THE OXIDATION POTENTIAL OF THE LEAD DIOXIDE ELECTRODE IN PERCHEORIC ACID SOLUTION

BY D. J. BROWN AND JOHN C. ZIMMER

RECEIVED MAY 14, 1929 PUBLISHED JANUARY 8, 1030

A great amount of work has been done on the lead dioxide electrode by those who used lead dioxide storage cell plates and sulfuric acid. A few used nitric acid. The concentrations were almost always high. Abegg,[1] based on these early results, gave the value +1.44 for the "normal potential." Glasstone,[2] the only more recent worker, concluded that "a mean value of 1.75 volts at 25° is indicated." The minimum concentration of acid used by Gladstone was 0.487 molar. Gerke[3] apparently considered none of the data suitable for the calculation of a value to include in his summary.

In our work the cell arrangement was

$$\text{Pt}, PbO_2 \mid Pb(ClO_4)_2, HClO_4 \mid \text{Hz, Pt}$$

The reaction of the cell is

$$PbO_2 + 2H^+ + H_2(g) = Pb^{++} + 2H_2O(l)$$

The free energy change for this reaction is

$$AF = -NFE, = -NFE_c - RT \ln \frac{a_{Pb^{++}} \times a_{H_2O}}{a^2_{H^+}}$$

in which E_c is the voltage after correcting for the pressure of the hydrogen and it is assumed that the activity of the PbO_2 is unity. The oxidation potential at unit activity is

$$E_0 = E_c + \frac{RT}{2F} \ln \frac{a_{Pb^{++}} \times a_{H_2O}}{a^2_{H^+}}$$

$$= E_c + \frac{RT}{2F} \ln \frac{\gamma m_{Pb(ClO_4)_2} \times a_{H_2O}}{(\gamma m_{HClO_4})^2}$$

In the first series of measurements (Table I) the concentrations of the perchloric acid and lead perchlorate were equimolecular and the same throughout the cell, then

$$E_0 = E_c - \frac{RT}{2F} \ln m + \frac{RT}{2F} \ln \frac{\gamma_{\mathrm{Pb(ClO_4)_2}} \times a_{\mathrm{H_2O}}}{\gamma^2_{\mathrm{HClO_4}}}$$

from the observed values $E' = E_c - RT/2F \ln m$ was calculated and extrapolated to zero concentration. If we assume that

$$\frac{RT}{2F} \ln \frac{\gamma_{\mathrm{Pb(ClO_4)_2}} \times a_{\mathrm{H_2O}}}{\gamma^2_{\mathrm{HClO_4}}} \doteq 0$$

on dilution, this extrapolated value is E_c.

In the second series (Table II) the concentration of the perchloric acid was kept constant throughout the cell and the concentration of the lead perchlorate was varied in the lead dioxide electrode. Since the concentrations of the lead perchlorate were relatively low, the liquid junction potentials were negligible.[4] The oxidation potential, E_0, was calculated assuming that the activity of perchloric acid[5] is the same as that of hydrochloric acid as determined by Randall and Young,[6] that the activity of water was unity and that the activity of the lead perchlorate was the same as that of barium chloride.[7] This second series was made as a check on the first. The first is the basis for the determination of the oxidation potential.

Experimental Part

Doubly distilled water was used in the preparation of all solutions. Perchloric acid was obtained by dilution of the 60% C. P. acid and standardized against sodium carbonate. Lead perchlorate was prepared by the action of this acid on purified lead carbonate from C. P. lead nitrate. The concentration of this solution was determined with dichromate according to the method of Brown and Moss.[8]

Two hydrogen electrode vessels of the Ostwald type and triplicate or quadruplicate hydrogen electrodes prepared by a modification of the method of Ellis[9] were used in each measurement. Hydrogen was prepared by electrolysis of 15% sodium hydroxide and passed successively through glass wool, 20% perchloric acid, M perchloric acid, and a washer containing the electrode solution. The purity of this hydrogen was established[10] by checking an electrode for which it was used against another which obtained hydrogen from the action of C. P. hydrochloric acid on C. P. zinc. It is known that a solution of lead acetate has a depressing effect on the hydrogen electrode and on the adsorption of hydrogen by

catalytic platinum. Denham and Allmand[11] and Maxted[12] showed that the amount of hydtogen adsorbed varied with the concentration of Pb^{++} ion. In our case it was discovered that hydrogen electrodes in 0.5 M perchloric acid and 0.5 M lead perchlorate did not show a definite equilibrium value, but fluctuated within a range of five millivolts, the value depending on the length of time hydrogen was furnished to the electrode. The same fluctuation occurred in the measurement employing 0.25 *M* lead perchlorate but to a less degree. At 0.1 M lead perchlorate concentration duplicate hydrogen electrodes checked within a maximum of 0.3 of a millivolt. In order to obtain further proof that the effect of lead perchlorate on the hydrogen electrode became negligible at 0.01 M or lower concentration of lead perchlorate duplicate hydrogen electrodes were set up one containing 0.01 M perchloric acid, and the other 0.01 M perchloric acid and approximately 0.01 M lead perchlorate. The potential difference was constant and of the order of 0.75 millivolt, no correction being made for ionic strength and consequent difference in activity of $H+$. In order to make this activity difference negligible, the observations of potential were made with quadruplicate hydrogen electrodes, two in 0.25 M perchloric acid and two in 0.25 M perchloric acid and 0.01 M lead perchlorate solutions and although those in the solution containing lead perchlorate required a longer time to attain equilibrium, the maximum variation was 0.4 millivolt. This is less than the variation in the lead dioxide electrode and consequently would not introduce sufficient error to make it advisable to discard the method as unsuitable if the average value of triplicate[13] or quadruplicate hydrogen electrodes be employed as the reference electrode value, as was done in our case, and taking into consideration the fact that the variation caused by lead perchlorate decreases as the concentration of lead ion becomes smaller.

Electrolytic lead dioxide was deposited on platinized platinum which had been treated with a blast lamp flame to give a rough surface, by electrolysis of basic lead perchlorate or lead nitrate, nitric acid solutions. The best results were obtained by electrolysis of solutions containing 0.1 to 0.5% lead nitrate and 1.5 to 2.5 N in nitric acid. In every case the first electrode plated of a series failed to attain a stable value and the lead dioxide did not adhere very well to the platinum. Electrodes plated with a current density of 0.01 to 0.03 amps./cm.^{2} and a potential drop of 2.2 volts for twenty minutes usually attained a stable value in three to five days and remained constant from three to ten days or longer and then decreased in potential either[12] at a slow uniform rate or abruptly at first and then very slowly. The following are representative:

[13] Glasstone, ibid., 121, 1456 **(1922).**

0.35 M $HClO_4$ and 0.01 M $Pb(ClO_4)_2$			0.001 M $HClO_4$ and $PbClO_4$	
5/ 7/28	set up	1.50369	4/16/28	Set up
5/12/28		1.50175*	4/17/28	1.37904*
5/21/28		1.50133*	4/18/28	1.37604*
5/28/28		1.49790	4/21/28	1.37621"
5/29/28		1.49649	4/24/28	1.37197

The values within the range represented by the starred values were used. The values given in the table are the average of five or six such values which checked within the limits given there.

Glasstone[13] also investigated dioxide prepared in the above manner and suggested that the presence of a trace of higher oxide, possibly PbO_3, was the cause of the high initial value. However, since the best results were obtained by electrolysis of solutions containing small amounts of lead under conditions at which Smith[10] and also A. Fischer and Vossen[14] found that the electrolytic deposit from lead nitrate acid solutions approached and ultimately attained the formula PbO_2 with decreasing lead content and since no one has been able to demonstrate the presence of high oxides in the electrolytic lead dioxide deposit[15] we concluded that the high initial values are due to an excess of energy stored in physical strains such as observed by Nielsen[16] for electrolytically deposited copper.

The decrease in potential following the period of stability is in all probability due to the slow formation of Pb^{++}, which is to be expected due to the value of the oxidation potential of lead dioxide in relation to that for the oxygen electrode. The period of stability varied directly with the length of time used to plate the electrode. After various lengths of time the lead dioxide lost its property of adhering to roughened platinum and in several cases the formation of reddish brown spots in the deposit was observed. One electrode plated for eight hours at approximately 0.003 amp./cm.^{2} was used in four measurements and each time attained a constant value after three or four days which checked that of freshly prepared electrodes. In all, this electrode was used for two and one-half months and was lost by an accident.

Cumming,[17] who also used lead dioxide deposited on platinum from lead nitrate nitric acid solutions, saturated his electrolytic solution with solid lead dioxide before plating in order to obtain an adhering deposit and good results. Cumming also reported that an electrolytic lead dioxide electrode first gave a high initial value, fell to one that remained constant for various lengths of time and then slowly dropped off.

Chemical lead dioxide was prepared by adding bleaching powder, sodium hypochlorite and bromine water solutions to boiling solutions of lead acetate, washing repeatedly with water, hot dilute nitric acid, again with water and drying at 80 to 110°. The four best grades of lead dioxide obtainable were repurified by boiling with 10% sodium hydroxide and then digested with dilute nitric acid, washed and dried. All this work was done and the electrodes were set up by inserting a smooth platinum foil in a quantity of lead dioxide in the bottom of the electrode vessel in an atmosphere free from hydrogen. Only the repurified dioxide and that prepared with bleaching powder gave constant potential values and those only in solutions containing 0.025 *M* or higher concentrations of lead perchlorate, even after twenty-four hours rotation and repeated purification with dilute nitric acid or perchloric acid to remove divalent lead, which was tested for by shaking up lead dioxide with nitric acid of perchloric acid decanting, adjusting the acid concentration and adding potassium chromate. Negative tests were obtained immediately after purification. However, the lead dioxide gave a test for Pb^{++} upon standing dry in stoppered amber bottles in the dark for a week. From the energy relations involved it would be expected that lead dioxide is unstable in neutral or acid solution. However, it would not be expected to decompose when dry in the dark and protected from hydrogen. The potentials of the repurified lead dioxides were initially high or low depending on whether they were prepared by chemical oxidation or electrolytic methods. The equilibrium potential value of the chemical lead dioxide remained constant indefinitely and agreed within a millivolt or two with the average stable value of a number of electrolytic lead dioxide electrodes.[13,15b]

The experimental half cell consisted of a pyrex test-tube with a sealed-in side arm and closed by a one-holed rubber stopper through which a glass tube with a platinum foil sealed in the lower end was inserted. Contact was made to the potentiometer by filling the tube with mercury and inserting the potentiometer lead.

Wquid contact was established between the electrodes by allowing the side arms to dip in a vessel which contained the same solution as the electrodes in the first series of measurements and in the second series contained the same concentration of perchloric acid as the hydrogen electrode. This intermediate vessel was protected from evaporation by a layer of purified paraffin, which was found not to affect the measured values in any way.

Temperature was maintained constant at 25 ± 0.03°. The potential differences were measured with a Leeds and Northrup Type K potentiometer, and a new Weston Standard cell calibrated by the U. S. Bureau of Standards.

In the following tables E_c is the average first stable value of five or six electrolytic lead dioxide electrodes.

TABLE I

EXPERIMENTAL DATA

Mole $HClO_4$ = mole $Pb(ClO_4)_2$	E_c, mv.	E'
0.1	1.432 ± 3	1.461
.025	1.417 ± 3	1.464
.1	1.407 ± 3	1.466
.0025	1.389 ± 2	1.467
.001	1.378 ± 2	1.467
E_0 by extrapolation of E'		1.467

TABLE II

EXPERIMENTAL DATA

$HClO_4$, mole (per 1000 g. of H_2O)	$Pb(ClO_4)_2$, mole (per 1000 g. of H_2O)	E_c	E_0
0.25	0.01	1.501	1.475
.25	.001	1.523.	1.467
.25	.0001	1.549	1.464
		E_0 average	1.469

Summary

1. The possible sources of error in the previous work on the lead dioxide electrode have been discussed.

2. The work of former investigators who found the first stable value of electrolytically prepared lead dioxide to agree within one or two millivolts with the potential of that obtained from chemical sources has been checked.

3. An attempt has been made to explain the high initial value and the final drop in potential of electrolytic lead dioxide. The factors involved in lengthening the stable period of this lead have also been studied.

4. The effect of lead perchlorate on the hydrogen electrode has been investigated and found to be proportional to the Pb^{++} concentration.

5. The standard oxidation potential of Pb^{++}–PbO_2 in molal H^+ has been measured by two methods and found to be 1.467 ± 0.003 volts.

SOME OF THE THERMODYNAMIC PROPERTIES OF AMMONIA. I. THE COMPRESSIBILITY OF AND AN EQUATION OF STATE FOR GASEOUS AMMONIA. THE VAPOR PRESSURE OF LIQUID AMMONIA

BY JAMES A. BEATTIE AND CHARLES K. LAWRENCE

RECEIVED JUNE 20, 1929 PUBLISHED JANUARY 8, 1930

1. Introduction

The compressibility of gaseous ammonia is of interest because the curvature of the isometries is greater than for any other gas, except steam, for which there is a considerable body of data. The earlier measurements either do not extend over a very wide range, or the volumes were uncertain. Roth[1] studied the pressure–volume–temperature behavior of ammonia from 30 to 180°, but his volumes were not definitely determined;

---

[1] Roth, *Wied.* **Ann., 11, 1 (1880).**

Brownlee, Babcock and Keyes[2] measured the compressibility for two isotherms, and determined the values of the constants of the Keyes equation of state for ammonia from the existing data, and Keyes[3] presented data for five isometries extending from 39 to 55 cc. per gram and from 60 to 164°. Holst[4] measured the pressure at several volumes and temperatures from 24 to 100° and from 3 to 21 atmospheres; and Bridgman[5] investigated the high pressure field from 1000 to 12,000 atmospheres for the temperature 30°.

Meyers and Jessup[6] of the Bureau of Standards made a study of the compressibility of ammonia in the low pressure region. The measurements were made by the isometric method and extended from 85.5 to 1300 cc. per gram and from -35 to $+300°$. -These data will be discussed in a later section.

In the present paper there is presented a series of pressure–volume–temperature measurements on gaseous ammonia, extending from 20 to 95 cc. per gram and from 75 to 325°. These data and those of Meyers and Jessup are correlated by means of an equation of state.

The vapor pressure of liquid ammonia has been measured by Cragoe, Meyers and Taylor[7] of the Bureau of Standards from -80 to $+70°$; and by Keyes and Brownlee[8] from the boiling point to the critical point. The data of the authors, which extend from 30 to 132°, agree very well with those of the Bureau of Standards and fairly well with the values of Keyes and Brownlee.

2. The Experimental Method

All of the measurements were made by the isometric method, the details[9] of which have been described in a paper on the compressibility of gaseous ethyl ether. Some modifications in the apparatus however deserve to be mentioned.

The Thermostat.—A larger thermostat was used in the present investigation. It was a liquid bath 36 cm. in diameter and 75 cm. deep, mineral seal oil being used at the lower temperatures and heavy cylinder oil at the higher temperatures. The stirring was accomplished by three sets of propellers each enclosed in a steel tube and geared together. One of these stirrer casings had a larger tube welded around its lower end, thus forming an annular space about 0.5 cm. in width and 20 cm. long which contained about 200 cc. of mercury. The expansion and contraction of this mercury operated a relay which turned on and off the electric current in the three internal heaters, one of which was placed on the top of each stirrer tube. Sufficient current was constantly passed through external heaters to raise the temperature of the bath to within about 2° of the desired value. The temperature regulation was ±0.001° over the entire range from 75 to 325°.

The temperatures were measured by a four-lead potential type platinum thermometer calibrated as described in the earlier paper. All temperatures are on the platinum scale.

The Pressure Gage.—The gage had been modified somewhat[10] and was calibrated against the vapor pressure of carbon dioxide at 0°, this value being taken as 34.401 atmospheres.[11]

The volume measuring device and piezometer were the same as those used in the measurements on ethyl ether but the connecting and riser block was simplified so that only one steel stopcock was used in the entire volume measuring system.

3. Filling the Piezometer

A commercial sample of liquid ammonia was allowed to stand in a vessel containing sodium for about three months, the gas phase being removed from time to time by "blowing off." The method of filling the glass piezometer was the same as that used for ethyl ether. The ammonia was distilled eight times, the first and last portion being rejected each time, and the ammonia frozen while the entire system was evacuated after each distillation. It was finally distilled into the glass bomb, which had been evacuated for six days, first at 400° and later at 350°. The ammonia was then frozen by liquid air and the bomb sealed. The amount of ammonia used was determined by weighing against a counterpoise which had approximately the same outside and inside volume as the bomb. The counterpoise was evacuated when weighing the loaded bomb so that the buoyancy correction was small.

After each loading the vapor pressure of ammonia was measured at 30°. No increase in vapor pressure was observed even when the gas space was reduced to 0.1 or 0.2 cc. In one case after the gas phase had been completely collapsed, it did not re-form for some minutes even though the external pressure was reduced to less than one atmosphere. After each series of measurements the vapor pressure was determined again but no evidence of a decomposition of the ammonia could be detected.

The method of calculation of the results has been fully described elsewhere.[9] All volumes are relative to those of mercury, whose density at one atmosphere and various temperatures was calculated from the Callendar and Moss equation.[12] The temperature coefficient of the compressibility of mercury used was

$$\frac{1}{V_0}\frac{d}{dp}\left(\frac{dV}{dT}\right) = 5 \times 10^{-9} \text{ atmospheres}^{-1} \text{ degrees centigrade}^{-1}$$

---

[10] See Keyes and Dewey, *J. Opt. Soc. Am.*, 14, 491 (1927).

[11] O. C. Bridgeman, This Journal, 49, 1174 (1927).

[12] Callendar and Moss, *Phil. Trans. Roy. Soc.*, 211, 1 (1912).

The measured pressures were corrected for the vapor pressure of mercury. For this purpose the saturated vapor pressures of Smith and Menzies[13] were used and a correction applied by the Poynting relation for the effect of pressure on vapor pressure.

Two runs were made: one extending from 95 to 35 cc. per gram, and the other from 40 cc. per gram to higher densities. In this latter run a leak developed at the higher pressures, so that the measurements at densities higher than 20 cc. per gram are too uncertain to include in the data, and the pressures of the 20 cc. per gram isometric may be in error by several tenths of an atmosphere.

4. Discussion of the Experimental Data

The data are given in Table II, in which the measurements of Meyers and Jessup are also included. Since these two sets of results cover different density ranges, they can only be compared by means of some smoothing function, and for this correlation the Beattie–Bridgeman equation of state[14] is used.

The method of determining the values of the constants from the experimental data has been given elsewhere.[14b] In Table I are given the form of the equation of state and the values of the constants in several sets of units. In the evaluation of the constants most weight was given to the authors' data, as they are at the higher densities. The comparison of the observed and calculated pressure is given in Table II, from which it can be seen that the average deviation of the equation from the measured values is 0.037 atmosphere or 0.077% for the author's data, and 0.012 atmosphere or 0.155% for Meyers and Jessup's data.

The pressures of Meyers and Jessup are all less than those calculated from the equation of state; but it should be noted that in the low pressure region the authors' measured pressures also tend to be less then the calculated values. It is quite evident from the results given in Table II that the general over-all difference between the two sets of data is less than 0.1%. There is, however, a slight difference in the trends of the two sets of measurements which is evident when the A and B functions are plotted against the density. Hence an equation was passed through the Bureau of Standards data alone. The values of the constants and a comparison of the observed and calculated pressures are given in Table III. The average deviation is 0.004 atmosphere or 0.043%. The great difference in the values of the constants for these data may be due either to the fact that the Bureau of Standards measurements are at low pressures where a very slight difference in trend causes a large change in the values of the constants or to the failure of the equation of state to represent the data near saturation within the experimental error, when the constants are determined from measurements at higher temperatures and pressures. It is probable that both of these factors enter into the present case, but it should be emphasized that the authors' data and those of Meyers and Jessup are in excellent agreement, and that the equation of state has reproduced these data very well.

TABLE III

COMPARISON OF THE PRESSURES CALCULATED FROM THE SPECIAL EQUATION OF STATE FOR THE DATA OF MEYERS AND JESSUP WITH THE OBSERVED PRESSURES

The calculated pressures were computed with the values of the constants given below, which were obtained from a consideration of the data of Meyers and Jessup *alone*. The values of the constants (see Table I for the form of the equation) in units of cc. per gram, atmospheres, °C. (T°K. = t°C. + 273.13) are

R	A_0	a	B_0	b	c
4.81824	3000	51.5	0.45	131	360×10^6

The observed pressures are given in Table IIB

Total average % deviation .043

5. Weight of a Normal Liter of Ammonia

The weight of a liter of a gas at 0° and one atmosphere, usually called the weight of a normal liter, can be calculated from an equation of state and the molecular weight. The weights of a normal liter of several gases[15] have been evaluated by means of the Beattie–Bridgeman equation of state and agree well with the experimental values. By use of the same method the weight of a normal liter of ammonia was computed using the molecular weight 17.0311 and the comparison with the observed values is given in Table IV. The experimental values are those selected by Blanchard and Pickering,[16] who make no attempt to explain the difference between the weight obtained at the Bureau of Standards, which is the result of two different investigators, and those of other careful observers, which

---

[16] Blanchard and Pickering, *Scientific Papers of the Bureau of Standards, 21,* 141 (1926).

are all very close to 0.7708. The equation based on the authors' determinations of the compressibility of ammonia leads to the value 0.7706, in good agreement with the earlier data; that based on the data of Meyers and Jessup gives a value of the normal density of 0.7715, agreeing with the Bureau of Standards measured value.

The weight of a normal liter obtained by Keyes[2b] from his equation of state is 0.7699 g.

TABLE IV

WEIGHT OR A NORMAL LITER OF AMMONIA

Source	Grams per liter
Calculated from values of constants of Table I	0.7706
Average of experimental values exclusive of those of Bureau of Standards	.7708
Calculated from value of constants of Table III	.7715
Bureau of Standards experimental value	.7713

6. The Vapor Pressure of Liquid Ammonia

The glass bomb was loaded with about 9 g. of liquid ammonia in the same manner as for a compressibility run. The vapor pressure was measured from 30 to 132°. At each temperature the volume of the vapor space was varied from about 80 cc. to less than 1 cc. Thus at 30° the following values were obtained.

Volume of vapor space (cc.)	76	5	2.4	1.8	0.8	0.2
Vapor pressure (atm.)	11.517	11.514	11.515	11.515	11.516	11.515

These values show that no inert gas was present as there is no increase of the vapor pressure with decrease in volume of the vapor space.

The results are given in Table V, in which are included the measurements made at the Bureau of Standards,[7] and those by Keyes and Brownlee.[8] The agreement with the pressures determined at the Bureau of Standards is better than 0.1%, the authors' pressures being higher, but this difference cannot be explained on the basis of permanent gas in the authors' ammonia since the pressure did not increase with decrease of the vapor volume.

TABLE V

VAPOR PRESSURE OF LIQUID AMMONIA

Temp., °C.	Vapor pressure in atmospheres Beattie and Lawrence	Bureau of Standards	Keyes and Brownlee	Temp. °C.	Vapor pressures in atmospheres Beattie and Lawrence	Keyes and Brownlee
30	11.515	11.512	....	100	61.779	61.816
40	15.343	15.339	....	110	74.83	74.84
50	20.074	20.059	....	120	89.98	89.80
60	25.815	25.797	....	125	98.45	98.08
70	32.717	32.687	....	130	107.6	106.9
80	40.894	....	40.902	131	109.6	108.8
90	50.526	....	50.558	132	111.5	110.6

7. Summary

The compressibility of gaseous ammonia has been determined from 20 to 95 cc. per gram and from 75 to 325°. These data agree with the measurements of Meyers and Jessup, which extend from 85.5 to 1300 cc. per gram to better than 0.1%. The constants of the Beattie–Bridgeman equation of state have been determined from these data and their values are given in Table I. The equation of state reproduces the data of the authors with an average deviation of 0.037 atmosphere, or 0.077% and the data of Meyers and Jessup to 0.012 atmosphere or 0.155%.

An equation was passed through the Meyers and Jessup data alone, which represents them to 0.004 atmosphere, or 0.043%.

The weight of a normal liter of ammonia calculated from the equation based on the authors' work is 0.7706 g. and that calculated from the data of Meyers and Jessup is 0.7715 g. The experimental value determined at the Bureau of Standards is 0.7713 g. and the average of all other careful workers is 0.7708 g.

The vapor pressures of ammonia have been determined from 30 to 132°. They agree very well with the Bureau of Standards values, which extend to 70°, and quite well with those of Keyes and Brownlee above 70°.

