (on account of the formation of colored decomposition products), any excess of the acid must be avoided and it is even favorable to keep the mixture just slightly alkaline. The condensation product (phenyl-substituted methyl isobutyl ketones or some chromanols) precipitates out and is filtered, or the supernatant liquid is decanted off and the residue repeatedly washed until free from inorganic substances. The product at this point should be light to golden yellow in color.

If the condensation product is insoluble in 10% aqueous sodium hydroxide solution (dichromanyl ethers), it is treated with a hot aqueous sodium or potassium hydroxide solution (10%) until the material acquires a yellow color. It is then cooled, whereby the product solidifies, and then well washed with hot and with cold water until free from alkalies. At this point, also, the product should have a bright yellow color.

The condensation products (the chromanols and the dichromanyl ethers) are insoluble in hot and cold water; some are soluble in dilute aqueous sodium hydroxide solution; they are soluble in alcohol, ether, chloroform, carbon tetrachloride, acetone, glacial acetic acid, benzene, petroleum ether, pyridine and concentrated sulfuric acid (deep red color). Since the products are quite difficult to crystallize, no general rule for their crystallization can be given, but it has been found that alcohol, ether, pyridine, benzene and ligroin are the most suitable crystallizing media.

In carrying out blank experiments under strictly similar reaction conditions with either mesityl oxide and sulfuric acid, or the monohydroxybenzenes and sulfuric acid, no such condensation products could be obtained.

Summary

1. New condensations of unsaturated ketones with phenols were investigated and the condensation system monohydroxybenzenes–mesityl oxide was studied. The condensation products are apparently chromanols or dichromanyl ethers, respectively.

2. These condensation products are valuable intermediates for the preparation of phenyl-substituted aldehydes and acids (by oxidation) and by the distillation of the acids or their sodium salts so obtainable, the corresponding isopropyl and isobutyl phenols can be synthesized; hence the condensation process just described furnishes an additional means for the introduction of alkyl groups into the benzene ring.

Further investigations of the condensation possibilities of unsaturated ketones, unsaturated aldehydes, unsaturated acids and unsaturated alcohols with phenols (both mono- and polyhydroxylic, mono- and polycyclic), aromatic hydroxy-aldehydes and aromatic hydroxy-acids are being carried on and positive results already have been obtained.

THE REACTIONS OF ALLYL ALCOHOL OVER ALUMINUM AND ZINC OXIDE CATALYSTS

BY PAUL E. WESTON AND HOMER ADKINS

RECEIVED AUGUST 20, 1928 PUBLISHED AUGUST 7, 1929

F. H. Constable[1] suggested that propionaldehyde was formed from allyl alcohol over copper through the intramolecular rearrangement of allyl alcohol, as in Equation 1.

$$CH_2{=}CHCH_2OH = CH_3CH_2CHO \qquad (1)$$

He demonstrated that it was not formed according to Equations 2 and 3

$$CH_2{=}CHCH_2OH = CH_2{=}CHCHO + H_2 \qquad (2)$$

$$CH_2{=}CHCHO + H_2 = CH_3CH_2CHO \qquad (3)$$

Evidence was presented in a previous paper[2] from this Laboratory that part if not all of the propionaldehyde formed over a zinc oxide catalyst from allyl alcohol resulted from the reduction of acrolein by allyl alcohol as in Equation 4

$$CH_2{=}CHCHO + CH_2{=}CHCH_2OH = CH_3CH_2CHO + CH_2{=}CHCHO \qquad (4)$$

It now seems certain that over alumina propionaldehyde is formed from allyl alcohol through intramolecular rearrangement. When allyl alcohol was passed over alumina at 330° gas was formed rapidly for a few minutes but the action died off within ten minutes after less than

---

[1] Constable, *Proc. Roy. Soc. London*, **113A**, 254 (1926).

[2] Weston and Adkins, THIS JOURNAL, 50, 1930 (1928).

200 cc. of gas had been produced. The catalyst was then dark colored but produced propionaldehyde at a fair rate. No acrolein was formed at any time and the amount of hydrogen produced was no more than a total of 10 cc. Moreover, there is no evidence that alumina will dehydrogenate any alcohol at 330°. Almost the only conceivable mechanism for the formation of propionaldehyde is that suggested by Constable (Equation 1).

The amounts of propionaldehyde formed in the interval from 40 to 110 minutes when 50 cc. of allyl alcohol per hour was passed over 0.6 cc. of various alumina catalysts at 330° is Catalyst (A), 1.48 g., (B), 0.43 g. and (C) 2.14 g. If the catalyst was previously dried for ten hours at 125° or for four hours at 420°, the amounts of propionaldehyde formed were as follows: Catalyst (A), 5.11 g., (B), 1.17 g. and (C), 3.62 g. If the alcohol was passed at a rate of 20 cc. per hour the amount of propionaldehyde was reduced to 1.12 g. for Catalyst (B) and to 2.97 g. for Catalyst (C). The relative reactivities of these catalysts are about the same as those shown for ethylene production from ethyl alcohol at 330°.

For the reasons given in the introduction to our previous paper we were interested in determining the effect of modifications of the catalyst upon its activity and upon the ratio of the reaction products. The method of experimentation has already been described on pages 1931, 1932 and the first paragraph on page 1934 of our previous paper. An abstract of the experimental results obtained in using 13 different zinc oxide catalysts is given in the table.

Table I

Formation of Propionaldehyde and Acrolein on Various Zinc Oxide Catalysts for the Period from 40 to 110 Minutes

	From zinc oxalate			From zinc hydroxide					From zinc oxalate plus 1% (molar) promoter				
Catalyst	1A	2A	3A	4B	5B	6B,	7B	8B	9C, H_3BO_3	10D CrO_3	11E NaOH	12F H_2SO_4	13G H_2WO_4
Aldehydes, g	1 58 (1 13)	1 48	1 56	1 25	1 71	1 66	2 64	2 02	1 73 (1 26)	2 48 (2 08)	2 75 (1 91)	1 14 (0 93)	3 10
Acrolein (molar), %	11 5, (14 0)	11 0	10 3	7 6	6 3	5 3	4 2	7 4	9 3 (10 1)	6 3 (8 5)	8 0 (9 4)	10 4, (11 2)	6 5
Acrolein, g	0 16 (0 15)	0 16	0 15	0 09	0 09	0 09	0 11	0 15	0 16 (0 12)	0 16 (0 17)	0 22 (0 17)	0 12 (0 16)	0 20

The figures in parentheses are for a rate of flow of 20 cc. of allyl alcohol per hour. **All** other figures are for a rate of flow of 50 cc. per hour of the alcohol. **All** experiments were duplicated at least once, 0.6 cc. of catalyst, as determined from the actual dimensions of the pellets, being used at **330°**.

An accurate comparison of catalysts as to their effect upon a given reaction depends upon obtaining a standard catalyst which is easily and precisely reproducible. For reasons which will be more fully developed in another paper by Dr. Paul E. Millington, the zinc oxide obtained through the thermal decomposition of zinc oxalate was chosen as a standard.

The first three experiments serve to illustrate the reproducibility of the catalysts from zinc oxalate. Three entirely different preparations were used, two of them from zinc carbonate and oxalic acid (1A and 3A), and one from zinc sulfate and oxalic acid (2A). The total activity, as measured by the total amounts of aldehydes formed, ranged from 1.48 to 1.58 g., while the percentage of acrolein ranged from 10.3 to 11.5%. The variation in the percentage of acrolein in duplicate experiments was generally less than 0.7% and rarely more than 1.0%. The amounts of aldehydes produced could not be checked so closely because the volume of the catalyst, and the activity of separate portions, varied slightly.

Catalysts prepared from zinc hydroxide could not be duplicated. (This fact is treated more fully in a paper by Dr. Paul E. Millington.) Even though two preparations were treated as nearly alike as possible, they would give different results, both in the amount of reaction and in the ratio of the two reactions. In Expts. 4 and 5 the catalysts were prepared in the same manner, yet the total activity was 1.25 and 1.71 g., and the percentage of acrolein was 7.5 and 5.3%, respectively. The method of washing the catalyst did not change its properties, because in Expt. 5 the catalyst was washed by repeatedly dropping the hot oxide into boiling water and in Expt. 6 all of the washing was done with cold water, yet they are alike both in activity (1.71–1.66 g.) and in percentage of acrolein (5.3–5.3%). However, the amount of washing seems to be important. The catalysts in Expts. 4, 5 and 6 were washed until they were free from sulfates. The catalyst used in Expt. 7 was washed only twice, and it contained considerable sulfate. This catalyst gave irregular results, the activity being very high (2.64 compared to 1.70 g.), and the percentage of acrolein being quite low (4.2%). These results are probably due to the large amount of sodium sulfate which it contained. Experiment 8 shows the results obtained with a catalyst which should be exactly like 3B, but which was prepared by Dr. Millington. This gave a different percentage of acrolein (7.4% instead of 5.3%) and had an entirely different activity (2.02 g. compared to 1.66 g.). Regardless of the variation in different catalysts from zinc hydroxide, the results were entirely different from those of the oxides from zinc oxalate. The catalysts from the hydroxides gave from 4.2 to 7.5% of acrolein, while those from the oxalates gave from 10.3–11.5% of acrolein.

Having chosen one catalyst as a standard, catalysts were prepared in which various acidic and basic compounds were incorporated, and then the ratio of the reactions was determined as usual. These promoters were chosen because of their known activity in modifying the ratio of dehydration to dehydrogenation of alcohols and having in mind the hypothesis of Professor Hugh Stott Taylor (Colloid Symposium Monographs, 4, 19 (1926), Chemical Catalog Co., Inc., New York City) with respect to the effect of acid and alkaline promoters or poisons. In all but one case the promoted catalysts had a greater activity than the standard catalyst, and also the ratios of the reactions were different. In view of the fact that the rate of alcohol flow and the activity of the catalyst affect the ratio of the reactions, it may seem at first that the selective activation is only apparent and not real. An examination of the data in the table and a consideration of the following reasoning, however, indicates that real selective activation of the catalyst for one or the other of these two reactions was accomplished.

It has been shown that a decrease in the rate of flow of allyl alcohol increased the percentage of acrolein in the products, as did also an increase in the volume of the catalyst for a constant rate of flow of alcohol. Increasing the activity of a catalyst then should have the same effect as increasing the volume of the catalyst, that is, increasing the activity of the catalyst should increase the percentage of acrolein in the reaction products. The data in the table show that decreasing the rate of alcohol from **50** to **20** cc. per hour (equivalent to increasing the activity of the catalyst) increased the percentage of acrolein from 11.5 to **14.0.** If the effect of these promoters on the catalyst were just the effect produced by an increase in activity, the percentage of acrolein should have increased, but *in* all *cases the percentage of acrolein decreased.* The addition of boric acid to the catalyst lowered the percentage of acrolein from **10.3** to 9.3, and then a decrease in the rate of flow of alcohol to **20** cc. per hour increased the percentage of acrolein back to **10.1.** In a similar manner the chromic acid lowered the percentage of acrolein to **6.3,** but a decrease in the alcohol rate increased the percentage of acrolein to 8.5, and so on for the other promoted catalysts. This shows that the increase in activity of the catalyst due to the promoter was accompanied by an effect opposite to that decreasing the rate of flow of alcohol, instead of the same effect, showing that the real selective activation of the catalyst for one or the other of these two reactions of allyl alcohol had been accomplished.

The nature and extent of modification of the ratio of the simultaneous reactions may be summarized as follows. If the 3A catalyst is used as a standard, boric acid lowered the percentage of acrolein by 1%. Chromic acid lowered it 4%, sodium hydroxide lowered it 2.3% and tungstic acid lowered it 3.8%. Sulfuric acid caused only a slight change in the ratio of the two reactions. The total aldehyde produced was increased by all those substances which lowered the percentage of acrolein. Sulfuric acid lowered the activity decidedly. The boron in the catalyst increased the amount of propionaldehyde produced from **1.40** to **1.57** g. and chromium increased it from 1.40 to **2.33** g., but neither of them changed the amount of acrolein produced (0.16 **g.).** Sodium hydroxide increased the propionaldehyde from 1.40 to 2.53 g. and also increased the acrolein from 0.16 to 0.22 g. Sulfuric acid decreased the propionaldehyde from 1.40 to 1.02 g., and also decreased the acrolein from 0.16 to 0.12 g. Tungstic acid increased the propionaldehyde from 1.40 to 2.90 g., and also increased the acrolein from 0.16 to 0.20 g., being like sodium hydroxide in its action, except that the changes were in different amounts. These results indicate that foreign oxides (assuming the added materials decomposed to give oxides) do effect a selective activation, but the result is specific for the particular oxide, and does not depend on its acidic or basic character.

The alumina catalysts formed by the incorporation of 0.01 mole of boric acid, chromic oxide (F), sodium hydroxide (G) or sulfuric acid (H) with aluminum ethoxide showed a marked lowering in activity for propionaldehyde formation, the figures for similar experimental conditions being as follows: standard Catalyst (D) 1.20 **g.,** (E) 0.56, (F) 0.87, (G) 0.62 and (H) 0.63 g.

Preparation of Catalysts

A. Alumina from hydrated alumina. Hydrated alumina was prepared by adding a very slight excess of ammonium hydroxtde to a dilute solution of aluminum nitrate. The precipitate was allowed to settle and was washed by decantatation three times. Finally it was filtered and dried in an oven at 125° for ten hours. *B.* Crystalline aluminum hydroxide. The product obtained from the Aluminum Company of America, New Kensington, Pa., was washed with water until free from alkali. *C* was alumina from aluminum isopropoxide. This was prepared in a manner similar to *D.* D. Alumina from aluminum ethoxide. Aluminum ethoxide was prepared by the reaction of amalgamated aluminum with dried ethyl alcohol. It had a boiling point of 194.5–203° (uncorr.) (7 mm.). The ethoxide was broken into small lumps and exposed to moist air for two weeks. The powdered material was made into pills as usual. E. Alumina plus boric acid. All of these promoted aluminas were prepared in the same general manner. One hundredth of a mole of the promotor was added to one mole of the fused aluminum ethoxide and the mass was stirred until it solidified. It was then hydrolyzed as in D. F. Alumina plus chromic oxide. Difficulty was encountered in getting all of the chromic acid in solution. This catalyst had a gray-green color, probably from the reduction of the chromium trioxide. G. Alumina plus sodium hydroxide. The aluminum ethoxide was moistened with the correct quantity of an ethyl alcohol solution of sodium hydroxide and then the mass was fused and stirred as in E and hydrolyzed. Sulfuric acid was added in a similar fashion to aluminum ethoxide to give catalyst H.

1A was zinc oxide from zinc oxalate which was obtained by the reaction of zinc carbonate with oxalic acid. One mole of oxalic acid dissolved in 400 cc. of hot water was added slowly to one-half mole of zinc carbonate held in suspension by vigorous stirring in one liter of boiling water. One hour was allowed for the reaction to become complete. The precipitated oxalate was dried, powdered, heated to 130° and dropped into boiling water. These operations were performed three times. Finally the dried oxalate was converted to the oxide by heating it at 400° for one hour. **2A** was zinc oxide from zinc oxalate which was obtained by the reaction of zinc sulfate with oxalic acid. One-half mole of zinc sulfate dissolved in 400 cc of water was added dropwisc to three-quarters of a mole of oxalic acid dissolved in 1000 cc. of water which was stirred vigorously. The precipitated oxalate was washed with cold water until one gram of it dissolved in dilute hydrochloric acid gave no precipitate with barium chloride in one hour. It was dried and heated at 400° for one hour. 3A was a second batch of 1A. 4B was zinc oxide from zinc hydroxide. One-half mole of zinc sulfate dissolved in 400 cc. of water was added dropwise to one and one-half moles of sodium hydroxide dissolved in one liter of cold water which was stirred vigorously. The precipitated hydroxide was washed with cold water, then twice by heating it to 130° and dropping it into boiling water. The final product showed *a* slight test for sulfate. It was converted into zinc oxide by heating it at 400° for one hour, 5B. A second batch of zinc hydroxide prepared according to 4B was divided into two parts, one of which was treated exactly like 4B. This was 5B. 6B. The second portion of the hydroxide in 5B was washed with cold water only, instead of dropping it into hot water. This was 6B. 7B. A third batch of zinc hydroxide was washed only twice with cold water so that it contained considerable sulfate. 8B was zinc oxide prepared by Dr. Paul E. Millington as described under 6B. 9C was zinc oxide (1 mole) plus boric acid (0.01 mole). This catalyst was prepared by covering one mole of zinc oxalate from 1A with a dilute aqueous solution containing 0.01 mole of boric acid and evaporating the whole mass to dryness. This "promoted" oxalate was then heated to convert it into the oxide, just as in the case of 1A. The other promoted oxides were made in a similar manner using appropriate solutes as indicated. Catalysts 9C, 10D, 11E, 12F and 13G were prepared by Dr. Paul E. Millington. 10D was zinc oxide (1 mole) plus chromic acid (0.01 mole). The green color of the catalyst indicated that some of the chromium trioxide was reduced to chromic oxide. 11E was zinc oxide (1 mole) plus sodium hydroxide (0.01 mole); 12F, zinc oxide (1 mole) plus sulfuric acid (0.01 mole); 13G, zinc oxide (1 mole) plus tungstic acid (0.01 mole).

Summary

Allyl alcohol is converted to propionaldehyde over alumina at 330°. This conversion apparently involves an intramolecular rearrangement. This is in contrast to the conversion of allyl alcohol to propionaldehyde over zinc oxide, which depends at least in part upon the reduction of acrolein by a molecule of alcohol.

The activity of alumina for the conversion of allyl alcohol to propionaldehyde was reduced by the addition of 1% boric acid, chromic oxide, sodium hydroxide or sulfuric acid. All except the last of these materials promoted the activity of zinc oxide toward allyl alcohol.

A study has been made of the effect of modifications of zinc oxide catalysts upon the relative amounts of acrolein or propionaldehyde produced from allyl alcohol at 330°.

The source of the zinc oxide determines its selective action toward the two reactions of allyl alcohol. For example, zinc oxide from zinc oxalate gave a higher percentage of acrolein than did zinc oxide from zinc hydroxide. The oxide from zinc oxalate could be reproduced easily, but that from zinc hydroxide could not.

The introduction of acidic or basic substances, such as boric acid, chromic acid, tungstic acid, sulfuric acid and sodium hydroxide, into the zinc oxide caused a selective activation toward one or the other of the two reactions, but the effect seems to be specific for the particular substance and does not depend on its acidic or basic character.

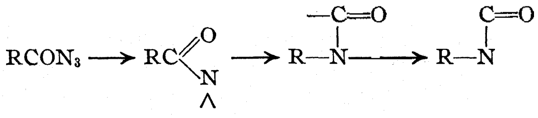
MADISON, WISCONSIN

THE MECHANISM OF THE AZIDE REARRANGEMENT

By Garfield Powell

Received October 30, 1928 Published August 7, 1929

The Beckmann rearrangement and other rearrangements involving the migration of a radical from carbon to nitrogen, including the azide rearrangement to isocyanate, involve a problem of mechanism which is still not solved, though the plausible univalent nitrogen explanation of Stieglitz[1] can be employed as a formulation of the rearrangement in many cases. In the case of the azides the rearrangement involves the univalent nitrogen, thus



Experimental support for the postulate by the examination of the products of decomposition of a di-azide compound has been adduced by Schroeter,[2] and the results are indeed a support of the hypothesis in that they are most simply and directly explained or, rather, represented theoretically, in such a way. There are, however, many possible theories of such mechanisms and the desirable test is one in which the phases postulated in the reaction are shown to exist. In the case of the univalent nitrogen hypothesis the question arises, indeed, as to the possibility of determining the truth of the hypothesis by ordinary chemical means at all. Thus the alkaline reduction of the azides leads to diacyl hydrazines, a reaction well formulated by the univalent nitrogen hypothesis, but not impossible to formulate otherwise. The acid reduction of azides to acid amides is of the same kind. Experiments by the author on the decomposition of azides in a neutral solvent in the presence of triphenylmethyl in the hope of isolating addition compounds of the formula $RCONM_2$ would, if successful, give more valuable support to the hypothesis because of the greater limitation of variables. Benzoyl azide decomposes in benzene solution to give nitrogen and phenyl isocyanate and if the univalent nitrogen phase formed an amide $RCONM_2$ by simple addition in the same solution with a body MM known to be stable in the same solution and not to react with phenyl isocyanate, the number of alternative formulations of the mechanism

would be thereby limited and the postulate gain in plausibility. The highly unsaturated univalent phase would not, in general, be expected to react by addition to other molecules while it is so smoothly capable of saturation by rearrangement but there seems, at first glance, some chance of reaction with bodies such as triphenylmethyl, which has, as conventionally represented, a primary valence capable of direct saturation. However, no reaction takes place and benzoyl azide decomposes in the presence of triphenylmethyl as easily and smoothly as when alone. This, from another point of view, is not unexpected, for whatever intermediary is postulated in the azide rearrangement, it is known to be, in the sense of practice, a saturated one; that is, addenda are not known and it has not been shown to be unusually reactive toward other molecules. Further, it is even stable to the very reactive triphenylmethyl and thus we have a representation of a highly unsaturated substance with one free valence (the unsaturation of triphenylmethyl has been used as an argument in favor of the free radical hypothesis) and its very opposite, in practice, represented with two free valences. There seems to be danger of forming wrong concepts from the simple representation $RCON<$ and it appears to the author that such phases might better be represented in parentheses thus $(RCON<)$, whereby the fact of non-reactivity toward external molecules is evidenced in the formulation. As to the most desirable test, success in the isolation of a simple addition compound would still not be conclusive, for the addition could still be formulated otherwise and the question as to how the compound $RCON_3$ became the compound $RCONM_2$ is one that has, possibly, no relation at all to the question as to how $RCON_3$ became RNCO. It seems that the phase of univalent nitrogen is really a representation of the unobservable dynamic of all reactions and the isolation of any resultants from any reactants leaves the problem still unsolved and still represented in the same way. The next most desirable test, in which the possible alternative formulations are increasingly limited by the chosen conditions of experiment, must therefore be devised, in the present case leading to failure. In the course of the work some new azides and a quinoline hydroximic acid were prepared. Their properties are described below.

Experimental

The decomposition of benzoyl azide into isocyanate and nitrogen was found to be complete in two hours of refluxing in benzene, the isocyanate being recovered as diphenylurea by the addition of aniline and the nitrogen collected and measured by using a current of carbon dioxide into potassium hydroxide to remove the gas. The experiment was repeated, the reaction flask now containing triphenylmethyl, and at the end, after cooling and precipitation of any isocyanate as urea, air was led in to decompose the unchanged triphenylmethyl. The conditions were varied as far as possible and in all cases about 50% of the triphenylmethyl was recovered as peroxide (the usual quantity), nearly all of the isocyanate as urea and no new compounds were recovered. The experiments were persisted in for a long time without success and no evidence of reaction could be obtained by examination of the residues.

Dibenzylacetazide.—In the preparation of acid azides by the interaction of the acid chloride and potassium azide, the employment of a water–acetone mixture was found convenient. Thus the addition of benzoyl azide in acetone to a concentrated solution of potassium azide in water gave, on separation and extraction, an almost theoretical yield of benzoyl azide in a state of purity. Similarly 2,4-dinitrochlorobenzene gave 2,4-dinitro-azidobenzene in purity and good yield, the reaction mixture being kept below 20° and poured into water after shaking. The solid thrown out was collected and recrystallized by dilution of acetone, or otherwise. The melting point is high (67–68°) and the product is colorless, giving on heating on the water-bath dinitrosonitrobenzene as yellow needles melting at TO°. Dibenzylacetazide was prepared in the same way. The reaction mixture was kept below 15° and, after good shaking, thrown into a large excess of water and again shaken until the globules solidified. The solid was collected and washed well with water, dissolved in acetone and water added till cloudy. The crystals were collected, washed with methyl alcohol, and dried in a vacuum desiccator; yield 90%; colorless solid, unstable. When isolated and dried in the desiccator for one hour a melting point (slow) was observed at 51-53'. On standing for one day it becomes completely liquid, gas bubbles arising. The same decomposition into isocyanate takes place on warming or melting.

Dibenzylmethylisocyanate.—A thick liquid, not solidifying in a freezing mixture, it resembles triphenylmethylisocyanate in being only slowly rearranged on heating with water. It is only slightly soluble in alcohol. On refluxing with alcohol in excess for one hour, collecting the solid thrown out when water is added, crystallizing from dilute alcohol and washing with ether, dibenzylmethylethylurethan is obtained, a colorless substance melting at 106–107° (uncorr.). On warming the isocyanate in benzene solution with aniline for a few minutes, and recrystallizing the product from benzene, **dibenzylmethylphenylurea** is obtained as fine silky needles melting at 153–154° (uncorr.). A specimen of the isocyanate was refluxed with water for six hours, the solid formed being occasionally broken up with a rod. Crystallized from benzene, recrystallized from alcohol, *sym.*-di-dibenzylmethylurea was obtained melting at 160–161° as described by Hurd.[3]

2-Phenyl-4-quinolylformhydroximic Acid (Atophane Hydroximic Acid).—The insolubility of the chloride of atophane prevents the formation of the hydroximic acid from the acid chloride and free hydroxylamine. The methyl ester was therefore prepared and the hydroximic acid prepared. Six grams of the methyl ester was dissolved, together with hydroxylamine hydrochloride (1.2 moles) in 50 cc. of methyl alcohol and to the solution was added sodium methylate (2 moles) in methyl alcohol. The mixture was kept just below the boiling point for seven hours and then brought down to small bulk by reduction of pressure, the salt filtered off and an excess of water added. A little of the unchanged ester is thrown out and filtered off. On acidifying, the hydroximic acid is thrown out as a white precipitate; yield, about 80%. It is washed well with water, then with alcohol and benzene successively in small quantities and again with methyl alcohol. Taken up in dilute soda and reprecipitated as before, washed as before, dried at 70° and then *in vacuo*, it analyzes for nitrogen as 10.35%, the calculated

---

[3] Hurd, THIS JOURNAL, 43,2242 (1921).

being 10.50% (a gas rush is hard to prevent in the analysis, even after careful grinding of the specimen with fine copper oxide). The compound is very slightly soluble in benzene, more so in ether, most in methyl alcohol and even in this case cannot be said to be more than somewhat soluble in the hot solvent, hydrolysis taking place. It is colorless, melting with gas evolution at 155–156° (uncorr.). It forms a copper salt, drying emerald green and not decomposing under 240°. The silver salt darkens after separation. The benzoyl derivative forms from the sodium salt in water on shaking with an ether solution of benzoyl chloride; it is soluble in methyl alcohol, insoluble in water and melts at 150–151°. It seems to suffer the ordinary decomposition with sodium hydroxide with the formation of an oily and very stable isocyanate.

Summary

A discussion of the azide rearrangement and the possibilities of test of the univalent nitrogen hypothesis is presented. An attempt to arrange an experiment limiting the alternative formulations of the rearrangement is given and the preparation of some azides and a quinoline hydroximic acid is described.

QUANTITATIVE CHANGES IN THE CHLOROPLAST PIGMENTS IN THE PEEL OF BANANAS DURING RIPENING[1]

BY HARRY VON LOESECKE

RECEIVED NOVEMBER 30, 1928 PUBLISHED AUGUST 7, 1929

Introduction

The purpose of this investigation was to gain some knowledge of the changes which the pigments in banana peel undergo during the process of ripening of the fruit, and the cause of the yellow color. It is a well-known fact that during maturation the fruit changes in color from green to yellow, but no quantitative data seem ever to have been collected indicating the relation of these pigments in the peel of the banana to one another during ripening.

The three pigments estimated were chlorophyll (a + b), xanthophylls and carotin. These are not the only pigments present, as during the process of separation there were indications of flavones and anthocyanins. These latter pigments are present in the cell sap, while chlorophyll, xanthophylls and carotin are present only in the specialized portions of the protoplasm known as plastids.

Method of Investigation

Each determination (Table I) represents the peel from three fingers and these fingers were taken from three separate hands on a specially

---

[1] This is one of a series of investigations carried out by the Research Department of the United Fruit Company, to be published in scientific journals.

selected stem.[2] The fruit was of one variety[3] and was ripened under controlled conditions as to temperature and humidity in specially constructed rooms.

The fruit was peeled, the pulp side of the peel scraped free from pulp, the peel cut into small pieces and ground in a mortar with sand. It was practically impossible to macerate green peel fine enough to remove all of the pigment, and even after repeated extractions the peel still showed very faint traces of green. Ripe peel could be mashed to a fine pulp and extraction was apparently complete.

Quantitative determinations of total sugars (calculated as invert sugar) were made on the pulp of the fruit from which the peel was taken.

The peel, prepared as above, was extracted in the cold with 30% aqueous acetone to remove gums and flavones. The chloroplast pigments were then extracted with pure acetone after the method of Schertz.[4] After the chlorophylls had been extracted and saponified to chlorophyllins, they were determined colorimetrically using a solution of chlorophyllins prepared from pure chlorophylls as a standard.

Xanthophylls and carotin, after extraction and separation from the chlorophylls, were determined colorimetrically using a solution of Naphthol Yellow as a standard for the former, and Naphthol Yellow and Orange G as a standard for the latter, after the method of Sprague.[5] It was found impossible to compare xanthophylls and carotin with these dyes by artificial light.

Results

The results of the determinations are given in Table I. The age of the fruit *from the time it* was *discharged from the boat* is given in the first column. In the second column chlorophylls are indicated, in the third xanthophylls, in the fourth carotin and the fifth total yellow pigments (carotin plus xanthophylls). All results are expressed in milligrams of pigment per kilogram of fresh peel.

The sixth column represents percentage of total sugar (as invert) in the pulp of the fruit from which the peel was taken. Prom researches extending over a period of two years during which more than six thousand determinations of total sugar in the pulp of the fruit were made, it has been established that total sugar is the best criterion of the ripeness of the fruit.

---

[2] Banana terms are perhaps a little confusing to the uninitiated. A single banana is called a "finger;" the group of fingers, known to the laity as a "bunch," is called a "hand," each containing from 14 to 20 individual "fingers." The cluster of "hands" attached to the stalk is called a "stem."

[3] A variety of *Musa sapientum* known as Gros Michel. This is the yellow variety most common on fruit stands.

0	70.1	7.21	1.22	8.43	0.93	
2	66.1	4.90	3.41	8.31	1.54	
3	14.1	5.15	3.39	8.54	6.52	V
5	00.0	5.00	3.69	8.61	8.25	

The last column, "Series," represents five different groups; in each group there are from two to five determinations depending upon the length of time the fruit was followed during ripening.

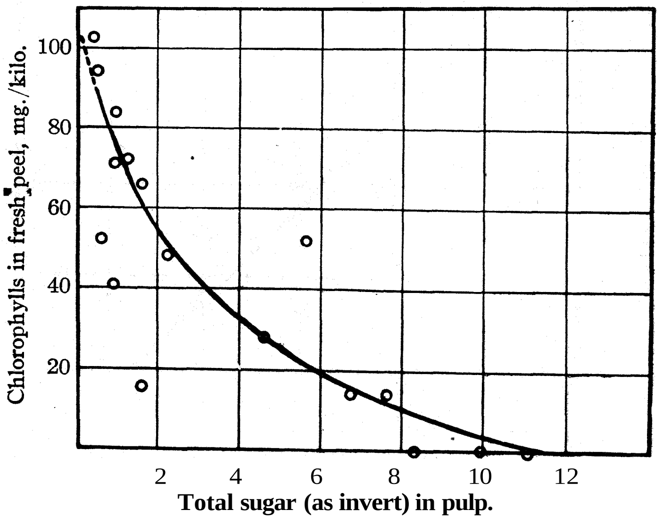

Fig. 1.—Relation of chlorophylls in banana peel to total sugar (as invert) in pulp.

It will be noticed that the total sugar in the pulp varies from 0.4% to nearly 1.0% at zero days (*i. e.*, at time of discharge from the boat). When picked from the tree the fruit contains less than 0.1% of total sugar as invert. Since the chlorophylls in the peel decrease rapidly at first with respect to sugar in the pulp, it follows that the peel of the fruit at the time of harvesting would contain more chlorophylls than at the time of discharge from the boat.

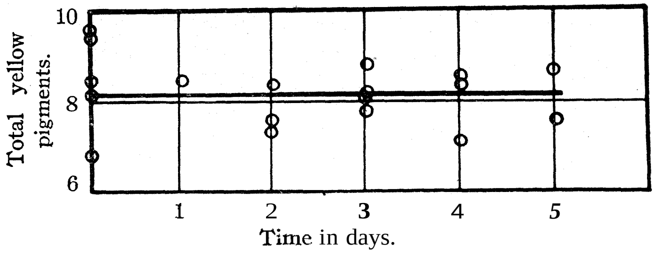

Fig. 2.—Total yellow pigments (xanthophyll and carotin) in banana peel with respect to time.

The amount of xanthophylls is always greater than the amount of carotin and the carotin to xanthophylls ratio changes at various stages during the ripening of the fruit.

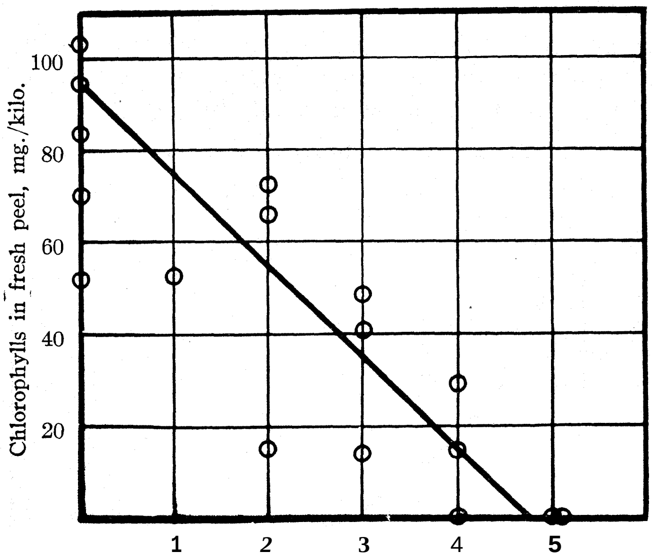

Fig. 3.—Decrease of chlorophylls in the peel of bananas during ripening in respect to time.

The total yellow pigments remain approximately constant throughout the maturation of the fruit (Fig. 2). In other words an unripe banana contains the same amount of total yellow pigments as a ripe banana, but in the case of the former the yellow color is masked by chlorophyll.

Acknowledgment

The writer wishes to express his appreciation to Dr. F. M. Schertz of the Bureau of Soils at Washington, D. C., for his kindness in supplying a sample of pure chlorophyll.

Conclusions

The pigments, chlorophyll (a + b), xanthophylls and carotin were determined in the peel of bananas. Prom the data obtained the following conclusions have been reached: the data indicate that the chlorophyll content of the peel ranges from 102.0 to 51.7 milligrams per kilogram of fresh peel in the unripe fruit at discharge from the boat and decreases as the fruit ripens. Chlorophylls decrease as a straight line function of time (Pig. **3).** The total yellow pigments (xanthophyll plus carotin) remain approximately constant throughout the maturation of the fruit. The amount of xanthophylls is always greater than the amount of carotin, the range of the former being from about 5 to 7 milligrams per kilogram of fresh peel, while the range of the latter is from 1.5 to **3.5** milligrams per kilogram of fresh peel.

THE STRUCTURE OF ALPHA-METHYLXYLOSIDE[1]

BY F. P. PHELPS AND C. B. PURVES

RECEIVED JANUARY 21, 1929 PUBLISHED AUGUST 7, 1929

Crystalline trimethylxylose, derived from the corresponding β-methylglycoside, was the first member of the methylated monosaccharides to which an amylene oxide ring structure could be assigned with certainty,[2] and at the time the opinion was expressed that not only α- and β-methylxyloside, but possibly xylose itself, were similarly constituted. The intervening years, however, have brought to light several cases in which methylating agents, applied to a reducing sugar, have produced derivatives of more than one ring type and, in this connection, the behavior of galactose and arabinose may be cited.[3] Pryde, Hirst and Humphries have shown that in the case of these two sugars methylation with methyl sulfate and alkali undoubtedly gives at least two ring forms. In the case of xylose also this method gives an impure product, the rotation

of the methylated products being too low in addition to the yield being small. Our own values using this method are in approximate agreement with those of Carruthers and Hirst,[4] using the same method, and are much lower than the values obtained when pure a- or β-methylxyloside was methylated with silver oxide and methyl iodide. Likewise, it is now well known that the condensation of a reducing sugar with acid methyl alcohol, if carried out at room temperature, yields a γ-methylglycoside, while at higher temperatures such as Fischer used a mixture containing largely the a- and β-forms is obtained. Our own work indicates that all three are formed at an intermediate temperature and that the equilibrium reached in acidified methyl alcohol is not an equilibrium between the a- and β-forms only but between the a-, β-, γ- and perhaps other forms as well, the predominating form being determined by the conditions, temperature playing a particularly important role. As only two of these three forms can have the same ring structure, the third must have a different ring and there is no known way to tell which, if either, of these rings exists in the parent sugar. It accordingly follows that any conclusions regarding the identity of ring structure in the sugar series, to be satisfactory, must be based upon nothing less than a direct experimental identification and correlation of the derivatives concerned. Such a correlation has now been made for a- and for β-methylxyloside.

The earlier methylations of this sugar were carried out by Carruthers and Hirst,[4] who used methyl sulfate and caustic soda to prepare the β-form and who used Fischer's method to condense xylose with methyl alcohol for the a-form. In the latter case after that portion of the β-methylxyloside which crystallized from the product had been removed, the residual crude sirup was treated with silver oxide and methyl iodide and gave a mobile liquid with the elementary composition of a fully methylated pentose. When heated in acid methyl alcohol it displayed a final specific rotation of 50.4°, a value in good agreement with that of 49.5° acquired by trimethyl-β-methylxyloside under similar circumstances. Such behavior has long been known to be characteristic of an α-β pair of methyl glycosides possessing the same ring structure,[5] and the reasonable inference was made that one more example of the same phenomenon had been encountered. While, therefore, it is true that trimethyl-a- and -β-methylxyloside have been correlated, the method used was an indirect one and a series of considerations led the present authors to doubt its reliability in this case. Thus the methylated glycosides examined by the former workers did not conform to the decisive test of similar ring structure devised by Purdie and Irvine[5] in that trimethyl-P-methylxyloside, when hydrolyzed with aqueous acid, yielded a

---

[4] Carruthers and Hirst, *J. Chem. Soc.*, 121, 2299 (1922).

[5] Purdie and Irvine, *ibid.*, 104, 9 (1904).

crystalline trimethylxylose, $[\alpha]_D$ 20° in water, while the impure α-isomer gave rise to a levorotatory sirup. Moreover, the correlation adopted by Carruthers and Hirst is pot valid if two trimethylxyloses, differing in ring type, happen to possess similar equilibrium rotations in acid methyl alcohol, a possibility which cannot be counted remote when it is remembered that Haworth and Westgarth[6] have recently prepared a second trimethylxylose with a specific rotation of 31.2" in water, or within 12" of the former figure. Third, in the preparation of trimethyl-β-methylxyloside from xylose by the methyl sulfate and sodium hydroxide, there is some uncertainty because of the small yield obtained, together with the suspicion that this method does not always yield a single product. If the trimethyl-8-methylxyloside contained a large unknown percentage of a second compound of similar properties and therefore difficult to separate and, as in this case, on hydrolysis yielded less than 50% of the theoretical amount of trimethylxylose, it would be difficult to say which of the two components in the parent mixture produced the trimethylxylose. A fourth consideration lay in the fact that a-methylglucoside, galactoside and arabinoside are directly correlated, in each case, to methylated derivatives which very probably possess an amylene oxide ring.' It follows that a similar structure must be assigned to the glycosides themselves and, if this is so, a computation in molecular rotations by the method of Hudson[S] leads to the conclusion that the 1:5 oxygen linking is not present in a-methylxyloside. As this is at variance with the accepted structure for the β-isomer, Dr. C. S. Hudson requested us to repeat the work of Carruthers and Hirst and to obtain more decisive experimental evidence on the matter.

The carefully purified crystalline a-methylxyloside was methylated by the silver oxide reaction and every care was taken to render the methylation complete. Although the trimethyl-a-methylxyloside could not be made to crystallize and purification was carried out by the uncertain method of distillation, the specific rotations determined, 121.7° in chloroform, 112.7° in water and 122° in methyl alcohol, are regarded as approximately correct. When methylated in similar fashion β-methylxyloside gave an excellent yield of the crystalline, fully methylated derivative. Purification was rigorous and the final constants were: m. p. 51°; $[\alpha]_D^{20}$ —69.5" in chloroform and —81.7" in water. Aqueous acid, of a lower concentration and at a lower temperature than that previously employed, hydrolyzed both trimethylmethylxylosides, 80–85% of the theoretical yield of crystalline trimethylxylose being isolated in each case. The two

[8] Hudson, THIS JOURNAL, 48,1434 (1926).

specimens of the sugar were then compared with each other and found to be identical. Mutarotation in water was swift, the initial specific rotation being 65° and the equilibrium rotation 17.7" in place of the value of 20° hitherto accepted as standard. Trimethylxylose occasionally displayed mutarotation in chloroform solution, the initial value of $[\alpha]_D^{20}$ 58" diminishing to 24°; also, the initial rotation to this solvent was quite erratic, lying anywhere between 58 and 45° after recrystallization from ether solution. In these cases it is possible that the sugar crystallized as a mixture of the a- and β-forms. The value of 58° is therefore to be taken with caution. One other point remained to be considered, for trimethyl-β-methylxyloside prepared by the methylation of xylose in alkaline solution had a specific rotation some 10° lower than the correct value of —69.5' in chloroform. The similar observation of Carruthers and Hirst was thus confirmed and, recrystallization failing to improve the constant, the possibility remained that the two methods of alkylation had produced isomeric substances. On hydrolysis, however, the specimen with the incorrect specific rotation also gave trimethylxylose in 75% of the theoretical amount and the discrepancy was seen to be due to an impurity, possibly an isomeric form, which was difficult to remove. This observation should be of value when it is desired to prepare a methylated sugar in a state of optical purity by the aid of methyl sulfate and of alkali.

Experimental[9]

Preparation of Trimethyl-β-methylxyloside.—(a) A 5-g. portion of pure crystalline β-methylxyloside, $[\alpha]_D^{20}$ —65" in water, was methylated in the standard fashion with 40 g. of silver oxide and 25 cc. of methyl iodide, a little methyl alcohol being present in this first methylation only to dissolve the glucoside. Acetone was used to recover the product, which was then submitted to a second and a third treatment with the same reagents. The final separation of the trimethyl-β-methylxyloside from the inorganic residues was effected by extraction with ether, the yield of the crude, crystalline material after evaporation of the ether being 5.52 g, or 88% of the theoretical. After three recrystallizations from petroleum ether, cooled in ice and salt, the specific rotation in purified chloroform was $[\alpha]_D^{20}$ —69.6' (0.2439 g. in 25 cc. of $CHCl_3$ rotated the plane of polarization 1.36" to the left in a 2-dm. tube). This value was not appreciably changed by two further recrystallizations, the value found being $[\alpha]_D^{20}$ in $CHCl_3$, —69.5" (0.3669 g. in 25 cc. gave a rotation of —2.04° in a 2-dm. tube). The average of four sets of readings by two observers was $[\alpha]_D^{20}$ in $CHCl_3$, —69.5'. The rotation in water was $[\alpha]_D^{20}$ —81.7' (0.2463 g. in 25 cc. read —1.62" in a 2-dm. tube). The substance melted sharply at 51°. Estimation of methoxyl by Zeisel's method: 0.3144 g. gave 1.3968 g. of silver iodide, corresponding to 58.7% of OCH_3; calcd., 60.2. A subsequent

---

[9] All methylations with silver oxide and methyl iodide were carried out in a round-bottomed flask equipped with an efficient water-cooled condenser, the two being united by a ground-glass joint in place of the customary rubber stopper. This innovation, while giving a product free from contamination by rubber and therefore more readily purified, required care in its use, as flask and condenser readily became cemented together.

larger-scale preparation (23 g.) after purification by several recrystallizations from ordinary absolute ether cooled in ice yielded substantially the same figures for the specific rotation, namely, −69.4° in $CHCl_3$ and −81.8" in H_2O.

(b) A 25-g. sample of carefully purified xylose was methylated as described by Carruthers and Hirst[4] first with methyl sulfate and alkali and then with 33 g. of silver oxide and 17 cc. of methyl iodide. The product crystallized on recovery from the latter process; yield, 20 g. or 64% of the theoretical. Once recrystallized from petroleum ether, 0.0684 g. dissolved in 25 cc. of chloroform and in a 2-dm. tube had an observed rotation of −0.34' and a specific rotation of −59.6". A second recrystallization failed to change this value (0.1268 g. in 25 cc. of the same solvent had α −0.60° and $[\alpha]_D$ −59.0"). It is to be noted that the yield was only 64% as against 88% in (a), and likewise that the rotation is about 10° lower.

Preparation of **Trimethyl-α-methylxyloside.**—(c) Pure a-methplxyloside, prepared by the method of Bourquelot,[10] $[\alpha]_D$ +154.0° in water, was methylated with 60 g. of silver oxide and 37.5 cc. of methyl iodide for a 7.5-g. sample. Methyl alcohol (2.5 cc.) was also present, in this first methylation, to enable the xyloside to dissolve. Three such operations, however, failed to complete the methylation, as was evident when the liquid product was distilled, the refractive index varying with the fraction on which it was observed: methoxyl, found, 58.4%; theoretical, 60.2%. Accordingly, the total distillate of 7 g. was remethylated with 8 g. of silver oxide and 5 cc. of methyl iodide. After recovery it was dissolved in water and extracted with chloroform in order to remove most of the lower methylated impurities and the sirup obtained from the anhydrous chloroform extract was methylated for a fifth time. Evaporation at 80° (20 mm.) freed the trimethylmethylxyloside from solvent, the last traces of which were eliminated during the distillation, bath 110" (10 mm.). Rejecting the first six drops of the distillate, the seventh was found to have n_D^{24} 1.4391 and the last n_D^{25} 1.4387. Since data drawn from the work of Carruthers and Hirst show that the change in refractive index per degree rise in temperature is −0.00036" for a methylated xylose, the indices quoted are regarded as equivalent. In an estimation of methoxyl groups by Zeisel's method, 0.11.51 g. gave 0.5208 g. of silver iodide; found: OCH_3, 59.7; calcd., OCH_3, 60.2.

In purified chloroform, $[\alpha]_D^{20}$ was +121.2°, 0.7273 g. having an observed rotation of 7.06" in 25 cc. of solution and in water +112.2°, values not appreciably changed by redistillation. After one redistillation $n_D^{22\ 8}$ of the fifteenth drop was 1.4398, that of the last, at 23°, 1.4397, while 0.4710 g. in 25 cc. of chloroform solution had a, 4.59" and $[\alpha]_D^{20}$ +121.7°. Trimethyl-a-methylxyloside, therefore, has a specific rotation in chloroform of the order of +121.5°. Similar measurements were made in water and in methyl alcohol; $[\alpha]_D^{20}$ in water was +112.7° (0.2942 g. in 25 cc. gave a rotation of 8.61° in a 2-dm. tube); $[\alpha]_D^{19}$ in CH_3OH was +122.2° (0.3791 g. in 25 cc. gave a rotation of +3.70° in a 2-dm. tube).

Preparation of **Trimethyl-α-xylose.**—(a) Pure trimethyl-β-methylxyloside, 6.29 g., dissolved in 120 cc. of 4% hydrochloric acid, was maintained at a temperature of 85°. The initial specific rotation of −73.1° increased, during seventy-five minutes, to a nearly constant value of +14.8°, whereupon the solution was neutralized with barium carbonate and filtered. In this preparation, trimethylxylose was isolated by a tedious extraction of the filtrate with large volumes of chloroform and by evaporation of the anhydrous extract to a sirup. A partial crystallization quickly occurred and the crystals were recrystallized from ice-cold ethyl acetate; yield, 2.3 g.; m. p. 91–92"; $[\alpha]_D$ f-54.3" in chloroform. The original mother liquors, on standing at 0° for two days, deposited a further 1.2 g.; m. p. 88–91°; $[\alpha]_D$ +53.8° in chloroform, while further quantities

[10] Bourquelot, *Ann. chim.*, 3,298 (1915).

were obtained from the residual sirup on longer standing. Eventually the yield of crystalline trimethylxylose reached **85%** of the theoretical. After two recrystallizations from ether, **0.5309** g. in **25** cc. of the chloroform solution had a rotation of **2.40'** or $[\alpha]_D$ +56.4°. The third and fourth crystallizations raised this figure to $[\alpha]_D$ +58.0° **(0.3223** g. **in 25** cc. of chloroform had $\alpha = 1.50°$), a value which was not obtained when climatic conditions were hotter and more humid.

Mutarotation in **Water.--0.2988** g. dissolved in **25.10** cc. had $\alpha =$ **0.55'** twenty minutes after solution, while the equilibrium rotation of +0.43° was reached in three hours. The corresponding specific rotations are $[\alpha]_D$ **4-23°** and $[\alpha]_D$ **+17.9°**, respectively.

(b) Recrystallized **trimethyl-β-methylxyloside,** $[\alpha]_D$ in $CHCl_3$ −59.6°, prepared by the direct methylation of xylose by methyl sulfate and alkali, was hydrolyzed under conditions similar to those detailed above. The specific rotation of the solution became practically constant at +16.2° and as this corresponds to an almost quantitative yield of trimethylxylose, the acid was neutralized with an excess of lead carbonate. Filtration removed the greater part of the inorganic salts from the well-cooled liquor and evaporation of the filtrate under diminished pressure left a dry residue from which hot ether readily extracted trimethylxylose. The sirupy product crystallized in stages when kept in the ice box for ten days, the final yield of crystalline material being 75% of the theoretical. Recrystallized from ether, the melting point was 90° and the mixed melting point with the specimen from (a) was **91–92'.** Mutarotation occurred in chloroform, **0.4477** g. of the trimethylxylose in **25** *cc.* of solvent gave a reading of $\alpha =$ **1.99'** or $[\alpha]^{20}_D$ +55.8°, falling in ninety minutes to the constant value $\alpha =$ **0.86"** or $[\alpha]^{20}_D$ +24.2°, not changed by catalysis with a trace of acid. In water the first observation was made one minute after solution, **0.2392** g. in **25** cc. having **a** = 1.16°, decreasing to the constant value of a = **0.34'** in one hour. The corresponding specific rotations were $[\alpha]^{20}_D$ +62.8° and final $[\alpha]^{20}_D$ +17.6°.

(c) **Liquid trimethyl-a-methylxyloside (2.48** g.) was dissolved in **4%** hydrochloric acid and the volume increased to **50** cc. by addition of the same reagent. When maintained at **85'** the specific rotation of the solution decreased from +109° to +19.4° in the course of **270** minutes. The yield of trimethylxylose, isolated **as** in (b), was **80%** of that theoretically possible; m. p. **91–92';** mixed melting point with the two specimens obtained above, **91–92"** in each case.

Mutarotation in Water.--0.2810 g. in **25** cc. of aqueous solution was read in **a 2-dm.** tube at **22°.**

Minutes	0.5	2	3	4	5	8	13
$[\alpha]^{20}_D$	62.1	57.4	55.2	52.4	50.8	43.9	35.5
Minutes	21	24	34	48	88	123	180
$[\alpha]^{20}_D$	28.4	27.1	22.8	19.4	18.5	17.7	17.7

Extrapolation from these data gave a value of +64° for the initial specific rotation of trimethyl-a-xylose in water, while in a duplicate experiment **$65'** was the figure obtained.

The authors record their warm appreciation of the interest Dr. C. S. Hudson has **taken** in the work. One of them (C. B. P.) also wishes to thank the Commonwealth **Fund** of **New** York for the Fellowship which made his collaboration possible.

Summary

Trimethyl-a-methylxyloside has been prepared from pure crystalline a-methylxyloside. After purification by distillation its constants were n^{23}_D, **1.4397;** $[\alpha]^{20}_D$ **in** $CHCl_3$, **+121.5°;** $[\alpha]^{20}_D$ **in** H_2O, **+112.7;** $[\alpha]^{20}_D$ in CH_3OH, **+122.2.**

Trimethyl-β-methylxyloside has been prepared in two ways: (a) from pure crystalline β-methylxyloside and (b) from pure xylose, using the methyl sulfate and sodium hydroxide method. After purification by recrystallization, *the* crystals resulting from (a) had the following constants: m. p. sharp at 51°; $[\alpha]^{20}_{D}$ in $CHCl_3$, –69.5"; $[\alpha]^{20}_{D}$ in H_2O, –81.7, while those resulting from (b) showed $[\alpha]^{20}_{D}$ in $CHCl_3$, –59.6°. As this value, which is about 10° low, did not change appreciably on recrystallization, it is concluded that this method gives a less pure product. *So* hydrolysis both trimethyl-a-methylxyloside and trimethyl-β-methylxyloside yield the same crystalline trimethylxylose. It is therefore concluded that these two substances contain the same ring structure, forming an α- and P-pair. They have thus been definitely correlated for the first time and likewise the parent substances, **a**- and β-methylxylosides, from which they were derived. The properties of the purified trimethyl-α-xylose were m. p. 91 to 92°; $[\alpha]^{20}_{D}$ in $CHCl_3$ (final), + 24.2; $[\alpha]^{20}_{D}$ in H_2O (initial), 64.5°; (final), 17.7°. It is to be noted that for the most part the constants given above differ quite materially from those previously recorded.

[COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

PROMOTER ACTION WITH OXIDE CATALYSTS FOR THE DECOMPOSITION OF ALCOHOLS[1]

BY HOMER ADKINS AND PAUL E. MILLINGTON

RECEIVED FEBRUARY 26, 1929 PUBLISHED AUGUST 7, 1929

It has been shown by experimental work described in a series of papers from this Laboratory[2] that the ratio of reaction products formed when alcohols are passed over solid catalysts is not primarily a function of the chemical nature of the catalyst mass but is determined by easily modifiable characteristics of the catalyst surface. Two explanations have been offered for this variation in the ratio of reaction products. Hugh Stott Taylor[3] in an extended discussion of our results among others stated that the oxides are dual catalysts, the metal part (metal ion) being dehydrogenating, and the oxygen part (oxide ions) being dehydrating. The ratio of the simultaneous reactions would then depend in part upon the ratio at the surface of active metal ions and active oxide ions. This latter ratio would depend upon the original distribution and upon the

---

[3] Taylor, "Colloid Symposium Monograph," The Chemical Catalog Company. Inc., New York City, 1926, Vol. IV, p. 25.

relative extent to which the two kinds of ions had been covered up by poisons. Upon the basis of this hypothesis the selective activation of catalysts observed in this Laboratory was dependent upon the relative occurrence in the catalyst surface of the two kinds of ions and upon selective poisoning of the one or the other kind of ions. Taylor further says that "the prediction can, therefore, be freely made that the presence of sulfate ion, and, for similar reasons, the anions of all the oxyacids, will cause an increase in dehydration ratio in the case of such predominantly dehydrogenating catalysts as uranium oxide, molybdenum oxide, ferric oxide and vanadium oxide." The adsorption of alkali ions will, on the contrary, favor dehydrogenation.

Adkins had previously suggested that the variation in the ratio of simultaneous reactions, was in part, a function of the space relationships of the active centers of the catalysts, i. e., that the direction of distortion of an adsorbed molecule would be determined by the chemical nature of the catalyst and also by the relative position in space of the adsorbing centers which are close enough together to exert their influence simultaneously upon a single adsorbed molecule. Differences in spacings of the centers of activity might produce different molecular fragments just as the size and shape of fragments of a piece of paper would be in part determined by the relationship in space of the two hands which tore the original sheet. On the basis of this hypothesis small amounts of added materials might modify the ratio of reaction products through their effect in disturbing the spacial relations of the active centers on the catalyst surface. Such effects would presumably be highly specific and unconnected with the acidity or alkalinity of the added material and would vary from alcohol to alcohol, as a spacing favorable for a high dehydrogenation ratio of one alcohol would not be likely to be favorable for all alcohols.

A criticism of these hypotheses necessitates that there be available very accurate data over considerable intervals of catalyst life on the ratio of reaction products over a variety of pure and promoted catalysts. The experimental work described in this paper was carried out in order to provide such data.

Apparatus and Method of Experimentation

The assembly of the apparatus used for this work is indicated in Fig. 1. The catalyst tube was of pyrex, of which the upper half, eighteen inches in length, was constructed of quarter-inch tubing and carried the male half of the ground-glass joint. The lower half was of half-inch tubing, fourteen inches in length. A Gooch filter plate was pressed against a slight constriction in the tube at a point which fell near the center of the furnace when the apparatus was assembled. The tube was indented for the entire length above the filter plate.

A fine capillary, drawn out at one end of a piece of ordinary capillary tubing, was connected by a section of rubber tubing to the female half of the ground-glass joint mentioned in the preceding paragraph, in such a way that the tip of the capillary extended well down into the wide part of the joint. Alcohol or other liquid, contained in a liter bottle, was forced through the capillary by means of compressed air, maintained at practically a constant pressure by a column of water confined in a rubber tube leading from a reservoir in an upper room to a storage bottle on the laboratory desk. This bottle carried a simple manometer and was connected through a sulfuric acid drying tower with the flask containing the alcohol. The lower part of the catalyst tube carried a rubber stopper over which was fitted a glass cup with an outlet for gases and condensed liquid. A small pyrex tube also projected through the cup, the tip of the tube pressing against the catalyst. Ordinarily this tube served only to hold the catalyst mass in place. If the temperature of the reaction was wanted, a thermocouple was inserted into the tube and the tip of the latter imbedded in the catalyst. Another potentiometer was connected to the thermocouple and the temperature read off as desired.

The liquid was vaporized in the upper part of the catalyst tube by means of a preheating device. This consisted merely of a fourteen-inch length of pyrex tubing wound with eighteen feet of No. 18 nichrome wire and covered with asbestos. A current of two amperes maintained a temperature of 170 to 180". A multiple unit furnace was used to heat the catalyst tube. It was maintained at the desired temperature, plus or minus three degrees, by a Leeds and Northrup controller through the medium of a thermocouple mounted on the tube close to the catalyst mass.

Two forms of sampling apparatus were used. The first consisted of a 300-cc. calibrated bottle filled with saturated sodium bromide solution and fitted with a three-way stopcock. A second bottle served as a reservoir for the salt solution as it was displaced from the first bottle by the incoming gases. The second form provided for the condensation of the vapors issuing from the catalyst tube. The condensing system consisted of a 200-cc. round-bottomed flask fitted with a short glass coil, which served as the inlet, and a small upright coil condenser. The whole was-immersed in an ice-bath and the uncondensed gases were collected over saturated sodium bromide solution in a calibrated three-liter bottle.

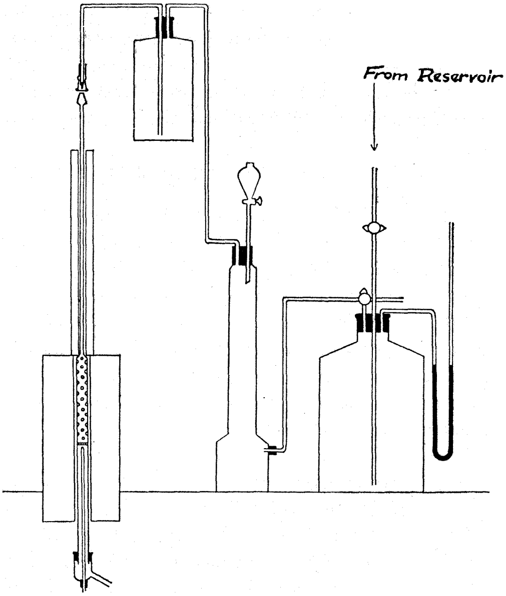

Fig. 1.—Apparatus for gas phase catalytic reactions.

The charge of the catalyst, consisting of quartered tablets 6 mm. in diameter, was placed against the Gooch filter plate and held in place by a wad of glass wool. Air, partially dried and purified by bubbling through sulfuric acid, was slowly passed over the catalyst for fifteen minutes at the temperature maintained for the succeeding reaction.

Samples of gas were ordinarily taken at atmospheric pressure in the 300-cc. bottles. The contents of the sampling bottle were well shaken to dissolve aldehyde and alcohol vapors, and to displace gaseous products from the condensate layer. When the condensate was extremely insoluble in the salt solution, this method was unreliable due to the comparatively large amounts of unsaturated hydrocarbons remaining dissolved in the condensate layer. In such a case the gases were first passed through the condensing system described above and collected in the calibrated three-liter bottle for a definite period. The condensing system was removed from the ice-bath without being disconnected from the gas holder, and the condensate refluxed under the short coil condenser until no more gas was evolved. The condensing coil, flask and reflux condenser were finally filled with boiling water to displace all of the gas they contained.

Gas Analysis.—The procedure used in determining the percentages of the constituents of the evolved gases was essentially that of Hempel. Samples were measured in a 100-cc. water-jacketed buret over water. Carbon dioxide, uncondensed acid and alcohol vapors were absorbed in 40% potassium hydroxide solution. Unsaturated hydrocarbons were removed by bromine water, oxygen by stick phosphorus and carbon monoxide by ammoniacal cuprous chloride. Hydrogen and methane were determined by combustion. When ethane was also present, hydrogen was absorbed in colloidal palladium[4] and the residue burned in an excess of oxygen.

Preparation of Catalysts

No. 1. Millington's zinc oxide *ex* sulfate was prepared by adding a 0.67 N solution of zinc sulfate dropwise to a well-stirred 0.67 N hot solution of sodium hydroxide. The precipitate was washed repeatedly with hot water and finally dried at 120° for twelve hours. There were traces of sulfate in the catalyst.

No. 2. Weston's zinc oxide *ex* sulfate was prepared by adding 0.5 mole of zinc sulfate dissolved in 400 cc. of water dropwise with rapid stirring to 1.5 moles of sodium hydroxide in a liter of cold water. The precipitate was washed twice with cold water, then twice by heating to 130° and dropping into boiling water. Traces of sulfate remained in the catalyst.

No. 3. Lazier's zinc oxide *ex* sulfate was prepared but was not used during the investigation reported on in 1926. The sodium hydroxide solution had been added to the zinc sulfate solution. The catalyst contained considerable sulfate.

No. 4. Lazier's zinc oxide *ex* sulfate "A" was the catalyst described under that symbol in 1926. It was prepared in the same way as No. 3.

No. 5. Zinc oxide *ex* acetate was made from the acetate; otherwise the procedure was the same as for No. 1.

No. 6. Zinc oxide *ex* zinc chloride was made similarly to No. 1.

No. 7. Zinc oxide *ex* zinc nitrate was made similarly to No. 1.

No. 8. Zinc oxide *ex* oxalate was prepared from zinc oxalate by heating to 400° for forty-five minutes. The oxalate was prepared by slowly adding a hot solution of 1.4 moles of oxalic acid in a liter of water to a vigorously stirred suspension or solution of 1.0 mole of commercial zinc oxide, zinc carbonate or zinc chloride. The mixture was then boiled for 0.5 hour, filtered and the oxalate washed several times with hot water, dried, powdered, heated to 130°, poured into boiling water, filtered and dried at various temperatures from 90 to 120°. The oxalate showed no test for sulfates or chlorides.

No. 9. Zinc oxide *ex* oxalate and chromic oxide was prepared by treating 50 cc. of a water suspension of 17.7 g. of zinc oxalate with 0.2 g. of chromic oxide. The mixture was heated to dryness and decomposed for forty-five minutes at 400° as in the case of No. 8; 0.01 mole of chromic oxide was calculated to be present for each mole of ZnO.

No. 10. Zinc oxide *ex* oxalate + B_2O_3 was the same as No. 9 except that 0.124 g. of boric acid replaced the chromic oxide; 0.01 mole of B_2O_3 per mole of ZnO.

---

[4] Paal and Hartmann, *Ber.*, 43, 243 (1910).

No. 11. Zinc oxide *ex* oxalate + WO_3 was the same as No. 9 except that 0.25 g. of commercial H_2WO_4 replaced the chromic oxide; 0.01 mole of WO_3 per mole of ZnO.

No. 12. Zinc oxide *ex* oxalate + V_2O_5 was prepared by grinding 0.182 g. of vanadium pentoxide with 17.7 g. of zinc oxalate and then heating to 400° as usual.

No. 13. Zinc oxide *ex* oxalate + ammonium vanadate was prepared similarly to No. 9 except that 0,234 g. of ammonium metavanadate, NH_4VO_3, was used instead of the chromic oxide.

No. 14. Zinc oxide *ex* oxalate + MoO_3 was prepared the same as No. 9 except that 0.18 g. of ammonium molybdate was used.

No. 15 Zinc oxide *ex* oxalate + H_2SO_4 was prepared by evaporating to dryness and heating to 400° a mixture of 18.9 g. of hydrated zinc oxalate and 19.5 cc. of 0.1024 *N* sulfuric acid.

No. 16. Zinc oxide *ex* oxalate + NaOH was prepared the same as No. 15 except that 5 cc. of 0.2 *N* sodium hydroxide replaced the sulfuric acid.

No. 17. Iron oxide *ex* ferrous oxalate was prepared by heating ferrous oxalate for one hour at 400°. The oxalate was prepared by precipitation from solutions of ferrous sulfate and oxalic acid.

No. 18. Iron oxide *ex* ferrous oxalate + H_2SO_4 was prepared in the same way as No. 15 except that ferrous oxalate replaced the zinc oxalate.

No. 19. Iron oxide *ex* ferrous oxalate + NaOH was prepared similarly to No. 16.

No. 20. Iron oxide *ex* ferrous oxalate + B_2O_3 was prepared similarly to Nos. 9 and 10.

No. 21. Ferrous oxalate *ex* oxalate + CrO_3 was prepared similarly to No. 9.

No. 22. Titania *ex* tetra-butyl orthotitanate was prepared by allowing tetra-butyl orthotitanate to hydrolyze over water at 50 to 60° in a partially evacuated desiccator.

No. 23. Titania *ex* tetra-ethyl orthotitanate was prepared similarly to No. 22.

No. 24. Titania as in No. 23 + B_2O_3 was prepared by adding 20 cc. of an alcoholic solution containing 0.062 g. of boric acid to 4.0 g. of titania and then evaporating the alcohol during stirring.

No. 25. Titania from the hydrolysis of a mixture of tetra-ethyl titanate and sodium hydroxide was prepared by allowing a mixture of 50 parts of tetra-ethyl orthotitanate and 1 part of sodium hydroxide to hydrolyze as in No. 22.

No. 26. Titania *ex* tetra-ethyl titanate + NaOH was prepared similarly to No. 24

No. 27. Alumina *ex* aluminum butoxide was prepared similarly to No. 22 except that the partially hydrolyzed material was heated to 80 to 90° from time to time during the hydrolysis.

No. 28. Alumina *ex* aluminum butoxidc + CrO_3 was prepared by the hydrolysis of a mixture of chromic oxide and aluminum butoxide.

No. 29. Alumina *ex* aluminum butoxide + sodium hydroxide was obtained similarly by allowing a butanol solution of the butoxide and sodium hydroxide to hydrolyze.

No. 30. Alumina *ex* aluminum butoxide + H_2SO_4 was obtained by passing sulfur trioxide into aluminum butoxide and then allowing the mixture to hydrolyze.

At least two preparations of each catalyst were made and used except for some of the promoted iron and aluminum catalysts. For all catalysts which are claimed to be reproducible the gas analyses in the reaction products agreed within less than 1%. The promoted catalysts are qualitatively but not quantitatively reproducible; that is to say, chromium-promoted catalysts were always found to be more efficient for dehydration than were boron-promoted catalysts although the exact figures would vary somewhat. The data plotted in Figs. 2 and 3 are the results of two or more runs made on different samples of the same preparation of a catalyst. The points on the curve represent actual experimental determinations and are not averages. It is believed that differences in percentage of gases which are greater than 0.4% are significant of actual differences between the catalysts concerned. In the case of zinc oxide catalysts, from 0.0 to 2.5% of carbon dioxide was found to be present in the gases of reaction. This has been calculated out of the results and the alkene and hydrogen calculated as though they constituted 100% of the gas. There seems to be no adequate explanation of the variation in the formation of carbon dioxide over zinc oxide catalysts. Catalysts usually decrease on standing with respect to the formation of carbon dioxide. Therefore there seems to be some easily modified characteristic of the catalyst surface which determines the formation of carbon dioxide.

Summary of Experimental Results

A study of the effect of promoters demands the selection of a standard catalyst which can be readily reproduced and which is not modified in activity by the operations necessary for the incorporation with it of the promoter. Precipitated zinc oxide is not such a catalyst, as may he seen from the data given in Fig. 2 for the behavior of ethanol over a number of precipitated zinc oxides.

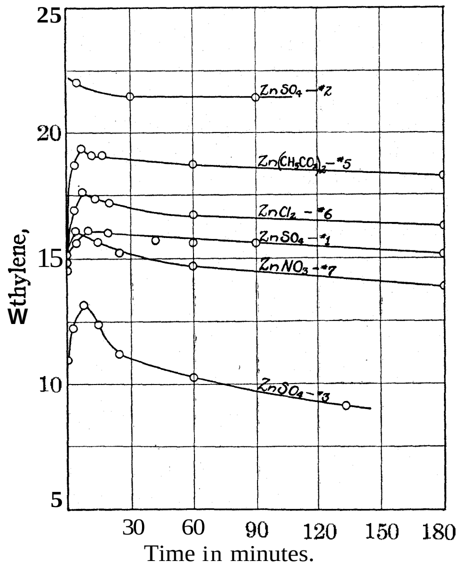

Fig. 2.—Percentage of ethylene in gaseous products from ethanol over various-precipitated zinc oxide catalysts.

Zinc oxide obtained by the ignition of zinc oxalate seemed to be an excellent standard catalyst. Several different preparations from zinc oxide and oxalic acid, from zinc chloride and oxalic acid, and from basic zinc carbonate and oxalic acid gave practically identical ratios of ethylene and hydrogen. The percentages of ethylene in two typical experiments are given below: 5 min., 25.7 and 25.8%; 20 min., 24.7 and 25.0%; 45 min., 24.0 and 24.3%; 90 min., 23.2 and 23.6%; 120 min., 23.3 and 23.7%. It is not feasible to incorporate promoters with zinc oxide through the use of water solutions because this treatment in itself modifies the ratio of dehydrogenation and dehydration shown by the catalysts. However, alcoholic solutions may be used for the addition to and removal of alcohol from zinc oxide without modifying its catalytic effects. Promoters may be incorporated with zinc oxalate through the use of aqueous solutions or suspensions.

The effect upon the ratio of dehydration to dehydrogenation of ethanol of adding small amounts of various materials to zinc oxide ex oxalate is shown in Fig. 3. The effect of some of these same promoters upon the ratio of gaseous products from ethanol over titania is shown in Table II. The percentage of alkene formed from ethyl, *n*-propyl, *iso*propyl and *iso*butyl alcohols over nine different zinc oxide catalysts is shown in Table III. The percentage of hydrogen present in the gaseous products equals the difference between 100 and the percentage of alkene shown in the table for a given set of conditions. The data obtained in the use of the alumina catalysts are not given in a table because all of them except the one containing sodium oxide gave a gas containing 98 to 99% ethylene after the removal of alkali-soluble materials amounting to about 5%. The sodium oxide aluminum catalysts had a very low activity and showed about nine parts of ethylene for one part of hydrogen. This effect of sodium oxide in lowering activity and producing hydrogen is characteristic. The volume of hydrogen produced is small and is in all probability due in part to the catalytic action of sodium oxide as distinguished from its promoter action.

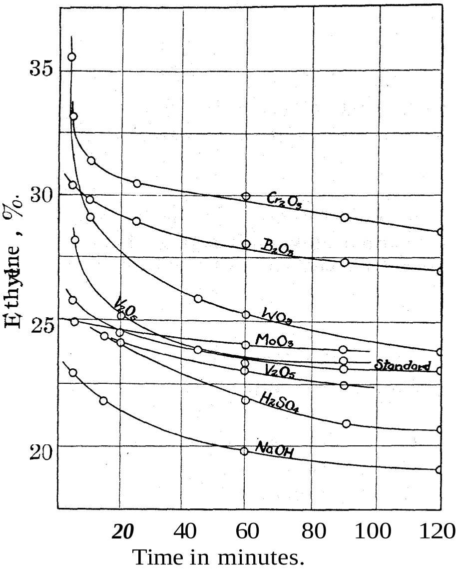

Fig. 3.—Percentage of ethylene from ethanol over "promoted" zinc oxide catalysts.

TABLE I

ETHANOL OVER IRON OXIDE CATALYSTS

Samples taken after 0.5 g. of catalyst had been used for one hour at 400°; rate of alcohol flow, 50 cc. per hour.

No.	Catalyst	CO_2, %	CO, %	C_2H_4, %	C_2H_6, %	H_2, %
17	Standard ex ferrous oxalate	10.2	1.1 to 1.7	6.1	7.5	76.2
18	Standard + H_2SO_4	4.8	1.1 to 1.7	7.0	7.5	80.8
19	Standard + NaOH	5.0	4.7	1.1	1.3	87.8
20	Standard + B_2O_3	6.2	1.1 to 1.7	10.8	18.9	64.0
21	Standard + CrO_3	8.4	1.1 to 1.7	7.1	8.8	75.6

A consideration of the data contained in the two graphs and the three tables brings out the following significant facts.

TABLE II

ETHANOL OVER TITANIA

Samples taken after 0.5 g. of catalyst had been used for five minutes at 400°.

No.	Catalyst	C_2H_4, %	C_2H_6, %	CH_4, %	H_2, %	Cc. of gas per min.

10	Standard + B_2O_3	28.1	..	7.7	..

The proportion of ethylene to hydrogen is always lower for catalysts from the precipitated zinc hydroxides than for the zinc oxide *ex* oxalate (see Fig. 2). The ratio is dependent upon the exact method of precipitation and washing and varies very widely. This variation in catalytic effect is not due to the presence of a sulfate for the same variation is found with catalysts prepared from nitrates, chlorides and acetates. There is no evidence available to show that the variation may not be due to differences in the amount of sodium hydroxide adsorbed by the precipitated zinc hydroxide.

The use of 1% of chromium, boron or tungsten oxide in a zinc oxide catalyst markedly increases the proportion of ethylene formed. The percentage of ethylene in some cases is increased by 40% of the value of the unpromoted catalyst. Vanadium and molybdenum oxides have relatively little effect in changing the ratio of dehydration and dehydrogenation of ethanol while both sulfur trioxide and sodium oxide decrease the proportion of dehydration (see Fig. 3).

The effect of a given promoter is neither qualitatively nor quantitatively constant, but is specific for a given alcohol. For instance, a sulfate lowers the percentage of alkene from ethanol and propanol and raises it for *iso*-propanol. Tungsten oxide, which shows but a slight promoter action for the formation of alkenes from ethanol and propanol, is a very active promoter for alkene formation from isopropanol and isobutanol. Chromium oxide, which is the most active of all the promoters used for ethanol, has very little effect upon the other alcohols. Boric oxide is a promoter for alkene formation from ethanol but in the concentration used is almost without effect upon isopropanol. These anomalous effects are even more marked in the case of some of the precipitated or *ex* hydroxide catalysts. For instance, Catalyst No. 3 gives only about 0.4 as much ethylene as the standard oxalate catalyst, yet it gives more propylene from propanol and almost 20 times as much isobutylene from isobutanol as does the standard oxalate catalyst. Lazier's "A" Catalyst and Millington's No. 1 Catalyst show similar divergent effects upon different alcohols.

Small amounts of sulfuric acid, sodium oxide, boron and chromium oxides in iron oxide decrease the formation of carbon dioxide from ethanol (see Table I). Of these promoters only boric oxide materially increases ethylene and ethane formation at the expense of dehydrogenation. Sodium oxide increases hydrogen at the expense of hydrocarbon, but the change is accompanied by so great a decrease in the activity of the catalyst that the change in ratio of products is of doubtful significance.

Boric oxide has little effect upon titania but sodium oxide increases ethane at the expense of ethylene, at the same time doubling the hydrogen and eliminating the formation of methane (see Table II).

It is obvious that Taylor's hypothesis and prediction as to the effect of acidic and basic promoters upon the ratio of dehydration and dehydrogenation is not supported by all of the experimental results stated above. Two promoters so unlike as sulfuric acid and sodium hydroxide show the same effect upon ethanol; that is to say, they lower the percentage of ethylene. These two promoters show opposite effects upon isopropanol (*i. e.*, they behave as predicted). It is unsafe to predict that a catalyst which shows high comparative dehydration for one alcohol will do so for another, for quite the reverse is often true. Promoters may not be classified as promoting dehydration or dehydrogenation except with reference to a specific compound.

In view of the failure of this hypothesis in the simple cases it is perhaps not necessary to raise the question as to the number and kind of ions which must be assumed to be present in a surface in order that four distinct primary reactions may occur simultaneously, as is sometimes true.

In previous papers by Bischoff, Nissen, Lazier and Adkins numerous examples have been given of the modification of the ratio of simultaneous reactions through changes in the method of preparation of the catalysts.

In the case of several of these catalysts this difference in ratio of reaction induced was really dependent upon the presence or absence of traces of certain promoters or inhibitors. In several other cases there is a *possibility* that this was true; in still other cases it seems certain that the ratio of reaction products was modified other than by the presence or absence of a promoter or inhibitor.

This was first demonstrated by Adkins for the reactions of esters over alumina from various aluminum alkoxides. It was demonstrated in the second case by Bischoff for the reactions of alcohols and other materials over titania from various sources. Lazier next obtained similar examples of selective activation with alcohols over zinc and iron oxide catalysts. The first of these attempts may be criticized in that the reactions of the esters are rather complicated and especially in that the range of selective activation was not very great. Bischoff's work may be criticized in that at that time the importance of boiling out the gases from the condensate was not realized. Moreover, it was not determined with certainty whether the C_nH_{2n+2} found was really ethane or methane or a mixture of the two. Lazier's results may be criticized in that in no case was he able to distil or otherwise rigorously purify the compound from which the catalyst was prepared.

It was of the highest importance, then, to demonstrate conclusively that the ratio of two competing reactions could be modified without the influence of a promoter. To this end tetra-ethyl and tetrabutyl orthotitanates were prepared and repeatedly distilled until they were demonstrated to be free from the usual metallic and acidic impurities. These two titanates were then hydrolyzed and used as catalysts against ethanol, using the best technique that has been developed in this Laboratory for the determination of the ratio of gaseous reaction products. The results as given in Table II are in general agreement with those of Bischoff and show conclusively that the titania from the butoxide and from the ethoxide differ very considerably in the ratio of ethylene and ethane produced while they give almost identical percentages of methane and hydrogen. These experiments demonstrate conclusively that selective activation may be obtained other than through the effect of catalyst promoters or poisons.

It is clear then (1) that the direction of shifting of the ratio of two competing reactions is not always dependent upon the acidity or basicity of the promoter, *(2)* that both the direction and amount of change in the ratio is specific for the alcohol and the catalyst and **(3)** that the ratio of competing reactions may be modified by other means than through the addition or removal of a compound from the catalyst. Some of these facts are out of harmony with the first hypothesis given in the introductory paragraph, while they are entirely in harmony with the hypothesis previously advanced from this Laboratory with regard to the possible importance of spacial relationships of the catalyst surface in determining the ratio of competing reactions. It must be admitted, however, that Adkins' hypothesis in its present form is of no value for predicting experimental results, and does not lead to positive experimental verification.

Lazier has suggested on the basis of unpublished work that the ratio of dehydration to dehydrogenation induced by a given catalyst is determined by the degree of hydration of the catalyst. Taylor called attention to this possibiiity in his address before the Colloid Symposium at Boston in 1926. The following facts would seem to have a bearing on the question. If a precipitated zinc oxide was brought up to reaction temperature (400°) and immediately used, there was first an increase in percentage of dehydration, followed by a slow decrease. This is clearly shown in Fig. 2. If, however, the catalyst was maintained at 400° in a current of dried air for fifteen minutes, there was no rise in alkene formation during the first few minutes of use (see Fig. 3). A prolonged preheating of an hour and a half increased ethylene formation by one per cent. or so over what it would have been after a fifteen-minute preheating and the rate of lowering of ethylene formation was decreased. Reheating a catalyst for thirty minutes in dry air after it has been in use for an hour or two restored the percentage of ethylene to approximately its former level. This reactivation may be repeated several times providing the catalyst has not become fouled. The passage of water vapor over the catalyst at 400" permanently impaired the dehydrating power of the catalyst, even when the catalyst was afterwards heated in dry air. These facts clearly show that the degree of hydration of the zinc oxide catalyst affects the ratio of dehydration and dehydrogenation of ethanol. It appears that the decrease in percentage of ethylene during the use of a zinc oxide is due to the accumulation of some volatile compound upon the catalyst. It seems questionable from a consideration of these facts whether the ratio of dehydration and dehydrogenation is a simple function of the degree of hydration of the catalyst.

Summary

The effect upon the ratio of simultaneous reactions of alcohols of the addition of small amounts of various acidic and basic oxides to zinc, iron, titanium and aluminum oxide catalysts has been experimentally investigated. The conclusions were reached (1) that the direction of the shift in the ratio of two competing reactions is not dependent upon the acidity or basicity of the promoter, (2) that both the direction and amount of change in the ratio is specific for the alcohol and the catalyst and (3) that the relative rate of competing reactions may be modified by means other than through the addition or removal of a compound from the

catalyst. These and other facts have been considered in their bearing upon the hypotheses which have been previously advanced to account for the variation in the ratio of competing reactions over various catalysts.

THE SULFONATION OF PHENANTHRENE.
I. A NEW MONOSULFONATE

BY LOURS FREDERICK FIESER

RECEIVED MARCH 6, 1929 PUBLISHED AUGUST 7, 1929

After a series of careful investigations, the results of which were published in 1902, Werner and his students[1] were able to show that three phenanthrene sulfonic acids may be obtained by the action of concentrated or fuming sulfuric acid on the hydrocarbon. Various methods of separating these isomers were elaborated and the compounds were all carefully identified and characterized. The yields, however, were poor, and the separation was a tedious process. In preparing large quantities of two of the acids according to Werner's methods, it has been found possible to introduce some improvements which render these substances more readily accessible and which also serve to cast further light on the course of the reaction.

Werner records that the best yields of the 2-acid (12%) and the 3-acid (18.6%) were obtained on heating phenanthrene with two molecular equivalents of concentrated sulfuric acid at a temperature of 120–130° for four and one-half to five hours. It was assumed that the greater part of the hydrocarbon was converted into disulfonic acids, and this conclusion has been confirmed by Sandqvist,[2] who found that disulfonic acids accompany the monosulfonic acids even when phenanthrene is sulfonated incompletely at room temperature. At a temperature of 100" or below, a third isomer, phenanthrene-9-sulfonic acid, which was not detected in the reactions carried out at 120–130°, is produced.

Before attempting to extend these observations, it seemed almost necessary to find some new method for the identification and the determination of the purity of the isomeric acids. Reactions such as the alkali fusion, or the preparation of the ester or the chloride, all require a fairly large sample of the dry salt, and they are all rather slow. A much more suitable derivative was found in the *p*-toluidine salt.. With this amine, the phenanthrene sulfonic acids all form crystalline salts whose melting points are characteristic and fairly well separated. One can quickly

identify a few milligrams of an acid or of any of its metal salts, whether it is in the solid form or in solution, by this method.

In working up the reaction mixture, Werner first neutralized the acid solution with barium carbonate and thus had the tedious task of extracting the rather sparingly soluble salt of the 3-acid, and the very slightly soluble salt of the 2-acid, with water and with dilute sulfuric acid, respectively. It was found much more convenient to prepare first a sodium salt mixture and to treat a solution of this with only enough barium chloride to cause the precipitation of the barium 2-salt. When the reaction mixture was stirred mechanically and the sulfonation conducted at 120° for four hours, the yields of the 2-acid and the 3-acid were 18 and 27%, respectively. When the reaction was stopped after three hours, the amounts of the two acids corresponded to 25 and 27%, respectively, of the theoretical quantity. That the observed yield of the 3-acid did not show an increase proportional to that for the isomer is due probably to the difficulty in separating all of the 3-acid from the disulfonates. The yield of the 2-acid, on the other hand, is easily determined. That the amount of this isomer which is produced decreases with the length of the reaction period doubtless is due to the conversion of the acid into disulfonic acids, as will be shown in the following paper.

The modified method of separation was also applied to the mixtures which result from the low-temperature sulfonation, and which are known to contain the 2-acid, the 3-acid and the 9-acid. Thus Werner[3] obtained these acids in 7, 9 and 6% yield, respectively, by sulfonating at 100° for eight hours, while Sandqvist raised the yield of the 9-acid to 7–14.5% by carrying out the reaction at 20° over a period of fifteen to twenty days.[2,4] In the present work the sulfonation was conducted at 60° for three days and the mixture was stirred mechanically for about half of the time. The 2-acid was easily removed in the form of the barium salt, and a considerable quantity of the 3-acid separated as the least soluble fraction on crystallizing the remaining product in the form of the potassium salt. The further working of the mixture involved many difficulties, most of which have been recognized by the earlier investigators. The mixture, however, is even more complex than these workers have realized, for it contains not only the 3-acid and the 9-acid, but traces of the 2-acid and an appreciable amount of a new isomer, phenanthrene-1-sulfonic acid. The presence of the 1-acid was only established in the present work through a fortunate circumstance. A sulfonate residue, which had yielded no pure products after several crystallizations, was fused with alkali in the hope that the phenanthrol mixture, particularly if it contained

[4] Sandqvist, Ann., 392, 76 (1912).

any dihydroxyphenanthrenes, might be separable. While this was not the case, it was found that the acetate mixture obtained on acetylation easily yielded pure 1-acetoxyphenanthrene on crystallization. It was then found possible to isolate the 1-acid from a similar sulfonate mixture, but the process is extremely tedious. The solubilities of the salts of the 1-acid, the 3-acid and the 9-acid all appear to be about the same, and the solutions have a pronounced tendency to remain supersaturated.[5] By carrying out a great many crystallizations of the potassium and ferrous salts, and by identifying the various fractions by means of the melting points of the p-toluidine salts, a part, at least, of the sulfonate mixture was separated into the pure components, the yields being as follows: 2-acid, 18%; 3-acid, 18%; 9-acid, 13%; 1-acid, 8%.

The sulfonation of phenanthrene at a low temperature thus gives a mixture of four of the five possible monosulfonic acids. Two of these acids, the 9-acid and the 1-acid, have not been found in mixtures obtained at 120–130°. Experiments with the former acid, as well as with the 2-acid and the 3-acid, failed to reveal any rearrangement on heating with sulfuric acid but indicated that the substances are all sulfonated further with great ease. Thus it is probable that the absence of two of the acids from the products obtained at the higher temperature is due simply to the disulfonation of these substances. The sulfonation of phenanthrene leads to the same number of isomers as the nitration, but neither the relative yields nor the positions of the substituents are the same; nitration, according to Schmidt and Heinle,[6] yields 9-nitrophenanthrene as the chief product, together with smaller quantities of the 2-nitro and 4-nitro and a very small amount of the 3-nitro derivatives.

Phenanthrene-1-sulfonic acid, I, was characterized by the preparation of the potassium and p-toluidine salts, the methyl ester and the corresponding quinone, II. The structure was established by conversion into 1-phenanthrol, III, which, unknown at the time of these experiments, has been synthesized recently by Shoesmith and Guthrie.[7] The properties agreed with the description given by these authors, while the methyl ether

and its picrate melted at the temperatures given by Pschorr, Wolfes and Buckow[8] for the synthetically prepared 1-methoxyphenanthrene and its picrate. From the acetate, which was oxidized and hydrolyzed, there was obtained I-hydroxyphenanthrenequinone, IV, which is the last of the four possible compounds of this type to be described.

Another compound obtainable from 1-phenanthrol, and one which is of particular interest in connection with the problem outlined in the first paper of this series,[9] is 1,4-phenanthrenequinone, V. This was prepared in good yield by- coupling I-phenanthrol with diazotized sulfanilic acid, reducing the azo dye and oxidizing the 4-amino-1-phenanthrol. On reductive acetylation to VI, followed by oxidation, the diacetyl derivative of 1,4-dihydroxy-9,10-phenanthrenequinone (VII) was obtained. This compound has been described by Brass and Stadler,[10] who adequately established the positions of the substituent groups, and the author is greatly indebted to Professor Brass for supplying him with a sample of the product. The substance was found to be identical with the material here described. The structure of the new isophenanthrenequinone, V, is thus definitely fixed, and it is also clear that both 1-phenanthrol and 3-phenanthrol[9] couple in the 4-position and behave, in this respect, like naphthols. With the isolation of V, all of the four possible homonuclear phenanthrenequinones are known.

Experimental Part

***p*-Toluidine** Salts of the Phenanthrene **Sulfonic** Acids.—In order to prepare such a salt the aqueous solution of the free acid, or of the sodium, potassium or ferrous salt, is treated with an excess of *p*-toluidine and hydrochloric acid, enough water is added to bring all of the material into solution at the boiling point and crystallization is allowed to take place. A barium salt should be boiled with dilute sulfuric acid, a little animal charcoal added and the filtered solution treated with *p*-toluidine. If the amine salt separates in an oily condition, the walls of the containing vessel should be thoroughly scratched, for these salts, particularly that of the 3-acid, may remain as oils for a short time even when nearly pure.

On the other hand, a fairly impure acid, or a mixture of pure isomers, gives a *p*-toluidine salt which remains as an oil almost indefinitely. This property characterizes a mixture of isomers nearly as definitely as the depression in the melting point, though this is large. In determining the melting point of one of the salts, the sample may be dried by pressing the material on a filter paper, but the capillary should not be placed in the melting-point bath when the temperature is greater than 130°, for, if the heating is commenced at a higher temperature, the material melts 20–30° below the true melting point. When the material is thoroughly dried in a vacuum at 100°, this behavior is not noted. The salts all sinter at temperatures slightly below the melting points. They are all moderately soluble in hot water, sparingly soluble in cold water and very readily soluble in alcohol.

TABLE I

p-TOLUIDINE SALTS, $C_{21}H_{19}O_3NS$

Salt of phenanthrene-( )-sulfonic acid	Melting point, °C.	Appearance	Analyses, % C (calcd., 69.01)	Analyses, % H (calcd., 5.24)
-1-	260 (267 corr.)	Needles	68.75	5.47
-2-	282 (291 corr.)	Flat needles or plates	68.82	5.17
-3-	217 (222 corr.)	Thick needles	68.85	5.47
-9-	229 (235 corr.)	Small needles	68.68	5.47

Sulfonation at 120–125° for Four Hours.—Three hundred and twenty-seven cc. of concentrated sulfuric acid was added to 500 g. of pure phenanthrene[11] in a 2-liter flask and the mixture was heated in an oil-bath and stirred by hand until it became sufficiently liquid to permit mechanical stirring. The temperature of the reaction mixture soon reached 120° and a temperature of 120–125° was maintained for just four hours. The reaction is exothermic, even after the disappearance of all of the phenanthrene, and the bath must be kept at a temperature about 4° below that of the mixture. The product first became green and some sulfur dioxide was formed; a dark brown sirup finally resulted. After heating and stirring for the time specified, this solution, while still hot, was dissolved in 3.5–4 liters of water and a concentrated solution of 400 g. of sodium hydroxide was added. After thorough cooling in an ice-bath, the precipitated sodium salt was collected on a large funnel, pressed well and washed well with a half-saturated sodium chloride solution. The filtrate contains a mixture of disulfonates.

The crude mixture of sodium salts was dissolved in 6–7 liters of water, to which there was added enough hydrochloric acid to render the solution slightly acid,[12] and a solution of 100 g. of barium chloride dihydrate was added to the boiling solution. After digestion of the fine precipitate of barium phenanthrene-2-sulfonate for a short time, the mixture was brought onto the funnel while at the boiling point. The filtrate, from which some material crystallized at once, was set aside to cool. The precipitated barium salt was digested at the boiling point with 6–7 liters of water and again collected. The filtered wash water contained, as shown by the melting point of a sample of the *p*-toluidine salt, only barium phenanthrene-3-sulfonate, which crystallized out after concentration of the solution. The main barium salt precipitate still contained a small amount of the 3-

---

[12] The solubility of the sulfonates is increased by the presence of a mineral acid but phenanthrene itself dissolves in a too strongly acidic solution.

salt, but the latter was removed, along with a little of the 2-salt, by a further boiling with 6–7 liters of water. This left the barium salt of the 2-acid in an essentially pure condition. The salts remaining in the last wash water were recovered by concentrating the solution, and they were separated by converting the barium salt mixture into a mixture of the potassium salts, dissolving this in boiling water, and adding 2 g. of barium chloride dihydrate. The precipitated salt, after washing with hot water, was the pure barium 2-sulfonate (2 g.), while the mother liquor yielded 9 g. of the 3-sulfonate.

The first filtrate from the precipitation of the main portion of the barium 2-sulfonate deposited crystals of the pure barium 3-sulfonate on cooling. The mother liquor was concentrated to a fairly small volume and saturated sodium chloride solution was added. The precipitated sodium salt was found to consist chiefly of the 3-sulfonate, and it was easily purified, after conversion into the potassium salt, by crystallization (76 g.). The mother liquor remaining from the salting-out with sodium chloride contained an appreciable amount of the 3-sulfonate, mixed probably with disulfonates, but its recovery is not easily accomplished. On boiling down the solution to a volume of 1 liter, a crystalline paste was obtained, and this was converted into the potassium salt and crystallized several times. It finally yielded 31 g. of the pure 3-sulfonate.

The total yield of barium phenanthrene-2-sulfonate was 175 g., while 146 g. of the barium salt and 107 g. of the potassium salt of phenantbrene-3-sulfonic acid were obtained. Determinations of the melting points of the *p*-toluidine salts showed that the products were free from all but traces of isomers, and the salts of the 3-acid, having been crystallized, were free from much inorganic material. The barium salt of the 2-acid contained only a small amount of barium sulfate, and from the results of alkali fusions it was judged that the material was 95% pure. On this basis the yields were: 2-acid, 18%; 3-acid, 27%.

Sulfonation at 120–125° for Shorter Periods of Tie.—When the sulfonation was carried out in the manner described above, with the exception that the reaction was stopped after two and one-half hours, a small amount of phenanthrene was unsulfonated. Only traces of phenanthrene remained when the reaction proceeded for three hours, and the yields were practically the same as for the shorter period. It is thus considered that ***the conditions most suitable for the preparation of the 2-acid and the 3-acid are: sulfonation for three hours with two molecular equivalents of concentrated acid at 120–125°.***

Owing to the increase in the yields when operating under the conditions specified, the washing of the precipitate of barium phenanthrene-2-sulfonate is not easily accomplished when working on a large scale and a slight modification of the above procedure is advisable. Instead of precipitating the barium salt from a solution of the crude sodium salt, the sodium salt was dissolved in water containing 50 cc. of concentrated hydrochloric acid (to aid in the dissolution of the salt) and the filtered solution was then neutralized with sodium hydroxide and allowed to crystallize. The crystals, consisting largely of the salt of the 2-acid, were dissolved in about 8 liters of water, 100 g. of barium chloride dihydrate was added, and the precipitate was collected and then digested with 6 7 liter portions of boiling water until the residual salt was found to be free from the isomers. It was often found that a single washing was sufficient for this purpose. The washings were concentrated to a small volume, sulfuric acid was added to precipitate the barium and the filtered solution was treated with potassium hydroxide to bring down a potassium salt mixture, which was set aside. The mother liquor from the sodium salt crystallization was concentrated and the product converted into the potassium salt. This was combined with the other batch of potassium salt and crystallized from water, giving a large quantity of the pure potassium 3-salt. The mother liquor, containing more of this salt together with some of the 2-salt, was concentrated, and the product was salted out with potassium chloride and washed free of sulfate ion.

A solution of this material was then treated with 10 g. of barium chloride dihydrate, the precipitate of the barium 2-salt was washed free of isomers and the washings were discarded. From the mother liquor there was obtained an additional quantity of the potassium 3-salt. The yields were: barium phenanthrene-2-sulfonate, 232 g. (25%); potassium phenanthrene-3-sulfonate, 225 g. (27%).

The Preparation of the **Phenanthrols.**—Werner[1] prepared 2-phenanthrol from the potassium salt of the 2-acid. If it is desired to prepare this salt from the barium salt, it is highly advisable to use the salt in the moist and finely divided condition in which it is first obtained; but the reaction with sulfuric acid is slow at best, and one should employ several fresh portions of acid. Barium sulfate carried through the filter is easily removed with animal charcoal. It is not necessary, however, to follow this rather tedious procedure, for the barium salt, prepared as described above, may be fused without difficulty. Thus 150 g. of the finely powdered salt was stirred into a melt from 450 g. of potassium hydroxide at a temperature of 290–300° in the course of fifteen minutes; the temperature was then raised to 325° and held there for five minutes. The fusion was then complete and a brown, oily layer of the phenanthrolate appeared at the top of the melt. After some cooling, but before solidification, the mass was added in small portions to a mixture of 1 liter of concentrated hydrochloric acid and about 2 kg. of ice. After thorough stirring, the phenanthrol, which was mixed with some barium sulfate, was collected, dissolved in dilute alkali and repreeipitated. The material at first separates in a finely divided condition, but when it is digested at the boiling point the particles soon become more compact and the material may be collected and washed very easily. The crude product is most conveniently purified by distillation at a pressure of 3 mm. If the barium salt used is free from any isomers, the 2-phenanthrol so prepared is completely pure and melts at 168°. The average yield was 65 g. (72%), about 8–10% of the precipitated material having been lost in the distillation. Pure 2-phenanthrol may be obtained from a mixture containing the more soluble 3-phenanthrol by crystallization from benzene, but only with the loss of a considerable amount of material. 3-Phenanthrol may be prepared in a similar manner, or from the potassium salt, and purified as suggested by Smith,[13] by-distillation in *vacuo.*

Sulfonation at **60°.**—Four hundred grams of finely powdered phenanthrene was mixed with 160 cc. of concentrated sulfuric acid and the temperature was kept at 60°. The mixture, which was frequently stirred, soon became pasty and somewhat green, and some sulfur dioxide was formed. After twenty-four hours, 80 cc. of concentrated acid was added and the mixture was stirred mechanically throughout that, and the following, day. After the reaction had proceeded for a total of three days, a viscous, bluish-green, homogeneous sirup resulted; this was dissolved in water and the solution was treated with an excess of sodium hydroxide (400 g.). The product contained some phenanthrene, which was removed by boiling a solution of the salt with animal charcoal. The filtered solution was allowed to cool and the crystalline product was subjected to the usual process of separating out the pure barium salt of phenanthrene-2-sulfonic acid, using 40 g. of barium chloride dihydrate. All mother liquors and washings were then concentrated and the material converted into the potassium salt, which was precipitated several times with potassium chloride solution in order to remove all sulfates and disulfonates. After three crystallizations of this potassium salt, a considerable quantity (95 g.) of the pure potassium 3-salt was obtained. The mother liquors were then combined and the product was converted into a ferrous salt mixture by the action of ferrous sulfate and dilute sulfuric acid. On crystallizing this salt several times, excellent needles of the ferrous salt of the 9-acid finally resulted, and from this material 70 g. of pure potassium phenanthrene-9-sulfonate was obtained by the action of po-

---

[13] Smith, J. *Chem. Soc.*, 109, 569 (1916).

tassium hydroxide. The material in the mother liquors was then converted into the potassium salt and this, after being freed from sulfates, was dissolved in water and treated with 5 g. of barium chloride dihydrate in order to precipitate a small quantity of the 2-acid still present.[14]

From this point on the separation of the combined product, which was collected in the form of the purified potassium salt, is extremely difficult and no systematic method of procedure can be specified. The mixture contains the 3-acid, the 9-acid and the 1-acid and, as stated in the introduction, the solubilities of the salts of these acids are all very nearly the same, and the separation is greatly complicated by the tendency to form supersaturated solutions. A systematic fractionation was undertaken at the outset, and potassium phenanthrene-1-sulfonate was first isolated from an intermediate fraction. The concentration of a preponderant quantity of this salt in a given fraction becomes apparent from the character of the p-toluidine salt which is obtained from it. The amine salt of this impure acid usually separates in the form of oily shreds which fail to solidify or else the solution sets to a gel. On further crystallization of the potassium salt a purification can be effected until excellent, large plates of the 1-salt are obtained, and the p-toluidine salt now has little tendency to remain in an oily or colloidal condition, but forms small, fine needles.

Little regularity was observed in the order in which the three potassium salts crystallize from the mixtures; the 3-salt may separate first, followed by the 1-salt, and then by more of the 3-salt. After dividing the material into six fractions, all solutions appeared to contain all three acids, with the exception of the "least soluble" fraction, which contained none of the 9-acid. It appears that the potassium 9-salt has somewhat less tendency to crystallize from the mixture than the other two, while the ferrous salt of the 9-acid tends to separate first. As a consequence, it is advisable to change occasionally to the ferrous salt and thus remove some of the 9-acid. The 1-acid and the 3-acid were isolated in pure condition only in portions of 0.5–2 g. at a time. This was done by carrying out numerous crystallizations, by carefully noting the appearance of the crystals separating, interrupting the process whenever a change or a pause in the crystallization was observed, and by identifying the products by means of their p-toluidine salts.

The separation finally effected was far from being complete; it was interrupted with 110 g. of the potassium salt mixture still on hand. The amounts of the salts isolated in pure condition were as follows: barium phenanthrene-2-sulfonate, 131 g. (18%); potassium phenanthrene-3-sulfonate, 127 g. (19%); potassium phenanthrene-9-sulfonate 86 g. (13%); potassium phenanthrene-1-sulfonate, 27 g. (4%).

The residual sulfonate mixture was partially identified as follows. It was subjected to alkali fusion and the phenanthrol mixture was distilled and then acetylated. After crystallizing this acetate mixture twice from alcohol, 20 g. of pure 1-acetoxyphenanthrene, m. p. 135–136°, was obtained, which brings the amount of phenanthrene-1-sulfonic acid which is known to have been produced in the sulfonation up to 8%.

Phenanthrene-1-sulfonic Acid

Metal Salts.—The potassium salt crystallizes from water in the form of large plates. The solubility in water is about the same as that of the 3-isomer. The salt is only sparingly soluble in alcohol, but dissolves readily in glacial acetic acid.

Anal. Calcd. for $C_{14}H_9O_3SK$: K, 13.19. Found: K, 13.22.

---

[14] It may be noted that the salts of the 2-acid remain in solution up to this point even though they are much less soluble than the salts of the isomers. According to Sandqvist (ref. 2, p. 8), the ferrous 2-sulfonate is but one-fourth as soluble at 20° as the ferrous 9-sulfonate,

The barium salt dissolves with difficulty in boiling water, but it only crystallizes from the well-concentrated solution. The ferrous salt crystallizes in the form of needles; it appears to be slightly more soluble than ferrous phenanthrene-9-sulfonate.

Methyl Ester.—A suspension of the potassium salt in dimethyl sulfate was boiled gently until all of the salt dissolved, and then heated on the water-bath for one hour. The solution was poured into water, the mixture was boiled for a few minutes in order to decompose the dimethyl sulfate and well cooled. The product was purified by crystallization from methyl alcohol, in which it dissolves readily; it formed colorless plates melting at 102°.

Anal. Calcd. for $C_{15}H_{12}O_3S$: C, 66.15; H, 4.45. Found: C, 65.87; H, 4.47.

Potassium **Phenanthrenequinone-1-sulfonic** Acid.—Three grams of potassium phenanthrene-l-sulfonate was dissolved in 25 cc. of glacial acetic acid and a solution of 3 g. of chromic acid in water, diluted with glacial acetic arid, was added while the temperature was kept at 100° by cooling. The yellow quinone, which began to separate after a few minutes, was brought into solution and allowed to crystallize slowly. The product (1.7 g.) was washed with alcohol and purified by adding about one volume of alcohol to four volumes of an aqueous solution and allowing crystallization to take place very slowly. Under these conditions large, orange-yellow plates were formed.

Anal. Calcd. for $C_{14}H_7O_5SK$: K, 11.98. Found: K, 11.94.

The quinone is very readily soluble in water and the yellow aqueous solution rapidly loses its color on the addition of alkali. The solution in concentrated sulfuric acid is deep red.

Derivatives of 1-Phenanthrol

Most of the material used for the following reactions was prepared from the acetate, which, in turn, was obtained from the mixture of the phenanthrene monosulfonates. The acetate appears to be much less soluble in alcohol than any of the isomers present and the isolation of the pure material is accomplished with ease. A fairly large quantity (6–10 g. from 100 g. of phenanthrene) may be obtained from the sulfonate mixture which remains after separating the greater part of the 2-acid, the 3-acid and the 9-acid.

1-Acetoxyphenanthrene crystallizes from alcohol or benzene in the form of long needles melting at 135–136°.

Anal. Calcd. for $C_{16}H_{12}O_2$: C, 81.33; H, 5.12. Found: C, 81.00; H, 5.14.

1-Phenanthrol.—Twenty grams of the acetate was warmed with 80 cc. of alcohol and 15 cc. of 6 N sodium hydroxide until the material dissolved. The solution was diluted with an equal volume of water and acidified, when the phenanthrol separated in the form of small, colorless needles; yield, 16 g. (97%), m. p., 155°. Fusion of pure potassium phenanthrene-l-sulfonate (10 *g.)* with potassium hydroxide (35 g.) at 300' gave a product which, after crystallization from benzene–ligroin, formed cotton-like clusters of colorless needles melting at 155° (157° corr.) and identical with the above product.

Anal. Calcd. for $C_{14}H_{10}O$: C, 86.57; H, 5.19, Found: C, 86.34, H, 5.27

The properties are in conformity with the observations of Shoesmith and Guthrie,[7] who prepared 1-phenanthrol synthetically.

1-Methoxyphenanthrene was prepared by the action of dimethyl sulfate and alkali. It formed long needles melting at 105° and the picrate melted at 154° corr. Pschorr, Wolfes and Buckow[8] give 105–106° and 153" corr., as the melting points of these substances.

Anal. Calcd. for $C_{15}H_{12}O$: C, 86.50; H, 5.81. Found: C, 86.35; H, 5.68.

1-Acetoxyphenanthrenequinone.—A solution of 1 g. of 1-acetoxyphenanthrene in

6 cc. of glacial acetic acid was treated with a solution of 1.2 g. of chromic acid at 70° and the temperature was kept at this point until the solution required no further cooling. The quinone, which separated on cooling, was washed with alcohol and with water, when it was nearly pure; m. p. 201°; 0.6 g. It dissolved readily in glacial acetic acid and the solution deposited orange, cluster-forming needles melting at 202° (206° corr.).

Anal, Calcd. for $C_{16}H_{10}O_4$: C, 72.17; H, 3.79. Found: C, 71.80; H, 4.08.

1-Hydroxyphenanthrenequinone.—The above acetate forms a soluble bisulfite addition product which, in a hot solution, readily undergoes hydrolysis with the formation of hydroxyphenanthrenequinone. The latter substance, being insoluble in sodium bisulfite solution, thus separates in crystalline condition. The red product which was obtained in this way was crystallized from alcohol. It dissolves readily in this solvent and the orange solution deposits very long, fiery red needles melting at 220° (227° corr.).

Anal. Calcd. for $C_{14}H_8O_3$: C, 74.98; H, 3.60. Found: C, 74.64; H. 3.89.

The solution of the quinone in concentrated sulfuric acid has an intense green color. The material dissolves in very dilute sodium hydroxide solution with the development of a grape-purple color, and the slightest excess of alkali precipitates an indigo-blue sodium salt.

The Preparation of 1,4-Phenanthrenequinone

The conversion of 1-phenanthrol into this quinone, through the azo dye and 4-amino-1-phenanthrol, was accomplished in the manner found useful for the isomeric ortho quinones,[9,15] though the yield was poorer, and the aminophenanthrol is more sensitive, than in the other cases. In the preparation of the quinone it is advisable to carry out the complete series of reactions without isolating any of the intermediates.

A solution of 2.1 g. of crystalline sulfanilic acid in 16 cc. of 0.6 N sodium hydroxide was diazotized by adding 0.7 g. of sodium nitrite and pouring the solution into a mixture of 2.5 cc. of concentrated hydrochloric acid and ice. This was coupled with a solution of 1.94 g. of 1-phenanthrol in 30 cc. of water and 5 cc. of 6 *N* sodium hydroxide. To the deep red solution of the azo dye which resulted, sodium hyposulfite solution was added and the mixture was heated until the 4-amino-1-phenanthrol which separated was completely colorless. The product was collected in an atmosphere of nitrogen, for it is ertremely sensitive to air-oxidation, it was quickly made into a very fine paste with about 100 cc. of water containing sulfur dioxide and 2.0 cc. of concentrated hydrochloric acid was added. The mixture was stirred very vigorously and heated to a temperature just below the boiling point. The pink solution was filtered from a small amount of undissolved material and this was warmed with a fresh quantity of dilute acid. The combined filtrates were cooled to room temperature, when a part of the amine hydrochloride was deposited as a fine powder. A solution of 1.2 g. of chromic acid and 1.2 cc. of concentrated sulfuric acid was then added, causing the separation of the yellow quinone in a finely divided condition. The mixture was warmed to 45° to increase the particle size and to complete the oxidation, before collecting the product. The crude material (1.2 g.) melted at 147" and contained a small amount of a black, insoluble substance. It is best purified by crystallization from ligroin with the use of animal charcoal. Pure 1,4-phenanthrenequinone forms light, fluffy, yellow needles melting at 153° (155" corr.); yield, 0.8 g. It dissolves readily in alcohol, benzene or glacial acetic acid; the solution in concentrated sulfuric acid is violet-red in color. The quinone dissolves only very slowly in acetic anhydride containing sulfuric acid.

Anal. Calcd. for $C_{14}H_8O_2$: C, 80.76; H, 3.88. Pound: C, 80.42; H, 3.88.

---

[15] Fieser, THIS JOURNAL, 51, 1896 (1929).

The hydrochloride of 4-amino-1-phenanthrol may be precipitated by adding hydrochloric acid to a solution of the salt, but it separates in the form of a gray powder and does not crystallize well. It was characterized by the preparation of a triacetyl derivative.

Triacetyl-4-amino-1-phenanthrol.—The hydrochloride (0.5 *g.)* was heated for one hour on the water-bath with an excess of acetic anhydride (5 ec.), 0.3 g. of fused sodium acetate was then added to complete the reaction and, after five minutes, the solution was poured into water. The product solidified rapidly and, when triturated with a little ether to remove some brown material, it was nearly pure. The substance dissolves very readily in methyl alcohol and the solutions have a decided tendency to remain in a supersaturated condition. When the solution is cooled rapidly and seeded, small colorless plates melting at 143° are obtained.

Anal. Calcd. for $C_{20}H_{17}O_4N$: C, 71.63; H, 5.11. Found: C, 71.56; H, 5.33.

1,4-Diacetoxyphenanthrene.—This compound was obtained by heating equal parts of 1,4-phenanthrenequinone, zinc dust and sodium acetate with 5 parts of acetic anhydride until the solution became practically colorless. The solution was diluted with glacial acetic acid, filtered, and poured into water, when the diacetate soon separated in nearly pure condition; yield, 95%; m. p. 137–138". It crystallizes well from ligroin, forming slender long needles melting at 140°.

Anal. Calcd. for $C_{18}H_{14}O_4$: *C,* 73.45; H, 4.79. Found: C, 73.17; H, 4.89.

1,4-Diacetoxy-9,10-phenanthrenequinone.—The oxidation of the diacetoxyphenanthrene does not proceed smoothly and care must be taken to avoid the hydrolysis of the product during crystallization. The oxidation was carried out in glacial acetic acid solution at 40°, using 1 g. of chromic acid to 1 g. of the diacetate. On completion of the reaction, the solution was diluted with water. An orange, semi-solid oil separated and this was triturated with cold alcohol in order to dissolve the oil and leave a clean yellow solid (0.3 g.). After two crystallizations from benzene–ligroin, golden yellow prisms melting at 181° (184° corr.) were obtained.

Anal. Calcd. for $C_{18}H_{12}O_6$: C, 66.65; H, 3.73. Found: C, 66.54; H, 3.81.

This compound has been described by Brass and Stadler,[10] who report a melting point of 183°. Through the kindness of Professor Brass in supplying a sample of 1,4-dihydroxyphenanthrenequinone, a direct comparison of the two products was possible. The sample was acetylated and the product crystallized from benzene–ligroin, when it melted at 181° and gave no depression on admixture with the above quinone. Color tests confirmed this identification.

Summary

Some improvements have been effected in the method of separating and identifying phenanthrene-2-sulfonic acid and phenanthrene-3-sulfonic acid, the chief products resulting from the sulfonation of the hydrocarbon at 120–130°. It was known that phenanthrene-9-sulfonic acid is also produced when the reaction is carried out at a lower temperature. In the course of the present work, a fourth isomer was discovered among the products of the low-temperature sulfonation and the new substance was found to be phenanthrene-1-sulfonic acid. It has been used in the preparation of a few new phenanthrene derivatives, the most interesting of which are 1-hydroxy-9,10-phenanthrenequinone and 1,4-phenanthrenequinone.

THE SULFONATION OF PHENANTHRENE.
II. DISULFONATION

BY LOUIS FREDERICK FIESER

RECEIVED MARCH 6, 1929 PUBLISHED AUGUST 7, 1929

It was observed as early as 1873 that disulfonic acids are produced in the sulfonation of phenanthrene along with the monosulfonic acids, even when the reaction is stopped before all of the hydrocarbon has been consumed,[1] and yet there is no information available concerning the nature of these disulfonic acids. When the sulfonation is conducted at 120–130°, under the conditions best suited for the preparation of the 2- and the 3-monosulfonates, over 40% of the phenanthrene is converted into disulfonates.[2] Having collected a certain quantity of this material as a by-product, it became a matter of interest to attempt to learn something of the composition of the mixture.

A method of isolating a mixture of the potassium disulfonates in a form free from inorganic salts was found, and some attempts were made to effect a separation of the isomers. This difficult task, however, was not accomplished. Among the obstacles, the extreme solubility of the potassium salts may be mentioned. Potassium sulfate crystallizes out first from a solution of the organic and inorganic salts; even the barium salt is very soluble. The tendency to form supersaturated solutions, so often noted with phenanthrene derivatives, is particularly marked with these salts. In addition to these unfavorable properties, one is confronted with an extremely complex mixture. From the results to be presented below, it may be said that there are probably twelve isomers present in the mixture.

In order to simplify the problem, a study was made of the disulfonic acids produced when pure phenanthrene-2-sulfonic acid and the 3-isomer are treated with sulfuric acid at 120–130°. In each case there was obtained a mixture of extremely soluble disulfonates having the unfavorable properties noted above, and a separation was not achieved. The mixtures were fused with alkali, but the phenanthrol mixtures, though easily purified by distillation at a reduced pressure, likewise resisted efforts to effect a separation. When the phenanthrol mixtures were acetylated, on the other hand, it was possible, by fractional crystallization, to isolate three pure diacetoxyphenanthrenes as the result of each sulfonation. While it is a relatively easy matter to separate the greater part of the chief constituent of each mixture, the isolation of the substances formed in smaller quantity was accomplished only after a great many fractionations.

[2] Fieser, THIS JOURNAL, 51, 2460 (1929).

As in the separation of the phenanthrene-monosulfonic acids, one encounters here the phenomena of supersaturation and of an order of Crystallization which is contrary to the solubility relationships. Though the separations were thus incomplete, it will be seen from the following results that a fairly comprehensive account is given of the course of the sulfonations. From potassium phenanthrene-3-sulfonate, there was obtained, on sulfonation and fusion, a phenanthrol mixture corresponding to 83% of the theoretical amount, while the distilled material amounted to 77%. Conversion into the diacetate was quantitative and 70% of this was separated into the pure constituents. The melting points of the isomers, and the amounts which were obtained in pure condition from the mixtures, are given in the following table.

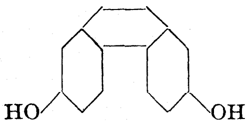
TABLE I

DIACETOXY-PHENANTHRENES OBTAINED

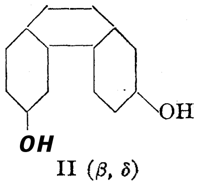
	From phenanthrene-3-sulfonic acid			From phenanthrene-2-sulfonic acid		
	α	β	γ	6	ε	ζ
M. p., °C.	124.5	122–123	184	122–123	181.5	125
Yield, %	59.1	10.0	0.9	54.1	2.1	1.0

The problem of determining the positions of the substituents in these compounds is to some extent simplified by the fact that they all yield diacetoxy-9,10-phenanthrenequinones on oxidation, showing that the second substituent has in no case entered the 9- or 10-position. While none of the phenanthrene derivatives correspond to known compounds, the quinone obtained from one of them, namely, ε-diacetoxyphenanthrenequinone, was found to be identical with 2,7-diacetoxyphenanthrenequinone which has been described by several investigators.[3,4] This proves that the ε-isomer, melting at 181.5°, is the diacetate of 2,7-dihydroxyphenanthrene, I.

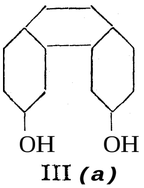
A further fact of value in the elucidation of the structural problem is that two of the substances listed in Table I are identical.



I (ε)



II (β, δ)



III (α)

The β-diacetate, which constitutes 10% of the product obtained from the 3-sulfonic acid, is identical with the δ-diacetate, which is the chief product

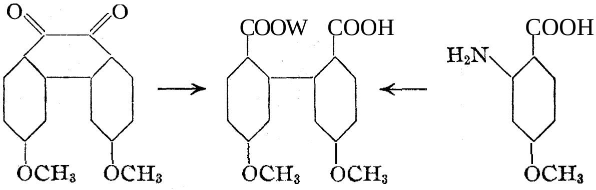
[4] Through the courtesy of Professor Brass, to whom the author wishes to express his thanks, a direct comparison of the two substances was possible.

resulting from the sulfonation of the 2-sulfonic acid. Assuming that no rearrangement has taken place, the diacetate which is obtained from both the 2-acid and the 3-acid must have a structure corresponding to 2,3-dihydroxyphenanthrene, or to 2,6(or 3,7)-dihydroxyphenanthrene, II. The former structure is not only improbable, but is definitely ruled out because the dimethyl ether and the dihydroxyphenanthrenequinone derived from the new dihydroxyphenanthrene are different from the known 2,3-dimethoxyphenanthrene[5] and 2,3-dihydroxyphenanthrenequinone.[6] The substance, therefore, may be assigned the structure of II.

From the foregoing it is seen that in three instances, in the production of a disulfonic acid from a monosulfonic acid, the second substituent has entered the unsubstituted, terminal benzene ring. It is not unreasonable to suppose that this rule also holds for the formation of the acid of the a-series, whence the substituents in this series are probably-in the 3,5-, the 3,6- or the 3'8-positions, since the 3,7-isomer is already known. It will be observed that the isomer in question is the chief reaction product. Recalling the fact that the monosulfonation of phenanthrene gives the 3- and the 2-acids as the chief products, while a relatively small amount of the 1(or 8)-acid, and none of the 4(or 5)-acid, is formed, it will be seen that the most probable structure for the a-series is represented by III, the 3,6-derivative.

The correctness of this conclusion was proved in the following manner. The dimethyl ether of the a-series was oxidized to a quinone, IV, and this was oxidized by hydrogen peroxide in glacial acetic acid solution. Two products were obtained, one having the properties of a lactone, the other (V) giving reactions characteristic of a diphenic acid, such as the formation of a fluorenorie on treatment with sulfuric acid. The same diphenic acid, V, was obtained synthetically from 4-methoxy-2-aminobenzoic acid, VI.



IV V VI

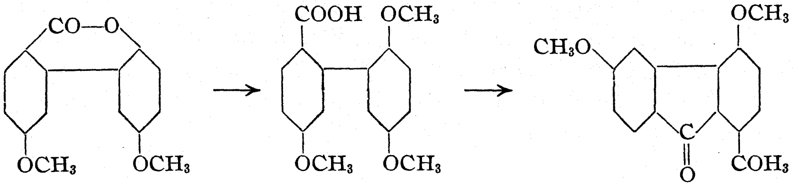
The formation of the lactone in the oxidation of 3,6-dimethoxyphenanthrenequinone represents a somewhat unusual reaction. The substance has the formula $C_{15}H_{12}O_4$. It dissolves in alkali only on long boiling. That this is not due to a lack of solubility of the sodium salt but to the slow opening of a lactone ring is shown by the result of methylation in

---

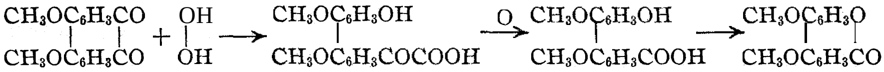
[5] Pschorr and Buckow, *Ber.*, **33, 1831** (1900).

[6] Brass, Ferber and Stadler, *ibid.*, 57, 127 (1924).

alkaline solution (followed by boiling with alkali), for a substance differing from the lactone by the elements of methyl alcohol is thus obtained and the new compound dissolves in cold carbonate solution. This methylated derivative yields a trimethoxyfluorenone on dissolution in concentrated sulfuric acid, indicating the presence of a carboxyl group adjacent to a diphenyl linkage. These facts point to the structures VII, VIII and IX for the compounds concerned. The lactone, VII, could not be obtained on treating 5,5′-dimethoxydiphenic acid with hydrogen peroxide, and it must, therefore, come directly from 3,6-dimethoxyphenanthrenequinone. It is probably produced as follows



VII VIII IX



$$\begin{array}{l}CH_3OC_6H_3CO\\ \quad | \qquad\quad |\\ CH_3OC_6H_3CO\end{array} + \begin{array}{l}OH\\ |\\ OH\end{array} \longrightarrow \begin{array}{l}CH_3OC_6H_3OH\\ \quad |\\ CH_3OC_6H_3COCOOH\end{array} \xrightarrow{O} \begin{array}{l}CH_3OC_6H_3OH\\ \quad |\\ CH_3OC_6H_3COOH\end{array} \longrightarrow \begin{array}{l}CH_3OC_6H_3O\\ \quad | \qquad\quad |\\ CH_3OC_6H_3CO\end{array}$$

According to this interpretation, the action of hydrogen peroxide on 3,6-dimethoxyphenanthrenequinone involves not only the usual splitting between the two ketone groups but also a cleavage of the bond between one ketone group and a benzene ring. So far as the author is aware, this type of oxidation has not been observed previously in the phenanthrenequinone series. It finds a certain parallel, however, in the alkaline oxidation of purpurin to 2,5-dihydroxybenzoquinone,[7] and a close analogy is found in the alkaline oxidation of alizarin to 2-hydroxy-1,4-naphthoquinone-3-vinylglyoxylic acid,[8] if it is true that this reaction involves, as the first step, the formation of a diquinone.

To return to the problem of determining the structures of the compounds listed in Table I, it will be seen that only the y- and the ζ-series remain to be accounted for. If it is again assumed that the second substituent enters the unsubstituted, terminal ring, only two structures remain for the y-series and two for the {-series: the γ-series must have the 3,5- or the 3,s-structure; the substituents in the {-derivatives must be in the 2,5- or the 2,8-positions. 2,5-Dihydroxyphenanthrenequinone, however, is a known compound,[9] and the dihydroxyphenanthrenequinone of the

---

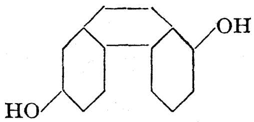
[7] Scholl and Dahll, *Ber.*, 57, 80 (1924).

[8] Scholl and Zinke, *ibid.*, 51, 1419 (1918).

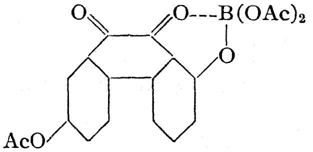
[9] Schmidt and Kampf, *ibid.*, 36, 3750 (1903), who first prepared this quinone, regarded it as 4,5-dihydroxyphenanthrenequinone, but the evidence of Christie and Kenner, J. Chem. *Soc.*, 470 (1926), and of Christie, Holderness and Kenner, *ibid.*, 671 (1926), convincingly supports the 2,5-structure.

ζ-series does not have the properties ascribed to this substance. It is probable, therefore, that the ζ-derivatives belong to the 2,8-series, X.

A very delicate means of confirming the structure assigned to the ζ-series, and of distinguishing between the two possible structures for the γ-compounds, was found in the application of the elegant method of Dimroth for the recognition of an hydroxyl group in a position adjacent to a quinone carbonyl group.[10] The method, which has been applied already to a few hydroxyphenanthrenequinones,[10b] consists in comparing the action of acetic anhydride on the quinone with the action of a solution of boro-acetic anhydride in acetic anhydride. With the latter reagent, ordinary acetylation takes place when the hydroxyl group is not adjacent to the carbonyl group, but an hydroxyl group in this favorable position, that is, in the 1- or &position in phenanthrenequinone, enters into the formation of a boro-acetate complex, which is characterized by having an intense color. Thus the quinone corresponding to X should yield the substance XI, and the formation of such a complex should be evident from the development of a distinctive color. With the absence of an hydroxyl group in the 1- or &position, both boro-acetic anhydride and acetic anhydride can be expected to yield a yellow or orange simple acetate.



X (ζ)

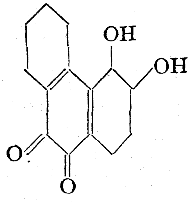


XI

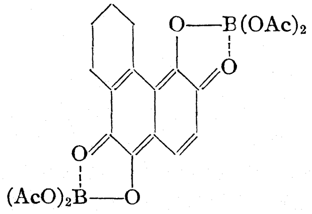
Before applying the Dirnroth test to the new dihydroxyphenanthrenequinones, it seemed desirable to extend Dimroth's observations by making at least a brief study of the action of the boro-acetic anhydride reagent on the various hydroxyphenanthrenequinones of known structure which have been prepared recently by the author. Experiment showed that the colors of the solutions in acetic anhydride and in the boro-acetic anhydride reagent were identical (usually pale yellow or orange) with quinones having the hydroxyl groups in the following positions: 2,5-, 2,6-, 2,7- and 3,6-, and to this list may be added, from Dimroth's results, the 2- and 3-derivatives. With the groups in the following positions, on the other hand, a striking change to green was observed in the presence of boro-acetic anhydride: 1,2-, 1,4-,[10b] 1,2,4-; while the color changed to red in the case of 1-hydroxyphenanthrenequinone, and 1,3,4-trihydroxy phenanthrenequinone gave a sparingly soluble red precipitate.

[10] (a) Dimroth and Faust, *Ber.*, **54**, 3020 (1921); (b) Dimroth, *Ann.*, **446**, 97 (1926); (c) Dimroth and Ruck, *ibid.*, **446**, 123 (1926); (d) Dimroth and Roos, *ibid.*, **456**, 177 (1927).

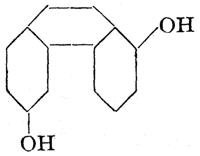
With only one compound was the behavior such as to constitute a possible anomaly. Morpholquinone, XII, though it contains no hydroxyl group in the favorable ortho position, imparts to a cold solution of boro-acetic anhydride a red color which becomes intensely purple on warming, and dark red crystals separate from the solution. On boiling, a deep green solution results. According to the theoretical analysis which Dimroth[10b] has made of the problem, it is possible that the formation of a complex is in this case due to a tautomeric change and that one of the products formed has the amphi-quinonoid structure, XIII, though the failure of 3-hydroxyphenanthrenequinone to form a complex renders this explanation unlikely. It is also possible that the two ortho hydroxyl groups enter into combination with the reagent, forming primary valence compounds of the type



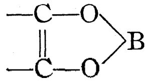
XII



XIII



XIV (γ)



$$\begin{matrix} —C—O \\ \| \\ —C—O \end{matrix}\!\!>\!B—OAc$$

, or complex compounds of the type described by Böesecken[11] and by Rosenheim and Vermehren.[12] A reaction of this character appears to be the more probable in view of the fact that the red precipitate first formed is not as easily attacked by water as the complexes obtained by Dimroth. Thus the present indications are that the unusual reaction of morpholquinone is connected with the presence of two adjacent hydroxyl groups. Since such a grouping is impossible for the two new dihydroxyphenanthrenequinones, it was felt that the test could be applied with confidence to these substances and the interesting behavior of morpholquinone was not studied further.

When the dihydroxyphenanthrenequinoneof the ζ-series was examined, it was found that boro-acetic anhydride produced an intense green coloration in the cold, and that this became purple on warming. The compound, therefore, has one group in the 1(or 8)-position and, since the other group is fixed at 2, and the compound differs from the known 1,2-isomer, the substance may be assigned the formula of the 2,8-derivative, corresponding to X. The isomer of the γ-series also forms a complex with boro-acetic anhydride, evident from the red coloration produced, and it is thus considered to be the 3,8-derivative, corresponding to XIV, though it is possible, if highly improbable, that it is 1,3-dihydroxyphenanthrenequinone.

---

[11] Boesecken, Chem. Zentr., II, 1341 (1923).

[12] Rosenheim and Vermehren, *Ber.*, 57,1337, 1828 (1924).

The conclusions concerning the new dihydroxyphenanthrenes, and the disulfonic acids from which they were obtained, may be summarized in the following way

$$\text{Phenanthrene-3-sulfonic acid} \longrightarrow \begin{cases} \text{3,6-Disulfonic acid (a-Series)} \\ \text{3,7(or 2,6)-Disulfonic acid (8-Series)} \\ \text{3,8-Disulfonic acid } (\gamma\text{-Series}) \end{cases}$$

$$\text{Phenanthrene-2-sulfonic acid} \longrightarrow \begin{cases} \text{2,6-Disulfonic acid } (\delta\text{-Series}) \\ \text{2,7-Disulfonic acid } (\epsilon\text{-Series}) \\ \text{2,8-Disulfonic acid } (\zeta\text{-Series}) \end{cases}$$

In the monosulfonation of phenanthrene, the substituent enters the 1-, the 2-, the 3- and the 9-positions; a second substituent, at least in the case of the 2- and the 3-acid, enters the 8-, the 7- and the 6-, or what may be termed the 1′-, the 2′- and the 3′-, positions. In each case, the predominant isomer is that produced by substitution in the 3(or 6)-position. In no instance has substitution in the 4(or 5)-position been observed.

Experimental Part

Experiments with the Disulfonate Mixture.—It was stated in Part I that the neutralization of the sulfonation product with alkali causes the monosulfonates to crystallize out completely, while the disulfonates are largely retained in the mother liquor. When an attempt was made to isolate the disulfonic acids, in the form of their potassium salts, by concentration of such a solution, there separated at the boiling point a substance which appeared to be gelatinous, but which was found to have a fine, hair-like structure and to consist largely of potassium sulfate. The addition of a large quantity of potassium hydroxide, however, brings about the precipitation of a mixture of potassium phenanthrene-disulfonates. The material may be freed from inorganic salts by repeated precipitation with potassium hydroxide, followed by washing with alcohol, and analyses agreed with the values calculated for a disulfonate. The material is extremely soluble in cold water and it could not be crystallized. Even the barium salt is very soluble in water and has little tendency to crystallize; the solutions have a soapy consistency. The *p*-toluidine salt separates as an oil only from a very concentrated solution. By fusion of the disulfonate mixture and distillation of the product, a solid phenanthrol mixture was obtained but this is not well adapted to a separation by fractional crystallization. It is very readily soluble in alcohol and very sparingly soluble in benzene. Crystallization of the mixture obtained on acetylating this material gave some promise of success and this method of separation was adopted in the experiments described below.

The Sulfonation of Potassium Phenanthrene-3-sulfonate.—The sulfonates used in carrying out these reactions were carefully freed not only from all traces of isomers but also from traces of potassium chloride, which interferes with the reaction. Ninety-four grams of the potassium 3-sulfonate was stirred into 94 cc. of concentrated sulfuric acid and the mixture was heated in an oil-bath at 130°. The temperature of the reaction mixture soon reached 125°, and it was then maintained at 125–130° for one and one-half hours.[13] The reaction is exothermic and it is necessary to keep the bath temperature about 10° below that desired for the reaction. The mixture was stirred thoroughly in order to break up the lumps which first formed. A clear, viscous solution usually resulted after about thirty- minutes, and at the same time a crystalline salt began to

---

[13] The results were the same when the heating was continued for three hours.

separate, so that, at the end of the specified time, a thick, almost solid, crystalline paste resulted. This was dissolved in 700–800 cc. of water and the solution was neutralized with a concentrated solution of about 200 g. of potassium hydroxide and then rendered slightly acid. The solution was next boiled down until the separation of solid material caused too much bumping, when it was poured, in portions, into an evaporating dish and dried in the oven.

The finely powdered mixture of disulfonates and potassium sulfate was fused with 700 g. of potassium hydroxide at a temperature of 280–305°. Fusion took place smoothly, giving a thick, brown melt. This was dissolved in water, to which ice was added, the greater part of the alkali was neutralized, and the hot, filtered solution was then acidified and cooled. The quality of the product was improved by a further precipitation from alkali, though the material slowly undergoes oxidation unless the solution is again acidified without delay. The dried phenanthrol mixture formed a gray powder weighing 55.5 g. and melting at about 175–200°. It was distilled at a pressure of 3 mm., taking care to avoid exposure of the molten material to the air, for it is easily oxidized. The distillate (51 g.) was dissolved in acetic anhydride and the solution was boiled for one hour and then poured into water. The diacetate mixture soon solidified and the crushed and well-washed material dried in the course of two days to a weight corresponding closely with the theoretical weight (71.3 g.). The product was somewhat green and melted at 95–125°.

The mixture of diacetates was first crystallized from a minimum quantity of alcohol in order to remove a small amount of acetic acid and oil, and then was subjected to a systematic fractionation from alcohol. The product at first separated in the form of a stiff paste of amorphous material, but, after six crystallizations, the top fraction formed blades of pure 3,6-diacetoxyphenanthrene (31.5 g.), while a further quantity (5 g.) of this isomer was soon separated as the least soluble of the remaining fractions. This isomer crystallizes in the form of long, flat blades having a characteristic gloss and melting, when perfectly pure, at 124.5'. On further crystallization the 3,8-isomer became concentrated in the top fraction along with the 3,6-derivative. For a time it was difficult to distinguish this mixture, which formed plates, from the pure 3'6-isomer, except that the melting point was a few degrees too low and not sharp. After further crystallization the melting point was raised to about 130°, at which point a fairly complete separation becomes possible. If a solution of the somewhat feathery plates is closely watched. a pause in the progress of the crystallization may be observed. If the solution is quickly filtered without undue disturbance, needles of the 3,8-isomer melting at 182–183° may be obtained, while blades of the nearly pure 3.6-isomer crystallize at once from the filtrate. Pure 3,8-diacetoxyphenanthrene forms long slender needles from alcohol and melts at 184°.

The 2,6-isomer becomes concentrated in the more soluble fractions and may be recognized from the fact that it forms clusters of stout needles melting at about 115–117". Though the crystals appear to be well-formed, the compound on further purification melts at 122–123° and forms small plates. The needle form, however, is not only characteristic of the material in a certain stage of purification, but it is an aid in effecting a separation. A mixture of these needles with blades of the 3,6-isomer may be warmed with alcohol until the blades are dissolved, without greatly affecting the compact needles.

While alcohol is preferred as a solvent with which to carry out the first crystallizations, a point is reached where further working of the mixture becomes unprofitable and it is then advisable to change to benzene–ligroin. Using the latter solvent, and having removed the greater part of the 3,6-isomer, it is found that the high-melting 3,8-diacetate is the first to crystallize. It first forms a crust of small crystals and then good, prismatic needles The 2'6-isomer again concentrates in the tail fractions and the 3,6-diacetate was obtained from intermediate fractions.

The separation was not carried to completion, but was interrupted when the following quantities of the pure isomers had been collected: 3,6-diacetoxyphenanthrene, 42.2 g.; 2,6-diacetoxyphenanthrene, 7.2 g.; 3,8-diacetoxyphenanthrene, 0.7 g.[14]

The Sulfonation of Sodium Phenanthrene-2-sulfonate.—A mixture of 63 g. of the salt and 63 cc. of concentrated sulfuric acid was heated at a temperature of 125–130° for just thirty minutes, when the reaction was found to be complete. The material in this case dissolved very easily and crystallization of the acid sodium salt did not take place. The reaction mixture was worked up and converted into a diacetate mixture in exactly the same manner as with the isomer. The crude phenanthrol mixture **(39.5** *g.)* gave 37.5 g. (71%) of distilled product, while the yield of the diicetate mixture was quantitative **(47.3** g.). The latter substance was somewhat oily until it was triturated with dilute sodium hydroxide solution.

The diacetate mixture was again fractionally crystallized from alcohol. On the first crystallization the material separated as an oil which soon solidified, but it thereafter formed crystals. After seven crystallizations, the greater part of the 2,6-diacetoxyphenanthrene was obtained from the top, or "less soluble," fractions (23 g.). The compound has been described above. The tendency to form needles when slightly impure was again noted.

2,7-Diacetoxyphenanthrene (m. p. 181.5") made its initial appearance in the very first mother liquor. The solution, which contained about one-fifth of the total product, was dark brown and contained ethyl acetate. On long standing it deposited hard crystalline clusters melting at about 120–140°. Once obtained in this condition, the diacetate was easily purified by crystallization from alcohol, for it now appears to be distinctly less soluble than either of the other isomers present. It forms small, thin plates when completely pure and when the solution cools slowly, though needle-like crystals were often obtained on rapidly cooling a solution.

The intermediate fractions, after the removal of small additional quantities of the 2,6-isomer, deposited a few of the hard clusters of the impure 2,7-diacetate, and the third isomer then made its appearance. 2,8-Diacetoxyphenanthrene first crystallized in the form of round clusters of needles radiating from a common base. The material had the appearance of a pure compound and melted fairly sharply at 117–118°, but after several crystallizations from alcohol and from benzene–ligroin, a constant melting point of 125" was found. The compound forms long slender needles from either solvent.

The amounts of the pure isomers which could be collected at a time were usually not over 0.1–0.2 g., and when the returns fell below this limit the solvent was changed. Before using benzene–ligroin, however, it seemed expedient to distil the collected material at a diminished pressure in order to remove moisture and some coloring matter. The glass-like product so obtained was caused to crystallize only by the use of alcohol, but it could then be crystallized from benzene–ligroin, From this solvent-pair, the 2,7-isomer separated first, followed by the 2,8-diacetate, while none of the 2,6-derivative could be collected.

The separation was discontinued when the following quantities of the pure isomers had been obtained: 2,6-diacetoxyphenanthrene, 25.6 *g.;* 2,7-diacetoxyphenanthrene, 1.0 *g.;* 2,8-diacetoxyphenanthrene, 0.5 g.

The 2,6-diacetoxyphenanthrene thus obtained was carefully compared with the product resulting from the sulfonation of phenanthrene-3-sulfonic acid, and the two substances, as well as their hydrolysis products and the dimethyl ethers, were found to be identical.

---

[14] The presence of this last isomer was overlooked in earlier experiments carried out on a smaller scale.

Diacetoxyphenanthrenes.—Since each of the five isomers has been described in the foregoing passages, it is sufficient to record here the analyses.

TABLE II

DIACETOXYPHENANTHRENES, $C_{18}H_{14}O_4$

Positions of substituents	M. p., °C.	Appearance	Analyses, % C, calcd : 73.45	Analyses, % H, calcd.: 4.79

The dihydroxyphenanthrenes are only sparingly soluble in toluene; they dissolve very readily in alcohol and they are moderately soluble in boiling water. They are conveniently crystallized from dilute alcohol or from a xylene–toluene mixture. No means was found for separating a mixture of isomers. The compounds may be distilled without loss if precautions are taken to avoid much contact of the molten material with the air. The specimens were colorless except as noted; attempts to remove the color in the cases of the last two compounds in the table were without avail. The dihydroxyphenanthrenes all form orange or yellow solutions in concentrated sulfuric acid. The alkaline solution exhibited a blue fluorescence with the 2,8-, the 3,6- and the 3,8-isomers, and all of the alkaline solutions slowly darkened on exposure to the air. Though it is theoretically possible to formulate quinones derivable from three of the compounds, none of the five isomers possesses the properties of a hydroquinone. 2,7-Dihydroxyphenanthrene, for example, might be expected to yield 2,7-phenanthrenequinone; but it is not attacked by silver oxide even in a boiling nitrobenzene solution. The other isomers are equally indifferent.

Dimethoxyphenanthrenes.—The ethers were prepared by methylation with dimethyl sulfate in alkaline solution. Their properties are all quite similar: they are very readily soluble in alcohol or benzene, and they form excellent, long, colorless needles on crystallization from methyl alcohol. In the case of the 2,6-isomer it is necessary to induce crystallization, best by seeding, for otherwise a sponge of amorphous material separates from the supersaturated solution. A mixture of benzene and ligroin is a less suitable solvent; with the 3.8-derivative, compact clusters of ill-formed crystals resulted. It is possible to effect a separation of mixtures of the isomeric ethers by fractional crystallization.

3,8	117	Needles	80.75	6.14

Diacetoxyphenanthrenequinones.—The conditions found most suitable for carrying out the oxidation of the diacetoxyphenanthrenes were as follows: 1 g. of the diacetate was dissolved in 8–10 cc. of glacial acetic acid and, while controlling the temperature to 60°, a solution of 1.1 g. of chromic acid in the minimum quantity of water, and diluted with glacial acetic acid, was added. A red solution resulted and in most cases it deposited the quinone, on cooling, in a crystalline condition. With the 2,7-isomer it was necessary to use more glacial acetic acid (19 cc.) in order to keep the diacetate in solution. The 2,8-isomer did not crystallize from the glacial acetic acid solution, and the addition of water caused the precipitation of an oil. When this was triturated with alcohol, a clean, solid product was obtained. With the other compounds it was only necessary to collect the crystalline material and to wash it thoroughly with alcohol, water, and again with alcohol, in order to obtain a good product. The yield, in the case of the 2,6-, 2,7- and 3,6-derivatives, was 0.5–0.7 g. of crystallized product, while the yield of the 2,8-isomer was much poorer. 3,8-Diacetoxyphenanthrenequinone was produced

TABLE V

DIACETOXY-9,10-PHENANTHRENEQUINONES, $C_{18}H_{12}O_6$

Positions of substituents	M. p., °C.	Appearance	Analyses, % C, calcd.: 66.65	H, calcd.: 3.73
2,6	216–217 (220–221 corr.)	Golden-yellow plates	66.42	3.80
2,7	238 (244 corr.)	Long slender orange needles	66.35	3.80

3,6	217 (232 corr.)	Fine yellow needles	66.39	4.01
3,8	217–218 (221–222 corr.)	Flat orange-yellow needles	66.43	3.82

in quantitative yield, which was a fortunate circumstance in view of the small amount of material available.

The isomers differ considerably in appearance and in their solubility relationships. The 2,6-derivative is moderately soluble in alcohol and crystallizes well from this solvent. With the 2,7- and the 3,6-derivatives, the solubility in alcohol is slight and the best solvent for the crystallization is glacial acetic acid. 2,8-Diacetoxyphenanthrenequinone dissolves readily in benzene and crystallizes well from a benzene–ligroin mixture. The 3,8-isomer gives a paste of poor crystals from glacial acetic acid but forms excellent crystals from alcohol or benzene. With all of the compounds several crystallizations are usually necessary before a pure product is obtained. Since the color reactions of these quinones are reactions characteristic of their hydrolysis products, they will be described below.

Dihydroxyphenanthrenequinones.—The diacetoxyphenanthrenequinones were hydrolyzed with alcoholic sodium hydroxide solution. The reaction proceeds in the cold, with the formation of an intensely colored solution, and a sodium salt soon begins to precipitate. The mixture is diluted with water and heated until all of the material passes into solution, and the filtered solution is acidified. The product often separates in a highly dispersed condition, but it becomes more easily filterable on digestion at the boiling point. A very good product was obtained in each case. Only two of the isomers were available in quantity sufficient for analysis.

2,6-Dihydroxyphenanthrenequinone.—While no solvent suitable for the crystallization of this material was found, the reprecipitated material gave satisfactory analytical figures. It was obtained as a reddish-brown powder, readily soluble in glacial acetic acid or alcohol, very sparingly soluble in xylene and rather hygroscopic. It is easily acetylated by acetic anhydride in conjunction with either pyridine or concentrated sulfuric acid.

Anal. Calcd. for $C_{14}H_8O_4$: C, 69.99; H, 3.36. Found: C, 69.88; H, 3.56.