THE EFFECT OF TEMPERATURE ON THE MOLECULAR SURFACE ENERGY OF BINARY MIXTURES. I

BY W. F. SEYER AND W. S. PECK

RECEIVED JUNE 24, 1929 PUBLISHED JANUARY 8, 1930

The surface tension of pure liquids has been a subject of much investigation of late. The molecular surface energy has also received a good deal of attention, though this property has been largely studied from the concentration point of view and little attention has been paid to the effect of temperature on surface energy. It is true that Ramsay and Aston[1] determined the surface tensions of a few binary mixtures over considerable ranges and from the results concluded that in those cases examined the molecular weight of the mixture could be taken as the mean of the values for the two substances, but their work was limited to mixtures somewhat similar in properties. An extensive series of measurements has been carried out by Kremann and Meingast.[2] Unfortunately, the temperature interval over which they measured the surface tension was small and consequently little could be learned from their figures in regard to the effect of temperature on the molecular surface energy of binary mixtures.

An interesting series of solubility relationships is that shown by the

solubility of hydrocarbons in liquid sulfur dioxide.[3] In seeking an explanation for the extraordinary solubility of benzene in liquid sulfur dioxide (the liquids are miscible in all proportions), it became desirable to know the surface tensions of various solutions at temperatures lying between their freezing and boiling points. It is reasonable to suppose that in the case of complete miscibility in such chemically divergent liquids as those above, some sort of compound formation ought to exist in their solutions. While the freezing-point curve gave no such indication of chemical combination, yet it was thought that the existence of unstable complexes in solution might not be altogether precluded, and an examination of Eotvos constant, Ke, and its behavior with temperature in solutions of varying concentrations, might show that this was the case. As a result of the work of Jaeger[4] and others, the exact significance of this constant is much in doubt. It has been shown to be dependent upon the nature and size of the molecule. In this respect it is no different from other so-called constants which are connected with the various properties of liquids. Ramsay long ago pointed out that the problem dealing with the molecular weights of liquids in solution is a complex one. Upon mixing and forming a homogeneous phase, the following possibilities present themselves: either one or both of the liquids may become associated; if already associated before mixing, they may become more or even less associated; they may associate one with the other, thereby forming what are usually referred to as solvates. Association should in any case be accompanied by a low value of the Eotvos constant. The breaking down of these complex molecules would then be reflected by an increased value of Ke which should reach a limiting value of 2.12 when all the molecules were in their normal state. A higher value than the theoretical cannot be satisfactorily explained by merely assuming dissociation of the normal molecule, and Walden and Swinne[5] have therefore put forward the suggestion that this can readily be accounted for, if the size of the molecule be taken into consideration. In a similar manner, a high value of the constant in the case of binary mixtures can be explained by the formation of complexes. Additional support of the above explanation would be found if it could be shown that this constant decreased with temperature. It was with this object in view that the following work was done.

Experimental Procedure

The most suitable method for measuring the surface tension of liquid mixtures over an extended range of temperature is the differential capillary rise method as described by Richards, Speyers and Carver.[6]

[6] Richards, Speyers and Carver, THIS JOURNAL, 46, 1196 (1924).

This method requires a knowledge of the densities of the liquids, for calculating surface tension, but as this has to be determined in any case before the molecular surface energy can be obtained, it was not considered a serious objection. The pyrex capillary tubes used were found to have a variation in diameter of less than one part in two thousand. Two of these tubes having radii of **0.1125** and **0.0236** cm. were fused together in such a way as to present the appearance of a tuning fork (Fig. **1**) The lower end of this was then sealed into a thick-walled pyrex tube, **2.5** cm. in diameter and **15** cm. in length. **A** second apparatus was made in the same way.

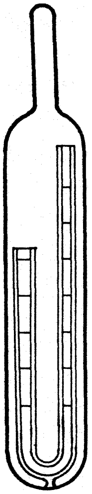

Fig. 1.

A Dewar tube served as a container for the liquids in which the surface tension tubes were to be immersed. **A** number of tubes were examined as regards their optical properties and the one selected as suitable was then tested further in the following manner. **A** surface tension tube was partly filled with water and allowed to come to room temperature. It was suspended above the Dewar tube and while in that position the difference in height of the two menisci was measured by means of a cathetometer reading to **0.05** mm. The tube was next immersed in the bath, which was also at room temperature, and the difference in height again measured through the walls of the Dewar. No difference in the two readings could be detected. Rotating the Dewar tube appeared to make no sensible difference in the cathetometer readings. Nevertheless, the tube was so marked that readings were always taken through the same region.

The next step was to determine the constant of the surface tension tubes. Richards has shown that for both tubes the following equation holds: $S = Khd$, where S is the surface tension, K a constant for the apparatus, h the corrected difference in height and d the density of the liquid minus the density of the vapor. Water was used to determine the value of the constant in the case of Tube **1** and benzene for Tube **2.** These tubes were first thoroughly cleaned with aqua regia, rinsed many times with distilled water and finally water was boiled in them for some time. The tubes were then drained and again rinsed with conductivity water. After several rinsings, Tube **1** about half full of water was boiled under reduced pressure until it was thought that all air had been expelled and then sealed. After the tube had been immersed in the bath for several hours at 20°, the difference in height in the two capillary tubes was measured and found to be **4.875** cm. The correction for curvature as calculated from the known radii of the two tubes amounted to **0.0295,** giving a corrected value of h equal to **4.8435.** Using this and taking the value of the surface tension of water as **72.80** and the density minus the density of the vapor as 0.9982, the constant comes out to be equal to **15.026.** The accuracy of this figure was then further tested by determining the surface tension of benzene at 20°. The corrected difference in height was found to be **2.1875.** Taking the density of benzene minus that of the vapor as **0.8787,** and inserting the above figures in the equation $S = Khd$, the surface tension of benzene is found to be **28.87.** Richards, Speyers and Carver in a series of careful measurements give the value as **28.88.** **A** second tube was then made and its constant determined in a similar manner. Its value was **18.482** and the correction for the menisci **0.0250.**

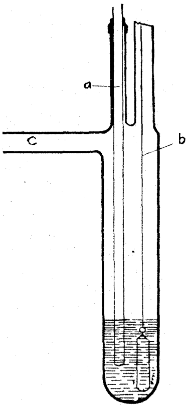

Fig. 2.

The densities were determined by three different methods. Those of the pure sulfur dioxide and of the solutions with benzene below −**10**° were determined by weighing a quartz bulb suspended in the liquid, which was held in a special tube (Fig. 2).

The stem of a platinum resistance thermometer (a) was placed in a limb of the tube, closed at the top with a piece of rubber. The thread for holding the sinker passed through (b). Dry air was gently blown through (c), except when actual weighings were being taken, to prevent any moisture from condensing in the bulb.

The tube itself was placed in a constant-temperature bath. The liquid inside was stirred by moving the sinker up and down. With a bulb having a volume of 8.5095 cc., the surface tension effect on the thread could be disregarded, and by always keeping the bulb the same distance below the surface, no difficulty was experienced in measuring to the fifth decimal place.

The density of pure sulfur dioxide above −15° was measured in a special form of apparatus (Fig. **3).** It was essentially a dilatometer enclosed in a stout glass tube which had been carefully selected with regard to its optical properties. The chief advantages of this form of dilatometer were its compactness and the large range over which it could be used, being limited in fact, solely by the strength of the glass walls. Operation was comparatively simple. After having been evacuated, the tube was filled to one-third of its volume with liquid sulfur dioxide and sealed. Liquid could be caused to run into the inner tube by merely inverting the apparatus and cooling the upper end. When enough liquid had run in, the apparatus was righted and placed in a constant-temperature bath. As soon as equilibrium had been established, the height of the liquid in the capillary tube was read and having previously determined the volume of the bulb up to a certain mark on the capillary, and knowing the radius of the capillary **(10.0282cm.)**, the density of the liquid easily could be calculated.

The temperature of the bath was next raised 10° and the height of *the* capillary read until there was no further rise. The error introduced by the distillation of liquid from the outside tube to the inner one, owing to the difference of temperature when the bath was first warmed, was found to be extremely small and therefore negligible. The length of the capillary was sufficient to cover a range of **20".** When the liquid in the capillary stood at the top the dilatometer was placed in a bath that was 20° higher than the one in which the last measurement had been taken and enough allowed to flow out so that when the temperature was again reduced **20°**, the liquid stood at the bottom of the capillary. Measurements could then be made over another **20"** interval.

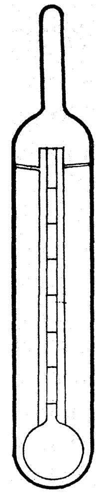

Fig. 3.

While the above method worked admirably for the pure sulfur dioxide liquid, much difficulty was encountered when attempting to measure the densities of the mixtures. This was due entirely to the wide range in boiling points comprising the mixture. The densities of these solutions were, therefore, measured in an ordinary dilatometer, sealed at the top. This, of course, introduced an error owing to the expansion of the glass, caused by the vapor pressures of the liquids. Calculation, however, showed that with the wall thickness used, no correction was necessary below 80° in the case of the different mixtures."

All the usual precautions were **taken** to insure reasonable purity of materials used. The sulfur dioxide was obtained from Baker and Company in small iron tanks. It was bubbled through six wash bottles in series, the first one being filled with an 85% sulfuric acid solution to remove any sulfur trioxide which might be present and the remainder with concentrated acid. The gas finally passed over several feet of phosphorus pentoxide. To test its purity, the freezing point was determined very carefully in the following manner. About **20** g. of liquid sulfur dioxide was condensed in a freezing-point tube which was so constructed as to permit stirring without admission of any moisture from the air. The temperature was measured by a standardized re-

---

[7] Horace Lamb, "Statics," Cambridge University Press, 1916.

sistance thermometer with a Mueller bridge as supplied by Leeds and Northrup. After a sufficient quantity of the sulfur dioxide had been condensed, the temperature of the cooling bath was slowly lowered until crystals formed in the freezing-point tube. It was then kept constant to within one-half of a degree until all the substance was frozen. The freezing point was found to be **−75.45°;** this did not vary more than **0.05°** while freezing was taking place. It was next allowed to melt very slowly, yielding the same figure as above for the melting point. To further test this point, sulfur dioxide was next prepared from pure sodium acid sulfite by treating it with concentrated sulfuric acid. Its melting point was **−75.43 ± 0.01°.** The purity of this latter material being known, the freezing point was taken as **−75.43 ± 0.05".** This is considerably lower than the value given by Walden and Centnerswer, *viz.*, **−72.7".** The Landolt and Bomstein tables, however, ascribe a value of −75.2°, to van der Goot. The freezing points being for all practical purposes identical, the gas from the tank was, therefore, used throughout. The benzene was the usual thiophene-free material supplied by Baker and Company and was further purified by several recrystallizations and then dried over sodium.

Proportions of Mixtures.—The wide range in boiling points of the two liquids necessitated special precautions, both in the manner of making the mixtures and in placing them in the density and surface tension tubes. Dry liquid sulfur dioxide was collected in a special glass reservoir from which it could be easily removed. To insure constancy of composition in the case of each series of measurements, it was necessary to prepare a considerable quantity of solution. This was done in the following manner. A thick-walled pyrex tube was sealed at one end and the other end sealed to a well-ground glass stopcock in such a way as to form a right angle. This container, after having been thoroughly cleaned and evacuated, was partially filled with a definite amount of benzene. Sulfur dioxide was next introduced until a solution was obtained which was approximately of the composition desired. The exact composition was then determined by weighing the tube. Distillation as a means of transferring the solution from the container to the different tube was out of the question, hence it was necessary to make sealed connections in every case and allow the solution, by inverting the container, to flow into the measuring apparatus. At the completion of each series of measurements, the composition of each solution was checked by allowing the sulfur dioxide to dissolve in alkaline solution of known strength and then titrating.

Measurement of Surface Tension.—All the temperatures were measured by a resistance thermometer which had been standardized by the U. S. Bureau of Standards and tested from time to time by determining the freezing point of water. The cathetometer could be read directly to 0.05 mm. and its accuracy was insured by focusing on a standard meter scale, standing upright beside the constant temperature bath.

Measuring the height of the liquids beolw 0° was found to be a rather difficult task. The difficulties increased with fall of temperature. Following the instructions of Richards, readings were always taken with a falling meniscus. This, however, as pointed out by Harkins and others, is apt to give too high a reading, unless sufficient time is allowed for the adhering liquid to drain back. Owing to the viscosity of sulfur dioxide at low temperatures, this required a considerable length of time. Indeed, the time required before the difference in height of the menisci became constant, when dealing with pure oxide at −50°, was between five and six hours. Irregularities in the heights and rates of fall such as are described by Bigelow and Washburn[8] when studying the variations in the surface tension of solutions were noticed. As these variations were more pronounced at low temperatures, they were at the time ascribed to the viscosities of the solutions.

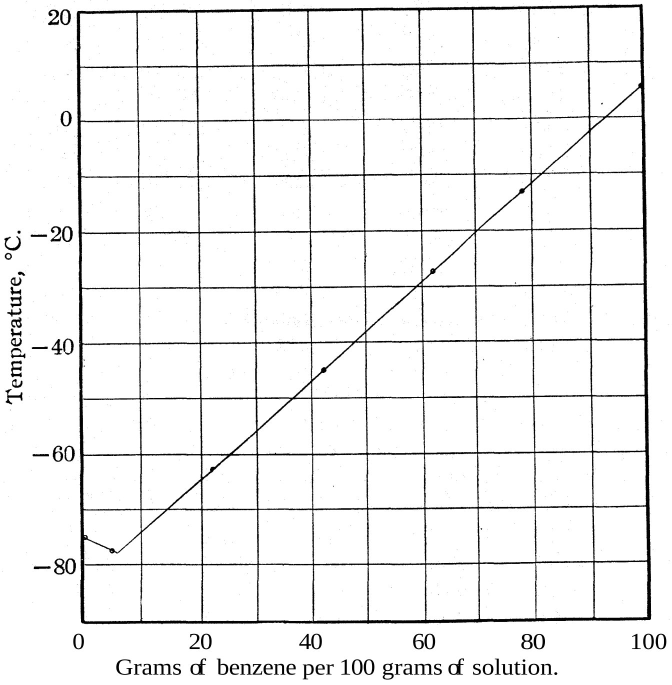

Fig. 4.—The freezing-point curve of benzene–sulfur dioxide solutions.

The densities and surface tensions of pure sulfur dioxide and of the solutions are given in the following tables. The vapor densities of the pure liquid from −50 to 0° were calculated by means of the perfect gas law and above zero by the law of Cailletet and Mathias. In calculating the vapor densities of the solutions the validity of Raoult's Law and the perfect gas law were assumed. The values of Ke were obtained by first plotting on a large scale the molecular surface energies against temperature and then calculating the constant by means of the values taken from the smoothed curve. The molecular weights in the case of the solutions were taken as

Discussion of Results

The densities found for the pure sulfur dioxide are slightly higher than the mean of those given in the critical tables. The surface tensions on the other hand are somewhat lower than those found by V. M. Stowe.[9] From the results obtained sulfur dioxide appears to be associated at temperatures below 20°, which is to be expected from the polar nature of the molecule. With reference to the solutions it is seen that *Ke* is greater in all cases than is either that of benzene (2.13) or of sulfur dioxide, which on the basis of the Walden and Swinne relationship between the value of *Kc* and the size of the molecule would indicate the existence of a larger molecule in the case of the solutions than is found in either of the two pure liquids. The simplest solvate molecule conceivable, although the freezing-point curve gives no indication of such, would be one molecule of benzene combined with one of sulfur dioxide which, by applying the equation discovered by the above-mentioned authors, $Ke = 1.90 + 0.011\,(\Sigma\sqrt{n\mathrm{A}})$ where $\Sigma\sqrt{n\mathrm{A}}$ represents the sum of the square roots of the atomic weights of the elements comprising the molecule, calls for a value of *Ke* equal to *2.34*. Solutions Nos. 2 and 3 apparently fulfil this condition at temperatures below 0°, the complex-molecule decomposing as the temperature rises. Solution No. 1 gives a constant value of *Ke* over the temperature measured. Its low value may be accounted for by assuming it to be the average of that of the excess benzene and that of the solvate. Solution No. 4 unfortunately shows an increasing value of *Ke*. It is difficult to find a satisfactory explanation to account for this increasing value on the basis of the above theory. Of course, at higher temperatures than 80° a decrease in the value of *Ke* might take place As this solution was composed of 77.93% of sulfur dioxide the value of 2.23 obtained at the temperatures below 0° might be due to the fact that some of the molecules of the sulfur dioxide were associated. If now the associated molecules were to break up faster than the solvate molecules as the temperature rose, a larger value of *Ke* would result. Irregular variations in the value of *Ke* are recorded by Ramsay and Aston.[1] Variations in the value of *Ke* with temperature are not limited to solutions but occur in nearly all pure liquids which are composed of com-

---

[9] Stowe, THIS JOURNAL, 51,410 (1929).

plicated and rather unstable molecules. Thus Jaeger[4] found, to give only a few examples, that ethyl acetate has a value of Ke between −74 and 0° of 2.50, which gradually falls to a value of 1.30 above 15°. A few cases show increasing values of *Ke* with rising temperature, *e. g.*, diethyloxalic acid has a value of 1.8 below 0°, which rises to 3.6 at temperatures above 146°. In still other cases the value of Ke passes through a minimum. While inaccuracies in measurement might be the cause of small variations in the value of Ke, as suggested by Livingston and Morgan,[10] they can scarcely be held to account for the gradual drift in the up or down value of *Ke*. In any case it appears that liquids composed of complicated molecules behave as do binary mixtures.

A satisfactory explanation of the foregoing will likely be found in a combination of surface absorption theories and that of orientation as put forward by Hunten and Maass.[11]

Summary

1. The freezing points, densities and surface tensions of pure sulfur dioxide and of sulfur dioxide and benzene solutions have been measured.
2. It has been shown that sulfur dioxide is associated at low temperatures.
3. The freezing-point curve shows no compound formation.
4. The values of the Eotvos constant for binary mixtures have been shown to be dependent upon concentration and temperature.

A COMPARISON METHOD FOR DETERMINING IONIZATION CONSTANTS WITH A QUINHYDRONE REFERENCE ELECTRODE

BY H. DARWIN KIRSCHMAN, BAKER WINGFIELD AND HOWARD J. LUCAS

RECEIVED JUNE 24, 1929 PUBLISHED JANUARY 8, 1930

Introduction

Within recent years, the potentiometric method[1,2] of determining ionization constants of weak acids has begun to displace the conductivity method. One disadvantage of the latter is that it is necessary to make conductance measurements not only of solutions of the acid but also of those of a salt of the acid in order to compute Λ_0; another disadvantage arises from the fact that in order to obtain moderately accurate results very pure water must be used for the preparation of the dilute solutions.

The usual potentiometric method in which the acid is titrated with a standard base to give a titration curve is not entirely satisfactory since (1) the accuracy of the constant is seriously affected by the difficulty of determining the inflection point in the voltage–ml. plot when the acid is weak, and (2) the liquid junction potentials vary while the titration is being carried on, due to the continued addition of water and of the positive ion. The method described in this paper has an advantage over the titration method in that the liquid junction potentials are for the most part eliminated.

Method

The method consists in determining the potential of the reference electrode represented at the left end of the cell below, first against a saturated solution of quinhydrone containing hydrochloric acid at various concentrations, and then against similar solutions containing the acid under investigation at a series of concentrations. The whole cell may be represented thus

Pt, KCl(0.09 N) + HCl(0.01 N) + Quinhydrone
KCl(0.09 N), HA(*c* N) + Quinhydrone, Pt

HA represents hydrochloric acid in one series of measurements and the acid under investigation in the other series.

From the data obtained when hydrochloric acid is used a curve is drawn by plotting the measured voltages against the logarithms of the mean ion activities, $C\alpha$ of the hydrochloric acid. When any other acid is used as HA in the above cell, it is possible to obtain the logarithm of the mean ion activity of this acid at any concentration from the corresponding voltage.

It is difficult to evaluate the liquid junction potentials when the junction is being continuously renewed, but it seems certain that the difference between the liquid junction potential when hydrochloric acid is used and when an organic acid of the same mean ion activity replaces it will introduce an error in the constants well within the limit of experimental error of the measurements.

Calculation of the Constant.—The ionization constant is calculated from the experimental data by means of the expression

$$K_A = \frac{a_{\pm}}{\left(C - \frac{a_{\pm}}{\alpha}\right)}$$

where $a_{\pm}$ is the mean activity of the ions, C is the molal concentration of the acid, and α is the mean activity coefficient.

This assumes (1) that the activity of the undissociated acid is equal to its concentration, (2) that the mean ion activity in the organic acid solution is the same as the mean ion activity in that hydrochloric acid solution which gives the same potential against the reference cell and (3) that the quinhydrone will affect the mean ion activity to the same extent in solutions of the same mean ion activity.

'She work of Randall and others[3] shows that at the concentrations of acid (0.02–0.0003 M) used in these measurements the first assumption is **fully** justified. Since the determination of the individual ion activities is a difficult operation, it is desirable to make the second assumption, which seems justifiable at the low concentrations of ions prevailing.

The solubility of the quinhydrone is small,[4] 0.018 mole per liter at 25°, and presumably about the same in the various solutions so that the last assumption is a reasonable one.

Apparatus and Materials

The cell used was similar to the type proposed by Kohn[5] and is shown in the figure, The inner cell containing the reference solution consisted of a glass tube 1.5 cm. in diameter and 15 cm. in length fitted with a ground-on glass cap and a removable electrode carrying a piece of bright platinum foil. The outer cell consisted of a 400-cc. beaker fitted with a rubber top through which passed the mechanical stirrer, the nitrogen bubbling tube, the inner cell and a glass tube carrying a piece of bright platinum foil which served as the second electrode.

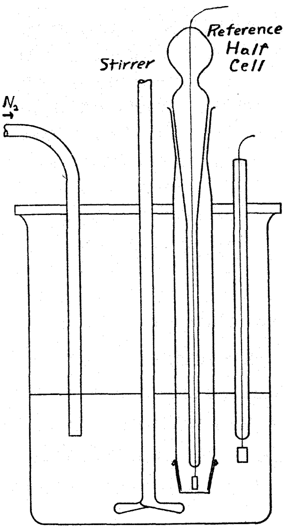

Fig. 1.

The e.m.f. measurements were made with a Leeds and Northrup Type K potentiometer. The cell was immersed in an oil thermostat maintained at 25 ± 0.02".

Eastman's quinhydrone was recrystallized twice from water at 70° and was dried over sulfuric acid in a vacuum desiccator.

Constant boiling hydrochloric acid was prepared by the distillation in an all-pyrex apparatus of concentrated C. P. hydrochloric acid previously diluted to a specific gravity of 1.11. At the observed pressure of 744.6 mm[6] one mole of hydrogen chloride is contained in 179.864g. of solution. A tenth-normal solution was prepared by diluting a weighed amount of this standard acid with a weighed amount of water. Lower concentrations were made by volume dilutions from this solution.

The potassium chloride was recrystallized four times from hot water and fused to dryness.

Benzoic acid of standard quality was purified by three crystallizations from hot water and a subsequent sublimation.

The *p*-cyanobenzoic acid was the same as that used in the research of Valby and Lucas.[7] A stock solution was prepared by dissolving a weighed quantity of the solid organic acid in water to a definite volume. This stock solution was diluted by volume to obtain the lower concentrations.

The water used in the preparation of all solutions was obtained by distillation of distilled water from sodium carbonate and potassium permanganate in an all-pyrex

apparatus in an atmosphere of nitrogen. Care was taken to prevent absorption of carbon dioxide and oxygen from the atmosphere.

Experimental Method

The glass cap of the reference half-cell was filled with 0.09 *N* potassium chloride solution and fastened to the cell with a rubber band. This provided a bridge of 0.09 *N* potassium chloride through the ground-glass joint. The excess liquid was removed by three washings with the reference solution and the half-cell filled to a depth of 3–4 cm. with the reference solution. The liquid levels were kept about the same in the outer and inner half-cells to minimize the drift in potential due to diffusion through the ground-glass joint during the measurements. To the 400-cc. beaker which served as the outer half-cell was added about 200 cc. of the hydrochloric or organic acid solution. The outer parts of the reference half-cell were washed with a small amount of the same solution, the two half-cells were assembled in the oil thermostat and connected to the potentiometer. Stirring was carried on at a slow rate by the motor-driven stirrer while purified nitrogen was passed through the outer half-cell at the rate of about 20 bubbles a minute. Voltage readings were made at five-minute intervals until equilibrium to within 0.1 millivolt was attained, which generally took from ten to fifteen minutes. This equilibrium value was usually about one millivolt lower than the initial reading. The bright platinum foil electrodes were found to give reproducible results throughout the entire series of measurements.

The reference half-cell was filled anew before each determination, since otherwise the observed voltage on a succeeding run would be materially lower.

All solutions used were saturated with quinhydrone at 45° by vigorous shaking for fifteen minutes in the presence of a small excess of the solute. The solutions were then brought to 25° by immersion in the thermostat and were shaken at intervals to aid crystallization of the excess quinhydrone.

Reference Curve.—Using the apparatus and methods described, measurements were made of the voltages produced by solutions of known concentrations of hydrochloric acid saturated with quinhydrone against the reference solution 0.09 N in potassium chloride and 0.01 *N* in hydrochloric acid, saturated with quinhydrone. The results are given in Table I.

The values of the logarithm of the mean ion activity in the organic acid solutions were obtained from the plot of the data of Table I. The values of the constant were calculated from the expression $K = a_{\pm}/(C - (a_{\pm}/\alpha))$. These values were then plotted against the logarithm of the concentration to obtain the constants at round concentrations which were compared in the case of benzoic acid in Table IV with those of some previous investigators obtained from conductance measurements.

It is seen that the values obtained by any one investigator agree very well but the divergence of the results of different investigators is quite con-

---

[9] Noyes, THIS JOURNAL, **46,** 1080 (1924).

siderable. These constants were calculated using ion concentrations rather than mean ion activities, but this difference is much less than the variation in results.

TABLE IV

The maximum deviation from the mean in the values for the ionization constant of *p*-cyanobenzoic acid is 3%. The mean value agrees with the value of **3.09** X 10^{-4} which Valby and Lucas[7] obtained by the conductance method.

Summary

Ionization constants of organic acids may be determined by means of a quinhydrone cell in which the reference half-cell is standard hydrochloric acid solution saturated with quinhydrone and containing potassium chloride.

The method is tested in the case of benzoic acid by a comparison of the values herein obtained with those reported by previous investigators and found to be in satisfactory agreement.

The ionization constant of *p*-cyanobenzoic acid is found to be $3.10 \pm 0.10 \times 10^{-4}$. This result likewise agrees well with the value recently obtained by the conductance method.

THE BEHAVIOR OF GLASS ELECTRODES OF DIFFERENT COMPOSITIONS

BY D. A. MACINNES AND MALCOLM DOLE

RECEIVED JUNE 25, 1929 PUBLISHED JANUARY 8, 1930

In a recent article[1] the authors have described a new form of glass electrode which can be made of small size, but with sufficiently low resistance for accurate work. The design of the electrode is shown in Fig. 1. The supporting tube B (which is usually about 4 mm. in diameter) holds the thin glass diaphragm D over its lower end. The tube is partially filled with hydrochloric acid (0.1 N in our experiments) into which is inserted a silver–silver chloride electrode C. The upper part of tube B is coated, inside and outside, with paraffin.

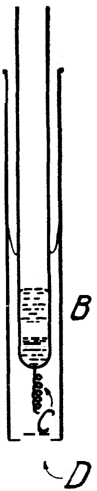

Fig. 1.

In the experiments to be described below the diaphragm D and supporting tube B were made as follows. A piece, weighing about 50 mg., of specially prepared glass for the diaphragm was first melted into the end of a pyrex tube of about 4 mm. diameter. The glass was then heated to a low red heat and blown into the form of a bubble with walls thin enough to show interference colors. The end of the tube B, which was of ordinary soft glass, was heated somewhat under red heat, and was then brought into contact with the bubble wall. If this operation is properly carried out the diaphragm will fuse onto the lower edge of the tube B. Such diaphragms are surprisingly strong. A group of tubes having these diaphragms over their lower ends held columns of nine centimeters of mercury for three weeks or more. No apparent difference in this time was observed whether the diaphragm was placed in tenth-normal acid or alkali or in water. The diaphragms are, however, easily broken by sudden jars.

The present investigation was undertaken with the purpose of finding the most suitable glass for the diaphragm.[2] The design of glass electrode just described is better than the original Haber form for comparing different samples of glass, since diaphragms of very nearly uniform and definite thickness can be selected and fused onto tubes of sufficiently uniform bore. Since commercial glasses are available with narrow ranges of composition

An apparatus involving the application of these electrodes to the determinaton of the hydrogen-ion concentration of very small amounts of liquids is described in J. *Gen. Physiol.*, 12, 805 (1929).

[2] Tests of commercial glasses, using the Haber form of glass electrode, have been made by Hughes, J. *Chem. Soc.*, 491 (1928), and Elder, THIS JOURNAL, 51, 3266 (1929).

only and contain a large number of components, some of which are definitely undesirable, it was decided to make our own samples of glass. These new glasses have, however, been compared with some commercial specimens. With the aid of Dr. Geo. W. Morey, to whom we are much indebted for assistance and suggestions, a platinum–rhodium wound furnace such as he has used in his researches on glass was constructed in the shop of the Geophysical Laboratory. The furnace is capable of reaching temperatures up to 1600°. We have also received useful suggestions from the Staff of the Bureau of Standards.

In making the glasses dry silica, calcium or magnesium carbonate and the carbonate of the alkali used were weighed out in the desired proportions and thoroughly mixed by grinding. The mixture was then melted in the furnace. It was found convenient to add the mixture a few grams at a time; otherwise the evolution of carbon dioxide causes the melt to flow over the edge of the crucible. After melting the sample it was held for an hour or so at 1200 to 1400° until all gas bubbles escaped from the melt, and to insure uniformity. The crucible and contents were then cooled, at first slowly and finally by quenching in a stream of cold water. This yielded material cracked into small pieces, some of which were suitable for making the thin diaphragms as already described.

For a first survey of the possible suitability of a glass for use as an electrode, three properties were measured, after the glass had been made into electrodes of the form shown in Fig. 1 with diaphragms of approximately 4 mm. diameter and about 0.001 mm. thickness. The properties chosen were (a) the potential existing in the diaphragm, (b) the resistance of the electrode and (c) the deviation from the theoretical potential when the electrode was placed in a buffer solution at P_H 8, and in an approximately 0.1 N sodium hydroxide solution of P_H 12.75.

(a) The potential in the glass was measured because, in the first place, it is a correction to the measured potential which must be made when the electrode is used for determining hydrogen-ion activities. Further, we have found by experience that if this "asymmetry potential" is large it is also likely to be varying and to require frequent determination. In addition, a glass with a large asymmetry potential is almost certainly otherwise unsuitable. The asymmetry potential was obtained by measuring the e.m.f. between the glass electrode and a silver–silver chloride electrode when both were placed in 0.1 N hydrochloric acid.

(b) The electrical resistance of the glass must not be too large, because a high resistance lowers the sensitivity of the measurements, and makes elaborate screening and insulation of the measuring instruments and of the cell necessary. Measurements of the resistance of the electrodes were carried out by shunting the electrometer with a 0.5 megohm resistance, after which it was connected in a circuit containing the glass electrode placed in hydrochloric acid, a silver–silver chloride electrode in the same solution and a known potential (1.2 volts). From the deflections obtained the resistances of the electrodes could be computed. With some of the harder glasses this method failed to yield quantitative measurements since the electrometer deflections were very small or zero, but in these cases the glasses were of no use for our purpose.

(c) To measure the effectiveness of a glass when used as an electrode for determining hydrogen-ion activity, the glass electrode was placed first in a buffer solution of PH 8 with which a saturated calomel electrode was connected, the arrangement being

$$\text{Hg} \mid \text{HgCl, KCl (satd.)} \parallel \text{soln. } \mathbf{A} \mid \text{glass} \mid 0.1\ N\ \text{HCl, AgCl} \mid \text{Ag}$$

If the glass surface is reversible to the hydrogen-ion activity, this combination can readily be seen to be equal in potential to the sum of the two cells

$$\text{Hg} \mid \text{HgCl, KCl (satd.)} \parallel \text{soln. } \mathbf{A} \mid H_2 \text{ and } H_2 \mid \text{HCl } (0.1\ N)\text{, AgCl} \mid \text{Ag}$$

The potential of the first of these cells[3] is at 25°

$$E = 0.2458 - 0.05915 \log a_H$$

(in which a_H is the hydrogen-ion activity of solution A) and of the second −0.3524.[4] The relation between the e.m.f. of Cell 1 and the hydrogen-ion activity is, therefore, at 25°

$$E = -0.1066 - 0.05915 \log a_H = -0.1066 + 0.05915\ P_H$$

If, therefore, the glass surfaces are reversible to the hydrogen-ion activity Combination 1 should have a potential of 0.3663 when Solution A is at *PH* 8 and of 0.6475 in the approximately 0.1 N sodium hydroxide which had a measured *PH* of 12.75. Any glass at all suitable for our purpose showed no deviations in the first test but in the strong alkali large variations from the theoretical potential were always observed.

A summary of the results of the three tests just outlined made on a series of glasses is given in Table I. If the composition of a glass is given in the table it was made in this Laboratory. Most of the figures given in the table are the average of measurements on several electrodes. Though an effort was made to make the diaphragms of the electrodes of the different glasses as nearly alike as possible in diameter and thickness, it was impossible to avoid some variation. However, it will be seen that the effects of changing composition are much larger than can be accounted for by any possible uncertainty in these dimensions. An idea of the reproducibility can be gained from the measurements of resistances of five electrodes made of glass No. 6, the measurements being 11.6, 10.6, 11.1, 15.0 and 10.7 megohms. This degree of reproducibility is possible be-

[4] From the results of Scatchard, THIS JOURNAL, 47, 641 (1925), involving a slight interpolation.

cause a fair estimate of the thickness of a given portion of a glass membrane can be obtained from the interference colors present. It will be seen that the hard glasses, which are the first mentioned in the table, have large potentials present in the diaphragm, large resistances and large deviations from the theoretical potential in alkaline solutions. An improvement in all these respects is to be noted in the "soft commercial" glass (No. 4 in Table I), which showed a rather high but rapidly decreasing membrane potential. The resistance of the electrodes is lower (about **100** megohms), which makes more accurate measurement possible. This resistance, however, increased with time. The error observed in the alkali solutions is also smaller than with the harder glasses.

A great gain in each respect is found in the soft glasses (5 and 6) prepared in this Laboratory. No. 5 has the same composition as that tested by Elder and Wright[5] and is intermediate in properties between the soft commercial glass and No. 6, which has very nearly the composition corresponding to the lowest temperature found on Morey's[6] triangular melting-point diagram for the system $CaO-SiO_2-Na_2O$. This glass is, so far as our experiments have been able to determine, the best for use in determining hydrogen-ion activity. There is a low, nearly zero, potential in the membrane, the resistance is low, and the error in alkaline solution is the smallest observed. A more detailed study of the e.m.f. relations when this glass is made into electrodes is given below.[7]

Glass No. 7 made by increasing the percentage of alkali and decreasing the lime, is definitely too soft. The errors obtained in alkaline solutions are large and increase rapidly. Glasses Nos. 8 to 11 were made by systematically varying the composition of the three components by small percentages from that of glass No. 6. All these samples were inferior to that glass in the constancy of the readings in alkaline solutions, if not inferior in other qualities.

Since suitable glasses for hydrogen-ion measurements are all very soft their solubility may lead to errors if they are used with unbuffered solutions for any length of time. Direct measurements have shown that glass No. 6 will give off about 7×10^{-10} equivalent of base in twenty-four hours per square millimeter of surface. We therefore recommend that the diaphragm only be made of this glass, and that ordinary soft glass be used for the supporting tube.

It seemed possible that a "finer grained" glass might be prepared which

would show desirable properties in alkaline solution if lithium were substituted for sodium, since lithium has a much lower atomic volume. A glass was therefore made in which the sodium oxide of sample No. 6 was replaced by lithium oxide. This glass (No. 12 in the table) crystallized readily. However, by sudden chilling a workable, very low melting material was obtained which could be blown into thin bubbles. The supporting tube had, however, to be heated to a lower temperature than usual in order to avoid melting the film. The initial resistance of this glass was very low and dropped rapidly, and the e.m.f. reading at *P*H 8, which was correct on the first day, was considerably in error on the second day. The error in strong alkaline solution was initially about the same as with glass No. 6, but increased very rapidly. The glass is quite hygroscopic and becomes cloudy in a few days. Glasses Nos. 13 and 14 were prepared with the idea of discovering whether any desirable effect could be produced by replacing a part of the sodium in glass No. 6 with lithium. The unexpected result was that the electrodes had too high resistances to be of practical use. The errors in alkaline solution were also large and increasing. Electrodes with very high resistances were also obtained when they were made from a glass (No. 15) in which the sodium oxide of No. 6 was replaced by half each of potassium and lithium oxides. Sample No. 16 was made at the suggestion of Dr. Morey, who found that a melt of the composition given would not crystallize after prolonged heating. The measurements show, however, that it has no properties which recommend it for use as a glass electrode.

It next became of interest to determine the range in which measurements made with electrodes constructed of our best glass (No. 6) agree with the hydrogen electrode. An apparatus shown diagrammatically in Fig. 2 was constructed with which a hydrogen electrode H could be compared with a glass electrode G in the same solution. Connection was also made from the vessel containing this solution to a saturated calomel electrode C so that the P_{H} of the solution and the constancy of the hydrogen electrode could be determined. The solution was saturated by a stream of carefully purified hydrogen entering by tube F. Arrangement was also made so that an alkaline solution could be added from the separatory funnel A to the solution in which the electrodes were dipped so that the P_{H} could be progressively increased. By means of the tube D the current of hydrogen also passed through the alkaline solution in the funnel A so that, since no oxygen was introduced, the hydrogen electrodes rapidly came to a new equilibrium when the P_{H} was changed. The results of such a comparison of the glass and hydrogen electrodes are given in Table II. Since the differences at low P_{H} values are inappreciable, the comparison was started at P_{H} 7.72, using a borax–boric acid buffer solution of approximately 0.1 *N* sodium-ion concentration.

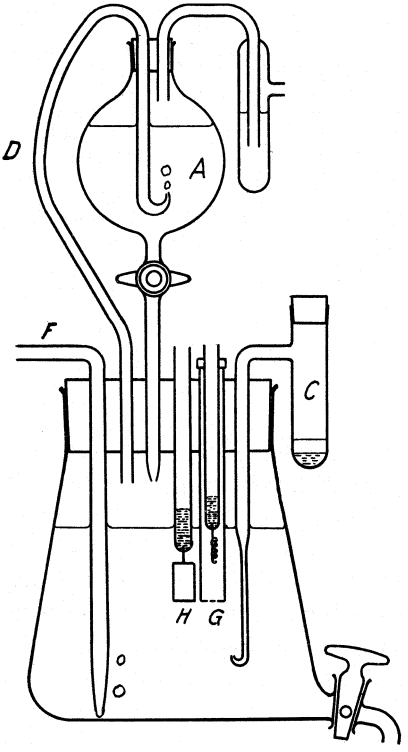

Fig. 2.

TABLE II

COMPARISON OF GLASS AND HYDROGEN ELECTRODES AT DIFFERENT P_{H} VALUES

P_{H}	7.72	8.20	8.73	9.23	9.83	10.47	11.64
Diff. between glass and hydrogen electrodes	0.3540	0.3540	0.3540	0.3540	0.3555	0.3577	0.3688

If the glass surface acts as a hydrogen electrode the potential of the combination

$$H_2 \mid \text{soln. A} \mid \text{glass} \mid 0.1\ N\ HCl, AgCl \mid Ag$$

should be constant and equal to that of the cell

$$H_2 \mid 0.1\ N\ HCl, AgCl \mid Ag$$

whatever the hydrogen-ion activity of solution A may be. The results illustrate the constancy of the difference (within 0.1 millivolt up to P_{H} 9.2) and the deviations to be expected at higher alkalinities. The difference is within 0.0016 volt of the value given by Scatchard[4] for cell (B), the variations possibly being due to a difference in the method of preparing the silver–silver chloride electrodes, and in a lack of control, in these experiments, of the hydrogen pressure. These results are plotted on Curve A in Fig. **3,** together with similar measurements (Curve B) in which the solution between the hydrogen and glass electrodes was kept saturated with sodium chloride (approximately 5.4 N). It will be observed that in this case the deviations from reversibility to the hydrogen activity begin at a lower PH value and are much greater than with the sodium-ion concentration at 0.1 N. The measurements were made with a potentiometer, using a Compton electrometer as a null instrument, in a constant temperature room at 25.0 ± 0.2°. Using glass No. 6 the resistance of the system is so low that ordinary care in screening is sufficient. In our work the leads were covered with a lead sheath, the cell was surrounded by a wire cage, and the necessary switches and tapping key were placed in a tin box. All these screens were, of course, grounded.

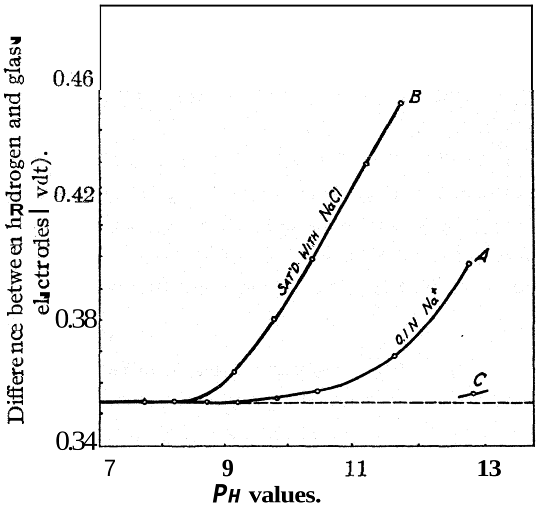

Fig. 3.

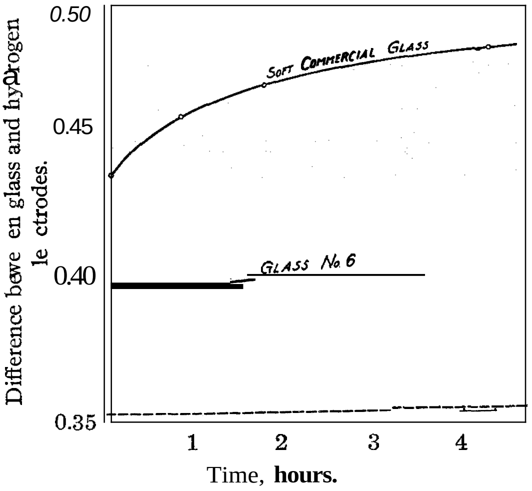

Fig. 4.

Incidentally Curve B also represents with quite sufficient accuracy the measurements of these deviations for glass No. 4 "soft commercial" of Table **I,** with the sodium-ion concentration at 0.1 *N*, showing that our glass No. 6 represents a decided improvement over glasses available in the market in the range of PH values in which the glass electrode is applicable. Furthermore we have observed that glass No. 6 shows steadier potentials in alkaline solution than any other that we have worked with. A comparison of two glasses under somewhat extreme conditions is given in the curves plotted in Fig. 4. The upper curve indicates the variation of the potential with time of the soft commercial glass, and the lower curve the corresponding variation of glass No. 6. It will be seen that the readings of the latter are roughly constant even in these strongly alkaline solutions.

Hughes[2] has shown, however, that these deviations in alkaline solutions depend upon the nature of the positive ions present. We have found, however, very small deviation at about P_H 13 when the base present is tetramethylammonium hydroxide; this is shown in Point C of Fig. 3. We hope to be able to present in the near future a theory explaining these deviations.

Summary

Using a form of glass electrode designed by the authors, the suitability of a series of specially prepared glasses for use as electrodes has been studied, and a few comparisons have been made with samples of glass of commercial origin. The electrodes were tested for "asymmetry potential," resistance and the amount of deviation in alkaline solutions of the measured potential from the theoretically predicted potential. The best of the glasses tested has the composition SiO_2, 72, Na_2O, 22 and CaO, 6%. The potential at the surface of this glass changes quantitatively with the hydrogen-ion activity up to P_H values of 9.5, though this limit is lowered in strong salt solutions.

CERIC SULFATE AS A VOLUMETRIC OXIDIZING AGENT. X. THE DETERMINATION OF THALLIUM

BY H. H. WILLARD AND PHILENA YOUNG

RECEIVED JUNE 28, 1929 PUBLISHED JANUARY 8, 1930

Introduction

A number of volumetric procedures for thallium have been proposed. Willm's method based upon the titration of thallous salt in hot hydrochloric acid solution with potassium permanganate has been the one most extensively used.[1] Hawley[1] found that if the permanganate was standardized against pure thallous sulfate in hot solution, using exactly the same

---

[1] Willm, *Bull. soc. chim.*, 352 (1863); Noyes, *Z. physik. Chem.*, 9, 603 (1892); Dennis and Doan, THIS JOURNAL, 18, 970 (1896); Marshall, *J. Soc. Chem. Ind.*, 19, 994 (1900); Hawley, THIS JOURNAL, 29, 300 (1907); Müller, *Chem.-Ztg.*, 33, 297 (1909); Berry, *J. Chem. Soc.*, 121, 394 (1922); Bodnár and Terényi, *Z. anal. procedure as in a determination of thallium, and if 0.10–0.16 g. of thallium was present, the results were accurate. He showed by a graph that the weight of thallium oxidized by 1 cc. of permanganate was almost constant within this range, but dropped rapidly with less than 0.1 g. of thallium. Berry[1] used the electrometric end-point and found, in agreement with Hawley, that the method was a very empirical one. Jílek and Lucas[1] reported good results if considerable potassium chloride was added to the hydrochloric acid solution of the thallous salt before the titration with permanganate. Nietzki[2] titrated a thallous salt with standard potassium iodide as long as a precipitate formed, obviously an inaccurate method. Feit[3] added potassium iodide and an excess of standard arsenite to a thallic salt, filtered off the thallous iodide and titrated the excess arsenite with standard iodine. His results were low and the method involved a preliminary oxidation of thallous salt. Thomas[4] substituted standard thiosulfate for arsenite. Sponholz[5] titrated a thallous salt with standard bromine water to a visual end-point, an inaccurate method because of the instability of the oxidizing agent and the uncertainty of the end-point. Marshall[1] oxidized a thallous salt, to which bromide was added, with a measured excess of standard sodium bromate in a hydrochloric acid solution, distilled the bromine formed into potassium iodide solution and titrated the iodine with thiosulfate. He stated that the method was rapid and accurate, but it has the disadvantages of requiring a special form of apparatus and two standard solutions. Zintl and Rienäcker[6] simplified this procedure by titrating thallous salt in hydrochloric acid solution with standard potassium bromate, using the electrometric method or methyl orange as internal indicator. Their results were accurate, and the procedure was simple and rapid. These same authors showed that thallic salt could be titrated with standard titanous chloride in acetic acid solution. Browning and Palmer[7] oxidized thallous oxide with ferricyanide in alkaline solution, filtered off the thallic oxide formed, acidified the filtrate with sulfuric acid and titrated the ferrocyanide with standard permanganate. Berry[1] checked this method using recrystallized thallous sulfate, obtained good results by drying the thallic oxide, but found only a fairly good agreement by titrating the ferrocyanide in the filtrate. The color change at the end-point was not sharp. Berry[8] titrated thallous ion in strong

[8] Berry, *Analyst*, 51, 137 (1926). After this paper had been submitted for publication, further work by this author appeared [*ibid.*, 54, 461 (1929)] in which he gave the results of a single titration of thallous chloride by ceric sulfate using iodine chloride

hydrochloric acid solution with potassium iodate, using chloroform as indicator.

Since nearly all of the volumetric methods for thallium except the bromate method of Zintl and Rienäcker[6] have serious disadvantages, the authors felt that a rapid and accurate procedure for thallium would be of value. The following material describes such a method based upon the direct titration of thallous salt with standard ceric sulfate.

Experimental

Very pure thallous sulfate was recrystallized from water, dried at 150° and used to prepare a standard solution. The ceric sulfate solution was prepared by the method described by the authors[9] from high-grade ceric oxide obtained from the Welsbach Company of New Jersey and was 0.5 M in sulfuric acid. It was standardized against sodium oxalate.[10]

Titration in Hydrochloric Acid Solution.—Measured volumes of the standard thallous sulfate solution were taken, diluted with water and acid, heated to the temperature indicated and titrated electrometrically at that temperature with standard ceric sulfate. A silver chloride–platinum

as catalyst and chloroform as indicator. He stated that under ordinary conditions ceric sulfate did not react with thallous salts and that even when iodine chloride was present the theoretical factor could not be used.

[9] Willard and Young, THIS JOURNAL, 51, 149 (1929).

[10] Willard and Young, *ibid.*, 50, 1322 (1928).

electrode system was used and a thermionic voltmeter, Type DP-2, from the General Electric Company. The silver chloride electrode in 0.1 N potassium chloride was placed directly in the liquid to be titrated. The quantities of the various substances and the results are indicated in Table I. One-tenth gram of thallium required about 10 cc. of 0.1 *N* ceric sulfate.

These results show that the titration of thallous salt with ceric sulfate is quantitative and satisfactory over a wide range of conditions: (a) room temperature if a large amount of hydrochloric acid is present and if the thallium content is not too high, (b) higher temperature if the volume of hydrochloric acid used is decreased or if the thallium content is large enough to cause much thallous chloride to be precipitated by the hydrochloric acid present, (c) a variation in volume of solution, (d) a variation in amount of thallium from 0.04–0.30 g. Experiments were not carried out beyond this range in thallium content. In many of the reactions, when within 0.1 cc. of the end-point the equilibrium was reached rather slowly. A sudden break in potential was followed by a slow increase for a minute or two. A complete titration never took more than ten minutes, and with a little experience required less time. At temperatures below 60°, the end-point break amounted to 200–250 mv. per 0.02 cc. of 0.1 *N* ceric sulfate, but in titrations made above 60°, the break was decreased to 40–100 mv. The type of titration curve obtained is illustrated in Fig. 1.