3,6-Dihydroxyphenanthrenequinone.—As precipitated from an alkaline solution, the material formed a light orange powder. It is very sparingly soluble in water, alcohol or glacial acetic acid, and only moderately soluble in nitrobenzene. Crystallization from the latter solvent gave orange-red micro-needles

Anal. Calcd. for $C_{14}H_8O_4$: C, 69.99; H, 3.36. Found: C, 69.81; H, 3.81.

An account of the color reactions of the five dihydroxyphenanthrenequinones is given in Table VI, while Table VII summarizes a series of

TABLE VI

COLOR REACTIONS OF THE DIHYDROXYPHENANTHRENEQUINONES

1,2,4	Faint purple to yellow	Green to red
1,3,4	Red to yellow	Red[16]

Comparison of ε-Diacetoxyphenanthrenequinone with 2,7-Diacetoxyphenanthrenequinone.—Since the ε-quinone, which, for convenience, has been called 2,7-diacetoxyphenanthrenequinone in the above passages. corresponded closely in properties with the substance known to have this structure,[3] a direct comparison was desirable This was greatly facilitated by Professor Brass, who kindly supplied a sample of the material, in an impure condition. After repeated crystallization from glacial acetic acid, the substance formed brown-red lumps of indefinite shape and the melting point was raised to 234°. The sample obtained in the present work had an entirely different appearance (long, orange needles) and melted at 238°, but mixtures of the two specimens always melted between these two temperatures. After assuring myself that other diacetoxyphenanthrenequinones which melt at about the same temperature exhibit a very decided depression when mixed with each other, I became convinced that the two specimens were identical, but that the material prepared from the diacetoxyphenanthrene was purer than that previously obtained. This conclusion was supported by the results of comparative color tests with the dihydroxyphenanthrenequinones obtained by hydrolyzing the two diacetates. The new compound, as precipitated from an alcoholic alkaline solution, has a dull blue color under certain lighting conditions, but the true color, clearly seen on rubbing the material on a glass slide, is dull red. The microscope revealed a mass of well-formed needles. The compound of known structure, which may be called the Anschiitz compound, after the discoverer, was also dull red when rubbed on glass but the crystalline structure was not well developed. The most characteristic color reaction of the Anschiitz compound, as described by Werner,[3c] is that the yellow-green solution in very dilute alkali becomes yellow on adding more concentrated alkali. Table VI shows that the present compound likewise gives this test. The only difference observed in a direct comparison was that the solutions of the Anschiitz compound were less bright than the others, and this was true of the solutions in concentrated sulfuric

---

[15] Dark red crystals separated on gently heating; the solution became brown and then intensely green on boiling.

[16] Dark red crystals were deposited.

acid and in pyridine. All of these observations indicate the identity of the two compounds and show that the method of preparation here described yields a better product than has yet been obtained by the older method of hydrolyzing the tetrazonium salt of 2,7-diaminophenanthrenequinone.

Proof of the Structure of the α-(3,6)-Dihydroxyphenanthrene

3,6-Dimethoxyphenanthrenequinone.—Thirty-two grams of 3,6-diacetoxyphenanthrene was hydrolyzed with alcoholic sodium hydroxide solution and the product was methylated with dimethyl sulfate in alkaline solution. The ether was purified by distillation at a pressure of 3 mm., when it melted at 102°; yield, 25 g. (96%). This material was dissolved in 170 cc. of glacial acetic acid, the solution was cooled to 60° and a solution of 27 g. of chromic acid was slowly added while the temperature was kept below 70° by cooling in an ice-bath. In the early stages of the reaction a tarry brown precipitate formed, but this soon dissolved and crystals of the quinone were deposited from a dark red solution. On completion of the reaction the solution was well cooled and the product was collected and washed with alcohol. A single crystallization from glacial acetic acid gave a pure product; yield, 16.2 g. (60%).

The quinone is sparingly soluble in alcohol and only moderately soluble in glacial acetic acid. It crystallizes well from the latter solvent, forming yellow needles melting at 235" (241° corr.).

Anal. Calcd. for $C_{16}H_{12}O_4$: C, 71.62; H, 4.51. Found: C, 71.36; H, 4.46.

Oxidation of **3,6-Dimethoxyphenanthrenequinone.**—A solution of 9 g. of this quinone in 450 cc. of glacial acetic acid was prepared and cooled to 90°. Six cc. of 30% hydrogen peroxide solution was then added and the solution was allowed to stand at 60–90° for two hours. Part of the quinone had crystallized at the end of this time; this was dissolved and the solution was again treated with 6 cc. of hydrogen peroxide solution. While the quinone did not again separate, it was found advisable to repeat this process after a further two hours and then to allow the solution to stand in a warm place overnight. The greater part of the acetic acid was then removed from the pale brown solution by distillation and water was added. This caused the separation of a dark brown oil, but this partially dissolved and partly solidified on adding an excess of alkali. After prolonged boiling the solid was all brought into solution, but the solution had such a dark brown color that it was treated with a little hydrogen peroxide and warmed until it become pale yellow.[17] The yellow product which precipitated on acidifying the solution, and after very thorough cooling, was triturated with a cold, dilute sodium carbonate solution until no more material dissolved. The residue was only slightly colored, and it was found to consist of the lactone described below in nearly pure form; yield, 0.9 g.; m. p. 190°. From the carbonate solution there was obtained 3.6 g. of 5,5′-dimethoxydiphenic acid, which was somewhat yellow, but fairly pure.

5,5′-Dimethoxydiphenic Acid (V).—Like the parent acid, this substance has a pronounced tendency to form supersaturated solutions. It dissolves very readily in alcohol or glacial acetic acid, moderately in water and is practically insoluble in benzene. The crude material was crystallized several times from dilute alcohol and then from methyl alcohol, when it was obtained in the form of colorless needles melting at 229" (234° corr.).

Anal. Calcd. for $C_{16}H_{14}O_6$: C, 63.56; H, 4.67. Found: C, 63.27; H, 4.69.

1,6-Dimethoxyfluorenone-4-carboxylic Acid.—The dimethoxydiphenic acid forms a brown solution in concentrated sulfuric acid which rapidly becomes deep red on warming. Such a solution was warmed at about 50° for one-half hour and then poured into

---

[17] The results were the same when this treatment was omitted, or when the crude oil was first treated with carbonate solution.

water.* This caused the separation of a finely divided yellow substance. The compound is only moderately soluble in glacial acetic acid, but it forms good, small, bright yellow crystals if the solution is cooled rapidly or seeded; otherwise an amorphous product slowly separates from a highly supersaturated solution. The compound decomposes alkali carbonates; it melts at 295° (303° corr.) and gives off carbon dioxide at that temperature,

Anal. Calcd. for $C_{16}H_{12}O_5$: C, 67.59; H, 4.26. Found: C, 67.32; H, 4.28.

For further characterization the fluorenonecarboxylic acid was converted into ***the amide,*** as follows: 1.2 g. of the acid was heated with 1 g. of phosphorus pentachloride at 130° until most of the phosphorus oxychloride had been removed. The crude acid chloride was dissolved in benzene, the solution was filtered from a small amount of the unchanged acid, and treated with dry ammonia. A heavy precipitate of the amide soon separated. This was triturated with dilute ammonia solution and crystallized from glacial acetic acid. Rapid cooling was again necessary for the production of good crystals as small, yellow needles, 0.6 g.; m. p. 261° (268° corr.).

Anal. Calcd. for $C_{16}H_{13}O_4N$: C, 67.83; H, 4.63. Found: C, 67.66; H, 4.97.

The Synthesis of **5,5'-Dimethoxydiphenic Acid.**—4-Methoxy-2-aminobenzoic acid was prepared according to the excellent directions of Ullmann and Dootson,[18] starting with *p*-toluidine, and the diazonium salt was reduced with an ammoniacal solution of cuprous hydroxide according to the general method of Vorländer and Meyer.[19] A cuprous hydroxide solution was prepared by adding a solution of 2.7 g. of hydroxylamine hydrochloride and 6.5 cc. of 6 N sodium hydroxide to a solution of 6.3 g. of copper sulfate and 7.5 cc. of concentrated ammonia water in 30 cc. of water. A suspension of 1.7 g. of 4-methoxy-2-aminobenzoic acid in 1.8 cc. of glacial acetic acid and 4 cc. of water was diazotized with a solution of 0.7 g. of sodium nitrite. The amine dissolved slowly on shaking the mixture, but a small amount of the azo compound was produced. The filtered solution of the diazotized amine was added in small portions to the well-cooled cuprous hydroxide solution, each portion producing a green foam which soon dissolved. The dark yellow-green solution became pale yellow on warming to the boiling point, when it was made acid to Congo Red paper and cooled well. The product, which contained much copper salt, was digested with sodium carbonate solution and the crude dimethoxydiphenic acid was recovered on acidifying the filtered solution.

The product was quite yellow, melted at about 190° and was only obtained in a pure condition after numerous crystallizations from methyl alcohol. It then formed colorless needles melting at 228°.

Anal. Calcd. for $C_{16}H_{14}O_6$: C, 63.56; H, 4.67. Found: C, 63.70; H, 4.63.

Mixtures of this acid with the acid, m. p. 229°, obtained from 3,6-dimethoxyphenanthrenequinone showed no depression in the melting point. The identity of the two substances was further confirmed by the conversion of the synthetic acid into 1,6-dimethoxyfluoreneone-4-carboxylic acid, which was found to melt at 295° and to be identical with the material already described.

Lactone of **1-Hydroxy-4,4'-dimethoxydiphenyl-1'-carboxylic** Acid **(VII).**—The carbonate-insoluble product resulting from the oxidation of 3,6-dimethoxyphenanthrenequinone was easily purified by crystallization from alcohol, in which it is moderately soluble, and from which it separates in the form of long, colorless needles melting at 191° (194° corr.).

Anal. Calcd. for $C_{15}H_{12}O_4$: C, 70.29; H, 4.72. Found: C, 70.21, 70.12; H, 4.67, 4.56.

---

[18] Ullmann and Dootsou, ***Ber.***, 51, 19 (1918).

[19] Vorliinder and Meyer, *Ann.*, 320,122 (1902).

The substance may be distilled without decomposition. The crystalline material dissolves only very slowly on boiling with alkali, though the resulting salt is very readily soluble in water. On acidifying the solution, even at a low temperature, the lactone and not the free acid results.

Since it is conceivable that the lactone is formed not from the dimethoxyquinone but from the dimethoxydiphenic acid, the latter compound was subjected to the action of hydrogen peroxide in glacial acetic acid solution; in no case was a trace of the lactone obtained, and the greater part of the dimethoxydiphenic acid could be recovered after the prolonged action of a large excess of hydrogen peroxide.

1,4,4′-Trimethoxydiphenyl-1′-carboxylic Acid (VIII).—This was produced by shaking an alkaline solution of the above lactone with dimethyl sulfate until a precipitate began to separate from the alkaline solution. The solution, which was kept strongly alkaline, was then boiled until traces of the ester were hydrolyzed and then acidified. An oily product separated and soon solidified. This was precipitated from a carbonate solution and then crystallized from alcohol and from benzene–ligroin. It formed small, colorless prisms melting at 147–148°.

Anal. Calcd. for $C_{16}H_{16}O_5$: C, 66.65; H, 5.60. Found: C, 66.57; H, 5.42.

1,4,6-Trimethoxyfluorenone (a).—The above acid dissolved in cold concentrated sulfuric acid to give an intensely crimson solution. After ten minutes the solution was poured into water, when an orange oil resulted. This soon changed to a yellow solid. It was washed with dilute alkali and crystallized from alcohol. It dissolves readily in this solvent and separates in the form of light clusters of small yellow needles melting at 157°.

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.09; H, 5.22. Found: C, 70.97; H, 4.85.

Summary

In order to gain an idea of the composition of the mixture of disulfonates which is produced by the action of sulfuric acid on phenanthrene, two of the pure monosulfonic acids were sulfonated and the products were at least partly identified by separating the mixtures of diacetoxyphenanthrenes which were obtained as the result of alkali fusion and acetylation. Derivatives of five new dihydroxyphenanthrenes were thus obtained, and it was possible to determine the structures of all of these compounds. From the results of this study, it was concluded that, when either the 2- or the 3-sulfonic acid derivative of phenanthrene is sulfonated, the second substituent enters the unsubstituted, terminal nucleus in the 6-, the 7- and the 8-positions.

THE MELTING POINTS OF NORMAL PARAFFINS

BY J. H. HILDEBRAND AND A. WACHTER

RECEIVED MARCH 12, 1929 PUBLISHED AUGUST 7, 1929

In connection with a study of the solubility relations of dicetyl which we are making, it became necessary to have a reliable value for the melting point of the substance. The value given in "International Critical Tables" is 75°, whereas our own material, synthesized according to the method of Sorabji,[1] purified by recrystallization four times from glacial acetic acid and then four times from benzene, gave a melting point of 70.2°. The last crystallization made no change in the melting point. The determinations were made by the aid of a standardized thermometer properly corrected.

A search of the original sources showed the following values, arranged in chronological order: 70,[1] 70.0,[2a] 68–70,[3] 69.8,[2b] 71,[4] 70,[5] 70.5,[6a] 74–75[7] and 70.5°.[6b]

These values all fall in the neighborhood of 70°, with the exception of the one by Levene, West and van der Scheer. It seemed rather surprising that the expert should have chosen for the tables a single value so divergent from all the others. We accordingly sought a further check, as follows. The normal paraffins might be expected to have melting points increasing regularly with molecular weight, for any differences in crystal form cannot involve much difference in energy with such soft substances as these. We accordingly plotted the melting points of the series from $C_{19}H_{40}$ to $C_{38}H_{78}$ against the number of carbon atoms, as shown in Fig. 1. The points are derived from the references already given. It will be seen that all the points fall rather close to a smooth curve excepting those of Levene, West and van der Scheer, for seven members of the series, these falling from 3 to 5° above the curve. In view of the concordance existing among practically all of the other data, we believe that the figures of these three collaborators should have been rejected instead of selected for "International Critical Tables." Since the curve we have drawn appears to express the other data satisfactorily, except for experimental uncertainties, we suggest the following temperatures read from it as the best values for the melting points of the normal paraffin hydrocarbons from $C_{19}H_{40}$ to $C_{36}H_{74}$.

THE VAPOR PHASE HYDROLYSIS OF PHENYL CHLORIDE AND BROMIDE

BY LYMAN CHALKLEY, JR.[1]

RECEIVED MARCH 14, 1929 PUBLISHED AUGUST 7, 1929

Introductory

Meyer and Bergius in their excellent work upon the hydrolysis of the phenyl halides[2] record an experiment in which water and phenyl chloride were heated under pressure to 300°. A trace of phenol was obtained. Except for this result there appears to be no mention in the literature of the possibility of effecting the hydrolysis of phenyl halides with water alone.

In the course of a search for new methods for the synthesis of phenol, the direct hydrolysis of phenyl chloride with water alone in the vapor phase was attempted and, rather surprisingly, found to be possible. In a preliminary experiment a few grams of chlorobenzene and water were passed at atmospheric pressure through a little silica gel heated to 500°. Phenol and acid were formed.

There was not available sufficient information in regard to the free energy changes involved to permit the calculation of the equilibrium at 500° in the reaction $C_6H_5Cl + H_2O = C_6H_5OH + HCl$. Yet before proceeding further it was desirable to know at least whether or not the equilibrium was such as to greatly favor the presence of phenyl chloride in the equilibrium mixture.

Therefore a preliminary attempt was made to reverse the original reaction. Hydrogen chloride and phenol were passed through silica gel heated to 500°. Phenol was recovered, and, except for a little discoloration, appeared to be pure. It crystallized at room temperature and was completely soluble in sodium hydroxide solution. No trace of phenyl chloride was found.

As these experiments indicated that the vapor-phase hydrolysis of phenyl chloride was, at least, an interesting possibility, the work reported in this paper was carried out.

This investigation was designed essentially as a first exploration of the field. After the work here reported was completed, a notice appeared of the filing of an English patent application[3] which seemed to indicate that the present line of experiment had already been anticipated in Germany; but since a detailed discussion of the German invention will probably not

[3] I. G. Application No. 10206 of April 4, 1928, Convention date April 6, 1927. Illus. Official J., 2054, 2149 (May 31, 1928).

be available for some years, the results of the present investigation are published with the idea that they may be of immediate interest.

My results indicate that at 300° and above chlorobenzene and bromobenzene can be hydrolyzed by water in the presence of a variety of catalysts. At temperatures around 500° the reaction is quite rapid. Phenol, the halogen acid and diphenyl ether appear to be the chief products. Silica gel, titania, thoria, zirconia, alumina and the blue oxide of tungsten were found to bring about the hydrolysis. The only catalyst that was tried which proved to be relatively inactive was a sample of kaolin. Titania and silica gel appear to be the most active.

Under the conditions of the experiments as they were carried out **it** proved easy to hydrolyze from 25 to 40% of the phenyl halide in one passage over the catalyst. The unhydrolyzed halide was recovered unchanged.

Experimental

Apparatus.—The apparatus used was the simplest that could be devised and consisted of a reservoir in which water and the phenyl halide were vaporized, a reaction tube which held the catalyst and was heated by a furnace and a receiver in which the products of the reaction were collected.

The reservoir was a 250-cc. distilling flask. In this were placed both the water and the phenyl halide, and the two were vaporized together, *i. e.*, the phenyl halide was steam distilled from the distilling flask. The vapor was passed through the catalyst held in a 1-meter pyrex tube having an inside diameter of about 2 cm. and heated by *a* 12-inch Hoskins' tube furnace. The lower end of the reaction tube was introduced directly into the mouth of a receiving flask in which the reaction products accumulated.

The side arm of the distilling flask reservoir was bent so that it would pass directly into the reaction tube when the latter was held in a vertical position. The gas-tight connection between the side arm of the distilling flask and the reaction tube was made with a rubber stopper. It was necessary to renew this stopper occasionally because of the disintegrating effect of the phenyl halides on the rubber.

Within the reaction tube the catalyst was supported on a spiral of pyrex glass rod, which was in turn held by a constriction in the reaction tube itself. **A** little pure shredded asbestos was usually placed on the glass spiral and the catalyst poured upon the asbestos. Fifty cc., the amount of silica gel used, filled 18 to 20 cm. of the tube. On top of the catalyst was placed sufficient shredded asbestos to fill the tube to above the region covered by the furnace. This asbestos filling was necessary to prevent drops of liquid which condensed in the side arm of the distilling flask from falling directly into the heated portion of the tube. The asbestos layer retained 1 to **3** g. of the reaction mixture.

The temperature of the furnace was determined and regulated by means of a thermocouple and a Brown control pyrometer, The thermocouple was placed in the furnace between the reaction tube and the furnace wall. Therefore, the temperature recorded was that of the furnace rather than that of the catalyst. However, with a not too rapid flow of gas the two temperatures do not differ greatly.

The reaction tube was connected with the receiving flask by means of a rubber stopper. **A** small glass tube which also passed through the rubber stopper provided an **air** vent. In a number of experiments this vent was connected with a wet test gas meter. In no case where the catalyst was heated to less than 700" was there any evidence of the evolution of gas. Of course, hydrogen halides would not show up on the dial of the gas meter, but in only one or two experiments war the reaction product saturated with halogen acid.

In the two experiments in which the catalyst was heated to above the melting point of pyrex, the glass reaction tube was replaced by a 3-ft. length of standard $^1/_4$-inch "Ambrac" pipe. This is a copper alloy containing approximately 75% of copper, 20% of nickel and 5% of zinc. The silica gel was supported in the Ambrac pipe on a spiral of copper wire.

Materials.—The first experiments were performed with Kahlbaurn's chlorobenzene. In later work this was replaced by Eastman "practical" chlorobenzene. Both Kahlbaum's and the pure grade of Eastman bromobenzene were used and no difference was noticed in their behavior.

The silica gel employed as catalyst was 8- to 14-mesh material obtained from the Silica Gel Corporation. The other catalysts were prepared in the laboratory.

Preparation of Catalysts.—Zirconia was prepared by precipitation with ammonium hydroxide from a solution of 100 g. of zirconium nitrate (Rahlbaum) in 500 cc. of water. The precipitate was washed by decantation, collected on a filter and dried at 195°.

Aluminum hydroxide was precipitated with ammonia from a solution of 300 g. of aluminum nitrate in a liter of water. The product was collected on a filter, partially dried at 195° and dried further in the reaction tube.

Ammonium tungstate (75 g.) was dissolved in a solution of 25 g. of sodium hydroxide in 500 cc. of water. Tungsten oxide was precipitated from this solution by the addition of 100 cc. of hydrochloric acid. The precipitate was collected on a filter, dried overnight at 195°, then washed repeatedly with water and again dried at 195°. The yellow oxide so produced was reduced in the reaction tube to the blue oxide. In Expt. 9, listed below, the reduction was carried out with formicacid. In Expt. 10 the reduction was effected with alcohol.

The thoria catalyst was prepared as follotvs: 22.3 g. of thorium oxalate was dissolved in a solution of 50 g. of ammonium bicarbonate in 350 cc. of water and the solution was evaporated on 60 cc. (30 g.) of granulated pumice. The product was dried at 130° and the thorium salt decomposed to thoria by heating in the reaction tube.

To prepare the titanium catalyst 100 g. of anhydrous titanium tetrachloride was poured into one liter of water and the mixture made alkaline with ammonium hydroxide. The product when dried at 195° was an orange-colored powder.

Operation.—In the performance of the experiments the catalyst was first charged into the reaction tube. The quantity of silica gel used was always 50 cc. when the glass reaction tube was employed. Fifty cc. of the thoria catalyst on pumice was also used. With the other catalysts, however, the effective volumes varied; and, as they actually changed in the reaction tuhe, these volumes were not constant and were usually less than 50 cc.

Known quantities of water and of the phenyl halide under investigation were placed in the distilling flask along with some chips of unglazed porcelain. The distilling flask with its contents was then weighed and connected with the reaction tube.

When the reaction tube was heated to the temperature at which the experiment was to be run, the mixture of water and phenyl halide was slowly distilled by means of a gas flame. As the gas supply was quite irregular, the rate of distillation varied from one experiment to another, and constituted the least controlled factor in the experiments.

At the conclusion of an experiment the distilling flask was again weighed with its contents. The receiving flask with the reaction products was also weighed. The weights of the materials entering into the reaction, and the materials recovered never differed by more than 3 g. This difference was accounted for largely, if not completely, by the liquid held on the asbestos packing in the reaction tuhe.

The reaction product was separated into its two components, an aqueous layer and an oily layer. The weights and volumes of these layers were determined, and a portion of the aqueous layer was titrated with $N/10$ potassium hydroxide. From this titration the quantity of acid liberated in the hydrolysis was determined. The small amount of acid dissolved in the oily layer was neglected. That the acid formed was actually hydrochloric or hydrobromic was determined in several cases by the precipitation of the silver halide.

In a number of experiments the reaction product was distilled; but as no efficient micro-fractionating column was available, distillation did not provide a satisfactory method for the determination of phenol. However, distillation did demonstrate the presence of diphenyl ether. A quantitative determination of this substance was not attempted.

Phenol was determined by the following procedure. The oily layer of the reaction product (or its distillation products) was extracted with 20% sodium hydroxide solution, the extract combined with the aqueous layer of the reaction product, the whole neutralized with hydrochloric acid, filtered, treated with excess of bromine water and the precipitated tribromophenol bromide dried and weighed. This method is not altogether satisfactory but is sufficiently accurate for the work here considered.

That the product of the hydrolysis was actually phenol was shown by the reduction of some of the tribromophenol bromide with sodium acid sulfite and comparison of the melting points of the tribromophenol so formed and of a mixture of this tribromophenol with Kahlbaum's tribromophenol.

When Eastman "practical" chlorobenzene was used small quantities of a difficultly water-soluble phenol were formed. The presence of this little-soluble phenol was shown by the fact that when the alkaline extract of a hydrolysis product prepared from "practical" chlorobenzene was neutralized the solution became cloudy. This behavior suggests that chlorophenol may have been formed from small quantities of dichlorobenzene present in the "practical" chlorobenzene used. This phenomenon was not observed when the purest grade of chlorobenzene and bromobenzene was used.

Results

In Table I are shown in considerable detail the data from eight experiments in which silica gel was used as the catalyst. Kahlbaum's chlorobenzene was used in Expts. 1 and 2. Eastman bromobenzene was used in Expts. 3, 4 and 5. Eastman "practical" chlorobenzene was used in Expts. 6, 7 and 8.

In Expts. 1 to 6, inclusive, the temperature of the furnace was 500°. In Expt. 7 it was 550° and in Expt. 8 it was 600°.

The same silica gel was used in Expts. 1 and 2. A fresh sample was used for Expt. 3 and this sample was left in the tube and used also for Expts. 4 and 5. However, between Expts. 4 and 5 the reaction tube with the catalyst in it was heated to 600° for an hour while a stream of air was blown through. A fresh sample of catalyst was used for Expt. 6. This was retained in the reaction tube for Expts. 6, 7 and 8, but was heated to 600° in air after each experiment. The silica gel darkens with use but the heating in air burns off the coloring matter and restores the gel to its original light color. The results show that it also restores the catalytic activity,

In Table II are shown the results obtained with other catalysts, and with

silica gel at low and high temperatures. In this table the quantity of acid formed is given alone as being the most accurate index of hydrolysis (except when the metal tube was used). Fresh samples of catalyst were employed for each of the experiments 9 to 16, inclusive, and for 21. In the low-temperature experiments (16 to 20) there was practically no fouling of the catalyst and, therefore, fresh catalyst was not needed. As the silica gel used contained a trace of acid it was necessary to wash it with steam until the condensate was neutral before beginning the experiments. Between Expts. 21 and 22 the silica gel was heated in air to 845° for fifteen minutes.

Discussion

The experiments recorded in Table I show that phenyl chloride and phenyl bromide are readily hydrolyzed by steam when passed over silica gel at 500 to 600°. If Expts. 1, 2 and 6 are compared it will be seen that the amount of hydrolysis increases as the rate of flow of the reaction mixture over the silica gel is diminished. There is, therefore, no reason to believe that equilibrium in the hydrolysis of phenyl chloride was reached in the experiments. It is probable that the reaction mixture of phenyl chloride and steam of the composition used would undergo a greater hydrolysis than 10% at 500° if its contact with the catalyst were prolonged.

[a] Faint trace of phenol. [b] Trace of phenol. [c] Phenol present.

At this same temperature, 500°, phenyl bromide hydrolyzes more completely than phenyl chloride under the conditions of the experiments. However, the phenyl bromide reaction mixture contained a higher molecular proportion of water than the phenyl chloride reaction mixture, and it was possible to pass the phenyl bromide over the catalyst at a slower rate.

At 550 and 600° phenyl chloride was found to hydrolyze to the extent of 38% under the conditions of the experiments.

In the last column of Table I are shown the yields of phenol obtained. The calculated yields of phenol corresponding to the halogen acid found are taken as 100%, and the figures given in the last column of Table I were computed on this basis. That is, for instance, the phenol found in Expt. 1 was 68.5% of 10.5% of the phenyl chloride used. The actual gross yield of phenol in Expt. 1 was about 7% of the phenyl chloride passed over the catalyst.

As already mentioned, the figures given for phenol yields are not very accurate, and that given for Expt. 5 is particularly questionable because of the small quantity of materials used in the reaction. However, it is safe to conclude that the chief reaction product is phenol but that the yield of phenol falls short of 100% of the phenyl halide hydrolyzed.

Under the conditions used a considerable amount of diphenyl ether is to be expected since Sabatier and Espil, working under conditions similar to those employed here, have shown that the system phenol–diphenyl ether–water comes to equilibrium when diphenyl ether constitutes about half, by weight, of the organic constituents.[4] Therefore, in calculating a net yield

---

[4] Sabatier and Espil, Bull. *soc. chim.*, [4] 15, 228 (1914).

from the hydrolysis, phenol and diphenyl ether should be considered together. There is not enough information to permit the calculation of such a net yield from these experiments, but it should be fairly good, at least.

Experiment 4 compared with Expt. **3** indicates a decrease in activity of the catalyst due to fouling. Experiment 5 indicates that the activity of the catalyst has been restored by the burning-off process.

The first results reported in Table II show that the hydrolysis of phenyl halides may be effected by a variety of hydration catalysts. As already pointed out, the various samples of catalyst were not used in the same state of subdivision and in the same amounts. As other factors also influence the activity of contact catalysts, the results obtained for the individual samples used cannot be rigidly compared. However, it appears that silica gel and titania are the most active; kaolin is the least active; and phenol was obtained from all of the experiments except the one in which kaolin was used.

Experiments 16 to **20** were carried out to learn something of the temperature range over which the hydrolysis took place. They show that at 300° both phenyl chloride and bromide hydrolyze at a measurable speed.

Conclusions

Phenyl chloride and phenyl bromide are readily hydrolyzed to the extent of at least **25** to 40% by passage of their vapor mixed with steam over silica gel at **500** to 550° and ordinary pressures.

The ability to catalyze the hydrolysis of the phenyl halides is not peculiar to silica gel but is possessed by a variety of hydration catalysts: silica gel, titania, alumina, thoria, zirconia and the blue oxide of tungsten. A sample of kaolin showed little activity.

Silica gel and titania appear to be the most active.

With silica gel as the catalyst the reaction proceeds at a measurable speed at 300° and above.

The products of the reaction are: the halogen acid, phenol, diphenyl ether and probably smaller quantities of other organic compounds. No pronounced halogenation of the phenol obtained in the primary reaction was noticed and no water-insoluble gases were evolved.

The activity of silica gel which has been fouled by use may be restored by heating the catalyst in air or oxygen. The activity of titania can be regenerated in the same way.

STUDIES OF CONJUGATED SYSTEMS. I. THE CHLORINATION OF PHENYLBUTADIENE[1]

BY IRVING E. MUSKAT AND K. A. HUGGINS

RECEIVED MARCH 15, 1929 PUBLISHED AUGUST 7, 1929

According to Thiele's[2] theory concerning the affinity relations in conjugated systems addition should take place in the 1,4-position. Many exceptions were found to this theory which were explained by Thiele by means of special assumptions. However, the exceptions have increased and there has arisen sharp criticism toward this theory.[3] We cannot here consider the results of the manifold investigations, indicating in each case its bearing on the Thiele theory; nor can we discuss the many explanations offered by various workers in this field regarding the mode of addition in conjugated systems. This much may be said, however, that in general there are two main views: according to the one view, held by Thiele, the addition depends merely on the valence relations in the original compound, while according to the other, the Hinrichsen view, the addition depends not only on the nature of the original unsaturated compound in which the addition is taking place, but also on the electrochemical nature of the entering atoms or groups.[4]

While not any of the many theories suggested explain all of the addition reactions to conjugated systems, nevertheless, it appears that in a series of cases the Hinrichsen view is in better accord with the facts than any of the other theories. Recent work by K. v. Auwers[5] on the addition of hydrogen and bromine to sorbinic acid and related compounds, and still more recent work by Kuhn and Winterstein[6] on the addition of hydrogen and bromine to the diphenyl-poly-enes, clearly indicate the inadequacy of the Thiele theory and offer supporting evidence for the Hinrichsen views.

[4] We shall not discuss in this paper the more recent work of Ingold, Claisen, Prevost, Farmer and others, who have shown that addition products in which the addenda are in the 1,4-positions are not necessarily due to 1,4-addition, but rather to a condition of equilibria in three-carbon prototropic systems. We shall be more concerned with the final addition product than the mechanism by which it was formed.

Because of the theoretical importance of the addition reactions of conjugated systems it was considered desirable to make a thorough investigation of such addition processes, particularly in simple conjugated systems. The present paper contains the results of an investigation on the chlorination of phenylbutadiene.

Phenylbutadiene was prepared according to the method of Carl von der Heide[7] by the condensation of cinnamic aldehyde with methyl magnesium bromide and the subsequent hydrolysis of the intermediate Grignard addition compound with 30% sulfuric acid. In order to become familiar with the technique and procedure involved in the use of an ozonizer as a tool in the study of such reactions, it was decided to repeat Straus'[8] work on the bromination of phenylbutadiene, in which he found that only 3,4-addition occurred. We confirmed his work in every particular.[9]

The chlorination of phenylbutadiene was then studied. It was found that phenylbutadiene readily absorbs two atoms of chlorine to form a dichloride which boils at 125° under 3 mm. pressure. The chlorination was carried out in various solvents and under different experimental conditions. Chloroform, ligroin, glacial acetic acid and carbon disulfide were used as solvents and the chlorination was carried out at temperatures varying from about -80 to about 150°. The same dichloride was obtained regardless of the experimental conditions. The only effect of the temperature of chlorination was in the amount of decomposition. The dichloride is fairly unstable and loses hydrogen chloride easily, so that at higher temperatures more decomposition takes place. However, in not one of the large number of experiments performed was a different dichloride obtained.

The structure of the dichloride was determined by ozonization. Three dichlorides are theoretically possible, depending on whether 1,2-, 1,4- or 3,4-addition takes place. On ozonizing the phenylbutadiene dichloride it was possible to obtain an 83% yield of benzaldehyde as calculated from its semicarbazone and the benzoic acid that was recovered. This proves beyond any doubt that chlorine adds to phenylbutadiene in the 3,4-positions. A number of ozonizations were made but in no case was it possible to obtain even the slightest indications for the presence of any of the aldehydes or acids to be expected from the oxidation of compounds resulting from the 1,2- or 1,4-addition of chlorine.

The phenylbutadiene dichloride can be further chlorinated to give a mixture of stereoisomeric tetrachlorophenylbutanes. The tetrachloride

---

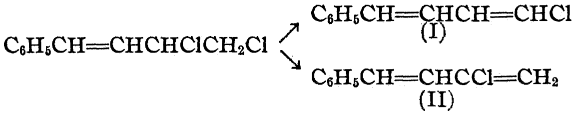
[7] Carl von der Heide, *Ber.*, 37, 2101 (1904).

[8] Straus, *ibid.*, 42, 2866 (1909).

[9] We worked up the ozonization product in a different manner. Straus obtained a 50–60% recovery of benzaldehyde, while we were able to recover 73% of the benzaldehyde.

can be completely reduced to phenylbutadiene or partially reduced with zinc to give again the same phenylbutadiene dichloride from which it was made. This shows that the chlorine is more easily removed from the 1,2-positions near the phenyl group, and again indicates the stability of the 3,4-dichloride.

Phenylbutadiene dichloride, when treated with aqueous potassium hydroxide at a temperature of 90° for several hours, loses a molecule of hydrogen chloride and is thus converted into phenylchlorobutadiene, with an almost theoretical yield. The same monochloride may be obtained by merely refluxing the phenylbutadiene dichloride for several hours, but this process entails a large loss due to polymerization. The phenylchlorobutadiene boils at 115.5° under 3.5 mm. pressure. It may be readily seen from the structure of the phenylbutadiene dichloride that hydrogen chloride may be eliminated in either of two ways, thus



$$C_6H_5CH{=}CHCHClCH_2Cl \begin{array}{l} \nearrow \; \underset{\text{(I)}}{C_6H_5CH{=}CHCH{=}CHCl} \\ \searrow \; \underset{\text{(II)}}{C_6H_5CH{=}CHCCl{=}CH_2} \end{array}$$

In order to determine the structure of the monochloride it was treated with a water suspension of silver oxide and warmed. On working up the reaction mixture y-phenylcrotonic acid ($C_6H_5CH{=}CHCH_2COOH$) was isolated. This proves conclusively that the phenylchlorobutadiene has Structure I, $C_6H_5CH{=}CHCH{=}CHCl$. Since the chlorine atom is removed from the 3-position in preference to the 4-position, it indicates that the 3-chlorine atom is relatively electronegative as compared with the 4-chlorine atom. The significance that this bears on the electronic concept of valence in organic compounds will be discussed in a later paper.

The phenylchlorobutadiene easily absorbs a molecule of chlorine to give a trichloro derivative, boiling at 140° under 5 mm. pressure. Again, there are three trichlorides that may possibly be formed, depending on whether 1,2-, 1,4- or 3,4-addition takes place. The phenylchlorobutene dichloride was ozonized in the same way as the phenylbutadiene dichloride. On hydrolysis of the ozonide formed, it was possible to recover a 50% yield of benzaldehyde as benzoic acid. The isolation of benzaldehyde proves conclusively that 3,4-addition has taken place and, therefore, the structure of the trichloride must be $C_6H_5CH{=}CHCHClCHCl_2$.

The phenylchlorobutene dichloride easily absorbs-another molecule of chlorine to give a pentachloride which boils at 162° under 5 mm. pressure. To judge from the constancy of the boiling point of the 1-phenyl-1,2,3,4,4′-pentachlorobutane, it does not consist of a mixture of stereoisomers as did the 1-phenyl-1,2,3,4-tetrachlorobutane previously described.

The experimental results recorded here lend support to the Hinrichsen view of addition to conjugated systems as contrasted to the Thiele view.

That is, the mode of addition to conjugated systems is not only a function of the conjugated compound itself, but also depends on the nature of the addendum. In general, hydrogen is added to the ends of the conjugated system, in the 1,4-positions, particularly so when the conjugation ends in oxygen $>C{=}C{-}C{=}O$. With other types of addition reagents, the halogens, halogen acids, etc., normal addition to the double bonds of the conjugated system is the rule, just as in the single ethylenic double bonds. More recent work by Ingold, Claisen, Prevost, Farmer and others seems to indicate that even in those cases where 1,4-addition is found, it is not due primarily to direct 1,4-addition but rather to a tautomerization of the 1,2-addition compounds. This will be discussed in a later paper.

Experimental Part

Phenylbutadiene Dibromide.—Phenylbutadiene was prepared according to the method of Carl von der Heide.[7] Phenylbutadiene dibromide was prepared according to the method reported by Straus.[8] The pure dibromide melted at 94°.

Phenylbutadiene dibromide (4.5 g.) was dissolved in chloroform and a current of ozonized oxygen was bubbled through the solution for several hours. An ozonizer similar to the one described by Harries[10] was used. The apparatus was arranged so that any desired ozone concentration, up to 20%, could be obtained. A 3–4% ozone concentration was used in these experiments. After the ozonization was completed the chloroform was removed by suction and the residual viscous ozonide was decomposed with water. To assure the complete decomposition of the ozonide, it was warmed on the water-bath for a short time. The mixture consisted of acids and aldehydes and was separated by extracting the alkaline solution several times with ether. The alkaline solution was then acidified and again extracted with ether. The ethereal solution was dried and the ether removed by vaporization. A solid (1.06 g.) remained which melted at 120". It was crystallized once from water and melted at 122°, the melting point of benzoic acid. A mixture with pure benzoic acid also melted at 122°.

The ethereal solution containing the aldehydes was again washed with alkali and the ether removed by vaporization. The residue, an oil, was treated with an aqueous solution of semicarbazide hydrochloride containing enough sodium acetate to neutralize the hydrochloric acid in combination with the semicarbazide. A semicarbazone (0.51 g.) was precipitated after a short time. This was removed and dried. It melted at 209°. It was recrystallized several times from alcohol and melted at 214°, the melting point of the semicarbazone of benzaldehyde. When it was mixed with the synthesized product the melting point of the mixture was not lowered. This corresponds to a 73.2% yield of benzaldehyde, while Straus was able to obtain only a 50–60% yield.

Phenylbutadiene Dichloride.—To prepare phenylbutadiene dichloride a stream of dry chlorine was allowed to pass into the pure phenylbutadiene. Absorption took place readily and the reaction mixture became very hot. Hydrogen chloride was liberated as the chlorination proceeded and the reaction mixture assumed a reddish color. When the theoretical quantity of chlorine was absorbed, the reaction mixture was distilled under reduced pressure. A light yellow oil distilled over at 125° under 3 mm. pressure. It was analyzed for chlorine by the Carius method. The analysis of the compound proves that it is a dichloride.

---

[10] Houben-Weyl, "Die Methoden der Organischen Chemie," 1924, Vol. III, p. 276.

Anal. Subs., 0.2322, 0.2596: AgCl, 0.3308, 0.3698. Calcd. for $C_{10}H_{10}Cl_2$: Cl, 35.28. Found: Cl, 35.25, 35.24.

The conditions under which phenylbutadiene was chlorinated were varied considerably. Various solvents such as chloroform, ligroin, carbon disulfide and glacial acetic acid were used, and the temperature was varied from about −80° (carbon dioxide snow and ether) to about 150°. However, in all cases only one dichloride was obtained. The use of a solvent decreased the amount of tetrachlorophenylbutane obtained, and lowering the temperature decreased considerably the extent of decomposition, but no other effect was observed. The phenylbutadiene dichloride distilled over completely at constant temperature under various pressures, which eliminates the possibility that it consists of a mixture of dichlorides having a constant boiling temperature. It could not be crystallized even in carbon dioxide snow and ether; it merely solidified to a glass.

The phenylbutadiene dichloride was subjected to ozonization and the ozonide thus formed was treated in a manner entirely analogous to that of the dibromide previously described. The acid and aldehyde portions were separated, the acid portion yielding benzoic acid, which was identified by the melting point of a mixture with known benzoic acid, while the benzaldehyde was removed as the semicarbazone. which was identified in a similar manner. From 5.5 g. of phenylbutadiene dichloride it was possible to isolate 2.01 g. of benzoic acid and 1.0 g. of semicarbazone of benzaldehyde. This corresponds to an 83% yield of benzaldehyde. In some cases the ozonide was treated with hydrogen peroxide, which oxidized all of the aldehydes to their corresponding acids. From 6 g. of the dichloride it was possible to isolate 2.5 g. of benzoic acid, which was identified by the melting point of a mixture with known benzoic acid. This corresponds to a 70% yield of benzaldehyde.

This proves conclusively that chlorine had added to phenylbutadiene in the 3,4-positions and not in the 1,2- or 1,4-positions. The structure of the dichloride must be $C_6H_5CH{=}CHCHClCH_2Cl$.

Tetrachlorophenylbutane.—Phenylbutadiene dichloride was dissolved in chloroform and a stream of chlorine gas was allowed to pass in until no more was absorbed. The chloroform was removed by vaporization and the residual reddish colored oil was distilled under reduced pressure. A clear, colorless oil began to distil over at 155" under 7 mm. pressure and the temperature rose gradually, without any abrupt change, to 166°. The distillate was redistilled at 7 mm. pressure and collected in three fractions; each fraction was analyzed for chlorine by the Carius method.

Anal. Fraction I (155–160°), subs., 0.2043: AgCl, 0.4333. Found: Cl, 52.46. Fraction II (160–164°), subs., 0.2637: AgCl, 0.5567. Found: Cl, 52.22. Fraction III (164–166°), subs., 0.2950: AgCl, 0.6203. Found: Cl, 52.02. Calcd. for $C_{10}H_{10}Cl_4$: Cl, 52.18.

It is quite obvious that the tetrachlorophenylbutane consists of a mixture of possibly three stereoisomers. No effort was made to separate them. The tetrachlorophenylbutane did not crystallize even when allowed to remain in a carbon dioxide snow and ether mixture for several hours.

The Reduction of Tetrachlorophenylbutane.—If tetrachlorophenylbutane is treated with powdered zinc at room temperature no reaction takes place. However, if the reaction flask is placed on the water-bath for a short time a vigorous reaction occurs. The product of the reaction depends on the quantity of zinc used.

Tetrachlorophenylbutane was treated with slightly more than two moles of zinc and the reaction mixture was warmed on the water-bath for several hours. The reaction mixture was then extracted with ether and the ethereal solution was dried over calcium chloride. The ether was removed by vaporization and the residual oil distilled under reduced pressure. It distilled at 86° under 11 mm. pressure, the boiling point of phenylbutadiene. That it was phenylbutadiene was further confirmed by the melting point of its tetrabromide, 146°. This shows that the tetrachloride was completely reduced.

The previous experiment was repeated and slightly less than half the amount of powdered zinc was used (one mole of zinc to one mole of tetrachloride). When all of the zinc had reacted the mixture was extracted with ether, the ethereal solution dried and the ether removed by vaporization. The residual oil was distilled under reduced pressure. It distilled sharply at 125° under 5 mm. pressure, the boiling point of 3,4-dichlorophenylbutane. It was ozonized and yielded benzoic acid as one of the oxidation products. This proves conclusively that the structure of the dichloride obtained by the partial reduction of the tetrachlorophenylbutane is identical with that of the dichloride obtained on chlorinating phenylbutadiene.

Phenylchlorobutadiene.—If phenylbutadiene dichloride is treated with an aqueous solution of potassium hydroxide and allowed to stand on the water-bath for several hours, one molecule of hydrogen chloride is eliminated, forming a monochloride. The monochloride was taken up in ether, thoroughly washed free from alkali, dried over calcium chloride, filtered, and the ether removed by vaporization. The residual oil was distilled under reduced pressure. It distilled almost completely at 115.5° under 3.5 mm. pressure. When very pure it crystallized in small, colorless plates, melting sharply at 53°. It was analyzed for chlorine by the Carius method. The analysis of the compound proves that it is a monochloride.

Anal. Subs., 0.0979, 0.1774: AgCl, 0.0849, 0.1536. Calcd. for $C_{10}H_9Cl$: Cl, 21.56, Found: Cl, 21.45, 21.42.

The same phenylchlorobutadiene may be obtained by simply refluxing the phenylbutadiene dichloride for several hours. However, there is a decided difference in the yield obtained by the two methods. The first method, that of warming the dichloride with aqueous alkali, gives an almost quantitative yield of the monochloride, while the second method, refluxing the dichloride, gives about a 60% yield of the monochloride. This is due to the fact that heating promotes the polymerization of the compound.

Phenylchlorobutadiene and water were introduced into a bomb tube, the tube was sealed, placed in a bomb furnace and gradually heated to 150–170°. It was allowed to remain at that temperature for several hours. On cooling the tube was opened and the contents removed. The water solution gave a decided halogen test with silver nitrate, which showed that the chlorine had been removed by hydrolysis. The degree of hydrolysis could be readily followed by the titration of the chloride ion in an aliquot sample of the water solution. The extent of hydrolysis was never more than 3 to 4% in the several experiments that were performed. The water solution gave a positive test for aldehydes with a fuchsin solution and therefore offers supporting evidence for Structure I, $C_6H_5CH{=}CHCH{=}CHCl$. Due to the slight hydrolysis, even at higher temperatures, it was not found possible to isolate the aldehyde.

In order to increase the extent of hydrolysis of the chloride, it was treated with slightly more than two moles of silver oxide suspended in water. No reaction was evident at ordinary temperature, but when the reaction mixture was warmed on the water-bath a reaction did occur and a silver mirror was deposited on the walls of the reaction vessel. This indicates that an aldehyde was formed due to the hydrolysis of the chloride, and that the silver oxide then oxidized the aldehyde to the corresponding acid, $C_6H_5CH{=}CHCH_2COOH$. The reaction mixture was acidified with nitric acid and extracted with ether. The ethereal solution was washed several times with alkali. The alkaline washings were acidified, extracted with ether, the ethereal solution was dried over anhydrous sodium sulfate and the ether was removed by evaporation. An oil remained which was taken up in carbon disulfide. On allowing the carbon disulfide to evaporate slowly, small crystals separated from the solution. These were removed and dried; they melted at 86°, the melting point of γ-phenylcrotonic acid, $C_6H_5CH=CHCH_2COOH$. This proves that the monochloride has Structure I. $C_6H_5CH=CHCH=CHCl$.

1-Phenyl-4-chloro-Δ'-butene-3,4-dichloride.—To prepare phenylchlorobutene dichloride a stream of dry chlorine was allowed to pass into pure phenylchlorobutadiene. Absorption took place readily and the mixture became very hot. The reaction mixture assumed a dark color during the chlorination but became colorless as soon as one mole of chlorine was absorbed. It was distilled under reduced pressure, distilling over at 140" under 5 mm. pressure. It was analyzed for chlorine by the Carius method. The analysis of the compound proves that it is a trichloride.

Anal. Subs., 0.2648, 0.2196: AgCl, 0.4838, 0.4008. Calcd. for $C_{10}H_{10}Cl_3$: Cl, 45.19. Found: Cl, 45.20, 45.19.

The phenylchlorobutene dichloride was subjected to ozonization and the ozonide thus formed was treated in a manner entirely analogous to that of the dichloride previously described. The acid and aldehyde portions were separated, the acid portion yielding benzoic acid, which was identified by the melting point of a mixture with known benzoic acid, while the aldehydes were removed as semicarbazones. The semicarbazones were separated by fractional crystallization into a low-melting semicarbazone (about 130°) and a high-melting semicarbazone (about 206°). However, these could not be purified enough for identification. In another experiment the ozonide was treated with hydrogen peroxide, which oxidized all of the aldehydes to their corresponding acids. From 1.04 g. of the trichloride it was possible to isolate 0.3 g. of benzoic acid, which was identified by the melting point of a mixture with known benzoic acid. This corresponds to a 50% yield of benzaldehyde.

Pentachlorophenylbutane.—Phenylbutadiene trichloride was further treated with an excess of chlorine gas until no more absorption took place. The chlorinated product was distilled under reduced pressure. A clear, colorless oil distilled over at 162° under 5 mm. pressure. It was analyzed for chlorine by the Carius method. The analysis of the compound proves that it is a pentachloride.

Anal. Subs., 0.1941, 0.1032: AgCl, 0.4541, 0.2399. Calcd. for $C_{10}H_9Cl_5$: Cl, 57.88. Found: Cl, 57.87, 57.51.

Summary

1. By chlorination of phenylbutadiene, a dichloride is formed whose structure was proved by ozonization to be a 3,4-derivative, rather than a 1,4-derivative as required by Thiele's theory of addition to conjugated systems.

2. The 3,4-dichlorophenylbutene was further chlorinated to give tetrachlorophenylbutane. It consisted of a mixture of stereoisomers boiling from 155–166° under 7 mm. pressure.

3. Tetrachlorophenylbutane was partially reduced with zinc to give the same 3,4-dichlorophenylbutene obtained by the direct chlorination of phenylbutadiene. It was also completely reduced with zinc to give phenylbutadiene.

4. 3,4-Dichlorophenylbutene loses a molecule of hydrogen chloride to give 1-phenyl-4-chlorobutadiene. Its structure was proved by converting it to γ-phenylcrotonic acid.

5. 1-Phenyl-4-chlorobutadiene absorbed one molecule of chlorine in the 3'4-positions to give 1-phenyl-3,4,4'-trichlorobutene. Its structure was proved by ozonization.

6. 1-Phenyl-3,4,4'-trichlorobutene was further chlorinated to give 1-phenyl-1,2,3,4,4'-pentachlorobutane.

7. Straus' work on the bromination of phenylbutadiene was confirmed in every particular.

TETRAMETHYLENE GLYCOL AND TETRAMETHYLENE CHLOROHYDRIN

BY W. R. KIRNER AND G. HOLMES RICHTER

RECEIVED MARCH 20, 1929 PUBLISHED AUGUST 7, 1929

Some work published by Bennett[1] suggested a new method for the synthesis of tetramethylene glycol. In the first two papers Bennett gives the preparation of b-hydroxybutyl benzyl ether and in the last paper Bennett and Hock described an experiment in which the benzyl group in an entirely different series of benzyl ethers was removed by means of hydrogen bromide, forming benzyl bromide, the residual portion of the ether remaining as an alcohol. By applying this reaction to Bennett's b-hydroxybutyl benzyl ether it was found that tetramethylene glycol could be obtained in good yield. The novelty of the reaction is the splitting of the benzyl ether with hydrogen bromide without converting either hydroxyl group of the glycol into a bromide. The glycol was characterized by preparing both the di-phenyl- and di-α-naphthylurethans.

Tetramethylene glycol has been a relatively rare substance and our purpose was to devise a method by which this valuable synthetic reagent might become more easily available. The older methods of synthesis are either very tedious or give poor yields. However, after this work had been completed an article appeared by Muller[2] describing the preparation of tetramethylene glycol by the Bouveault–Blanc reduction of diethyl succinate with a yield of 54%. This is a considerable improvement over the yield reported by Böeseken,[3] who obtained a 31% yield using the same method. Müller ascribes his higher yield to the use of thoroughly dry alcohol and a more efficient method of isolation of the final product. Miiller's method thus appears to offer the cheapest and simplest method of preparing tetramethylene glycol which has been published to date.

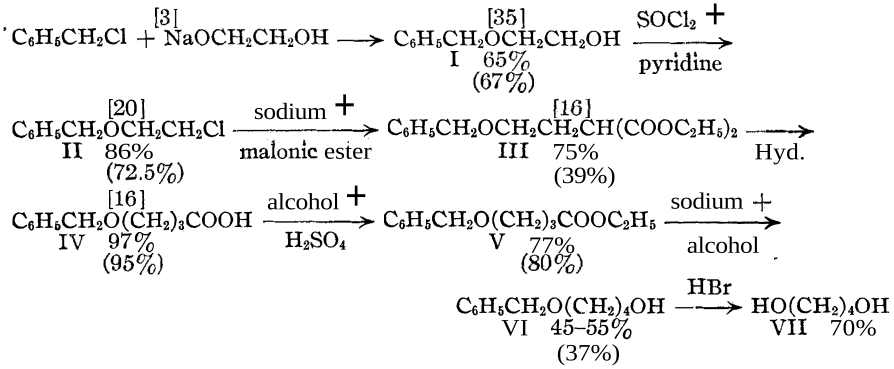
Tetramethylene glycol was converted into tetramethylene chlorohydrin by means of Darzens' reaction,[4] with a yield of approximately 50%. Bennett and Heathcoat[5] have very recently synthesized the chlorohydrin by the action of sulfur monochloride on the glycol but they state that their method gives the chlorohydrin "in poor yield and in an impure state." They obtained a fraction boiling at 86° at 15 mm. consisting of crude tetramethylene chlorohydrin which disappeared when redistilled under reduced pressure, producing much hydrogen chloride and presumably forming tetramethylene oxide. Our product boiled at 84–85" at 16 mm. and if distilled at a pressure much higher than this it also showed a tendency to lose hydrogen chloride. However, we succeeded in obtaining a pure product (by fractional vacuum distillation), as is indicated by the good agreement obtained between the calculated and observed values for the molecular refraction and in the chlorine content. The phenylurethan and α-naphthylurethan were prepared. The former is a new compound and melted at 54°. The α-naphthylurethan melted at 69–70'; Bennett and Heathcoat give the melting point as 66°.

Experimental

The following equations illustrate the method which was used for the preparation of the tetramethylene glycol. The yield in each step is indicated under the substance prepared and Bennett's yield is given in parentheses. The figures in brackets above the various compounds indicate the number of times the quantities given by Bennett were multiplied and shows the rather large scale on which these reactions were run. The over-all yield is 11%.



$$\overset{[3]}{C_6H_5CH_2Cl} + NaOCH_2CH_2OH \longrightarrow \underset{\substack{\text{I}\ \ 65\%\\(67\%)}}{\overset{[35]}{C_6H_5CH_2OCH_2CH_2OH}} \xrightarrow[\text{pyridine}]{SOCl_2\ +}$$

$$\underset{\substack{\text{II}\ \ 86\%\\(72.5\%)}}{\overset{[20]}{C_6H_5CH_2OCH_2CH_2Cl}} \xrightarrow[\text{malonic ester}]{\text{sodium} +} \underset{\substack{\text{III}\ \ 75\%\\(39\%)}}{\overset{[16]}{C_6H_5CH_2OCH_2CH_2CH(COOC_2H_5)_2}} \xrightarrow[\text{Hyd.}]{}$$

$$\underset{\substack{\text{IV}\ \ 97\%\\(95\%)}}{\overset{[16]}{C_6H_5CH_2O(CH_2)_3COOH}} \xrightarrow[H_2SO_4]{\text{alcohol} +} \underset{\substack{\text{V}\ \ 77\%\\(80\%)}}{C_6H_5CH_2O(CH_2)_3COOC_2H_5} \xrightarrow[\text{alcohol}]{\text{sodium} +}$$

$$\underset{\substack{\text{VI}\ \ 45\text{–}55\%\\(37\%)}}{C_6H_5CH_2O(CH_2)_4OH} \xrightarrow{HBr} \underset{\text{VII}\ \ 70\%}{HO(CH_2)_4OH}$$

In the preparation of β-chloro-ethyl benzyl ether (II) by Darzens' reaction we used pyridine whereas Bennett used dimethylaniline. In our work the temperature was not allowed to rise above 55° during the addition of the thionyl chloride and the mixture was not heated to drive

---

[5] Bennett and Heathcoat, *J.* Chem. *Soc.*, *272* (1929).

off sulfur dioxide but was merely allowed to stand overnight. This illustrates another case where good yields of a chloride can be obtained by this method without heating the reaction mixture.[6]

The improved yield of diethyl-β-benzyloxyethylmalonic ester (III) is ascribed to the use of thoroughly dried alcohol which was used in the malonic ester condensation. A good grade of absolute alcohol was further dehydrated by the irreversible hydrolysis of ethyl acetate as recommended by Smith,? and distilled directly into the apparatus used for the reaction. The mixture was merely stirred and refluxed over a period of five days and not heated under pressure as recommended by Bennett and Hock.

In the reduction of the ethyl-y-benzyloxybutyrate (V) thoroughly dry alcohol was also used. About 100 g. of ester was reduced in each run. It was found that small amounts (4–6 g.) of the glycol, which was probably formed by the splitting of the benzyl ether by the metallic sodium,[8] could be recovered from the aqueous solutions by saturating them with anhydrous potassium carbonate and then extracting with alcohol.

Bennett and Hock's procedure for the splitting of benzyl ethers was modified as follows and found to give better yields: 66 g. of the benzyl ether were treated with 175 cc. of concentrated hydrobromic acid and allowed to stand for three days (without adding any hydrogen bromide). Potassium carbonate was added until the mixture was just neutral and any unreacted material was extracted with benzene, the benzene extract being washed with water to remove any glycol. The aqueous solution, plus that obtained from washing the benzene layer, was saturated with potassium carbonate and extracted with alcohol. On distilling off the alcohol, carbonate precipitated out; this was again extracted with alcohol and the alcohol distilled off. A residue is thus obtained which is distilled in vacuum and which yields the glycol; 20.7 g. of glycol was obtained and 6.2 g. of unchanged benzyl ether was recovered. This corresponds to a yield of 69% based on the ether which reacted; boiling point of tetramethylene glycol, 107–108° at 4 mm.; melting point, 19–19.5°; $d_4^{20} = 1.0171$; n_D^{20}, 1.4467; M_D (calcd.), 23.722; M_D (found), 23.651. The di-phenylurethan was prepared according to the directions of Hamonet.[9] Crystallization from chloroform gave a product melting at 179.5". Hamonet gives the melting point as 180–181°. The di-or-naphthylurethan was also prepared by warming the glycol with or-naphthyl isocyanate. Crystallized from xylene it melted at 198.5–199°. Bennett and Heathcoat give the melting point as 198'.

Anal. Calcd. for $C_{26}H_{24}O_4N_2$: N, 6.55. Found: N, 6.49.

Tetramethylene **Chlorohydrin.**—Twenty grams of the glycol was dissolved in pyridine (17.6 g.) in a 200-cc. three-nerked flask fitted with a stirrer, dropping funnel and reflux condenser. The flask was placed in a water-bath maintained at 55° and 26.4 g. of thionyl chloride was added drop-wise during one hour. The temperature of the bath was then raised to 80° for one hour to drive off the sulfur dioxide. The reaction mixture was then worked up in the usual way; yield, 11.4 g. (47%). Tetramethylene chlorohydrin boils at 84–85' at 16 mm. If distilled at a pressure much higher than this it tends to lose hydrogen chloride, presumably forming tetrahydrofuran; d_4^{20}, 1.0883; n_D^{20}, 1.4518; M_D (calcd.), 27.064; M_D (found), 26.893.

Summary

1. A new method of synthesis of tetramethylene glycol has been devised. Müller's method (published after this work had been completed), involving the reduction of diethyl succinate, appears to be cheaper, simpler and more rapid.

2. Tetramethylene chlorohydrin was isolated in a pure state for the first time; its physical properties were determined and its phenylurethan and a-naphthylurethan were made, the former being a new derivative.

THE CHEMICAL COMPOSITION OF CORN (ZEA MAYS) SEEDLINGS. I. THE ISOLATION OF XYLAN AND CELLULOSE FROM THE CELL WALLS[1,2]

BY KARL PAUL LINK

RECEIVED MARCH 23, 1929 PUBLISHED AUGUST 7, 1929

Introduction

In the course of a general investigation on the nature of corn (Zea Mays) seedling blight, it was deemed expedient to investigate the chemical com-

---

[1] Published with the permission of the Director of the Wisconsin Agricultural Experiment Station.

[2] This publication comprises part of a thesis submitted to the Graduate Faculty of the University of Wisconsin in June, 1925, in partial fulfilment of the requirements for the degree of Doctor of Philosophy. The research was concluded during 1925–1927 while the author was a Fellow of the International Education Board posted at the University of St. Andrews, Scotland, and the University of Graz, Austria. The author wishes to acknowledge his indebtedness to Sir James Irvine, D.Sc., F.R.S., Principal and Vice Chancellor of the University of St. Andrews, for the privilege of extending the research while a student in his laboratory and for advice and help received. The author is likewise indebted to Professor Fritz Pregl, Director of the Medico-chemical Institute of the University of Graz, under whose personal direction the micro-analytical analyses were conducted. To the Board of Directors of the International Education Board, New York City, the author wishes to extend his thanks for the Fellowship grant received which enabled him to complete the work in the laboratories mentioned.

position of the seedlings with the purpose of correlating chemical composition with disease resistance. A preliminary report was made in 1923,[3] wherein the general purposes of the investigation were presented. This paper deals primarily with the studies made to determine the nature of the chemical constituents that compose the cell walls of the corn seedling.

It is of importance, and also of general interest to plant biochemistry, to know whether the environmental factor, temperature, can modify or alter the nature of the chemical components laid down in the cell wall. Of equal significance is the question, "Are the cell wall substances formed in the early stages of plant growth the same as those in the mature plant?" In cellulose chemistry the question frequently arises,[4] "Is there one true cellulose, $(C_6H_{10}O_5)_n$, universally distributed throughout nature, and made up of glucose units linked in an identical manner, or are there many types and kinds of cellulose?" The criterion commonly used to designate a true cellulose is the cotton fiber. Cotton is regarded as the standard example of a normal cellulose.[5]

The corn seedling lends itself very readily to a study of the general considerations mentioned. Very sensitive responses to the environmental factor of temperature are exhibited by the corn plant. At the optimum growing temperature, 24°, the rate of development of the seedlings is approximately four to five times that attained at the temperature of 12". The cell walls of the corn seedling are relatively free from lignin. In the epidermal and endospermal layers there are some suberized and cutinized cells, but the incrustating substances are of such a nature that they can be readily removed. The necessity of applying strong oxidizing reagents to approach the study of the polysaccharide constituents is thereby eliminated. Nitrogenous substances of a very stable and resistant nature are likewise not found in the corn seedling. The nitrogenous compounds present can be readily removed without attacking the basic cell wall structure.

Experimentation

The studies here recorded were conducted on two lots of corn seedlings produced at 12 and 24°.[6] The separate batches of seedlings were grown in soil in the Wisconsin

[5] Hess, "Die Chemie der Zellulose und ihrer Begleiter," Akademische Verlagsgesellschaft, Leipzig, 1928. This work also contains a very complete treatise on the chemical nature of the substances that accompany cellulose in nature.

[6] The results presented throughout the experimental part of this paper are those obtained by the study of seedling tissue grown at 24°. Tissue grown at 12° was studied in the same manner. The general analytical results obtained from comparable preparations of either 12 or 24° tissue were the same. The quantitative differences found are referred to in the discussion and will be presented in detail in a forthcoming publication.

constant temperature chambers[7] to the same stage of development. The seedlings planted at a depth of two and one-half inches were harvested when they reached the stage where the coleoptile ruptured the leaf sheath. At 24° five days are required, while at 12° the seedlings reach this stage in twenty to twenty-two days. After removing the soil by washing with water, the sprouts (radicle and plumule) were separated from the endosperm and immediately steeped in 95% alcohol.[8] A sufficient quantity of alcohol was used to keep the final concentration above 70% after dilution by the water from the tissue. The alcohol was subsequently boiled under a reflux condenser for five hours to kill the tissue.

Preliminary Extraction to Remove Non-polysaccharide Substances.—The alcohol in which the seedlings were preserved was filtered off at the pump. The tissue was then ground in a Nixtamal mill using alcohol as the liquid medium. It was subsequently transferred to a large Soxhlet, after Sando,[9] and extracted, first with 90% alcohol for twenty-four hours and finally with 99% alcohol for ten hours. After the alcohol imbibed by the tissue had been removed in a current of air at 25°, the tissue was ground in a drug mill and finally in a ball mill until all particles could pass through a 120-mesh sieve. It was then extracted for twenty-four hours with ether in a Soxhlet and finally with petroleum ether (b. p. 90–110°). The use of the fat solvents was found to be very advantageous since they removed wax and gum-like substances that had remained intact during the alcohol extraction.

Extraction of Protein, Pectin and Incrustating Substances.—After the removal of the fats, pigments and sugars, the tissue was digested for thirty-six hours in 1% ammonium hydroxide solution at 25°, and pressed free from the extraction liquors in a hand press. The excess ammonia was removed by washing with warm water (65°).

[8] In all of the investigations conducted on the nature of the cell wall constituents of the corn seedling, it was found advantageous to refrain from dehydrating the green seedling tissue by the direct application of heat. The seedlings were therefore killed by steeping them in alcohol. They were also preserved in this medium. The various fractions extracted from the cell walls were likewise never dehydrated above the temperature of 25" until most of the moisture (96–98%) had been removed through the use of organic solvents. Alcohol of successively increasing concentrations and then dry ether were used to dehydrate the preparations. By the application of these solvents a flaky and friable physical consistency was always secured in all of the products obtained. The products were also always remarkably free from discoloration.

If a freshly precipitated xylan preparation is dehydrated directly, either by the application of a current of air or in a vacuum desiccator over calcium chloride, a hard, cohesive, leathery, discolored mass is obtained, from which the last traces of water cannot be removed except by heating in a vacuum at 95° for an extended period. A xylan product prepared by direct dehydration has quite different solubility properties than one first dehydrated by the use of organic solvents. Thus a xylan preparation dehydrated directly over calcium chloride was found to be only partially soluble in hot water and required fourteen hours for complete solution in 1% sodium hydroxide, whereas a similar preparation first dehydrated in alcohol and ether and then over calcium chloride, was readily soluble in boiling water and went into solution in 1% alkali in one hour at 22°. A cellulose preparation dehydrated at 30° in a current of air could not be converted into the triacetate by the method used in this investigation. It was likewise only slowly soluble in Schweitzer's reagent. On the other hand, the cellulose preparations that had first been dehydrated by the use of organic solvents could be readily acetylated and dissolved rapidly in Schweitzer's reagent.

[9] Sando, *Ind. Eng. Chem.*, 16, 1125 (1924).

This extraction was then followed by the chlorine dioxide–sodium sulfite treatment of Schmidt and Graumann,[10] to remove coloring matter and residual lignin- and cutin-like substances. After six treatments with an aqueous chlorine dioxide solution containing approximately 0.25% of the gas, followed successively by six treatments with 2.0% sodium sulfite, these reagents had no further effect. By washing copiously with water at 65° the free chlorine and sodium sulfite were removed from the tissue. The water imbibed by the remaining polysaccharide substances was removed by suspending the residue for twelve hours, first in 95%, then in 98%, and finally in 99.5% alcohol, after which the alcohol was removed by shaking in a large quantity of absolute ether for fifteen hours. By drying in a vacuum desiccator (15-mm. pressure at 25°) over calcium chloride, the ether and any traces of alcohol still remaining were removed. From the aforementioned extractions the final product obtained was a snow-white amorphous powder.

Extraction of **Xylans.**[11]—One hundred grams of the dry product prepared as above, containing 0.33% of ash and 0.67% of nitrogen, was successively extracted five times for twenty-four hours with one liter of 5.0% sodium hydroxide (carbonate free) by shaking on a machine in a glass-stoppered bottle containing small glass rods. A sixth extraction did not remove more material. To the combined alkaline extracts 95% alcohol was added until complete precipitation was produced. The xylan precipitate was allowed to settle, whereupon the major portion of the liquid could be siphoned off. It was found that the precipitated xylan was most efficiently washed free from alkali. by centrifuging, using 50% alcohol containing 10% acetic acid as the washing medium. It was then suspended in 95% alcohol for twelve hours and finally in 99.5% alcohol for twenty-four hours. The alcohol in turn was replaced by ether. Approximately 23.0 g. of xylan was obtained. This is equivalent to 8.5-9.0% of Xylan A, based on the original dry weight of the seedlings. The analysis and properties of this preparation designated as Xylan A are given below.

Extraction of Xylan **B.**—The cell wall material, intact after the separation of Xylan A, had an ash content of 0.37% and contained 0.36% of nitrogen. The quantity of xylan determined by the 12% hydrochloric acid distillation after Krober and Tollens[12] was 11.0% (based on the dry weight of the Xylan A free residue). The residue freed from Xylan A was therefore subjected to a 10% sodium hydroxide (carbonate free) extraction at 60° in the identical manner described above. After four extractions no more xylan was removed. The xylan was precipitated, washed and dried as already described. The yield of Xylan B was approximately 3.0–4.0%, based on the original dry weight of the seedling tissue.

Purification of Xylan **A.—Xylan** A was purified by reprecipitating it from an ammoniacal copper hydroxide solution after a method similar to that employed by Hess.[13] Ten grams was dissolved in 1 liter of 25.0% ammonium hydroxide containing 10 g. of copper hydroxide. By shaking the solution for one hour practically complete solution was obtained. A small amount of flocculent matter remained which was

---

[11] The term hemicellulose was employed by C. Schulze, *Z. physiol. Chem.*, 16, 387 (1892), to denote a substance similar in character to cellulose, which is easily hydrolyzed by weak acids. The Xylans A and B, extractable with 5 and 10% alkali, are likewise quantitatively removed by a 2.50% sulfuric acid hydrolysis. They are therefore hemicelluloses according to the Schulze classification. The writer prefers the more exact terminology, Xylan A and B, to the term "Hemicellulose."

[12] Kröber and Tollens, *J. Landwirtsch.*, **48**, 357 (1900); *Z. angew. Chem.*, **15**, **477** (1902).

[13] Hess, Messmer and Ljubitsch, *Ann.*, **444**, 287 (1925).

removed by centrifuging. This material had a nitrogen content of 8.0%. It was therefore not further considered since it was undoubtedly of a proteinaceous nature. To the clear solution obtained after the removal of the afore-mentioned nitrogen-containing substance, glacial acetic acid was added until the solution was just faintly alkaline. The xylan was thereby precipitated, centrifuged and washed, first with 50% alcohol containing 10.0% of acetic acid to remove the copper, and finally with 95.0% ethyl alcohol to remove the acetic acid. The water was removed with alcohol and the alcohol with ether as stated above.

Properties of Xylan A.—The xylan product obtained consisted of a fine, snow-white amorphous powder, free from nitrogen[14] and contained only 0.22% ash. It is soluble in hot water and forms a thin jell on cooling which exhibits marked swelling properties when alcohol is added. In weak alkalies it is readily soluble at room temperature and can be quantitatively thrown out of solution by the addition either of acidified alcohol or glacial acetic acid. It does not reduce Fehling's solution and is levorotatory. The specific rotation (2-dcm. tube) in 1% sodium hydroxide lies between the values —80.00 and —83.86' (the specific rotation of the various xylans so far isolated varies between the values —70 to —85°).[15] The ultimate analysis showed C, 45.23; H, 6.09 (Pregl-micro method). Calcd. for xylan, $(C_5H_8O_4)_n$, 132.06: C, 45.44; H, 6.11. Distillation with 12% aqueous hydrochloric acid gave an amount of furfural estimated as the phloroglucide compound corresponding to 94.6% of xylan. In view of the later experiments reported, which indicate the absence of other pentoses, the figures quoted refer to pentosans in the form of xylan.

Hydrolysis of Xylan A.—Two grams of Xylan A corrected for ash and moisture were treated with 10 cc. of 72.0% sulfuric acid at 15° for two hours. Within this time solution was invariably complete. After adding sufficient water to produce a 2.0% acid solution, the solution was heated under a reflux condenser for two hours. In some of the preparations a very small amount of flocculent material resisted hydrolysis. After cooling, the solution was neutralized with the requisite quantity of barium carbonate and filtered at the pump. The barium precipitate was extracted twice with boiling water, the washings were combined with the original filtrate and concentrated to a sirup in a vacuum of 15 mm. at 45°. The sirup was taken up with water, filtered free from a small inorganic residue, clarified with activated blood charcoal, again filtered and finally made up to a volume of 100 cc. The reducing value of 10-cc. aliquots was determined by the Shaffer and Hartmann[16] method: found, 93.30%, calculated as xylose. Arabinose was absent from the hydrolyzed solution, since the di-phenylhydrazine test of Neuberg[17] was negative. The phenylosazone of xylose, m. p. 154–159 (from alcohol),

---

[14] The preparations are designated nitrogen-free on the basis of the macro-Kjeldahl method. Ridge, *Textile Institut*, **15**, 94 (1924); *C. A.*, **18**, 1752 (1924), has shown that when the nitrogen content of supposedly nitrogen-free cotton fibers (fibers subjected to the bleaching and weak alkali washing process) is determined by a method capable of detecting a nitrogen content of the low order of 0.001%, the fibers still contain approximately 0.035% of nitrogen. Nitrogen determinations made by the Pregl-micro Kjeldahl method on the various xylan and cellulose preparations reported in this paper never revealed a significant nitrogen content. The highest nitrogen value found was in a cellulose prepared from seedlings grown at 12° wherein the nitrogen content was 0.053% (Pregl-micro Kjeldahl method). It is therefore reasonable to regard the preparations as practically nitrogen free.

[16] Shaffer and Hartmann, *J. Biol. Chem.*, *45*, 365 (1921).

[17] Neuberg and Wohlgemuth, *Z. physiol. Chem.*, *35*, 40 (1902).

was obtained by treating a portion of the hydrolyzed solution with phenylhydrazine and sodium acetate. No mannose phenylhydrazone separated. The crude osazone precipitate obtained was completely soluble in dry acetone, which indicates that the osazone of glucose was not present. As a means of further identification, the Bertrand test for xylose was applied.[18] The characteristic boat-shaped needles of the double cadmium salt, $(C_5H_9O_6)Cd_2 + CdBr_2 + 2H_2O$, were obtained. The xylose was also procured in the free state by taking up the sirup from the hydrolysis of 5 g. of the xylan in enough absolute alcohol to insure complete solution. The alcohol was then concentrated until turbidity set in, whereupon glacial acetic acid was added. On seeding with an authentic specimen of d-xylose and standing for forty-eight hours in an ice chamber, the xylose crystallized out; yield, 3.96 g., 70.0% of the theoretical; m. p. 140–143°, $[\alpha]^{20}_{D}$ in water, +18.1°.

The above critical examination of the fraction extracted with 5% sodium hydroxide, designated as Xylan A, shows conclusively that it is an authentic xylan, uncontaminated with either arabinose, mannose or glucose.

Purification, Properties and Analysis of Xylan B.—Xylan B was purified and analyzed in the identical manner prescribed for Xylan A. The general properties were much the same. Xylan B was found to be free from arabinose, mannose and glucose. The ultimate analysis was in agreement with the theoretical value for $(C_5H_8O_4)_n$, the furfural yield was 93.5% and the percentage of xylose determined by reduction after the acid hydrolysis was 91.2%. The furfural and reducing value are slightly lower than those reported for Xylan A. The specific rotation in 1% sodium hydroxide was —79.20". The amount of flocculent material that resisted the sulfuric acid hydrolysis was appreciably more than that of Xylan A. This undoubtedly accounts for the lower furfural and reducing values as well as the lower specific rotation.

Isolation of Pure Cellulose, $(C_6H_{10}O_5)_n$.—The cellular residue still intact after the 10% sodium hydroxide extraction was washed free from alkali, first with 50% alcohol containing 10% acetic acid and subsequently with 65% alcohol. It was then dried in alcohol and ether. The product was free from nitrogen and contained 0.69% of ash, mostly silicon dioxide. Although no more pentose-yielding extracts could be obtained with alkali, the product still gave considerable furfural when subjected to the 12% hydrochloric acid Kröber–Tollens distillation. The yield of furfural varied between 2.3 and 4.6%. The residue also liberated carbon dioxide when heated with 12% hydrochloric acid after the method of Nanji, Paton and Ling.[19] The furfural-yielding substances present, *which are not true pentosans,* belong either to the class of cellulosic compounds that Hägglund[20] terms furfuroids or are similar to oxidized celluloses. Heuser and Stöckigt[21] reported that the so-called oxidized cellulose liberates carbon dioxide when heated with dilute hydrochloric acid. The possibility that the carbon dioxide and furfural might come from glucuronic acid residues as Schmidt and coworkers[22] have found must also be considered.

To remove these ill-defined and poorly characterized substances it was necessary to subject the residue remaining after the Xylan B extraction to two two-hour treatments at 30° with 15% sodium hydroxide. The characterization of the substances extracted with the 15% alkali is now in progress. Due to the present lack of concise information on this class of substances, a detailed discussion will be deferred. The residue remaining after the 15% sodium hydroxide extraction was washed free

from alkali and dried in the manner previously described. Fifty grams of a xylan-free residue yielded approximately **40.0** g. of a white, amorphous product. The cellulose prepared from corn seedlings, which had first been extracted with alkali until all xylan, furfuroid and oxidized cellulosic material had been removed, displays the important chemical properties of cotton cellulose.

Analysis of the Cellulose.—The ash content was **0.86%** (silicon dioxide). It was free from nitrogen. The ultimate analysis showed C, **44.40;** H, **6.15.** Calcd. for $(C_6H_{10}O_5)_n$: C, 44.44; H, **6.21.** With the zinc chloriodide reagent the cellulose preparation gives the characteristic violet color. It is completely soluble in ammoniacal copper solutions (Schweitzer's reagent) and can be quantitatively reprecipitated by the addition of acetic acid.[23] When subjected to the **12%** aqueous hydrochloric acid distillation of Krober and Tollens the cellulose yielded only traces of furfural. Only minute quantities of carbon dioxide are formed in the same distillation determined by the method of Nanji, Paton and Ling.

The triacetate, $(C_6H_7O_5(CH_3CO)_3)_n$, was prepared after the excellent method of Barnett, as modified by Irvine and Hirst[24] for the preparation of esparto cellulose triacetate. It was snow-white in color and differed from cotton cellulose acetate prepared in the same manner by being more flaky and softer in texture. The specific rotation of a chloroform solution (c = **1.3)** was **−22.1°**; moisture content, **1.08%;** ash, **0.28%;** **C, 49.85;** H, **5.35** (Pregl-micro method). Calcd. for C, **50.00;** H, **5.55.** The acetyl value calculated as acetic acid was **62.2%.** The theoretical value for cellulose triacetate is **62.51%.**

The yield of α-cellobiose-octa-acetate, $C_{12}H_{14}(COCH_3)_8O_{11}$, obtained by subjecting the cellulose to a simultaneous acetylation and hydrolysis varies between the values of **46** and 48% after the method of Hess[26] and **38** to **40%** after the method of Freudenberg.[26] After purification according to the method used by Hudson,[27] the octa-acetate showed m. p. **223°** and specific rotation in chloroform +41.6°. The accepted values are m. p. 221.5–222°, $[\alpha]^{20}_{D}$ in chloroform +41.3°. The yield of glucose, obtained as the methylglucoside, $C_6H_{14}O_6$, using the method of Irvine and Hirst, was 90.0% of the theoretical. The methylglucoside showed a permanent specific rotation of +157.2° in water and the m. p. 165–166°. Its methoxyl content was **7.68%** (Pregl-micro Zeisel method); theoretical: OCH_3, **7.77.** The only osazone detectable after hydrolysis with sulfuric acid, as described under Xylan A, was the osazone of d-glucose m. p. **204–208°.** Xylose, mannose and galactose (by mucic acid method) were absent.

Discussion

The cell walls of the corn seedling contain xylan, $(C_5H_8O_4)_n$. The total xylan content as determined by the furfural distillation and estimated as the phloroglucide compound varies between 10–12% of the original dry weight of the tissue. The xylan can be fractionated. Approximately 85–90% of the xylan is extractable with 5% sodium hydroxide (Xylan A), the remainder can be extracted with 10% sodium hydroxide (Xylan B).

In their purified state the two xylans, A and B, are snow-white amor-

---

[23] The specific rotation values of the corn seedling cellulose in alkaline copper solutions determined after the method of Hess, *Ann.*, 466, 1 (1928), will appear in a subsequent publication.

phous powders, soluble in boiling water and readily soluble in 1% sodium hydroxide. The chemical analysis and a study of their properties showed them to be essentially identical. They differ from each other in their initial solubility and in their behavior toward the zinc chloriodide reagent. This color test was until recently regarded to be specific for true cellulose.[28] One of Hess' co-workers[29] was the first to show that it was not specific for cellulose. Lüdtke found that a mannan isolated from the ivory nut gave a positive test with the reagent. Hess and Lüdtke[30] have also reported that a xylan from bamboo stalks gives a positive test, whereas a xylan isolated from the sulfite liquors of pine wood did not give the test. The Xylan A isolated from the corn seedling gave no color with the reagent, whereas Xylan B gave the typical violet color, formerly prescribed as specific for cellulose. A satisfactory explanation for this difference in apparently similar xylans is wanting. The ultimate composition agreed with the calculated value for $(C_5H_8O_4)_n$. The specific rotation determined in 1% sodium hydroxide varied between the values —79.20 to —83.00'. In each case the osazones obtained after hydrolysis with acid were identical under the microscope and melted at 154–160° without decomposition. The recrystallized xylose showed the correct initial and permanent specific rotation of $[\alpha]_D^{20} + 18.0$ and melted at 140–143°.

Although the xylans prepared from corn seedlings grown at 12 and 24°, respectively, are identical chemically, there is a quantitative difference in the distribution of the xylan fractions. The seedlings grown at 12° contain 10–15% more Xylan A than the 24° seedlings. Xylan B varies proportionally, being lower in the 12° seedlings than in the 24° seedlings. The total xylan content of the seedlings is approximately the same at either temperature. Chemically the xylan of the corn seedling is identical with the xylan of the mature corn plant (forthcoming paper). Its properties are similar to those assigned by other workers to xylans from various sources.[31]

About 7% of the furfural-yielding substances in the corn seedling are not true pentosans. These substances appear to be similar to the poorly characterized oxidized celluloses and furfuroids (see Hagglund, "Holzchemie" and Hess, "Chemie der Zellulose." They can be brought into solution by the use of 15% sodium hydroxide. In a forthcoming paper these substances will be discussed.

It has also been shown that the cell wall of the corn seedling contains pure

cellulose. Approximately 14–18% of the dry weight of corn seedlings is composed of authentic cellulose possessing the formula $(C_6H_{10}O_5)_n$ and convertible quantitatively into glucose on hydrolysis. The cellulose in corn seedlings, when freed from xylan and furfuroids by alkali, displays the essential chemical properties of cotton cellulose. The ultimate analysis agreed with the theoretical value of $(C_6H_{10}O_5)_n$; it is soluble in Schweitzers reagent and can be quantitatively reprecipitated. The triacetate was identical with cotton cellulose triacetate prepared in the same manner (see Table I). Hess ("Chemie der Zellulose," p. 391) has shown that cellulose acetate preparations obtained by various methods can be regarded as chemically identical even though they show some variance with respect to the physical properties like solubility, swelling properties, viscosity in solution, and film-building capacity. The variations are presumably due to the phenomenon of molecular association so commonly exhibited by solutions of polysaccharide substances. The corn seedling cellulose can also be converted into cellobiose-octa-acetate in yields comparable to those obtained with cotton cellulose. Corn seedlings produced at 24° contain approximately 4% more true cellulose than the 12" seedlings, but the cellulose in both cases is identical.

Physiologically it is significant that cell walls of four-day-old corn seedlings grown at 24° and twenty-day old seedlings grown at 12° (same stage of anatomical development) contain the same xylan, $(C_5H_8O_4)_n$, and the same cellulose, $(C_6H_{10}O_5)_n$, found in mature corn plants and in mature plants of other species. In the cell walls of the corn seedlings the basic structural cellulose has intimately associated with it the pentosan xylan. Xylose usually accompanies glucose in nature since these two sugars are structurally related. How the xylan is actually associated with the cellulose is unknown.

The researches of Irvine and Hirst[4] have illustrated the intimate association of xylan and cellulose in esparto grass. Hess and Lüdtke[30] have reported the simultaneous occurrence of xylan and cellulose in pine wood. Lüdtke[32] has found the same to be true in bamboo stalks. Hägglund and co-workers'' have likewise recorded the accompaniment of xylan with cellulose in pine wood.

Through the brilliant contributions of Haworth,[34] Hirst,[35] Levene,[36] and others we now know that in their stable forms d-glucose and d-xylose have the 1,5-oxide ring structure. From Haworth's work[37] it is easy to perceive

how d-glucose through oxidation and subsequent decarboxylation of the resulting uronic acid could give rise to d-xylose.

Lüdtke has demonstrated that the cellulose in the ivory nut[29] and in bamboo stalks[32] is a true cellulose. To this list can be appended the cellulose of the corn plant. It appears that there is one true cellulose, $(C_6H_{10}O_5)_n$, universally distributed in the plant world.

Summary

1. Corn seedlings grown at 12 and 24° to the stage where the coleoptile ruptures the leaf sheath contain 10–12% of xylan, $(C_5H_8O_4)_n$, and 16–18% of $(C_6H_{10}O_5)_n$ cellulose.
2. The xylan can be fractionated, 85–90% can be extracted with 5% sodium hydroxide (Xylan A) and the remainder with 10% sodium hydroxide (Xylan B).
3. In the pure state the Xylans A and B are soluble in hot water, are strongly levorotatory and can be quantitatively hydrolyzed into d-xylose.
4. The hexose cellulose is composed entirely of glucose residues, is convertible into cellulose triacetate, into cellobiose-octa-acetate and into the methyl glucoside. In these respects and also in its high molecular complexity the compound resembles the cellulose of cotton.
5. No sugars other than xylose and glucose have been detected in the hydrolysis products obtained from the cell wall constituents of the corn seedling.
6. Temperature does not alter the qualitative nature of the xylan and cellulosic constituents laid down in the cell walls, but alters slightly their quantitative distribution.
7. The xylan of the corn seedling is similar to the xylans obtained from

other plant species. The cellulose is identical with the normal cotton cellulose.

THE CHEMICAL COMPOSITION OF CORN (ZEA MAYS) SEEDLINGS. II. THE ISOLATION OF A DEXTRIN SIMILAR TO THE TRIHEXOSAN OBTAINED BY THE THERMAL DEPOLYMERIZATION OF POTATO STARCH

BY KARL PAUL LINK[1]

RECEIVED MARCH 23, 1929 PUBLISHED AUGUST 7, 1929

Introduction

Dextrins are usually regarded as the intermediate products formed in the course of the hydrolysis of starch to maltose and glucose by diastatic enzymes.[2] Numerous dextrins formed in the course of the degradation of the starch molecule have been studied by various early workers;[3] recently more thoroughly by Samec[4] and Ling and Nanji.[5]

The occurrence of dextrins or dextrin-like substances in the growing plant has frequently been reported.[6] In no case, however, have the dextrins been isolated in a sufficiently pure state to permit definite characterization

[1] This publication comprises part of a thesis submitted to the Graduate Faculty of the University of Wisconsin, in June, 1925, in partial fulfilment of the requirements for the degree of Doctor of Philosophy. The research was concluded during 1925–1927 while the author was a Fellow of the International Education Board posted at the University of Zurich, Switzerland, and the University of Graz, Austria. The author wishes to acknowledge his indebtedness to Prof. Paul Karrer, Director of the Institute of Chemistry, University of Zurich, for the privilege of extending the research while a student in his laboratory and for advice and help received. The author is likewise indebted to Professor Fritz Pregl, Director of the Medico-Chemical Institute of the University of Graz, under whose personal direction the micro-analytical analyses were conducted. To the Board of Directors of the International Education Board (New York City) the author extends his thanks for the Fellowship grant which enabled him to complete the work in the laboratories mentioned.

and identification. The order of the molecular aggregation of the dextrins present in plant tissue may vary from $(C_6H_{10}O_5)_2$, the anhydride of maltose, to the high state of polymerization found in starch, $(C_6H_{10}O_5)_n$. It is also possible that many of the dextrins reported present in the growing plant belong to the cellulose dextrin series and represent intermediate compounds used in the formation of cell wall tissue.

In 1922 Pictet[7] reported the isolation of a trihexosan, $(C_6H_{10}O_5)_3$, obtained by the thermal depolymerization of potato starch in glycerin at the temperature of 200–210°. By heating potato starch in glycerin until the solution just failed to give a color reaction with iodine, and then quickly removing the solvent by vacuum distillation at the same temperature, a transparent, vitreous, light brown solid was obtained, soluble in water and precipitable with ethyl alcohol. Upon purification by reprecipitating with alcohol, the product was procured as a white, amorphous, slightly hygroscopic powder, molecular weight, 503; α_D^{20} + 162.2 in water. Sjöberg[8] reported the formation of a dextrin, by the action of amylose on amylopectin, identical with the trihexosan of Pictet. The same product was obtained by Pringsheim by the action of glycerin on glycogen at the temperature of 200°.

Since 1922 it has been known[10] that the radicle and plumule of corn seedlings (Zea Mays) contain dextrins, varying in amounts from 1.25 to 3.00% of the total dry weight of the seedlings. The dextrin content was found to be highest in seedlings grown near the optimum temperature of growth, namely, at 24–28°. At these temperatures the quantity of dextrin present is usually double the value found in seedlings grown at 12–14°.

It was noted that the dextrins present in the seedlings grown at 24–28° could be roughly divided into two fractions. The fractions were both soluble in water and dilute alcohol (below 40%) but insoluble in alcohol of over 80% concentration. By adding sufficient alcohol to an aqueous solution of the dextrins to insure a concentration of 40%, one fraction was precipitated which gave a faint red color with iodine solution. By increasing the concentration of the alcohol to over 75%, a second fraction fell out, which in the crude state gave a faint yellow test with iodine. Enough of this second fraction was prepared to enable a study to be made thereupon. The dextrin fraction precipitated by 75% alcohol was found to be very similar to the trihexosan, $(C_6H_{10}O_5)_3$, obtained by Pictet. It comprises about 65% of the total dextrin content of the seedlings. The fraction precipitated by 40.0% alcohol is a complex mixture of higher dextrin aggregates, a report of which will be made later.

Experimentation

Corn seedlings were grown at 24–28° by germinating them in soil, in the Wisconsin constant temperature soil tanks.[11] The seedlings, planted at a depth of 2.5 inches, were harvested when they reached the stage where the coleoptile ruptured the leaf sheath.[12] They were then removed from the soil, washed and separated from the remaining endosperm tissue. The method of killing plant tissue at 98°, followed by rapid drying at 65° in a current of air, previously reported by the writer, was used to preserve the tissue.[13] The dried tissue, containing approximately 6–8% of water was prepared for the chemical investigations in the identical manner used by the writer with other plant tissue.[14]

Extraction of Fat, Pigments, Waxy Constituents and Sugar.—Four kilos of the ground tissue was extracted in a large Soxhlet with ether for thirty-six hours and then with petroleum ether (b. p. 90–110°) for fifteen hours. After removing the fat solvents, the extraction was continued for twenty-four hours with 95.0% alcohol to remove the sugar present.

Extraction of Dextrins.—The fat, pigment and sugar-free residue was placed in a large bottle with 20 times its weight of 20.0% alcohol and extracted by shaking upon a machine for six days. The extraction was repeated for two days with a fresh portion of alcohol. No more dextrins could be removed with 20.0% alcohol after the second extraction. The large volume of 20.0% alcohol was then concentrated carefully in a vacuum of 15 mm. at 40° to one-seventh of the original volume. Alcohol (99.0%) was added until the concentration approximated 40.0%. The solution was then kept in an ice chamber at 2° for four days, during which time the separation of the dextrin fraction that gave a positive reaction with iodine was complete. After the precipitated dextrin was filtered, sufficient 99.0% alcohol was added to the filtrate to produce a concentration of 85.0%. On standing for five days at 2° the precipitation of the second dextrin was complete. The yield of the crude product was 72.0 g. This was purified by dissolving in water and reprecipitating with alcohol. After six reprecipitations the product was obtained as an amorphous snow-white powder, free from ash and nitrogen. The yield of the purified product was 63.0 grams.[15]

Properties and Analysis of the Dextrin.—The dextrin does not reduce Fehling's solution, gives no color with iodine and has a feeble insipid taste. It decomposes at 220–230" without melting. The specific rotation in water is $[\alpha]^{20}_{D}$, +163.6. The ultimate analysis showed C, 44.44; H, 6.19 (Pregl micro method); calcd. for $(C_6H_{10}O_5)_3$: C, 44.44; H, 6.21%. On hydrolysis in 2.5% sulfuric acid it was converted into glucose in 92.0% yields. The osazone prepared from the hydrolyzed solution showed m. p. 204–208°, the m. p. for glucosazone. The nono-acetyl derivative, $C_{36}H_{48}O_{24}$, prepared after the method of Pictet, showed m. p. 152–153°; $[\alpha]^{20}_{D}$, +125.9° in chloroform.

The dextrin (trihexosan) was converted into the monomethyl derivative, methoxyl content 17.40% (Zeisel–Pregl) in the manner employed by Kuhn and Zeise.[16] The

[12] At this stage the seedlings are emerging from the soil. The photosynthesis of food materials has not begun. All the chemical constituents present in the seedlings are therefore derived from the embryo and endosperm reserves.

[14] Link, *ibid.*, 45, 439 (1923).

[15] The product was dried first in 95.0%, then in 99.5%, alcohol. The alcohol was replaced by ether, which was in turn removed at 15 mm. pressure in a vacuum desiccator over calcium chloride.

[16] Kuhn and Zeise, Ber., 59, 2314 (1926).

monomethyl derivative gave no color with iodine and could not be saccharified with diastatic enzymes. Upon hydrolysis in 5% hydrochloric acid it gave 6-monomethylglucose, isolated as the osazone, m. p. 176–179°, identical with the figure given by Helferich and Becker.[17]

An attempt was made to determine the molecular weight of the unsubstituted product by the cryoscopic method, but consistent values could not be obtained. Using water as the solvent, the values found varied between 510 and 639. Pictet reported the molecular weight of 503 for the unsubstituted trihexosan and 871 for the mono-acetyl derivative. The molecular weight determinations of the mono-acetyl derivative varied between the values 820 to 960° with chloroform as the solvent and 790 to 980 with glacial acetic acid as the solvent.

Discussion

The properties and analyses of the dextrin isolated from the corn seedling indicate that it is quite comparable to the trihexosan, $(C_6H_{10}O_5)_3$, prepared by Pictet by the thermal depolymerization of potato starch in glycerin at 200–210°. It is prudent not to consider the dextrin from the corn seedling as strictly identical with the trihexosan of Pictet, since the molecular weight determinations are not in agreement with the figures reported by Pictet.[18]

The molecular weight determinations of polysaccharide compounds and their derivatives have long since been known to give contradictory results. Time and time again the chemist has been deceived by drawing rigid conclusions from molecular weight data obtained in the study of amorphous polysaccharide substances. The work of Karrer,[19] Bergmann,[20] Pringsheim,[21] Hess[22] and their co-workers has revealed the most unsuspected and unconquerable difficulties, due to the tendency of polysaccharide substances to form molecular aggregates through association. Molecular weight determinations of amorphous substances should be accepted with precaution, as Karrer has pointed out in his monograph.[23] Therein he states that he had failed to obtain the trihexosan of Pictet and the dihexosan of Pringsheim and Sjöberg in a true crystalline condition, as these workers had reported. Furthermore, Karrer questions the homogeneity of both the dihexosan and trihexosan. The argument is advanced that trihexosan can be hydrolyzed to maltose by enzymes, without the simultaneous formation of glucose, and that it can likewise be converted into acetobromo-

[23] Karrer, "Die Polymere Kohlenhydrate," Akademisches Verlagsgesellschaft, Leipzig, 1925, pp. 86–88.

maltose by the action of acetyl bromide, without the formation of acetobromoglucose. From these experiments Karrer concludes that the trihexosan, $(C_6H_{10}O_5)_3$, cannot be a three-membered glucose structure (that is, one molecule of glucose with one molecule of maltose), but that it must be a higher glucose polymer, which would yield maltose quantitatively upon hydrolysis and acetobromomaltose by the action of acetyl bromide. Karrer rejects the validity of the molecular weight determinations of the trihexosan and regards any conclusion drawn therefrom as presumptuous.

Pictet adhered to the belief that the trihexosan, $(C_6H_{10}O_5)_3$, represents the basal structural unit of the potato starch molecule, since it could be obtained in yields of the order of 90.0%. Sjoberg obtained both a dihexosan and a trihexosan from starch by enzymatic hydrolysis and concluded that the Pringsheim theory of the basal di- and trihexosan structure of starch was correct. According to this theory, the dihexosan is regarded as derived from the amylose and the trihexosan from the amylopectin of the starch grain. A dextrin comparable to dihexosan could not be isolated from the corn seedling. The dextrins present, besides the one closely related to Pictet's trihexosan, are of a higher molecular order.

Since the corn seedlings had not begun the photosynthetic process at the stage at which they were harvested, the dextrins in the tissue may be regarded as derived from one or both of two sources. They might have been translocated from the endosperm through the scutellum into the radicle and plumule—or they might have been synthesized from the sucrose present. Maltose appears to be absent from the radicle and plumule of the corn seedling at the stage of the rupturing of the leaf sheath by the coleoptile.

The chemical properties of the dextrin isolated (tabulated in Tables I and II) indicate that it is logical to regard it as a member of the starch dextrin series rather than of the cellulose dextrin series. Micheel,[24] one of Hess' co-workers, has recently isolated an amorphous trihexosan by the acetolysis of cellulose with hydrobromic acid and acetyl bromide. The physical constants and properties of the trihexosan isolated by Micheel indicate that it is not identical or related to the trihexosan obtained from starch.

It appears, therefore, that the dextrin isolated from the corn seedling represents a glucose polymer of the starch dextrin series, rather than of the cellulose dextrin series, and that it is not a polysaccharide substance directly used in the synthesis of the structural elements of the cell wall. It is possible that the dextrin is used as a respiratory material in the metabolism of the seedling.

In the following table the properties and physical constants of the dextrin isolated from the corn seedling are listed for comparison with those of

In concluding the author wishes to acknowledge his indebtedness to Dr. James G. Dickson, of the Department of Plant Pathology, for advice and criticism received throughout the course of this investigation.

Summary

A dextrin has been isolated from the radicle and plumule of corn seedlings, which appears to be similar to the trihexosan, $(C_6H_{10}O_5)_3$, obtained

by the thermal depolymerization of potato starch. The dextrin comprises approximately 65% of the total dextrin content of the corn seedlings. Since the dextrin belongs to the starch dextrin series, it appears probable that it is a polysaccharide substance used in the respiratory process of the seedlings.

MONOARYLGUANIDINES. II. BENZOXAZOLEGUANIDINE[1]

BY G. B. L. SMITH, J. H. KANE[2] AND C. W. MASON[3]

RECEIVED MARCH 23, 1929 PUBLISHED AUGUST 7, 1929

Introduction

Since o-aminophenol reacts with organic compounds containing the nitrile group to form benzoxazoles,[4] it was thought that this type reaction might be employed as an additional confirmation of the cyanoguanidine formula of dicyandiamide.[5] Dicyandiamide was first prepared by Beilstein and Geuther,[6] and the present name was given to the compound by Haag.[7] In addition to the Bamberger formula three other possible structural configurations have been suggested.[8] The Bamberger α-cyanoguanidine formula, originally suggested with very little substantial proof, is now generally accepted, and probably the most convincing arguments for the correctness of this formula have been advanced by Hale and Vibrans,[9] who reviewed the literature concerning dicyandiamide and studied the product of the reaction between acetylacetone and dicyandiamide. Blair and Braham[10] believe that this structural configuration explains the formation of biguanide and guanidine salts when dicyandiamide is fused

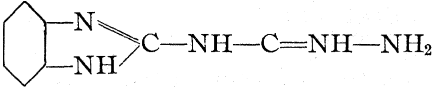
with ammonium salts. On the other hand, Werner and Bell[11] have not accepted this formula and more recently Hart,[12] a student of E. C. Franklin, assumed the Pohl @-cyanoguanidine formula in writing the equation for the reduction of dicyandiazide to dicyandiamide.[13]

In addition to the condensation of o-aminophenol with a nitrile group, benzoxazoles may be formed by condensation of o-aminophenol with a carboxyl group[14] or with an acid amide,[4a] and benzimidazoles may be prepared by substituting o-phenylenediamine for o-aminophenol. Ziegelbauer[15] and Pellizzari[16] have prepared a compound which they called o-phenylenebiguanide by the interaction of *o*-phenylenediamine and dicyandiamide and Pellizzari assigned the formula

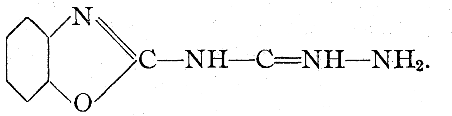


to this compound.[17]

This reaction is of peculiar interest in connection with the present investigation as it also gives simple proof of the presence of the nitrile group in the dicyandiamide molecule.

Reaction between o-Aminophenol and Dicyandiamide.—Ammonia is copiously liberated when *o*-aminophenol and dicyandiamide in molecular proportions are fused. When heated under a reflux in an alcoholic solution of hydrochloric acid, they react to form the hydrochloride salt of a new base. This salt may be isolated by crystallization from the alcoholic solution; when dissolved in water and treated with a solution of sodium hydroxide, the free base is obtained. The mother liquor from the original reaction gives ammonia on treatment with an excess of a solution of sodium hydroxide and practically one mole for each mole of reacting substances was obtained. The base was found to have the formula $C_8H_8N_4O\cdot H_2O$, and several monobasic salts of $C_8H_8N_4O$ were prepared.

The following evidence is offered as proof that this substance is benzoxazoleguanidine,



(1) The base does not give reactions characteristic of the phenylhydroxy or phenylamino

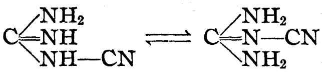
[17] The authors of this paper prefer to call the substance benzimidazoleguanidine. The preparation has been repeated in this Laboratory and a new sulfate, $C_8H_9N_5\cdot H_2SO_4\cdot 2H_2O$ has been prepared; H. A. Roth, "Thesis," Polytechnic Institute of Brooklyn, 1928.

groups. (2) A diacetyl derivative has been prepared.[18] (3) A quaternary methyl iodide derivative has been prepared.[19]

This reaction between o-aminophenol and dicyandiamide to form benzoxazoleguanidine gives direct positive evidence of the presence of the nitrile group in the dicyandiamide molecule. It also confirms the conclusion of Pellizzari regarding the structure of o-phenylenebiguanide (benzimidazolguanidine). All these results may be explained by assuming either the Bamberger or the Pohl formula. It is indeed highly probable that dicyandiamide is a tautomeric compound and, therefore, an equilibrium product which may be represented by the following



$$\mathrm{C}\begin{cases}\mathrm{NH_2}\\ \mathrm{=NH}\\ \mathrm{NH{-}CN}\end{cases} \rightleftharpoons \mathrm{C}\begin{cases}\mathrm{NH_2}\\ \mathrm{=N{-}CN}\\ \mathrm{NH_2}\end{cases}$$

The facts here presented are entirely consistent with this view.

Experimental

Crude Benzoxazoleguanidine Hydrochloride.—One hundred grams of *o*-aminophenol[20] was dissolved in a mixture of 100 cc. of concentrated hydrochloric acid and 100 cc. of 95% alcohol and heated to boiling under a reflux for fifteen minutes. Eighty grams of dicyandiamide[21] was added and the heating was continued for two hours. On cooling crystals formed which were separated by filtration and a second crop was secured by concentration of the mother liquor to half volume. The product thus obtained was dark in color and was used for the subsequent preparation of the base; yield, 130 g.

Ammonia Produced in the Reaction.—An aliquot portion of the mother liquor from the above reaction was treated with a concentrated solution of sodium hydroxide and the liberated ammonia was distilled into an excess of standard acid. The ammonia was determined in the usual manner and 91% of the theoretical (corresponding to 1 mole of NH_3 for each mole of dicyandiamide and o-aminophenol) was recovered.

Benzoxazoleguanidine Monohydrate (Base).—Fifty grams of crude benzoxazoleguanidine hydrochloride was dissolved in 300 cc. of boiling water and 13 g. of potassium hydroxide dissolved in 50 cc. of water was added. The base precipitated immediately and after cooling was filtered, washed with cold water and dried; yield, 45 g. This procedure gives a product somewhat yellow in color, but purification may be effected by dissolving in hot water, treating with vegetable charcoal and recrystallizing, or by dissolving in alcohol and pouring into a large volume of cold water.

Benzoxazoleguanidine monohydrate forms glistening pearly very pale yellow platelets. It is very soluble in alcohol and sparingly soluble in water. Molecular weight determinations of the dehydrated base in acetone by elevation of the boiling point yielded results varying from 170–180. Neither alcoholic nor aqueous solutions of the base gave

---

[18] The fact that a triacetyl derivative could not be prepared may be attributable to steric hindrance due to the electronegative character of the benzoxazole ring. The electronegative character of this compound is demonstrated by its low activity as an accelerator of vulcanization of rubber; Smith and Wise, *Ind. Eng. Chem.*, 20, 298 (1928).

[19] This reaction is characteristic of benzoxazoles; Fischer, *J. prakt. Chem.*, [2] 73, 436 (1906).

[20] Practical grade, obtained from the Eastman Kodak Co.

[21] Obtained from the American Cyanamide Co.

any coloration with a solution of ferric chloride, showing thereby the absence of the phenylhydroxy group. Also, an aqueous suspension of lead dioxide in acetic acid gave no color reaction with solutions of benzoxazoleguanidine, indicating the absence of a primary amino group attached to the benzene nucleus. o-Aminophenol gave positive color reactions in each case.

Salts of Benzoxazoleguanidine.—Benzoxazoleguanidine nitrate, sulfate, hydrochloride and picrate were prepared by dissolving 10 g. of the base in the least possible amount of boiling water and treating immediately with a slight excess of the respective acid. The salts are all sparingly soluble in water and crystallized when the solutions were cooled. The salts of the strong acids hydrolyzed in aqueous solution and could be titrated with a standard aikali using phenolphthalein as indicator. Analyses recorded with the exception of the nitrate are all gravimetric determinations by standard methods. The analytical and other data for the base and salts are given in the accompanying table.

Diacetylbenzoxazoleguanidine.—Three grams of benzoxazoleguanidine, dissolved in alcohol, was heated with 15 g. of acetic anhydride for forty minutes. The solution was cooled and then poured into cold water and diacetylbenzoxazoleguanidine precipitated; m. p. 209–210°.

Anal. Subs., 0.5000, 0.5000: 7.81, 7.70 cc. of 1.0 *N* HCl. Calcd.: N, 21.54. Found: N, 21.87, 21.54.

Iodide of Quaternary Methylbenzoxazoleguanidine.—Benzoxazoleguanidine was heated with an excess of methyl iodide under a reflux for four hours. Alcohol was added to form a clear solution and the heating was continued for three hours. The solution was cooled and poured into ether and a crystalline product precipitated; m. p. 192–194".

Anal. Subs. 0.5000, 0.5000: 15.64, 15.52 cc. of 0.1 N $AgNO_3$. Calcd.: I, 39.90. Found: I, 39.7, 39.4.

Microscopical Notes

Base (Monohydrate).—Recrystallized from hot water, by cooling, or from alcohol by dilution with water, the base gave thin, lath-shaped forms, single or in forked and curving clusters; ends jagged, or rarely oblique, with angles of about 70 or 56°; double refraction strong, with parallel extinction and positive elongation edgewise and flatwise. The index of refraction for vibrations crosswise of the crystals is 1.635; lengthwise of the crystals, 1.495. The axial plane is apparently parallel to the elongation.

Recrystallized from 95% alcohol by evaporation, the crystals are the same phase as above, for they may grow directly on them, with no optical discontinuity; six-sided plates, in coffin shapes or in obtuse-ended forms, are common, together with elongated trapezoidal plates. The angles and optical orientation of these crystals indicate that they are identical with those obtained by recrystallization from water, but with somewhat different "habit." Their plane of symmetry corresponds to the transverse plane of the long lath-shaped forms. The six-sided plates show symmetrical extinction flatwise and edgewise in one position. The other edge view exhibits oblique extinction, about 38°, and since the axial plane is inclined to the plane of the plates in a similar direction, the crystals may be assigned to the monoclinic system. The refractive index for vibrations crosswise of the coffin-shaped forms is 1.495; lengthwise, 1.635. The double refraction is probably positive. When heated dry, the crystals become opaque and melt. The melt supercools markedly but eventually crystallizes. Probably dehydration is not complete by melting without continued heating, since the crystals of the hydrate may grow into the melt.

Hydrochloride.—Recrystallized from hot water by cooling, lath-shaped forms, single or clustered, appear first; some show ends obliquely truncated (60°). Their double refraction is strong, with an extinction of about 25° to the long direction of the plates and nearly parallel to their oblique ends. The axial plane is nearly perpendicular to these end faces and corresponds to the lower refractive index (1.490) for this view of the crystals; the other refractive index is about 1.61. 2 V is large, $r < v$, and the crystals are probably negative. They probably belong to the triclinic system. As crystallization proceeds further, other more complex crystals make their appearance as rhomb-shaped plates, generally rounded, and often with the acute angles truncated. They are not single crystals, but are lamellar aggregates or twins. Their polarization colors are anomalous, and they do not extinguish but change hue when rotated between crossed nicols. Their interference figures are very distinctive and indicative of their composite nature; nearly straight dark bars appear alternately in the two 45° positions, but do not rotate.

Sulfate.—When recrystallized from hot water by cooling, the compound forms radiating clusters of strongly curving delicate plates, and opaque mossy rosets. Crystals formed more slowly are lath-shaped, but with poorly defined end faces. They show oblique extinction, the maximum angle being 25'. Their double refraction is strong, with only positive elongation observed.

Recrystallized from sulfuric acid (about 10%), trichiten rosets appear, and on further concentration, rhomb-shaped plates. Laminated growths are frequent. The trichiten rosets are probably identical with the phase described above, but the rhomb-shaped plates, separating from more concentrated acid, are probably the acid salt. By varying the acid concentration in the drop, either phase can be made to grow at the expense of the other. The acid sulfate crystallizes in tablets with obtusely pointed ends, the terminal angles being about 130'. Actually they are monoclinic prisms flattened in the direction of the C axis, the plane of symmetry being crosswise of the longer tablets and parallel to the acute diagonal of the shorter, rhomb-shaped ones. Multiple lamellar twinning in the basal plane is common but does not appear to alter the symmetry of the crystals as a whole. Birefringence is strong, positive, with 2 V large and $r < v$, or else inclined dispersion. Interference figures show only one of the optic axes, which lie in the plane of symmetry of the crystals with the acute bisectrix inclined to the basal plane of the tablets. The crystals may be assigned to the monoclinic system.

Nitrate.—It recrystallizes from hot water in sheaves and rosets of tiny rounded platelets, strongly birefringent.

Picrate.—Recrystallized from hot water, it gives fine thin blade-like and leafy crystals, strongly birefringent, pleochroic in two shades of yellow. The faces and angles are not well defined.

Summary

The reaction between o-aminophenol and dicyandiamide results in the formation of benzoxazoleguanidine. This reaction gives direct proof of the presence of the nitrile group in the dicyandiamide molecule. The properties of a number of derivatives of benzoxazoleguanidine are described.

THE SYNTHESIS OF THE ISOMERIC 2-BUTENES[1]

BY WILLIAM G. YOUNG,[2] ROBERT T. DILLON[2] AND HOWARD J. LUCAS[3]

RECEIVED APRIL 3, 1929 PUBLISHED AUGUST 7, 1929

Introduction

It was necessary to prepare the *cis* and *trans* forms of 2-butene in a pure condition before a satisfactory method of analysis involving the three normal butenes could be developed. The synthesis of 1-butene has already been reported.[4]

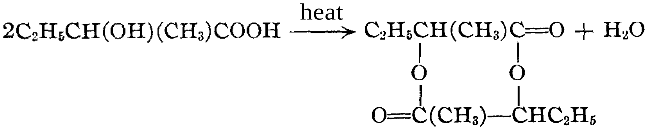
The preparation of the isomeric forms of 2-butene from the two naturally occurring a-methylcrotonic acids, *viz.*, angelic and tiglic acids, has been described by Wislicenus and his co-workers.[5] Since angelic acid is the less stable form, rearranging under the influence of heat or light to the more stable tiglic acid, it is desirable to use a synthetic method which produces as large a yield of angelic acid as possible. The thermal decomposition of a-methyl-a-hydroxybutyric acid[6] serves this purpose. In this work the desired hydrocarbons have been synthesized from methylethyl ketone by the reactions shown in Equations 1, 2, 3, 6 and 7.

$$CH_3CH_2COCH_3 + NaHSO_3 + NaCN \longrightarrow CH_3CH_2CH(OH)(CH_3)CN + Na_2SO_3 \quad (1)$$

$$CH_3CH_2CH(OH)(CH_3)CN + 2H_2O + HCl \longrightarrow CH_3CH_2CH(OH)(CH_3)COOH + NH_4Cl \quad (2)$$

$$CH_3CH_2CH(OH)(CH_3)COOH \xrightarrow{\text{heat}} \underset{\text{angelic acid, tiglic acid}}{CH_3CH{=}C(CH_3)COOH} + H_2O \quad (3)$$

$$CH_3CH_2CH(OH)(CH_3)COOH \xrightarrow{\text{heat}} CH_2{=}C(C_2H_5)COOH + H_2O \quad (4)$$



$$2C_2H_5CH(OH)(CH_3)COOH \xrightarrow{\text{heat}} \begin{array}{l} C_2H_5CH(CH_3)C{=}O \\ \qquad\qquad\;\; | \qquad\;\; | \\ \qquad\qquad\;\; O \qquad O \\ \qquad\qquad\;\; | \qquad\;\; | \\ \qquad O{=}C(CH_3){-}CHC_2H_5 \end{array} + H_2O \quad (5)$$

$$CH_3CH{=}C(CH_3)COOH + HI \longrightarrow CH_3CHICH(CH_3)COOH \quad (6)$$

$$CH_3CHICH(CH_3)COOH + Na_2CO_3 \longrightarrow CH_3CH{=}CHCH_3 + NaI + NaHCO_3 + CO_2 + H_2O \quad (7)$$

In agreement with Wislicenus and his co-workers we obtained the higher boiling isomer from angelic acid and the lower boiling from tiglic acid,

---

but the boiling points of our products were somewhat different, being +2.95–3.05° and +0.30–0.40° instead of +2.0–2.7° and +1.0–1.5°, respectively. These workers assigned the *cis* structure to the lower boiling and the *trans* structure to the higher boiling hydrocarbon, whereas Pfeiffer[7] claimed just the reverse. We prefer Pfeiffer's structures and have used them in this paper. We hope definitely to establish the structures by measuring the electric moments of the hydrocarbons and of their dibromides. With bromine at 0° the *cis* hydrocarbon yields a dibromide, b. p. 75.6–75.8° (corr.) at 50.0 mm., and the *trans* yields a dibromide, b. p. 72.7–72.9° (corr.) at 50-mm. pressure. Tentatively we have assumed that the higher boiling dibromide is the racemic and the lower boiling is the meso form, since the recent work of Terry and Eichelberger[8] indicates that when bromine adds to the olefin bond the addition is *trans*. Further confirmation is shown by the fact that in the reaction of these dibromides with potassium iodide in methanol the meso isomer has the higher reaction rate. This agrees with the observation of C. van Duin[9] who found that the meso-dibromosuccinic acid has a higher reaction rate with potassium iodide in 75% ethanol than the racemic.

General Discussion of the Method

In the cyanhydrin reaction (Equation 1) best results were obtained when the procedure usually employed for other compounds[10,11] was modified by using a minimum quantity of water, changing the order in which the chemicals were added and maintaining a temperature of 35° during the reaction. The hydrolysis of the cyanhydrin (Equation 2) should be carried out at temperatures below 90°, since the resulting acid sublimes rapidly at temperatures above 90".

It is absolutely essential to obtain the α-hydroxy-α-methylbutyric acid in a high degree of purity, since Blaise[6] has shown that when traces of hydrogen chloride are present in the hydroxy acid, the yield of angelic acid is very small. This is due to the catalytic effect of hydrogen chloride upon the rate with which angelic acid is converted into the more stable tiglic acid. In this work a very pure halogen-free product, having a melting point higher than any previously reported, was obtained by a single distillation at reduced pressure. This procedure is superior to the previous tedious method of crystallization from benzene, which must be followed by two weeks' desiccation over solid sodium hydroxide. The yields obtained by different procedures are shown in Table I.

[a] Method from "Systematic Organic Chemistry," ref. 10.
[b] Method from "Organic Syntheses," ref. 11.
[c] Method described in this paper.

In the decomposition of the hydroxy acid (Equations 3, 4 and 5) best results were obtained by removing the low-boiling decomposition products from the reaction flask as soon as they were formed. The purification of the resulting angelic and tiglic acids involves a separation from a-ethylacrylic acid, not previously reported as a product of this decomposition (Equation 4). The effect of temperature upon the rate with which angelic acid is converted into tiglic necessitates low-pressure distillations with small quantities of material. By a combination of fractional crystallization and fractional distillation at 12 mm. through a bead column 50 cm. long, angelic and tiglic acids were obtained in a high degree of purity with yields of 20% each. This corresponds to a 40% conversion of the hydroxy acid into the desired products, which is a 6% higher yield than that reported by Blaise.[6]

The reaction of hydrogen iodide[12] with tiglic acid in chloroform solution (Equation 6) proceeded satisfactorily, but the conversion of angelic acid into its hydriodide was difficult since the addition compound slowly isomerized into tiglic acid hydriodide. This change was markedly accelerated by iodine, which must not be present in the chloroform solution of hydrogen iodide. Even though the reaction flask was kept in the dark at 3° during the seven days required for the completion of the reaction, some iodine was formed. The addition of some molecular silver removed the iodine and led to higher yields of the angelic acid derivative. Great care was taken to obtain these two hydrogen iodide addition compounds in a high state of purity since contamination of either one with some of its isomer would result in a mixture of butenes instead of a pure substance.

The decomposition of the above iodo acids into the isomeric 2-butenes (Equation 7) was done in sodium carbonate solution.[5] After the materials were mixed at 5°, gas evolution took place in three distinct stages. As the temperature was slowly raised to 20–30°, carbon dioxide was evolved.

---

[12] Prepared by the method of Dillon and Young, THIS JOURNAL, 51, 2389 (1929).

This was removed from the gas stream by absorption in sodium hydroxide solution. Apparently little or no butene was formed during this first stage. At higher temperatures butene but no carbon dioxide was evolved. Finally, above 60°, the carbon dioxide resulting from the decomposition of the sodium bicarbonate swept the apparatus free from butene. The angelic acid derivative was the more stable, as shown by the fact that the second stage started at 30°, whereas the corresponding temperature was 20° for the tiglic acid compound. A rapid increase in temperature during the decomposition of the angelic acid hydriodide resulted in a yield of butene 20% higher than that previously reported. This result was anticipated since it was assumed that, of the two possible reactions, decomposition and hydrolysis, the former would have the greater temperature coefficient. The yields obtained at the different steps and the physical constants of the various products are shown in Table II.

Experimental

α-Hydroxy-α-methylbutyric Acid.—This acid was obtained through the cyanhydrin reaction from methylethyl ketone. Crude methylethyl ketone, b. p. 72–80", was distilled in a 90-cm. bead column and the fraction distilling at 78–80' was used. In a 3-necked, 3-liter flask equipped with a mechanical stirrer, a reflux condenser and a dropping funnel were placed 400 g. of cracked ice, 50 g. of water, 165 g. (3.2 moles) of 95% sodium cyanide and 216 g. (3.0 moles) of methylethyl ketone, b. p. 78–80'. While the solution was being vigorously stirred, 380 g. of sodium metabisulfite (equivalent to 4.0 moles of sodium bisulfite) in 480 g. of water was introduced from the dropping funnel during the course of ten to fifteen minutes. When all but about one-quarter of the solution had been added, the temperature had risen to 35°. A cooling bath of ice and water was then placed outside the flask and a temperature of 30–40° was maintained for ten minutes after the last of the bisulfite had been added. By this time the reaction was finished. The mixture was cooled to 0°, at which temperature the solubility of the cyanhydrin in the salt solution is negligible. The oily cyanhydrin was poured off from the mushy salt layer, 50–100 ml. of water was added to the latter and the additional oil which rose to the top on shaking was again poured off. The crude cyanhydrin, 320–330 g., was hydrolyzed by heating at 90–100° under a reflux cooler with 400 g. of C. P. concd. hydrochloric acid. It was not advisable to heat the solution above 100°, since considerable hydrogen chloride and a-hydroxy-a-methylbutyric acid was lost by volatilization. At the end of seven hours the reaction was usually complete. The solution was cooled to room temperature and without removal of the large amount of ammonium chloride, 100 g. of hydrated sodium sulfate was added. This effects a marked decrease in the concentration of the hydrochloric acid, which is largely converted into sodium hydrogen sulfate and sodium chloride. The solution was cooled to −15° and the mixture of salts was filtered off. The organic acid was not affected by this treatment since its ionization constant is weaker than the second ionization constant of sulfuric acid. Unless the greater part of the hydrochloric acid was removed, the mutual solubilities of this solution and ether were so large that a considerable amount of water and hydrochloric acid dissolved. However, by the procedure adopted a satisfactory extraction of the hydroxy acid by ether could be made. The ether solution was dried with anhydrous sodium sulfate, the ether was distilled off and the α-hydroxy-α-methylbutyric acid was purified by distillation at low pressures. The acid may also be purified by crystallization from petroleum ether at −15°, but this is a more laborious and less satisfactory process since some hydrogen chloride remains in the product. The yield by the distillation method was 64.5% and the material melted at 72.5° (corr.).[13] In Table 1 a comparison is made of the yields obtained by different methods.

Angelic and Tiglic Acids.—The decomposition of α-hydroxy-α-methylbutyric acid was accomplished by slowly heating approximately 100–125 g. in a 250-ml. round-bottomed distilling flask provided with a 75-mm. bead column in the neck. At a slow rate of heating the decomposition products came over at 150–190°, but if the heating was too rapid considerable hydroxy acid would distil over and the temperature would rise above 190°. It was therefore necessary to heat slowly for a period of one and one-half to three hours in order to allow the slow reaction of decomposition to take place. As soon as no more water distilled, the temperature was raised to 210°, the receiver was changed, and the temperature carried to 240°. A small amount of undecomposed hydroxy acid came over at 210–215°, and considerable lactide at 235–240°. The latter represents 20–25% of the original material. The first fraction, approximately 100 cc., consisted of two phases of approximately equal densities. A separation of the desired unsaturated acids from dissolved water and from the water phase was conveniently accomplished by adding 50 ml. of petroleum ether to 200 ml. of the first distillate (from two decomposition experiments). The petroleum ether solution was dried with anhydrous sodium sulfate and the solvent was distilled off. No attempt was made to isolate any methyl ethyl ketone present. The residue of unsaturated acids was fractionally distilled at 12 mm. through a 50-cm. bead column. The results of the first distillation, as shown in Table III, indicate that a satisfactory separation had been made. After a second distillation at 12-mm. pressure the two main fractions were cooled. Solid angelic and tiglic acids separated out from the respective fractions and were filtered off on a platinum cone from the mother liquor, which was again fractionated.

The angelic and tiglic acids were obtained in a high state of purity by this procedure. The constants are listed in Table II.

From the fraction boiling below angelic acid, a-ethylacrylic acid, m. p. −16°, has been isolated. This material, which has not previously been reported as a product of this decomposition, represents 11% of the original hydroxy acid.

---

[13] Boecking, *Ann.*, 104, 18 (1880), reported 66° and 68".

TABLE III

UNSATURATED ACIDS FROM DECOMPOSITION OF α-HYDROXY-α-METHYLBUTYRIC ACID; RESULT OF FIRST FRACTIONATION

Fraction	Material	B. p., °C. (corr.)	Press., mm.	Yield, %
1	α-Ethylacrylic acid	76.5–83°	12	11.0
2	α-Ethylacrylic acid and angelic acid	83–85	12	2.0

5	Tiglic acid	94–96	12	17.0
6	Same and α-hydroxy-α-methylbutyric acid	96–115	12	2.0

The Hydriodides of Angelic and Tiglic Acids.—The addition of hydrogen iodide to the unsaturated acids was carried out according to the general method of Talbot.[5] Since this operation requires careful manipulation, the details of which are not mentioned by Talbot, it is desirable that the procedure developed in carrying out this step be described in detail.

An anhydrous solution of hydrogen iodide (0.6–0.7 N) in chloroform was made by passing pure, anhydrous hydrogen iodide[12] into 700 ml. of dry chloroform contained in a 2-liter pyrex distilling flask provided with a ground-glass stopper carrying an inlet tube reaching nearly to the bottom. The chloroform was kept at −15° and the side arm, which constituted the outlet tube, was provided with a drying tube containing phosphorus pentoxide. The concentration of hydrogen iodide was determined at intervals by titrating 2.00-ml. portions against 0.115 *N* NaOH. As soon as the required amount of hydrogen iodide was in solution (53.7–57.7 g.), the unsaturated acid (27.0–29.0 g., dissolved in chloroform) and 1 g. of molecular silver were quickly added. The molal ratio of hydriodic acid to the organic acid should not be less than 1.5 to 1. The outlet tubes of the flask were sealed off in a flame and the ground-glass stopper was tied in and coated with sealing wax. The flask was placed in the dark in an ice box and kept at 3° for seven days. It was then cooled to −15°, the side arm opened, the inlet tube removed and a capillary tube inserted in its place. The flask was heated by a water-bath at 30° and the chloroform was distilled at 20-mm. pressure. Low-temperature distillation was desirable since the decomposition of hydriodic acid and the change of the angelic to the tiglic acid derivative must be kept at a minimum. The residue was extracted at 30–35° with the least possible amount of petroleum ether, b. p. 40–60°, filtered to remove silver iodide and the filtrate was cooled to −15°. The crystalline hydriodide obtained by this procedure was pure when tiglic acid was the starting material but was a mixture when angelic acid was used. In the latter case the mixture contained large quantities of the stable tiglic acid hydriodide. This impure product was extracted twice at room temperature with 5-ml. portions of the petroleum ether and then dissolved at 30–35° in 20 ml. of the solvent. This solution was cooled and three crops of crystals were removed as the cooling progressed. Pure angelic acid hydriodide, m. p. 57.5–58.5°, constituted the first two crops, but the third crop and likewise the material obtained from the crystallization of the 5-cc. extractions were mixtures, as shown by the melting range of 39–52'. Although a small amount of the pure angelic acid hydriodide can be obtained by working up this crude material, it is not practicable to do so.

The Isomeric 2-Butenes.—The butenes were generated in a 3-necked, 3-liter flask provided with a mechanical stirrer, a dropping funnel and an outlet tube. To the latter were attached in series a spiral washing bottle containing aqueous sodium hydroxide for removing carbon dioxide, a calcium chloride drying tube, a receiving tube surrounded by an ice–hydrochloric acid bath at −30 to −35°, a specially designed flask containing bromine for absorbing any uncondensed butene and a drying tube of calcium chloride.

The reaction flask was immersed in a vessel of ice water, **71.5** g. **(0.314** mole) of the angelic or tiglic acid hydriodide was placed in the flask and **26.6** g. **(0.25** mole) of sodium carbonate dissolved in **650** ml. of water at **5°** was rapidly added through the dropping funnel. The liquid was stirred and the temperature of the bath was slowly raised. **A** lively evolution of carbon dioxide took place at 10° in the case of the tiglic acid and at 15° in the case of the angelic acid derivative. The temperature of the bath was increased as fast as the absorber would take care of the carbon dioxide. This corresponds to a rate of **20** to 30° per hour until 45–50° was reached. At 20° the gas from the tiglic solution and at 30° that from the angelic solution began to pass the absorber, and soon afterward the evolved gas seemed to be nearly pure butene. The temperature was increased more rapidly above 45° since the gas evolution had dropped off. At **65–70°** the evolution of carbon dioxide was again rapid and swept the residual butene into the receiver. Practically complete condensation of the butene **was** accomplished since not more than 1 ml. of dibromobutane was recovered from the bromine absorption flask.

When these hydrocarbons were separately distilled in the apparatus especially designed for this purpose, each distilled completely over a temperature range of 0.1°, as shown in Table II.

The Isomeric 2,3-Dibromobutanes.—These were prepared by slowly distilling the pure butenes into an all-glass reaction flask kept at −15° and adding from time to time small amounts of bromine. After the formation of the first quantity of dibromide the butene was always kept slightly in excess in order to avoid the formation of tribromides. At the end of the reaction, a slight excess of bromine was added to remove the last traces of butene. The products were immediately washed with dilute sodium bisulfite solution, sodium bicarbonate solution and water and were then dried with anhydrous calcium chloride. They were fractionally distilled at 50-mm. pressure in order to avoid the isomeric change which Faworsky[14] noted at more elevated temperatures. The small distillation range of each of the dibromides (Table II) indicates that a single substance and not a mixture of isomers is formed in each case.

Summary

Starting with methyl ethyl ketone, the cis- and trans-2-butenes have been synthesized in a high state of purity.

Necessary details are given for the preparation and purification of the following intermediate compounds: α-hydroxy-α-methylbutyric acid, angelic acid, tiglic acid, angelic acid hydriodide, tiglic acid hydriodide, the isomeric 2-butenes and the corresponding dibromobutanes.

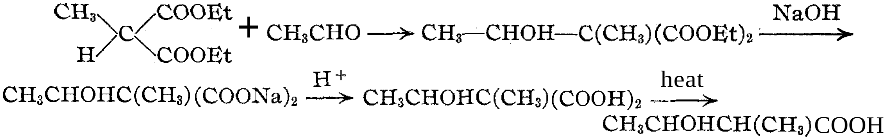
THE CONDENSATION OF ACETALDEHYDE WITH METHYLMALONIC ESTER. METHYLATIONS WITH METHYL BROMIDE

BY HOWARD J. LUCAS AND WILLIAM G. YOUNG[1]

RECEIVED APRIL 3, 1929 PUBLISHED AUGUST 7, 1929

In developing a method for synthesizing the isomeric 2-butenes, it was thought that the decomposition of β-hydroxy-α-methylbutyric acid might give a yield of the unsaturated angelic and tiglic acids higher than that which was obtained by the decomposition of or-hydroxy-a-methylbutyric acid. The attempt was therefore made to synthesize the β-hydroxy acid from methylmalonic ester through the following steps



$$(CH_3)(H)C(COOEt)_2 + CH_3CHO \longrightarrow CH_3\text{—}CHOH\text{—}C(CH_3)(COOEt)_2 \xrightarrow{NaOH}$$

$$CH_3CHOHC(CH_3)(COONa)_2 \xrightarrow{H^+} CH_3CHOHC(CH_3)(COOH)_2 \xrightarrow{heat} CH_3CHOHCH(CH_3)COOH$$

It soon became evident that the method was less satisfactory than the one finally adopted,[2] in which the a-hydroxy acid was obtained from methylethyl ketone.

It is the purpose of this paper to describe the synthesis of the diethyl ester of 3-hydroxybutane-2,2-dicarboxylic acid by the condensation of acetaldehyde with methylmalonic ester.

Discussion

The use of methyl iodide for the quantity production of methylmalonic ester is an expensive procedure. We have found methyl bromide to be a satisfactory methylating agent with both malonic ester and acetoacetic ester. From the standpoint of cost it possesses a distinct advantage over methyl iodide, and for one who must prepare his own reagent in quantity it possesses in addition the decided superiority of greater convenience, since the bromide can be prepared, purified and used in one operation. The yields obtained are, in the case of malonic ester, as satisfactory as any described in the literature and in the case of acetoacetic ester are somewhat better.

The condensation of acetaldehyde with methylmalonic ester was carried out by heating the reactants with acetic anhydride for fifty hours in sealed tubes at 104°. This reaction is undoubtedly similar to the one between acetaldehyde and malonic ester[3] in which ethylidene malonic

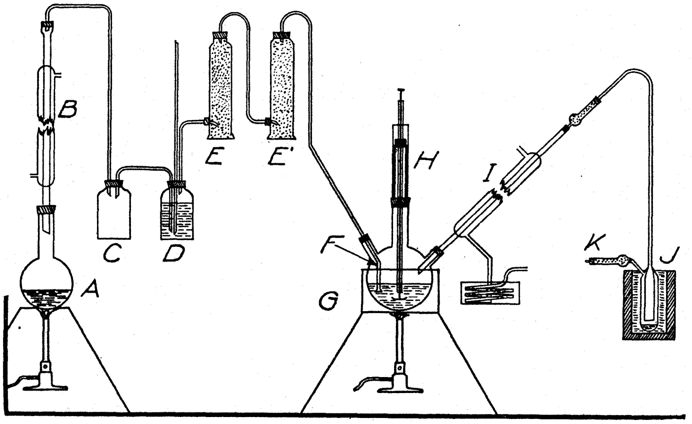
ester is produced by the loss of water, involving the α-hydrogen atom. The condensation product from methylmalonic ester does not contain an a-hydrogen atom and thus an ethylidene derivative is not produced. However, a small amount of unsaturated ester results from the loss of water, involving a γ-hydrogen atom.

The condensation mixture was fractionally distilled at reduced pressure. Molecular weight determinations on the various higher fractions by the micro-method of Smith and Young[4] made it possible to tell which fractions contained the desired hydroxy ester. This procedure is a valuable aid in determining the approximate composition of various fractions.

Experimental

Methyl Bromide as a Methylating Agent.—The methyl bromide, generated in a 2-liter flask, *A* (see figure), from 215 g. (6.7 moles) of methanol, 266 g. (2.6 moles) of sodium bromide, 695 g. (7.0 moles) of 95% sulfuric acid and 230 g. of water according to the directions of Bygden,[5] was purified by passing it through concentrated sodium hydroxide, D, soda lime, *E*, calcium chloride, E', and led through the large tube *F*, flared at the lower end to a diameter of 22 mm., into the three-necked, 3-liter flask, *G*. This contained a solution of sodium malonic ester prepared from 350 cc. of absolute ethanol, 25 g. (1.1 moles) of metallic sodium and 160 g. (1.0 mole) of malonic ester (Eastman). The **flask** *G* was surrounded by a water-bath at 80–85° and the solution was agitated with a mechanical stirrer, H. **A reflux** cooler, **I**, condensed the alcohol



A, methyl bromide generating flask, 2-liter; B, reflux cooler; C, safety bottle; D, concentrated sodium hydroxide; E, soda lime tower; E', calcium chloride tower; *F*, flared inlet tube; G, flask, 3-liter, containing sodium malonic ester in ethanol; *H*, mechanical stirrer (mercury seal); **I**, reflux cooler; *J*, tube at −15°; K, calcium chloride tube.

vapor, and any unreacted methyl bromide was condensed in the tube *J*, kept at −30° by an ice–hydrochloric acid mixture and provided with a calcium chloride tube, K. The generation of the methyl bromide was regulated by the rate of heating of the flask *A* and was made as fast as was consistent with effective purification. Soon after the gas flow was started sodium bromide precipitated in the reaction mixture and during an hour and one-half no trace of methyl bromide condensed in the tube J. Shortly after this a liquid began to collect in *J*. The reaction mixture was then tested with litmus and found to be neutral. The alcohol was distilled by heating the flask in an oil-bath at 125–130°, the least quantity of water was added for dissolving the salt, the resulting oil layer separated and the aqueous phase was extracted three times with 50 cc. of ether. The ether extracts and the crude ester were combined and dried overnight with anhydrous sodium sulfate. The ether was removed from the dried solution by heating over a water-bath at 50–80°, and the residue of crude methyl malonic ester was fractionally distilled through a 30-cm. bead column at reduced pressure, the main fraction boiling at 113.5–114° at 4648 mm. The yield was 80%. Since the boiling points of malonic, methylmalonic and dimethylmalonic esters lie within three and one-half degrees of each other,[6] the purity of the product obtained by the procedure outlined could not be told by its boiling range. Nevertheless, it was largely the desired methylmalonic ester, as shown by conversion to the free acid and decomposition of this to the monobasic acid. Now the melting point of 125.5–126.5° obtained for the dibasic acid does not distinguish between malonic and methylmalonic acids,[7] but the boiling point of the monobasic acid, 140–141°, indicated that the latter was largely propionic acid. The absence of acetic acid in this product, and therefore of malonic ester in the methylated ester, was likewise indicated by the successive values of 14.0 and 12.5 obtained for the Duclaux numbers.[8] These values were a trifle high for propionic acid, indicating the presence of a small quantity of isobutyric acid.

The methylmalonic ester prepared above had properties identical with the product obtained when methyl iodide was used, following the method of Conrad.[9] The melting points of the methylmalonic acids and the Duclaux numbers of the monobasic acids obtained by both methods were identical. It is thus evident that methyl iodide may be replaced by methyl bromide in a malonic ester synthesis.

Methyl bromide was likewise used in the synthesis of methylacetoacetic ester with satisfactory results. The product, obtained in 83% yields, was identical with that obtained by the use of methyl iodide.

Diethyl Ester of 3-Hydroxybutane-2,2-dicarboxylic Acid.—A mixture of 40 g. (0.23 mole) of methylmalonic ester, 47.0 g. (0.46 mole) of acetic anhydride and 21.0 g. (0.48 mole) of acetaldehyde (freshly prepared by the depolymerization of paraldehyde) was divided into portions of 35 cc. each, sealed in tubes and heated at 140° for fifty hours. The tubes were opened and the combined reaction mixture was fractionally distilled at reduced pressure. The fractions obtained are shown in Table I.

By running molecular weight determinations on several of the higher fractions by the camphor method of Smith and Young,[4] it was possible to identify the fractions containing the desired hydroxy ester, which has a molecular weight of 218. Two more fractionations of distillates 5, 6, 7 and 8 gave a fraction boiling at 94–98' at 2 mm. This material, after washing with sodium carbonate solution, distilled at 100–106° under 3–5 mm. pressure and weighed 17 g. The yield was 63%, based on the methylmalonic ester

reacted. The results of molecular weight determinations by the camphor method on this purified product were 215 and 221 (theoretical, 218). The density, d^{21}_{4} was 1.0732.

Anal. Subs., 0.2180, 0.2101: H_2O, 0.1510, 0.1467; CO_2, 0.4405, 0.4247. Calcd. for $C_{10}H_{18}O_5$: H, 8.31; C, 55.0. Found: H, 7.76, 7.81; C, 55.1, 55.1.

Attempts to saponify the ester with alcoholic potassium hydroxide gave a reddish brown precipitate of high molecular weight. We were unsuccessful in obtaining a derivative with acid chlorides, the reaction yielding instead an unsaturated compound, probably the unsaturated ester. Apparently with acid chlorides water is eliminated very easily as might be expected from derivatives of β-hydroxy esters, although with acetic anhydride at 104°, a condition prevailing in the condensation reaction, dehydration was not an important factor, for the fraction of unsaturated ester did not exceed 10%. The presence of the hydroxyl group was demonstrated, since on addition of sodium hydrogen was evolved and a solid was formed. In order to establish completely the identity of the diethyl ester of 3-hydroxybutane-2,2-dicarboxylic acid, it was converted into the diamide.

Diamide of 3-Hydroxybutane-2,2-dicarboxylic Acid.—When 7.0 g. of the hydroxy ester was shaken with concentrated ammonium hydroxide the oil slowly went into solution during the course of eight days. From the aqueous solution evaporation yielded a white solid, readily soluble in water and sparingly soluble in absolute alcohol. Recrystallization from hot absolute alcohol gave 3 g. of pure white prisms melting at 209.5° (corr.) with decomposition. From 0.1042 g. there was obtained 16.40 cc. of nitrogen by the Dumas method, corresponding to 17.82%, whereas the theoretical value calculated from $C_6H_{12}O_3N_2$ is 17.48%.

The authors are indebted to Mr. R. T. Dillon for the analysis of the diamide.

Summary

Methyl bromide may satisfactorily replace methyl iodide in the preparation of the methyl derivatives of malonic ester and acetoacetic ester.

Acetaldehyde in the presence of acetic anhydride condenses with the ethyl ester of methylmalonic acid to produce the diethyl ester of 3-hydroxybutane-2,2-dicarboxylic acid.

DERIVATIVES OF 2,5-DIBROMONITROBENZENE

BY L. CHAS. RAIFORD AND B. C. BREN

RECEIVED APRIL 8, 1929 PUBLISHED AUGUST 7, 1929

Of the dibromonitrobenzenes, the 2,5-isomeride[1] has been studied but little. Three derivatives were found on record, and of these only one was a reduction product, *viz.*, the aniline, which was prepared in the usual way.[2] The present report includes observations on the aniline and on products obtainable by reduction in alkaline mixtures.

Of the products theoretically possible by alkaline reduction the azoxy and azo compounds were obtained in small yields. Attempts to prepare the hydrazo compound and the isomeric benzidine by starting with the nitro compound were unsuccessful. When the azo compound was subjected to the action of stannous chloride and hydrochloric acid, as directed by Jacobson,[3] with the hope of converting it to the hydrazo compound and rearranging the latter to the benzidine, a yield of 42% of 2,5-dibromo-aniline was obtained and nothing else could be isolated from the mixture.

Following the directions of Knoevenagel,[4] 2,5-dibromo-aniline was diazotized with amyl nitrite and converted into a nearly colorless diazonium salt that decomposed explosively above 117°. Boiling this salt with water gave no phenol, but reduction of its alcoholic solution with stannous chloride and hydrochloric acid gave 2,5-dibromo-aniline and 59% of the ammonia required by the equation.[5] The diazonium salt readily reacts with

$$C_6H_3Br_2N_2X + 6(H) \longrightarrow C_6H_3Br_2NH_2 + NH_4X$$

the aniline, when the experiment is conducted by Noelting and Kopp's[6] method, to give a nearly quantitative yield of the diazoamino compound, which latter could not be rearranged to the aminoazo body. Reduction of this product with stannous chloride and hydrochloric acid gave 2,5-

---

[1] Many derivatives of the 2,5-dichloro compound have been prepared by Noelting and Kopp [*Ber.*, 38, 3506 (1905)] and by Crowell and Raiford [THIS JOURNAL, 42, 145 (1920)].

[2] Meyer and Stuber [*Ann.*, 165, 180 (1873)] obtained the aniline by reduction of the nitro compound with tin and hydrochloric acid, but recorded no yield. Meldola and Andrews [*Proc. Chem. Soc.*, 11, 110 (1895)] could not reduce with zinc dust and acetic acid, and found that the alcoholic solution must be boiled with tin and hydrochloric acid to give satisfactory results.

[3] Jacobson, *Ann.*, 287, 147 (1895).

[4] Knoevenagel, *Ber.*, 23, 2995 (1890).

[5] Fischer [*Ann.*, 190, 78 (1878)] found that the diazonium salt from aniline is reduced by sodium sulfite to phenylhydrazine, while Meyer and Lecco [*Ber.*, 16, 2976 (1883)] obtained the same results with stannous chloride and hydrochloric acid.

[6] Noelting and Kopp, *Ber.*, 38, 3507 (1905).

dibromo-aniline and ammonia.' With β-naphthol the diazonium salt coupled to give an azo dye.

Derivatives of 2-Nitro-4-bromo-anisole.—This ether," obtained here from the dibromonitrobenzene by Blom's[9] method, was converted to the corresponding azoxy compound in four different experiments. The methyl alcoholic solution was reduced (1) with metallic sodium as directed by Starke;[10] (2) with sodium amalgam by Kanonnikow's[11] method; (3) by Brand's[12] electrolytic method and (4) by treatment with aqueous sodium hydroxide and zinc dust at 45° or below. The corresponding azo compound was obtained by (1) reduction of the azoxy derivative with sodium amalgam at 70°; (2) by reduction of the nitroanisole with sodium amalgam at 70°; (3) by electrolytic reduction of the nitro compound as directed by Elbs and Kopp,[13] and (4) by treatment of the alcoholic solution of the nitro compound with zinc dust and alkali, as recommended by Starke for reduction of o-nitro-anisole. Continued treatment with excess of zinc gave a small yield of what appeared to be the hydrazo compound.[14] This product was converted to the benzidine by the usual treatment with hydrochloric acid, while an attempt to benzoylate it caused rearrangement and the formation of the dibenzoylbenzidine.[15] The benzidine was further characterized by diazotization and coupling the product with β-naphthol to give an azo dye.