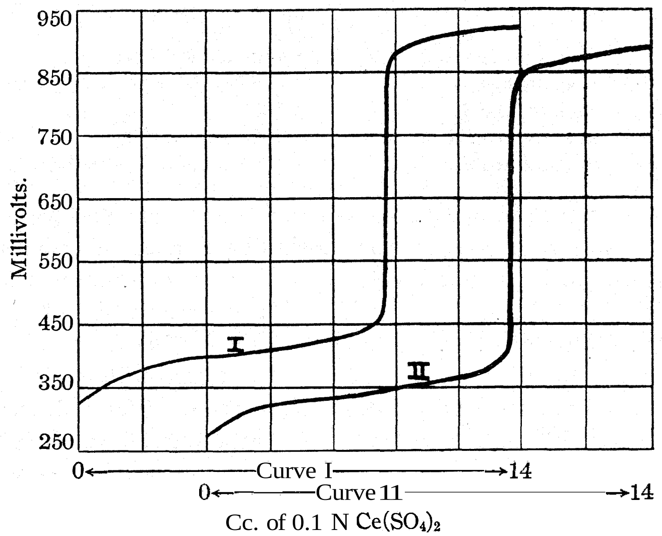

Fig. 1.—Curve I—25 cc. of Tl_2SO_4 (0.1008 g. Tl) + 145 cc. H_2O + 30 cc. concd. HCl titrated at 55–57° with 0.1 N $Ce(SO_4)_2$. Curve II—25 cc. of Tl_2SO_4 (0.1008 *g*. Tl) + 115 cc. H_2O + 60 cc. concd. HCl titrated at 34–36° with 0.1 N $Ce(SO_4)_2$.

To test this method further, the thallous sulfate solution was standardized volumetrically by the method of Zintl and Rienäcker.[6] Twenty-five cc. of the standard thallous sulfate was mixed with 165 cc. of water and 10 cc. of hydrochloric acid (sp. gr. 1-18), the solution heated to 50° and titrated electrometrically at that temperature with a standard potassium bromate solution, the oxidizing power of which had been accurately determined in this Laboratory against Bureau of Standards arsenious oxide. A comparison of the weights of thallium in 25-cc. portions of the standard thallous sulfate solution is given in Table II.

TABLE II

CONCENTRATION OF THALLOUS SULFATE SOLUTION

Method of determination	*Weight of Tl in 25 cc. of solution*
From the weight of Tl_2SO_4	0.1008
Titration with standard $KBrO_3$	0.1008 and 0.1009
Titration with standard $Ce(SO_4)_2$	0.1008 (average value from Table I)

Since in the titration of thallous salt the solution is colorless until an excess of ceric sulfate is present, the possibility of using a visual end-point was investigated. An initial volume of 200 cc. containing the amount of hydrochloric acid indicated in Table III was used, the solution heated to the given temperature and titrated without further application of heat. If an equal volume of water is taken as a comparison liquid, the slightest change in color at the end-point is easily seen. Blank determinations made at 70 and 80° on 200 cc. of water containing 20 cc. of hydrochloric acid (sp. gr. 1.18) and 3–5 cc. of sulfuric acid, sp. gr. 1.83 (since sulfuric acid is present in the ceric sulfate added), showed that 0.05 cc. of 0.1 N ceric sulfate was required to give a pale yellow color. Unless sulfuric acid was added, the ceric sulfate was reduced by the hydrochloric acid. This blank correction has been applied to the results given in Table III.

TABLE III

TITRATION OF THALLOUS SALT WITH 0.1 *N* CERIC SULFATE IN HYDROCHLORIC ACID SOLUTION. VISUAL END-POINT

HCl, *sp. gr. 1.18, present,* cc.	*Temperature,* °C. Init.	Final	Tl *taken,* g.	Tl *found,* g.	*Character of reaction*
40	55	50	0.1008	0.1008	Rapid
20	65	55	.1008	.1009	Too slow
60	35	34	.1008	.1008	Rapid
20	90	75	.1008	.1009	Very rapid
20	98	80	.1008	.1009	Very rapid

Thus it is seen that for a visual end-point the results are most satisfactory when a smaller volume of acid is used and the titration made in a very hot solution. Under these conditions the color produced by the excess ceric sulfate is more permanent.

If 5 cc. of sulfuric acid (sp. gr. 1.5) or 5 cc. of perchloric acid (70–72%) was added to a volume of 200 cc. containing 40 cc. of hydrochloric acid (sp. gr. 1.18) and thallous salt, the reaction with ceric salt was slower than in the absence of these acids, but the results were quantitative. With larger amounts of these acids the reaction was too slow. Nitric acid, even in small amounts, caused the results to be erratic. Titrations in which no hydrochloric acid was present were not possible.

The effect of the presence of various metals which occur with thallium in ores was tested. The volume of solution at the beginning of the titration was 200 cc. in every case. Results are shown in Table IV.

TABLE IV

EFFECT OF THE PRESENCE OF VARIOUS METALS ON THE VOLUMETRIC DETERMINATION OF THALLIUM

Metallic ions added, g.	HCl (sp. gr. 1.18) present, cc.	Temp. during titrn., °C.	Tl taken, g.	Tl found, g.	Character of reaction
0.5 Fe (as $FeCl_3$)	30	55–57	0.1008	0.1011	Rapid, satis.
.1 Cu (as $CuSO_4$)	30	55–57	.1008	.1008	Slightly slow, satis.
.1 Cd (as $CdCl_2$)					
.1 Bi (as $BiCl_3$)					
.1 Sn (as $SnCl_4$)					
.1 Pb (as $PbCl_2$)					
.1 Hg (as $HgCl_2$)					
.1 Zn (as $ZnCl_2$)					
.1 Cr (as $CrCl_3$)	60	34–35	.1008	.1007	Rapid, satis.
.1 Cr (as $CrCl_3$)	30	55–57	.1008	?	Results high
.1 Te (as K_2TeO_3)	60	33–35	.1008	.1007	A little slow at end-point
.1 Te (as K_2TeO_3)	30	55–57	.1008	.1010	A little slow at end-point
.1 Se (as H_2SeO_3)	60	33–35	.1008	.1006	A little slow at end-point
.1 Se (as H_2SeO_3)	30	55–57	.1008	.1008	A little slow at end-point
.1 As (as H_3AsO_4)	60	33–35	.1008	.1009	Rapid, satis.
.1 Sb (as $SbCl_5$)	60	33–35	.1008	.1007	Rapid, satis.

Thus salts of Cu^{++}, Fe^{+++}, Cd^{++}, Bi^{+++}, Sn^{4+}, Pb^{++}, Hg^{++}, Zn^{++}, SeO_3^{--}, TeO_3^{--}, AsO_4^{---}, Sb^{5+} and Cr^{+++} cause no interference in the titration of thallous ion with ceric sulfate. If Cr^{+++} is present, the acid concentration should be kept high and the temperature low to prevent any oxidation of chromium.[11] Trivalent arsenic and antimony interfere, as would be expected.[12] Zintl and Rienacker[6] in their bromate method for thallium found that Fe^{+++} caused their results to be low and erratic. They did not test the effect of selenium and tellurium, which may occur with thallium in ores.

Summary

1. Thallium may be rapidly and accurately determined by titration of thallous salt in hydrochloric acid solution with standard ceric sulfate.

---

[11] Willard and Young, THIS JOURNAL, 51, 139 (1929).

[12] Willard and Young, *ibid.*, 50, 1372 (1928).

The end-point may be determined electrometrically, or visually if the solution is colorless. In the former case the titration may be made at room temperature if the concentration of hydrochloric acid present is high or at temperatures up to 60° if the concentration of hydrochloric acid is decreased. Above 60° the end-point break is usually unsatisfactory. For the visual end-point the most satisfactory conditions are low concentration of hydrochloric acid and a temperature of 80° or higher.

2. Results obtained by this method and by the bromate titration method of Zintl and Rienacker agree very closely.

3. Fe^{+++}, Cuf^{+}, Bi^{+++}, Cd^{++}, Pb^{++}, Sn^{4+}, Hg^{++}, Zn^{++}, SeO_3^{--}, TeO_3^{--}, AsO_4^{---}, Sb^{5+} and Cr^{+++} are without effect.

THE QUANTITATIVE DETERMINATION OF OSMIUM BY MEANS OF STRYCHNINE SULFATE[1]

BY S. C. OGBURN, JR., AND L. F. MILLER

RECEIVED JUNE 28, 1929 PUBLISHED JANUARY 8, 1930

The analytical separations of osmium and ruthenium from the other metals of the platinum group have been based largely on the volatility of their tetroxides from acid and alkaline solutions, respectively. The use of certain organic complexes in the formation of stable coördinated salts with the metals of this group is well known and in some cases they have been used to effect their quantitative removal.[2] Those of the oximes, aromatic nitrosoamines and hydroxyquinolines are especially useful in this connection with platinum and palladium, and 6-nitroquinoline has recently been added to the list as a quantitative reagent for palladium.[3]

In studying the analytical reactions of the platinum metals, one of us[2] found that when a saturated aqueous solution of strychnine sulfate was added to a slightly acidulated solution of sodium chlorosmate, a heavy canary-yellow precipitate was produced, which on settling left a clear supernatant liquid which gave no test for osmium with hydrogen sulfide on boiling, nor with thiourea—a test which will detect one part of osmium in one hundred thousand parts of solution. Following this evidence, the work upon which this paper is based was started with the view of determining whether or not this reagent could be used as a means of quantitatively separating osmium from solutions of its pure salts or from mix-

---

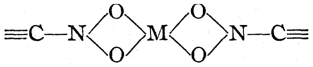
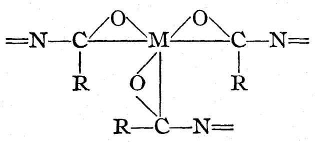
tures of osmium with the other metals of the platinum group. After some preliminary work was carried out in treating solutions of each of these metals which contained one milligram of metal per cubic centimeter of solution, it was found that in every case a precipitate was obtained with the strychnine sulfate solution. In the case of ruthenium, however, it was found that due to differences in the solubilities of the precipitate obtained with that of the osmium, in ethyl alcohol, a separation of these two metals could be effected, as will be shown later in the paper.

Although the empirical formula of strychnine, $C_{21}H_{22}O_2N_2$, is well known, its constitution is still a subject of some doubt. Perkin and Robinson[4] have stated that within the molecule there must be *a* quinoline nucleus which probably contains a benzene ring and, since carbazole is formed on reduction with zinc, there must be a carbazole nucleus.

In the case of hydroxyquinolines forming coordinated salts with metals, Bargallini and Bellucci[5] state that the condition is $\equiv C-O-M-N\equiv$ where M is one metallic equivalent and in which the ring is closed by a secondary valence. In the case of 6-nitroquinoline with palladium,[3] the structural condition is



As will be shown in this paper, the osmium salt formed with strychnine is not an additive or double salt but a true coördinated one in which the structural condition is



The stability of this salt lends itself to the quantitative separation of osmium from solutions of its pure salts, and in making use of the differences in solubility in ethyl alcohol of this salt and the corresponding ruthenium one, and in the absence of the other metals of the group, a clear cut separation is effected.

Experimental Part

Preparation of Solutions. (a) The Sodium **Chlorosmate** Solution.—Several sealed tubes containing one gram each of pure crystalline osmium tetroxide were broken beneath the surface of a 10% solution of sodium hydroxide to which sufficient ethyl alcohol was subsequently added to produce the slight reducing action necessary to cause the formation of sodium osmate. This dear rich red solution was then treated with an excess of concentrated hydrochloric acid and heated to the boiling point. This is necessary to change any osmyl chloride to the sodium chlorosmate form. This greenish to golden yellow solution was diluted, filtered into a glass-stoppered bottle

---

[5] Bargallini and Bellucci, *Gazz. chim. ital.*, 53, 605 (1923).

and kept in a cool dark place. In this form the solution is stable for several weeks, as analyses showed. Before using this solution, however, for any quantitative work it was analyzed. This analysis consisted simply in treating a known volume of the chlorosmate solution with previously determined c. p. zinc until all of the osmium was completely reduced to the metallic condition. Carefully prepared Gooch crucibles were used to contain the metal during the washing and drying operations. The analyses ran as follows

Weight of metallic osmium, g.	0.0073	0.0073	0.0072
Amount of solution used, cc.	4.0	4.0	4.0

(b) The Strychnine Sulfate Solution.—A saturated solution of this reagent was prepared at room temperature, and contained 3.2% of the salt.

Preparation of the Osmium Compound **and** the Determination of its Empirical Formula.—Approximately 135 cc. of the sodium chlorosmate solution was treated with an excess of the saturated strychnine sulfate solution. The heavy canary-yellow precipitate was immediately formed and after warming on a water-bath for a few minutes to aid in its coagulation, it was filtered through finely pored paper and washed well to remove chlorides. It was then dried in the usual manner and preserved in a desiccator. The filtrate was free from osmium, as shown by the negative tests given with such reagents as thiourea, hydrogen sulfide and zinc dust.

An analysis of the yellow compound was then made which included determinations for osmium, carbon and hydrogen. The carbon and hydrogen were determined by the usual organic combustion[6] method in which complete oxidation of the compound was attained with the formation of carbon dioxide, water and some osmium tetroxide. In the soda-lime tube of the combustion train some absorption of the volatile osmium tetroxide occurred with the formation of sodium osmate. After weighing, the quantity of osmium absorbed was determined and this amount was deducted in order to obtain the true value of carbon dioxide retained. Approximately 0.2-g. samples were used. About ten such determinations were made. Typical analyses ran as follows

Weight of sample, g.	0.1500	0.1500	0.2000	
Weight of water, g.	.0737	.0797	.0997	
Wt. of carbon dioxide, corr., g.	.3330	.3306	.4180	
Hydrogen, %	5.51	5.94	5.58	Mean value, 5.67
Carbon, %	60.54	60.10	57.00	Mean value, 59.21

The osmium content of the compound was determined by complete oxidation of the osmium in the sample and the subsequent absorption of the volatile tetroxide in 20% sodium hydroxide to which a small quantity of alcohol had been added to aid in the complete conversion to sodium osmate.

The oxidation process was carried out in an oxygen combustion train in which pure dry oxygen was slowly admitted to a transparent vitreosil combustion tube into whose outlet end was sealed, by means of asbestos cement, the entrance end of a wash bottle containing the alcoholic sodium hydroxide solution.

After prolonged preliminary heating, during which all of the volatile matter from the cement was driven off and each connection tested, the determinations were made. When all of the original sample had been completely volatilized, the temperature was maintained at a red heat for about five minutes. After cooling, the contents of the wash bottle was treated with an excess of concentrated hydrochloric acid, diluted and

---

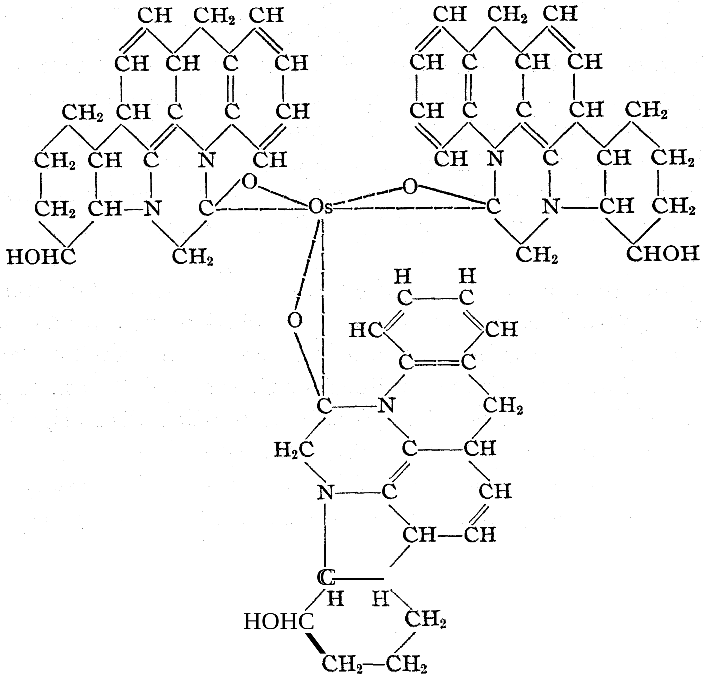
[6] See Clark, "A Handbook of Organic Analysis," 2d. ed., Edward Arnold, London, England, pp. 191–198.

treated with zinc. After complete reduction of the osmium had taken place, it was washed free from chlorides, dried and weighed. Considering the small amount of osmium in the sample taken, these determinations gave very good checks.

Weight of sample, g.	0.2000	0.2000	0.2000	
Weight of osmium recovered, g.	0.0354	0.0351	0.0350	
Oxmium, %	17.70	17.55	17.50	Mean value, 17.58

In order to ascertain whether this compound was a simple additive one, tests were made for the chloride and the sulfate ions on a solution of it in nitric acid. As neither ion was detected, the existence of a coördinated salt was indicated.

Two types of coordination were considered: the one in which the osmium replaces hydrogen and in which the ring is closed by a secondary valence as suggested by Bargallini and Bellucci in the case of hydroxyquinolines, and the other, in which the osmium links with the carbonyl group, forming a conjugated ring system shown in the fore part of this paper. This latter type of linkage is comparable with the structural condition shown in the palladium compound[3] previously described and also with Lowry's[7] study of factors influencing coordination and the use of coordination compounds in analysis. In this paper he states that "the stability of the coördination complex depends largely on the formation of a conjugated ring system in which the metallic ion M acts as a member of a pseudo-aromatic ring."



---

[7] Lowry, J. Soc. *Chem. Ind.*, 42, 462 (1923).

By inspection it will be found that the mean values of the analysis of the yellow osmium compound agree rather closely with the calculated analysis of the compound $(C_{21}H_{22}O_2N_2)_3Os$ in which the osmium exhibits a coordination number of six. In this case the osmium forms a conjugated ring system with the carbonyl group of the strychnine by sharing two pairs of electrons with each three molecules of strychnine. This configuration is represented graphically as indicated.

The osmium atom, with an atomic number of seventy-six, contains two, plus eight, plus eight, plus eighteen, plus eighteen, plus twenty-two electrons in the successive shells. The tetravalent osmium ion, as in the salt sodium chlorosmate used, therefore, contains eighteen electrons in the outer shell, and requires fourteen more to complete the shell of thirty-two. By drawing into this shell one pair of electrons in each of three atoms of oxygen and three atoms of carbon, the osmium coordination number of six is satisfied but there remains a deficiency of two electrons to complete the outer shell, thus rendering the compound stable to the maximum extent. This deficiency, however, is permissible with the formation of stable salts as ascertained by Lowry[8] in which he states that "this shortage of electrons is, however, tolerated much more readily than a surplus as is indeed indicated by the fact that a shortage of three, two and one electrons, respectively, is found in the coordinated compounds, $K_3(Cr{\cdot}6CN)$, $K_2(Pt{\cdot}4CN)$ and $K_3(Fe{\cdot}6CN)$."

The Removal of Osmium from a Solution of Sodium Chlorosmate.—After having determined from the analysis of the yellow osmium compound the gravimetric factor of 0.1758 for its osmium content, a series of analyses was made of sodium chlorosmate solutions of known osmium content, to check the accuracy of this factor and to show the ease with which the reagent, strychnine sulfate, could be used for the quantitative estimation of this metal.

The previously prepared osmium solution, having stood for about forty-five days, was slightly decomposed. The solution was filtered and the osmium content determined by means of zinc reduction as previously described. Close checks were obtained for the value 0.0014 g. of osmium per cubic centimeter of solution. It will be recalled that originally this solution analyzed 0.0018 *g.* per cubic centimeter.

Five cubic centimeter portions of this chlorosmate solution were treated with an excess of strychnine sulfate solution and the resulting canary-yellow compound filtered. After carefully washing with distilled water until free from chlorides, it was dried to 105° in an electric oven, cooled and weighed. The results of three such determinations were found to coincide with the theoretical weight of the precipitate as calculated by use of the gravimetric factor mentioned above.

---

[8] Lowry, *J. Soc. Chem. Ind.*, **42**, 316 (1923).

	Soln. boiled during pptn.		Soln. pptd. cold.
Sodium chlorosmate used, cc.	5.0	5.0	5.0
Osmium per cc., g.	0.0014	0.0014	0.0014
Total osmium in soln., g.	.0070	.0070	.0070
Actual wt. of osmium ppt., g.	.0402	.0406	.0399
Theoretical wt. of ppt., g.	.0400	.0400	.0400

From these data it is conclusively shown that osmium may be quantitatively removed from solutions of its salts by means of a saturated solution of strychnine sulfate, and by use of the gravimetric factor 0.1758 the percentage of osmium in the original sample may be calculated from the weight of the washed and dried canary-yellow precipitate obtained. It is also shown that the solubility of the precipitate in water up to its boiling point is negligible. Following the preceding work, a 0.0400-g. sample of the precipitate was allowed to stand overnight in 20 cc. of distilled water at room temperature. On analyzing this solution for osmium by the nascent hydrogen reduction method (zinc and hydrochloric acid) no trace of osmium was found. The thiourea test also failed to detect any metal.

The Separation of Osmium from Ruthenium.—Strychnine sulfate gives with a slightly acidulated solution of ruthenium trichloride a yellow precipitate which is partially soluble on boiling. In no case is this precipitation complete. In the experimental work on the separation of the precipitates obtained by the use of this reagent on solutions containing both osmium and ruthenium, numerous solvents were tried under varying conditions in an effort to effect a complete separation of the osmium compound. Of these, ethyl alcohol was found effective as a means to this end.

A solution containing 0.0014 g. of osmium and 0.0016 g. of ruthenium in soluble form (sodium chlorosmate and ruthenium trichloride) was treated with a small excess of the saturated solution of strychnine sulfate. Immediate precipitation followed. An equal volume of 95% ethyl alcohol was then added and the mixture boiled until the precipitates dissolved. Upon cooling, the osmium compound reprecipitated and after standing for one and one-half hours, it was filtered.[9] The filtrate gave no test for osmium with β-naphthalamine hydrochloride.[10] The results of these determinations were:

Weight of osmium, g.	0 0014	0 0014
Weight of osmium precipitate, g.	.0076	.0078
Theoretical weight of precipitate, g.	.0080	.0080

---

[9] Preliminary tests showed no contamination of this precipitate by the ruthenium compound. The latter remained in solution, on cooling, for a period of several days.

[10] The test with thiourea or other usual reagents for osmium cannot be used in the presence of ruthenium. The blue color produced by the reaction of the β-naphthylamine hydrochloride with osmium is a delicate and characteristic test which can be used in the presence of ruthenium. See Ref. 2.

Due to the small quantities of metals used, these small deviations may be regarded as within the limits of experimental error. Such determinations show that osmium may be removed quantitatively from a mixture containing one of its salts with that of ruthenium by means of strychnine sulfate.

Summary

A new quantitative method for the determination of osmium is given. The metal is removed from a solution of sodium chlorosmate by means of a saturated aqueous solution of strychnine sulfate. The composition of the compound formed was found to be $(C_{21}H_{22}O_2N_2)_3Os$, a coordinated salt in which osmium exhibits a coordination number of six. By use of the gravimetric factor, 0.1758, the percentage content of the osmium may be obtained from a direct weighing of the canary-yellow precipitate.

Strychnine sulfate reacts with the formation of precipitates with all of the platinum metals, but the precipitate formed with ruthenium is soluble in boiling ethyl alcohol, from which it does not easily separate on cooling even after a period of several days. This method may be used in effecting a separation of osmium from ruthenium since the former compound reprecipitates completely on cooling the alcoholic solution.

THE HIGH-TEMPERATURE EQUILIBRIUM BETWEEN SILICON NITRIDE, SILICON AND NITROGEN

BY W. B. HINCKE AND L. R. BRANTLEY

RECEIVED JULY 6, 1929 PUBLISHED JANUARY 8, 1930

Plan of the Investigation

This investigation is a continuation of the researches in progress in this Laboratory on high-temperature equilibria.[1] The method devised by Prescott and used by Prescott and Hincke[1d] in studying the equilibrium of the system aluminum carbide, nitrogen, aluminum nitride and carbon was employed. This method consists in heating by an electric current to various temperatures (measured by an optical pyrometer) the solid reaction mixture (in this case the silicon nitride and silicon) within a graphite tube a few millimeters in diameter and a few centimeters long placed within a pyrex bulb, and in measuring the pressures produced. In this article are described measurements made of the dissociation pressures of silicon nitride from 0.27 to 5.49 mm. through a temperature range from 1606 to 1802°K.

---

[1] (a) Prescott, THIS JOURNAL, 48, 2534 (1926); (b) Prescott and Hincke, *ibid.*, 49, 2744 (1927); (c) Prescott and Hincke, *ibid.*, 49, 2753 (1927); (d) Prescott and Hincke *ibid.*, 50, 3228 (1928); (e) Prescott, *ibid.*, 50, 3237 (1928); (f) Prescott and Hincke, *Phys. Rev.*, 31, 130 (1928).

It has been shown by Weiss and Engelhardt[2] and by Funk[3] that the compound produced, when silicon is heated in nitrogen at 1300 to 1450° as long as the gas continues to be absorbed, is the normal nitride, Si_3N_4. The nitride produced in the experiments here described presumably had this composition, since the conditions of heating were substantially the same.

The authors wish to express their thanks to Dr. C. H. Prescott, Jr., whose suggestions and criticisms have been of great assistance.

Apparatus and Procedure

The temperature measurements in this investigation were made by means of an optical pyrometer with a disappearing filament; the details, corrections and limitations of these measurements have already been described.[1b,f] The furnace, the devices for introducing nitrogen and the McLeod gages have also been described.[1d]

The silicon used was a C. P. Eimer and Amend preparation which had been ground to pass a 200-mesh sieve. The preparation upon treatment with hydrofluoric and nitric acids, evaporation with nitric acid and ignition of the residue yielded 2% of oxides, corresponding to about 1% of metallic impurity.

In the procedure adopted there was placed loosely in the middle zone of the graphite tube a charge of 0.1 g. of finely powdered silicon. After complete evacuation, the apparatus was filled at one atmosphere with (tank) nitrogen that had been passed through a purifying train, and the furnace was heated to 1675°K. for thirty minutes. This converted about 75% of the charge to silicon nitride.[4] The apparatus was then evacuated, after which it was ready for the equilibrium measurements.

In all of the determinations the temperature of the furnace was held constant, and the equilibrium pressure was found by taking the mean of the final pressures of a forward and a reverse reaction wherein the pressure in the glass bulb containing the graphite furnace increased and decreased, respectively. To hold the furnace at a constant temperature it sufficed to keep the current through it constant, which was done by means of a standard resistance and a potentiometer. A shower of tap water was caused to play continuously over the glass bulb containing the graphite tube while equilibrium measurements were being made. This prevented excessive outgassing of the glass walls and contamination of the nitrogen. A gas micro-analysis apparatus[1d] was used to determine the partial pressure of nitrogen at the end of each experiment. In all the satisfactory runs the nitrogen formed more than 92% of the gases in the bulb.

For the preliminary formation of silicon nitride the current was drawn from a 1-kilowatt transformer. During the measurements it was taken from storage batteries. To maintain the furnace at 1802°K. about 80 amperes at 10 volts was required.

The Equilibrium Measurements

The first equilibrium determination was made at **1675°K.** The pressure of the nitrogen in the bulb built up from a vacuum to **0.47** mm. in the course of one hour, the gas then containing 92% of nitrogen. The apparatus was then again evacuated and filled to 0.90 mm. of nitrogen, as measured when the furnace had become hot; in this case the pressure of the gas decreased

---

[2] Weiss and Engelhardt, *Z. anorg. Chem.*, 65, **78** (1910).

[3] Funk, *ibid.*, **133,** 67 (1924).

[4] No silicon carbide was formed at this nitrogen pressure by the reaction of silicon with the graphite furnace; moreover, it was found that silicon carbide is inert to nitrogen under the conditions of these experiments.

in one hour to 0.762 mm., and the gas contained 95% of nitrogen. Two one-hour runs were then made, one at 0.57 mm. and the other at 0.675 mm. of nitrogen, but these showed no measurable change in pressure. Finally a run of two hours with increasing pressure was made, starting from an initial pressure of 0.336 mm. and stopping at 0.553 mm. of nitrogen. The gas analysis showed 100% of nitrogen in this run, which was to be expected because of the pumping off of the outgassed impurities in the previous runs. It was observed that a pellet reacted more slowly after some hours of heating, probably owing to loss of some of the silicon from the charge by volatilization and to sintering of the silicon nitride into a more compact mass.

The pellets removed from the furnaces after each equilibrium determination always gave the characteristic ammonia test on heating with concentrated alkali, and under a low powered microscope showed a white sintered mass speckled with darker particles of silicon.

In each determination the true equilibrium pressure of the nitrogen corresponding to any temperature was assumed to be the average of the two pressures which had been attained in a forward and a reverse run. Each of the two pressures always approached a limiting value that seemed to be as far as the reaction would go within a reasonable time. These pressures, however, did not differ very greatly from one another. At temperatures above 1800°K. sublimation of the silicon and sintering of the silicon nitride were so rapid that a pellet became only slowly reactive after a few runs. This permitted, nevertheless, a range of about 200° over which the equilibrium could be studied.

Table I gives the final pressures (in millimeters) observed at each temperature. There are shown in each case the highest pressures (marked "increasing") which were attained by the forward reaction (decomposition of the nitride) and the lowest pressures (marked "decreasing") which were attained by the reverse reaction. These pressures are always the partial pressure of the nitrogen in the gas (found by multiplying the total pressure by the fraction of nitrogen present). The mean values of these two pressures for each pair are taken as the equilibrium pressures. The correspond-

TABLE I

EQUILIBRIUM PRESSURES OF THE REACTION AT VARIOUS TEMPERATURES AND THE CORRESPONDING FREE ENERGIES

Absolute temp., T	$10^4/T$	Final pressure in mm.			Pressure $\times 10^4$ in atm.	Free energy, A P
		Increasing	Decreasing	Mean		
1606	6.225	0.179	0.361	0.27	3.5	50,800
1638	6.110	.382	.537	.46	6.0	48,300
1675	5.971	.553	.762	.66	8.7	46,900
1709	5.850	1.110	1.335	1.22	16.1	43,700
1739	5.750	2.215	2.675	2.44	32.0	39,700
1779	5 625	3 560	4.65	4.11	54.0	36,900
1802	5.550	5.05	5 93	5.49	72.0	35,300

ing values expressed in atmospheres are given in an adjoining column. In the last column of the table are given also the values (derived as described below) in calories of the free-energy increase (AF) attending the reaction $Si_3N_4(s) = 3Si(s)$ or (1) $+ 2N_2(g)$.

In Fig. 1 are plotted as full circles the mean values of $\log_{10} p$ (in mm.) against $10^4/T$. The straight line was drawn so as to fit best the full circles. The corresponding observed "increasing" and "decreasing" values are shown by half-circles.

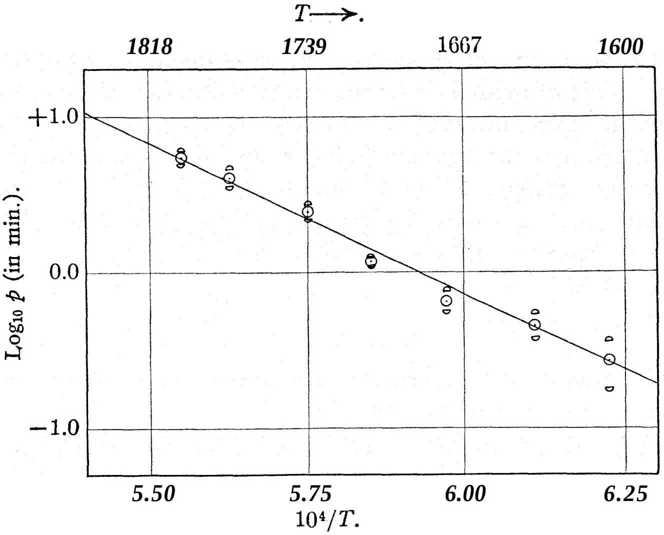

Fig. 1.

The final relation between the equilibrium pressures in atmospheres and the absolute temperature is given by the equation

$$2.3 \log_{10} p \text{ (in atm.)} = 19.75 - \frac{44,500}{T}$$

Since the melting point of silicon is approximately 1687°K., there should be a slight change in slope of the line at this temperature due to the heat of fusion of the silicon, but the data are not accurate enough to show this change in slope.

Thermodynamic Calculations

The chemical reaction is $Si_3N_4 = 3Si + 2N_2$. The free-energy increase (ΔF) attending it when the nitrogen pressure is one atmosphere may then be derived from the equilibrium pressure p in atmospheres by the familiar equation $\Delta F = -RT \ln K$, where $K = p^2$ and $R = 1.987$. From the determinations of the equilibrium pressure p are thus obtained the values of A F given in the last column of Table I.

From these values of the free-energy increase one obtains the function

AF = 176,300 − 78.35*T* for absolute temperatures between 1600 and 1800°. From this it follows that the heat-content increase A H is 176,300 calories in this temperature range. The function shows also that at an absolute temperature of 2250° (assuming it to hold up to this temperature) the free-energy increase becomes zero and therefore that the dissociation pressure becomes one atmosphere at this temperature.

Summary

The pressure of nitrogen at which equilibrium prevails between silicon nitride, Si_3N_4, and its elements at absolute temperatures ranging from 1606 to 1802°K. has been determined by an experimental method previously described. This pressure is 0.27 mm. at 1606°K. and 5.5 mm. at 1802°K. Within this temperature interval the free-energy increase *AF* at one atmosphere attending the reaction $Si_3N_4 = 3Si + 2N_2$ was found to be expressed by the function *AF* = 176,300 − 78.35 T calories. From this it follows that the heat-content increase ΔH at 1700°K. is 176,300 cal.; **also** that the dissociation pressure of the nitride becomes one atmosphere at about 2250°K.

THE RATE OF REACTION IN A CHANGING ENVIRONMENT

BY GEORGE SCATCHARD

RECEIVED JULY 10, 1929 PUBLISHED JANUARY 8, 1930

In the study of the reaction rates described in the following paper[1] there were developed methods which are of general applicability to the treatment of rates in non-ideal solutions in which the deviations change during the course of the reaction. Graphical methods applicable to this problem were presented in an earlier paper;[2] the present method is analytical and therefore much easier to apply. Although approximate, it is in most cases as accurate as the rate measurements.

The treatment is based upon the theory of Bronsted[3] that the mechanism of the reaction is the formation and decomposition of a "critical complex," so that for the simple bimolecular reaction

$$A + B \rightleftharpoons X(= AB) \longrightarrow D + E$$

the rate is given by

$$-\frac{dC_A}{dt} = KC_AC_B\frac{f_Af_B}{f_X} \tag{1}$$

---

[1] Ashdown, THIS JOURNAL, 52,268 (1930).

[2] Scatchard, *ibid.*, 48,2259 (1926).

[3] Bronsted, *Z. physik.* Chem., 102,169 (1922), and many later papers. The method is more general than this theory, however. For example, it may be applied to the simple activity theory merely by replacing f_X by 1.

where C represents concentration and f activity coefficient. It makes no difference, except for convenience, whether the concentrations are expressed as mole fractions, or weight or volume concentrations, for the units of the C and f terms cancel.[4] The rate expression should contain the concentration and activity coefficient of every molecule which enters into the complex, whether it be reactant, catalyst or solvent. If the reaction may proceed by more than one mechanism, there should be a term on the right-hand side, each with its own value of K, for each critical complex formed. It is certain that those reactions proceed by more than one mechanism which occur both with and without a catalyst, or with two different catalysts. It is probable that the phenomenon is much more general. The fact that the effect of changing solvent on the rate is much larger than the change of activities of the reactants, so much larger that it is extremely improbable that any change in the activity coefficient of a critical complex can explain it, is most simply accounted for by assuming that the solvents enter into the complexes, so that the mechanism is not the same in different solvents.

Dilute Electrolytes.—Except from the rate measurements themselves, the activity coefficient of the critical complex can be determined only for electrolyte solutions so dilute that the activity coefficient of an ion depends only upon its valence. The Debye–Hückel expression for the activity coefficient of an ion in water at 25° is

$$-\ln f_i = \frac{1.16 z_i^2 \sqrt{\mu}}{1 + 0.328 a \sqrt{\mu}} \qquad (2)$$

where f_i is the activity coefficient, z_i the valence of the ion, negative for a negative ion, and μ is the ionic strength in moles per liter. The numerical constants vary with the temperature and the dielectric constant of the solvent, a is the apparent diameter of the ion in Ångström units, and is generally between 0 and 5. In very dilute solutions it may be neglected to give the Debye–Hückel limiting law.

If the same size be attributed to all the ions

$$\ln \frac{f_A f_B}{f_X} = \frac{-1.16 \sqrt{\mu}}{1 + 0.328 a \sqrt{\mu}} [z_A^2 + z_B^2 - (z_A + z_B)^2] = \frac{2.32 z_A z_B \sqrt{\mu}}{1 + 0.328 a \sqrt{\mu}} \qquad (3)^5$$

For a more complicated complex, the valence term, $z_A z_B$, is replaced by the sum of all the cross products of the z's. This equation shows immediately the conclusions drawn by Bronsted that the rate should have no primary salt effect for a reaction between an ion and a neutral molecule, that the rate should increase with increasing salt concentration for reac-

---

[4] The equation may be written so that the f and C terms occur only as products, f C (f_X and dC_A occurring together), which, like activities, are ratios and so pure numbers. The numerical value of K does depend on the conventional definition of unit activity.

[5] A similar expression using the Debye–Hiickel limiting law is given by Brönsted and Livingstone, THIS JOURNAL, 49, 435 (1927).

tions between two ions of the same sign, and should decrease for reactions between ions of opposite signs. Within the range of its applicability it gives quantitatively the magnitude of these changes. Bronsted's application is limited to reactions where the ionic strength and therefore the activity coefficients are constant during the course of the reaction.

When the ionic strength varies, the use of Equation **3** introduces a variable exponential which leads to difficulty in integration. The activity of an ion may also be expressed by

$$f_i = \frac{1}{1 + 1.16x_i^2\sqrt{\mu}} \qquad (4)^6$$

For small values of $z_i^2\sqrt{\mu}$, Equation 4 gives the same result as Equation **3,** with $a = 1.77z_i^2$. The corresponding value of a decreases slowly with increasing concentration, becoming 1.54 when $z_i^2\sqrt{\mu}$ is 1. This expression represents the data as well as any which does not introduce specific constants.

Then

$$\frac{f_A f_B}{f_X} = \frac{1}{1 - 2.32z_A z_B\sqrt{\mu}} \text{ when } z_A z_B \text{ is negative, and} \qquad (5a)$$

$$\frac{f_A f_B}{f_X} = 1 + 2.32z_A z_B\sqrt{\mu} \text{ when } z_A z_B \text{ is positive} \qquad (5b)$$

Since the ionic strength is a linear function of the extent of the reaction, it can be expressed as $\sqrt{\mu} = \sqrt{\mu_0}\sqrt{1 + gx}$, where x is the extent of the reaction, μ_0 is the initial ionic strength, and $\mu_0(1 + g)$ is the ionic strength when the reaction is complete $(x = 1)$. Simplification in integration without significant loss in accuracy may be obtained by replacing $\sqrt{1 + gx}$ by $1 + gx/2$. The difference between the two expressions is less than 10% even when the ionic strength is doubled or halved.

Not many reactions have been studied with a large change in ionic strength and without complicating factors such as the formation of unknown amounts of complex ions or of weak electrolytes. The studies of Yost[7] on the oxidation of ammonia by persulfate ion indicate that the slow reaction is

$$S_2O_8^{=} + Ag(NH_3)_2^{+} \longrightarrow 2SO_4^{=} + Ag^{+++} + 2NH_3$$

Since the complex silver ion is regenerated in the subsequent rapid reaction, the reaction is apparently unimolecular, and $z_A z_B = -2$. The expression for the rate is then

---

[6] Two ways of expressing Equation 2 as a power series are

$$f_i = 1 - 1.16\,z_i^2\sqrt{\mu} + (0.673\,z_i^4 + 0.380\,z_i^2a)\mu + \dots\dots$$
$$1/f = 1 + 1.16\,z_i^2\sqrt{\mu} + (0.673\,z_i^4 - 0.380\,z_i^2a)\mu + \dots\dots$$

Since a is positive the two coefficients of μ compensate in the second expression, but add in the first. This is true also in the higher terms, so the first two terms of the second expression (Equation 4) give a much more accurate expression of Equation 2 than the corresponding terms of the first.

[7] Yost, THIS JOURNAL, 48, 374 (1926).

$$\frac{dx}{dt} = KC_{Ag}(1 - x)\frac{f_A f_B}{f_X} = \frac{KC_{Ag}(1 - x)}{1 + 4.64\sqrt{\mu_0}\sqrt{1 + gx}}$$

$$\frac{dx}{1 - x}(1 + 4.64\sqrt{\mu_0}\sqrt{1 + gx}) = KC_{Ag}dt \qquad (6)$$

or, approximately

$$\frac{dx}{1 - x}[1 + 4.64\sqrt{\mu_0}(1 + gx/2)] = KC_{Ag}dt \qquad (7)$$

Integrating between the limits t = 0 and $t = t$ gives, in the two cases

$$\ln\frac{1}{1 - x} + 4.64\sqrt{\mu_0}\left[\sqrt{1 + g}\ln\frac{(\sqrt{1 + g} + \sqrt{1 + gx})(\sqrt{1 + g} - 1)}{(\sqrt{1 + g} - \sqrt{1 + gx})(\sqrt{1 + g} + 1)} - 2(\sqrt{1 + gx} - 1)\right] = KC_{Ag}t \qquad (8)$$

$$[1 + 4.64\sqrt{\mu_0}(1 + g/2)]\ln\frac{1}{1 - x} - 2.32g\sqrt{\mu_0}\,x = KC_{Ag}t \qquad (9)$$

Neglecting the change of environment during the reaction (putting $g = 0$), gives

$$(1 + 4.64\sqrt{\mu_0})\ln\frac{1}{1 - x} = KC_{Ag}t \qquad (10)$$

Table I shows the application of these equations to two measurements of Yost starting with 0.0138 *M* $(NH_4)_2S_2O_8$ and 0.0059 M $AgClO_4$. The initial ammonia concentrations are 0.0687 *M* and 0.1123 M. The ionic strength changes from 0.0473 to 0.0887, so that $g = 0.875$. The first column gives the time, the second the fraction of persulfate ion converted, and the last three columns give the values of the constants computed by Equations 10, 8 and 9. Comparison of the last two columns shows that the error introduced by the approximation of Equation 7 is negligible. By Equation 10 or by the ideal solution law the constant decreases about 20%. By either of the other two equations there is no trend up to 90% conversion. As shown by the figures in parentheses, the decrease beyond this point may be prevented by decreasing the observed values of the persulfate-ion concentration by one unit in the last place given, which should be within the experimental error.

TABLE I

OXIDATION OF AMMONIA BY PERSULFATE ION

$NH_3 = 0.0687$ M					$NH_3 = 0.1123$ M				
Time	x	$K_{(10)}$	$K_{(8)}$	$K_{(9)}$	Time	x	$K_{(10)}$	$K_{(8)}$	$K_{(9)}$
5.5	0.18	12.4	12.6	12.6	5	0.22	16.7	17.1	17.1
15.5	.41	11.7	12.3	12.3	17	.54	15.4	16.4	16.4
26	.59	11.8	12.7	12.7	26	.70	15.6	16.9	17.0
40	.73	11.2	12.2	12.3	39.5	.83	15.1	16.7	16.8
57	.84	11.0	12.2	12.3	57.5	.91	14.5	16.2	16.5
91	.94	10.2	11.5	11.7 (12.2)	91	.97	13.2	15.2	15.4 (16.6)
125	.97	0.95	11.0	11.3 (12.1)	125	.99	11.6	13.5	13.6 (15.9)

It is possible, however, that this decrease is due to the fact that Equation 5 gives too small a correction for the changing activity coefficients in this case. Yost found that with 0.0086 M $K_2S_2O_8$, 0.005 M $AgClO_4$ and 0.383 M NH_3, a change in KOH concentration from 0.0170 *M* to 0.0904 M decreased K by 32%. According to Equation 5 the decrease should be 23%, while according to the Debye–Hückel limiting law it should be 45%.

The measurements of King[8] on the same reaction are affected by some disturbing factor at the start. Integrated from the first reading rather than from zero time, however, Equations 8 or 9 give values of K without a trend.

Non-Electrolytes,—There are in the literature descriptions of many reactions between non-electrolytes whose rates change during the course of the reaction, so that they do not give constants for a reaction of any order. Although the term $f_A f_B / f_X$, or its equivalent for reactions of other types, cannot be determined independently, an approximate expression can be derived so that it may be determined from the rate measurements themselves.

The activity coefficient of a non-electrolyte in dilute solution in another non-electrolyte may be expressed by

$$\ln f_1 = gm_1 \text{ or } f_1 = e^{gm_1} \qquad (11)$$

in which m_1 is the molality and g a constant.[9] Where gm_1 is large, this gives only a very rough approximation. As for the electrolyte solutions, we will substitute an expression which is the same as (11) for small values of gm_1, and which for larger values agrees as well with the experimental data.

$$-\ln f_1 = \ln (1 - gm_1) \quad 1/f_1 = 1 - gm_1 \qquad (12)^{10}$$

Figure 1 shows the values of the activity coefficients, $f = a/m$, for *iso*-amyl alcohol and for propionic acid in dry nitrobenzene, two examples of very large deviations, computed by Brown and Bury[11] from their freezing point measurements. The broken lines are for Equation 11 and the full lines for Equation 12, the constants in both cases being selected to give agreement at 1 M. For the alcohol the agreement of the two equations

---

[8] King, THIS JOURNAL, 49, 2689 (1927). Dr. King has been kind enough to send me the manuscript of his article with Mr. F. I,. Griswold which indicates that under these conditions the reaction does not go quantitatively to nitrogen but part of the ammonia is oxidized to nitrate ion. We are agreed that this finding has no effect on the conclusions of this paper. The constants should be increased, but not more than 0.2%.

[9] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923, p. 275. In their notation, $g = -2h$.

[10] Equation 12 may be derived from Equation 11 by expansion of $1/f_1$ as a power series.

[11] Brown and Bury, J. Phys. Chem., 30, 696 (1926). The values there tabulated are the activity divided by the mole fraction.

is about the same. For the acid, Equation 12 fits much better, although still only fairly well.

The reaction mixtures are not binary, however, and a term must be added to our expression to include every substance whose concentration varies, giving for our type reaction

$$1/f_A = 1 - g_{AA}m_A - g_{BA}m_B - g_{DA}m_D - g_{EA}m_E \qquad (13)$$

Since the concentration of each substance is a linear function of the extent of the reaction, we may write

$$1/f = 1 - G_A - G'_A x \qquad (14)$$

where G_A and G'_A are functions of the initial composition of the solution. If the ratios of the concentrations are constant, the G's are proportional to the concentrations. Equation 14 with similar expressions for f_B and f_X permits integration, but it is generally desirable to simplify first by ignoring relatively small terms in Equation 13.

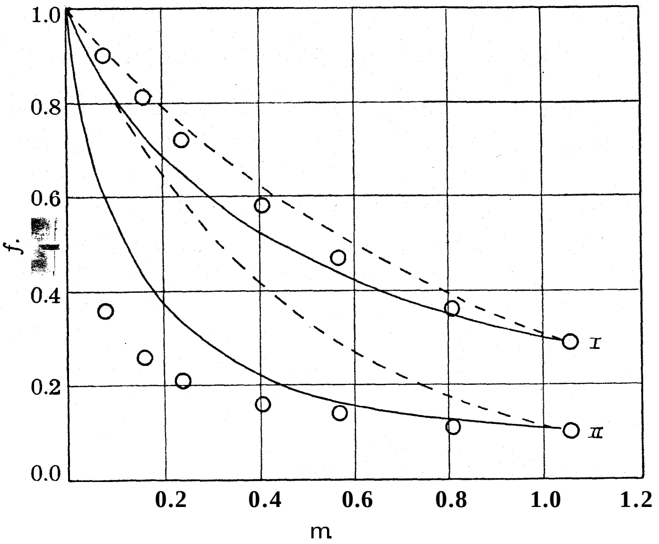

Fig. 1.—Activity coefficients in dry nitrobenzene: I, iso-amyl alcohol, g=1.17 (Eq. 11), = 2.32 (Eq. 12); II, propionic acid, g=2.18, 8.51.

The Magnitude of the Deviations.—The value of g in Equation 11 or 12 is closely related to the change of activity of the solute as the medium changes from pure solute to pure solvent. This may be seen by expanding Margules' equation in terms of activities instead of partial pressures[12]

$$RT\ln\frac{f}{f_0} = \frac{\beta}{2}(1-N)^2 + \frac{\gamma}{3}(1-N)^3 = \left(\frac{\beta}{2}+\frac{\gamma}{3}\right) - (\beta+\gamma)N + \left(\frac{\beta}{2}+\gamma\right)N^2 - \frac{\gamma N^3}{3} \qquad (15)$$

---

[12] See Hildebrand, "Solubility," Chemical Catalog Co., Inc., New York, 1924, p. 48.