2-Nitro-4-bromophenetole obtained by Blom's method was converted into the azo compound by the various methods described above for the anisole. Attempts to reduce further with stannous chloride and hydrochloric acid did'not give the hydrazo compound and the expected diphenetidine, but 4-bromo-o-phenetidine. However, the hydrazo compound was obtained in small yield directly from the nitro compound, by the method used with the anisole. It was readily oxidized to the azo compound as explained above.

Experimental Part

The 2,5-dibromonitrobenzene used as starting material in this work was obtained by nitration of p-dibromobenzene, as outlined by Crowell and Raiford[16] for the chlorine compound. The derivatives were prepared by the standard methods indicated, the details of which will be omitted. The physical constants and analytical data for these products are shown in Tables IA and IB.

Summary

1. 2,5-Dibromo-aniline has been converted into a diazonium salt that did not give a phenol when boiled with water, but which coupled with β-

---

[7] Fischer [*Ann.*, 190, 78 (1878)] found that the unsubstituted compound gave aniline and phenylhydrazine.

[a] A product which appeared to have this composition was reported by Meldola and Andrews, Proc. Chem. *Soc.*, 11, 110 (1895). to melt at 234–235°.

[b] Analytical data were not satisfactory.

naphthol to give an azo dye. It coupled with aniline to give a diazo-amino compound, but the latter could not be rearranged into the isomeric aminoazo compound. Treatment of the diazonium salt with stannous chloride and hydrochloric acid did not give the expected hydrazine, but regenerated the amine and split off ammonia.

2. Of the reduction products expected in alkaline mixtures, only the azoxy and the azo compounds were obtained.

3. The monobromo-anisole and phenetole prepared from the dibromonitrobenzene gave, in addition, the respective hydrazo compounds.

IOWA CITY, IOWA

BETA-PHENYLISOBUTYLMETHYL KETONE AND ITS DERIVATIVES. THE SYNTHESIS OF ALPHA- AND OF BETA-PHENYLISOVALERIANIC ACIDS

BY ALFRED HOFFMAN

RECEIVED APRIL 12, 1929 PUBLISHED AUGUST 7, 1929

When mesityl oxide is added to benzene in the presence of anhydrous aluminum chloride, condensation takes place with the formation of a ketone $C_{12}H_{16}O$. It is likely that the hydrogen chloride addition product of mesityl oxide is formed first and then reacts with the aluminum chloride setting free hydrogen chloride. Thus a trace of hydrogen chloride catalyzes the reaction and an evolution of the free gas takes place only at the very end.

The presence of the carbonyl group in the new substance is shown by the formation of the oxime and the semicarbazone. If the latter, which is formed quantitatively, is fractionally crystallized, all fractions have the same melting point, showing that the ketone is a single substance and not a mixture of isomers.

As a methyl ketone it is easily oxidized by sodium hypobromite solution with the formation of a phenylisovalerianic acid which is identical with the one prepared by Eijkman[1] by the action of benzene on β,β-dimethylacrylic acid in the presence of aluminum chloride and characterized by a nitro derivative melting at 175°. In order to decide between the alpha and the beta forms of the acid, Eijkman treated his substance with benzaldehyde under the most varied conditions. As he failed to obtain any indication of a condensation, he inferred that there was no methylene group adjacent to the carboxyl group and that therefore his acid was the alpha form. This is not what might be expected in the present case. The chlorine of the addition product of mesityl oxide and hydrogen chloride has for good reasons been considered attached to the tertiary carbon atom, so that after replacement with phenyl and oxidation, β-phenylisovalerianic acid should be obtained. In order to decide the question, both alpha and beta acids were prepared by the malonic ester method. The results, as shown in the experimental part, give conclusive proof that the acid obtained from the ketone, and therefore also Eijkman's acid, is the beta form and that the reactions were as follows

$$(CH_3)_2C{=}CHCOCH_3 \longrightarrow (CH_3)_2CClCH_2COCH_3 \longrightarrow (CH_3)_2C(C_6H_5)CH_2COCH_3 \longrightarrow (CH_3)_2C(C_6H_5)CH_2COOH$$

β-Phenyl*iso*butyl methyl ketone does not react with sodium bisulfite. With a mixture of nitric and sulfuric acids it gives a nitro compound, which is soluble in sodium carbonate solution with a blood-red color. It is likely that this compound, which was not isolated in a pure state, contains a nitro group attached to an aliphatic carbon atom. Treated with

---

[1] Eijkman, *Chem. Centr.*, **II**, 1100 (1908).

an excess of bromine in acetic acid, the ketone gives a crystalline tetrabromo derivative.

Of interest is the action of the ketone on heating with anhydrous zinc chloride. A mixture of hydrocarbons is obtained from which it is possible to isolate in fairly good yield a well-crystallizing substance melting at 130.5–131°. According to boiling point, molecular weight determination and analysis its formula is $C_{24}H_{28}$. It is therefore formed from two molecules of water. The hydrocarbon does not react with bromine in chloroform solution, even on heating or with the addition of iron powder or iodine. Boiled with concentrated nitric acid it gives a trinitro derivative, which is not soluble in sodium carbonate solution. Toward oxidizing agents the hydrocarbon is very resistant. Thus boiling with dilute nitric acid is without effect. Chromic acid in glacial acetic acid solution does not act in the cold; on boiling the solution slowly turns green. Most of the hydrocarbon remains intact; the rest seems to be completely oxidized, as no products such as benzoic acid or ketones could be isolated. Permanganate in moist acetone solution is not decolorized in the cold.

Boiling with aqueous permanganate for 142 hours gave but a small amount of manganese dioxide. The hydrocarbon was likewise unaffected by grinding with manganese dioxide and 50% sulfuric acid at 50°. According to these results about all that can be said as to the constitution of the hydrocarbon is that it is a very stable, saturated substance, probably of a cyclic nature.

The ketone may be reduced in the usual way with sodium and alcohol to form the corresponding alcohol, β-phenyl*iso*butylmethylcarbinol.

On treatment with zinc chloride, this alcohol loses a molecule of water, giving the hydrocarbon $C_{12}H_{16}$. The latter is unsaturated and easily oxidized in contact with air. Attempts to purify such material by distillation over sodium resulted in the loss of most of it by polymerization. It probably has the structure $(CH_3)_2C(C_6H_5)CH{=}CHCH_3$. Attempts to prove this by means of the oxidation products with chromic acid were not successful. A complicated mixture of ketones was obtained which was separated into fractions; these were converted into semicarbazones and recrystallized. Acetophenone was identified by mixed melting point; phenylacetone and propiophenone were absent. A special search was made for α-phenyl*iso*butyraldehyde in the fraction boiling around 110° (14 mm.). This fraction, however, did not reduce ammoniacal silver solution, nor could a high-melting semicarbazone be obtained.

Experimental Part

Preparation of β-Phenyl*iso*butyl Methyl Ketone.—Ninety grams of anhydrous aluminum chloride in granular form together with 200 cc of benzene is placed in a 500-cc. wide-mouthed Erlenmeyer flask. The latter is provided with a short vent-tube and a stirrer and cooled with water. Fifty grams of mesityl oxide is dropped in during an hour with thorough stirring, which is then continued for three hours longer. The mixture is poured on ice and the water separated. The oil is washed with water, filtered, poured into sodium carbonate solution and steam distilled to remove the excess benzene. The ketone itself is but slightly volatile with steam. After cooling, the oil is separated, dried over calcium chloride and distilled under diminished pressure; yield, **72** g.; calcd., **89** g. The product boils at 124° **(14 mm.)** and is pure enough for preparative purposes. It contains, however, a trace of halogen and discolors after standing for some time. In order to purify it, the semicarbazone is prepared, recrystallized and steam distilled with a large excess of phthalic anhydride. The ketone thus obtained is a water-white, highly refractive liquid which remains colorless indefinitely. The odor is somewhat like that of camphor, with a suggestion of roses; b. p. **134" (22** mm.); 252° corr. **(760 mm.)**; sp. gr. 25°/25°, **0.972.**

Anal. Calcd. for $C_{12}H_{16}O$: **C, 81.8; H, 9.09.** Found: C, **81.5;** H, **9.00.**

Preparation of the Semicarbarone.—Twenty-five grams of ketone was added to a concentrated aqueous solution of **17** g. of semicarbazide hydrochloride and **22** g. of crystallized sodium acetate with the addition of enough methyl alcohol to render the mixture homogeneous. After standing for twenty-four hours the product was recrystallized from methyl alcohol; yield, **31** g.; m. p., **163–164".**

Anal. Calcd. for $C_{13}H_{19}ON_3$: N, **18.03.** Found: N, **18.33.**

Preparation of the Oxime.—Ten and seven-tenths grams of ketone was treated with an aqueous solution of **4.5 g.** of hydroxylamine hydrochloride, **5.4 g.** of sodium bicarbonate and enough methyl alcohol to render it homogeneous. After standing for several hours at 50°, the product was poured into water, extracted with ether and distilled under diminished pressure; yield, **9.3** g.; b. p. 181° **(27 mm.)**; m. p. 52–54° (not recrystallized).

Anal. Calcd. for $C_{12}H_{17}ON$: N, **7.33.** Found: **N,** ***7.7.***

Preparation of the Tetrabromo Ketone.—The ketone reacts with bromine with explosive violence and therefore a diluent is necessary; **8.8** g. of ketone in **20** cc. of glacial acetic acid is gradually treated with **35** g. of bromine. After standing for a day, water is added, the red oil taken up with ether and washed with sodium bisulfite solution to remove excess bromine. The ether is evaporated and the residue recrystallized from methyl alcohol; it gives a crystalline, white powder; m. p. 96–98°.

And. Calcd. for $C_{12}H_{12}OBr_4$: Br, **65.0.** Found: Br, **64.9.**

Preparation of the Hydrocarbon, $C_{24}H_{28}$.—Sixteen and seven-tenths grams of ketone and **12** g. of anhydrous zinc chloride were heated in a small Erlenmeyer flask on a gauze over a free flame. The zinc chloride slowly dissolved and the mixture turned a vivid carmine. At about 180° a lively reaction took place and the liquid divided into two layers. On cooling, both layers solidified. The upper, white crystalline layer was dissolved in petroleum ether and distilled under diminished pressure. The use of an Anschiitz flask is advisable for this as the distillate has a tendency to solidify and clog up the side-neck. The fraction boiling from 150–230° **(18** mm.) **(8.6** g.) was pressed out between filter paper and recrystallized from petroleum ether; b. p. **195" (18** mm.); **m.** p. 130.5–131° corr. The material crystallized well in flat, white needles or plates.

Anal. Calcd. for $C_{24}H_{28}$: C, **91.1;** H, 8.9. Found: **C, 90.8;** H, **8.8.** *Mol. wt.* 0.021 **g.** of subs. in **0.132** g. of camphor gave 20° depression of melting point. Calcd. for $C_{24}H_{28}$: mol. wt., **316. Found: 318.**

Preparation of Trinitrohydrocarbon.—Two grams of hydrocarbon was refluxed with **30 cc.** of nitric acid **(1.42)** for nine hours. The oil finally dissolved without noticeable reaction but separated again on cooling. It was washed with water and recrystallized from much methyl alcohol; yield, **0.3** g. as fine white needles; m. p. 180–184°.

Anal. Calcd. for $C_{24}H_{25}(NO_2)_3$: N, 9.3. Found: N, 9.03.

Reduction of Ketone.—Ten grams of ketone was refluxed with 100 cc. of absolute alcohol in a one-liter flask and 20 g. of sodium was added rapidly through the condenser. After the reaction had quieted, 50 cc. more alcohol was added to dissolve the excess sodium. Then 68 cc. of water was added and the ethyl alcohol distilled off in an oil-bath. Water was added to the residue, the carbinol extracted with ether and distilled under diminished pressure; yield, 9.2 g.; b. p. 132–133° (17 mm.), sp. *gr.* 25°/25°, 0.960. It has little odor.

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.89; H, 10.1. Found: C, 80.32; H, 9.9.

Dehydration of the **Carbinol.**—Seventeen and seven-tenths grams of the alcohol was heated with 14.5 g. of anhydrous zinc chloride over a free flame for one and one-half hours. After a slight reaction the mixture separated into two layers. After cooling, the upper layer was poured off and distilled; yield, 14.2 g.; b. p. 96–98° (17 mm.); sp. gr. 25°/25°, 0.889.

Anal. Calcd. for $C_{12}H_{16}$: C, 90.0; H, 10.0. Found: C, 88.1; H, 9.73.

The product was evidently not quite pure; it reacted instantly with bromine in chloroform. On oxidation with chromic acid in acetic acid solution, a complicated mixture was obtained boiling from 90° (18 mm.) to 150° (24 mm.). On recrystallizing the semicarbazones of the various fractions the only one identified was a small fraction of m. p. 186–189°. Mixed with acetophenone semicarbazone it melted at 187–189°.

Oxidation of the Ketone to **β-Phenylisovalerianic** Acid.—Seventeen and six-tenths grams of ketone was shaken with sodium hypobromite solution prepared from 24 g. of sodium hydroxide, 48 g. of bromine and 100 g. of ice and water. The mixture became warm after about five hours and at the end of 20 hours the reaction was complete. After separating the bromoform and filtering, the aqueous solution was acidified with dilute sulfuric acid with the addition of a little sodium bisulfite. An oil separated which solidified on standing. It was pressed out between filter paper to remove oily impurities and recrystallized from petroleum ether; yield, 11.2 g.; m. p., 58–58.5°.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.1; H, 7.86. Found: C, 73.9; H, 7.9.

The nitro derivative, prepared by heating with 75% nitric acid, melts at 169–172°.

The methyl ester boils 120° (11 mm.); 123° (12 mm.).

The anilide was prepared as follows for the purpose of further comparison with the synthetic α- and β-acids: 1.5 g. of acid and 2.3 g. of aniline were heated for nine hours in a small distilling flask in a graphite bath so that water and aniline slowly distilled off. The product was dissolved in ether, shaking out with dilute sulfuric acid and with sodium carbonate solution, the ether removed and the residue recrystallized from 60% methyl alcohol with the use of bone black; m. p., 122–123°.

Anal. Calcd. for $C_{17}H_{19}ON$: C, 80.6; H, 7.5. Found: C, 80.5; H, 7.2.

α-Phenylisovalerianic Acid.—The ethyl ester of phenylacetic acid was condensed with ethyl oxalate by means of alcohol-free sodium ethylate to form phenyloxalacetic ester. This, on heating, lost carbon monoxide, giving phenylmalonic ester. This method[2] is not very satisfactory, so it is welcome that a new method has recently appeared.[3] As found by Nelson and Cretcher in a similar case, the alkylation of phenylmalonic ester does not work well, much phenylacetic ester being formed. Eighteen and nine-tenths grams of phenylmalonic ester was added to a solution of 1.85 g. of sodium in 35 cc. of absolute alcohol and 25 g. of *iso*propyl iodide run in.

$$NaC(C_6H_5)(COOC_2H_5)_2 + (CH_3)_2CHI \longrightarrow (CH_3)_2CHC(C_6H_5)(COOC_2H_5)_2 \longrightarrow (CH_3)_2CHCH(C_6H_5)COOH$$

The solution remained clear until heated and then slowly became cloudy. After boiling for fourteen hours it had become neutral. The alcohol was distilled off, water added, the product extracted with ether and distilled; yield, 12.3 g.; b. p., 165–190° (31 mm.). According to analysis it was a mixture of about one part of phenylacetic ester with three parts of *iso*propylphenylmalonic ester. Boiled with a solution of 16 g. of potassium hydroxide in 68 cc. of water it dissolved completely in about ninety hours. Alcoholic potassium hydroxide or more concentrated aqueous solutions did not work as well. The acid was liberated by adding dilute sulfuric acid and extracting with ether. Yield: 5.4 g.; b. p., 165–168° (25 mm.). As little gas was given off during the distillation, one molecule of carbon dioxide had been split off during the long boiling. Pickard and Yates[4] found the same in the case of phenylallylmalonic ester. In order to remove the phenylacetic acid present, the acid was boiled with water and barium carbonate, the aqueous solution of the very soluble barium salts filtered and treated with silver nitrate solution. The granular precipitate of silver salts was thoroughly washed with water to remove the fairly soluble silver phenylacetate. The salt of α-phenylisovalerianic acid is only slightly soluble.

Anal. Calcd. for $C_{11}H_{13}O_2Ag$: Ag, 37.9. Pound: Ag, 38.1.

To obtain the free acid, 9.7 g. of silver salt was shaken with ether and 5 g. of nitric acid in 100 cc. of water; yield, 5.1 g.; b. p., 159–160° (14 mm.); m. p., 60°. The odor is similar to that of phenylacetic acid but more disagreeable and clinging. The acid prepared from the ketone as well as the synthetic β-acid does not have a pronounced odor.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.1; H, 7.86. Found: C, 74 1; H, 7 89.

It was not found possible to obtain a solid nitro compound by heating with 75% nitric acid.

The anilide melted at 132–133°.

Anal. Calcd. for $C_{17}H_{19}ON$: C, 80.6; H, 7.5; N, 5.53. Found: C, 81.1; H, 7.7; N, 5.8.

$$C_6H_5C(CH_3)_2Cl + NaCH(COOC_2H_5)_2 \rightarrow C_6H_5C(CH_3)_2CH(COOC_2H_5)_2 \longrightarrow C_6H_5C(CH_3)_2CH_2COOH$$

β-Phenylisovalerianic Acid.—Dimethylphenylcarbinol was prepared by the action of methylmagnesium iodide on acetophenone and the hydroxyl substituted with chlorine by saturating with dry hydrogen chloride at 0°.[5] These reactions worked smoothly. The crude chloride prepared in this manner from 18.6 g. of the carbinol was poured on ice, extracted with ether, washed with sodium bicarbonate solution and dried carefully with anhydrous sodium sulfate. The ethereal solution was then added to a solution of 3.2 g. of sodium and 22 g. of ethyl malonate in 35 g. of absolute alcohol. The clear mixture gradually became cloudy and after twelve hours contained considerable precipitate. It was still slightly alkaline but became neutral after the ether and part of the alcohol had been distilled off. Water was added and the product extracted with ether. On distilling almost all came over up to 119°, 17 mm. Evidently the chief reaction is

$$C_6H_5CCl(CH_3)_2 + NaCH(COOC_2H_5)_2 \longrightarrow C_6H_5C(CH_3){=}CH_2 + H_2C(COOC_2H_5)_2 + NaCl$$

A small residue boiled at 150–180° (13 mm.); yield, 4.3 g. Without further purification it was boiled with 7.5 g. of potassium hydroxide in 14 cc, of water. The oil dissolved in two hours, with the exception of a few drops having a strong odor; these were distilled off with steam. The liquid was acidified with sulfuric acid and extracted twice with ether. After removing the ether, the residue was heated to 200° in an oil-

	1 + 3	57.5–58.5	166–170	121–123

Summary

Mesityl oxide has been found to react with benzene in the presence of anhydrous aluminum chloride to give β-phenyl*iso*butyl methyl ketone. Of the latter a semicarbazone, an oxime, a nitro and a tetrabromo derivative have been prepared. Treated with anhydrous zinc chloride the ketone yields a saturated, stable, crystalline hydrocarbon, $C_{24}H_{28}$, which gives a trinitro derivative. The ketone was reduced to the carbinol, from which an unsaturated hydrocarbon, $C_{12}H_{16}$, is produced by the action of zinc chloride. On oxidation with sodium hypobromite solution, the ketone gives a phenylisovalerianic acid which is identical with one described by Eijkman as the a-phenyl acid. By the synthesis of both the a- and the β-phenylisovalerianic acids by the malonic ester method, it is shown that the acid from the ketone is the β-acid. The true a-acid has not before been prepared.

STUDIES ON POLYMERIZATION AND RING FORMATION. I. AN INTRODUCTION TO THE GENERAL THEORY OF CONDENSATION POLYMERS

BY WALLACE H. CAROTHERS

RECEIVED APRIL 13, 1929 PUBLISHED AUGUST 7, 1929

Polymerization frequently leads to substances of very high molecular weights, and the problem of the structure of high polymers is attracting a great deal of attention, especially because such important materials as rubber, cellulose, proteins and resins either are high polymers or have certain properties which are common to high polymers.

The conditions which Berzelius[1] was concerned to recognize by the term polymer were the presence of the same atoms in the same proportions in compounds having different molecular weights. These conditions are satisfied by the members of a great many thousand pairs of compounds which are not now regarded as polymers. Thus, of the compounds paracetaldehyde, butyric acids and hydroxycaproic acids, only the first would now be considered a polymer of acetaldehyde, although there is nothing in the conditions of the Berzelius definition to exclude the others. Hence, whatever the term polymer may mean now, it does not mean precisely what Berzelius intended, and the conditions which he set up are not sufficient to define it. In current attempts to define this term[2] it is still stated that a polymer and its monomer must have the same atoms in the same proportions. But this condition is not satisfied by the polyoxymethylenes (see Table I) which are universally considered to be polymers of formaldehyde. It seems desirable, therefore, to attempt to formulate a definition which will be in so far as possible in accordance with both the current usage and the essential facts.

The structures of a good many polymers, including some of very high molecular weights, are known either completely or in part and an examination of their formulas shows some interesting relationships (see Table I). They are characterized by a recurring structural unit, so that if this is represented by $-R-$, the structure of these polymers may be represented in part by the general formula $-R-R-R-R-R-R-R-R-$, etc., or $(-R-)_n$. In this formula n may be small as in paracetaldehyde $(n = 3)$, or it may be very large as in the polyoxymethylenes. The end valences may be united as they are in paracetaldehyde to form a ring, or they

[1] Berzelius, *Jahresbericht*, 12, 63 *(1833)*.

[2] Hess, "Chemie der Zellulose," Leipzig, 1928, p. 577; Meerwein, Houben-Weyl, "Die Methoden der organischen Chemie," Leipzig, 1923, Zweite Auflage, dritter Band, p. 1013; Staudinger, Ber., 58, 1074 (1920).

may be saturated by univalent groups such as H— and —OH to form an open chain of the type $\text{H}(\text{—R—})_n\text{OH}$ as they are in α-polyoxymethylene. It seems probable that cellulose and silk fibroin are of this type, and in any event it may be observed that no high polymer is certainly known to be cyclic.[3] There are polymers which do not conform to the type $(\text{—R—})_n$ but those which do will be called linear whether the chain is open or closed; and the subsequent discussion is concerned only with these.

The structural units —R— are bivalent radicals which, in general, are not capable of independent existence. The presence of a recurring structural unit is, of course, characteristic of most organic compounds (e. g., $\text{—CH}_2\text{—}$ in aliphatic compounds), but in the case of polymers there exists a molecule, the monomer, corresponding to the structural unit, and from which the polymer may be formed or to which it may be degraded.

Examination of the formulas of Table I will show that two types of polymers may be distinguished. In the first type, which includes paracetaldehyde, rubber, polystyrene and polyoxymethylenes, the molecular formula of the structural unit is identical with that of the monomer, *i. e.*, the formula of the structural unit, —R—, is isomeric with that of the monomer. In the second type, which includes the polyethylene glycols, cellulose and silk fibroin, the molecular formula of the structural unit differs from that of the monomer by H_2O, *i. e.*, the monomer is H—R—OH. The transformation of polymers of the first type into their monomers is brought about simply by heating, and the reverse transformation (polymerization) occurs spontaneously or by the action of catalysts. In the second type, degradation to the monomer occurs by hydrolysis, and if the reverse process were to take place it would require the elimination of water among many molecules. This would be polyintermolecular condensation.[4]

These two classes will be distinguished as (1) addition or A polymers. The molecular formula of the monomer is identical with that of the structural unit. The monomer can be obtained from the polymer by thermolysis or the polymer can be synthesized from the monomer by self-addition. (2) Condensation or C polymers: the molecular formula of the monomer differs from that of the structural unit. The monomer can be obtained from the polymer by hydrolysis or its equivalent or the polymer can be synthesized from the monomer by polyintermolecular condensation. Polymerization then is the chemical union of many similar molecules

---

[3] However, Staudinger, in his latest papers, favors the view that polystyrene and rubber are very large rings, *Ber.*, 62,241 (1929).

[4] The term condensation is used here to name any reaction which occurs with the formation of a new bond between atoms not already joined and which proceeds with the elimination of elements (H_2, N_2, etc.) or of simple compounds (H_2O, C_2H_5OH, NH_3, NaBr, etc.). Examples are the Wurtz reaction, Friedel–Crafts reaction, esterification, etc.

either (A) without or (C) with the elimination of simpler molecules (H_2O, HCl, $NaCl$, NH_3, etc.).[5]

Assuming that polyintermolecular condensation exists, the above examples and definitions and their implications provide ample reason for referring to this process as a type of polymerization. These examples, of course, do not provide any proof that this process as distinct from and independent of A polymerization does exist. This proof will appear incidentally in the following discussion, which is concerned with the general principles involved in the formation of condensation polymers.

Polyfunctional Compounds.—Polyintermolecular condensation requires as starting materials compounds in which at least two functional groups are present in the same molecule (*e. g.*, hydroxy acids, HORCOOH, might lead to poly-esters, HORCOORCOORCOORCOORCOORCO—, etc.; amino acids, to poly-amides, $NH_2RCONHCONHRCONHRCONHRCONHRCO$—, etc.).

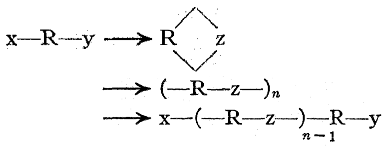
Among compounds having more than one functional group, those of the type x—R—y may be called bifunctional, $R''x_3$, trifunctional, etc. In these formulas R stands for a bivalent radical (R" for a trivalent radical) and x and y for functional groups capable of reacting with each other in a known fashion to form the new functional group z. Thus x—R—y ⟶ —R—z—, where —R—z— evidently represents a structural unit which will appear in the product and which may be present 1, 2, 3, . . . *n* times. Reactions of this type will be called bifunctional regardless of the number of molecules involved. Reactions of the type x—R—x + y—R′—y ⟶ —z—R—z—R′— may be called bi-bifunctional. All such reactions may, at least by hypothesis, pass through the stage x—R—x—R'—y which is equivalent to x—R—y, and for purposes of discussion they may therefore be classed as simple bifunctional reactions. Reactions of the type $R'x_3 + Ry_2 \longrightarrow$ *product* will be called tri-bifunctional. Similarly there may be tetra-bifunctional, tri-trifunctional reactions, etc., and all these may be classed together as polyfunctional reactions. The present discussion is concerned only with bifunctional reactions.

Bifunctional Reactions.—These always present two possibilities: they may be intramolecular or intermolecular. If intramolecular they can

---

[5] It would not be difficult to suggest examples in which a single polymer might belong to either or to both of these classes depending upon the method by which it was synthesized. So far as cellulose is concerned there is little to justify its classification as a C rather than as an **A** polymer other than the criteria which are set forth in the above definitions, and these may at present appear somewhat arbitrary. Thus even if cellulose were synthesized by the dehydration of glucose, this might occur by the formation of a glucosan which subsequently polymerized by self-addition. It may be observed, however, that of the two trimethylglucosans which might conceivably polymerize in this way to form trimethylcellulose, one is known and does not polymerize, and the other is probably incapable of existence on stereochemical grounds. See Freudenberg and Braun, ***Ann.***, 460,288 (1928).

lead only to the simple monomeric ring I. If intermolecular they may lead either to a polymeric ring II or to a polymeric chain III.



I

II

III

These obviously represent three possibly competing reactions.

The question now arises, what factors will determine which of these possible courses a bifunctional reaction will take? It is obvious, for example, that in general dilution would favor intra- over intermolecular reaction.[6] Temperature and catalysts might favor either one or the other. It appears, however, that structural and stereochemical factors will usually be more important than any others. That is, though it may be possible in some bifunctional reactions to control the choice between intra- and intermolecular reaction by suitable adjustment of experimental conditions, this choice will, in general, be almost completely determined by the nature of the reacting molecules.

The effects of these factors may be stated as follows. (1) If the product of intramolecular reaction would be a ring which, on stereochemical grounds, is incapable of existence, reaction will be intermolecular. This is apparently the case with p-$NH_2C_6H_4CH_2CH_2Cl$, which reacts with itself intermolecularly,[7] and not as had previously been supposed[8] with the formation of the so-called dihydro-p-indole? The utility of this very obvious principle is somewhat diminished by the fact that, in the present state of stereochemical knowledge, it is sometimes impossible to predict whether a given ring system will be capable of existence or not.

(2) Bifunctional reactions which can lead to the formation of 5- or 6-rings almost invariably proceed intramolecularly. This well-established fact is responsible for the existence of the majority of the very large number of 5- and Brings which is known.

(3) Bifunctional reactions which, if intramolecular, could lead only to larger-than-6-rings, generally proceed intermolecularly and lead to polymeric products. If this rule were free from any exceptions, it would necessarily follow that the polymeric products would always be of the open-chain type, III.

Although a great many bifunctional reactions have been studied in the hope of forming large rings, our information as to the precise nature of the

The above formulas for the polyoxymethylenes, polystyrenes and rubber have been well established especially by the work of Staudinger and his students: *Helv. Chim. Acta*, **5,** 785 (1922); **7,** 23, 842 (1924); **8,** 41, 65, 67 (1925); **9,** 529 (1926); **11,** 1047, 1052 (1928); *Ber.*, **53,** 1073 (1920); **57,** 1203 (1924); **59,** 3019 (1926); **60,** 1782 (1927); **61,** 2427 (1928); **62,** 241, 263 (1929); *Ann.*, **447,** 97, 110 (1926); *Z. physik. Chem.*, **126,** 425 (1927); *Kautschuk*, 237 (1927). For the formulas for cellulose, silk fibroin and rubber see Freudenberg and Braun, *Ann.*, **460,** 288 (1928); Meyer and Mark, *Ber.*, **61,** 593, 1932, 1939 (1928); Meyer, *Naturwissenschaften*, **42,** 790 (1928). The formulas for cellulose and silk fibroin are not, of course, regarded as finally established.

products of these reactions is very meager. That they do not usually proceed intramolecularly follows from the fact that very few large rings are known. It is true that such reactions frequently do not proceed at all under conditions which, in analogous cases, lead to the formation of 5- and 6-rings; but the formation of the latter often proceeds under conditions which do not permit intermolecular reaction even among unifunctional compounds (compare the formation of γ-lactones in the presence of a large excess of water, with the esterification of acetic acid). There are, however, a good many types of reaction which are intermolecular among simple compounds, which are practically free from side reactions, and which by suitable adjustment of experimental conditions may be forced to completion. It should be possible to conduct reactions of these types even when bifunctional, so as to obtain analytically homogeneous products whether they proceed intramolecularly or not. These simple principles have been repeatedly applied to bifunctional reactions in this Laboratory, and they have seldom failed to lead to analytically homogeneous products. Moreover, where the formation of 5- or 6-rings was excluded by the nature of the reacting materials, these reactions have, *without exception,* led to *high polymers.* This fact provides a possible explanation for the meagerness of the information which is available concerning the precise nature of the products of such bifunctional reactions. High polymers frequently have properties which make their investigation very difficult. Moreover, if a chemist is expecting a reaction to lead to materials of simple properties, he is usually inclined to regard the appearance of a resinous or sirupy product which neither can be crystallized nor distilled as signifying only that the experiment has failed. When the products of such reactions have been capable of purification and have shown the expected analytical composition, they have frequently been assumed to be dimeric (and cyclic) for no other reason than that they were obviously not monomeric. In this connection it 'should be emphasized that substances of very high molecular weights may nevertheless be microcrystalline and very soluble (see the following paper).

Some of the points discussed above are illustrated by the following examples.

Anhydrides of the acids of the series $HOOC(CH_2)_xCOOH$ are known in which x has all values from 1 to 8 inclusive. Of these only succinic and glutaric anhydrides are monomeric. These are, respectively, 5- and 6-rings. The other anhydrides which, if monomeric, would be 4-, 7-, 8-, 9-, 10- and 11-rings, are all highly polymeric.[10]

[10] For malonic anhydride see Staudinger and Ott, *Ber.,* 41, 2214 (1908). For the other anhydrides see Voerman, *Rec. trav. chim.,* 23, 265 (1904). The cryoscopic data which Voerman presents on phenol solutions have no bearing on the molecular weights of the anhydrides, since even succinic anhydride reacts rapidly with phenol to form phenyl succinate; Bischoff and von Hedenstrom, *Ber.,* 35, 4076 (1902). Farmer and Kracov-

Hydroxy-acids of the series $HO(CH_2)_xCOOH$ may condense with themselves. Only those in which x is 3 or 4 yield monomeric lactones.[11] These lactones are 5- and Brings, respectively. This series of acids now includes those in which x has all values from 8 to 16 inclusive.[12] The lactones corresponding to the acids in which x has the values 12 to 16 are also known,[12b] as well as the 17-membered lactone of the unsaturated acid, hexadecene-(7)-ol-(16)-acid-(1).[13] All of these lactones are perfectly stable substances and can be distilled without decomposition;[14] and yet none of these lactones has been synthesized by a bifunctional reaction.[15] They were synthesized by the oxidation of the corresponding cyclic ketones with persulfuric acid. By heating the acids, products are indeed obtained which have the same analytical composition as the lactones, but[1]"' they are "polymeric-like." The properties of the known lactones of this series indicate that lactones cannot be intermediates in the formation of these polymers. The formation of these must, therefore, involve C polymerization.

Amino acids of the series $NH_2(CH_2)_xCOOH$ are known in which x has the values 3, 4, 5 and 6. When x is 3 and 4, intramolecular anhydride formation occurs spontaneously at the melting point of the acids, the products being the 5- and 6-membered rings, pyrrolidone and piperidone.[16]

ski have recently obtained adipic anhydride in a monomeric form, *J. Chem. Soc.*, 680 (1927).

[11] On this point no data are available for those in which x is 5 and 6 [THIS JOURNAL, 46, 2838 (1924); *Ber.*, 60, 605 (1927); *ibid.*, 33, 864 (1900)]. The analogous acids, $CH_3CHOH(CH_2)_2CH(CH_3)CH_2COOH$ [Baeyer and Seuffert, *ibid.*, 32, 3619 (1899)] and $C_2H_5CHOH(CH_2)_4COOH$ [Blaise and Kohler, *Compt. rend.*, 148,1772 (1909)], have been prepared, and by heating are converted at least partially into the 7-membered lactones. The acid $C_2H_5CHOH(CH_2)_5COOH$ has also been prepared. On heating, it also loses water, but the 8-membered lactone is not formed. The product is a lactide-like material which cannot be distilled without decomposition (Blaise and Kohler).

[12] (a) Lycan and Adams, THIS JOURNAL, 51, 625 (1929); (b) Ruzicka and Stoll, *Helv. Chim. Acta.*, 11, 1159 (1928). Since this paper was written a great deal of further information concerning these acids has become available in the paper of Chuit and Hausser, *ibid.*, 12, 463 (1929'1.

[13] Kerschbaum, *Ber.*, 60, 902 (1927).

[14] This indicates that large heterocyclic rings are not less stable than their lower homologs. Their physical properties are such as would be expected from the known properties of their lower homologs. The mere presence of a large ring does not result in the development of any of those unusual secondary, residual, or supermolecular forces which are sometimes supposed to confer "polymeric" properties on relatively simple molecules.

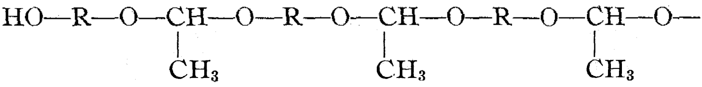
[15] Kerschbaum (ref. 13) records various attempts to prepare ambretollid by the methods commonly used for the preparation of lactones. By heating the acid he obtained traces of an oil which had the odor of the lactone. (It is powerfully odorous.) The product was, however, for the most part, a gelatinous material *soluble* in *alkali*. For the usefulness of the method proposed in German Patent Application 150,677, see Ruzicka and Stoll, ref. 12 b.

[16] Gabriel, *Ber.*, 22,3338 (1889); Schotten, *ibid.*, 21,2240 (1888).

When x is 5 the acid is, on heating, converted to the extent of 20 to 30% of the theoretical into the 7-membered lactam. "The rest of the acid is converted into a viscous gelatinous mass which could be obtained in a state of only approximate purity and which, according to the analysis, is isomeric with the 7-membered lactam; that is, it is a polymeric product."[17] Where x is 6 no trace of the corresponding lactam could be obtained by heating the acid, although this lactam (suberone-isoxime) is a known and stable substance.[18] By heating the acid a product was obtained having the same composition as this lactam, but it was an undistillable solid, insoluble in most solvents.[17]

The compounds $Br(CH_2)_xNH_2$, where x is 4, 5 and 6, react with themselves with the formation of secondary amines containing the structural unit $(—CH_2—)_xNH—$. Where x is 4 and 5 the products are the monomeric 5- and 6-rings, pyrrolidine and piperidine.[19] Where x is 6 the amount of the monomeric base (7-ring) formed was too small to permit purification.[20] The product was for the most part an oil which solidified to a waxy solid. It could not be distilled in vacuum without decomposition, and though no molecular weight determination is recorded, v. Braun seems inclined to regard it as dimeric. Its properties are obviously more consistent with a more highly polymeric structure.

An interesting example of a bi-bifunctional reaction is found in the reaction between glycols and acetaldehyde (or acetylene). This presents the possibility of forming cyclic acetals, , or polyacetals,



$$HO—R—O—\underset{\displaystyle CH_3}{\underset{|}{CH}}—O—R—O—\underset{\displaystyle CH_3}{\underset{|}{CH}}—O—R—O—\underset{\displaystyle CH_3}{\underset{|}{CH}}—O—$$

, etc. This reaction has been studied by Hill and Hibbert.[21] Ethylene and trimethylene glycols gave in excellent yields the cyclic acetals which are 5- and Brings. Tetramethylene glycol gave in poor yield a volatile compound which was apparently the monomeric cyclic acetal containing a 7-ring. A considerable part of the product was an undistillable sirup. The products from octamethylene and decamethylene glycols were also undistillable sirups. No molecular weight determinations are recorded. Hill and Hibbert

recognized of course that these sirups might have the polymeric linear structure indicated above, but seemed inclined to regard them as simple rings of a peculiar kind.

The only reaction which has led to the formation of large carbon rings from open-chain compounds is the action of heat on certain salts of dibasic acids.[22] In no case are these large rings the chief products of this reaction, nor can it be established that they are primary products, since the reaction takes place at high temperature. If polymeric products were formed they would be decomposed thermally. High polymers could not appear in the distillate from which the products are isolated, because high polymers cannot be distilled. These features sharply distinguish this reaction from other truly bifunctional reactions which might, but which do not, so far as our information goes, lead to rings of the same type.[23]

Any theory which attempts to explain why 5- and 6-rings are formed very readily and larger rings with very great difficulty must take into account the fact that these larger rings are not less stable than the smaller. A satisfactory theory is already available. The Baeyer strain theory in its original form is made untenable by the existence of the higher cyclopar-affins, and has been replaced by the Sachse–Mohr theory which permits the existence of non-planar and strainless rings and which has besides a great deal of other evidence in its support.[24] The features of this theory essential to the present argument are exceedingly simple. They involve the assumption of the tetrahedral angle in the carbon valences and of free rotation about each carbon–carbon single bond in a chain. No description of stereochemical relations can be as convincing as a demonstration with suitable models.[25] Such models show that there is a certain inevitability in the formation of 5- and 6-rings and a large degree of fortuity in the formation of larger rings. This question has been considered in some detail by Mohr.[26] Regarding the possibility of the forma-

[23] For example, the action of metals on a dihalide, $Br(CH_2)_xBr$. Thus decamethylene bromide reacts rapidly and very smoothly with metallic sodium, but no cyclodecane is formed. See Franke and Kienberger, *Monatsh.*, **33**, 1189 (1912). This reaction will be discussed in a later paper.

[24] See Huckel, "Der gegenwärtige Stand der Spannungstheorie," *Fortschritte Chem. Physik und physik. Chem.*, Band 19, Heft 4, 1927.

[25] Ordinary (preferably quite small) wire tetrahedra may be joined by short pieces of rubber tubing in such a way that the arms which are being connected over-lap. This provides free rotation about the union, but prevents bending. This method of union insures that any model which is built up is practically strainless (*i. e.*, the tetrahedral angle is always retained) and at the same time is sufficiently mobile to illustrate the multiplicity of forms which long chains and large rings can assume.

[26] Mohr, *J. prakt. Chem.*, 98,348 (1918).

tion of a cyclic ketonic ester by the internal condensation of sebacic ester he says:

> The molecule of sebacic ester is a very long chain. The multiplicity of forms which this molecule can assume is extraordinarily great. It is clear that by the random collisions of the molecuies, fewer molecules of sebacic ester will in unit time assume the form necessary for ring closure than is the case with adipic ester under the same conditions, since this contains in its molecule only four methylene groups, and four less points of rotation than does sebacic ester. To bring the two ends of the sebacic ester molecule together in the least forced fashion apparently requires a very small amount of energy or none at all. Unfortunately, however, we have not the means arbitrarily and with the least possible expenditure of energy to bring about the desired change in form of the molecules and to hinder the undesired. In this connection we are left entirely to chance, that is, to random collision, which will bring about a given form the more rarely the more forms are possible, *i. e.*, the longer the chain between the two carboxyl groups.

In perhaps two dozen cases it is well established that a bifunctional reaction proceeds fairly smoothly with the formation of a larger-than-6-ring. These cases include more 7-membered than larger rings, and more aromatic than aliphatic compounds. The Sachse–Mohr theory would lead one to expect that the formation of 7-rings would not be very much more difficult than the formation of 6-rings. The bifunctional reactions discussed in the examples offered above all involve purely aliphatic compounds, and for the most part the chains are unsubstituted. In most of these examples the formation of a 7-ring occurs to a certain extent, and the formation of the corresponding 8-ring not at all. It appears that in such 7-atom chains the probabilities of intra- and intermolecular reaction are about equal. The addition of one more atom to the chain diminishes the probability of intra- with respect to intermolecular reaction to such an extent that only the latter appears. These relations may be somewhat modified by the presence of substituents on the chains and even by the nature of the reacting groups in ways which it is, at present, impossible to predict. It is evident, however, that if two atoms of such a chain are adjacent atoms of a benzene ring their position with respect to each other is fixed, and the chances of intramolecular reaction are greater than in an analogous simple chain of the same length. (The latter will have one more axis of rotation than the former.) It is therefore not surprising that in $NH_2(CH_2)_6Cl$ intramolecular reaction occurs only to a slight extent, and in *o*-$NH_2C_6H_4(CH_2)_4Cl$ almost quantitatively.[27] Other similar examples might be cited.

There is also some evidence to indicate that even simple substituents such as methyl groups on a chain may increase the tendency toward the formation of larger rings.[28] Researches in the diphenyl series have established that substituent groups suitably placed may completely inhibit

rotation about a nearby single bond, and a similar effect in aliphatic chains is at least conceivable. Any restriction of the freedom of rotation of the atoms of a chain would, on the basis of the Sachse–Mohr theory, increase the chances of ring formation.

The process of polyintermolecular condensation finds no mention in treatises on polymerization. This may be due to the fact that such a process is not admitted to exist, or that it is not admitted to be polymerization. The examples cited above, and others to be described later, prove that such a process does exist, and that it may result in the formation of very large molecules. Whether it is to be regarded as polymerization or not will depend upon the definition which is adopted for that term. The definitions offered above include it as a special type of polymerization. This classification'finds more to justify it than the analogies which are recognized in these definitions.

The process of A polymerization (the only type which appears to have been generally recognized) results in the formation of large molecules from small; and it has come about that any process which has this result is called polymerization. Since, however, A polymerization is by definition a process of self-addition, chemists have often been misled to the assumption that condensation leads directly only to small molecules, and that if large molecules are formed from small as the apparent result of condensation, this is due to the intervention of some unsaturated molecules capable of undergoing A polymerization.[29] It is quite certain, however, that in many such cases (*i. e.*, in all cases of true C polymerization) no such intermediate products occur. This is a matter of important practical implications. The reactions involved in the formation of A polymers must, in the nature of the case, be for the most part reactions which are peculiar to the process of polymerization. For this reason the mechanism of A polymerization still remains somewhat obscure. Hence, the mere assumption that unsaturated intermediates intervene in a reaction which leads to high polymers contributes little to one's understanding of the mechanism of the process, or the structure of the product. In those cases in which this assumption is wrong its use leads one to regard as complicated and

---

[29] Thus, Drummond, *Inst. Rubber Ind.*, 4, **43** (1928), states, "Where resins are formed by a preliminary condensation as are the phenol-formaldehyde products, it is logical to assume that in the preliminary reaction, unsaturated atomic linkings are introduced which provide the necessary arrangement for polymerization subsequently to occur." Scheiber, *Chem. Umschau, Fette, Oele, Wackse Harze,* 15,181 (1928), is even more explicit: "Für den Aufbau organischer Stoffe kommen bekanntlich nur zwei Prozesse in Betracht, und zwar Kondensationen und Polymerisationen. Vorgange der ersterep Art fuhren im allgemeinen zu Molekulverbänden beschränkter Grösse—. . Bei Polymerisationen hingegen kommt es in manchen Fallen zur Ausbildung extrem grosser Moleküle. . ."

mysterious a process which may be simple and obvious. C polymerization merely involves the use in a multiple fashion of the typical reactions of common functional groups. Among bifunctional compounds these reactions may proceed in such a way as to guarantee the structure of the structural unit, —R—, in the polymer, $(\text{—R—})_n$, formed. It is one of the immediate objects of the researches to be described in subsequent papers to discover how the physical and chemical properties of high polymers of this type are related to the nature of the structural unit.

Summary

Linear polymers conform to the type —R—R—R—R—R—, etc., which is characterized by a recurring structural unit. The structural unit —R— is a bivalent radical. Two types of polymers are recognized. (1) Addition or A polymers: the polymeric molecule is converted by heat into a monomer having the same composition as the structural unit, or the polymer is formed by the mutual addition of a number of such monomers. (2) Condensation or C polymers: the polymeric molecule is converted by hydrolysis or its equivalent to a monomer which differs in composition from the structural unit by one H_2O (or HCl, NH_3, etc.), or the polymeric molecule is formed from numbers of the monomers by a process of polyintermolecular condensation. Rubber, polystyrene, polyoxymethylene and paracetaldehyde are A polymers. Cellulose, silk fibroin and hexa-ethylene glycol are probably C polymers.

Substances of the type x—R—x and x—R—y are called bifunctional. In these formulas —R— represents a bivalent radical and x and y functional groups capable of reacting with each other in a known fashion to form the new functional group, z. Reactions of the type x—R—y ⟶ *product* are called bifunctional and those of the type x—R—x + y—R—y ⟶ *product* are called bi-bifunctional. Such reactions will lead to compounds containing the structural units —R—z— and —R—z—R—z—. Bifunctional reactions will be intramolecular and will lead to the monomeric product,  when this can be a 5- or 6-ring. If the monomeric product can only be a larger-than-6-ring, reaction will usually be intermolecular and the product a polymer of the type —R—z—R—z—R—z—R—z—R—z—, etc.

STUDIES ON POLYMERIZATION AND RING FORMATION. II. POLY-ESTERS

BY WALLACE H. CAROTHERS AND J. A. ARVIN

RECEIVED APRIL 13, 1929 PUBLISHED AUGUST 7, 1929

An example of a bi-bifunctional reaction is found in the reaction between a dibasic acid and a dihydric alcohol, $HOOC—R'—COOH + HO—R''—OH$, which, if it is conducted so as to involve both functional groups of each reactant, must lead to an ester having the structural unit, $—OC—R'—CO—O—R''—O— = —R—$. In accordance with the thesis developed in the previous paper, esters formed in this way will be polymeric unless the number of atoms in the chain of the structural unit is less than seven. In this paper esters are described in which the number of atoms in the chain of the structural unit is 7, 8, 9, 10, 11, 12, 14, 15, 16, 18. and 22 atoms. All these esters are highly polymeric, and, although some of them have been prepared by various methods, no monomeric form of any of them has as yet been isolated.

Preparation of the Esters

The following method was used for the preparation of the solid esters whose properties are listed in the table. The acid together with a 5% excess of the glycol was placed in a Claisen flask provided with a receiver and condenser, and the flask was heated in a metal-bath. At about 160° (bath temperature) reaction set in. Water distilled off freely during the first hour (temp., 175-185°) and very slowly if at all during the succeeding two hours at the same temperature. The receiver was now changed, the flask provided with a very fine capillary and heating continued under a good vacuum (usually less than 0.2 mm.) for about three hours, the temperature of the bath being raised to 200–250°. During this period little or no distillate collected (provided only a 5% excess of glycol was used). The residue, which was a slightly dark and, at 150°, more or less viscous liquid, was poured from the flask. The amount of this residue corresponded with the theoretical (based on the acid used), and the amount of water actually collected approached the calculated more closely the larger the sample used (60–90%). The esters were purified by crystallization.

Ethylene malonate was prepared by heating ethyl malonate and glycol in the same fashion. There was some decomposition (evolution of gas) when the residue was heated to 240° in *vacuo.* This residue was a thick sirup which could not be induced to crystallize. It was dissolved in acetone, filtered and heated for several hours at 175–190° in high vacuum. Nothing corresponding to a monomeric ethylene malonate was found on redistilling the distillates from this preparation.

The preparation and properties of some esters not included in the table are described in the Experimental Part of this paper.

Structure of the Esters

The conclusion that these compounds are esters and that they contain the structural unit —R— indicated above follows directly from the method of preparation and is supported by the analytical data and chemical behavior. Comparison of Cols. 4 and 5 in Table I shows that the carbon and hydrogen percentages in general agree with those calculated for —R—. So also did saponification numbers where these were determined. The products of saponification of the esters are the acids and glycols from which they were prepared.

That the esters are not monomeric 7-, 8-, 9-, . . ., 22-membered rings is indicated by their physical properties and by their molecular weights. In Col. 7 are given the molecular weights calculated from the observed boiling point elevations or freezing point lowerings, and in Col. 8 the solvents and methods used. The solvents used in the ebullioscopic determinations include chloroform, ethylene chloride, benzene and acetone. Those used in the cryoscopic determinations include benzene, glacial acetic acid and diphenyl ether.

In these determinations it was necessary to use rather large samples to obtain boiling point or freezing point changes of 0.02 to 0.05°. Judged by their self-consistency, the values obtained with the use of freezing benzene have about the same relative accuracy as is ordinarily attained with simple compounds. With other solvents, and especially in the boiling point determinations, observations were much less consistent. This was due in part at least to changes of surface tension, associated no doubt with molecular size, since there was much foaming. The values obtained by this method are recorded, since for some of the esters they are the only ones available, and for others they clearly indicate that the order of magnitude of the apparent molecular weights is quite independent of the character of the solvent used.

The lowest molecular weight observed for any of the solid esters was 2300 and the highest 5000. The mean of all the determinations is 3200, and for purposes of calculation the molecular weight of each ester has been assumed to be approximately 3000. Such a molecular weight corresponds with a value of 8 to 20 (depending on the length of the chain of the structural unit) for n in the general formula $\text{—(—CO—R}'\text{—CO—O—R}''\text{—O—)—}_n$. It can scarcely be supposed that the molecules present in a given sample are all identical so far as the values of n are concerned, but their crystallinity and a certain homogeneity in such physical behavior as solubility indicate that the varieties of molecular species present in a given sample probably do not include a very wide range.

The disposition of the valences at the ends of the chains in the above formula cannot as yet be definitely decided. A cyclic structure is rendered improbable by the same considerations which led us to expect that these esters would be polymeric and which have been discussed in the previous paper. Esters prepared by the method indicated above are definitely not acidic, and since the detection of a carboxyl group in a molecule having a weight of 3000 to 5000 should present no difficulties, no carboxyl groups can be present at the ends of the chains. Attempts to detect the presence of hydroxyl groups have not as yet succeeded. Ethylene succinate crystallizes unchanged from acetic anhydride, and is not affected by phenyl or naphthyl isocyanate. Nevertheless we are inclined to assume that hydroxyl groups are present at each end of the chain due to the presence of one more molecule of glycol than acid: $HO—R''—O—(—CO—R'—CO—O—R''—O—)_n—H$. The failure of these groups to react with reagents may be ascribed to the operation of the same factors which set a limit to the size of the molecules formed.

In general the analytical values agree more closely for such a formula than for a cyclic formula. In Col. 6 of Table I are given the carbon and hydrogen percentages calculated for this formula assuming a molecular weight as close as possible to 3000. The means of the deviations between the carbon and hydrogen percentages found and those calculated for the —(—R—)—, formula are –0.48 and –0.01%; while the deviations calculated for the $HO—(—R—)_n—R'—OH$ formula are –0.31 and –0.11%.

Assuming a molecular weight of 3000 the chains, $H—[—O—(CH_2)_y—O—CO—(CH_2)_x—CO—]_n—O—(CH_2)_y—OH$, would contain 170–200 atoms and their lengths would lie between 249 and 280 Å.[1] Their lengths are therefore of the same order of magnitude as that assumed by Meyer[1] for the cellulose chains (100 glucose units per chain = 510 Å.). The molecular cohesions calculated from the data presented by Meyer[2] lie between 250,000 and 300,000 cal. or 3.3 to 4 times the heat of separation of a carbon-carbon bond (75,000 cal.). These molecular cohesions are, however, only about 10% of those calculated for a cellulose chain of 500 Å.

The structure of these esters will be discussed in more detail later in the light of experimental work which is not yet completed.

Properties of the Esters

All the esters of the type $—(—CO—(CH_2)_x—CO—O—(CH_2)_y—O—)—$ with the exception of ethylene malonate are crystalline solids. The property of crystallinity is not very highly developed, but it is quite definitely present.[3] This fact is of interest because examples of crystalline highly polymeric substances are not very numerous. As with all crystalline substances of this class, it is not possible to develop large crystals. Ethylene succinate when it separates from a melt or from concentrated solutions (in chloroform) crystallizes in doubly refracting spherolites (microscopic) which grow to what appear to be star-like groups of needles.

---

[1] The values C = 1.5 Å. and O = 1.1 Å. are taken from Meyer, *Naturwissenschaften,* 42, **782** (1928).

[2] Ref. 1, p. 790.

[3] So far as they have been examined in this respect, all these esters give sharp x-ray diffraction patterns.

From dilute alcohol solutions it separates in discrete microscopic needles.[4]

Crystallized ethylene succinate and decamethylene sebacate are dusty powders which have a great tendency to become electrified. Some of the intervening members are quite soft and even somewhat sticky. Ethylene succinate solidifies from a melt as a hard, brittle, opaque, white mass. Decamethylene sebacate solidifies to a white, brittle, waxy solid.

The non-crystalline members include ethylene malonate, ethylene fumarate and ethylene, trimethylene, hexamethylene and decamethylene phthalates. The phthalates and the fumarate evidently have less symmetry than the saturated straight-chain purely aliphatic type. The lack of crystallinity of the malonate may be associated with the low melting point of the malonic acid; or it may be due to the fact that considerable decomposition occurred during the process of esterification.

The melting points of the solid esters are not very sharp and they depend somewhat upon the rate of heating. This latter effect is noticed especially with ethylene succinate.

When the crude reaction mixture is dissolved in chloroform and precipitated with benzene, the resulting dusty white powder melts in a capillary tube at about 102". If, however, the tube is placed in a bath which has already been heated to 96° the sample melts at once. The two melting points are called the slow and instantaneous melting points, respectively, and they are best observed on a bloc Maquenne. Samples which are dusted on the bloc when it is below 96° do not melt until it reaches 102°, but as soon as the bloc reaches 96" samples melt the instant they touch it. Both these temperatures may be changed somewhat by repeated crystallization, but a sample whose melting point has been raised by repeated crystallization may suddenly show the original melting point on further crystallization. By long extraction with boiling absolute alcohol in which it is practically insoluble, ethylene succinate is modified so that the instantaneous and slow melting points coincide at about 107–108°, and from the extracts may be isolated a very small amount of lower-melting material. When such a high-melting sample is again crystallized from a mixture of chloroform and benzene or ether, the melting point usually drops, and one observes again the instantaneous melting point of 96" and the slow melting point 102°. The melting point of such samples may also be raised by long heating just below 100°, and both melting points then gradually approach 107°. When a 96, 102° sample is quickly melted, then allowed to solidify in an agate mortar and powdered, the instantaneous melting point is lowered somewhat, and the slow melting point may be either raised or lowered, depending upon the time during which the molten material is heated.

Attempts to define the melting point more clearly by heating or cooling curves on fairly large samples were unsuccessful.[5] Apparently the viscosity of the melt is so great

---

[4] Incidentally these are the forms in which Hess' trimethylcellulose crystallizes, and the photomicrographs (Figs. 78, 80 and 81) which he presents ("Die Chemie der Zellulose," Leipzig, 1928, p. 432) for this substance would serve almost perfectly as pictures of ethylene succinate. The crystallinity of this trimethylcellulose therefore provides no guarantee either than it contains only a single molecular species, or that the molecules present are not very large.

[5] Some experiments were kindly made for us by Dr. E. L. Skau with the special apparatus which he has devised for the precise determination of the melting points of pure organic compounds.

as to make the process of crystallization slow even in the presence of previously formed crystals and under a considerable temperature gradient.

The erratic behavior of the melting points may be associated with the fact that all these esters are hygroscopic, but the absorption of water cannot be the sole cause for this behavior, for samples of ethylene succinate having various melting points were stored over 20% sulfuric acid for ten days and all of them gained considerably in weight without changing in physical appearance or melting point.

Anomalies in melting points are not unknown among compounds of definite constitutions and relatively low molecular weights. One may cite, for example, the fact that sucrose separates from methyl alcohol in crystals melting at 169–170° and from other solvents in crystals melting at 179–180°, and these two forms do not show any detectable chemical differences.[6] But the case of ethylene succinate appears to be more complicated and confused than this. Its melting point depends upon its history in a fashion which can as yet be defined only to the following extent—it always rises and approaches 107° as it is, while still in the solid state, heated or extracted with boiling absolute alcohol.

Among the other esters these irregularities were less pronounced. Nevertheless, the melting points are not very characteristic and no attempt was made to crystallize them to constant melting points. Instead they were crystallized two to six times depending upon the color and softness of the sample. The melting points recorded are the highest observed for complete melting and are usually within 5° of the lowest observed for any sample of the same material. The melting range was usually less than 2°. The melting point of the decamethylene ester of a given acid was higher than that of the hexamethylene ester. The melting point of the hexamethylene ester was higher than that of the trimethylene ester, which was in turn lower than that of the ethylene ester. With one exception, the adipic ester of each glycol melted lower than either its succinic or sebacic ester.

All of these esters are, when molten, quite viscous. Those which do not crystallize on cooling become more or less hard, tough and glassy. The use as resins of esters formed by the action of polybasic acids on polyhydric alcohols has been covered by numerous patents.[7] The impression seems to prevail that all such esters are resins. Of the esters described in this paper the majority are crystalline. The phth: lates which we have prepared are, however, all resinous. Ethylene phthalate is quite tough and moderately hard. Neither this ester nor the trimethylene, hexamethylene nor decamethylene esters of the same acid have been described in the scientific literature. As the length of the alcohol chain increases, these phthalates become progressively softer. Decamethylene phthalate has the cousistency of a moderately thick sirup.

None of these esters is volatile. Each of them has been heated to

---

[7] See for example U. S. Patents Nos. 1,108,332; 1,091,627; 1,091,628; 1,091,732 1,108,329; 1,108,330; 1,108,331; 1,642,079; 1,678,105; 1,098,776; 1,098,777; 1,424,137; 1,413,144; 1,413,145; 1,667,199; 1,667,200; 1,119,592; 1,141,944; 1,663,183.

200° in *vacuo* without showing any tendency to distil. Ethylene succinate heated for three hours at 250° under a pressure of 2 mm. is not changed in properties, and its analytical composition (carbon, hydrogen and saponification number) is not changed. It shows no tendency to distil or to evolve any volatile products when heated to 280° at a pressure of 1 micron. At 350° ethylene succinate undergoes complete thermal decomposition, the products being ethylene, acetaldehyde, succinic anhydride, carbon, etc.[8]

All of these esters are insoluble, or nearly so in water, alcohol, petroleum ether and ether.[9] The least soluble of the saturated aliphatic esters is ethylene succinate. It is more or less soluble in hot ethyl acetate, acetic acid, acetic anhydride, ethyl succinate and acetone, and it crystallizes from these solvents on cooling. It is insoluble in benzene. The other saturated aliphatic esters with the exception of ethylene malonate are readily soluble in cold benzene and at least moderately soluble in acetone, ethyl acetate and glacial acetic acid. The solutions are noticeably viscous only when fairly concentrated (e. g., 10% or stronger). This fact and the rapidity with which solution occurs lead us to believe that the solutions are true molecular dispersions.

Although none of these esters is soluble in water they are all somewhat hygroscopic. This property is especially pronounced in those poly-esters which are not crystalline. The drying of these resins was very difficult and, as the analytical results indicate, was not always successful. Drying to constant weight was complicated by the tendency to foam when heated in *vacuo*.[10]

Other Methods of Preparation

The only detailed study of poly-esters of the type here described which we have found is reported in a paper by Vorländer.[11]

Ethylene succinate was first prepared by Lourenço[12] by heating succinic acid and ethylene glycol to 300° (m. p. about 90"). Subsequently Davidoff[13] prepared Lourenço's ester and identified it with one which he obtained by heating silver succinate with ethylene bromide. Vorländer

[8] Tilitschejew, *J. Russ. Phys.-Chem. Soc.*, *57*, 143 (1925).

[9] It is interesting to note that Freudenberg and Braun's trimethylcellulose, like ethylene succinate, is insoluble in ether and carbon tetrachloride, but quite soluble in chloroform [*Ann.*,460,288 (1928)].

[10] It is interesting to observe that inulin, a polymeric substance of a different type, but probably of the same degree of molecular complexity as the esters here described is also quite hygroscopic. *Cf.* Drew and Haworth, J. *Chem. Soc.*, 2690 (1928).

[11] Vorländer, *Ann.*, 280, 167 (1894). See also Bischoff, *Ber.*, 27, 2940 (1894); 40, 2779, 2803 (1907). Glycol esters of adipic acid are referred to in German patent 318,222, *Chem. Zentr.*, II, 536 (1920).

[12] Lourenço, *Ann. chim. phys.*, 293 (1863).

[13] Davidoff, *Ber.*, 19,406 (1886).

studied this latter compound in detail and showed that its chemical behavior was in all respects what would be expected of an ethylene ester of succinic acid. He also identified it with Lourenço's ester and with one obtained by the action of succinyl chloride on the disodium derivative of ethylene glycol.

Vorlander found that his ethylene succinates prepared from silver succinate and from succinyl chloride had apparent molecular weights ranging from 265 to 321 in freezing phenol and in freezing acetic acid. He supposed them to be dimeric, and in accordance with this view was able to prepare the same compound from silver succinate and di-(β-chloro-ethyl)-succinate. This method of synthesis evidently merely establishes that the compound was probably not monomeric.

The properties which Vorlander records for ethylene succinate agree in general with those which we have observed. We have found that it is possible to prepare ethylene succinates having, within certain limits, various melting points (and molecular weights) by heating succinic acid and glycol in various proportions. The highest melting (102") is that described above. It was prepared from acid and excess glycol. Vorlander and other writers on this subject ascribe to ethylene succinate a melting point of 88–90". We have obtained samples showing this melting point by using the acid and glycol in equivalent amounts; and, by using excess acid, have obtained lower-melting samples. These ethylene succinates differ somewhat in solubility, but they are alike in physical appearance, in their lack of volatility and in their viscpus character when molten. All of these materials are highly polymeric. We have also prepared ethylene succinate from silver succinate and ethylene bromide according to Vorlander's directions. This reaction does not proceed smoothly, and our product was slightly colored and melted at 75° instead of at 90°. Nevertheless, molecular weight determinations in boiling ethylene chloride gave values ranging from 1400 to 2000. We think, therefore, that Vorlander's molecular weight determinations must be in error; and this conclusion is supported by the fact that the properties which he records and which we have observed are not consistent with so low a molecular weight as 288.

We have also prepared ethylene succinate from ethyl succinate and glycol. It is also highly polymeric. Thus the methods which have been used for the preparation of this compound include four separate and distinct methods commonly used in the preparation of esters. They all lead to products of the expected composition but of high molecular weights. There is not the slightest reason for supposing that the monomeric ethylene succinate should be incapable of existence, or even that it should be unstable, but it still remains unknown. These facts find their explanation in the thesis developed in the previous paper.

Vorlander also prepared ethylene maleate and ethylene fumarate by the silver salt method. He could not obtain any consistent values for the molecular weights of these materials. We have prepared the fumarate from ethyl fumarate and the maleate from maleic anhydride. Our preparations differ from those of Vorlander in several respects. Thus, our maleate was crystalline and our fumarate resinous. The reverse was true for Vorlander's compounds. Neither our analytical values nor his agree well with the calculated. These esters appear to be much more complicated in their behavior than ethylene succinate. They both become completely insoluble on heating.

Experimental Part

Ethylene Phthalate **No.** 1.—Ethylene glycol 62 g. (1 mole) and phthalic anhydride 74 g. (0.5 mole) were heated together for eight hours at 190° under ordinary pressure and for three hours at 300° under 3 mm. The viscous residue was heated with boiling water for twenty minutes, dissolved in chloroform, filtered and precipitated with ether, and then dissolved in acetone, filtered and precipitated with water. It was then dried by heating to 160–170°. The resulting glassy resin was fairly hard when cold, and became softer on heating. All attempts to induce it to crystallize failed. It was neutral: 2 g. required 0.03 cc. of 0.23 N NaOH for alkalinity toward phenolphthalein. It was soluble in chloroform, acetone, ethyl acetate and acetic acid; insoluble in petroleum ether, ether, benzene, alcohol and water.

Anal. Substance dried to constant weight in high vacuum at 70°. Calcd. for $C_{10}H_8O_4$: C, 62.48; H, 4.19; molecular weight, 192; saponification number, 96. Calcd. for $H[O(CH_2)_2OOCC_6H_4CO]_{25}O(CH_2)_2OH = C_{252}H_{206}O_{102}$: C, 62.15; H, 4.28; molecular weight, 4864; saponification number, 97.3. Found: C, 61.86, 61.95; H, 4.29, 4.30; molecular weight by micro boiling point method in ethylene chloride, 4830, 5070, 4680, 4690; saponification number, 95.7.

Ethylene Phthalate **No.** 2.—This was prepared in the same way as No. 1, but with a 20% excess of phthalic anhydride and was purified in a similar fashion. Appearance and solubility were the same as for No. 1.

Anal. After drying to constant weight in high vacuum at 70°. Found: C, 62 11, 62.07; H, 4.29, 4.33; molecular weight, by method of Menzies and Wright in ethylene chloride, 2940, 2700, 3020; by micro boiling point method in ethylene chloride, 3030, 2930; saponification number, 96.2.

Ethylene Phthalate **No.** 3.—Prepared by heating diethyl phthalate (0.5 mole) with ethylene glycol (1 mole) in the same fashion and purified as before. Appearance and solubility were the same as for No. 1.

Anal. after drying to constant weight in high vacuum at 70°. Found: C, 62.35, 62.14; H, 4.40, 4.37; molecular weight, by freezing point lowering in diphenyl ether, 2070, 2030; by method of Menzies and Wright in ethylene chloride, 1990, 2100, 2050, 1770; by micro boiling point method in ethylene chloride, 2100, 1870.

Ethylene Phthalate **No.** 4.—This was prepared by stirring vigorously 19 g. of glycol (added slowly) with 60 g. of phthalyl chloride and 51 g. of dry pyridine in 125 cc. of chloroform at 0–5°. The reaction mixture was washed thoroughly with dilute acid and dilute sodium carbonate and water, and decolorized with Darco. After drying the chloroform solution the ester was precipitated with ether. The yield was 53 g. It resembled the other ethylene phthalates, but its solutions in chloroform were less viscous —0.016 poise for a 20% solution at 27° as compared with 0.027–0.031 poise for the other ethylene phthalates. Its apparent molecular weight was also lower.

Anal. after drying to constant weight in high vacuum at 70°. Found: C, 61.64, 61.64; H, 4.28, 4.30; molecular weight, by method of Menzies and Wright in ethylene chloride, 1550, 1610; saponification number, 99.5, 99.6.

Hydrolysis of Ethylene **Phthalate.**—Twenty grams of ethylene phthalate was refluxed for sixty-four hours with 60 g. of 48% hydrobromic acid. After neutralization with sodium carbonate, the reaction mixture was steam distilled, From the distillate was isolated 16.7 g. or 86.6% of the calculated amount of ethylene bromide, b. p. 131–134'. The residue on acidification gave 16.3 g. or 93.6% of the calculated amount of phthalic acid. This on conversion to the anhydride melted at 130–131°.

Trimethylene **Phthalate.**—Seventy-four grams (0.5 mole) of phthalic anhydride and 38 g. (0.5 mole) of trimethylene glycol were heated at 250° for two hours under ordinary pressure and under diminished pressure for two hours. The residue was dissolved in benzene, treated with Darco, filtered and precipitated with ether. When cold it was a clear, glassy solid, somewhat softer than ethylene phthalate. It was soluble in chloroform, benzene, acetone, ethyl acetate and acetic acid; slightly soluble in alcohol; insoluble in ether, petroleum ether and water.

Anal. Calcd. for $C_{11}H_{10}O_4$: C, 64.08; H, 4.89; molecular weight, 206. Calcd. for $H[OOCC_6H_4COO(CH_2)_3]_{15}O(CH_2)_3OH = C_{168}H_{158}O_{62}$: C, 63.63; H, 5.05; molecular weight, 3168. Found: C, 63.68, 63.51; H, 5.17, 5.12; molecular weight by micro boiling point method in ethylene chloride, 3180, 3030.

Hexamethylene **Phthalate.**—Twenty-nine and six-tenths g. of phthalic anhydride and 23.6 g. of hexamethylene glycol were heated to 180–190° under atmospheric pressure for two and one-half hours and then for one and one-half hours at 250° under 5 mm. In addition to the water, some phthalic anhydride collected in the receiver. The residual dark gum was purified by dissolving in benzene, decolorizing with Darco, and precipitating with ether. It formed a clear, light brown, sticky gum. Solubility: solvents are the same as for trimethylene phthalate, but hexamethylene phthalate is more soluble.

Anal. after drying to constant weight in high vacuum at 70". Calcd. for $C_{14}H_{16}O_4$: C, 67.75; H, 6.50; molecular weight, 248. Calcd. for $H[O(CH_2)_6OOCC_6H_4CO]_7O(CH_2)_6OH = C_{194}H_{126}O_{30}$: C, 67.35; H, 6.85; molecular weight, 1855. Found: C, 66.74, 66.84; H, 6.75, 6.85; molecular weight by freezing point lowering in benzene, 1700, 1830.

Decamethylene **Phthalate.**—Seven and four-tenths g. of phthalic anhydride and 9 g. of decamethylene glycol were heated at 190–200° for two hours under atmospheric pressure, and at 210–220° for one and one-half hours at 5 mm. The residue was dissolved in benzene, decolorized with Darco and precipitated by petroleum ether. It was a clear, light brown, thick, sticky sirup. Solubility: solvents for decamethylene phthalate are the same as for hexamethylene phthalate, but the former is more soluble.

Anal. after drying to constant weight in high vacuum at 70°. Calcd. for $C_{18}H_{24}O_4$: C, 71.01; H, 7.95; molecular weight, 304. Calcd. for $H[O(CH_2)_{10}OOCC_6H_4CO]_7O(CH_2)_{10}OH = C_{136}H_{190}O_{30}$: C, 70.80; H, 8.39; mol. wt. 2303. Found: C, 70.66, 70.44; H, 8.21, 8.26; molecular weight by freezing point lowering in benzene, 2250, 2060.

Ethylene **Fumarate.**—Fifty-seven and three-tenths g. of diethyl fumarate (0.33 mole) and 25 g. of ethylene glycol (0.4 mole) were heated for ten hours in a stream of nitrogen, the temperature being gradually raised from 190 to 230° and the pressure being reduced at the end to 4 mm. The residue weighed 35 g. or 75% of the calculated amount. It was accompanied by some insoluble material from which it was freed by solution in chloroform, filtration and precipitation with ether. It was washed several times with dry ether. It formed a transparent, slightly yellow, moderately tough mass. After drying it became insoluble in the common solvents.