In this equation N is the mole fraction, and f the activity divided by the mole fraction; β and γ are constants; f_0 is the activity coefficient of the pure substance. When $N = 0$, $f = 1$ and $\ln f = 0$, so

$$RT \ln 1/f_0 = \left(\frac{\beta}{2} + \frac{\gamma}{3}\right)$$

$$RT \ln f = -(\beta + \gamma)N + \left(\frac{\beta}{2} + \gamma\right)N^2 - \frac{\gamma N^3}{3} \qquad (16)$$

For dilute solutions we may neglect the terms in N^2 and N^3 and replace the mole fraction by the concentration in moles per thousand grams of solvent or per liter of solution, with the appropriate change of constant. For the former this gives Equation 11. The neglected terms give deviations in the same direction as does Equation 12.

For binary mixtures it is possible to predict the value of $g_{11} = \frac{-N(\beta + \gamma)}{mRT}$ by the methods of Hildebrand or of Mortimer.[13] For mixtures of two non-polar substances, for which the γ term in Equation 15 is generally small, these methods are quite precise. For one non-polar and one polar component they are only approximate. For both these cases g_{11} is negative. For mixtures of two polar substances these methods may fail completely because such mixtures have a tendency to chemical reaction. If there is chemical combination between the solute and the solvent g_{11} is positive, but Equation 12 still holds approximately.

If a second solute forming an ideal solution in binary mixture with the solvent ($g_{22} = 0$) is added to a solution containing a non-ideal solute, its effect will be the same as diluting with the solvent and $g_{21} = -\frac{n_1}{n_0}g_{11}$, where n_1/n_0 is the mole ratio of the first solute to the solvent. For dilute solutions g_{21} will be small relative to g_{11}. Moreover, $g_{12} = g_{21}$. This is most simply obtained from the expression, given by Bjerrum,[14] $\frac{d \ln f_1}{dn_2} = \frac{d \ln f_2}{dn_1}$, but it may also be obtained from the fact that the change must be the same for the ideal solute as for the solvent.

If there is a third solute which forms an ideal solution with the first, and so does not with the solvent, $g_{31} = g_{13} = g_{11} = g_{33}$, and, of course, $g_{32} = g_{23} = g_{12} = g_{21}$.

If the added solute does not form an ideal solution with either the solvent or the first solute, there are two possibilities. If the solution is intermediate in its properties between the two solutes, $g_{41} = g_{14}$ will be positive; if it is not, $g_{41} = g_{14}$ will be negative and will lie between g_{11} and g_{44}. There is then a possibility that g_{41} may change sign with changing concen-

---

[13] See Hildebrand, Ref. 12, pp. 99–116.

[14] Bjerrum, Z. physik. Chem., **104**, 423 (1923).

tration instead of remaining constant, but it is improbable that this should happen in dilute solution unless g_{41} is always small enough to be negligible.

If two of the components are polar, the situation may be very considerably complicated. If the two solutes react together their effect on each other may be very much greater than that of either on itself. If either or both react with the solvent, it may be very much less.

It is possible to make some tentative conclusions regarding the effect of changing environment on the activity coefficient of the critical complex. Since the complex formation may be assumed to involve the more active groups, and therefore to screen them, the complex may be taken as less polar than its most polar component, and possibly less polar than either. If the complex also contains solvent molecules, which is probably quite often the case, it may be a more ideal solute than any of its components other than the solvent. This term will tend to make the deviations from ideality less than would be predicted from the simple activity theory.

Illustration.—As an example of the application of the method we may take the action of *p*-nitrobenzoyl chloride with some of the simpler alcohols in ether solution, which is considered in detail in a paper which follows.' Not many ether solutions have been studied accurately, but the freezing points of benzene from solutions of ether are almost identical with those from solutions of toluene, which are known to be nearly ideal. Therefore ether may be taken as not much different from benzene as a solvent. Figure 2 shows the freezing-point curves of ether, toluene, benzoyl chloride and propyl alcohol in benzene.[15] The freezing points of solutions of ethyl acetoacetate[16] are identical with those of ether or toluene up to 1 molal (the limits of the measurements), so the esters should behave as ideal solutes and have little effect on the activity coefficients of the other solutes. Benzoyl chloride does not differ very greatly from the ideal solutes, so we may assume, with considerable probability, that the activity coefficient of nitrobenzoyl chloride is near unity and equal to that of the critical complex. The acid chloride should also have little effect on the activity coefficient of the alcohol. The alcohols, however, should show large deviations depending largely on their own concentration. The hydrogen chloride formed in the reaction shows a great tendency to chemical combination; it forms stable compounds with ether. Its effect on the activity coefficients appears to depend upon its relative reactivity with the solute and with the solvent, which is most easily determined from the rate measurements themselves. For hutyl alcohol the rate was found to be unchanged when one mole of hydrogen chloride was added to one mole of alcohol and one of chloride in a thousand grams of ether. Further confirmation was obtained from the fact that the curves

---

[15] "International Critical Tables," Vol. 4, pp. 112, 116, 177,

[16] Auwers, *Z. physik. Chem.*, **12,693 (1893).**

for initial concentrations of one molal and of one-half molal fit together smoothly as functions of the alcohol concentration, showing that one-half mole of hydrogen chloride plus one-half of ester have no effect on the rate. So only the change of the activity coefficient of the alcohol due to changes in its own concentration need be considered. The higher alcohols behave as does butyl. Not enough measurements were made on propyl alcohol to determine the effect of the hydrogen chloride.

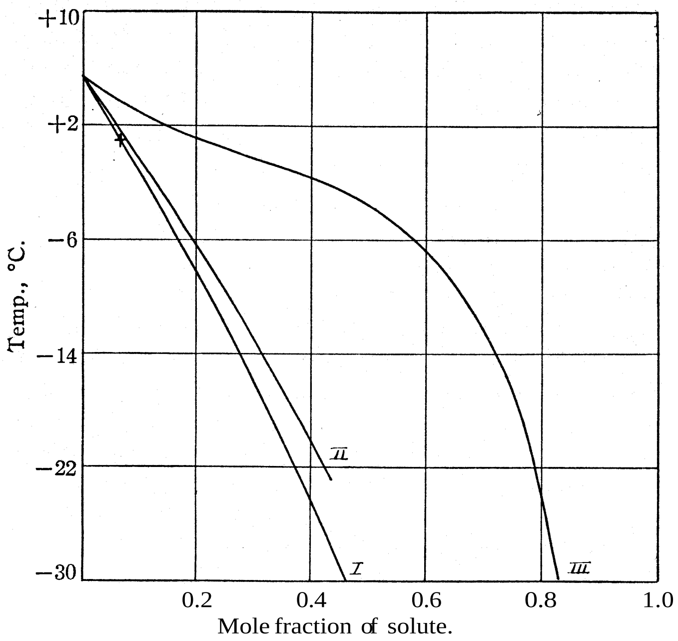

Fig. 2.—Freezing points of benzene solutions: I, toluene, ether; ethyl acetoacetate to +; II, benzoyl chloride; III, propyl alcohol.

For ethyl alcohol, an excess of one mole of ester shows no effect on the rate, but half a mole of ester and half of hydrogen chloride retard the action considerably. It seems that hydrogen chloride combines with ethyl alcohol more readily than with ether. The existent measurements may be fitted by assuming that the effect of the acid on the activity coefficient of the alcohol is equal to that of an equal concentration of the alcohol itself, or that $g_{31} = g_{11}$, so that the activity coefficient may be regarded as constant during the course of the reaction, but varying with the initial concentration of alcohol. Methyl alcohol behaves similarly but $g_{31} = g_{11}$ is considerably larger than for ethyl alcohol.

Summary

There is given an analytical method for the treatment of reaction rates in non-ideal solutions where the environment changes during the course of the reaction, based on approximate equations for the change of activity coefficient with concentration.

By use of Bronsted's theory of reaction mechanism, the method is applied to the oxidation of ammonia by persulfate ion in the presence of silver ion.

The principles by which the activity coefficients in non-electrolyte mixtures may be approximately evaluated are given, and illustrated by their application to the reaction of p-nitrobenzoyl chloride with certain alcohols.

THE PHOTOCHEMICAL DISSOCIATION OF TRIATOMIC MOLECULES. HYDROGEN CYANIDE

BY DONALD STATLER VILLARS

RECEIVED JULY 11, 1929 PUBLISHED JANUARY 8, 1930

The remarkable success of Franck, Kuhn and Rollefson[1] in explaining the absorption spectra of the Group I halides leads one to the query whether the same mechanism does not hold also in the case of polyatomic molecules. Its importance to photochemistry cannot be neglected, especially in view of the attempt of Franck and Scheibe[2] to explain in a reasonable manner the photolysis of hydrogen iodide in aqueous and hexane solutions. According to Franck and Kuhn[3] an "atomic"[4] molecule may be dissociated photochemically into a normal atom plus an excited atom. Only two continuous absorption regions in the near ultraviolet should result, depending on which is the one excited. On the other hand, an "ionic"[5] molecule may be dissociated photochemically into two normal atoms, one way in addition to those in which the "atomic" molecule may dissociate. In this case an extra absorption region is to be found to the red side of the spectrum and at a distance corresponding to the energy difference ${}^2P_{1/2} - {}^2P_{1\,1/2}$ of the halogen ground doublet. The first step toward the application of their theory to polyatomic molecules is the consideration of triatomic molecules. When several of these have been investigated it will be time to take up the more complicated ones. Terenin[6] has already studied triatomic molecules, two atoms of which are similar. As this is likely to lead to degeneracy complications in the analysis of the spectra, it was thought desirable to choose

[4] An atomic molecule may be defined as one which when given sufficient vibrational energy will dissociate into atoms.

[5] An ionic molecule may be defined as one which when given sufficient vibrational energy will dissociate into ions.

[6] Terenin, Z. *Physik*, 44, 713 (1927); 49, 882 (1928); Nature, 118, 843 (1926).

a triatomic molecule all three atoms of which are different. For this purpose hydrogen cyanide seemed ideal. It possesses the unique advantage (over Terenin's diatomic halides) that the spectra of its partial decomposition products are well known. Thus if hydrogen cyanide will dissociate in any of the four modes

$$\begin{aligned} HCN + E_1 &= H + C + N && (1) \\ HCN + E_2 &= H + CN && (2) \\ HCN + E_3 &= C + NH && (3) \\ HCN + E_4 &= N + CH && (4) \end{aligned}$$

we should be able to identify by its fluorescence any excited decomposition molecule which was not in a metastable state. The investigation of hydrogen cyanide seems to have an advantage over the original one of Franck and Kuhn in that we are not likely to be disappointed by getting metastable products. In this work a calculation was first made of these different dissociation energies and this was then checked by trying to locate experimentally the predicted absorption spectra of hydrogen cyanide.

The Heat of Dissociation of Normal Hydrogen Cyanide.—The heat of dissociation of normal hydrogen cyanide may be calculated from the equation

$$\begin{array}{llllll} HCN + Q & + \frac{1}{2}D_{H_2} & + \frac{1}{2}D_{N_2} & + S_C & = H + C + N \\ -1.39\text{[7]} & + \frac{1}{2}4.38\text{[8]} & + \frac{1}{2}9.5\text{[9]} & + 6.10\text{[10]} & = 11.65 \text{ v.} \end{array}$$

where Q is the heat of formation from the element molecules (values given in volts; 1 v. = 23 kilo cal.), D the heat of dissociation of the element molecules and S_C the heat of sublimation of diamond.

In order to calculate the heats of dissociation for Reactions 2, 3 and 4 we must know the heats of dissociation of the respective dissociation products. Two of these have been calculated elsewhere.[11] Heitler and Herzberg[12] have found the heat of dissociation of CN to be 9.7 v., the products being, according to Mulliken,[13] a normal ^3P C atom and an excited ^2D N atom. The dissociation of CN into two normal atoms then should be 9.7 − 2.4 = 7.3 v. The probable error in this value may amount to as much as +0.8 v. by mistaking the excitation energy of the excited atom.[14]

With these values we get for the heats of dissociation of normal hydrogen cyanide

[11] Villars, THIS JOURNAL, 51, 2374 (1929); $D_{NH} = 4.65$ v.; $D_{CH} = 3.55$ v.

[12] Heitler and Herzberg, *Z. Physik*, 53, 52 (1929).

[13] Mulliken, *Phys. Rev.*, 32, 761 (1928).

[14] Heitler and Herzberg believe the excited atom to be a 1.6 v. ^5S C atom instead of a 2.4 v. ^2D N atom.

$E_1 = 11.65$ v. (H + C + N) $E_3 = 7.0$ (C + NH)
$E_2 = 4.35$ (H + CN) $E_4 = 8.1$ (N + CH)

These figures show that in a thermal collision process Reaction 2 should greatly outweigh the other three. The velocity of such a dissociation should be represented by an activation energy equal to or less than $4.35 \times 23 = 100$ kilo cal. A rough calculation[15] was made to see what the speed of decomposition according to (2) would be if the heat of activation were 3.1 v. At 1000°K. there should be a 0.2% change per second at 1 atm. It was a very surprising experimental observation that hydrogen cyanide gas at one atmosphere pressure did not take on any visible change when heated in a furnace at 1000°. The liquid which was condensed in the tube protruding outside the furnace, however, turned brown, showing that a slow reaction was taking place, the products probably condensing out as rapidly as they were formed.

The Photochemical Dissociation of Hydrogen Cyanide.—That hydrogen cyanide is most likely not an "ionic"[16] molecule even though it has an electric moment (it has an infra-red absorption spectrum) is attested by the fact that its ionization constant in water is 10^{-9}. If this is true, then, according to Franck's theory, a photochemical dissociation in an elementary act should not be possible unless one of the products comes off in an excited state. The excitation energies of the different products of dissociation are as follows (doubtful values given in parentheses)

$\mathrm{H} + 10.15\text{ v.} = \mathrm{H}^*$
$\mathrm{N}(2s)^2(2p)^3\ {}^4S + 2.35 = \mathrm{N}^*(2s)^2(2p)^3\ {}^2D$
$+ 10.38 = \mathrm{N}'(2s)^2(2p)^2(3s)\ {}^4P$
$\mathrm{C}(2s)^2(2p)^2\ {}^3P + (2.0)^{17} = \mathrm{C}^*(2s)^2(2p)^2\ {}^1D$
$+ (3.2)^{17} = \mathrm{C}'(2s)^2(2p)^2\ {}^1S$
NH 32: $+ 3.7 = \mathrm{NH}^*\ {}^3\Pi^{18}$
$\mathrm{CH}\ {}^2\Pi_n + 2.9 = \mathrm{CH}^*\ {}^2\Delta_i$
$+ 3.2 = \mathrm{CH}'\ {}^2\Sigma$
$\mathrm{CN}\ {}^2\Sigma + 1.8 = \mathrm{CN}^*\ {}^2\Pi$
$+ 3.2 = \mathrm{CN}'\ {}^2\Sigma$

The energies necessary for the different photochemical dissociation possibilities are then as follows

$4.35 + 1.8 = 6.2$ v. $\mathrm{H} + \mathrm{CN}^*\ {}^2\Pi$ (2a)
$+ 3.2 = 7.6$ $\mathrm{H} + \mathrm{CN}'\ {}^2\Sigma$ (2b)
$7.0 + 2.0 = 9.0$ $\mathrm{C}^*\ {}^1D + \mathrm{NH}$ (3a)
$+ 3.2 = 10.2$ $\mathrm{C}'\ {}^1D + \mathrm{NH}$ (3b)
$+ 3.7 = 10.7$ C + NH* 311 (3c)
$8.1 + 2.4 = 10.5$ $\mathrm{N}^*\ {}^2D + \mathrm{CH}$ (4a)
$+ 2.9 = 11\ 0$ $\mathrm{N} + \mathrm{CH}^*\ {}^2\Delta_i$ (4b)
$+ 3.2 = 11.3$ $\mathrm{N} + \mathrm{CH}'\ {}^2\Sigma$ (4c)

Thus it is seen that the photochemical dissociation which takes the least amount of light energy is also that which would give a hydrogen atom and a CN molecule (this time in an excited state). Unfortunately, the only spectrograph at my disposal was an E_1 Hilger which takes photographs of wave lengths down to 2100 Å. (5.9 v.). A check over this range nevertheless seems of use to make sure we have not gone astray in the above calculations. An error of 0.8 v. in the dissociation products of CN would lower the above expected convergence limit from 6.2 to 5.4 v. (=2280 Å.), a point where we might have hopes of detecting absorption if it occurred. The presence or absence of an absorption spectrum at wave lengths below 2800 Å. (**4.35** v.) should also throw light on our conclusions as to the type of binding between the H and CN part of the molecule.

Apparatus

The hydrogen cyanide used was prepared by dropping 1-1 sulfuric acid on solid potassium cyanide.[19] The evolved gas was at first dried by passing it over a tube of phosphorus pentoxide 130 cm. long and condensed by an ice-salt (—14") mixture surrounding the first tube of a distilling train. The yield was not good and at a later date when the gas was being prepared a second time the yield was only a few per cent. This was found to be caused by the substitution of a phosphorus pentoxide drying tube **2** meters long, a close examination revealing a sirupy combination product of $P_2O_5 \cdot x$HCN. In the final apparatus no drying was attempted and the gas was purified from water by five fractional distillations. After the distillation and before sealing off, the hydrogen cyanide would be frozen in both tubes to prevent its decomposition by heat and the apparatus evacuated.[20] As it was discovered that hydrogen cyanide has marked solvent action on De Khotinsky cement, the last distillation from pyrex to the quartz absorption cell was made through a quartz–pyrex glass joint. The liquid was quite stable and did not turn brown until after its subjection to an electric discharge or to a high temperature and pressure.

By supporting the cell proper in a furnace and controlling the temperature of the ice condensed in the tube leading from the cell to a point outside the furnace, both temperature and pressure could be regulated easily. This tube dipped into a Dewar filled with a mixture of alcohol and dry ice. The temperature in the Dewar was controlled by a toluene thermometer and that in the furnace by a Chromel–Alumel thermocouple.

The furnace consisted of a specially molded porcelain core with two side tubes sticking out of its center at right angles, the smaller one to house the thermocouple leads, the larger one to introduce light for a fluorescence experiment. The core was wound with 50 feet of No. 12 Chromel wire and surrounded by a packing of Sil-o-cel. The openings were closed by fused quartz windows to prevent convection. This furnace when drawing 19 amperes from a 110-volt main would reach the temperature of 1000" in an hour and a half.

The light source used was a hydrogen discharge tube built according to the specifica-

---

[19] The method recommended in "Organic Syntheses," Vol. VII, 1927, p. 50, had the great disadvantage that the sodium cyanide solution cakes and plugs up the apparatus, after which it has to be dismantled before the preparation can be continued.

[20] The hydrogen cyanide was found to gum up the mercury badly in a mercury vapor pump, so only the supporting Hi-Vac pump was used.

tions of Bay and Steiner.[21] It was found that the spectrum of such a tube cleaned itself up after several hours of running and that it was not necessary to run the discharge beforehand at a higher load in a continuous stream of hydrogen as has been recommended by other authors.

An E_1 Hilger quartz spectrograph was used. Owing to its high dispersion and the twelve quartz reflecting surfaces through which the light from the lamp had to pass, a period of thirty minutes was required to give a satisfactory exposure.

In some of the photographs the light source used was an iron arc. This was because at the crucial moment a leak had developed in the hydrogen lamp, putting it out of commission.

Results and Discussion

Absorption.—The transmission spectrum of hydrogen cyanide at 741 mm. and 25° is exactly that of the lamp for wave lengths between 2240 and 6593 Å. To investigate the region below 2240 Å., Schumann plates were used. In this case the spectrum of the iron arc is identical with that transmitted through the hydrogen cyanide (atmospheric pressure) as far as the limit of the spectrograph (2094 Å.).

In order to increase the probability of absorption at the wave lengths accessible to the quartz spectrograph, the expedient was used of raising the molecules to higher initial vibrational quantum levels by increasing the temperature of the gas. Thus, assuming the distribution law, $N = N_0 e^{-E/kT}$, at room temperature (300°K.), 2% of the molecules have an energy 0.1 v. greater than average. At 1000°K. this number has increased to 32%, while the percentage of those having 1 v. excess energy has increased from the negligible amount of 10^{-15} to 0.001%. At 1273°K. the number having 1 v. excess energy should be about 0.01%. We might, therefore, hope to increase our absorption some 10^{13} times by raising the temperature to 1000°. Of course, there are reasons why this attempt should fail. The number of absorbing molecules may still be so small as to be negligible. Moreover, in the photochemical dissociation of hydrogen chloride, absorption sets in 1.1 v, beyond the convergence limit, the distance beyond depending on the loss in stability of the molecule in the excited state. If the stability of hydrogen cyanide changed on excitation by the same amount as in hydrogen chloride, so that its absorption maximum is 1.1 v. beyond its convergence limit, then we should not be able to detect absorption until well down in the Schumann region (1700 Å.).

Our attempt was, indeed, unsuccessful. The continuous spectrum of the hydrogen discharge was photographed after passing through hydrogen cyanide at 1000" at a pressure of 1 mm. No absorption could be observed. The investigation of hydrogen cyanide in a vacuum spectrograph should prove very fruitful, but first of all the difficulties introduced by its solvent action on cements and on mercury must be overcome.

As a final resort, the hydrogen cyanide was allowed to reach atmospheric

---

[21] Bay and Steiner, *Z. Physik*, 45, *337* (1927).

pressure at 1000° and the spectrum photographed from 2240 to 2800 Å. The spectrograms were run through a microphotometer but no detectable absorption was evident. Contrary to expectation, the hydrogen cyanide did not decompose rapidly under this treatment. The vapor remained perfectly colorless to the eye, but the liquid started to turn brown, and thereafter was completely changed to a brown solid within a couple of weeks. The liquid had been prepared six weeks before being used, during which time it remained perfectly clear and colorless.

The fact that hydrogen cyanide gas shows no absorption between 2800 and 2240 Å. falls in line with the assumption that it is not an "ionic" molecule. As it certainly does not show an ionic character in aqueous solution, it seems extremely doubtful that the results reported by Andant and Rousseau[22] concerning its photolysis in light of wave lengths 3650, 3130 Å. and below could have been caused by pure hydrocyanic acid.

Fluorescence.—On the chance that the sought continuous absorption might set in immediately after the calculated convergence limit, the pressure in the cell (room temperature) was reduced to about 1 mm. by freezing the hydrogen cyanide in carbon dioxide snow and the cell was illuminated with light from a silver arc, which should furnish quite a few wave lengths in the region 1967 to 1802 Å. There was no visible fluorescence (1.8 v. excitation of CN) nor ultraviolet fluorescence (3.2 v. excitation of CN). The lines appearing were the silver lines. Neither could one observe at the temperature of 1000° a visible fluorescence of the red CN bands against the background of the relatively cold window. It is not at all surprising that we have failed to excite fluorescence by the silver arc, for the intensity of its short wave lengths (1967–1802 Å.) must have been considerably reduced in the passage of the light through the air and the quartz cell wall.

Polymerization.—Either the treatment of the hydrogen cyanide gas with light of these extremely short wave lengths or else an extremely slow chemical reaction (two months) had initiated, by the time the first absorption measurements had been completed, a decomposition or a polymerization of the hydrogen cyanide liquid in the cell. This was at first indicated by a yellowish color in the liquid, which became darker and darker. I am inclined to favor the former hypothesis for the following reasons. The polymerization of hydrogen cyanide to colorless plates of $(HCN)_3$ occurs after a long period of heating of the pure substance at 100°, or after a long irradiation with sunlight in the presence of epichlorohydrin.[23] A trace of potassium cyanide or of an alkali carbonate catalyzes the polymerization of hydrogen cyanide to a black substance, out of which can be crystallized the $(HCN)_3$. Cyanogen, on the other hand, polymerizes to black or dark brown

---

[22] Andant and Rousseau, Compt. *rend.*, 184, 1553 (1927).

[23] Abegg, "Handbuch der anorganischen Chemie," Leipzig, 1909, Vol. III, Part 2, p. 236.

paracyanogen. If our hypothesis is correct, it is quite reasonable that the steps should be the following

$$\mathrm{HCN} \longrightarrow \mathrm{H} + \mathrm{CN}$$
$$2\mathrm{CN} \longrightarrow (\mathrm{CN})_2 \longrightarrow (\mathrm{CN})_x$$

Further evidence that the decomposition products of hydrogen cyanide most readily obtained are H and CN is that when a faint emission spectrum was induced in the cell which contained the brown deposit, the 0,0(3), 1,1(1) and 2,2(0) CN($^2\Sigma$ − $^2\Sigma$) bands were the most intense (intensities in parentheses). Two other bands were observed, the 0,0(1) N_2^+ band and the 0,1(1) of the second positive nitrogen group. All bands were very thin and were shaded toward the violet. Still further evidence that we have here a decomposition of hydrogen cyanide rather than a direct polymerization lies in the micro-analysis of the residual gas in the cell after opening it up under water and dissolving out the hydrogen cyanide left. A small bubble of insoluble gas remained, which was introduced into the top of a tube 6.25 mm. in diameter and mixed with an approximately equal volume of oxygen gas. A platinum resistance spiral in the top of the tube was then made to glow, and after the gases were cooled, a decrease in volume of 0.053 ± 0.008 cc. had occurred. This is an indication that hydrogen was the residual gas.

Summary

Summarizing, it may be stated that our calculations of the minimum energy required to dissociate hydrogen cyanide by a photochemical act are not contradicted by any experimental results. The supposition that hydrogen cyanide is not an "ionic" molecule is supported by the fact that it has no absorption spectrum between 4.35 and 5.9 v. (2800 and 2100 Å.). The dissociation into H and CN should require the least energy thermally (4.35 v. = 100 kilo cal.) as well as photochemically (6.2 v. = 1990 Å.), compared with dissociations into CH plus N and NH plus C. Evidence has been adduced to support the hypothesis that the brown coloration which hydrogen cyanide acquires comes from an initial decomposition into H and CN and a subsequent polymerization of cyanogen to paracyanogen, rather than that it is due to a direct polymerization of the hydrogen cyanide to $(HCN)_3$.

THE SOLUBILITIES OF HELIUM, NEON AND ARGON IN WATER AND SOME ORGANIC SOLVENTS

BY AXEL LANNUNG

RECEIVED JULY 15, 1929 PUBLISHED JANUARY 8, 1930

The distribution of a solute between two solvent media has been discussed recently in two papers by Bjerrum,[1,2] in which, especially, the relationship between the partition of electrolytes and non-electrolytes is treated according to the theoretical considerations of Born.[3] While the partition coefficient V of a non-electrolyte is defined as the ratio of its equilibrium concentrations in the two media, for a binary strong electrolyte, for example, sodium chloride

$$V_{\text{NaCl}} = \sqrt{\frac{[\text{Na}^+]^{\text{II}}[\text{Cl}^-]^{\text{II}}}{[\text{Na}^+]^{\text{I}}[\text{Cl}^-]^{\text{I}}}}$$

where $[\text{Na}^+]^{\text{I}}$ denotes the concentration at equilibrium of the sodium ion in the medium I and so on.

The partition coefficient V_n of a non-electrolyte is related to A, the reversible work of transferring one molecule from its solution in one medium to a solution of the same concentration in the other medium by the formula

$$A, = kT \log, V_n$$

For the binary electrolyte sodium chloride the corresponding relation is

$$A_{\text{NaCl}} = 2kT \log_e V_{\text{NaCl}}$$

where A_{NaCl} is the reversible work of transference of an ion pair Na+ + Cl^- from the one medium to a solution of the same concentration in the other. The transference work A_{NaCl} can be split into two parts, an electrical work due to the charge on the ions and a specific work depending on the configuration of the ions. This may be expressed by the equation

$$A_{\text{NaCl}} = A_{n(\text{Na}^+)} + A_{n(\text{Cl}^-)} - E^{\text{I}}_{(\text{NaCl})} + E^{\text{II}}_{(\text{NaCl})}$$

where $A_{n(\text{Na}^+)}$ and $A_{n(\text{Cl}^-)}$ represent the transference work for molecules similar to Na^+ and Cl^- in all respects except in not being electrically charged, while $E^{\text{I}}_{(\text{NaCl})}$ and $E^{\text{II}}_{(\text{NaCl})}$ represent the electrical work of discharging the ion pair Naf + Cl^- in the media I and II, respectively. As many ions may be regarded as spherical, E^{I} and E^{II} can be calculated by means of Born's Formula

$$E_{\text{NaCl}} = \frac{\epsilon^2}{2D}\left(\frac{1}{r_{\text{Na}^+}} + \frac{1}{r_{\text{Cl}^-}}\right)$$

r_{Na^+} and r_{Cl^-} are the radii of the ions, $- \pm \epsilon$ their charges and D is the dielectric constant of the medium. The other work terms, $A_{n(\text{Na}^+)}$

and $A_{n(Cl^-)}$, cannot be calculated, but it is reasonable to suppose that they will be equal to the corresponding transference work for molecules of the inert gas type of the same size as Na^+ and Cl^-. In order to test this hypothesis it is of importance to have data for the partition coefficients of the inert gases between various solvents. With this end in view I undertook the present measurements at the suggestion of Professor Bjerrum.

Apparatus

Owing to the considerable difference between the solubilities of helium, neon and argon, apparatus of three different sizes were used. The design was based on that of v. Antropoff,[4] with certain improvements to increase the accuracy. In particular the glass spiral, used by v. Antropoff to enable the absorption bulb to be shaken independently of the rest of the apparatus, was dispensed with and the apparatus shaken as a whole; this had the double advantage on the one hand of considerably decreasing the undesirable dead space and on the other of making the apparatus less fragile and thus easier to handle.

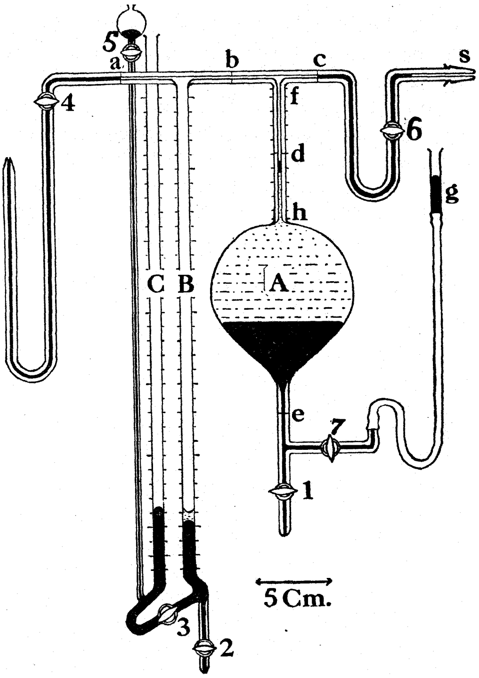

Fig. 1.

The apparatus is shown diagrammatically in Fig. 1. The absorption bulb **A** had a capacity of 88, 310 and 587 cm.^{3} in Apparatus **I, II** and **III**, respectively; the rest of the apparatus was substantially the same in all three. Behind the manometer BC, which also served as a gas buret, was a scale. The buret tube B had an internal diameter 0.5 cm., a length of 35 cm. and capacity of about 7 cm.^{3} The apparatus was fixed in a 4-mm. thick aluminum frame with bands of brass or where desired of transparent celluloid; the siphon beyond a was free from the frame.

Calibration,—The apparatus was placed in a specially constructed air thermostat, whose temperature could be varied from 2 to 45° and kept constant to within ±0.03°. After evacuation through **6**, mercury was let in through 1 until it filled the absorption bulb **A** and the capillary as far as b and c. By letting out mercury through 1 and weighing it the volume between b, c and d was determined; similarly the vertical capillary, which was graduated from f to h, was calibrated; finally, the volume of the absorption bulb from d to e was determined by the same method.

The coefficient of expansion of the glass was determined by measuring the capacity of the absorption bulb A at two different temperatures.

The gas buret was calibrated by a similar method from the marks a and b to the bottom by letting out mercury 0.2 cm.^{3} at a time through *2*.

---

[4] v. Antropoff, *Z. Elektrochem.*, 25,269 (1919).

By reading through a telescope at a distance of 1 m. it was easy to attain an accuracy of 0.1 mm. or of 0.002 cm.^{3}

Technique.—Before each series of measurements the apparatus was cleaned throughout with a warm mixture of chromic and sulfuric acids. All the stopcocks except 6 were thoroughly smeared with Ramsay grease, the apparatus was evacuated through 6 and then, mercury being let in through 1, was filled completely as far as the open ends of the siphon tube, the manometer tube C and the movable reservoir g.

To the ground glass joint s was connected an L-tube the other end of which dipped into a bottle containing pure solvent, and solvent was drawn into A by letting mercury run out through 1. When A was half full of the solvent, the L-tube was disconnected from s, the stopcock 6 was quickly dried with cotton wool and greased. Half the remaining mercury was now let out through 1, while air dried over calcium chloride was sucked in through 6. The ground glass joint s was then connected through two drying towers containing sulfuric acid and bits of glass tubing to a manometer and an oil suction pump. By shaking the apparatus the mercury was set into wave-like motion; this facilitated the escape of air and vapor bubbles, which otherwise tended to collect at the mercury surface. When most of the air had been sucked away either bumping occurred or else vapor bubbles formed only at the surface; to reduce the loss of liquid by bumping, 6 was opened only at intervals. Usually the apparatus was kept evacuated overnight and after repeated shaking and suction through 6, one could show that all air had been removed by shaking for a time with 6 closed, letting mercury in through 7 so that the solvent surface was approximately at d and then opening 3, when the mercury would rush up the tube B, hitting the top with a metallic clang and then filling the rest of the tube as far as the solvent surface at d, no air bubbles being visible. If, on the other hand, an air bubble formed, the suction and test were repeated.

When the solvent was free from air and shut is as described in such a way that it nowhere was in contact with any stopcocks, the apparatus was placed in the air thermostat and brought to 20.0°, the temperature at which it was calibrated, the cock 3 being open. By opening 7 and moving the small reservoir g, the surface of the solvent could be kept in the vertical part of the capillary.

When the temperature was approximately correct, the apparatus was again taken out of the thermostat and the siphon tube sunk into a beaker filled with mercury; the gas which was stored over mercury in small glass vessels was sucked in through the siphon tube by closing 3 and opening 4 and 2. When the gas buret was nearly full, mercury was sucked from the beaker through the siphon tube to a, and 2 and 4 were then closed. Then by opening 7 and raising the reservoir g a few drops of solvent were pressed over into the gas buret in order to saturate the gas with the solvent vapor. After lowering the reservoir g until the solvent surface was at f and attaching rubber tubing to the glass joint s, a small quantity of mercury was blown over from the horizontal capillary to the surface of the solvent; the rest of the mercury was then sucked back to c, 3 was opened and by letting mercury out through 2 the mercury levels in the tubes B and C were adjusted to be approximately the same. The apparatus could now be brought to the exact temperature of the air thermostat without any fear of loss of gas through absorption. As the bulb A and vertical capillary hf constituted a very sensitive thermometer, it was easy to tell when temperature equilibrium was attained by the surface of the mercury in the capillary remaining steady. The height of the mercury and solvent surface in the buret tube as also that of the mercury in the open tube C were read through the telescope. The atmospheric pressure was read on a Fortinette Standard Barometer. From these data could be calculated W, the volume of the gas at standard temperature and pressure (S. T. P.).

Saturation of the solvent was brought about by letting out through 1 about 1 cm.3

of mercury, which was weighed, and then putting the apparatus into the air thermostat, where it was mechanically shaken as a whole with the frame. The rate of shaking was adjusted to be in resonance with the natural period of swing of the liquid. As absorption took place the mercury rose in the buret tube B, but by opening 5 at intervals more mercury could be let into C so as to keep the levels in C and B approximately equal. When the liquid had reached saturation, which generally took about one hour, the liquid levels in B and C were again read; from these one can calculate directly the pressure of the gas remaining and also its volume, since the volume from d to the surface of the liquid in A is equal to the volume of the weighed mercury let out through 1 corrected by an amount equal to any change in the volume of the small quantity of the solvent in b.

The thermostat temperature was then altered and the measurements of pressure and volume were repeated after saturation was attained.

At the end of series of measurements the cock 3 was closed, the ground glass joint s was connected to the suction pump and the mercury in the capillary around 6 was sucked out. Air was let in through 6 and the mercury in A was let out through 1. The volumes of the solvent, the mercury and the bulb at the various temperatures were calculated from the volumes at 20° and the various coefficients of expansion. When necessary a small correction to the volumes of the liquids and bulbs was applied for the variation of pressure in the apparatus; this was generally avoided by measuring at pressures very near that of the atmosphere.

The Materials Employed.—The helium, neon and argon were bought from Linde's Liquid Air Factory. According to their specification the helium contained as impurity only 0.5% by volume of neon, the neon only 1% of helium and the argon only 0.5% of nitrogen. The densities of the argon and neon were in agreement with this; the spectrum of the helium showed faint neon lines. For the technique of handling and storing these gases the reader is referred to Travers, "The Experimental Study of Gases." A Topler–Antropoff[4] pump was found to be especially convenient for this part of the work.

The water used had a specific conductivity 2×10^{-7}.

The methyl alcohol (Methanol B. A. S. F.) was distilled over magnesium strips freshly cut from a block.[5] The first third of the distillate was rejected.

The ethyl alcohol (Alcohol absolutus, Ph. dan.) was distilled twice over freshly prepared quick lime.[6]

The acetone (Kahlbaum's "zur Analyse") was used after showing the absence of water, aldehyde and acid.

The benzene was Kahlbaum's "zur Molekulargewichtsbestimmung" and had a melting point of 5.48°.

The cyclohexane, from Poulenc Frères, was shaken for a considerable time with fuming sulfuric acid, separated in a separation funnel and shaken with water until neutral. After keeping over phosphorus pentoxide for several days, it was distilled over phosphorus pentoxide; the first quarter was rejected and the remainder had a melting point of 6.0°. Cyclohexane of this purity was used for the solubility determinations of argon. Later the remainder was distilled over sodium and a fraction with a melting point of 6.3° was used; previously recorded melting points are 6.4[7] and 6.5°.[8]

Cyclohexanol "pur" from Poulenc Frères was fractionated twice in *vacuo;* the fractions used had melting points of 23.6 to 23.9°; E. Schreiner and O. E. Frivold[9] found a melting point of 23.9°.

Results

The absorption coefficient α as defined by Bunsen is given by the formula

$$\alpha = \frac{(W \div w)P_0}{W_L \times P}$$

where W is the volume at S. T. P. of the gas originally introduced; w is the volume at S. T. P. remaining after absorption; W_L is the volume of the

is the equilibrium distribution ratio of the volume concentrations of the gas in the solution and in the vapor phase. The relation between 1 and *a* is $1 = \alpha T/273$, where T is the absolute temperature at which the measurement was made.

Comparison with Older Measurements.—In Tables VII, VIII and IX the results of the present measurements are compared with those of former workers. From here onward the expression solubility will always mean the Ostwald coefficient, *l*. The careful measurements of Cady, Elsey and Berger[10] of the solubility of helium in water are in good agreement with our own, but those of v. Antropoff[4] and Estreicher[11] are not. The last mentioned measurements are very uncertain for three reasons: first, the volume of gas absorbed was small in comparison with the total volume used; second, owing to the large dead space, it was often necessary to let in the gas in two portions; third, he attempted to measure the volume of gas in the dry state, which is practically impossible. V. Antropoff's measurements of the solubility of neon in water are uncertain because he used only 26 cm.^{3} of water, and of a total volume of 6.1 cm.^{3} of neon no more than 0.3 to 0.6 cm.^{3} was absorbed. The large increase of solubility with rising temperature found by v. Antropoff with neon seems improbable, when contrasted with the behavior of helium and argon.

Winkler's[12] measurements of the solubility of argon in water are in fair agreement with our own, but those of Estreicher again deviate from ours. Ramsay, Collie and Travers[13] find that one volume of water at 18.2° absorbs 0.0073 volume of helium, but, as they state in the same paper that helium is insoluble in ethyl alcohol and benzene, these measurements can only have been provisional.

Effect of Temperature on Solubilities.—As seen from the tables the solubility of each of the three gases is least in water; in the organic solvents the order of the solubilities is roughly but not exactly the same for all three gases. In each solvent helium has the smallest and argon the greatest solubility. All the solubilities are less than 0.5. In the organic solvents the solubility increases with rise of temperature and in general the more so the lower the solubility. This holds always when comparing the three gases in a given solvent and generally when comparing the various solvents for a given gas. These features can be clearly seen from Fig. 2, in which $-\log_{10} l$ is plotted against $1/T$. In this figure are included as well as our own measurements those of v. Antropoff[4] for krypton and xenon, as well as Ramstedt's[14] measurements for radon. Apart from water, whose behavior will be discussed later, in all cases straight lines are obtained and in

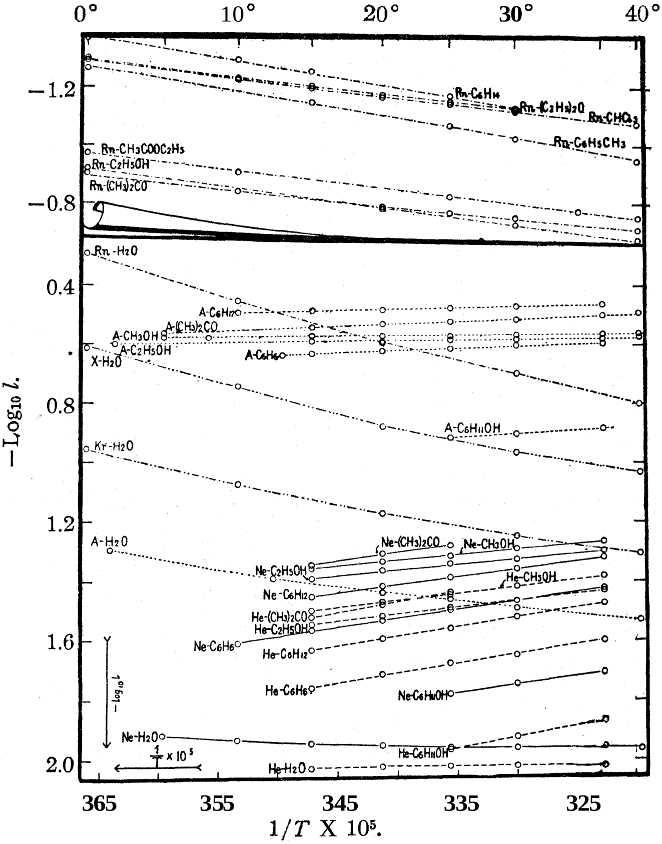

Fig. 2.—Solubility-temperature curves.

---

[14] E. Ramstedt, *Le Radium*, 8, 253 (1911), figures taken from A. Schulze, *Z. physik. Chem.*, 95, 257 (1920).

general the higher the line the smaller the gradient. In the case of radon, where the solubility is especially high, being over 1, the gradients are negative; that is to say, the solubility decreases with increase of temperature and the more the greater the solubility. It appears that as the temperature increases, the solubility in all cases tends toward a number of the order of magnitude unity. An apparent exception to this regularity is the behavior of xenon in aniline; as its solubility is about 0.5, we should expect it to vary only slightly with the temperature; however, v. Antropoff himself admits these measurements to be uncertain.

This regularity also holds for the diatomic molecules H_2, N_2, CO and also for CO_2 in organic solvents with exception of H_2 in aniline.[15] Apparently the generally accepted idea that the solubility of gases decreases with rise of temperature is due to most measurements having been made with water as solvent, whereas it is clear from the figure that water behaves quite exceptionally as compared with organic solvents, for water as contrasted with the other solvents straight lines are not obtained. As water in liquid state is so highly associated at low temperatures, one would expect anomalies in the temperature coefficient of many of its properties; among these are its dissolving power of both monatomic and diatomic gases. De Villard[16] and De Forcrand[17] show the formation of a crystalline hydrate of argon at 0° and 150 atm. This shows the existence of strong attraction between water and argon molecules. Corresponding hydrates of neon and helium are not known and the temperature–solubility curves also deviate less from normal behavior, the solubility of helium in water being almost independent of the temperature. It seems not unlikely that there exist organic solvents, especially those with small polar molecules, whose behavior would be intermediate between normal and–that of water.

From the Clapeyron–Clausius equation

$$\frac{d\ \log_e l}{d(1/T)} = \frac{u}{R}$$

where u is the heat of solution at constant volume, it is clear that straight lines in Fig. 2 denote u constant over the temperature interval in question. As already mentioned this is the case for all the solvents used except water.

Integration of this equation for constant u gives

$$\log_e l = \frac{u}{RT} + \log_e a$$

or

$$l = a\ e^{u/RT}$$

The values of u and a can be obtained directly from the slopes and intercepts on the axes of the straight lines. In Table X are given the values

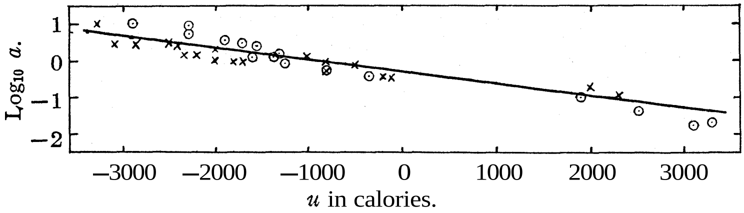
of u in calories and of $\log_{10}$ a obtained from our own measurements as well as those of Just and of Ramstedt. Values are also given for the heat of evaporation of the solutes in the pure state at their respective boiling points under a pressure of one atmosphere. The data for radon and neon are taken from Gmelin's "Handbuch der anorganischen Chemie," and the remainder from "International Critical Tables," Vol. 5. It is interesting to see that in going from helium to neon and from neon to argon the differences in the heats of solution are approximately the same as the differences in the heats of evaporation for the pure liquids.



×, 1-atomic; O, 2-3-atomic.

Fig. 3.

From Fig. 3, in which $\log_{10}$ a is plotted against u, it appears that there is an approximate linear relation between them. If u is measured in calories, the relation is approximately

$$-\log_{10} a = 0.3 + \frac{u}{3000}$$

It has been suggested on theoretical grounds by Tammann[18] that a should have the value unity. As already mentioned, this suggestion is not quite in agreement with our experimental results.

[18] G. Tammann, *Z. anorg. allgem. Chem.*, 158, 17 (1926).

With a view to the later application of the measured solubilities to the determination of the hypothetical partition coefficients of monatomic molecules of arbitrary size, it is of importance to study the possibility of interpolation of the partition coefficients of helium, neon and argon between the various solvents. In Table XI are given the partition coefficients V and the partition exponents $\log_{10} V$ between cyclohexane and the other solvents at 25°. Cyclohexane has been chosen as standard because it is non-polar and so not associated. The partition coefficient with benzene is nearly the same for the three gases, the solubility in benzene being 30% less. The partition coefficient with cyclohexanol, which contains a polar hydroxyl group, is about 2.5, and is greatest for argon. In the remaining cases the partition coefficient also increases in the order helium, neon and argon. The differences in the partition exponents $\log_{10} V_A - \log_{10} V_{He}$ and $\log_{10} V_A - \log_{10} V_{Ne}$ are given in Cols. 4 and 5 in Table XI. They decrease in the same order as the dielectric constant, D, but there is not exact proportionality.

Table XI

The present research was carried out at the Chemical Laboratory of the Royal Veterinary and Agricultural College, Copenhagen. I am much indebted to Professor Bjerrum for his continuous interest in my work and for providing such good facilities.

Summary

1. The solubilities l, of helium, neon and argon in water, methyl alcohol, ethyl alcohol, acetone, benzene, cyclohexane and cyclohexanol were determined in the temperature interval 15 to 37°.

2. Log l varies linearly with $1/T$ for the organic solvents, but not for water.

3. In the formula $l = ae^{u/RT}$, where u is the heat of solution, it is found that for monatomic molecules, diatomic molecules and for carbon dioxide there is an approximate linear relation between log a and u.

STUDIES ON THE THERMOCHEMISTRY OF THE COMPOUNDS OCCURRING IN THE SYSTEM $CaO-Al_2O_3-SiO_2$. II. THE HEAT OF SOLUTION OF CALCIUM HYDROXIDE IN $HCl\cdot200H_2O$[1]

BY THORBERGUR THORVALDSON AND WELDON G. BROWN

RECEIVED JULY 16, 1929 PUBLISHED JANUARY 8, 1930

Introduction

Thomsen[2] reports two determinations of the heat of solution of hydrated lime in $HCl\cdot300H_2O$, giving the values 30.41 and 30.57 or a mean of 30.49 kg. calories per mole. The calcium hydroxide is described by Thomsen as a moist powder, 80.88 g. of the material containing 74 g. of $Ca(OH)_2$. Berthelot[3] determined the heat of solution of calcium hydroxide in water and the heat of neutralization of the solution by hydrochloric acid (1 equivalent in 2 liters). He obtained thus the value 30.96 kg. calories per mole for the heat of solution of calcium hydroxide in hydrochloric acid.

An accurate value for the heat of solution of calcium hydroxide in $HCl\cdot200H_2O$ was required in connection with the present studies. Since the two values given above differ by 1.5% and are for different concentrations of acid, it was decided to redetermine the heat of this reaction.