Anal. after drying to constant weight in high vacuum at 70°. Calcd. for $C_6H_6O_4$: C, 50.70; H, 4.22. Found: C, 51.95, 51.89. H, 6.06, 6.12. Molecular weight determinations could not be made because of the lack of solubility after drying.

Ethylene Maleate.—Thirty-two and five-tenths g. of maleic anhydride (0.33 mole) and 18.6 g. (0.30 mole) of glycol were heated at 195–200° for four hours, and then for some time at 210–215° under reduced pressure. The residue (40 g.) was separated from some insoluble material by solution in warm ethylene chloride and filtration. It was precipitated by cold ether. The product separated as an oil but solidified on standing at 5–10' for two hours. It was a white powder. Most of it melted between 88 and 95°. After drying *in vacuo* it had become insoluble in the common solvents including ethylene chloride and it did not melt below 250°.

Anal. after drying to constant weight in high vacuum at 70°. Calcd. for $C_6H_6O_4$: C, 50.70; H, 4.22. Found: C, 49.87, 49.70; H, 4.36, 4.28. Molecular weight determinations could not be made because of the lack of solubility after drying.

For his kind assistance in the analytical work we here express our thanks to Mr. Wendell H. Taylor.

Summary

The following esters have been prepared: ethylene malonate, ethylene succinate, trimethylene succinate, ethylene adipate, trimethylene adipate, hexamethylene succinate, hexamethylene adipate, ethylene sebacate, trimethylene sebacate, decamethylene succinate, hexamethylene sebacate, decamethylene adipate, decamethylene sebacate, ethylene maleate, ethylene fumarate, ethylene phthalate, trimethylene phthalate, hexamethylene phthalate and decamethylene phthalate. Their molecular weights have been determined. They are all highly polymeric. Their properties are described and their structures are discussed.

WILMINGTON, DELAWARE

A NEW SERIES OF ANESTHETICS. ACYLANILINE DERIVATIVES

BY WALTER H. HARTUNG AND J. C. MUNCH

RECEIVED APRIL 25, 1929 PUBLISHED AUGUST 7, 1929

While working in these Laboratories with m-aminobutyrophenone, it was found that this compound produced anesthesia in the lips and tongue. Examination revealed further that an aqueous solution of its hydrochloride also was anesthetic to the lips and tongue and when injected subcutaneously into animals. This fact was of sufficient interest to warrant investigation of other bases, and their salts, of the same general type as aminobutyrophenone. Accordingly, a series of acylanilines and acyltoluidines was prepared, a series of anesthetics to which no previous reference has been found.

Table I lists those compounds that have been prepared and established by analysis, for only the first two have been previously recorded; the table also includes preliminary data on the toxicity and anesthetic potency of the hydrochlorides as compared to cocaine and novocaine. Other pharmacological studies will be published in an appropriate journal.

Higher homologs have been prepared, but because of the insolubility of their salts in water, due to hydrolysis, they have not been analyzed and, hence, are not included here.

TABLE I

COMPOUNDS AND ACTIVITIES

		M. L. D. of HCl salt mg/kg subcut to guinea pigs	Duration of anesthesia of 1 mg. applied to rabbit cornea, min.
1	m-Aminobutyrophenone	750	20
2	o-Aminobutyrophenone	Over 1000	25
3	m-Aminovalerophenone	Over 1000	25–90
4	(3-Amino-4-methyl-phenyl) ethyl ketone	Over 1000	3
5	(3-Amino-4-methyl-phenyl) propyl ketone	1000	7–14
6	(3-Amino-4-methylphenyl) isopropyl ketone	850	14
7	(3-Amino-4-methylphenyl) *n*-butyl ketone	1000	40
8	(3-Amino-4-methylphenyl) *iso*butyl ketone	500	45
9	Cocaine	60	30
10	Procaine	500	30

It is seen that in order to produce anesthesia at all, the alkyl portion of the ketone must be at least a propyl group, for the ethyl ketone derivative (No. 4) is practically inactive;[1] also, the isopropyl ketone (No. 6) is somewhat less active than the n-propyl compounds (Nos. 1 and 5). The toxicity is surprisingly low. While in the more highly anesthetic compounds the ratio of minimum effective dose to minimum lethal dose is quite high, yet it has been found that a solution of the salts injected subcutaneously into animals is quite irritating, probably because the salts of these aniline derivatives are so highly hydrolyzed in solution and free acid is formed.

Procedure

All of these compounds can be prepared easily, particularly the toluidine derivatives, according to the following scheme

$$\mathrm{ARCOR} \xrightarrow{\mathrm{HNO_3}} \mathrm{AR(NO_2)COR} \xrightarrow{\mathrm{H_2}} \mathrm{AR(NH_2)COR}$$

The mixed arylalkyl ketones were prepared from the appropriate acid chloride and benzene or toluene by the Friedel–Crafts reaction. All the ketones used here are described in Beilstein.

The nitro compounds were obtained by adding the ketones slowly to cold agitated fuming nitric acid in the ratio of 75 cc. of acid to a tenth mole of ketone, the temperature being kept below +10°. Fuming nitric acid was found most satisfactory in nitrating butyrophenone; it was also discovered that if most of the fumes were first removed by bubbling air through the acid, the nitration of butyrophenone went more smoothly

---

[1] This compound produces no anesthesia when injected subcutaneously in dogs.

and to greater extent. Hence for all subsequent nitrations fuming acid from which most of the fumes had been expelled was used. After complete addition of the ketone the mixture was allowed to stand in the ice-bath for another minute and then poured into excess ice water. In cases where the resulting nitro ketone was a solid, it was filtered off, washed and recrystallized from an appropriate medium; when liquid, it was quickly drawn off in a separatory funnel, washed with bicarbonate solution to remove adhering acid, dried and distilled. The yields varied from 60 to 80%.

The position taken by the entering nitro group was proved by oxidation to the aromatic acid, which was then identified.

The reduction proceeded very smoothly by dissolving the nitro ketone in an equal weight of acetic acid, adding an equal weight of mossy tin, warming and slowly adding sufficient concentrated hydrochloric acid to dissolve all of the metal. The amine was isolated by adding excess alkali, extracting with ether, drying and distilling. The yield of the amine was from 60 to 80% based on the nitro compound.

The hydrochloride salts were prepared by adding to an ethereal solution of the free base an absolute alcoholic solution of hydrogen chloride. The salt usually came down immediately and could be recrystallized from a concentrated solution in absolute alcohol; the mother liquors, however, retained the greater part of the salt in solution; it could be forced out by dilution with ether.

Experimental

***m*-Aminobutyrophenone and o-aminobutyrophenone,** with their corresponding intermediates, have been described by Morgan and Hickenbottom.[2]

Table II contains a tabular summary of the data concerning the other intermediate nitro compounds, and in some cases their semicarbazones.

TABLE II

NITRO COMPOUNDS

Ketone	Recryst. from	M. p. or b. p., °C.
m-Nitrovalerophenone	Liquid	145–150 (3 mm.)
(3-Nitro-4-methylphenyl) ethyl[a]	Dil. alc.	51
(3-Nitro-4-methylphenyl) propyl	Toluene	77.5
(3-Nitro-4-methylphenyl) isopropyl	Ligroin	41.0
(3-Nitro-4-methylphenyl) n-butyl	Ligroin	48.0
(3-Nitro-4-methylphenyl) *iso*butyl	Ligroin	54.5

The nitro ketones were oxidized with dilute nitric acid and in each case gave *m*-nitrobenzoic acid or the *p*-methyl-*m*-nitrobenzoic acid.

[a] This compound is described in Beilstein, 4th ed., Vol. VII, p. 318.

Summary

1. Acylanilines and acyltoluidines have anesthetic properties, particularly their hydrochlorides, if there is at least a butyrophenone skeleton.
2. Data concerning eight such compounds are given.
3. Six of the eight amines are new and are described together with their intermediates and, in some cases, their derivatives.

ROTENONE. I. REDUCTION PRODUCTS OF ROTENONE

BY F. B. LAFORGE AND L. E. SMITH

RECEIVED APRIL 29, 1929 PUBLISHED AUGUST 7, 1929

Rotenone, the active insecticidal principle of Derris *elliptica*, has been the subject of numerous investigations in recent years.[1] As it is perhaps natural to expect in the case of such a complicated compound, the published chemical articles contain numerous errors, corrections and retractions. It is indeed only in the past year that the empirical formula of rotenone has been established with certainty.

A large share of what is known of the chemistry of the compound has been contributed by the Japanese. Nagai[2] seems to have been the first to isolate it in a pure state. He gave it its present name and showed that it contained a keto group. Ishikawa[3] found that the compound was optically active, and Kariyone[4] showed the presence of methoxyl and an unsaturated bond, and obtained tubaic acid of the formula $C_{12}H_{12}O_4$

---

[1] The Insecticide Division of the Bureau of Chemistry and Soils has collected and abstracted over 250 articles on *Derris,* and a publication entitled "A Bibliography of *Derris (Deguelia)* Species Used as Insecticides," by Dr. R. C. Roark, will be issued shortly in multigraphed form.

by fusion with potassium hydroxide. Takei[5] in his first article added some facts to those found by the other Japanese investigators, but most of his results were reinterpreted in another publication[6] in which he finally decided upon the empirical formula $C_{23}H_{22}O_6$, which brought it into agreement with the figures obtained by him and others with respect to the methoxyl content and the analytical figures obtained for the phenylhydrazone, various empirical formulas having been proposed by previous investigators.

Butenandt[7] repeated some of the work of the Japanese chemists and established with certainty the empirical formula finally decided upon by Takei. He also prepared a number of new and important derivatives, but the facts so far obtained are insufficient to establish its constitution.

The investigations which will be described in this article deal principally with results obtained by the direct hydrogenation of rotenone and by the action of metallic zinc in alkaline alcoholic solution.

The simplest reduction product of rotenone, dihydrorotenone, was prepared by Kariyone by hydrogenation with palladium–barium sulfate catalyst and is described as prisms, melting at 216°, $[\alpha]_D^{20}$ $-222°$, yielding an oxime of melting point 258°.

Butenandt repeated the preparation of dihydrorotenone, according to the directions of Kariyone, confirmed the results of the Japanese investigator with respect to its physical properties and revised the formula to $C_{23}H_{24}O_6$. He employed dihydrorotenone for subsequent reactions to test a theory regarding the formation of his "derritol."

We have made a large number of experiments on the hydrogenation of rotenone with both palladium–barium sulfate and platinum oxide catalysts in acetone and acetic ester solutions, but our results differ widely from those reported by Kariyone and Butenandt.

With the first-mentioned catalyst in acetone solution, absorption of hydrogen takes place until about 56 cc. per gram of rotenone is consumed, when the reaction practically stops. With platinum catalyst, it proceeds rapidly to about the same point, but continues at a much slower rate without any definite end-point. In both cases two compounds are formed, if the reaction is discontinued after about one molecule of hydrogen has been absorbed. Since one product is an acid and the other a neutral compound, the two are easily separated by agitating the ethereal solution of the mixture with dilute sodium hydroxide solution. The acid is precipitated in crystalline form from the alkaline solution by the addition of mineral acid, whereas the neutral compound crystallizes on evaporation of the ethereal solution. Both are easily purified, the

[6] Takei, Ber., 61, 1003 (1928).

[7] Butenandt, Ann., 464, 253 (1928).

acid by crystallization from dilute alcohol, and the neutral compound from 95% alcohol. The combined yields of the two are about equal to the quantity of rotenone reduced. The acid crystallizes in needles and melts at 209°, the neutral substance in prisms melting at 164°. Both have the same empirical formula, $C_{23}H_{24}O_6$.

The optical rotation of the neutral compound was found to be $(\alpha)_D^{20} = 225''$. It yielded an oxime melting at 258°, the same compound that was obtained by hydrogenation of rotenone oxime. There seems to be no doubt that the neutral compound is dihydrorotenone, and except for the melting point, where we have noted a very great discrepancy, our results are in agreement with those found by Kariyone.

Both the acid and dihydrorotenone are capable of further reduction. On long continued reduction with platinum catalyst in acetic ester solution, the acid takes up another molecule of hydrogen, yielding a new acid of the formula $C_{23}H_{26}O_6$, melting point 215°.

Dihydrorotenone is more slowly reduced under the same conditions, and yields as one of the end-products the same acid as does the original acid product, perhaps together with some of the dihydrodesoxyrotenone of Butenandt, in which the keto group is reduced.

From these results, it is apparent that the rotenone molecule is simultaneously attacked in two places on catalytic reduction. One reaction probably involves the simple reduction of an unsaturated bond, yielding dihydrorotenone, the other, the opening of a lactone linkage to form an acid which still contains the original double bond of rotenone. Further reduction of either compound then leads to the same end-product, an acid containing four hydrogen atoms more than rotenone.

Butenandt obtained an acid $C_{23}H_{26}O_6$, melting point 206°, by the reduction of rotenone with platinum catalyst in saturated alcoholic ammonia, which may be identical with the acid described above of the same formula.

The isorotenone described by Takei does not absorb hydrogen as does rotenone, and it seems likely that it contains no unsaturated bond, but a ring structure instead.

Among the derivatives prepared by Butenandt is a phenolic compound of a bright yellow color, containing the original keto group, but possessing two carbon atoms less than rotenone, and named by him "derritol." It is formed with a compound called rotenol in which the keto group is probably reduced to an alcoholic group. These compounds result from the reduction of rotenone with zinc dust in alkaline alcoholic solution.

We have found that by slight modification of this method, either of these compounds may be made the predominating product. Two or more by-products of lower molecular weight are formed in this reaction, and have been isolated in crystalline form.

According to Butenandt's theory, the presence of a double bond is essential to the formation of derritol, since he was unable to obtain a corresponding compound from dihydrorotenone. It seems doubtful, however, that Butenandt was working with dihydrorotenone, for this compound readily gives a derivative of the formula of dihydroderritol as well as dihydrorotenol, when subjected to the alkaline zinc reduction process. The first-mentioned compound is, however, colorless instead of yellow, but it gives the same phenol reaction with ferric chloride as does derritol. Isorotenone, which probably contains no double bond, is also readily converted into isoderritol and isorotenol by reduction with zinc in alkaline solution. It seems probable, therefore, that whatever the mechanism of the reaction leading to the formation of derritol may be, it is not dependent upon the presence of a double bond.

Rotenone.—The preparation of rotenone is so simple as to require no detailed description. Three or four extractions of the coarsely ground, dried root with ether is sufficient to dissolve out all the rotenone, which crystallizes in nearly pure state from the concentrated extract. It is recrystallized from about 20 parts of boiling absolute alcohol. Crystallization takes place so rapidly on cooling that it is necessary to filter on a hot funnel. A little decolorizing carbon is used to obtain a pure white product. Rotenone melts at 163°. The yield of pure product varies with the quality of the *Derris* root. A fairly good material yields 2.5% of recrystallized rotenone, although we have analyzed samples containing less than 0.5%, while some Japanese chemists claim a yield of more than 6%.

Dihydrorotenone.[4,7]**—Four** grams of rotenone was added to 30 cc. of acetic ester containing about 0.3 g. of platinum oxide catalyst[8] previously saturated with hydrogen, and the solution was shaken in a hydrogen atmosphere. About 250 cc. is absorbed in three or four minutes, but if sufficient time is allowed, 400 cc. or more will be taken up. The reduction in this case, however, was discontinued after the absorption of about one equivalent of hydrogen. The solution was poured off from the catalyst, diluted with 100 cc. of ether and extracted several times with 5% aqueous potassium hydroxide.

The ether acetic ester solution was dried and evaporated to a colorless sirup which readily crystallized on cooling. The crystalline cake was rubbed up with a few cubic centimeters of alcohol, filtered and dried. The yield was in one experiment 1.9 g.; in another carried out under the same conditions, 1.7 g. The material is easily recrystallized from 95% alcohol, from which it is deposited in prisms often 1 mm. or more in length. The loss on recrystallization is small, and hence the compound is easily purified. After one recrystallization the compound melts at 164°, and further recrystallization does not alter the melting point. The analytical figures agree for the expected formula for dihydrorotenone.

Anal.[9] Subs., 0.0893, 0.0820, 0.0821: CO_2, 0.2285, 0.2100, 0.2107; H_2O, 0.0490,

---

[8] R. Adams and R. L. Shriner, THIS JOURNAL, 45, 2171 (1923).

[9] It is necessary to mix the substance with copper oxide in order to obtain satisfactory results.

Found: C, 69.77, 69.82, 69.98; H, 6.09, 6.07, 6.28; OCH_3, 15.27, 15.90. 0.3153 g. of subs. in 15 *cc.* of benzene rotated in a 2-dm. tube −9.46°; $[\alpha]^{20}_D$ = −225.2'.

Acid Reduction Product.—The aqueous alkaline extract from the reduction mixture yields a crystalline product on the addition of an excess of hydrochloric acid. The compound is best purified by dissolving in hot alcohol and adding an equal volume of hot water to the solution. The compound crystallizes in needles which melt at 209°.

If the reduction has been carried too far, a mixture of two acids is obtained, which will be referred to later.

The yield is, as in the first case described, 1.7 g., and 1.9 g. in the second. In another experiment, in which 6 g. of rotenone was reduced, 3 g. of acid was obtained, together with 2 g. of pure dihydrorotenone. Similar results were obtained in a number of other runs. The compound may be titrated but the end-point is not sharp.

Reduction of Rotenone **with** Palladium–Barium Sulfate Catalyst.—One and a half grams of rotenone was reduced in acetone solution with 0.5 g. of palladium–barium sulfate catalyst, according to the directions of Butenandt and Kariyone.

The absorption of hydrogen ceased in about thirty minutes, when 84 cc. had been taken up. This volume of hydrogen corresponds to the theoretical quantity for two atoms per molecule of rotenone. The solvent was evaporated and the residue dissolved in ether, and the two resulting compounds were separated in the manner described above. With palladium–barium sulfate catalyst the dihydrorotenone predominates in the mixture, 1.04 g. being isolated. The same acid was formed as in the cases where platinum was used, the yield amounting to 0.45 g. In another experiment in which 2 g. of rotenone was employed, 1.5 g. of dihydrorotenone was obtained.

Reduction of Dihydrorotenone.—One gram of dihydrorotenone was subjected to long-continued hydrogenation with 0.2 g. of platinum oxide catalyst in acetic ester solution. After about three hours, 20 cc. of hydrogen had been absorbed and the product was worked up as in previous cases. The ethereal solution of the reaction products was extracted with dilute potassium hydroxide, and on acidification yielded 0.08 g. of acid. It was recrystallized from 50% acetic acid. The product crystallizes in needles melting at 215°.

Anal. Subs., 0.0728: CO_2, 0.1854; H_2O, 0.0436. Calcd. for $C_{23}H_{26}O_6$: C, 69.30; H, 6.58. Found: C, 69.44; H, 6.65.

The neutral reduction product was probably mostly dihydrorotenone, but may have contained the dihydrodesoxyrotenone of Butenandt.

Reduction of the Acid Reduction Product of Rotenone.—One-half gram of the acid product described above, as obtained by reduction of rotenone, was subjected to a second reduction with platinum catalyst in acetic ester solution. About 36 cc. of hydrogen was taken up in fifteen minutes. The solution was evaporated and the crystalline product recrystallized from hot 50% alcohol. It crystallized in needles which melted at 215'. A mixture of this product and the acid obtained from dihydrorotenone melted also at 215°.

Anak. Subs., 0.0903: CO_2, 0.2285; H_2O, 0.0524. Calcd. for $C_{23}H_{26}O_6$: C, 69.30; H, 6.58. Found: C, 69.00; H, 6.46.

Apparently the two acids obtained—the one from dihydrorotenone and the other from the first acid reduction product—are identical.

If rotenone is allowed to absorb more than two atoms of hydrogen, a mixture of the partly and fully hydrogenated acids is obtained.

Oxime of Dihydrorotenone.—The oxime of dihydrorotenone is readily obtained either by hydrogenation of rotenone oxime[6] or by the action of hydroxylamine on dihydrorotenone.

Two grams of rotenone oxime in 50 cc. of acetone containing 0.4 g. of platinum catalyst, which had been saturated with hydrogen, absorbed 120 cc. of hydrogen in three to four minutes. The solvent was evaporated and the product recrystallized from absolute alcohol, in which it is difficultly soluble. It crystallizes in long needles and melts with decomposition at 256–257°. The yield is quantitative.

The same compound is also obtained when 1.6 g. of dihydrorotenone, 1.1 g. of hydroxylamine hydrochloride, 1.2 g. of anhydrous sodium acetate and a few drops of acetic acid in 20 cc. of absolute alcohol are boiled for from four to five hours under reflux. The oxime crystallized out on cooling and was recrystallized from absolute alcohol. The yield was 1.2 g. of product, melting at 256° with decomposition. A mixed melting point of the compound with that obtained by reduction of rotenone oxime showed no depression.

Kariyone also records 256° as the melting point of dihydrorotenone oxime.

Anal. Subs., 0.0948: CO_2, 0.2325; H_2O, 0.0512. Subs., 0.0212, 0.0229: AgI, 0.0249, 0.0264. Calcd. for $C_{23}H_{25}O_6N$: C, 67.15; H, 6.08; $2OCH_3$, 15.09. Found: C, 66.88; H, 6.00; OCH_3, 15.50, 15.24.

Benzenesulfonic Acid Derivative of Rotenone **Oxime.**—Five grams of rotenone oxime prepared by the directions of Takei was dissolved in 20 cc. of dry pyridine and 2 g. of benzenesulfonic acid chloride was slowly added. After about eighteen hours, the solution was poured into 100 cc. of 5% sulfuric acid. The amorphous precipitate crystallized in a few minutes. It was washed with water and recrystallized by dissolving in 30 cc. of hot alcohol and adding 15 cc. of hot water. It was again recrystallized from 90% alcohol and yielded 4 g. of white needles, melting at 143°.

Anal. Subs., 0.0242: AgI, 0.0212. Subs., 0.0225, 0.0230: 1.22, 1.22 cc. of $N/30$ HCl. Subs., 0.1481: $BaSO_4$, 0.0576. Calcd. for $C_{29}H_{26}O_8SN$: $2OCH_3$, 11.29; N, 2.55; S, 5.82. Found: OCH_3, 11.57; N, 2.53, 2.48; S, 5.34.

Numerous attempts were made to effect the Beckmann rearrangement on the compound, without success. Both alkaline and acid reagents decompose the compound in such a manner as to yield only tarry products from which nothing definite could be isolated.

Dihydrorotenone **Iso-oxime.**—Dihydrorotenone oxime is apparently converted into an isomeric compound by the action of concentrated hydrochloric acid. One gram was allowed to stand in contact with 15 cc. of concentrated hydrochloric acid for three days. It turned yellow, but the color disappeared on dilution with water. The product was recrystallized from absolute alcohol and formed long needles, melting at 270 to 273" with decomposition. The yield was quantitative.

Anal. Subs., 0.0999: CO_2, 0.2453; H_2O, 0.0537. Subs., 0.0225, 0.0208: AgI, 0.0252, 0.0243. Calcd. for $C_{23}H_{25}O_6N$: C, 67.15; H, 6.08; $2OCH_3$, 15.09. Found: C, 66.96; H, 5.96; OCH_3, 14.80, 15.44.

Preparation of Rotenol and **Derritol.**—In following the directions of Butenandt[7] for the preparation of these derivatives, it was found that while the yield of rotenol was fairly good, the product obtained from the alkaline extract was very difficult to crystallize and the yield of derritol very unsatisfactory. However, if the alcoholic potassium hydroxide solution containing the rotenone was first heated nearly to boiling, and the zinc dust was added subsequently, the yield of derritol was greatly improved. It was also found that by varying the percentage of potassium hydroxide, the quantities of both rotenol and derritol obtained could be varied at will.

Below are listed some typical runs, 3 g. of rotenone being used in each case.

Potassium hydroxide, %	5	10	15	20
Rotenol, grams	2.0	1.1	0.9	C.2
Derritol, grams	0.1	0.65	0.95	1 15

If larger quantities of rotenone were employed, mechanical stirring was necessary to obtain corresponding yields. The melting point of pure derritol was found to be 164°, instead of 161" as recorded by Butenandt, and rotenol melted sharply at 120° instead of 115°. The optical rotation of derritol was measured, with the following result: 0.1700 g. of substance in 5 cc. of $CHCl_3$ rotated in 1-dm. tube −2.25"; $[\alpha]^{20}_D = -66.2°$.

On concentrating the derritol mother liquors, a small quantity of another crystalline substance melting at 161° was obtained. The methoxyl content of this substance was about 1% higher than that of derritol.

Anal. Subs., 0.0207, 0.0213: AgI, 0.0279, 0.0283. Found: CH_3O, 17.80, 17.55

Since the yield was small, no further work was done on this compound.

The mother liquors of rotenol contain traces of an oil with a terpene-like odor; this oil is volatile with steam and can be isolated from the distillate by ether extraction. It has not yet been identified.

Preparation of Dihydrorotenol and **Dihydroderritol.**—The dihydrorotenol and dihydroderritol were prepared in the same manner as described for the preparation of rotenol and derritol. With 15% potassium hydroxide and 3 g. of dihydrorotenone, the yield of the alkali-insolublecompound (dihydrorotenol) was 0.8 g. It was recrystallized from methyl alcohol and melted at 131°. This is in agreement with the melting point of dihydrorotenol obtained by Butenandt. The yield of the alkali-soluble fraction was 0.5 g. Recrystallized from dilute methyl alcohol, it formed white needles, melting at 122°. It gives a strong color test for phenol with ferric chloride and the analysis indicates that it is dihydroderritol.

Anal. Subs., 0.0635, 0.0623: CO_2, 0.1576, 0.1550; H_2O, 0.0360, 0.0365. Subs., 0.0233: AgI, 0.0295. Calcd. for $C_{21}H_{24}O_6$: C, 67.74; H, 6.45; $2OCH_3$, 16.66. 'Found: C, 67.68, 67.84; H, 6.30, 6.51; OCH_3, 16.72.

Preparation of Isorotenol and **Isoderritol.**—The isorotenone used in the preparation of isorotenol and isoderritol was prepared by the method of Takei.[6] The product so obtained had a melting point of 184°. This figure is about 7° higher than that recorded by Takei, but confirms the figure found by Wright.[10] However, since the analytical data of both Takei and Wright for carbon and hydrogen were at some variance from the theoretical, the carbon and hydrogen determination was repeated on our product.

Anal. Subs., 0.0907, 0.0906: CO_2, 0.2324, 0.2320; H_2O, 0.0460, 0.0447. Calcd. for $C_{23}H_{22}O_6$: C, 70.05; H, 5.59. Found: C, 69.88; 69.84; H, 5.63, 5.48.

Isorotenone was treated with 15% potassium hydroxide and zinc in the same manner that has been described for the preparation of rotenol and derritol. From 3.0 g. of isorotenone, 0.9 g. of the product (isorotenol) insoluble in alkali was obtained. It crystallized from methyl alcohol in white needles, melting at 133°.

Anal. Subs., 0.0653, 0.0670: CO_2, 0.1611, 0.1711; H_2O, 0.0371, 0.0363. Subs., 0.0202: AgI, 0.0240. Calcd. for $C_{23}H_{24}O_6$: C, 69.67; H, 6.10, $2OCH_3$, 15.65. Found: C, 69.35, 69.63; H, 6.31, 6.03; OCH_3, 15.69.

[10] Wright, THIS JOURNAL, 50,3355 (1928).

The alkali-soluble portion gave 0.9 g. of a compound (isoderritol) which crystallized from methyl alcohol in light yellow plates, melting at 150°.

Anal. Subs., 0.0728, 0.0773: CO_2, 0.1814, 0.1925; H_2O, 0.0381, 0.0409. Subs., 0.0209: AgI, 0.0268. Calcd. for $C_{21}H_{22}O_6$: C, 68.07: H, 5.99; $2OCH_3$, 16.75. Found: C, 67.93, 68.00; H, 5.81, 5.88; OCH_3, 16.93.

Summary

Hydrogenation of rotenone results in the formation of a neutral and an acid compound as primary products.

The neutral compound is dihydrorotenone and is formed by the simple reduction of an unsaturated bond. Dihydrorotenone melts at 164°, instead of 216° as recorded by Kariyone.

The acid is easily separated from the reaction mixture and has the same empirical formula as dihydrorotenone, $C_{23}H_{24}O_6$.

On further reduction, both compounds yield the same end-product, an acid containing four more hydrogen atoms than rotenone. It seems likely that the molecule of rotenone is first simultaneously reduced in two places, while further hydrogenation results in the acid, $C_{23}H_{26}O_6$.

Contrary to Butenandt, dihydrorotenone is converted into dihydroderritol and dihydrorotenol by treatment with zinc in alkaline alcoholic solution.

Isorotenone yields isoderritol and isorotenol by the same treatment.

From these results, it follows that the formation of derritol is independent of the presence of an unsaturated bond in rotenone.

The preparation and properties of some other rotenone derivatives are described.

SYNTHESIS IN THE DIPHENYL ETHER SERIES. I. PREPARATION OF SOME SIMPLE DERIVATIVES[1]

BY C. M. SUTER

RECEIVED MAY 2, 1929 PUBLISHED AUGUST 7, 1929

Since diphenyl ether is now readily available, a further study of its derivatives and their preparation from the parent substance seems desirable. Most of such derivatives previously prepared have been made by the reaction between the salt of a phenol and an aromatic halogen compound.[2]

The preparation of o- and *p*-nitrodiphenyl ether by the nitration of

---

[1] Presented before the Division of Organic Chemistry at the Columbus meeting of the American Chemical Society, May, 1929.

[2] See Raiford and Colbert, THIS JOURNAL, 48, 2652 (1926), for recent work and bibliography.

diphenyl ether has been investigated by Mailhe and Murat,[3] who used fuming nitric acid in acetic acid solution. They claimed complete separation of the two isomers by freezing out the para derivative. No yields were reported. The *p*-nitro isomer was also obtained by Ryan and Drumm[4] in their nitration of diphenyl ether with nitrogen oxides or nitric acid, but no satisfactory method of preparation was indicated.

The method of Mailhe and Murat was found to be unsatisfactory because of the formation of alkali-soluble products and the necessity of using a large excess of nitric acid. Addition of sulfuric acid to the nitrating mixture increased the formation of tar. A very suitable method was found in the use of acetic anhydride as a solvent for the diphenyl ether, the nitric acid being added in acetic acid solution. This method was studied in detail to find the optimum conditions for a high yield of the mononitro derivatives. A table of results and details of the method are given in the experimental part.

The ortho and para isomers are not readily separable by fractional distillation as their boiling points at 20 mm. are only 4° apart. The para isomer is only partially separated by cooling to 0°, the remaining oil containing about 25% of this product. Since the amines obtained by reduction of this mixture are easily separated by the difference in solubilities of their sulfates, further purification of the nitro compounds was not attempted.

The corresponding nitriles were prepared from the two amines. These upon hydrolysis gave the acids which have been previously prepared by other methods.[5]

The bromination of diphenyl ether has been previously studied by Mailhe and Murat,[6] who reported a mixture of bromo and dibromo derivatives in which the bromine entered only the para positions. The structure of these compounds was proved by Le Fèvre and co-workers.? Repetition of the bromination using equimolecular quantities of bromine and the ether gave only 47% of *p*-bromodiphenyl ether, the rest of the bromine forming the dibromo derivative and a trace of higher brominated product. The large amount of dibromo compound formed indicates that the presence of a bromine atom in one ring inhibits only slightly the entrance of a second bromine atom in the other ring. This is in contrast to the influence of the nitro group, since in nitration of diphenyl ether it is possible to obtain a high yield of mononitro derivatives with the formation of comparatively little dinitro compounds.

[7] Le Fèvre, Saunders and Turner, J. *Chem. Soc.*, 1168 (1927).

Bromination of the *p*-nitro- and p-acetaminodiphenyl ethers gave only the compounds containing the bromine in the second para position, indicating that in general in diphenyl ether derivatives the tendency for bromine to enter the ortho position is small.

Experimental

Nitration of Diphenyl Ether.—Best results were obtained as follows. A solution of 100 cc. (2.4 moles) of fuming nitric acid (sp. gr 1.52) in 300 cc. of glacial acetic acid was added over a period of two hours to a well-stirred solution of 340 g. (2 moles) of diphenyl ether in 400 cc. of acetic anhydride kept in a water-bath at a temperature of 25–30°. After three and a half hours longer the reaction mixture was poured into water, the precipitated oil washed twice and distilled under reduced pressure. The mononitro compounds came over at 193–210° (uncorr.) at 14 mm., a mixture of 50 *g.* of dinitro isomers remaining in the distilling flask; yield, 370 g or 86% of the theoretical.

From 700 g. of the mononitro mixture kept at 0° overnight was obtained 270 g. of practically pure *p*-nitrodiphenyl ether by filtering and washing the crystals with methyl alcohol. Since reduction indicated about 25% of para isomer in the remaining oil, 54% of the original mixture was the para derivative. After two crystallizations from the same solvent the melting point was 57°; reported, 56, 60–61°.

The effect of various changes in the above method of nitration upon the yield obtained is indicated in Table I.

TABLE I

CONDITIONS AND YIELDS

$(C_6H_5)_2O$, moles	$(C_6H_5)_2O$ solvent, *cc.*	HNO_3, moles	HNO_3 solvent, *cc.*	Nitro, %	Dinitro, %	$(C_6H_5)_2O$ recovered, %
0 5	AcOH, 200	2.5	None	26	Trace	42
.5	AcOH, 75	1.5	AcOH, 100	36	Trace	14 (0.5 mole H_2SO_4)
.5	Ac_2O, 100	0.75	Ac_2O, 100	82	10	Trace
.5	Ac_2O, 100	1.0	Ac_2O, 100	62	33	None
.5	Ac_2O, 100	2.5	Ac_2O, 100	Trace	106	None (some trinitro?)
2.0	Ac_2O, 400	2.0	AcOH, 300	71	5	15
2.0	Ac_2O, 400	2.4	AcOH, 300	86	10	2
2.0	Ac_2O, 400	2.7	AcOH, 300	78	18	None
2.0	Ac_2O, 300	2.4	AcOH, 300	77	8	13
2.0	Ac_2O, 400	3.0	AcOH, 400	78	15	None

The first two reactions were run at 45–50', the others at 25–30°. In the reactions involving 2 moles of the ether the time of the reaction was five hours and twenty minutes. In the others it was about three hours.

***p*-Aminodiphenyl** Ether.—This was prepared by two methods: reduction of the nitro compound with iron powder and hydrochloric acid, or by the use of zinc and calcium chloride in a water–alcohol mixture. The latter gave the better results. To a well stirred mixture of 80 g. of zinc dust and 20 g. of calcium chloride in 75 cc. of water and 200 cc. of 95% alcohol on a steam-bath was added slowly **43** g. (0.2 mole) of the nitro compound. The reaction was very vigorous. After an hour the mixture was filtered to remove zinc oxide and unchanged zinc. The filtrate upon cooling deposited a few crystals of the hydrazo compound. These were removed and the solution diluted with water, which gave a light yellow mass of the amine; yield, 37 g., theoretical amount of crude product; m. p. 75–80"; reported m. p. 83.5° for the pure amine.[8] The crude product was readily purified by distillation, b. p. 187–189" (corr.) at 14 mm.

o-Aminodiphenyl Ether.—This was prepared similarly to the method given for the para isomer by reducing the mixture of nitro compounds, dissolving the mixed amines in hydrochloric acid and precipitating the *p*-amine as the sulfate, which is practically insoluble in cold water.[9] The yield in a typical run was 54% of ortho and 21% of para derivative. The o-amine distilled at 172–173° (corr.) at 14 mm., m. p. 44-45'; previously reported, 44°.[10]

The acetyl derivative solidified only after standing for several days. Recrystallized from dilute methyl alcohol, the melting point was 81°.

Anal. Calcd. for $C_{14}H_{13}O_2N$: N, 6.17. Found: N, 6.02, 6.16.

***p*-Cyanodiphenyl** Ether.—Thirty-seven grams of finely-divided p-aminodiphenyl ether was warmed on a steam-bath with 60 cc. of concentrated hydrochloric acid and 150 cc. of water. The suspension of amine hydrochloride was cooled to 0° and diazotized with 15 g. of sodium nitrite in 40 cc. of water. After half an hour the mixture was neutralized with sodium carbonate and poured into a cold solution of 25 g. of commercial cuprous cyanide in 25 g. of sodium cyanide and 150 cc. of water. The copious brown precipitate first formed evolved nitrogen when warmed to room temperature. The remaining oil was taken up with benzene, the benzene evaporated and the oil distilled, giving 15 g. of light yellow oil, b. p. 187–188° (corr.) at 14 mm. This gave a low nitrogen analysis.

Anal. Calcd. for $C_{13}H_9ON$: N, 7.17. Found: N, 6.65, 6.74.

Upon standing the oil partially solidified. The crystals were recrystallized from petroleum ether, giving colorless needles, m. p. 47°.

Anal. Calcd. for $C_{13}H_9ON$: N, 7.17. Found: N, 7.10.

Since the crude product gave a slight test for chlorine, the impurity present was probably *p*-chlorodiphenyl ether, as its boiling point would be close to that of the nitrile.

Upon hydrolysis with alcoholic potassium hydroxide the acid was formed in theoretical amount, m. p. 159–161°, which checks that previously obtained.[11]

o-Cyanodiphenyl Ether.—This was prepared similarly to the *p*-cyano derivative. The o-amine hydrochloride is readily soluble, which facilitates diazotization; yield, 15 g. of yellow oil, b. p. 188" (corr.) at 14 mm. Analysis for nitrogen gave low results.

Anal. Calcd. for $C_{13}H_9ON$: N, 7.17. Found: N, 6.75, 6.88.

The nitrile on hydrolysis gave the acid (m. p. 113°), which has previously received considerable attention because it offers a method for preparing xanthone.[12]

***p*-Bromo-*p*-nitrodiphenyl** Ether.—This has been previously prepared from *p*-bromophenol and *p*-nitrochlorobenzene.[2] Fifty grams of bromine was added slowly with stirring to a solution of 64.5 g. of p-nitrodiphenyl ether in 150 cc. of carbon tetrachloride. The mixture was then refluxed to complete the reaction. The solvent was evaporated and the residue recrystallized from 300 cc. of methyl alcohol; yield, 82 g. of white needles, m. p. 64"; reported previously, 65–66°.

***p*-Bromo-*p*-aminodiphenyl** Ether.—This was prepared by Le Fèvre and co-workers[7] but was not obtained in a pure state. The following method of preparation was found to be satisfactory: 29.4 g. of nitro compound was dissolved in 100 cc. of 95% alcohol,

---

[8] Ullmann and Sponagel, *Ann.*, 350, 105 (1906).

[9] Haeussermann and Teichmann, *Ber.*, **29**, 1446 (1896).

[10] Ullmann, *ibid.*, **29**, 1881 (1896).

[11] Griess, *ibid.*, **21**, 980 (1888).

[12] Graebe, *ibid.*, **21**, 502 (1888).

18 g. of iron powder added and 10 cc. of concentrated hydrochloric acid run into the well-stirred mixture slowly, After four hours on the steam-bath, the mixture was filtered hot, the filtrate diluted with water and the precipitated amine recrystallized from methyl alcohol; yield, 22 g. or 84%; m. p. 109°.

Anal, Calcd. for $C_{12}H_{11}ONBr$: N, 5.28. Found: N, 5.32, 5.28.

p-Bromo-p'-acetaminodiphenyl Ether.—This was prepared in two ways: by bromination of the acetaminodiphenyl ether and by acetylating the amine. One cc. of bromine was added to 4.5 g. of the acetyl derivative dissolved in 30 cc. of acetic acid and the solution warmed for a minute. Upon cooling, the hydrabromide salt of the desired product crystallized out, 3.1 g. of slightly yeilow product, m. p. 180–183" (uncorr.), which lost its hydrogen bromide upon standing. Dilution of the filtrate gave 1.8 g. of the bromo-acetamino compound, which was also obtained by recrystallizing the hydrobromide salt from dilute alcohol, m. p. 162–163° (corr.).

Anal. Calcd. for $C_{14}H_{12}O_2NBr$: N, 4.57. Found: N, 4.59, 4.64.

Bromination of Diphenyl Ether.—To a solution of 85 g. (0.5 mole) of diphenyl ether in 100 cc. of carbon tetrachloride was added 80 g. (0.5 mole) of bromine slowly with occasional shaking. Hydrogen bromide was steadily evolved. When the reaction was complete. the solvent was distilled off and the residue fractionated under diminished pressure. There were obtained 20 g. of diphenyl ether, 59 g. of p-bromodiphenyl ether, b. p. 160–165° at 14 mm., and a residue of the dibromo derivative soluble in petroleum ether, together with a trace of higher brominated products insoluble in petroleum ether.

Summary

1. The nitration of diphenyl ether has been studied in detail and a satisfactory method for preparing the mononitro derivatives outlined.

2. Ortho and para aminodiphenyl ethers are easily separated by the difference in solubility of their sulfates.

3. A number of bromine derivatives of diphenyl ether have been prepared.

4. A bromine atom in one ring of diphenyl ether affects only slightly substitution in the second ring, which is in contrast to the influence of the nitro group.

SCHIFF BASES DERIVED FROM 5-CHLOROVANILLIN

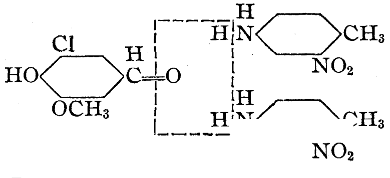
BY RAYMOND M. HANN, GEORGE S. JAMIESON AND E. EMMET REID

RECEIVED MAY 9, 1929 PUBLISHED AUGUST 7, 1929

The intermolecular condensation of aldehydes and amines with subsequent loss of water leads to the formation of the well-known Schiff's bases. Compounds of this class containing the vanillin nucleus as an integral part of their structure have been investigated by a number of workers. Senier and Forster,[1] in carrying out a series of studies upon the thermotropic properties and the effect of actinic light upon Schiff's bases, prepared a series of vanillin amines. Hann[2] studied the effect of the introduction of iodine into the vanillin residue upon the thermotropic properties of the resulting bases when the iodinated aldehyde was condensed with various amines. Hann and Spencer[3] isolated chlorovanillalaniline and chlorovanillal-or-naphthylamine. 2-Bromovanillin and 6-bromovanillin have been condensed with benzidine by Raiford and Stoesser,[4] and a number of bases from 5-bromovanillin and 5,6-dibromovanillin have been prepared by Raiford and Hilman.[5]

In the present paper is described a further series of compounds of 5-chlorovanillin with aromatic amines. In a majority of cases the reaction products were obtained quite readily in crystalline condition upon cooling an organic solvent containing molecular proportions of the necessary components.

In one instance, that of m-toluidine, no crystalline product could be isolated although the marked deepening of the color as the reaction mixture was heated indicated a progressive formation of the chromophore C=N—. That this conclusion was warranted was proved by separation of the picrate of 5-chlorovanillal-*m*-toluidine upon addition of alcoholic picric acid. Hantzsch and Schwab[6] reported derivatives of a type in which one molecule of aldehyde condensed with two molecules of an amine, and in this study such a reaction product was encountered with nitro-p-toluidine. The reaction in this case may be considered to proceed in the following manner



Senier and Forster, J. *Chem. Soc., 107, 452* (1915).

Hann, J. *Wash. Acad. Sciences,* 14, 79 (1924).

Hann and Spencer, THIS JOURNAL, 49, 535 (1927).

Raiford and Stoesser, *ibid.,* 49, 1077 (1927).

[5] Raiford and Hilman, *ibid.,* 49, 1571 (1927).

[6] Hantzsch and Schwab, Ber., 34, 834 (1901).

Unsuccessful attempts were made to prepare derivatives of chlorovanillin with o- and *p*-nitro-anilines, 2,4-dichloro-aniline and trinitroaniline.

Experimental

The general procedure adapted was to weigh out 3 g. of chlorovanillin and an equimolecular proportion of the desired amine, add 25 cc. of 95% alcohol (or more if necessary for complete solution), heat to boiling and allow to digest at boiling temperature for two to two and one-half hours. Upon cooling, the reaction product usually separated in crystalline condition, or if an oil it could be induced to crystallize by scratching with a glass rod. The crude reaction product was recrystallized from alcohol to constant melting point, dried and analyzed. All melting points were taken with Anschiitz thermometers and stems totally immersed in the heating bath. Table I gives a summary of the results.

TABLE I

SCHIFF'S BASES DERIVED FROM 5-CHLOROVANILLIN

Name	Formula	Appearance	M. p., (corr.), °C.	Analysis (Kjeldahl–Gunning–Arnold Method) Wt., g.	0.1 N HCl consumed, cc.	Nitrogen, % Found	Calcd.
5-Chlorovanillal o-toluidine	$C_{15}H_{14}O_2NCl$	Almost colorless cryst. powder	115	0.1022	3.5	4.80	5.10
5-Chlorovanillal *p*-toluidine	$C_{15}H_{14}O_2NCl$	Canary-yellow glistening leaflets	142	1125	4.0	4 98	5.10
5-Chlorovanillal m-nitro-aniline	$C_{14}H_{11}O_4N_2Cl$	Light yellow powder	160	.1141	7.4	9 08	9 14
5-Chlorovanillal *p*-chloro-aniline	$C_{14}H_{11}O_2NCl_2$	Orange-yellow cryst. powder; light yellow with gentle heat	128	1548	4.8	4.34	4.73
5-Chlorovanillal cymidine	$C_{18}H_{20}O_2NCl$	Sl. yellow glistening truncated prisms	146–147	.1068	3 4	4.46	4.41
5-Chlorovanillal *p*-anisidine	$C_{15}H_{14}O_3NCl$	Brilliant straw-colored needle-like crystals	131	.2352	7.9	4.70	4.80
5-Chlorovanillal benzidine	$C_{28}H_{22}O_4N_2Cl_2$	Yellow powder	251–252	.1041	4.1	5 52	5.38
5-Chlorovanillal *m*-aminobenzoic acid	$C_{15}H_{12}O_4NCl$	Yellow hard cryst. crust	207	.1541	5 2	4.73	4.58
5-Chlorovanillal *p*-aminophenol	$C_{14}H_{12}O_3NCl$	Iridescent brick-red granules	150	.1229	4 3	4.90	5 05
5-Chlorovanillal *o*-dianisidine	$C_{22}H_{21}O_4N_2Cl$	Orange powder	188	,1226	5 8	6.63	6 79

The picrates of the Schiff's bases crystallize readily from alcoholic solutions and it is sometimes possible to obtain the picric acid addition product when the base itself cannot be isolated. In the present study the picrates were obtained by dissolving one gram of the pure base in 10 cc. of 10% alcoholic picric acid, heating to boiling and then allowing to cool, when the picrate separated. It was usually pure, but was recrystallized once from 95% alcohol before analysis. The results are given in Table II.

[a] Dried at 120° for five hours.

5-Chlorovanillal-*bis*-nitro-*p*-toluidine.—Five g. of nitrotoluidine (1-CH_3-2-NO_2-4-NH_2) and 6.1 g. of pure chlorovanillin were dissolved in 25 cc. of absolute alcohol and the solution was refluxed for two and one-half hours. Upon standing overnight in the ice box, the reaction mixture solidified to a mass of orange-yellow crystals. These were recrystallized twice from 95% alcohol, from which the compound separated in hard yellow flower-like crystalline rosets which melted at 125° (corr.) to a clear yellow oil. Although the experiment was repeated three times no compound formed by a condensation of a single amine molecule could be isolated.

The picrate of the *bis*-compound separated in bright yellow micro-crystals when one gram of base was treated with 10 cc. of 10% alcoholic picric acid. It melted, although not sharply, at 148° to a clear red oil.

Anal. Base, subs., 0.1697: 0.1 N HCl, 14.1 cc. Calcd. for $C_{22}H_{21}O_6N_4Cl$, 11.85. Found: 11.64. Picrate, subs., 0.2019: 0.1 *N* HCl, 20.1 cc. Calcd. for $C_{28}H_{24}O_{13}N_7Cl$: N, 13.97. Found: N, 13.94.

Summary

Chlorovanillin has been condensed with o-, m- and p toluidines, *m*-nitro-aniline, p-chloro-aniline, cymidine, *p*-anisidine, nitro-p-toluidine, benzidine, m-aminobenzoic acid, p-aminophenol and dianisidine, and the condensation products have been characterized by the preparation of their addition products with picric acid.

BALTIMORE, MARYLAND, AND WASHINGTON, D. C.

NOTES

Reduction with Alcohols of Cinnamaldehyde to Beta-Phenylpropionaldehyde.—It was shown in a previous paper[1] that acrolein was reduced over alumina by propanol at 330° according to the equation

$$CH_2{=}CHCHO + CH_3CH_2CH_2OH = CH_3CH_2CHO + CH_3CH_2CHO \qquad (1)$$

Since it seemed possible that this was a general reaction for 2,3-unsaturated aldehydes, and since it offered a means of reducing the carbon to carbon double bond without reducing the carbon to oxygen bond, attempts were made to reduce cinnamaldehyde to β-phenylpropionaldehyde according to the equation

$$C_6H_5CH{=}CHCHO + C_3H_7OH = C_6H_5CH_2CH_2CHO + C_2H_5CHO \qquad (2)$$

The reduction was performed by passing 100 g. of cinnamaldehyde dissolved in 100 cc. of propanol over 5 g. of alumina catalyst (from hydrated alumina) at 330° and at the rate of 75 cc. per hour. The liquid product was distilled at atmospheric pressure to remove the low-boiling fraction (propionaldehyde, propyl ether, propyl alcohol and water) and under a pressure of 40 mm. of mercury to separate the β-phenylpropionaldehyde. Twenty grams of β-phenylpropionaldehyde was obtained, b. p. 130–133" at 40 mm.; 55 g. of cinnamaldehyde was recovered, b. p. 155–158° at 40 mm.; and 15 g. of a dark brown, viscous liquid boiling above 250° remained. The β-phenylpropionaldehyde was identified by the preparation of the oxime which was recrystallized until it had a melting point of 97° (corr.). The melting point is given in the literature as 93–94.5°.

From the amounts of the products obtained, it is estimated that 35% of the cinnamaldehyde and 50% of the propyl alcohol introduced had reacted in some way. About 60% of the cinnamaldehyde which reacted was converted into β-phenylpropionaldehyde, the rest having undergone polymerization, decomposition, etc. About 50% of the alcohol which reacted was used in the formation of propionaldehyde and β-phenylpropionaldehyde, almost all of the remainder forming propyl ether, except a very small amount which was converted into propylene and water.

Similar reactions occurred and approximately the same yields of β-phenylpropionaldehyde were obtained using 50 g. of cinnamaldehyde in 100 cc. of methanol, ethanol or propanol.

Acetoxymercuric Chloride, $CH_3COOHgCl$.—The replacement of hydrogen in organic compounds by mercury, mercuration, is practically always

---

[1] Weston and Adkins, THIS JOURNAL, 50, 1930 (1928).

effected by the use of mercuric acetate.[1] Other mercuric salts, like the nitrate and sulfate, may be used less conveniently. Salts like mercuric chloride which are not hydrolyzed do not give the mercuration reaction. For instance, pure phenol can be refluxed for days with mercuric chloride without giving any organic mercury compound.[2] With mercuric acetate, phenol gives a mixture of mono- and di-mercurated products instantly.

Since the chloromercuri compounds are often easier to purify than the acetoxymercuri compounds, a common practice is to mercurate a substance with mercuric acetate and immediately add sodium chloride to produce the chloromercuri compound.

A double salt of mercuric chloride and mercuric acetate, $HgCl_2 \cdot Hg(OCOCH_3)_2$ is recorded in the literature.[3] It was thought that this might really be a mixed salt, $ClHgOCOCH_3$, and might be used as a mercurating agent to give the chloromercuri compounds directly. The results showed that the salt is actually a *mixed* instead of a double salt but that it cannot be used for mercuration.

The salt was prepared from equimolar quantities of mercuric chloride and mercuric acetate in water solution. Evaporation under a variety of conditions gave large clear rhombic crystals entirely different from either of the original substances.

Anal. Subs. 0.1745, 0.1729: Hg, 0.1185, 0.1173. Calcd. for $C_2H_3O_2ClHg$: Hg, 67.97. Found: Hg, 67.91, 67.84.

Dimethylaniline, phenol and *p*-cresol were selected as substances easy to mercurate.[1] From dimethylaniline a white crystalline product was obtained which gave no precipitate with sodium hydroxide but gave mercuric sulfide with hydrogen sulfide. It did not melt. It was therefore not a mercurated dimethylaniline but a molecular compound similar to that obtained from dimethylaniline and mercuric chloride. When the mixed salt was heated for two weeks with a large excess of pcresol in aqueous alcohol, inorganic mercury still remained. No mercurated cresol could be isolated. A similar negative result was obtained with phenol.

These results show not only that the acetoxymercuric chloride cannot be used in place of mercuric acetate as a mercurating agent but that it is very stable in solution. If it gave any appreciable amount of mercuric acetate in solution, the latter would mercurate the substances tested.

This mercuric salt should be subjected to a physical chemical study.

NEW BOOKS

Volumetric Analysis. By I. M. KOLTHOPP, Professor of Analytical Chemistry at the University of Minnesota, with the collaboration of Dr. Ing. H. MENZEL, Dresden. Translated by N. HOWELL FURMAN, Ph.D., Associate Professor of Analytical Chemistry, Princeton University. Vol. II. Practical Volumetric Analysis. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, 1929. xiv + 552 pp. 18 figs. 15 X 23.5 cm. Price $5.00.

This book represents, beyond all question, a scholarly, interesting and valuable contribution to the literature of analytical chemistry and one which deserved translation. The original intention had been to write merely a treatise on the underlying theories of titration methods with the idea that H. Beckurt's revision of F. Mohr's well-known book would still serve as a text-book of practical methods, but since the publication of the Beckurt book there has been such a marked development in this branch of analytical chemistry that it seemed wise to write a new, critical and comprehensive work. The text of Beckurt, however, has been used freely in the preparation of this new book. To give some idea of the thoroughness with which Dr. Kolthoff has combed the journal literature, it may be mentioned that there are about one thousand footnotes and in one case more than fifty references are given in a single footnote. There is hardly a paper written during the last fifteen years on volumetric procedure that does not receive consideration or mention.

The book is not intended as a text for beginners. The discussion presupposes a considerable knowledge of chemical principles and only rarely are the directions given in sufficient detail for the beginner to follow.

[1] Chavanne and Becker, Bull. *soc. chim. Belg.*, 36, 591 (1927).

Moreover, for the sake of completeness many methods are mentioned which have not been found useful and the beginner could not fail to become bewildered by the mass of material contained in such a small space.

The book, despite its title, is not written for the practical man who merely wants to know how to make analyses and get results. Such a person cares little for the scientific explanation of the chemical principles involved and is more interested in the analysis of ores than of solutions of fairly pure substances. He wants to know the best method, if such there be, rather than all possible methods that are good. In this book, for example, the ferrocyanide method of titrating zinc solutions is considered in considerable detail, and the results of some careful experimentation by the author are given (although he overlooked the excellent monograph by Nissenson and credited to W. W. Scott a method recommended by F. G. Breyer of the New Jersey Zinc Co. in Scott's book). For the analysis of zinc ores, on the other hand, the reader is referred to the voluminous work of Lunge–Berl and this is the very thing that will interest the practical man.

The comments which Dr. Kolthoff makes upon the various methods are interesting and good. For the most part, chemists will agree with his conclusions. Outside of the book by Clark and Lubs, there is probably no English text that compares with this in the discussion of suitable indicators for neutralization titrations. Again, with respect to the selection of proper standards, the discussion is most painstaking and methods of testing and preparing many suitable standards are given.

Besides the usual methods of acidimetry and alkalimetry, oxidation–reduction and precipitation, methods are given involving the use of potassium bromate, potassium iodate, ceric sulfate and titanous chloride as titrating agents. The methods include the examination of organic substances and all sorts of nitrogen compounds, as well as inorganic substances.

The work of the translator has been faithfully done and he has included, with the cooperation of Dr. Kolthoff, about fifty pages of material not found in the original text. The book is practically free from misprints. At times the translation is too literal and the English rather awkward. Thus the use of the word performance on page 205 instead of *procedure* is a little unusual and the sentence on page 46, "The test of utility by means of *very* exactly performed titrations, on *the* other hand, remains after it has been once *performed*," is just a bit difficult to understand and arises from the attempt to translate literally. So faithful to the original text has Dr. Furman been, that he gives an atomic weight table as published in 1925 rather than change a figure in the original text.

Acting upon the suggestion of Schoorl, Kolthoff enthusiastically advocates the use of "rational" rather than "international" atomic weights because the more accurate values are based upon weighings corrected for air displacement. Thus he gives three atomic weight tables in the book, one of international atomic weights for 1925, Schoorl's *rational* table and one of atomic weights rounded to 0.1 per cent. In the opinion of the reviewer this practice is more likely to lead to confusion than if the latest table of international atomic weights is used alone. Schoorl's point may be a good one but there is little chance of the *rational* table being adopted. It is most important that chemists should all use the same atomic weights to avoid confusion.

W. T. HALL

Analytical Chemistry. Volume II. Quantitative Analysis. Based on the text of F. P. TREADWELL, Late Professor of Analytical Chemistry at the Polytechnic Institute of Zurich. Translated, enlarged and revised by WILLIAM T. HALL, Associate Professor of Analytical Chemistry, Massachusetts Institute of Technology. Seventh edition. John Wiley and Sons, Inc., New York, 1928. xiii + 848 pp. 152 figs. 15 X 23.5 cm. Price, $6.00.

The seventh edition contains numerous minor changes and a syllabus of the two semester course in analytical chemistry as given to students of chemical engineering at the Massachusetts Institute of Technology.

Considering the size and contents of the book, the material has been brought up to date in the case of magnesium and others but in the case of potassium the improvements of Smith and others have been omitted. It may be necessary in another edition to omit the details of methods which are obsolete and unreliable since they are only of historical importance. It is highly desirable that the relative precision and accuracy of the various methods of analysis of the same constituent be given.

A considerable amount of the theory is taken up in the class room, according to the syllabus. This feature necessitates references to other textbooks and articles in the journals. In this connection some space should be devoted to constant-boiling hydrochloric acid.

The milliequivalent of iodine is given as 0.12685 (p. 553) instead of 0.12693. The word "currents" (p. 464) was erroneously used in the electrometric titration discussion.

The book is surprisingly free from typographical errors.

The foregoing statements are suggestions from the ideal standpoint. Treadwell and Hall's book is and should be in the library of every chemist who aims to do precise and accurate analysis.

STEPHEN POPOFF

Photometric Chemical Analysis (Colorimetry **and** Nephelometry). Vol. II. **Nephelometry.** BY JOHN H. YOE, Ph.D., Professor of Chemistry, University of Virginia. With contributions by HANS KLEINMANN, M.D., Ph.D., University of Berlin. John Wiley and Sons, Inc., New York, 1929. xvi + **337** pp. **44 figs.** 15 X 23.5 cm. Price, $4.50.

Nephelometry and the rapid development that this branch of chemical analysis has undergone within the past decade are well epitomized in

Volume II of "Photometric Chemical Analysis." The latter initiates a systematic discussion of a subject which has heretofore been accessible only in scattered publications. Part I of "Nephelometry" is devoted to the history and description of various types of nephelometers, directions for use, nephelometric research and the theory of nephelometry. The remaining two parts discuss various inorganic and organic determinations, respectively. In the inorganic section comprising Part II the determinations of ammonia, arsenic, calcium, chlorine, phosphorus and sulfur are described in detail, while nephelometric procedures for acetone, amylase, dichloro-ethyl sulfide, fats, lipase, nucleic acids, pepsin, proteins, purine bases and trypsin constitute Part III. From a critical point of view it would appear that the chapter on the theory of nephelometry could be amplified to the distinct advantage of the book and might well include a discussion of coalescence and the factors influencing particle size. On the other hand, the discussion of the nephelometric constant appears to be somewhat labored. Furthermore, it will probably prove advantageous in future editions to transfer some of the material, such as the bisulfite method for lead and the ferrocyanide method for zinc, of Volume I to Volume II. These are nephelometric rather than colorimetric methods.

The thanks of all who are interested in this type of analytical procedure are due the author for so adequately crystallizing the literature of nephelometry and presenting it within such convenient compass.

LAWRENCE T. FAIRHALL

The Industrial Development of Searles Lake Brines. By JOHN E. TEEPLE, Ph.D., Consulting Chemist and Chemical Engineer. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York City, 1929. 182 pp. 60 figs. 15.5 X 23.5 cm. Price, $3.00.

It is a great pleasure to American chemists, whether in the industrial or the theoretical field, to have at last this story of the Searles Lake development, which all have heard about and but few have known about. Now at last we can know something about it—not all, by a large margin, but still a great deal; and all American chemists can now have a substantial pride both in the success of an immensely important enterprise, and in the courage which Dr. Teeple has shown in publishing some of the real facts about the work. Perhaps Dr. Teeple doesn't think that it has required courage to give the world the data on this magnificent piece of phase-rule work; but whatever it is that has given us the result, Dr. Teeple has it to an extent that is commendable, and it is to be hoped that his example may be copied.

Part I of the book gives a running tale of the history and development of the plant. The Searles Lake brine is essentially a seven-component system. The commercial output consists of pure potassium chloride and borax. The separation has required a carefully designed and well operated plant—which means good chemical engineering; and it has required an exact knowledge of the various equilibria possible in this system at a variety of temperatures—which means good physical chemistry. The combination is not new, but it has not been overworked in this country. May this book convince many that it is a profitable combination!

Part II contains the equilibrium data and diagrams. Under the *32* headings there are given data for sixteen systems of two components, thirty-eight of three components, and one of six components; some are reported on at one temperature only, many of them at several temperatures. The sulfates, carbonates, borates and chlorides of sodium and potassium form the majority of the systems. For each isotherm, the composition of the isothermally invariant solutions is given in units of weight and in molar units; the univariant systems are usually represented by straight lines. The sum total of this huge mass of data can be appreciated only after careful study. It is a compilation of phase-rule work which has no equal in American chemistry, and ranks with the classic investigations of van't Hoff and his colleagues on the Stassfurt salt deposits. There is very clearly still more to be printed about these systems, and it is to be hoped that in time each of them will be given to us in the detail necessary for complete usefulness. May Dr. Teeple and his coworkers thus increase still further our debt to them for this admirable investigation.

ARTHUR E. HILL

Anorganische und Organische Entfärbungsmittel. (Inorganic and Organic Decolorizing Agents.) By Dr. LEOPOLD SINGER, Vienna. Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1929. xi + 251 pp. 15.5 X 22.5 cm. Price, unbound, R. M. 20; bound, R. M. 21.50.

The author points out that in spite of the increasing importance of decolorizing agents no comprehensive summary of the work that has been done upon them exists. The present volume is designed to fill this gap. The field is, however, so large that the author has restricted himself to a consideration of the articles and patents that have appeared since the war.

Both inorganic and organic decolorizing agents, that is, both decolorizing earths and decolorizing charcoals are covered. The headings of the chief chapters are as follows: Occurrence, Properties, Theories of Decolorization, Manufacture, Use, Regeneration. At the end of the book, there is an excellent list of the patents dealing with decolorizing agents.

The treatment is intentionally non-critical; it is also brief in its discussion of the separate articles and there is no claim for completeness. The book is valuable in that it furnishes a convenient and reasonably complete compendium of the recent work on decolorizing agents. It will surely be of great use to investigators in this field.

ARTHUR B. LAMB

The Pyrolysis of Carbon Compounds. BY CHARLES DEWITT HURD, Associate Professor of Chemistry, Northwestern University. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., 419 Fourth Ave., New York, 1929. 807 pp. 15.5 X 23.5 cm. Price, $12.50.

The pyrolysis of carbon compounds is a branch of organic chemistry that is rapidly growing in importance from both the practical and theoretical point of view. Processes involving pyrolysis are being used in industry extensively and, to a limited degree, in the interpretation of the mechanism of the severing of molecules by heat. Much of the work in this field of organic chemistry has been largely empirical. There is a great opportunity at present to extend the work through experimentation planned to gain clearer concepts in regard to the strength of the forces of attraction between atoms and to the variations in electron affinities associated with changes in structure. The appearance of this monograph is, accordingly, especially timely.

The author has been particularly successful in gathering the large amount of material scattered throughout the literature. Much of it, no doubt, could not be found by consulting indexes only. The extensive array of facts has been well systematized and is presented in an interesting way. Wherever the facts warranted generalizations, they have been made. The several chapters deal with the various types of compounds, such as hydrocarbons, halogen compounds, acids, esters, etc. Molecular rearrangements produced by heat are considered in addition to reactions of decomposition.

On account of the large number of facts assembled, the author felt it inadvisable to include any consideration of the effects of catalyzers in reactions of pyrolysis. One naturally is averse to prolonging a book beyond 800 pages. It is the opinion of the reviewer, however, that even a brief treatment of the effect of catalyzers on the pyrolysis of the several classes of compounds would have added to the excellence of the book.

This monograph should be available to all students specializing in the study of organic chemistry, and to research workers in industrial laboratories. The author has accomplished a real service, which will lead to increased activity in the study of an important division of the science.

ACTIVITY COEFFICIENTS OF CADMIUM CHLORIDE AND BROMIDE

BY WALTER W. LUCASSE

RECEIVED NOVEMBER 6, 1928 PUBLISHED SEPTEMBER 5, 1929

When this investigation was started, the only recent electromotive force data from which the activity coefficients of the cadmium halides could be calculated were those of Horsch for cadmium chloride. His measurements using cadmium amalgam, led to values of the electromotive force for cells of the type

$$Cd \mid CdCl_2 \mid AgCl \mid Ag$$

and covered the range from very high dilution up to 0.0074 M with single points at 0.0995 and 6.62 M. In view of the peculiar properties of the cadmium halides, the low conductance ratios of their aqueous solutions, their tendency to form complex ions and other anomalous behaviors, it seemed well to study cells of this type somewhat more fully at higher concentrations and to extend the work to the other halides.

In the present paper are given results of measurements of cells of the type

$$Hg, Cd \mid CdCl_2 \mid AgCl \mid Ag$$

and

$$Hg, Cd \mid CdBr_2 \mid AgBr \mid Ag$$

from 0.01 M to 6 M and from 0.01 M to 3 M, respectively.

Recently Getman[2] has published values for the activity coefficients of the cadmium halides calculated, however, from measurements of cells using as the negative electrode mercury and the appropriate mercurous halide, except in the case of cadmium iodide where two series of determinations were made, one with silver–silver iodide electrodes and the other with lead amalgam–lead iodide electrodes.

Apparatus, Materials and Procedure.—The cell used was of the simplest type, being in the form of a straight tube about 2 cm. in diameter and 15 cm. in height. Connection

---

[1] Horsch, THIS JOURNAL, 41, 1787 (1919).

[2] Getman, *J. Phys. Chem.*, **32**, 91 (1928); 32, 940 (1928).

with the amalgam in the bottom of the tube was made by means of a sealed-in platinum wire. The other electrode was supported in the upper part of the solution by means of a rubber stopper which served also to prevent evaporation.

The electrodes were made in the manner described by Noyes and Ellis,[3] the silver being formed from silver oxide as was done by Lewis.[4] The silver chloride or bromide was formed on the electrode by making it the anode in a 0.75 M hydrochloric or hydrobromic acid solution for about five hours with a current of 0.004 ampere. A number of different sets of electrodes were made up throughout the course of the investigation, replacement being necessary more frequently with the bromide than with the chloride electrodes. Before using, the electrodes were tested against each other in each case in order to make sure that no inconsistencies were introduced from this source.

The cadmium amalgam was made by electrolyzing a solution of cadmium sulfate over a mercury cathode. When the electrolysis was completed the amalgam was allowed to flow into a small evacuated flask which was then pumped out until the last traces of moisture had been removed. As soon as it had been sealed off the flask was inverted and set aside for several days so that any oxide might rise to the surface and thus be removed. Finally, the lower part of the amalgam was allowed to flow into a large evacuated flask containing such an amount of mercury as to bring its concentration to that used. Just before making a series of determinations a quantity of the amalgam was drawn into an evacuated tube so built that a stream of hydrogen could be passed over the amalgam as it was being transferred into the cell.

Standard solutions of cadmium chloride and bromide were prepared by dissolving the purified salts in conductivity water and the concentration was determined by gravimetric analysis. These standard solutions were then diluted quantitatively by weight with boiled, twice distilled water to give the solutions used in the measurements.

In making the electromotive force measurements, the solution was introduced into the empty cell and after placing the silver–silver halide electrode in position, the cell was suspended in the thermostat. It was allowed to remain thus for about four or five hours in order to come to temperature and so that the electrode might come to equilibrium with the solution. At the end of this time, the electrode was removed for an instant while a few cc. of the amalgam were introduced. A reading of the electromotive force was immediately taken, followed by others at about half-hour intervals for the next three hours. The first reading showed no definite trend of variation from the subsequent ones but frequently, due perhaps to the temperature change caused by introducing the amalgam, varied more widely from the later readings than they did among themselves. In such cases the first reading was disregarded. Otherwise a mean of all of the readings throughout this period was taken as the value of the cell. The variation of the accepted readings was always very slight, never more than five hundredths of a millivolt, and showed no particular trend. In several cases the cell was allowed to stand for twenty-four hours after taking these readings. It was usually found at the end of this time that the electromotive force had dropped slightly, never, however, more than half a millivolt. All measurements were made at 25 ± 0.01°.

Results

In Table IA are given the results obtained from the cells containing cadmium chloride. The first column gives the molality of the solution (moles of salt per 1000 g. of water) and the second the observed electromotive force. Plotting these values led to a smooth curve continuous

with one obtained from the results of Horsch (E_2, Table II, of his paper) save for a displacement of 0.0686 volt. This displacement represented largely the difference in electromotive force of the cell with pure cadmium and with the amalgam of the concentration used but was due in part also to the differences in the potentials of the silver–silver chloride electrodes used. The electrodes used by Horsch were made by electrolytic deposition and when measured against hydrogen in 0.01 M hydrochloric acid led, upon taking 0.00924 as the value of the activity of H^+ and Cl^-, to the value −0.2258 for the standard silver–silver chloride potential. Electrodes made in the manner indicated above have been carefully studied and found to lead to a value of −0.2233. Taking into account this difference in the electromotive force[3,5] contributed by the silver–silver chloride electrodes in the two series, the correction to convert the electromotive force of the cell measured to what would be obtained with pure cadmium electrodes amounts to 0.0661 volt.

The activity coefficient of the electrolyte may be calculated from the electromotive force of a cell of the type used by means of the equation

$$E = E_0 - \frac{RT}{nF} \ln (4m^3\gamma^3) \qquad (1)$$

This equation upon introducing the numerical values, including that of

---

[5] *See also Gerke, Chemical Reviews, 1,* 377(1925).

the standard electrode potential of cadmium as calculated by Lewis and Randall[1,6] (0.3976), becomes for calculating the activity coefficient

$$\log \gamma = 4.28026 - \log m - 11.27\,E \qquad (2)$$

To the values of the measured electromotive force as given in the second column, 0.0661 volt was added as indicated above and from the result there was subtracted the value of the standard potential of the silver–silver chloride electrode (0.2233). In this manner were obtained the values of E given in Col. 3, from which the values of the activity coefficients in Col. 4 were calculated by means of Equation 2.

In Table IB are given values of the activity coefficient at certain concentrations calculated from the data of Horsch. In the first row are given the concentrations (molality X 10^4) and in the second the values of the activity coefficients at the corresponding concentrations as calculated by Lewis and Randall[7] on the assumption that at very high dilutions the values are the same as for barium chloride. In the third row are given values calculated in the same manner as those in Part A using, however, the value for the silver–silver chloride potential found by Horsch. The points determined by Horsch at the four lowest concentrations have been omitted because of the experimental uncertainty in this region. Both calculations lead to identical results at the concentrations higher than those given in IB (*i. e.*, at 0.003519, 0.0074, 0.0995 and 6.62 M). Due to a difference in interpolation between 0.0074 and 6.62 *M*, the values given by Lewis and Randall at round concentrations between 0.01 and 0.1 M vary considerably, especially at the lower concentrations, from those here given.

Above 0.05 M the values given in Table IA agree satisfactorily with those of Getman. Below this point, however, there is a marked difference in the form of the two curves, the values determined by Getman rising much more rapidly with increasing dilution. In Table II are given the results from cells containing cadmium bromide. The column headings have the same significance as in Table IA and the method of calculation was the same. The value of the standard potential of the silver–silver bromide electrode[8] was taken as 0.0734 and after correcting in the same manner as above to the value of the electromotive force with pure cadmium as electrode the calculation was made from the values in Col. 3 by means of Equation 2.

Above 0.02 M the agreement between these values of the activity coefficient and those given by Getman is satisfactory. Below this concentration there is again a sharper rise in his values than would be indicated by the points given here.

Discussion

The above method of computing the activity coefficient, because of using their value of the standard electrode potential of cadmium, is essentially accepting the extrapolation of Lewis and Randall[9] as a basis and was resorted to after attempts had failed to fit the data satisfactorily to the functions of Hückel and Brönsted.[10] This was due, very probably, to the presence of complex ions[11] whose equilibria would have to be taken into account in order to work out such a solution. It is possible also that the introduction of the higher terms[12] of the Debye-Hückel theory might lead to a more satisfactory expression of the results.

However, the deviations from the limiting law, unless very large errors have been made in the above assumptions, take place in an unusual manner and become apparent at very low concentrations. This can be seen from Table III, in which are given the values of the activity coefficient at very high dilutions. In the first column is given the molality and in the second the corresponding value of the activity coefficient of a bi-univalent electrolyte as calculated by the equation

$$\log \gamma = -1.749 \sqrt{m}$$

---

[9] The calculation of the activity coefficients of cadmium chloride would have been considerably simplified by accepting their value at some one concentration but, considering also the cadmium bromide, the method used seemed preferable.

a form to which the limiting function of Debye and Huckel may be reduced.[13] In the third column are given the values of the activity coefficient of barium chloride as calculated from the equation of Huckel using the constants obtained by Harned.[14] The equation agrees very well with the experimental data and we have assumed that it holds likewise at low concentrations. The percentage difference between the two values is given in the following column and indicates the magnitude of the deviation from the limiting law which might be expected in the case of a bi-univalent electrolyte. The fifth column gives the values of the activity coefficient of cadmium chloride as calculated above from the data of Horsch. The relatively large deviations given in the last column between these values and those calculated by the limiting law indicate the marked difference in the behavior of cadmium chloride from that of the more typical bi-univalent electrolytes.

The relation between the values of the activity coefficients of cadmium chloride and bromide given above and the molality can be expressed with a fair degree of accuracy over a considerable concentration range by the equation of Harned[15]

$$\log \gamma = \alpha m - \beta m^{\alpha'}$$

The constants a, β and a' were found to have the values 0.6, 1.75 and 0.38 for cadmium chloride and 0.2, 1.48 and 0.308 for the bromide. The activity coefficients calculated by these equations are given in the last columns of Tables I and II. By changing the constants somewhat closer agreement with the experimental values over shorter or over different

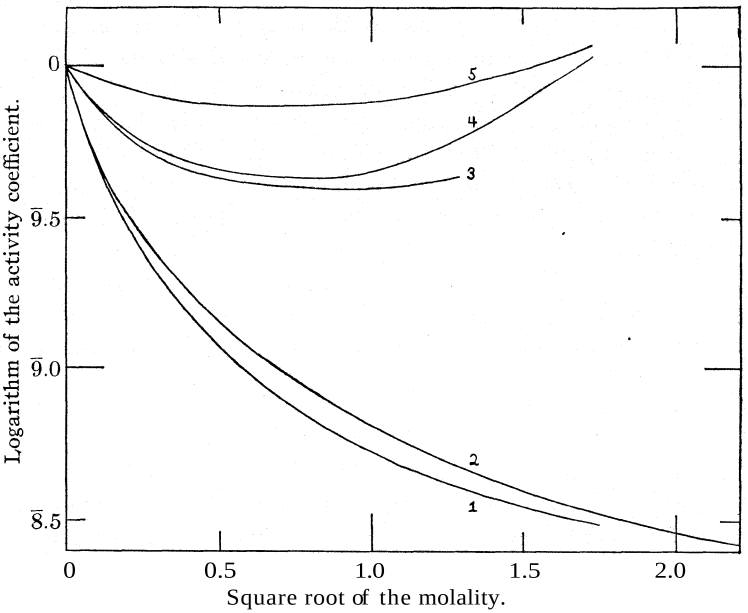
concentration ranges could be obtained. This would be without point, however, in view of the uncertainty of the extrapolation.

How different the behavior of the cadmium halides is from that of typical strong electrolytes can be seen further from Fig. 1, where the logarithms of the activity coefficients of cadmium chloride and bromide from Tables I and II, of lithium chloride from the data of MacInnes and Beattie[16] and of barium and strontium chloride are plotted against the square root of the molality. The curves of the alkaline earth chlorides all exhibit minima at concentrations below 0.7 M.[17] The activity coefficients of the cadmium halides show little if any such tendency even at very high concentrations. The point determined by Horsch at 6.62 M cadmium chloride leads to the value 0.025 for the activity coefficient and taken in conjunction with the values given in Table I might indicate a slight minimum in the region of the nearly saturated solution. However, from the general form of the three curves this seems unlikely. At moderate and high concentrations the values of the activity coefficients of the cadmium halides fall much below those of a typical bi-univalent electrolyte. Thus the values for cadmium chloride at 0.01, 0.1 and 1 M are 0.503, 0.219 and 0.065 as against



1, $CdBr_2$; 2, $CaCl_2$; 3, $BaCl_2$; 4, $SrCl_2$; 5, LiCl.

0.723, 0.499 and 0.397 calculated by Harned for barium chloride at the same concentrations.

By the nature of their assumption the values of the activity coefficient of cadmium chloride calculated by Lewis and Randall lie everywhere below those of barium chloride except at very high dilutions, where they are considered to be equal. Thus the values given at the first four concentrations in Table IB are considered to be the same for both salts. It seems not unlikely, however, that at very high dilutions the values for cadmium chloride might rise slightly higher than those for barium chloride. However, in view of the uncertainty of the data in this region and the very slight differences in the values of the activity coefficients of the alkaline earth chlorides at 0.0001 M (all very nearly 0.961) as calculated by the equation of Hückel, using the constants determined by Harned, it cannot be regarded as significant that the values given in Table IB cross in the neighborhood of 0.0003 M, below which concentration the values for cadmium chloride are markedly higher (0.970 at 0.0001 M) than those for barium chloride.

If the cadmium halides behave like typical strong electrolytes at all, it is only at extremely low concentrations. At moderate and high concentrations their behavior becomes such as to preclude them unquestionably from consideration as completely dissociated.

Summary

In the above paper are given values of the electromotive force at 25° of the cell Hg, Cd | CdX_2 | AgX | Ag. The concentrations of the cadmium chloride and bromide, represented by CdX_2, were varied from 0.01 to 6 *M* and from 0.01 M to 3 M, respectively.

From these data values of the activity coefficients of the salts have been calculated over these concentration ranges.

THE TRANSFERENCE NUMBERS OF CADMIUM CHLOFUDE AND BROMIDE

BY WALTER W. LUCASSE

RECEIVED NOVEMBER 6, 1928 PUBLISHED SEPTEMBER 5, 1929

The transference numbers of an electrolyte can be calculated from the results of measurements of concentration cells with liquid junction if the activity coefficient of the electrolyte is known as a function of the concentration. In the present paper are given values of the electromotive force of cells of the type

$$\text{Ag} \mid \text{AgX} \mid \text{CdX}_2\ (0.1\ \text{M}) \mid \text{CdX}_2\ (m) \mid \text{AgX} \mid \text{Ag}$$

in which X represents the chloride or bromide ion, and m is varied from 0.01 to 6 M and from 0.01 to 3 M, respectively. The preceding paper gives values of the activity coefficient over these concentration ranges.

The solutions were the same as those used in measuring the cells without liquid junction and the electrodes were made up in the same manner. The cells used were the same as those in a previous study[1] and consisted of three parts, the middle compartment containing an approximately one-to-one mixture of the solutions surrounding the electrodes in the end compartments. In each case about four hours were allowed to elapse between the time the cell was introduced into the thermostat and the time of taking the first reading. From four to six readings were then taken at half-hour intervals, the mean of which was accepted as the value of the cell. The variation in these readings was always very slight, seldom more than a few hundredths of a millivolt. All measurements were made at 25 ± 0.01°.

In Col. 3 of Table I are given the values of the electromotive force of the above cell at the molality (moles of salt per 1000 g. of water) given in the first column. To facilitate comparison the corresponding normal concentrations (equivalents per liter of solution) are given in the second column.

The method used in calculating the transference numbers was the same as that for the alkaline earth chlorides[2] which, although a somewhat disadvantageous modification of the method of MacInnes and Beattie,[3] was

---

[1] Lucasse, *J. Phys. Chem.*, 30, 562 (1926).

[2] Lucasse, THIS JOURNAL, **47**, 743 (1925). See, however, Jones and Dole, *ibid.*, **51**, 1073 (1929). In the present case a method depending upon algebraic analysis, although highly desirable, would be more difficult of application than in the case of barium chloride, in part because of the failure to find a suitable relationship between the concentration and the activity. The dangers inherent in the graphical method have been reduced to some extent by taking into account also the ratios of the electromotive force values of the two types of cells between each concentration interval. The form of the curve and the accuracy of the values, especially below 1 M, are as nearly true, it would seem, as can be obtained from the data at the present time.

here employed for the same reasons as given in the earlier paper. For a bi-univalent electrolyte the transference number of the cation is related to the electromotive force of a cell of the above type and the activity by the equation

$$dE_t = -t_+ \frac{3RT}{2F} d \ln a_\pm$$

The values of E_t were therefore plotted on a large scale as ordinates against the values of log A, at the corresponding concentrations, given in Col. 4. These latter (log A = 1000 log *a,)* were obtained from the preceding paper. The slope of the curve (dE_t/d log A) at each value of log A was then determined graphically and divided by the constant factor $3RT/2F$ (*i. e., 0.088733).* Finally, the values of the transference number thus obtained were plotted against log A and the values given in the last column of the table read directly from the smooth curve passing through the points.

In Table II are given the results obtained from the cells containing cadmium bromide. The column headings have the same significance as in the previous table.

Data at 25° with which to compare these results are very meager. However, Jahn and his associates have made a number of measurements of the transference numbers of cadmium chloride, bromide and iodide at 18° in solutions from about *0.005* to about *1* N by gravimetric methods.[4] His highest concentration for the bromide is about *1.1* N and up to this point the agreement is very satisfactory. Beyond this point the values continue to decrease, passing through zero at about 2.7 N to negative

1.314	2.48	− .01178	1.97248	.015
1.896	3.49	− .01164	2.05843	− .068
3.0815	5.38	− .01000	2.18070	− .185

values. This is not surprising in view of the tendency of these salts to form complex ions. The values for cadmium iodide pass through zero at a concentration of about one-half normal.

The agreement for cadmium chloride is less satisfactory. Jahn's results for this salt cover the range from about 0.006 to 0.12 N and vary irregularly between 0.427 and 0.432, from which Noyes and Falk[5] give the constant value over this range of 0.430 in their table of "best values." Throughout this range the values here determined are much higher and, furthermore, pass through a minimum. Beyond 0.12 N they rise to a maximum, after which they fall continuously, passing through zero at about 7.4 N to negative values. If these inflection points are erroneous the values of the cation transference number from these results remain practically constant at about 0.480 up to about normal concentration, after which they decrease continuously. Although the deviation of the E_t-log A curve from a straight line is very slight, it seems nevertheless too great in view of the number of points determined in this region to attribute to experimental error. The peculiar variation of the transference numbers of cadmium chloride in dilute solutions may perhaps better be assigned to changes in the nature of the ionic complexes in this region.

It would appear from Jahn's values for cadmium bromide that at concentrations below those compared here the transference numbers may have had smaller values, indicating a minimum at low concentrations.

---

[5] Noyes and Falk, THIS JOURNAL, 33, 1436 (1911).

Of this however it is impossible to be certain because of the small number of points and the experimental difficulties at high dilutions. In addition to this possible peculiarity of the transference numbers of the cadmium halides is the fact that all, as indicated above, pass to negative values at high concentrations. Again, while it is the general rule that values below 0.5 approach this quantity with increasing temperature, the results of Bein[6] on cadmium chloride would indicate that here too we find exceptional behavior, the values rising to markedly greater than 0.5.

Summary

Measurements at 25° of cadmium chloride and bromide concentration cells with liquid junction have been given at concentration ranges from 0.01 to 6 M and from 0.01 to 3 *M*, respectively.

From these data and the results from cells without liquid junction, the cation transference numbers of the salts have been calculated.

THE HEAT OF ADSORPTION OF GASES BY SOLIDS

BY K. F. HERZFELD

RECEIVED DECEMBER 28, 1928 PUBLISHED SEPTEMBER 5, 1929

Recently a number of measurements have been published for the heat of adsorption of gases by solids, showing a marked change of the heat with the amount of gas adsorbed. This change can be either a decrease[1] or an increase.[2] The first case can easily be explained by assuming the presence of spots with different affinity in the solid.[3] The spots with the higher affinity will adsorb the first part of the gas, and will in general give off larger amounts of heat.. To give a more detailed description of these sensitive spots Taylor[2,4] has pointed out that the surface of metals used in adsorption experiments is very rough. The atoms lying on the top of a small hill will be bound less strongly to their surroundings than the atoms in a flat surface. Accordingly they will have more of their chemical affinity left free to bind the atoms of the adsorbed gas in analogy to an idea familiar in organic chemistry. In the case of heteropolar salts as adsorbing substance, Kossel[5] has shown by direct calculation that the

electric force on the surface of a crystal is rather weak for *a* flat surface, stronger in a place where a new molecular layer starts above a large flat surface, forming a step, and strongest in a place where a corner is formed, or where only one or two ions project out of a flat surface. Such an explanation cannot hold in the cases in which the heat of adsorption increases with increasing adsorption, because, as we have said before, if the change in the amount of heat is due to differences in the adsorbing spots, the adsorption will start in the spots where the energy difference is highest (at least if these energy differences are above a certain limit), as we shall discuss in the second part. A possible explanation of the increase can be found in the assumption that neighboring adsorbed molecules attract each other, because one sees easily that the number of places where two or more adsorbed molecules lie close together will increase relatively stronger with the amount of gas adsorbed than the number of places with isolated adsorbed molecules. One could argue that the mutual attraction of the molecules could not amount to more than the heat of evaporation of these molecules when present in a bulk of liquefied gas, and could accordingly not account for the actual increase in heat of adsorption, which is much higher, but this argument proves to be wrong on account of a fact pointed out by DeBoer.[6] If we assume the adsorbing forces to be of an electrical nature, the molecules will be polarized (this term being used now to mean as well the orientation of molecules carrying a permanent dipole as the displacement of charges inside the molecule, which is usually meant by this term). Now this polarization of the molecules will set up much stronger forces between them than in the absence of an external field, in the same way in which two rods of soft iron which do not attract each other appreciably outside of an external magnetic field act on each other strongly if magnetized by an outside source. In the first part of the paper we intend to discuss the amount of interaction which can be produced in this way; in the second part, we are going to discuss the relation between the amount of gas adsorbed and the heat of adsorption.

Interaction of Adsorbed Molecules[7]

If the idea discussed in the introduction is proved, then it turns out that even in the case mentioned first (of a decrease of the heat of adsorption with the amount of gas adsorbed) there might be another reason for it apart from the possibility that different spots have a different sensibility. For the sake of simplicity we are going to discuss the adsorption of a gas without permanent dipoles on the surface of a heteropolar salt—for example, the adsorption of hydrogen or oxygen on the surface of rock salt

---

[7] Similar ideas have been developed, although in less detail, by A. Magnus, *Z. Electrochem.*, 34, 531 (1928).

or fluorite. There will be then in general two types of spots on the surface which can adsorb, the positive and the negative ions of the lattice. Let us assume, for the sake of convenience. that one of these two will adsorb slightly more strongly than the other; for example, in the case of fluorite the calcium ions will adsorb more strongly than the fluorine ions on account of their double charge. Accordingly, first the calcium ions on the surface will be covered by adsorbed gas molecules. It might now happen that the size of the gas molecules is so large that no more gas molecules can be adsorbed between them on the fluorine ions even if we increase the gas pressure. Then, without interaction of the molecules, one would expect for a uniformly flat adsorbing surface no change in the heat of adsorption up to this saturation point; but, instead, we would get a decrease because now all adsorbed gas molecules are polarized in the same direction, all being adsorbed on ions of the same kind, and would, accordingly, repel each other, decreasing the heat of adsorption the nearer they get to each other, which means the more the surface is covered. If, on the other hand, the size of the gas molecules is such that it does not obstruct adsorption on neighboring ions of opposite sign, these adjacent gas molecules will be polarized in opposite directions, and will accordingly attract each other, increasing in this way the heat of adsorption.

Let us now assume that a molecule of the adsorbed gas gets, under the influence of an electric force E, a polarization p

$$p = \alpha E \tag{1}$$

a is connected with the dielectric constants of the gas under normal conditions, ϵ_0, and the number of molecules N_0 contained in one cubic centimeter under these conditions is by the formula

$$\epsilon_0 - 1 = 4\pi N_0 \alpha \tag{2}$$

The energy of an adsorbed gas molecule at 0 temperature taken negatively will then be, calculated for one mole

$$U_0 = N_L \frac{\alpha}{2} E^2 \tag{3}$$

where N_L is the number of molecules per mole. In this formula the molecules are supposed to be *so* far apart that they do not act on each other. On the other hand, if we have two molecules with the polarization p_1 and p_2 at the distance r, their mutual electrostatic energy will be

$$\pm \frac{p_1 p_2}{r^3} \tag{4}$$

with the $-$ sign in case of opposite polarization and the $+$ sign in case of polarization in the same direction. The outside fields are assumed to be parallel. They will be in general (at least approximately) at right angles to the surface, due to the symmetry at the positions of equilibrium for adsorbed molecules. If we now consider a pair of adjacent gas molecules adsorbed on two different spots suited for adsorption and situated close to each other, with the electric fields E_1 and E_2, their total energy will be (again taken with the negative sign)

$$\frac{U}{N_L} = p_1E_1 \pm \frac{p_1p_2}{r^3} + p_2E_2 - \frac{p_1^2}{2\alpha} = \frac{p_2^2}{2\alpha} \tag{5}$$

(+ sign for opposite polarization, − sign for same polarization)

Here the first and third members give the electrostatic work gained by generating the dipole p_1 in the electrostatic field E_1 (motion of a charge e over a distance l_1, $el_1 = p_1$) and the dipole p_2 in the field E_2. The fourth and fifth members am the elastic energy stored up in the distorted molecules, while the second member corresponds to the mutual electrostatic energy of the dipoles according to (4).

The strengths of the dipoles p_1 and p are such that they make the potential energy to a minimum, and are accordingly given by the equations

$$\frac{\partial}{\partial p_1}\frac{U}{N_L} = E_1 \pm \frac{p_2}{r^3} - \frac{p_1}{\alpha} = 0$$

$$\frac{\partial}{\partial p_2}\frac{U}{N_L} = E_2 \pm \frac{p_1}{r^3} - \frac{p_2}{\alpha} = 0$$

or

$$p_1 = \frac{\frac{E_1}{\alpha} \pm \frac{E_2}{r^3}}{\frac{1}{\alpha^2} - \frac{1}{r^6}} \qquad p_2 = \frac{\frac{E_2}{\alpha} \pm \frac{E_1}{r^3}}{\frac{1}{\alpha^2} - \frac{1}{r^6}} \tag{6}$$

From this we get the negative energy of the pair

$$\frac{U}{N_L} = \frac{p_1E_1}{2} + \frac{p_2E_2}{2} = \frac{1}{2}\,\frac{\frac{E_1^2 + E_2^2}{\alpha} \pm \frac{2E_1E_2}{r^3}}{\frac{1}{\alpha^2} - \frac{1}{r^6}} \tag{7}$$

In the simplest case we put $E_1 = E_2$. This will hold either if the molecules are adsorbed only by a single kind of ion (negative sign, repulsion), or if the adsorbing power of both ions is about equal, as in potassium chloride, and the size of the molecules so that they can be adsorbed by neighboring ions. Then we get as energy per mole (not per pair of moles)

$$U = \frac{N_L}{2}\,\frac{F_1^2}{\frac{1}{a} - \frac{1}{r^3}} = \frac{N_L\alpha F^2}{2}\,\frac{1}{1 \mp \frac{a}{r^3}} \tag{8}$$

α and r^3 being referred to one molecule are cumbersome numbers. We introduce instead the numbers referring to 1 mole by multiplying with N_L in numerator and denominator of the fraction α/r^3, and use the equation in the form

$$U = \frac{N_L\alpha\, E^S}{2}\,\frac{1}{1 \mp \frac{N_L\alpha}{N_Lr^3}} \tag{8'}$$

The second factor gives the relative change of the heat of adsorption. To evaluate this numerically, we proceed in the following way. According to Equation 2

$$N_L\alpha = \frac{22,400}{4\pi}(\epsilon_0 - 1) \qquad (2')$$

where 22,400 is the number of cc. in a mole of a gas under normal conditions. The units in (1') are cc. The following table gives some examples

Gas......	H_2	O_2	N_2	CO	CH_4	C_6H_6
$N_L\alpha$......	0.55	0.80	1.13	1.28	1.70	6.04

On the other hand, N_Lr^3 can be calculated as follows.

If we have adsorption on each ion of a rock salt lattice, N_Lr^3 will be the volume of 1 mole of ions, or half the mole volume of the salt. If adsorption takes place only on positive ions, N_Lr^a will be four times the mole volume.

If we consider the adsorption on a metal to be of a similar nature[8] (see later), adsorption at the places where atoms sit will result in repulsion of the adsorbed molecules (positive sign). However, for a face-centered lattice like copper we would have to use half the molecular volume if we assume molecules to be adsorbed by positive ions in the lattice points, and molecules with opposite polarization adsorbed between them by electrons distributed uniformly in the space between the ions. If, on the other hand, adsorption could occur only at the lattice points occupied by metal atoms, the volume would have to be twice the molecular volume. The next table shows some examples.

	Adsorption on same kind of ions only (Repulsion between adsorbed molecules)			**Adsorption on both kinds of spots (Attraction between adsorbed molecules)**		
Substance......	NaCl	**Cu**	**Pt**	NaCl	**Cu**	**Pt**
N_Lr^3..........	107.6	10.05	12.9	13.5	3.56	4.56

Calculation of (8) from the data in the two tables shows that the mutual repulsion in the first case (repulsion) could not change the heat of adsorption appreciably for a salt, and might change it by about 10% on a metal in the case of small gas molecules. On the other hand, attraction between adsorbed molecules will increase the heat of adsorption by about 10% on salts and up to 40 or 50% on metals (again for simple molecules). This number will be made somewhat larger if not only pairs but groups of more molecules are formed. For example, if there is a group of three molecules, one adsorbed by a sodium ion and two on opposite sides of it, each adsorbed by a chlorine ion, the influence is increased by a factor of about 4/3.

We have computed this change only relative to the electrostatic part of the energy of adsorption. Compared with the total energy of adsorption this fraction might be less if a large part of the energy of adsorption is due to Van der Waals forces, as Lennard-Jones[9] suggests. On the other

---

[9] J. E. Lennard-Jones and Beryl M. Dent, *Trans. Faraday Soc.*, **24**, 92 (1928).

hand, it might be more if in the total heat of adsorption there is present a large negative part due to the forces of repulsion which act between the gas molecules and the adsorbing solid, and fix the position of equilibrium of the adsorbed gas molecules. These latter forces might play a more important part here than in the lattice energy of heteropolar crystals, because the force of attraction in adsorption changes more strongly with the distance than the inverse second power;[9] but, in any case, it seems that for the adsorption of carbon monoxide on copper,[2] one would not expect the rise to more than the double value.

We have to justify now our assumption that the adsorption forces in the case of metals are of the same nature as those in heteropolar salts. The newer development of the electron theory by Sommerfeld[10] has removed the difficulties which adhered to the older form of the theory, and has again made reasonable the old assumption that a metal is built up as a lattice of positive ions with the free electrons distributed approximately uniformly[11] between them. In this case there will be an electrostatic field on the surface of the metal of a type very similar to the one on the surface of a crystal like rock salt. However, it seems somewhat doubtful to the author whether the same idea can be applied to carbon (charcoal). If so, in this case the distance between neighboring atoms is $1.5 \cdot 10^{-8}$ cm., and the repulsing forces due to adsorbed molecules polarized in the same direction would require the introduction of 2.04 cc. as the value for $N_L r^3$ in (8), giving a very strong decrease of the heat of adsorption with the amount of gas adsorbed. If, on the other hand, adsorption on spots of opposite character could be possible, this could not be in the middle of the line between two atoms of carbon on account of the short distance but would have to be in the center of the ring formed by each group of six atoms in graphite. In this case the number to be inserted in (8) would have to be ~ 2 cc. To account in this way for the curve given by Polanyi[1] one would, therefore, explain the initial decrease of the heat of adsorption as due to the fact that gradually less sensitive spots come into action. The increase after the minimum would be due to the formation of pairs or larger groups with mutual attraction. The final sharp maximum with corresponding quick fall might mean the covering of much less sensitive places.

Thermodynamic Consideration of the Increase in the Heat of Adsorption.—The foregoing discussion might alleviate a difficulty which seems connected with the experimental result that the heat of adsorption increases. From the thermodynamical standpoint it is clear that the processes which will first take place are the ones where the decrease in free

---

[10] A. Sommerfeld, *Z. Physik*, *47*, 1 (1928).

[11] H. Bethe, *Ann. Physik*, *87*, 55 (1928); J. E. Lennard-Jones and H. J. Woods, *Proc. Roy. Soc. London*, 120,727 (1928).

energy is largest, while the experiment shows that at the same time the decrease in total energy is relatively small, and will be much larger for later processes of adsorption. This difficulty has been pointed out by the author to Dr. Kistiakowsky and Dr. Taylor, and has been mentioned by them.[2] R. E. Burk,[12] in his recent report on contact catalysis, states that it is perfectly possible that a large change in free energy is connected with a small change in total energy due to a large difference in the chemical constants. While this is quite true in principle, the difficulty in the present case rests just on the numerical values which seem possible from a kinetical standpoint, and it might be of interest to discuss the question here in general.

In any physical or chemical equilibrium the probability that a molecule will be in a certain state is proportional to[13]

$$ve^{+U/RT} \tag{9}$$

Here U is the negative potential energy in this state calculated for 1 mole, while v is the "average available volume" in the phase space which belongs to this state. Here we have assumed that the classical theory holds, the temperature being high enough to insure equipartition for the kinetic energy.

v is a product, each factor belonging to one degree of freedom. The connection between (9) and the free energy, p, is given by

$$e^{-\mu/RT} \sim ve^{+U/RT} \tag{9'}$$

where μ is the free energy of the system per mole. Some additional members referring to the kinetic energy are left out due to the fact that we have left out the corresponding factors in v. If we now want absorption to occur first at places with smaller heat of adsorption $(+$ U), these places must have a correspondingly higher v. If the logarithm of (9') is taken this statement is equivalent to the usual statement that a small change of the total energy might be overcompensated by a large change in the chemical constants (or the specific heats). To compensate for an increase in the heat of adsorption, there must be a factor 10 in v for each increase of about 1400 calories at room temperature, as $e^{-1400/RT}$ is about $^1/_{10}$th. We have therefore to discuss next the factor v.

(A).—When a gaseous molecule is bound, the three degrees of freedom of translation go over into three degrees of oscillation around the position of equilibrium. The corresponding factors in v are

$$\left(\frac{1}{\nu}\sqrt{\frac{kT}{2\pi m}}\right)^3 \tag{10}$$

Accordingly, for a given gas these factors are in the ratio ν_2^3/ν_1^3 for two different positions. From our knowledge of infra-red vibration it would

---

[12] R. E. Burk, *J. Phys. Chem.*, **32**, 1601 (1928).

[13] K. F. Herzfeld, *Physik. Z.*, **22**, 186 (1921); **23**, 95 (1922); "Kinetische Theorie der Wärme," Braunschweig, 1925.

seem improbable that the ratio of frequency for different positions could be larger than 2:1. A similar conclusion can be reached if we assumed that the potential energy of the molecule is given by an expression like $\frac{A}{r^m} - \frac{B}{r^n} = U$. A simple calculation shows that the frequency is given by

$$4\pi^2 M\nu^2 = \frac{mn}{r^2} U$$

This formula also makes it improbable that for a given substance the frequency might vary more than two-fold. This means that these three degrees of freedom could, at the utmost, be responsible for a change in v by a factor 8, which would compensate an energy difference of 1250 calories. (As in general the higher energy will correspond to a higher frequency, the change in v is in the right direction.)

(B) Internal Vibrations.—Burk suggests that the internal vibration of the molecule might be affected. Considering the strength of the internal forces compared with the strength of the adsorption forces, it seems improbable that the change in frequency of the internal vibration would be more than, let us say, 12%. Each internal degree of freedom will produce a factor similar to one of the three factors in (10). Accordingly, one would expect at the utmost compensation for 60 calories for each internal degree of freedom. The same will be true for an influence upon the vibration of the molecules of the adsorbing solid. It seems to the author, therefore, that this part can be neglected.

(C) Rotations.—If we have to deal with a gas molecule which is not monatomic, this gas molecule will have rotational degrees of freedom, two in number for a diatomic molecule or a straight molecule like carbon dioxide, three for all other molecules. For the adsorbed molecule it might be that on all spots adsorbing these rotations will be changed into oscillations of the axis of the molecule around an equilibrium direction. In this case we get in v again factors of the form (10). There will be two of them. for a straight molecule, three for a more complicated one. This will mean for the ratio of the two v's for two different spots a ratio of $(\nu_2/\nu_1)^2$ or $(\nu_2/\nu_1)^3$. In numbers this might make a factor of four or eight, if we assume again that the frequencies cannot be changed more than by a factor of two. Accordingly, this might compensate for 800 or 1250 calories. We might get a stronger effect if we assume that in one of the spots the molecule might turn freely, while in the other one it might only be allowed to oscillate. For example, it might be that on adsorption at a flat plane a molecule might turn freely around an axis perpendicular to this plane, while if adsorbed in a corner and accordingly fixed by more than one spot it might be forced to oscillate only.

To make an estimate for this case, consider a permanent dipole in a homogeneous electric field, E. This dipole will either rotate or oscillate around the field according to the strength of the field. A short calculation shows that Expression 9' takes the form

$$v_0 \frac{kT}{pE}\left(e^{+pE/kT} - e^{-pE/kT}\right)$$

where v_0 is the value of v for the rotation of a free molecule and p is the moment of the permanent dipole. If pE, the amount of potential energy at absolute zero, is sufficiently large compared with kT, this takes the form

$$v_0 \frac{kT}{pE} e^{U/RT}$$

showing that here we have in fact a factor kT/pE smaller than that appearing before the e-power with the larger energy. This formula is essentially no different from the formula just mentioned above because we have to deal here with vibrations around a given axis in two dimensions, in which case, according to our previous reasoning, we should have a factor proportional to $(\nu_2/\nu_1)^2$ and, on the other hand, pE is proportional to $\sim v^2$. But the factor which we find here cannot be much smaller than $^1/_{10}$th (corresponding to $NpE \sim 6000$ small calories), and would accordingly compensate for about 1400 small calories (for half this amount, if there were only one degree of freedom; for 1.5 the amount if there were all three degrees of freedom of rotation).

(D) A Majority of Spots with Low Heat of Absorption.—If we assume that there are two kinds of spots, one with a low heat of absorption, U_1 (number of these spots per square centimeter, N_1), and one with high heat of absorption, U_2 (number of these spots per square centimeter, N_2), we will get for the ratio of molecules adsorbed on these two kinds (n_1, n_2) if we make assumptions similar to Langmuir's

$$\frac{n_2}{N_2 - n_2} = \frac{n_1}{N_1 - n_1}\frac{v_2}{v_1} e^{(U_2 - U_1)/RT} \tag{11}$$

We call $n = n_1 + n_2$ the total number of molecules adsorbed and introduce the abbreviation

$$A = \frac{v_2 N_2}{v_1 N_1} e^{(U_2 - U_1)/RT} \tag{12}$$

Then a rather complicated calculation shows that the (differential) heat of adsorption will be given by

$$U_1 + (U_2 - U_1)\frac{1}{1 + \dfrac{AN_1N_2}{[(1-A)n_2 + AN_2]^2}} \tag{13}$$

The slope of this curve is shown to be

$$\frac{(U_2 - U_1)\, 2N_1N_2A(1-A)}{\left[(1-A)n_2 + AN_2 + \dfrac{AN_1N_2}{(1-A)n_2 + AN_2}\right]^3} \tag{13'}$$

Accordingly this expression will have the sign of $1 - A$, and will be positive (rising heat of adsorption) if A is smaller than 1, which means that the larger heat of adsorption of spots No. 2 can be compensated not only by a smaller volume v_2 but also by a smaller number of spots N_2. But if this is so, then the resulting curve will not have the form given by Taylor and Kistiakowsky,[2] because if one calculates now the next differential quotient, which measures the curvature of the line, it turns out to be given by the following expression, which appears multiplied with essentially positive factors (even powers)

$$(U_2 - U_1)\,\frac{A\,\frac{N_1}{N_2} - \left[A\left(1 - \frac{n_2}{N_2}\right) + \frac{n_2}{N_2}\right]^2}{A\left(1 - \frac{n_2}{N_2}\right) + \frac{n_2}{N_2}}$$

A discussion of this expression shows that with A smaller than 1 this expression is positive, which means a line curving upward, while in the experimental curve the slope is steadily decreasing with an increase in the amount adsorbed. It is not quite out of the question that such a form could be explained if we assume more than two different kinds of spots present,[14] but from the present assumption it would follow that N_1 large compared with N_2 does not explain the experimental facts.

(E) Formation of **Pairs.**[15]—We consider, now the effect of the attraction between two neighboring molecules. To simplify the formulas we assume that there will always be two adjoining spots on the adsorbent at which adsorption might take place. For example, in the case of a heteropolar salt as adsorbent there might be always pairs of ions sticking out scattered over a plane surface. We call N the number of these double spots per square centimeter, n the total number of adsorbed gas molecules per square centimeter, n_2 the number of pairs, and n_1 the number of adsorbed gas molecules occupying alone a spot which could hold two. We have, therefore, $n = n_1 + 2n_2$. Furthermore, we use the abbreviation

$$B = 4\,\frac{v_2}{v_1}\,e^{(U_2 - U_1)/RT} \tag{14}$$

We now compare the probabilities that a newly adsorbed molecule will either form a pair with one already adsorbed or will stay single. In the first case it will have to go in an empty place, the neighbor of which con-

---

[14] In fact, Kistiakowsky's calculations can be formally explained in this way. He gets a curve of the appropriate form by writing for the heat of adsorption

$$\Sigma_j N_j\,\frac{(W_j - w)\,e^{W_j/RT}}{1 + n^r k_j\,e^{W_j/RT}} : \;\Sigma_j\,\frac{N_j\,e^{W_j/RT}}{1 + n^r k_j\,e^{W_j/RT}}$$

If we write now $W_j - w = N_j$, $e^{W_j/RT} = v_j\,e^{U_j/RT}$, $v_j = e^{W/RT}\,k_j$, $N_j' = N_j/k_j$. This can be put into the form

$$\Sigma_j U_j\,\frac{N_j' v_j\,e^{U_j/RT}}{1 + n^r v_j\,e^{U_j/RT}} : \;\Sigma_j\,\frac{N_j' v_j\,e^{U_j/RT}}{1 + n^r v_j\,e^{U_j/RT}}$$

but then we have again the difficulty of explaining the large differences in the v's which would be given by the expression $v_j = k_j\,e^{W/RT}$.

[15] See also J. Frenkel, *Z. Physik*, 26,117 (1924).

tains already one adsorbed molecule. There are n_1 such places per square centimeter. On the other hand, if it should stay single it will have to go to a spot formed by two ions on which there is not yet any adsorbed molecule. There are $N - n_1 - n_2$ such spots. We get, therefore, the equation of our adsorption isotherm

$$\frac{n_2}{n_1} = \frac{n_1}{N - n_1 - n_2}\frac{B}{4} \tag{15}$$

Eliminating n_2 and calling the fraction x, which gives the amount adsorbed in terms of the saturation amount, $x = n/2N$, a short calculation gives the formula

$$n_1 = \frac{N}{B-1}\left(\sqrt{(B-1)4x(1-x)+1} - 1\right) \tag{16}$$

From this we get for the differential heat of adsorption

$$U_2 - (U_2 - U_1)\frac{1-2x}{\sqrt{(B-1)4x(1-x)+1}} \tag{17}$$

From this it follows that for a very small amount adsorbed (x negligible) the differential heat of adsorption will be U_1, as in this case all molecules will be single. With increasing amount adsorbed the relative amount of pairs will increase. For x very small the formula will be $U_1 + (U_2 - U_1)2Bx$, giving an increase in heat of adsorption. If B is comparatively large, we will have in the middle part of the range (x neither too small nor too close to 1) approximately the formula

$$U_2 - (U_2 - U_1)\frac{1-2x}{2\sqrt{Bx(1-x)}}$$

Finally, at the upper end, when $1 - x$ is very small, we get $U_2 + (U_2 - U_1)$ $2B(1 - x)$, a final linear increase ending up with a value $2U_2 - U_1$. The final differential heat of adsorption is much larger than half the heat of adsorption of one pair ($^1/_2\ 2U_2$) because, if we form one pair by adding one molecule at a place where another sits, we get not only the heat of adsorption U_2 of the newly added molecules, but we increase also the heat U_1 of the first molecule to U_2. (This is the same thing Polanyi[1] calls the heat of compression developed in the substance already adsorbed by further adsorption.) Roughly the curve which gives the heat of adsorption as a function of the amount adsorbed would look like Fig. 1. Unfortunately, it seems difficult to get this into agreement with the first part of the experimental curve. If we assume that U_1 is 5000 cal., and $U_2 - U_1 = 6000$ cal., we

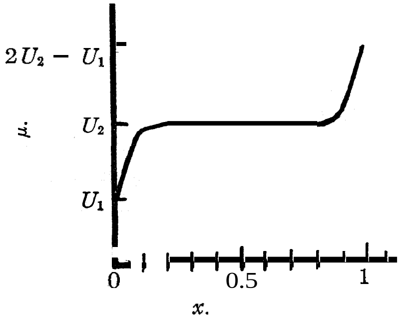

Fig. 1.—Heat of adsorption depending on the amount of gas adsorbed, if there is formation of pairs of molecules or dissociation.

have adjusted starting and end-point to the values 5000 and 17,000. Prom what we have seen before, this will make B = 400 even if we make v_1/v_2 equal to 100, which is the best we can do. This will give us for $x = {}^1/_{10}$th the differential heat of adsorption 10,600, and for $x = {}^9/_{10}$th, the value 11,400. In other words, there will be a very steep rise from 5000 to 10,600 during the adsorption of the first tenth of the gas; then only a rise of 800 more calories during the next ${}^8/_{10}$ths, and finally again a steep rise of 5600 calories during the last tenth of adsorption. The only way in which this could be smoothed out would be to make B smaller, but this would again necessitate making v_2/v_1 smaller, and as stated before there seems to be no way to do it. The decrease of the heat of adsorption beyond the maximum will, in any case, have to be explained by the presence of a different kind of adsorption spots, which are not included in N and which might be the spots on the plane surface. The inclusion of these in a way similar to (D) or to Kistiakowsky[14] might make somewhat smoother transitions in the first part of the curve, but would probably necessitate a higher value for $U_2 - U_1$, offsetting this advantage.

(F) Dissociation.—We have finally to consider the possibility advocated by Taylor and Kistiakowsky that on the spots with the lower heat of adsorption the molecules might be dissociated (into atoms for diatomic molecules, into other parts for larger molecules). In this case the lower heat of adsorption would be due to the energy necessary to dissociate the adsorbed molecule. If we again call N the number of available spots, assume furthermore that such a spot can be occupied either by a molecule (number n_2), or an atom (number n_1) we get the following equations for the adsorption

$$n_2 + \frac{n_1}{2} = n \quad \text{and} \quad \frac{n_2}{N - n_2 - n_1} - \frac{n_1^2}{(N - n_2 - n_1)^2}\frac{C}{4} \tag{18}$$

where C is an abbreviation for

$$C = 4\,\frac{v_2}{v_1^2}\,e^{(U_2 - U_1)/RT} \tag{19}$$

Here v_1 is the corresponding volume for one adsorbed atom; accordingly, v_1^2 is the volume for both atoms, U_1 is the heat developed by adsorption and subsequent dissociation into two atoms. If we again call x the ratio of the total amount adsorbed to the saturation amount $\left(\text{this time } x = \frac{n}{N}\right)$, we again get Equation 16, only with C instead of B. In the same way we get for the differential heat of adsorption, Equation 17 with C instead of B, and all of the subsequent discussion remains unchanged. The only task left is to discuss the numerical value of C, which amounts to discussing the ratio v_2/v_1^2. Now, as we said before, we can divide v_2 into two factors, $v_2 = v_2'v_2''$. Here v_2' is due to the oscillation of the molecule as a whole around its position of equilibrium, and accordingly the discussion under (A) applies. It follows that if we write for v_2/v_1^2 the expression v_2'/v_1 X v_2''/v_1, the first factor will be 8 to 10 at the best.[16] v_2'', on the other hand, is due to the motions of the adsorbed molecules around a certain direction, as stated in (C), and this motion might either be an oscillation or a free rotation. In the first case the ratio will be $(\nu_1/\nu_2)^3$, or again a factor of 10 at the best. In the latter case we get for this ratio $8\pi^2\nu_1^2I/kT$, where **I** is the moment of inertia. With a frequency of $\nu_1 = 10^{13}$ (wave length, 30μ), and a moment of inertia of 10^{-40}, this would make a factor 20, with a wave length of 100μ ($\nu_1 = 3 \times 10^{12}$) and $\mathbf{I} = 10^{-41}$, as in the case of hydrogen, the value would be 0.2. So it seems impossible to expect for v_2/v_1 anything smaller than 0.01, but probably the value will he much larger; accordingly for the same difference $U_2 - U_1$ measured experimentally, C will be at least as large as B. Accordingly, the interpretation of the effect as dissociation into atoms will lead to even greater difficulties than the assumption of formation of pairs discussed under (E).

Thermodynamical Comparison of Two Gases with the Same Heat of Adsorption

From what we have said before it will now be easy to answer the question under what conditions the amount of gas adsorbed on the same adsorbent under the same external pressure will be different for two gases with approximately the same heat of adsorption, or in other words, comparing the two gases when the same amounts are adsorbed, under which conditions the equilibrium pressure will be different. The equilibrium pressure will be inversely proportional to the expression (9'). If we have the same U, it will be inversely proportional to v. First of all, as far as the vibrations of the molecule, as a whole, are concerned (A of the preceding part), it is merely a question of how different the forces can be for the same energy; here, too, we might assume that these forces will surely not vary more than the ratio 1:4, giving at the utmost the factor 8. As far as the influences are concerned which are mentioned in (C), it seems possible that if one molecule is rotating freely, and the other one only oscillating around one direction, the latter might have a vapor pressure 20 times as great as the former. It might be that if we compare a mole-

---

[16] **Here the ratio is not really $(v_1/v_2)^3$ because the two things compared have not the same masses, but is $(m_1v_1^2/m_2v_2^2)^{3/2}$, or the ratio of the quasi-elastic forces to the third power, which is really the expression to which our discussion applies, but probably in this case it will be $m_1v_1^2$ which will be greater than $m_2v_2^2$, because the forces which bind the atom to the adsorbent are greater than the forces which bind the molecule, in spite of the fact that U_2 is larger than U_1. U_1 is not the heat liberated if we adsorb two atoms out of the gaseous state, but the heat liberated if we first adsorb a molecule and then dissociate it in the adsorbed state. For a detailed discussion see, for example, M. Polanyi, *Z. Elektrochem.*, 27, *142 (1921)*. From what we have said before it is more probable that v_2'/v_1 is 10 than $^1/_{10}$th.**

cule without permanent dipole, like H_2, with a molecule with permanent dipole, like H_2O, these conclusions might apply. Finally, if we compare molecules which dissociate with molecules which do not and adsorb only very small amounts, we might expect for the dissociating molecules a vapor pressure lower than that for the non-dissociating. This follows in the manner shown. The vapor pressure p_1 of the first kind will be proportional to $(n_1^2/N^2)v_1^2e^{(U_1/RT)}$ if so little is adsorbed that practically all is dissociated and only a small part of the surface covered. On the other hand, the vapor pressure of the non-dissociating type, p_2, will be proportional to $(n_2/N)v_2e^{(U_2/RT)}$. If, then, $U_1 = U_2$, and the same amount of moles, $n = n_2 = 2n_1$, is adsorbed, we find

$$\frac{p_1}{p_2} = \frac{n}{4N}\frac{v_1^2}{v_2}$$

The latter factor has been discussed in the last section of the preceding part while the first factor is small compared with one and proportional to the amount adsorbed.

Summary

In the first part it is shown that the increase in heat of adsorption with the amount of gas adsorbed can be explained by the interaction of the dipoles in neighboring molecules which are set up if we assume that the adsorption is mainly due to electric forces. In this case the interaction can be much stronger than the usual heat of evaporation would lead us to expect.

In the second part the thermodynamical difficulty connected with an increase in heat of adsorption is discussed. It is shown that the best explanation seems to be the formation of groups of adsorbed molecules sticking together.

Finally, the equilibrium pressures of different gases with the same heat of adsorption are compared.

ACTIVITY COEFFICIENTS OF ELECTROLYTES. III. THE PRINCIPLE OF SPECIFIC INTERACTION IN MIXTURES OF HIGH VALENCE ELECTROLYTES[1]

BY VICTOR K. LA MER AND R. GRAHAM COOK

RECEIVED FEBRUARY 6, 1929 PUBLISHED SEPTEMBER 5, 1929

1. Introduction

One of the most promising attempts to account for the specific deviations from the laws of uniform behavior of given valence type which individual strong electrolytes exhibit at concentrations other than those of extreme dilution, was presented by Bronsted[2] in a paper entitled "The Principle of Specific Interaction of Ions," published previous to the appearance of the theory of Debye and Hückel.[3] The purpose of this investigation was to subject this principle to *a* more extended test by studying mixtures of higher valence types of salts than in previous tests, in order to determine its limits of applicability. The fundamental physical assumption of the principle of specific interaction is that those specific effects which are due to electric forces should occur only between ions of *opposite* sign, since they approach each other closely while the electrical interaction between ions of *like* sign may be considered uniform, since on the average these ions are far apart.

This postulate may be expressed as follows.[2,3] If we let A_1B and A_2B represent two solvent salts with an anion in common (B), and having the same *equivalent* concentration, and let X represent an arbitrary cation and Y an arbitrary anion, present in small amount in the two solvents, then

$$\frac{f_{X(A_1B)}}{f_{X(A_2B)}} = F\ (A_1, A_2) \tag{1a}$$

and

$$\frac{f_{Y(A_1B)}}{f_{Y(A_2B)}} = F\ (A_1, A_2, Y) \tag{2a}$$

That is, the *ratio of the activity coefficients*, f, of the same cation in two equally strong solutions having an anion in common is a *function* only *of the nature of the two cations of the solvents;* the ratio of the activity coefficients of the same anion in two equally strong solutions having an anion in common is a function of the nature of the cation considered and the cations

---

[1] The material for this paper is constructed from a dissertation submitted by R. Graham Cook to the Faculty of Pure Science, Columbia University, in partial fulfilment of the requirements for the Degree of Doctor of Philosophy, May, 1928. An abstract was presented before the Division cf Physical and Inorganic Chemistry at the Swampscott (September, 1928) Meeting of the American Chemical Society.

[2] Brönsted (a) THIS JOURNAL, 44,877 (1922); (b) 45,2898 (1923).

[3] For a review and summary see La Mer, Trans. *Am. Electrochem. Soc.,* 50, 631 (1927).

of the two solvents. By equally strong solutions here is meant solutions of the same *equivalent* concentration, that is, where the total number of charges, irrespective of sign, is the same in each solution.

When solvents of the type AB_1 and AB_2, where the cation is common, are employed, Equations 1a and 2a become

$$\frac{f_{X(AB_1)}}{f_{X(AB_2)}} = F(B_1, B_2, X) \tag{1b}$$

$$\frac{f_{Y(AB_1)}}{f_{Y(AB_2)}} = F(B_1, B_2) \tag{2b}$$

As a result of these equations we should have the follo ing solubility relations, when we take AgCl, AgBr and TlCl as simple examples of uni-univalent saturating salts for purposes of illustration, and KNO_3, $NaNO_3$, $NaClO_3$, etc., to represent the aqueous solvents in which they are dissolved, namely,

$$\frac{S_{AgCl(KNO_3)}}{S_{AgCl(NaNO_3)}} = \frac{S_{AgCl(KClO_3)}}{S_{AgCl(NaClO_3)}} = \frac{S_{TlCl(KNO_3)}}{S_{TlCl(NaNO_3)}} = --- \tag{3}$$

and similarly when the terms cations and anion are interchanged

$$\frac{S_{AgCl(KNO_3)}}{S_{AgCl(KClO_3)}} = \frac{S_{AgCl(NaNO_3)}}{S_{AgCl(NaClO_3)}} = \frac{S_{AgBr(KNO_3)}}{S_{AgBr(KClO_3)}} \tag{4}$$

2. Plan of the Investigation

Although considerable experimental data[2,4] have been accumulated in support of the theory, the evidence has been confined to the use of solvent salts of the simple uni-univalent type, with the exception of an important series of measurements[2b] involving Na_2SO_4 and NaCl as the solvents for two $(1, -1)$ and two $(1, -2)$ types of saturating salts having the ion $[Co(NH_3)_4C_2O_4]^+$ as cation.

In no case have any of the tests involved solubility data where the ions of opposite sign in the solute and solvent salts (*i. e.*, X and B, and Y and A) were both of a valence higher than unity. Such a test is of particular interest since La Mer and Mason[5] found extremely marked deviations from the Debye limiting law under these conditions even at very high dilutions. They found entirely normal results for the solubility of **(3, — 1)** salts involving the luteo cobaltic cation in the presence of solvent salts containing univalent anions, but when they employed sulfate solvents, the experimental curve for $-\log f$, when plotted against the square root of the ionic strength, gave no evidence of fusing into the limiting law of Debye and Huckel. If it can be shown that the principle of specific interaction holds at 0.1 N concentrations for these salts, then one should have little fear in applying it to mixtures which obey the present form of Debye theory.

---

[4] Güntelberg, Z. *physik.* Chem., 123, 199 (1926).

[5] La Mer and Mason, THIS JOURNAL, 49, **363** (1927). See also the next paper of this series, *ibid.*, 51, 2632 (1929), where the same behavior is found for $La(IO_3)_3$.

Because of the important theoretical significance of this result, we first repeated La Mer and Mason's measurements at low concentrations on independently and freshly prepared salts (Parts 5 and 6). It also seemed desirable to determine whether or not the solubility ratios, when B_1 and B_2 were of different valence, retained the same numerical value when the common solvent cation A was changed in valence; and similarly when the common anion B was changed in valence and the solvents cations A_1 and B_2 are of different valence. If the equivalent concentration is the appropriate scale for comparisons regardless of the valence type of solvent, then no change should occur in these cases. Such a result, however, would conflict with the Debye-Hückel theory, for this theory predicts that the contribution due to primary Milner effect (ideal value dependent only on valence type and independent of specific properties) is proportional to the ionic strength and not to the equivalent concentration.

We should expect, therefore, to obtain constant ratios only when the ratios of the ionic strengths of the solvents remain unchanged at the same equivalent concentration. This proves to be the case.[6]

3. Experimental

The saturating salts employed in this investigation were (1) luteo-cobaltic di-ammino tetra-nitro cobaltiate, $Co(NH_3)_6[Co(NH_3)_2(NO_2)_4]_3$, which we shall represent hereafter by the symbol "LN₃" (S_0, the solubility in moles per liter in pure water, is 1.64 X 10^{-4}); (2) luteo-cobaltic di-ammino di-nitro oxalo cobaltiate, $Co(NH_3)_6[Co(NH_3)_2(NO_2)_2C_2O_4]_3$, symbol, "LOn₃" ($S_0 = 0.826 \times 10^{-4}$); (3) luteo-cobaltic ferricyanide, $Co(NH_3)_6Fe(CN)_6$, symbol, "LF" ($S_0 = 0.30 \times 10^{-4}$); and (4) luteo-cobaltic cobalticyanide, $Co(NH_3)_6Co(CN)_6$, symbol, "LC" ($S_0 = 0.22 \times 10^{-4}$). The first two, the tri-univalent salts, were employed in that part of the investigation where the conclusions of La Mer and Mason[4] were to be tested. All four were used as saturating salts for the experimental test of the specific interaction theory. The LN_3 salt became so soluble in tenth normal salt solutions that it was not possible to run a whole series of measurements on the same sample of saturating salt, and only a few measurements were made on this salt. On the other hand, it was possible to measure the solubility of the LOn_3 salt in a complete series of solvent salts, using the same sample throughout.

---

[6] Brönsted, ref. 2b, p. 2908 recognized the error in assuming that the primary Milner effect is determined by the equivalent concentration, but since he finds, p. 2909, "that the identity of values found by comparing two isotopic salts with a common cation appears only when the equivalent concentration is used" and "not at the same molar concentration or ionic strength"—a conclusion which our data also support (see data for $TlIO_3$ in the following paper)—it seemed desirable to obtain data bearing on this point in hopes of discovering an appropriate scale or scales for purposes of camparison. As far as we are aware no data bearing on this question have been presented.

The method used and the various precautions to be observed in carrying out the solubility determinations have been described in detail previously.[7] The original thesis should be consulted for further details concerning these measurements.

4. Preparation of Materials

Luteo-cobaltic Nitrate.—This salt was prepared by the iodine method of Biltz[8] and recrystallized from dilute nitric acid, washed with water containing a little nitric acid and finally thoroughly washed with 95% ethyl alcohol. It was dried in the oven at 100°.

Ammonium **Di-ammino** Tetra-nitro **Cobaltiate.**—The method given by Jdrgensen[9] was followed. The salt was twice recrystallized from water and allowed to dry spontaneously.

Ammonium **Di-ammino** Di-nitro Oxalo **Cobaltiate.**—This salt was obtained by adding to a solution of the above salt a solution of oxalic acid, in the correct molecular proportions according to the direction of Jörgensen.[10] It was once recrystallized from water. The luteo-cobaltic saturating salts were prepared from the above salts by methods previously described.[5,11]

Salts of Potassium and **Sodium.**—Potassium nitrate, potassium chloride, potassium sulfate, sodium chloride, sodium nitrate and sodium sulfate: the best "C. P." grades obtainable were twice recrystallized from redistilled water, dried in the oven at 120°, ground in an agate mortar and dried again at 120° for twenty-four hours.

Salts of Magnesium—Concentrated solutions of all salts gave no qualitative tests for calcium, barium, strontium, sodium, potassium or ammonium ions as impurities, except magnesium chloride, which contained very small amounts of ammonia, as described later.

Magnesium Sulfate.—A "C. P." product was twice recrystallized, dried in the oven at 50° for three days, then kept in a desiccator over phosphorus pentoxide for a week. The "apparent" molecular weight of the hydrate was determined by igniting a weighed sample to constant weight in a crucible, thus determining the magnesium as magnesium oxide. It was kept in a glass-stoppered bottle sealed with paraffin.

Magnesium Chloride.—Of all the solvent salts employed, this was the only one which was found to contain ammonium salts in appreciable amounts. A sample of Kahlbaum's "zur Analyse" grade was found to have the least amount of ammonia present. A 100-cc. aliquot of 0.1 N $MgCl_2$ solution contained ammonia equivalent to 0.15 cc. of 0.02073 N HCl. Thus one liter of the salt solution would contain only 0.5 mg. of NH_3. A stock solution of the $MgCl_2$ was made up, the chloride determined by titrating against 0.1034 N silver nitrate solution (Mohr method), and the solution diluted to 0.1000 N and re-checked against the silver nitrate solution before use.

Lanthanum Salts.—Samples of the hydrated salts were obtained from the Welsbach Company, who especially purified the salts to free them from cerium and other rare earths. Tests for cerium by the sensitive hypochlorite method[12] gave negative results.

Lanthanum Nitrate.—The apparent molecular weight of the hydrated salt was determined by igniting a weighed sample to lanthanum oxide.

Lanthanum Chloride.—The apparent molecular weight of this hydrate was determined by analyzing for chloride by the Mohr method. All salts were kept in glass-stoppered bottles sealed with paraffin.

Water.—Distilled water was redistilled over potassium permanganate acidified with phosphoric acid, through a block tin condenser, with steam escaping. The combined ammonia and indicator "blank" on water prepared in this manner amounted to 0.04–0.05 cc. of 0.02073 N HCl for a 100-cc. aliquot. The water was stored in pyrex "resistance glass" bottles, but never for a period longer than a week or ten days.

5. The Data at High Dilution

The solubility relations of two tri-univalent cobaltammines in very high dilutions of aqueous potassium sulfate at 25° are given herewith.

Table I

Luteo-cobaltic Di-ammino Tetra-nitro Cobaltiate, LN_3

HCl = 0.01031 N. Sample aliquot, 100 cc. Water blank, 0.06 cc.

The column "Av. cc. of HCl" gives the average amount of acid used to neutralize the ammonia distilled for the number of determinations indicated in the second column. "Av. dev." represents the average deviations of the individual determinations from this average. The fifth column gives the solubility of the saturating salt in moles per liter at 25 ± 0.007°. μ is the ionic strength. The last column gives the values for the relation log S/S_0, where "S" is the solubility of the saturating salt in the neutral salt solution and "S_0" the solubility in pure water.

6. Discussion of Results

The values obtained for the solubility of the present preparations of the two luteo-cobaltic salts in pure water agree with those found by La Mer and Mason for the LN_3 salt within 0.6%, and for the LOn_3 salt within 0.2%.

Similarly, their results, in which they found marked deviations from the theory given by Debye and Hückel for the case where these two cobalt-ammine salts were dissolved in potassium sulfate solutions, have been confirmed. The deviations have been found to persist down to even more dilute solutions, namely, to a solution of 0.0002 M K_2SO_4. In the figure the values of log S/S_0 are plotted against the square root of the ionic strength. I represents the curve for the LN_3 salt, II the curve for the LOn_3 salt, while the dotted lines represent the curves demanded by the limiting law for the respective salts. The experimental curves give no evidence whatever of fusing into the theoretical at the highest dilutions possible with this salt. The initial slopes of these experimental curves for

The upper curve is II, the lower I. The dotted lines represent the slopes of the Debye–Hückel limiting law for each salt. ⊡, This investigation; ⊙, La Mer and Mason.

the highly dilute regions (μ = 0.0005 – 0.002, and 0.001 – 0.0027) give "apparent" values for the constant α' of 1.4, which is nearly three times the theoretical value at 25°, namely, 0.504.[5,7]

8. Discussion of Results

Tables III, IV and V give the respective solubilities in 0.1 N solutions of the solvents indicated. It was impossible to include lanthanum sulfate as one of the solvent salts since crystals of some less soluble salt, possibly a double salt, separated out. Table VI summarizes the anion solubility ratios for the four saturating salts; also the ideal values for the ratios as predicted by the Debye-Hückel limiting law. Table VII gives the cation ratios in the presence of the common anions.

According to Equations 1 and 2, the bracketed groups labeled (a), (b), (c), etc., designate groups within which the ratios should be identical if the principle of specific interaction holds for all valence types of solvents at the same equivalent concentration. The numerical values in group (a) are not necessarily equal to those in group (b) since they represent ratios for two different valence types of saturating salts. Groups (c), (d) and (e) of Table VII should be constant within each group but not necessarily to each other, since here the anions of the saturating salts are different (Equation 2a).

If the principle of ionic strength were true at 0.1 N concentrations, all of the values in groups (a), (b), (c), (d) and (e) should be equal to unity, which is obviously not the case; the deviations from this principle vary from 2.7 to 8.7% for groups (c), (d) and (e), while the corresponding variations from the principle of specific interaction are 0.2% for NO_3^- to Cl^- in group (c) to 3.4% between Cl and SO_4 in group (d). Table III contains the most striking departure from the ionic strength principle which we have ever noted. The solubilities of the (3, – 3) LC salt change from 2.381 to $5.920 \cdot 10^{-4}$ mole liter in passing from 0.1 *N* $MgCl_2$ to 0.1 *N* K_2SO_4. The ionic strengths of the solvents are identical yet the ratio of the solubilities is 2.55 instead of 1.00.

In considering groups (f), (g), (j), (h), (k) and (i), where the ratios involve ions of different valence, it will be observed that the values remain constant only when the ideal values as given by the Debye limiting law also remain constant. In other words, *it is only when the ratios of the ionic strengths of the solvents remain constant, as well as the equivalent concentrations, that the numerical comparisons of principle of specific interaction can be applied.*

The solubility ratios for SO_4/Cl or SO_4/NO_3 change by 25% for LOn₃ and by 35% for LC, when the common univalent cation (K or Na) is exchanged for the bivalent cation Mg. A similar result holds for the cation ratios K/Mg in Table VII when the common anion changes from NO_3 or Cl to SO_4.

According to the Debye-Hückel theory, one might expect that this difficulty could be avoided by making all comparisons at the same ionic strength but, as can be pointed out more clearly in the next paper with $TlIO_3$, this procedure does not seem to work in agreement with the earlier statement of Brönsted.[13]

Nor does the equally plausible scheme of comparing *only the activity deviations* at the same equivalent concentrations, instead of the total activity coefficient, assist very materially. The reader may readily verify this statement by dividing the observed ratios in Tables VI and VII by the corresponding ideal values to eliminate the change in primary Milner effect. The change in the ideal values with valence type is too small to bring about the desired constancy.

Accepting the restriction that the valence types of the solvents must be chosen such that the comparisons do not involve a change in the ideal value, our data furnish some excellent confirmations of the principle of specific interaction. Thus the NO_3/Cl, SO_4/Cl and SO_4/NO_3 ratios are identical for the LN_3 and LOn_3 salts within 0.2% in the presence of K ion, as they should be, since the saturating salts contain the same cation (verification of Equations 1 and 2). This confirmation is particularly significant in view of the fact that not only are the ratios quite different from the ideal values for 0.1 *N* levels, but the Debye limiting law breaks down completely for both of these salts at such small additions as 0.0002 M K_2SO_4 (Parts 5 and 6).

Although the values in group (b) show slight variations when the common cation changes from K to Mg and finally to La, it should be noted that

---

[13] Ref. 2 a, p. 2909; *see* ref. 6.

changing the anion of the saturating salt from C^{---} to F^{---} produces a variation of only 0.2% in the presence of K and of 0.6% in the presence of Na. The constancy of the K/La and K/Mg ratios when the common anion is changed from NO_3 to Cl also deserves mention in extending the limits of applicability to higher valence types of solvents.

Since the saturating salts involve two different valence types, we can calculate the ratios of the interaction coefficients r_i of chlorides and nitrates, and of sulfates and chlorides, on the luteo cobaltic ion from the values given in Table VI by the methods outlined in detail by Brönsted,[14] and also, the ratios of the salting out coefficients (r_u).

The products of r_u by r_i give r_f, the ratios of the activity coefficients. These calculations yield

TABLE VIII[a]

CHLORIDE/NITRATE RATIOS

In presence of cation	r_i	r_u	r_f
K^+	0.883	1.043	0.921
Na^+	0.976	1.016	0.992
Mg^{++}	1.008	1.010	1.018
La^{+++}	0.872	1.045	0.911

CHLORIDE/SULFATE RATIOS

In presence of cation	r_i	r_u	r_f
K^+	8.60	1.001	8.60
Na^+	9.39	0.988	9.28

[a] The ratios of the interaction coefficients do not appear to be entirely independent of the other ions in the solution, as demanded by the principle. The nature of the calculation, however, makes the values extremely sensitive to small errors in the measurements, so that the disagreements may not be as marked as appears at first sight. Using (1, −1) and (1, −2) as saturating salts, Bronsted found the salting out ratio $r_u(Cl/SO_4)$ to be about 1.01, while our ratios based on (3, −1) and (3, −3) saturating salts are 1.00 and 0.99 in the presence of K and Na, respectively.

Summary and Conclusions

The principle of specific interaction has been given an extensive experimental test by means of solubility measurements on high valence types of mixtures, using (3,−1) and (3,−3) saturating salts in the presence of (1,−1), (1,−2) (2,−1), (2,−2) and (3,−1) types of solvent salts at 0.1 N concentrations. It is shown that the principle can be extended to higher valence solvents provided that comparisons are restricted to types in which the ratio of the ionic strengths remains unchanged when changing the common solvent ion at the same equivalent concentration.

The results of La Mer and Mason, in which they found very marked deviations from the limiting law of Debye and Hückel at high dilutions when the ions of opposite sign are of high valence, have been confirmed.

The principle of specific interaction retains its validity in these cases in

---

spite of the failure of the Debye limiting law to hold at concentrations as low as 0.0005μ.

ACTIVITY COEFFICIENTS OF ELECTROLYTES. IV. THE SOLUBILITIES OF LANTHANUM AND THALLOUS IODATES IN AQUEOUS SALT SOLUTIONS AND THE PRINCIPLE OF SPECIFIC INTERACTION[1]

BY VICTOR K. LA MER AND FREDERICK H. GOLDMAN

RECEIVED FEBRUARY 6, 1929 PUBLISHED SEPTEMBER 5, 1929

1. Introduction

The purpose of this investigation was to determine (a) whether or not the highly abnormal results (from the viewpoint of the present form of the Debye-Hiickel Theory) obtained in this Laboratory by La Mer and Mason,[2] and since confirmed by Dr. Graham Cook,[3] for the solubilities of tri-univalent cobaltammines dissolved in solvents containing high valence anions were general phenomena, or simply specialized cases peculiar to the cobaltammine family; and (b) in how far Bronsted's principle of specific interaction would hold for other types of salt mixtures where the principle of ionic strength and the present form of the Debye-Hiickel theory have proved to be inadequate.

To answer these questions the solubility of lanthanum iodate was measured, using aqueous solutions of the chlorides, nitrates and sulfates of potassium, sodium, magnesium, lanthanum and zinc as solvents. Lanthanum iodate is particularly suited for this study since La^{+++} is the only trivalent cation, aside from the cobaltammine ions like $[Co(NH_3)_6]^{+++}$, which does not appreciably hydrolyze in aqueous solution. The neutrality of the lanthanum solutions was proved by colorimetric tests and by the fact that iodine was not liberated on addition of potassium iodide until free acid was added.

Similar studies were made of the solubility of thallous iodate in order to have a symmetrical uni-univalent salt with the same anion for comparison with lanthanum iodate.

These saturating salts are stable[4] and of an appropriate order of solubil-

[1] Preliminary reports of this work were presented at the Detroit (September, 1927) and Swampscott (September, 1928) meetings of the American Chemical Society. The present paper is constructed from a Dissertation by F. H. Goldman submitted to The Faculty of Pure Science, Columbia University, in October, 1928, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

ity, the solubility of lanthanum iodate being 0.0008901 molar at 25°, while thallous iodate is 0.001844 molar. The latter is nine times as insoluble as thallous chloride, which has been much used by previous investigators.[5] The iodate can also be analyzed more accurately and more easily than the chloride. Thus one mole of thallous iodate reacting with potassium iodide furnishes six equivalents of iodine; while one mole of lanthanum iodate furnishes eighteen equivalents! Furthermore, it is possible to use solutions of salts with an ion in common as solvents, *e.* g., lanthanum sulfate, lanthanum chloride, lanthanum nitrate, without causing the solubility to decrease below the point of analytical detection.

The only previous[6] solubility measurements on lanthanum iodate were made by Harkins and Pearce.[7] They measured the solubility of this salt in the presence of lanthanum nitrate, lanthanum ammonium nitrate and sodium nitrate. In utilizing these measurements to test the validity of the principle of ionic strength, Lewis and Randall[8] say, "Unfortunately an error seems to have slipped into the first two of these series" (lanthanum nitrate and lanthanum ammonium nitrate). This criticism adds particular interest to the study of this salt, since in the light of La Mer and Mason's investigations it is reasonable to suppose that the difficulty might be due to the failure of the principle of ionic strength and not to the data.

2. Theoretical

Debye and Hückel,[9] on the basis of the first approximation of the solution of the Poisson-Boltzmann equation, attempt to take "ion size" into account to explain the individual deviations from the limiting law which appear in the less highly dilute solutions. They get the following expression[10] for the activity coefficient of the solute

$$-\log_{10} f = \frac{\alpha' \, (-Z_1Z_2) \, \sqrt{\mu}}{1 + \text{“}a\text{”} \, \kappa} \tag{1}$$

where "*a*" is the distance of closest approach of the ions in Å. (10^{-8} cm.) units and $\kappa = 0.327 \times 10^8 \sqrt{\mu}$. This expression seems to hold very well for the lower valence types of salts up to concentrations of about 0.2μ, but is inadequate in the case of aqueous solutions where high valence ions of opposite sign are involved, as well as for most non-aqueous solutions.

[9] Debye and Hückel, *Physik. Z.,* 24, *185, 343 (1923).*

[10] See ref. 2, p. *417, Eq. 2.* This equation contains a misprint. The fraction should read $1/(1 + x)$ not $x/(1 + x)$.

For extremely dilute solutions (κ small), the denominator approaches unity, and Equation 1 reduces to the limiting law, which is independent of specific properties of the ions. In a saturated solution the activity coefficient of the solute is determined by the following relationship[11]

$$\log S/S_0 = \log f_0/f \qquad (2)$$

S is the solubility of the saturating salt in the salt solution under consideration; S_0 is the solubility of the saturating salt in pure water; f_0 is the activity coefficient of the saturating salt in water, which may arbitrarily be set equal to unity for a very slightly soluble salt, but can be determined by extrapolating the curve obtained in high dilution to infinite dilution.

The activity coefficient determined from Equation 2 is an observed value; that determined from Equation 1, a calculated value. From Equation 1 it can be seen that all deviations between the observed and calculated values of $\log f$, if negative, could be accounted for by assuming a larger value for "a." On the other hand, positive deviations could only be accounted for in this equation by assuming negative values of "a," which are physically absurd.

Gronwall, La Mer and Sandved[12] have recently obtained a complete solution of the Poisson-Boltzmann equation, whereby additional terms involving *only* the parameter "a" are introduced into Equation 1. This obviates the difficulty of negative values of "a," and they are thus able to account entirely for the discrepancies between theory and experiment *for salts of symmetrical valence types* up to values of $x = a\kappa$ equal to about 0.3, using values of "a" which are physically reasonable. The calculations for the unsymmetrical types studied by La Mer and Mason[2] are too complex for a complete theoretical treatment along these lines, but it appears likely that when the necessary numerical computations are available for these types, this purely mathematical extension will also account for most of these deviations.

In the meantime it is desirable to see how far the experimental results can be correlated with less complicated semi-empirical treatments, of which Brönsted's principle of specific interaction appears to be the most promising. For the development of this theory the reader must consult the original papers[13] and the preceding article."

3. Preparation of Materials

Lanthanum Iodate.—Sixty grams of cerium-free lanthanum nitrate in solution and 130 g. of potassium iodate in solution were added dropwise and simultaneously to approximately fifteen liters of distilled water, the addition taking four to five hours. The mixture was thoroughly agitated by an electric stirrer and the stirring continued for three or four days. The precipitate was washed by decantation four times and then allowed to digest for two weeks in about two liters of water at 70° with stirring. The salt

so obtained was "sedimented"[2] in a tall narrow cylinder (2 X 100 cm.) several times and the finer material remaining at the top each time was rejected.

Thallous Iodate.--Eighty grams of potassium iodate in solution and 100 g. of thallous nitrate were added dropwise and simultaneously to six liters of water at 60° with constant stirring. The precipitate was allowed to digest and the stirring continuecl. The salt was washed by decantation six times with water, after which it was placed in a beaker containing 500 cc. of water and allowed to digest on a hot-plate at 80°. It was then "sedimented" to obtain crystals of uniform size.

The same preparations of potassium, sodium, magnesium and lanthanum salts whose purification has been described in detail in the preceding paper (La Mer and Cook) were used in this work. In addition lanthanum sulfate, especially freed from cerium for us by the Welsbach Company, was used. Its "apparent" molecular weight was determined by precipitating a sample as oxalate, igniting, moistening with nitric acid and reigniting to the oxide. Kahlbaum's "Zur Analyse" zinc sulfate was dried to constant weight in an air-bath and kept in a desiccator over sulfuric acid.

The solubility measurements were performed with the same apparatus and with the same necessary precautions that have been described in detail in the first paper of this series.

Lanthanum iodate was determined by dissolving three grams of potassium iodide in 10 cc. of boiled water in a 500-cc. iodine flask, adding a 25-cc. aliquot of solution from a volumetric flask, then three rinsings with distilled water and finally 2 cc. of 9 M sulfuric acid. After standing for five minutes in the dark, the contents were then titrated with sodium thiosulfate from a weight buret, using starch as indicator. Duplicate determinations checked to one part in two thousand. The average deviation of eleven determinations of the solubility of lanthanum iodate in water extending over a period of five months was only nine parts in ten thousand. Equilibrium was checked by allowing a solution saturated at 35° to flow through a column of lanthanum iodate at 25°. No change in solubility was found when the saturated solution was allowed to run through the column a second time. Blanks on the potassium iodide were negative.

The thiosulfate solutions were restandardized each week against potassium permanganate and could be checked to 0.1%.[14]

When the same analytical method was tried for thallous iodate a difficulty was encountered. An insoluble yellow precipitate was obtained when sodium thiosulfate was added in the course of the titration. In the presence of thallous ion thiosulfate is reduced to thallous sulfide.[15]

The following modification was found satisfactory. Sodium arsenite was used instead of sodium thiosulfate; only one cc. of nine molar sulfuric acid was added. The flask was then placed in the dark for five minutes, fifty cc. of a solution containing 3 g. of sodium bicarbonate was added and the contents of the flask titrated with standard sodium arsenite, using starch as an indicator. The end-point was obtained by back titrating with standard iodine solution. Determinations differed from one another by not more than four parts in a thousand.

The sodium arsenite solution used was 0.0150 N and was prepared as a primary standard according to directions in Scott,[16] using Kahlbaum's "Zur Analyse" arsenious oxide, and checked against potassium permanganate.[17] The two methods agreed to one part in a thousand.

4. Discussion of Data

Table I gives the solubility of lanthanum iodate in aqueous solutions of potassium chloride, potassium sulfate and lanthanum nitrate. The concentrations of the solvent salts are given in Col. 2. Column 4 gives the value of the logarithm of the ratio of the solubility in the particular solvent, to the solubility in pure water, S_0. When the values $z_1 = 3$, $z_2 = -1$ and $\alpha' = 0.505$ are introduced, Equation 1 takes the limiting form

$$-\log f = 1.515\sqrt{\mu} \qquad (3)$$

at 25° using 78.77 for D, the dielectric constant of water.

TABLE II

SOLUBILITY OF $La(IO_3)_3$ AT 25° IN VARIOUS 0.1 *N* SOLVENTS

Sample No. 2

Solvent	No. of detns.	Solubility, mole/liter	Solvent	No. of detns.	Solubility, mole/liter
S_0	5	0.0009426	$M/10$ KNO_3	4	0.001679
$M/30$ $La_2(SO_4)_3$	2	.001830	$M/10$ $NaNO_3$	3	.001654
$M/60$ $La_2(SO_4)_3$	2	.001532	$5M/100$ K_2SO_4	4	.003370
$M/30$ $La(NO_3)_3$	3	.0009398	$5M/100$ Na_2SO_4	4	.003326
$M/30$ $LaCl_3$	4	.0009233	$5M/100$ $MgSO_4$	2	.002997
$M/10$ NaCl	2	.001627	$5M/100$ $Mg(NO_3)_2$	4	.001766
$M/10$ KCl	2	.001648	$5M/100$ $MgCl_2$	4	.001739

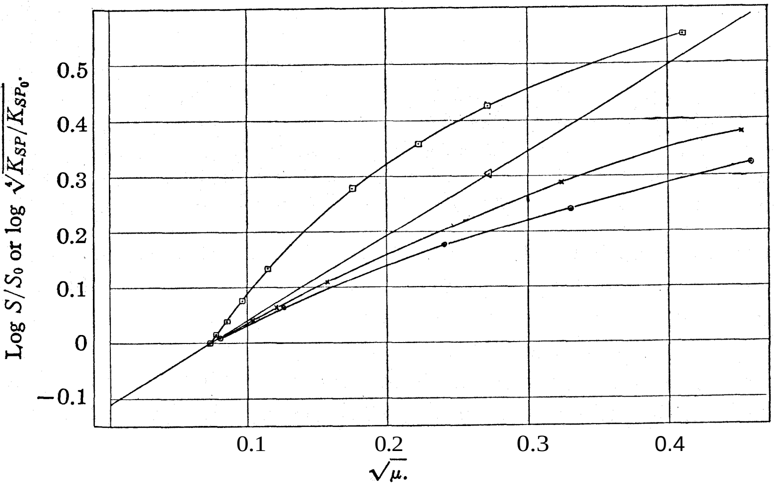
From this equation $-\log f_0 = 0.1107$. By introducing this value into Equation 2 we get the values for $-\log f$ given in Col. 5. Column 8 gives $-\log f$ calculated from Equation 3, and Col. 9 gives the difference between this value and the observed value.

It should be noted that of the three solvents in this table, potassium sulfate has the greatest effect on the solubility of lanthanum iodate. The solubility of lanthanum iodate is three and one-half times as great in a 0.1 N solution of potassium sulfate as in pure water. In addition potassium sulfate exhibits marked positive deviations from the limiting law.

In the case of lanthanum nitrate, which has an ion in common with lanthanum iodate, it is necessary to consider the ratio of the stoichiometric solubility product constants[n] rather than the solubilities. Therefore in the case of lanthanum nitrate, Col. 3 represents log $\sqrt[4]{Ksp/K_0sp}$. It is interesting to note that in changing the concentration of lanthanum nitrate from 0.003333 M to 0.01667 M the solubility of lanthanum iodate instead of decreasing, actually increases almost 6%, showing that in the case of a salt of high valence type the depression in solubility due to the common ion effect is soon obliterated by the more important factor, the change in the activity coefficient of the saturating salt. This is better seen by examining the data for the solubility of this salt in lanthanum sulfate, a (3,–2) solvent salt with an ion in common (see Table 11). At sixtieth molar (0.1 *N*) the solubility is already 55% higher than in pure water!

These data should be of interest to the analytical chemist, especially when planning new procedures. For instance, before washing a precipitate with a salt solution having an ion in common, the point where minimum solubility occurs should be determined, instead of relying entirely on a stoichiometrical calculation of the solubility product.

The results in Table I are plotted in Fig. 1. The line marked "limiting tangent" is the limiting law of Debye and Hückel. From the figure it is evident that the curve for potassium sulfate does not fuse into the theoretical slope, but shows a maximum deviation, or "hump;" also that while the potassium chloride and lanthanum nitrate curves do fuse into the theoretical line, the latter deviates less than the former from the limiting law. This behavior is quite parallel to that observed by La Mer and Mason[2] (see their Figs. 2 and 3) using cobaltammines.



▽—Limiting tangent; ⊙—KCl; ⊡—K_2SO_4; ×—$La(NO_3)_3$.

Fig. 1.

The solubility of thallous iodate is given in Table III. The column headings have the same significance here as in Table I.

Figure 2, which represented these results graphically, as in Fig. 1, shows the same type of curve in solutions of potassium sulfate but here the "hump" which was so pronounced in the case of lanthanum iodate, although present, is barely discernible. In the case of magnesium sulfate as solvent the deviations from the limiting law are negative and of the usual character.

Potassium chloride behaves differently with thallous iodate than with lanthanum iodate. The curve is a straight line exhibiting only positive deviations. At 0.1 *N* the solubility in potassium chloride solution is almost as great as that in potassium sulfate (see Table III). Sodium sulfate and sodium chloride show the same behavior as the potassium salts.

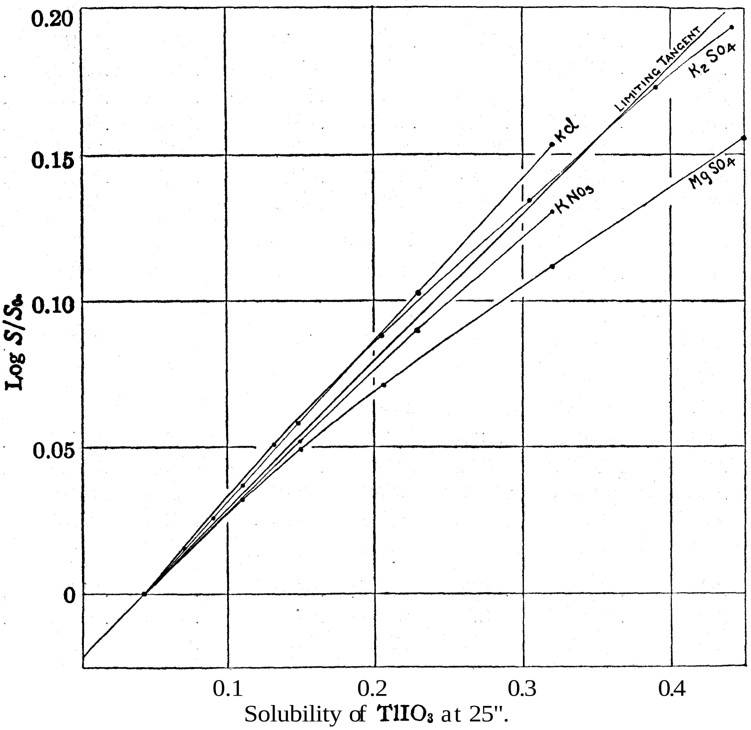

Fig. 2.

Table II contains the solubilities of lanthanum iodate in 0.1 *N* solvents, in order to determine the various solubility ratios for testing the principle of specific interaction.

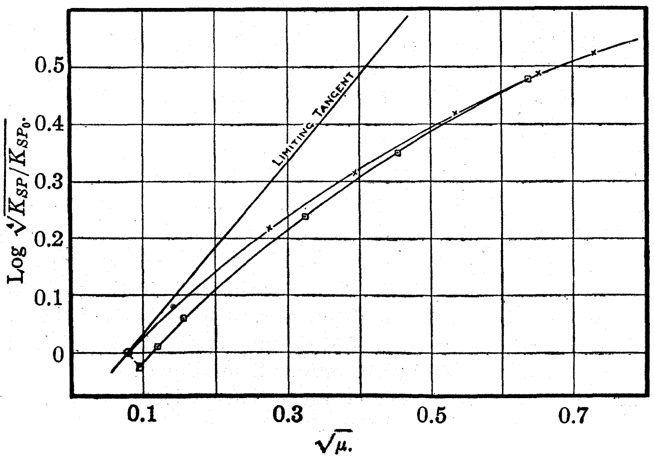
Table IV contains Harkins and Pearce's[7] data for lanthanum iodate recalculated according to modern theory. Harkins and Pearce state their results only in terms of equivalents, which we interpret in the case of the



×—$La(NO_3)_3 \cdot 2NH_4NO_3$; ⊡—$La(NO_3)_3$.

Fig. 3.

double salt to mean three and not five equivalents per mole. The corresponding curves using lanthanum ammonium nitrate and lanthanum nitrate as solvent salts are given in Fig. 3. Except for the most dilute solutions the agreement with the principle of ionic strength is excellent. Lewis and Randall's failure to confirm their principle in this case evidently rests upon a miscalculation due to the unfortunate ambiguity attached to Harkins and Pearce's meaning of the term equivalent of double salt.

5. Solubility Ratios

Tables V and VI contain the solubility ratios for the saturating salts, $La(IO_3)_3$ and $Tl(IO_3)_3$, in various 0.1 N solvents to test the principle of specific interaction. If the equivalent concentration is the correct scale

SO_4	1.003		1040	1.038	0.985	0.982	0.933	1.056	

[a] Bronsted (ref. 13 a, p. 889) obtains 1.005 for this ratio in the presence of Cl and ClO_3 ions using praseo iodate as the saturating salt. On the basis of Hall and Harkins' values for the freezing point depression of KIO_3 and $NaIO_3$, the principle of specific interaction predicts a value of 1.004 for this ratio. Using Equations 18 and 19 of ref. 13 a we obtain a value of 1.036 for the ratio of interaction for iodate ion; $r_i = r_{IO_3}(Na/K)$ and a value of 0.986 for $r_u = r(Na/K)$ the salting out ratio for Na/K, taking $R_I = 1.004$ and R_{III} (the K/Na solubility ratio for $La(IO_3)_3$) = 1.013 from Table V. The *agreement* between our value for $r(Na/K) = 0.986$ and Brönsted's value (1.011) is not entirely satisfactory.

for these comparisons regardless of the valence type of the solvent, then the ratio within each individual column should be constant. The bracketed values correspond to ratios for which the primary Milner effect is identical, as indicated by the ideal value for the ratio as given by the Debye limiting law. The data substantiate the conclusion of the previous paper that the ratios are constant at 0.1 N only when the ideal value remains unchanged; also that a comparison of the activity deviation coefficients instead of the total activity coefficient at the same equivalent concentration will not yield constant ratios in all *cases since* variation in the ratios which occurs is very much greater than the corresponding change in the ideal value.

On the other hand, limiting the comparisons only to solvent ratio types which should have the same ideal value, we find the principle of specific interaction to be confirmed, as witnessed by the constancy of the bracketed values. In Table V the greatest discrepancy (0.5%) occurs for the NO_3/Cl ratio in passing from the K to the La salts.

The SO_4/NO_3 and SO_4/Cl ratios agree to within 0.2 and 0.05%, respectively, in changing the common cation from K to Na. Since the observed values (2.007 and 2.045) differ markedly from the ideal value (1.281), indicating highly specific effects for the SO_4 ion as opposed to the NO_3 or Cl ion, we must look upon this agreement as an excellent proof that the individual specific interactions are restricted to the ions of opposite sign at least up to 0.1 N. The constancy of the cation ratios of the type K/Mg and Na/La when changing the common anion from NO_3 to Cl is significant for the same reasons, since in previous tests the observed ratios and the ideal ratios have been almost identical, that is to say, the systems chosen have obeyed the Debye limiting law quite closely or have exhibited similar deviations from it.

Table VII gives the solubility ratios for $TlIO_3$ in solvents of various types at the same ionic strength. According to the Lewis and Randall principle of ionic strength,[8] all the ratios should be unity, which is obviously not the case. Although at 0.1 μ the ratios approach their corresponding ideal values somewhat more closely than at 0.1 N, this is partly due to the fact that the higher valence solvents are more dilute in the former case. On the other hand, the constancy of the ratios within a given group is not as good in Table VII as in Table VI. Thus the NO_3/Cl ratio for Mg differs

TABLE VII

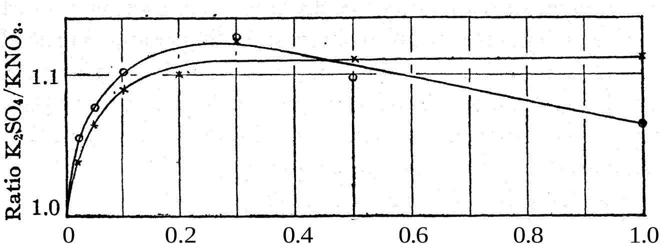
$TlIO_3$ SOLUBILITY RATIOS

Concentration (ionic strength) $\mu = 0.1$ to test principle of ionic strength. Ideal value 1.000 for all.

	NO_3/Cl	SO_4/NO_3	SO_4/Cl		**K/Na**	**K/Mg**	**Na/Mg**
K	0.949	1.021	0.969	NO_3	1.002	1.013	1.011
Na	.949	1.023	.971	Cl	1.002	1.032	1.030
Mg	.967	0.9707	.938	SO_4	1.000	1.066	1.065

by only 0.6% from the identical values for Na and K as cations at 0.1 N, while the corresponding difference amounts to 1.8% at 0.1 μ. Likewise, the K/Mg and Na/Mg ratios in the presence of NO_3 and Cl differ by 0.6% at 0.1 N, whereas the difference becomes 1.9% at 0.1 μ.

Bray and Winninghoff[5a] and Butler and Hiscocks[5b,18] have determined the solubility of thallous chloride in the presence of potassium sulfate and potassium nitrate as solvent salts. From these data the ratio $[S_{TlCl(K_2SO_4)}]/[S_{TlCl(KNO_3)}]$ can be calculated at different concentrations of added salts.



X—TlCl; O—TlIO$_3$.

Fig. 4.

These results appear in Table VIII and are plotted in Fig. 4 together with our data on thallous iodate. Values interpolated from the solubility curves are given in parentheses. Up to 0.3 N the principle of specific interaction is confirmed as well as could be expected when we note that many of the ratios are obtained by combining data from different observers.

Summary and Conclusions

The activity coefficients of lanthanum and thallous iodates have been determined in aqueous solutions of the chlorides, nitrates and sulfates of potassium, sodium, magnesium and lanthanum at 25° by solubility measurements. The usual form of the Debye-Hückel theory does not account for the behavior of a high valence salt like lanthanum iodate in K_2SO_4 solutions. The data show uniformly positive deviations from the Debye-Hückel limiting law and do not fuse into the theoretical curve at least down to concentrations as low as 0.0002 mole of added salt. This behavior is consequently to be looked upon as a general phenomenon and not an isolated one confined to the cobaltammine family. Saturating salts of the (1,–1) type like $TlIO_3$ exhibit positive deviations in sulfate solvents but to a far less marked degree than with $La(IO_3)_3$.

Harkins and Pearce's data for $La(IO_3)_3$ dissolved in $La(NO_3)_3$ as solvent are substantially correct. Lewis and Randall's suggestion that their data for $La(NO_3)_3 \cdot 2NH_4NO_3$ as solvent are in error is not justified and evidently arises from a misinterpretation of the term equivalent of double salt used by Harkins and Pearce.

Bronsted's principle of specific interaction has been tested at 0.1 N concentrations for both saturating salts in various valence types of solvents. Excellent agreement with the requirements of this principle is found whenever the solubility ratios compared at the same equivalent concentration also involve the same ratio of ionic strengths even though the ratios deviate markedly from the ideal value predicted by the Debye limiting law as in the case where sulfates or higher valence cation solvents are involved. The solubility ratios for TlCl and for $TlIO_3$ have been compared for a number of solvents at various concentrations.

MOLECULAR ORIENTATION AND THE PARTIAL VAPOR PRESSURES OF BINARY MIXTURES.
I. SYSTEMS COMPOSED OF NORMAL LIQUIDS

BY C. P. SMYTH AND E. W. ENGEL

RECEIVED FEBRUARY 16, 1929 PUBLISHED SEPTEMBER 5, 1929

Although many measurements have been made of the vapor pressures of solutions containing but one volatile component and the total vapor pressures of great numbers of binary mixtures of volatile liquids have been determined, few experimental data are available on the partial pressures of binary liquid mixtures. Many partial pressures have been calculated from total pressures by means of equations, theoretical and empirical, the success of the calculations depending not only upon the nature of the equations but, unfortunately, upon that of the mixtures as well. An equation recently developed by Langmuir[1] seemed to offer a means not merely of calculating partial pressures but also of learning much about the molecular condition of liquids. In order to examine the applicability of this equation and in order to gain information which might be coordinated with the results of studies of the dielectric polarization of liquids, the measurement of partial vapor pressures was undertaken.

Apparatus and Procedure

The apparatus employed (Fig. 1) was similar in many respects to that used by Sameshima.[2] The vessel A, which had a capacity of 200 cc., contained the liquid mixture, the partial vapor pressures of which were to be measured. A was immersed to the level of the ground-glass stopper S in a carefully regulated thermostat, the temperature of which was approximately 2° above the temperature at which the pressures were to be measured. Superheating was prevented by stirring the liquid electrically by means of a current through platinum spiral B, which was carried by a tube entering the vessel through a ground joint with a mercury seal. The temperature of the boiling liquid was read on the thermometer T, which was suspended by a platinum wire from a hook on the stopper S. The thermometers used were of short range, calibrated in fifths of a degree and standardized at the U. S. Bureau of Standards. The large side tube C was wound with an electric heater, which prevented the condensation of any vapor in C and its subsequent direct return to A. The condensers, D and D′, were surrounded by insulated copper jackets, E and E′, which were filled with solid carbon dioxide in the form of "dry ice." The low temperature obtained with the solid carbon dioxide prevented the escape of vapor and consequent change in the composition of the liquid, which occurred in the preliminary experiments when ice was used for the condensation of the more volatile liquids. In the case of liquids of high freezing point, solidification in the condenser was prevented by inserting a thin sheet of asbestos between the condenser bulbs and the "dry ice." The vapor condensed in D flowed down into the bulb

[2] Sameshima, THIS JOURNAL, 40, 1482 (1918).

F, which had a capacity of about 4 cc. The bulb ordinarily filled within three minutes after the liquid had begun to boil in A and then overflowed through G back into A.

With the aid of the carboys, H and J, which functioned as stabilizers, the pressure was maintained constant during a run by means of the manometer K and a rotary oil pump. When the pressure had been lowered by the pump to a point where the liquid in A boiled at the desired temperature, the platinum wire L, sealed through a small glass tube and attached to a length of copper wire, was adjusted so that its end was at the top of the mercury column, the adjustment being made by sliding the copper wire through the soft wax seal X. This wire and the wire sealed into the manometer at K were connected through a relay, which turned the pump off and on as the mercury column made or broke contact with the wire L at its surface, the pressure thus being kept so constant that no variations could be observed on the manometer N.

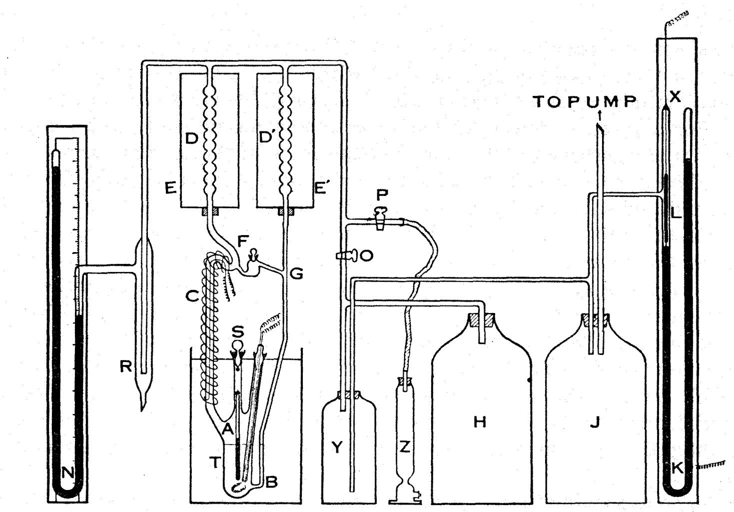

Fig. 1.—Apparatus for vapor pressure measurements.

In order to avoid pressure gradient between A and the manometer N, the tubing used was, for the most part, of 10-mm. internal diameter. The trap R was inserted to keep any liquid which might get into the upper part of the apparatus from running down into the manometer, but this precaution proved unnecessary. The stopcocks O and P were employed to open the main apparatus to atmospheric pressure, while maintaining low pressure in the carboys when desired. Bottles Y and Z contained calcium chloride.

A measurement was carried out in the following manner. About 100 cc. of a mixture, the composition of which was approximately that desired, was placed in Vessel A. The pressure was gradually reduced until, when the electrical stirrer was turned on, the liquid began to boil. The pressure was then regulated until the thermometer constantly indicated the desired temperature. The liquid was allowed to boil for some time, the temperature being kept under careful surveillance. It was found that five or ten minutes were normally sufficient for the attainment of equilibrium conditions, but, for the sake of safety, thirty or forty minutes were usually allowed. The liquid condensed in F now had the composition of the vapor in equilibrium with the liquid in A; 3- or 4-cc. samples were pipetted out of A and F and analyzed by the measurement of their refractive indices as was done by Zawidski.[3] If the mole fractions of the two components of the liquid in F were A and B and the total pressures read on Manometer N were P, the partial pressures of the liquid in Vessel A were AP and BP.

Because of deviations from the ideal gas laws, the partial pressures calculated in this manner are not identical with the pressures which the vapors of the components would exert if allowed to occupy the same volume separately.[4] The results of other investigators have shown that these deviations cause errors of less than 1% in the apparent molecular weights of a large number of vapors measured between 70 and 100°, and Sameshima[2] has found the deviations in mixtures of ether and acetone vapors at 25° to be so small as to be without appreciable effect upon the values of the partial pressures calculated upon the assumption of the applicability of Dalton's law. Even though the deviations may have an appreciable effect in some of the mixtures here studied, the effect should be too slight to impair the use of the results in the examination of Langmuir's theory.

The indices of refraction for the sodium D line were measured with a Pulfrich refractometer, a temperature of 20°, constant within 0.01°, being obtained by a flow of water from carefully adjusted thermostats. The probable error of a measurement was 0.00007. For a given system from twelve to fifteen mixtures of known composition were made up and measured. The molar composition of the mixture corresponding to the observed refractive index if the refractive index were a linear function of composition was calculated and subtracted from the known composition. The differences between the theoretical and the known mole fractions obtained in this way were plotted against the theoretical mole fractions to give a curve which was used to correct the theoretical composition of an unknown mixture of the two liquids calculated from the refractive index on the assumption that the latter was a linear function of the composition. The accuracy of this method of analysis depended upon the precision of the index measurements and upon the difference between the indices of the two components of the mixture. The probable error in the mole fraction was usually 0.001-0.003. The probable error of the partial pressure data was somewhat dependent upon the nature of the liquids under investigation and upon the temperature of the measurement, but was normally 2 ± 1 mm.

In order to ascertain whether or not the apparatus functioned properly, the system benzene–carbon tetrachloride was investigated, the partial pressures being found to duplicate the measurements of Zawidski within the experimental error.[3] The vapor pressure–temperature curves obtained for a number of the pure substances under investigation were found to agree well with the data in the literature.

Purification of Materials

The purification of the materials used is described below. Under each material are given the values of physical constants which serve as criteria of purity. In addition to the boiling point and the refractive index for the sodium D line at 20°, the melting point and the density were occasionally measured. The vapor pressures measured at several temperatures agree well with those given in Landolt-Bornstein, "Tabellen," 5th ed., Berlin, 1923, as previously remarked.

***n*-Hexane.**—A synthetic product obtained from the Eastman Kodak Company was washed repeatedly with slightly diluted sulfuric acid, then with alkaline permanganate solution, dried over sodium, and distilled; b. p. 68.8°; $d_4^{20} = 0.6600$; $n_D^{20} = 1.37508$.

---

[3] Zawidski, *Z. physik. Chem.*, 35,129 (1900).

[4] Dolezalek and Schulze, *Verhandl. deut. physik. Ges.*, 14, 1091 (1912); Schulze, *ibid.*, 15,488 (1913); *Physik. Z.*, 14,922 (1913).

n-**Heptane.**—Material obtained from the Ethyl Gasoline Corporation was found to require no purification; m. p. −90.5°; b. p. 98.4°; d_4^{20} = 0.6838; n_D^{20} = 1.38767.

Carbon Tetrachloride.—The best product obtainable from Merck was dried over fused calcium chloride and distilled. A fraction boiling constantly at 76.4° was employed; b. p. 76.4'; n_D^{20} = 1.46026.

n-Butyl Chloride.—A material of good quality obtained from the Eastman Kodak Company was refluxed gently for half an hour over an equal volume of concentrated sulfuric acid, distilled, washed with water until free of sulfate, dried over fused calcium chloride and fractionated. A fraction boiling from 77.3 to 77.6° was employed; n_D^{20} = 1.40173.

Ethyl Bromide.—A material obtained from the Eastman Kodak Company was washed several times with cold, concentrated sulfuric acid, then with water until all sulfate was removed, dried over fused calcium chloride and fractionated. The fraction boiling at 38.3–38.4° was employed. Two lots thus prepared gave values of 1.42403 and 1.42408 for the refractive index; d_4^{20} = 1.4586; n_D^{20} = 1.42405.

Ethyl Iodide.—A material obtained from Merck was washed with a very dilute caustic potash solution until decolorized. Several drops of the caustic solution were added in excess and the material was then separated, thoroughly washed with water, dried over fused calcium chloride and fractionated. A fraction distilling without any perceptible change in temperature at 73.2° was employed. The vapor pressure of this material, 355.0 mm. at 50°, differs from Regnault's value 364.0 mm. given in Landolt-Bornstein, "Tabellen," but agrees satisfactorily with the more accurate value of Zawidski,[3] 353.4 mm.; b. p. 73.2°; d_4^{20} = 1.9292; n_D^{20} = 1.51330.

n-Butyl Bromide.—Material obtained from the Eastman Kodak Company was washed with cold concentrated sulfuric acid, then with sodium carbonate solution, dried over fused calcium chloride and fractionated. A fraction boiling from 100.4° to 100.6' was employed; n_D^{20} = 1.43984.

Ethyl Alcohol.—Ordinary 95% alcohol was refluxed over quicklime to which a small stick of sodium hydroxide was added. The refluxing was continued for 75–100

hours, the lime being renewed four or five times. An exceptionally good quality of powdered lime was finally used and the material distilled off; b. p. 78.4–78.5°; n_D^{20} = 1.36130.

n-Butyl Alcohol.—Material obtained from the Commercial Solvent Corporation was refluxed over lime and twice fractionated. A fraction boiling between 117.1 and 117.2" was employed; n_D^{20} = 1.39942.

Results

The vapor pressures of several pure liquids are given in Table I and in Table II are the partial vapor pressures of the binary mixtures. In a system A–B the less polar liquid is, as a rule, designated as A, but where there is no polarity or little difference in polarity, other considerations may determine the order. For each system the column under B gives the mole fraction of component B in the mixture and the columns under p_A and p_B give the partial pressures of components A and B over the mixture.

Langmuir[1] has employed the principle of independent surface action to derive the following expressions for the partial vapor pressures of a mixture of two liquids, A and B

$$p_A = P_A A e^{S_A \varphi \beta^2/kT} \text{ and } p_B = P_B B e^{S_B \varphi \alpha^2/kT} \qquad (1)$$

in which p_A and p_B are partial pressures of Components A and B, respectively; P_A and P_B are vapor pressures of the pure liquids A and B, respectively; A and B are mole fractions of components A and B; S_A and S_B are surface areas of molecules of A and B; a and β are surface fractions of Components A and B

$$\alpha = \frac{S_A A}{S_A A + S_B B} \text{ and } \beta = \frac{S_B B}{S_A A + S_B B} \qquad (2)$$

k is the Boltzmann constant = 1.372 × 10^{-16}; T is the absolute temperature; and φ the "mixture energy," is a constant, dependent upon the molecular surface energies and independent of concentration.

For a mixture of two liquids, A and B, the molecules of one of which substances are enclosed by two kinds of surface, A and C, those of the other being enclosed by surfaces B and D

$$\varphi = ab\gamma_{ab} + ad\gamma_{ad} + bc\gamma_{bc} + cd\gamma_{cd} - ac\gamma_{ac} - bd\gamma_{bd} \tag{3}$$

in which a and c are the fractions of the surface of molecule A which are A-surface and C-surface, respectively, and b and d are the fractions of the surface of molecule B which are B-surface and D-surface, while γ_{ab} is the energy per sq. cm. of interface between surfaces A and B, γ_{ad} is the energy per sq. cm. of interface between A and D, etc.; φ is shown to be the energy per sq. cm. of molecular surface required for the transfer of a molecule of A from pure liquid A to pure liquid B or for the transfer of a molecule of B from pure liquid B to pure liquid A. The somewhat hypothetical surface areas of the molecules, expressed in square Ångstroms (10^{-16} cm.^{2}) are calculated from the densities by supposing that the liquids consist of close-packed spheres and the fractions of molecular surface, a, b, c, etc., used in the present paper are estimated from a comparison of the values of $V^{2/3}$ for the different groups, where V is the molar volume of the group at the boiling point of the liquid. It is assumed that the areas of the different kinds of surfaces in contact with one another are proportional to the fractions of the molecular surfaces involved, thus being calculable on the basis of a random orientation of the molecules. The value of γ for a certain kind of surface in a molecule is regarded as independent of the nature of the rest of the molecule, Thus γ should be the same for a hydrocarbon surface whether it be that of the heptane molecule or of the ethyl group in the ethyl alcohol molecule or of the butyl group in butyl chloride. Similarly, the energy per sq. cm. at a chlorine–hydrocarbon interface should be the same whether the chlorine is in carbon tetrachloride or butyl chloride, and whether the hydrocarbon is in another butyl chloride molecule or an alcohol or a heptane molecule. For binary mixtures in which fewer kinds of surface are involved, Equation **3** is simplified by the elimination of some of the terms, as will appear when it is applied to the results of the present investigation, in which only two or three kinds of surface are generally involved. This makes it possible to calculate the values of γ when φ is obtained for different mixtures.

Equation 1 may be written in the form

$$\varphi = 2.303\frac{kT}{S_A\beta^2}\log\frac{p_A}{P_AA} \text{ and } \varphi = 2.303\frac{kT}{S_B\alpha^2}\log\frac{p_B}{P_BB} \tag{4}$$

and used to calculate the value of φ, which, if the assumptions of the theory were rigidly correct, should be constant and the same for both partial pressure curves. Since the values of φ are greatly affected by experimental error, particularly at the ends of the partial pressure curves, it has seemed best to interpolate the values of p_A and p_B at intervals of 0.1 in the mole fraction and, for the sake of comparison, to designate the values of

φ calculated from the one partial pressure curve as φ_A and those from the other curve as φ_B. In Table III the first column gives the mole fractions of Component B from 0.1 to 0.9, and the succeeding columns give, for different systems, the values of p_A/p_AA and p_B/p_BB and the values of φ calculated from them. The deviations of p_A/p_AA and p_B/p_BB from 1 measure the deviations of the mixtures from Raoult's law.

The hexane–heptane mixtures are not included in Table III, because the linearity of the partial pressure curves shows that φ is 0. This supports the assumption involved in Langmuir's treatment that the energy, γ, between like surfaces, such as R–R, Br–Br, etc., is 0, since, for this system, Equation 3 simplifies to $\varphi = \gamma_{\text{R-R}}$ and $\varphi = 0$. The butyl chloride–butyl bromide mixtures are omitted from Table III because of the approximation of their curves to linearity and the heptane–ethyl iodide results at 30° are

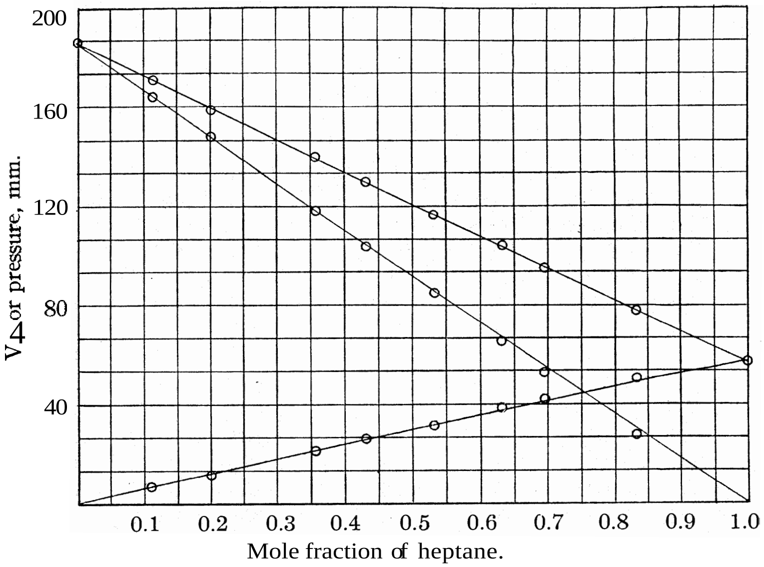

Fig. 2.—Hexane (A)–heptane (B) at 30°.

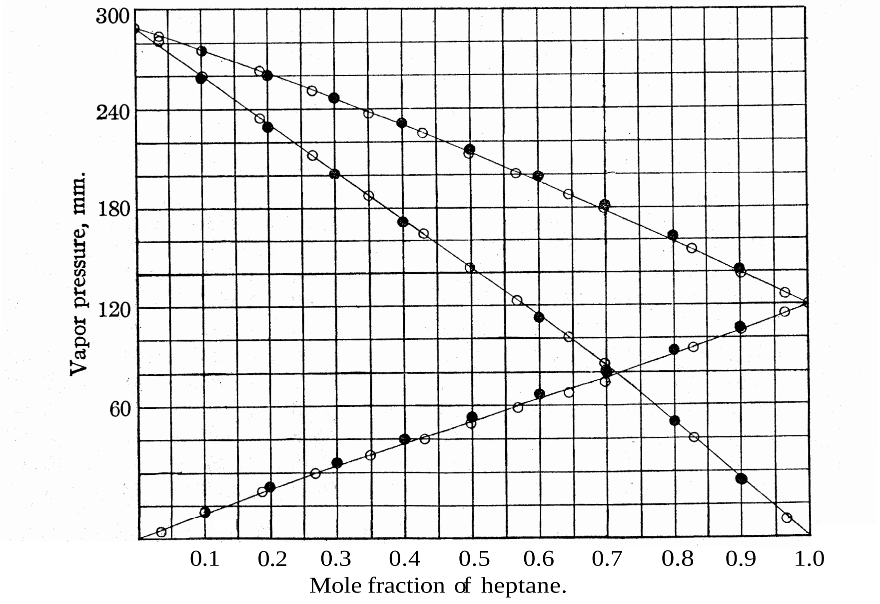

Fig. 3.—Carbon tetrachloride (A)–heptane (B) at 50°.

also omitted because of their resemblance to those at 50°, the values of φ at **30** and 50° differing by no more than the probable error. The results

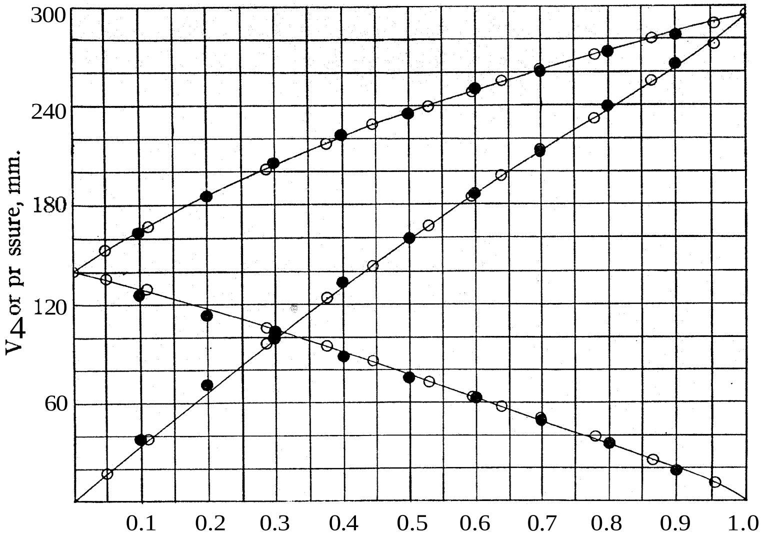

Fig. 4.—Heptane **(A)-butyl** chloride (B) at 50°.

are represented graphically in Figs. 2–9, in which the vapor pressures in mm. of mercury are plotted as ordinates against the mole fractions of

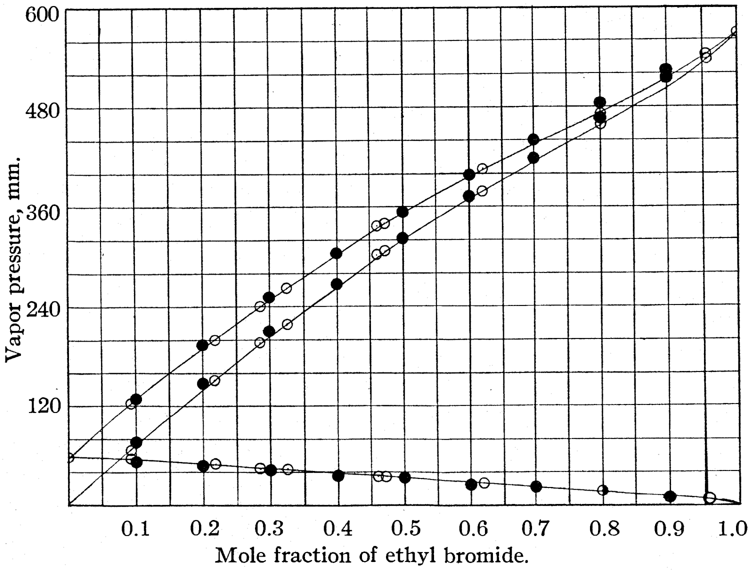

Fig. 5.—Heptane (A)-ethyl bromide (B) at 30°.

Component B as abscissas. The total pressure curve is, of course, uppermost and the partial pressure curve of Component B starts at the lower left-hand corner, while that of A starts at the lower right-hand corner. The experimental points are shown as hollow circles and the points calculated from φ as filled circles. Where the vapor pressure curves are straight, φ being 0, no calculated points are shown as they would obviously fall on the straight experimental lines. In the ethyl bromide–ethyl iodide system (Fig. 9) the departure from linearity is so slight as to render uncertain the value of φ, which is small in most of the mixtures and dependent upon concentration, as indicated by the curve in which the values of φ obtained from the pressures of the ethyl iodide are plotted as ordinates, shown at the right of the diagram, against the mole fractions of ethyl iodide as abscissas. In spite of the smoothness of this curve, great importance cannot be attached to it because φ is calculated from such small deviations.

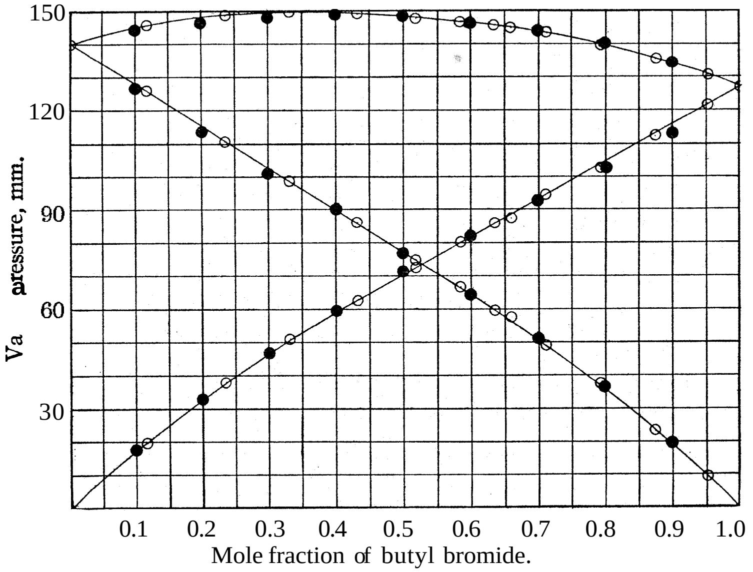

Fig. 6.—Heptane (A)–butyl bromide (B) at 50°.

Since the values of φ calculated from individual vapor pressures are subject to a considerable variation, φ may advantageously be obtained by plotting the values of $\log p_{\text{A}}/p_{\text{A}}A$ in Equation 4 as ordinates against those of β^2 as abscissas, or of $\log p_{\text{B}}/p_{\text{B}}B$ against those of α^2. If φ is constant, a straight line is thus obtained, the slope of which, when divided by $S_{\text{A}}/2.303kT$ or $S_{\text{B}}/2.303kT$, as the case may be, gives φ. The curves thus obtained for the heptane-ethyl iodide system show a tendency toward **a** slight deviation from linearity to give a curve with a point of inflection.

This deviation from linearity tends to increase with increasing difference in the polarity of the components. However, the curves are approximately linear for the systems heptane–butyl bromide, heptane–butyl chloride and heptane–carbon tetrachloride, and show no great deviation for heptane–ethyl bromide, although here the curvature is more pronounced. The curves for the ethyl bromide–ethyl iodide system show no approach to linearity, so that no constant value of φ can be obtained to use in calculating γ. The value of φ for hexane–heptane is 0 and for butyl chloride–butyl bromide so small as to be indistinguishable from 0. These values of φ are used to calculate the values of γ shown in Table IV, in which the

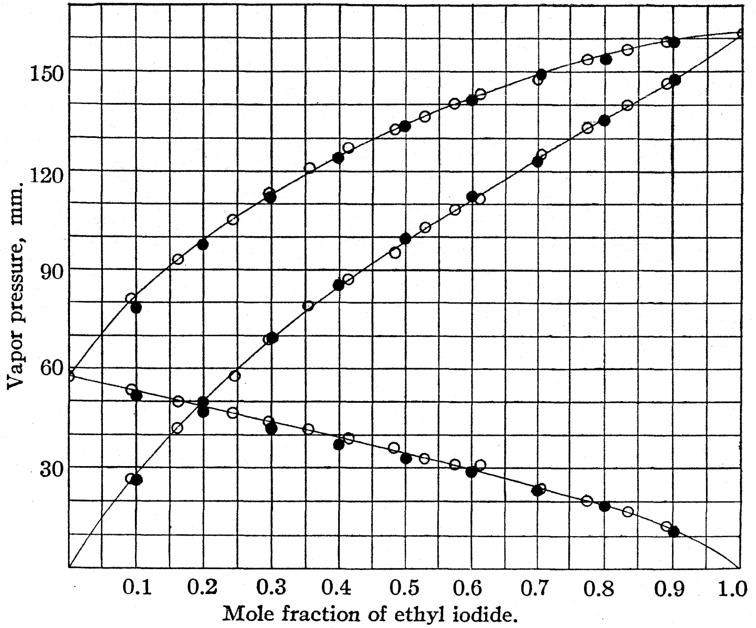

Fig. 7.—Heptane (A)–ethyl iodide (B) at 30°.

TABLE IV

VALUES OF SURFACE ENERGY, γ

I	58.8	Cl-I		..	..	4.1

last column gives, for comparison, the values estimated by Langmuir. The molecules or radicals and their areas used in the calculation of the sixth column are shown in the first two columns. The calculation of the areas is, at best, a rough approximation, but, when the arbitrary character of the whole method of employing the molecular areas is considered, it becomes evident that the values assigned can have little significance as absolute quantities.

The value of γ_{R-Cl} determined from the heptane–carbon tetrachloride system should be the most accurate value in Table IV, for only two kinds

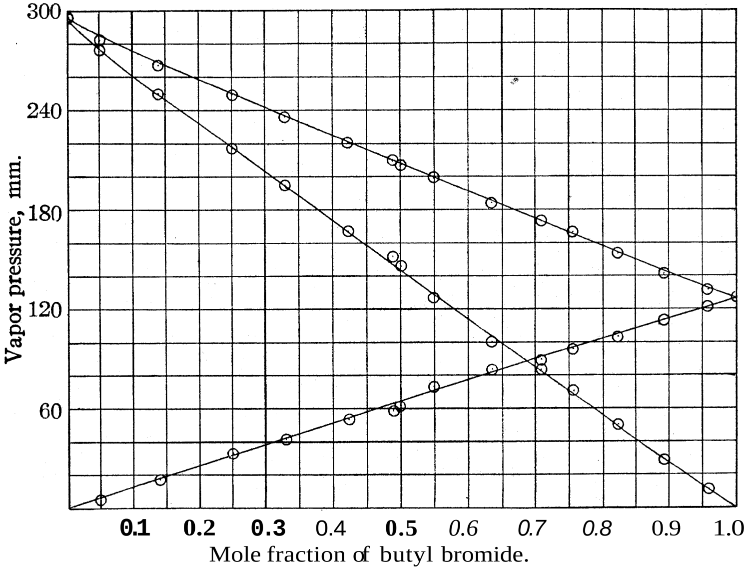

Fig. 8.—Butyl chloride (A)–butyl bromide (B) at 50°.

of surface being involved in the system, Equation 3 simplifies to $\varphi = \gamma_{R-Cl}$, thus eliminating the doubtful fractions of surfaces. The value of γ_{R-Cl} determined from the heptane–butyl chloride system is very dependent upon the surface areas used, as shown by the fact that, when surface areas consistent with those of Langmuir are taken, a value of 37.0 is obtained instead of 10.0. It is certain that the great difference between the value of γ_{R-Cl} obtained from the carbon tetrachloride–heptane system and that from the heptane–butyl chloride system can be due only in part to experimental error or the use of incorrect surface areas, and must, therefore, be attributed to a more fundamental cause. The values of γ_{R-I} obtained from the heptane–ethyl iodide system, because of the different surface areas used, differ from Langmuir's figure which, in this one case, could be calculated directly from experimental data. When the values of the surface areas used by Langmuir are employed, good agreement is obtained at

30°. For the system butyl chloride–butyl bromide, φ is only approximately 0 and one can, therefore, say only that $\gamma_{\mathrm{Cl-Br}}$ is small, presumably lower than Langmuir's value of 4.1 for $\gamma_{\mathrm{Cl-I}}$, as the surface energy between chlorine and bromine might be expected to be less than that between chlorine and iodine.

These systems show linearity, in some cases very approximate, when $\log p_{\mathrm{A}}/p_{\mathrm{A}}A$ is plotted against β^2 and $\log p_{\mathrm{B}}/p_{\mathrm{B}}B$ against α^2, and the experimentally determined vapor pressures may be satisfactorily reproduced by the use of a single value of φ, in spite of the considerable variation shown by the individual values of φ in Table III. The definitely established difference between the value of $\gamma_{\mathrm{R-Cl}}$ obtained from the heptane–carbon tetrachloride system and that from the heptane–butyl chloride system is significant since it indicates that the energy between surfaces is not always dependent only upon the kinds of surface involved, thus showing that the principle of independent surface action is limited in its applicability. The carbon tetrachloride molecule has no electric moment, while the butyl chloride molecule contains a large dipole.[5] The superposition of the forces of the dipole upon those of the chlorine surface presumably causes $\gamma_{\mathrm{R-Cl}}$ as measured for the heptane–butyl chloride mixtures to be different from the energy between hydrocarbon and chlorine surfaces where no dipole is present. As these are dipoles of the same order of magnitude present in the other alkyl halides here studied, it is probable

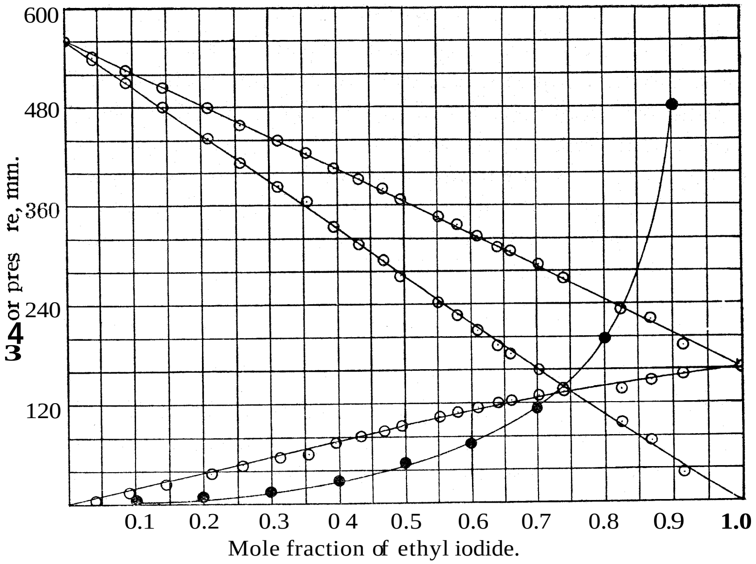

Fig. 9.—Ethyl bromide (A)–ethyl iodide (B) at 30°.

---

[5] Smyth, *Chem. Reviews* (1929).

that the values of γ obtained from these systems are all influenced more or less by the fields due to these dipoles, which may also affect the results by bringing about molecular orientation. It is apparent that the lack of generality of the principle of independent surface action and the frequent absence of random orientation, as well as the uncertainty in estimating surface areas, prevent the accurate determination of absolute values for the surface energies and limit the applicability of the theory. These results will be further discussed in a subsequent paper, where they will be contrasted with the behavior of systems containing an alcohol as one component.

Summary

An apparatus is described for the measurement of the partial vapor pressures of binary liquid mixtures by a dynamic method. The pressures of eight different combinations of supposedly normal liquids and of several of the pure components are tabulated.

The data are used to examine Langmuir's theory of molecular surface energies, which is found to have an approximate applicability. Deviations from the theoretical behavior are ascribed to the presence of electric doublets in the molecules.

MOLECULAR ORIENTATION AND THE PARTIAL VAPOR PRESSURES OF BINARY LIQUID MIXTURES. II. SYSTEMS CONTAINING AN ALCOHOL

BY C. P. SMYTH AND E. W. ENGEL

RECEIVED FEBRUARY 16, 1929 PUBLISHED SEPTEMBER 5, 1929

The apparatus described in Part I was used to determine the partial pressures of six different binary systems containing an alcohol as one of the components. The purification of the materials and the values of the physical constants used as criteria of their purity have been given in Part I.[1] Because of the somewhat different behavior of these systems containing an alcohol, it has been deemed advisable to treat them in a separate paper and contrast the results with those given by the supposedly normal liquids discussed in Part I. The experimentally determined partial pressures, p_A and p_B, of the components A and B are recorded in Table I, the composition of the mixtures being given in terms of the mole fraction B of the alcohol. The values of the partial pressures are interpolated graphically at intervals of 0.1 in the mole fraction of B and used to calculate the values of p_A/p_AA, p_B/p_BB, φ_A and φ_B, as was done in Part I,[2] the results

being recorded in Table II. In Figs. 1–6 the vapor pressures in millimeters of mercury are plotted as ordinates against the mole fractions B as abscissas. The total pressure curve is uppermost and the partial pressure curve of the alcohol starts at the lower left-hand corner, while that of the other component, A, starts at the lower right-hand corner. The values of φA and φB are plotted as ordinates on the same diagrams against those of B as abscissas, the points being indicated by filled circles.

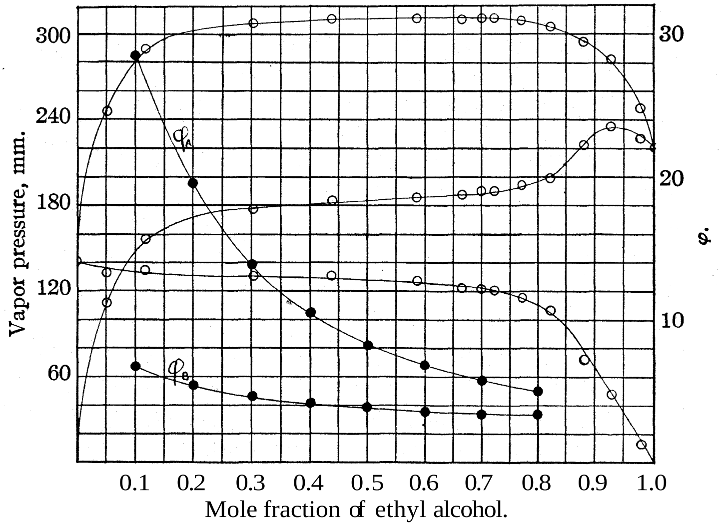
analysis, but careful checking of the method of analysis eliminated this possibility. The rise is found to decrease with rising temperature, which may be expected to reduce abnormalities arising from molecular association



Pig. 1.—Heptane (A)–ethyl alcohol (B) at 50°.

or intermolecular action. No such maximum appears in the curves for the mixtures of ethyl alcohol with other substances than heptane, but in the heptane–butyl alcohol system (Fig. 2), the beginning of a rise is indicated from B = 0.7 to B = 0.8 which might lead to a maximum in the neighborhood of B = 0.9. Unfortunately, however, this region could not be investigated as the butyl alcohol mixtures containing a little heptane bumped so violently, apparently because of an abnormally high surface tension, that the vapor pressures could not be measured. It appears that some complex formation may occur in this region of the heptane–alcohol mixtures, but the dielectric behavior of the mixtures shows no irregularity in this region and an attempt at explanation is unwise until more definite knowledge is obtained.

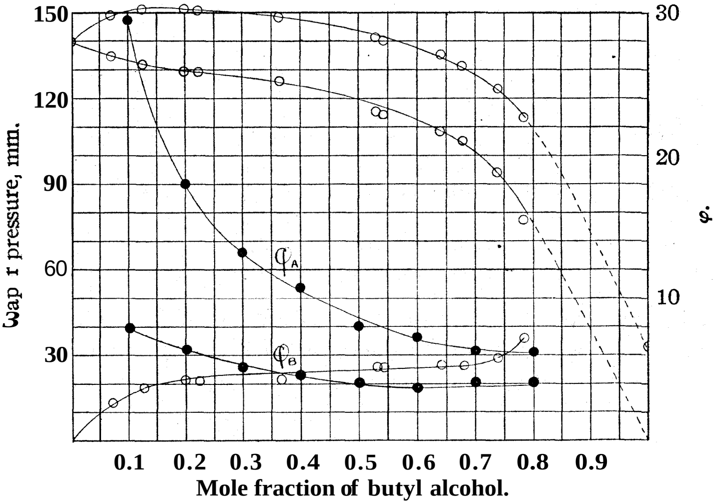


Fig. 2.—Heptane (A)–butyl alcohol (B) at 50°.

Table II shows that these systems deviate much more from Raoult's law than do the normal liquids considered in Part I, the value of p_B/P_BB for B = 0.1 in the heptane (A)–ethyl alcohol (B) system at 30° being 6.778 as compared to the theoretical 1 of Raoult's law. The deviation of the partial pressure of a component from Raoult's law increases with decreasing concentration of the component. The values of φ are larger and vary more widely than those for the mixtures in Part I. Indeed, the variation of φ is so great that it is impossible to select a value from those in Table II for *a* system with any expectation of reproducing the partial pressures from it.

As an illustration of the manner in which a single value of φ fails to reproduce the experimentally observed vapor pressures, Fig. 4 shows as partly filled circles the pressures for the ethyl bromide-ethyl alcohol system, calculated by means of the **Langmuir** equation, the value of φ being taken from Table III as 5.88. A similar failure in the calculation of the pressures has been found to occur in the other systems. The calculated points are, however, omitted from the other figures in order to avoid too great complication of the diagrams.

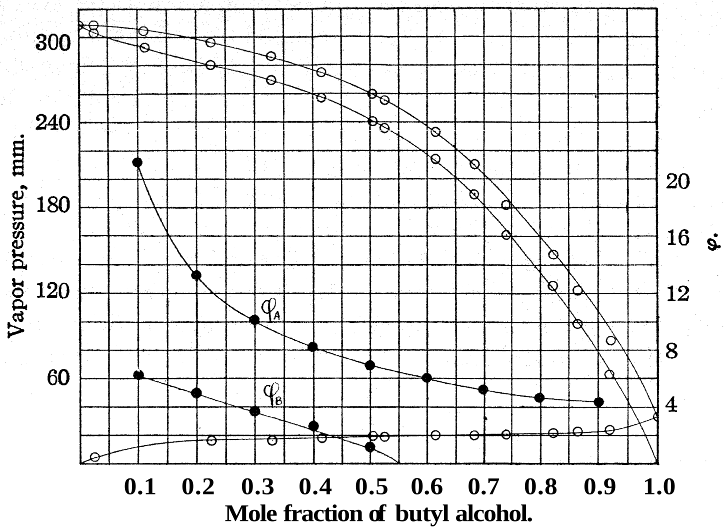

Fig. 3.—Carbon tetrachloride (A)-butyl alcohol (B) at 50°.

If $\log p_A/P_AA$ is plotted against β^2 and $\log p_B/P_BB$ against α^2, straight lines are not obtained, as should be the case if φ were constant. When log

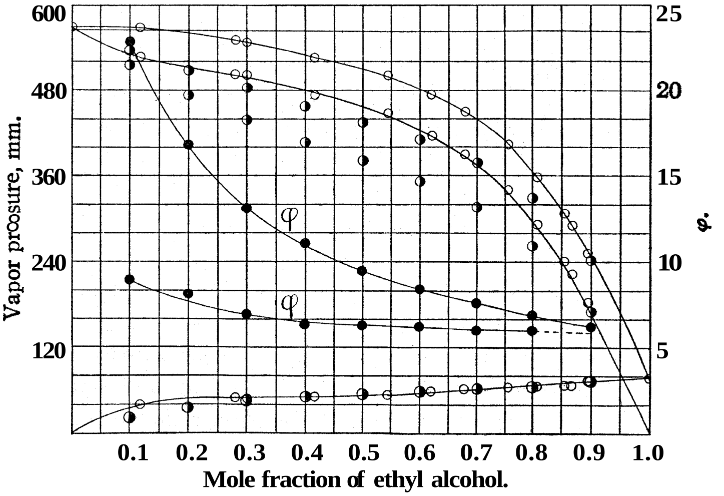

Fig. 4.—Ethyl bromide (A)-ethyl alcohol (B) at 30°.

$(\log(p_A/P_AA))$ is plotted against $2 \log \beta$ and $\log(\log(p_B/P_BB))$ against $2 \log \alpha$, portions of the curves obtained are linear and average values of φ

are calculated from these portions. The curves for the two components give somewhat different values of φ, but the values from the curves for the non-alcoholic components which are constant over a wider concentration range will be used in discussion.

For the sake of comparison, all the values are given in Table III together with the values of the surface energy calculated from them, the values of γ from Part I being used when necessary in the calculation. The first column gives the interface for which γ is calculated, the second column the temperature at which the vapor pressures were determined, the third under A gives the component from the partial pressures of which the values of φ in the fourth column are obtained and the values of γ calculated from them are in the fifth column. The sixth column under B gives the alcohol from the partial pressures of which the values of φ and γ in the remaining columns are calculated. At the foot of the table are given the values of γ used in calculating the surface energies for the halogen–hydroxyl interfaces, together with the surface areas (in square Ångströms) not previously used in Part I.

TABLE III

VALUES OR φ AND γ FOR SYSTEMS CONTAINING AN ALCOHOL

Interface	t, °C.	A	a	γ	B	a	γ
R–OH	30	C_7H_{16}	5.77	68 2	C_2H_5OH	7.05	83.3
R–OH	50	C_7H_{16}	6.1	72.4	C_2H_5OH	7.6	89.9
R–OH	70	C_7H_{16}	6 78	80.2	C_2H_5OH	8.67	102 5
R–OH	50	C_7H_{16}	4 7	97.7	C_4H_9OH	6.4	133 1
CI–OH	50	CCl_4	4 0	101.6 (80.8)	C_4H_9OH	7.25	95.7
Br–OH	30	C_2H_5Br	5.88	64 9	C_2H_5OH	8.34	81.8
Br–OH	50	C_4H_9Br	4.47	108 9 (92 4)	C_4H_9OH	6.65	134.6 (118.2)
I–OH	30	C_2H_5I	6.85	70 0	C_2H_5OH	6 67	68.9

Areas: OH = 24.7; C_2H_5OH = 849; C_4H_9OH = 112.5. Values of γ used in calculations: R–OH = 73.7 for C_2H_5OH; 97.7 for C_4H_9OH (but values in parentheses are calculated from R–OH = 73.7); R–C1 = 0.6; R–Br = 6 8 for C_2H_5Br, 9.2 for C_4H_9Br; R–I = 7 9.

Possessed of the same uncertainties as the values obtained in Part I, these results are rendered more difficult of interpretation by the greater effect of molecular orientation in the mixtures. The energy at an interface where an hydroxyl group is involved is evidently so large in comparison with the energies at the other interfaces that the orientation of the alcohol molecules relative to one another must be more important in determining the behavior of the system than their orientation relative to the molecules of the other component or the orientation of the molecules of the other components relative to one another. For example, in an ethyl bromide–ethyl alcohol mixture at 30°, if an hydroxyl surface is in contact with bromine, γ is 64.9, if in contact with hydrocarbon, γ is 68.2, but, if in contact with another hydroxyl, y is 0, while, if a bromine surface is in contact with hydrocarbon, y is 6.8 as compared to 0 when the bromine is in contact with another bromine.

It is evident that when a butyl compound is used to obtain γ, the resulting value is higher than when an ethyl compound is used. Thus, the value of γ_{R-OH} at 50° is 72.4 when ethyl alcohol is used and 97.7 when butyl is employed and γ_{Br-OH} is 64.9 when the ethyl compounds are used and 108.9 in the butyl mixtures. Similarly, in Part I, it was found that the value obtained from the heptane–butyl bromide mixtures was higher than that from the heptane–ethyl bromide system. This difference could be largely eliminated by adjustment of the values of the surface areas, but, as these are derived by a consistent procedure from experimental data, their treatment as adjustable constants is not justifiable. The mean value $\gamma_{R-OH} = 73.7$ is used in calculation where ethyl alcohol is concerned and the value 97.7 for the mixtures containing butyl alcohol, but, for the sake of comparison, the value 73.7 is also used with the latter and the results thus obtained are shown in parentheses. It is safer to compare molecules with the same hydrocarbon chain. One may thus conclude from the values for the ethyl compounds that γ_{R-OH}, γ_{Br-OH} and γ_{I-OH} are not very different from one another and, similarly, from those for the butyl compounds, that γ_{R-OH}, γ_{Cl-OH} and γ_{I-OH} differ little from one another, and that all are much larger than those for the interfaces considered which do not contain hydroxyl. The values in Table III are not sufficiently accurate to warrant their arrangement in a definite order, but it may be concluded that γ_{R-OH}, γ_{Cl-OH} and γ_{I-OH} are of the same order of magnitude and are much larger than the values for the hydro-

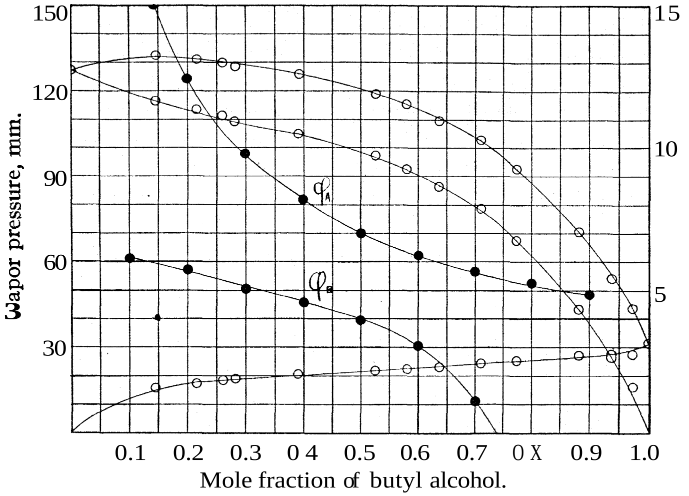

Fig. 5.—Butyl bromide (A)–butyl alcohol (B) at 50°.

carbon–halogen and halogen–halogen interfaces. The values of γ_{R-OH} and γ_{R-OH} are quite different from those of Langmuir, 33.7 and 49.6, respectively, but when Langmuir's value 33.7 is used for γ_{R-OH} instead of 73.7 in calculating γ_{Br-OH} from the data for the ethyl bromide-ethyl alcohol system, the value 49.5 is obtained, which shows how dependent these results are upon one another as well as upon the uncertain surface fractions.

Langmuir examined the effect of molecular orientation in a hexane–ethyl alcohol mixture by means of a necessarily approximate method and was misled by a numerical error to the belief that the effect was very slight, but concluded that it might be important in some liquids, particularly in those whose molecules act as dipoles. Consequently, a second term was introduced into the exponent of the original equation to take care of the energy of orientation in such liquids. When this equation is applied to these systems, a straight line is sometimes found but the frequent failure to obtain linearity shows that the equation is not generally applicable, although, of course, the mere presence of an additional adjustable constant renders it more capable of reproducing experimental data.

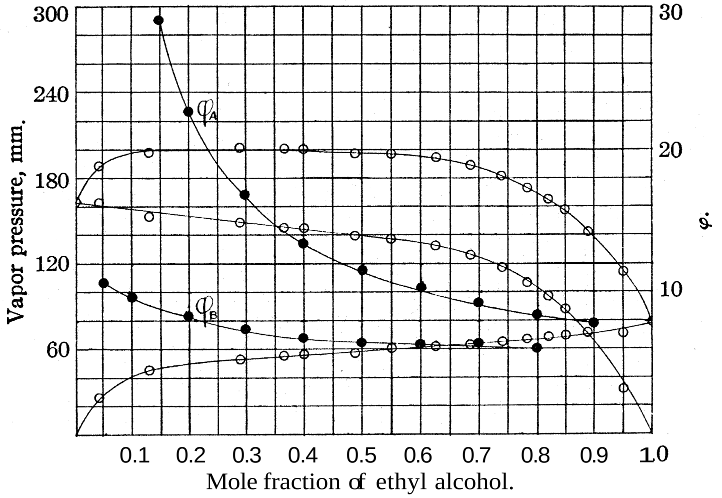

Fig. 6.—Ethyl iodide (A)–ethyl alcohol (B) at 30°.

A general explanation of the deviations of the mixtures from normal behavior may be given in qualitative terms. The field of force around a molecule due to a doublet in its interior depends not merely upon the electric moment of the doublet, but also upon its location in the molecule. Thus the diethyl ether molecule has an electric moment of 1.14×10^{-18} e.s.u.,[3] the resultant, presumably, of two dipoles located in the regions of

[3] Stuart, *Z. Physik*, 51,1490 (1928).

attachment of the ethyl groups to the oxygen atom. The ethyl groups serve as a shield for the dipoles and thus prevent the molecule from being surrounded by a strong field of force. Ether, consequently, behaves as a normal unassociated liquid, even measurements of dielectric polarization at room temperature failing to give evidence of interference of the molecular force fields with one another. The ethyl alcohol molecule has two somewhat similar doublets located in the regions where the ethyl group and the hydrogen are attached to the oxygen atom, the resultant moment[4] being 1.74×10^{-18}. The ethyl group may be pictured as partially screening one side of the molecule from the action of the doublets, but the doublets are close to the surface on the hydroxyl side of the molecule and a strong molecular field results. Alcohol, consequently, shows properties which cause it to be termed a highly associated liquid, and its dielectric behavior is abnormal in the extreme. The water molecule, of electric moment[3,5] 1.8×10^{-18}, possesses two doublets similar to those in the alcohol molecule, but has no ethyl group to serve as a screen. The resultant powerful molecular field renders water a strongly associated and very abnormal liquid. If the higher alcohols are considered, it is evident that with increasing size of the hydrocarbon chain, which contains no appreciable doublets, the doublets at the hydroxyl group will be more and more screened from those in neighboring molecules and the effects of their fields thereby reduced. Consequently, the alcohols become less abnormal with increasing molecular weight.

Ethyl bromide, in spite of the moment, 1.86×10^{-18}, possessed by its molecule, is ordinarily termed a normal liquid.[6] Its doublet should lie in the region of attachment of the ethyl group to the bromine atom and should thus be screened not only by the ethyl group but also by the large bromine atom, which should greatly reduce the molecular field as compared to that of the ethyl alcohol molecule. In ethyl iodide the screening effect of the large iodine atom should be greater than that of the bromine atom, and this, taken in conjunction with the slightly smaller moment of the molecule,[7] 1.67×10^{-18}, should give a smaller molecular field. In conformity with this the dielectric behavior of the two substances shows that the ethyl bromide molecules affect one another more strongly than do those of ethyl iodide. This effect is also apparent in the vapor pressures given in Part I, for the heptane-ethyl bromide system shows a somewhat greater variation in the values of φ, presumably as the result of orienting forces, than is found in the heptane–ethyl iodide system. Butyl bromide, in which the longer hydrocarbon chain should reduce the effect of the mo-

lecular dipoles upon one another, shows but slight variation in the value of φ, and the heptane–butyl chloride mixtures behave similarly.

It appears that the deviations of liquids from the behavior required by the Langmuir equation may be qualitatively explained in terms of the forces acting between the molecular dipoles. Forces which greatly restrict the freedom of orientation of the dipoles in an externally applied electric field may yet be insufficient to impair seriously the validity of the Langmuir equation. As the effects of the dipoles upon one another depend not only upon their electric moments but also upon their location in the molecules and upon the sizes and shapes of these molecules and probably upon the electronic constraints in them, it appears impossible to formulate any generally valid expression for the exact quantitative representation of the interaction of molecular dipoles. Evidently the assumptions upon which the Langmuir equation is derived are too simple to permit of its general and exact application, but the approximate agreement between the calculated and the observed results for the less polar liquids and the general trend of the surface energies calculated indicate that the theory bears a relation to fact beyond a mere resemblance of the equation to the Duhem thermodynamic equation, and the idea of molecular surface energies may lead to most interesting results in spite of the difficulties in its exact quantitative application.