Apparatus and Experimental Procedure

The calorimeter was of the Richards adiabatic type, with a modification in the method of stirring which prevented diffusion or convection of air between the calorimeter and the environment. The stirrer, the Reckmann thermometers and the method of introducing the sample into the calorimeter are described in the first paper of this series.[4]

The air gap between the calorimeter can and the jacket was 6 mm. wide. A negative thermal head[5] of 0.01 ± 0.005° was maintained between the outside jacket and the calorimeter. It was found that fluctuations in

[5] Thermal head: temperature of calorimeter *minus* temperature of jacket.

the thermal head within these limits did not introduce an appreciable error since the leakage under a negative thermal head of 0.020 ± 0.001°, with a heat capacity of 598 cal./deg., was only 0.001° for thirty-minute intervals. Under a negative thermal head of 0.05° the rise in temperature per ten-minute interval was 0.002° while the corresponding value for a head of 0.10° was 0.0045°. Barry[6] has shown that wider air gaps than the one used in this work decrease the thermal leakage materially for heads of 0.05° and higher; but as the leakage for the thermal head maintained in the determinations described in this paper was negligible, the small air gap was used in preference to a wider one in order to reduce the volume of air in the calorimeter and the uncertain correction for vaporization.

Specific Heats.—The values used in calculating the heat capacity of the calorimeter system were: gold,[7] 0.031; gold alloy (80% **Au,** 20% Cu)[7] 0.044; $Ca(OH)_2$,[7] 0.27; $HCl \cdot 200H_2O$[8] (18 to 20°), 0.9826 (20° cal.). All weights were corrected to vacuum.

Purification of Materials

Calcium Carbonate and Calcium **Oxalate.**—The general procedure used in the preparation of pure calcium oxide is described in the first paper of this series. Similar precautions were taken to assure purity of reagents, thorough washing of precipitates and separation of mother liquors and wash waters. The acids and other reagents were always either freshly redistilled or freshly recrystallized when used.

Sample A.—Calcium carbonate was dissolved in hydrochloric acid, reprecipitated from dilute solution by ammonium carbonate, redissolved in hydrochloric acid and the calcium precipitated as the oxalate by ammonium oxalate.

Sample **B.—Calcium** nitrate was recrystallized eight times and the calcium precipitated as calcium carbonate. The carbonate was then dissolved in hydrochloric acid and the calcium precipitated from a hot dilute solution as the oxalate.

Sample C.—A very pure sample of calcium nitrate was recrystallized twice in vessels of fused silica and the calcium precipitated as the carbonate,

Sample D.—A very pure sample of recrystallized calcium chloride was treated with excess of bromine and milk of lime, boiled, filtered and changed to the nitrate by repeated evaporation with excess of nitric acid. The solution was filtered and the nitrate was then recrystallized five times in glass and three times in platinum vessels and the calcium precipitated as calcium carbonate (calcite).

Sample E.—Calcium nitrate of high purity was treated with excess of bromine and milk of lime, boiled, filtered, recrystallized twice and the calcium precipitated as calcium carbonate (calcite).

$HCl \cdot 200H_2O$.—The acid was first redistilled, the condenser tube being fused silica, the middle fraction collected in silica flasks and diluted to $HCl \cdot 200H_2O$. The adjustment was made by titrations with pure sodium carbonate and by gravimetric determinations of chloride.

[7] "International Critical Tables," 1929, Vol. V, pp. 92, 120, 99.

[8] Richards, Mair and Hall, THIS JOURNAL, 51,727 (1929). This is calculated from the values in mayers for 18 and 20° given in Table I, p. 729. According to a private communication from Dr. Mair, the values given in calories for $HCl \cdot 200H_2O$ at 18 and 20° **are** in error.

Saturated Lime-Water.—Excess of pure calcium oxide was shaken with freshly redistilled carbon dioxide-free water. The saturated solution was allowed to stand in contact with excess of calcium hydroxide and was protected from contamination with carbon dioxide.

Preparation of Calcium Hydroxide.—Calcium oxide was prepared from the pure samples of calcium carbonate and calcium oxalate as required, by ignition in platinum crucibles to constant weight in an electric muffle. The oxide was then hydrated in two different ways: by prolonged exposure to water vapor in an evacuated vessel at 21°, or by exposure to saturated steam in an autoclave at 150° for twenty-four hours or more. Precautions were taken to prevent access of carbon dioxide to the material during the preparation. The crucibles were then transferred to a vacuum desiccator over calcium oxide and kept there until constant in weight, when the heat of solution of the material in $HCl \cdot 200H_2O$ was determined. Determinations of the heat of solution of samples hydrated at 21°, containing on the average 13% of water in excess of that required to form $Ca(OH)_2$, were also made. The results are recorded in Tables I, II and III.

It was found that the calcium oxide placed over water in an evacuated vessel absorbed water vapor very rapidly until it had taken up 11 to 15% in excess of the amount required to form calcium hydroxide. All except the last few tenths of a per cent. of this excess of water was removed when the crucible was placed in vacuum over calcium oxide. This last portion of water was held very firmly and was not removed from the samples used for determining the heat of solution. The material prepared in steam at 150° differed in this respect and was almost of the theoretical composition after drying over calcium oxide. When samples of calcium hydroxide, prepared by the two methods and dried to constant weight over lime, were exposed over a saturated solution of ammonium sulfate at 21° (aqueous tension about 15 mm.) the hydroxide which had been prepared at room temperature took up from 3 to 8 times as much water during twenty-four hours of exposure as samples hydrated in steam at 150°.

Microscopic examination of the samples of calcium oxide and of the calcium hydroxide prepared from it by the two methods indicated marked physical differences. The particles of calcium oxide retained the shape and the size of the calcite crystals from which they were formed by ignition. They were weakly birefringent. Hydration by exposure of the ignited calcite to water vapor at 21° still left the shape and size of particles unchanged. The hydrated material had a refractive index[9] of 1.573 ± 0.002 and appeared very weakly birefringent when the sensitive tint plate was used.

The samples prepared by hydration of the ignited calcite in steam at 150° were composed of plates and prisms which were anisotropic and had the indices of refraction given by Ashton and Wilson.[10]

It seems probable that the particles of the calcium hydroxide prepared at 21° have a very large internal as well as external surface and that this is the reason for the large capacity of the material for taking up water vapor.

The literature contains some evidence for the formation of a dihydrate of calcium oxide below 60°. Haslam, Calingaert and Taylor[11] attempted

without success to prepare this hydrate and, further, found no evidence for its existence from their study of the solubility curve for calcium hydroxide. The relative values obtained for the heat of solution of calcium hydroxide as given in Tables I, II and III do not indicate the formation of a higher hydrate when calcium hydroxide takes up water vapor at 21°.

NOTES ON TABLES I, II AND III

(a) The weight of $HCl \cdot 200H_2O$ used in each experiment was 600.4 g. The water equivalent of the apparatus was 8.2 cal./deg., and the total heat capacity 598.2 $cal._{20°}$.

(b) The figures in the column headed "corr. rise" were corrected for (1) stirring, (2) stem exposed, (3) setting of thermometer and (4) variation in the temperature of the sample of calcium hydroxide from 20° at the time of introduction into the calorimeter.

Discussion of the Experimental Results

One small correction should be applied to the values obtained in Tables I, II and III. The air in the calorimeter system, which amounted to about 600 cc., was no doubt saturated with water vapor (at the tension of $HCl \cdot 200H_2O$ at 18°) at the beginning and practically saturated at 20° at the end of each experiment. The calculated amount of heat absorbed by evaporation is 0.18 calorie per gram of CaO. Applying this correction, the isothermal heats of solution of the three samples of calcium hydroxide in $HCl \cdot 200H_2O$ at 20.0° become 554.0, 551.0 and 550.8 $cal._{20°}$ per gram of CaO, or 31.06, 30.89 and 30.88 kg. $cal._{20°}$ per mole, respectively.

Thus the value obtained for the heat of solution of the calcium oxide hydrated at room temperature is 3 calories per gram higher than that obtained with the material hydrated in steam at 150°. This difference is much in excess of the probable experimental error of the determinations. Further, the material which contained on the average 0.43% of water in excess of the theoretical amount (Table I) gives a higher heat of solution than the samples which contained within 5 parts in 13,000 of the theoretical quantity of water of hydration for $Ca(OH)_2$.

The optical examination suggests that the calcium hydroxide prepared at room temperature may not be crystalline and that the two may differ in the energy of crystal lattice. The difference in the rate of adsorption of water vapor by the samples prepared by the two different methods suggests that they may differ in surface energy. Either of these, or both combined, might be the cause of the difference in the value for the heat of solution.

Photographs of the x-ray diffraction pattern of samples of calcium hydroxide prepared by both these methods were made. In each case the same diffraction pattern was obtained and this was identical with that given by Harrington.[12] The results cannot be considered to exclude entirely the possibility of differences in lattice energy at the time of the determination of the heat of solution, as in each case some time elapsed between the preparation of the sample and the making of the x-ray photograph. The samples, however, appeared unchanged when the photographs were taken.

The fact that the particles of the calcium hydroxide prepared at room temperature retained the shape and size of the calcite crystals from which they were prepared and, therefore, probably possessed internal surface,

---

[12] Harrington, *Am. J. Sci.*, [5] 13, 467 (1927).

excluded the possibility of making an estimate of the relative effective surface area of the samples. An approximate measure of the surface energy of the material can, however, be obtained by determining its heat of adsorption or its heat of wetting. From Tables I and III it appears that when calcium hydroxide of the composition CaO + 32.56% of H_2O prepared at room temperature adsorbs an additional 12.6% of water vapor, 3.2 calories per gram of CaO are given out. To obtain further evidence as to differences in surface energy, the heat of wetting of samples of calcium hydroxide prepared by each of the methods was determined.

Determinations of the Heat of Wetting of Calcium Hydroxide.—The same calorimeter was used as for the determination of the heat of solution. The sample of calcium hydroxide was introduced in the usual way after the calorimeter, containing saturated lime-water, had come to thermal equilibrium at 20°. The results are given in Tables IV, V and VI.

TABLE IV

HEAT OF WETTING OF CALCIUM HYDROXIDE, PREPARED BY EXPOSURE OF CaO TO WATER VAPOR AT 21° WITH SUBSEQUENT DRYING OVER CaO, BY SATURATED LIME-WATER

Total heat capacity, 607 cal./deg.

		32.65			3.3

[a] Each of the groups 1A and B, 2A and B, etc., represent successive runs without changing the lime-water in the calorimeter. The temperature rise for the first run of each group given in the fourth column is, in each case, a few thousandths of a degree higher than for the remaining runs in the group. This was shown, both by titration with acid and by measurement of electrical conductivity of the lime-water in the calorimeter before and after an experiment, to be due to supersaturation. The conductivity electrodes were mounted within the calorimeter and in this way it was found that the supersaturation reached a maximum in less than one minute after the first sample of calcium hydroxide was introduced and that it did not change with the addition of further samples

[b] In Experiments 4 and 5 the supersaturation was found to be 12.7 and 12.1%, respectively. A correction was made for this supersaturation, using 50 cal. per gram of CaO as the heat of solution of calcium hydroxide in water, in calculating the heat of wetting.

The occurrence of supersaturation under these conditions is of special interest since Goldammer[13] has reported that although calcium oxide is capable of forming supersaturated solutions, calcium hydroxide is not.

TABLE V

HEAT OF WETTING OF CALCIUM HYDROXIDE, PREPARED BY EXPOSURE OR CAO IN STEAM AT 150° WITH SUBSEQUENT DRYING OVER CAO IN SATURATED LIME-WATER

3B	3.95	32.19	507	.009	1.2
	Mean	32.13			1.0

No supersaturation was produced with the material hydrated in steam at 150°.

TABLE VI

HEAT OF WETTING OF CALCIUM HYDROXIDE, PREPARED BY EXPOSURE OF CAO TO WATER VAPOR AT 21° AND CONTAINING A LARGE EXCESS OF H_2O IN SATURATED LIME-WATER

Total heat capacity, 607 cal./deg.

Expt.	CaO, g.	H_2O, %	Temp. rise, °C.	Supersaturation		Heat of wetting, cal. per g. of CaO
				%	Temp. rise, °C.	
1B[a]	3.94	43.3	0.003			0.5
1C	3.95	43.7	.002			.3
2A	3.98	42.0	.007	7.8	0.005	.3
2B	4.08	42.4	.004			.6
3A	3.70	47.1	.009	8.0	.005	.7
3B	4.01	48.1	.004			.6
	Mean	44.4				0.5

[a] Each of the experiments in the same group (A, B, etc.), represents successive runs without changing the lime-water in the calorimeter. The temperature rise for the initial "A" runs is in each case a few thousandths of a degree higher than for the remaining runs (B, C) on account of supersaturation. The supersaturation as determined by titration is given in the fifth column and the rise in temperature, calculated for the supersaturation found, is given in the sixth column.

The values obtained for the heat of wetting of the various samples of calcium hydroxide indicate that difference in surface energy is at least mainly responsible for the variation in the values obtained for the heat of solution. If we subtract in each case the value obtained for the heat of wetting from the value for the heat of solution of calcium hydroxide prepared by the same method, we obtain the following results.

---

[13] Goldammer, *Pharm. Centr.*, 26, 442 (1890).

Prepared by hydration	Cal. per g. of CaO
In steam at 150°	550.0
In water vapor at 21° (13% excess of water)	550.3
In water vapor at 21° (0.43% excess of water)	550.7

These values are in good agreement. While subtracting the heat of wetting does not necessarily eliminate entirely the factor of surface energy, as the material having the larger specific surface has still greater surface energy at the solid--liquid interface, yet this difference is probably small as compared with the heat of wetting. One would, therefore, expect that 550.0 $cal._{20°}$ per gram of CaO is close to the true value for the isothermal heat of solution of calcium hydroxide, possessing a negligible quantity of surface energy, in $HCl \cdot 200H_2O$ at 20°; but considering that the three values obtained above agree very nearly within the probable experimental error, it would probably be best to take the mean value 550.3 $cal._{20°}$ per gram of CaO, which corresponds to 30.85 kg. $cal._{20°}$ (129.0 Kj.) per mole of $Ca(OH)_2$.

Summary and Conclusions

1.. Calcium hydroxide prepared by three methods gave the following values for the isothermal heat of solution at 20° in $HCl \cdot 200H_2O$: (a) prepared from CaO in water vapor at 21°, dried over quicklime, 554.0 $cal._{20°}$ per gram of CaO (31.06 kg. $cal._{20°}$ per mole); (b) prepared from CaO in steam at 150°, dried over quicklime, 551.0 $cal._{20°}$ per gram of CaO (30.89 kg. $cal._{20°}$ per mole); (c) prepared as (a) but not dried over quicklime, 550.8 $cal._{20°}$ per gram of CaO (30.88 kg. $cal._{20°}$ per mole).

2. Samples of calcium hydroxide prepared by methods (a) and (b), while appearing very dissimilar under the microscope, gave the same x-ray diffraction pattern.

3. Samples of calcium hydroxide prepared by methods (a) and (c) gave supersaturated solutions when added to saturated lime-water, but samples prepared by method (b) did not behave in this manner.

4. The above three samples had the following average heats of wetting in saturated lime water at 20°: (a) 3.3, (b) 1.0, (c) 0.5 cal. per gram of CaO.

5. Subtracting the heat of wetting in each case from the corresponding heat of solution, one obtains the following values: (a) 550.7, (b) 550.0, (c) 550.3 $cal._{20°}$ per gram. The average value 550.3 $cal._{20°}$ per gram of CaO or 30.85 kg. $cal._{20°}$ (129.0 Kj.) per mole is considered to be the most reliable value for the isothermal heat of solution of calcium hydroxide in $HCl \cdot 200H_2O$ at 20°.

6. No evidence was found that a hydrate of lime higher than $CaO \cdot H_2O$ forms at 21°.

RELATIVE RATES OF REDUCTION OF AROMATIC NITRO COMPOUNDS[1]

BY JOHN R. SAMPEY

RECEIVED JULY 16, 1929 PUBLISHED JANUARY 8, 1930

The method recently developed[2] for a study of the valence forces influencing the carbon–halogen bond in halogen phenols and halogen naphthols has been applied, in a slightly modified form, to the determination of the relative rates of reduction of a number of aromatic nitro compounds. The work was undertaken to obtain quantitative data upon the effect of various groups upon the rate of reduction of the nitro group to the amino group by an acid stannous chloride solution. The work was extended to show that, in addition to the nature and position of the various groups introduced into the benzene nucleus, the speed of the reduction is influenced markedly by factors which control the hydrogen-ion concentration of the solution.

Method of Reduction.—The method of reduction was briefly as follows: exactly 50.00 cc. of an alcoholic hydrochloric acid solution was pipetted into a 300-cc. Erlenmeyer flask, the air was displaced by a stream of nitrogen, just enough weighed $SnCl_2 \cdot 2H_2O$ was introduced to make the solution equivalent to exactly 50.00 cc. of a tenth normal iodine solution, the flask was placed in a thermostat heated to 75°, and when the contents of the flask had reached this temperature, a weighed sample of the nitro compound was introduced. At the end of a definite period of time the flask was removed, cooled and the excess stannous chloride titrated with a standard tenth normal iodine solution.

The addition of a weighed sample of the solid $SnCl_2 \cdot 2H_2O$ for each reduction is more tedious than the former method of using a standard solution of this reducing agent, but this method has an advantage in that it permits of a more exact control of the concentration of the reducing agent; in the former procedure some oxidation inevitably took place during the preparation of the standard solution and we were never able to prepare two solutions of exactly the same reducing strength. The weight of the $SnCl_2 \cdot 2H_2O$ required to reduce 50.00 cc. of the $N/10$ iodine solution had to be determined by actual titration, for it was found that different samples of the salt of C. P. grade varied slightly in composition. The weight used in each of the reductions reported in this paper was 0.6000 g.

The alcoholic hydrochloric acid solution used in Table I was prepared by making up 20.00 cc. of 37% hydrochloric acid to exactly one liter with 95% alcohol. This concentration of acid was more than enough to form

---

[2] Sampey, THIS JOURNAL, 49, 2849 (1927).

both the stannic chloride salt and the hydrochloride of the amine. The concentration of the nitro compound taken for each reduction was exactly equivalent to the concentration of the stannous chloride solution, *e. g.*, 0.0700 g. of dinitrobenzene would oxidize as much stannous chloride as 0.1025 g. of nitrobenzene. Each of the nitro compounds was carefully purified before reduction.

[a] Because of the insolubility of the nitro compound, it was added before the stannous chloride; the reduction was timed from the addition of the stannous chloride, after the solution reached the temperature of the thermostat.

One of the interesting observations to be made from Table I is found in the relative rates of reduction of the ortho, meta and para isomers of the same compounds: the meta isomer lies intermediate, instead of in contrast to the ortho and para; the ortho is reduced the most rapidly, the para most slowly in every case except with the three nitrobenzoic acids. It is also worth noting that the corresponding chloro-, bromo- and iodo-nitrobenzenes are reduced at nearly the same rate; this is in sharp contrast to the effects produced on the speed of reduction by the introduction of certain of the other groups. Table I is not as complete as desired, because a number of the nitro compounds prepared and purified were too colored after reduction to permit the detection of the end-point in the iodine titration.

From the previous work[3] on the removal of halogens by acids when ortho or para to amino groups, there was the possibility that the rate reported for the reduction of o- and *p*-nitro-iodobenzene and of 2,4-dibromonitrobenzene might also be due to the removal of the positive halogen. When samples of these halogen nitro compounds were heated for more than an hour in the presence of more than enough stannous chloride to reduce all the nitro groups, there was no removal of the halogen atoms. Only when the acidity of the solution was increased several fold did we note the removal of the halogen along with the reduction of the nitro group.

Effect of Hydrogen-Ion Concentration.—An increase in the hydrogen-ion concentration of the solution had a marked effect upon the rate of reduction of the nitro compounds. The alcoholic hydrochloric acid solutions used in Table II were prepared as follows:

Solution A	37% HCl, 10.00 cc.	Water, 100.00 cc.	Abs. alcohol to 500.00 cc.
Solution B	37% HCl, 30.00 cc.	Water, 100.00 cc.	Abs. alcohol to 500.00 cc.
Solution C	37% HCl, 50.00 cc.	Water, 100.00 cc.	Abs. alcohol to 500.00 cc.
Solution D	37% HCl, 100.00 cc.	Water, 100.00 cc.	Abs. alcohol to 500.00 cc.

The accuracy with which these solutions were made may be judged by the two check analyses, for a fresh solution was prepared for each reduction. The 100.00 cc. of water included in each of these solutions was added for reasons set forth in Table III. Exactly 50.00 cc. of each of these solutions was introduced into the Erlenmeyer flask for the reduction; the quantities of the o-nitrotoluene and stannous chloride were the same as in Table I.

TABLE II

EFFECT OF ACIDITY UPON THE RATE OF REDUCTION OF O-NITROTOLUENE

	Soln. A		Soln. B		Soln. C		Soln. D	
Reduction time, min.	15	15	15	15	15	15	15	15
0.1 N iodine, cc.	37.5	37.4	32.5	32.7	28.8	28.9	18.1	17.9
Amt. reduced, %	25.0	25.2	35.0	34.6	42.4	42.2	63.8	64.2

The pronounced increase in the rate of reduction with an increase in the acidity of the solution becomes more interesting when compared with the results of Adams, Cohen and Rees[4] on the reduction of aromatic nitro compounds to amines with hydrogen and platinum-oxide platinum black as a catalyst; they found that appreciable quantities of hydrochloric acid lowered the rate of reduction.

---

[3] Nicolet and Sampey, THIS JOURNAL, 49, 1796 (1927).

[4] Adams, Cohen and Rees, *ibid.*, 49, 1093 (1927).

Inhibitory Effect of Water.—In the runs reported in Table II, 100.00 cc. of water was added to each alcoholic solution in order to lessen any effects which might have been produced by a change in the moisture content as the acidity of the solution was increased. In Table III evidence is presented of just how pronounced is the inhibitory effect of water on the rate of reduction. The solutions used in Table III were made up as follows:

Solution A	37% HCl, 10.00 cc.	....,	Abs. alcohol to 500.00 cc.
Solution B	37% HCl, 10.00 cc.	Water, 30.00 cc.	Abs. alcohol to 500.00 cc.
Solution C	37% HCl, 10.00 cc.	Water, 100.00 cc.	Abs. alcohol to 500.00 cc.
Solution D	37% HCl, 10.00 cc.	Water, 190.00 cc.	Abs. alcohol to 500.00 cc.

No effort was made to prepare a more anhydrous solution than Solution A, because of the insoluble nature of $SnCl_2 \cdot 2H_2O$ in such a solution. The concentrations of o-nitrotoluene and stannous chloride were the same as in the previous reductions.

TABLE III

EFFECT OF MOISTURE UPON THE RATE OF REDUCTION OF O-NITROTOLUENE

	Soln. A		Soln. B		Soln. C		Soln. D	
Reduction time, min.	15	15	15	15	15	15	15	15
0.1 N iodine, cc.	29.5	29.6	31.3	31.0	37.5	37.4	40.8	41.0
Amt. reduced, %	41.0	40.8	37.4	38.0	25.0	25.2	18.4	18.0

Effect of Stannous Chloride Concentration.—In Table IV the concentration of the stannous chloride was varied over a wide range. If we assume from the equation

$$\underset{a}{3SnCl_2} + \underset{b}{RNO_2} + 7HCl = 3SnCl_4 + RNH_2 \cdot HCl + 2H_2O$$

that each molecule of RNO_2 which is reduced is done so rapidly and completely, then at the time t when we measure $a-x$, we must consider that the concentration of the nitro compound, b, has become $b-x/3$; *i. e.*, three moles of stannous chloride have been used for each mole of RNO_2 disappearing. Then from the integration of the equation

$$\frac{dx}{dt} = K(a - x)\left(b - \frac{x}{3}\right)$$

we obtain

$$K = \frac{-3}{t(3b - a)} \ln \frac{a(3b - x)}{3b(a - x)}$$

This equation can be used except where $a = 3b$; in Run III below, where $a = 3b$, the integration of the equation

$$\frac{dx}{dt} = \frac{K}{3}(a - x)^2$$

becomes

$$K = \frac{3x}{at(a - x)}$$

In Table IV are set forth the results of substituting the data in the above equations when the concentration of the stannous chloride was increased ten-fold. In order to reduce the effects of any change in hydrogen-ion concentration, acetic acid was used as the solvent: 50.00 cc. of water and 10.00 cc. of **37%** hydrochloric acid were added to 500.00 cc. of glacial acetic acid; 50.00 cc. of this solution and 0.1313 g. (0.0167 moles) of ***m*-**nitrochlorobenzene were introduced into an Erlenmeyer flask for each reduction. The amounts of stannous chloride ranged from 0.1500 g. to 1.5000 g., which gave a concentration in terms of moles, estimated from titrations against a standard iodine solution, of 0.0125 to 0.1250.

TABLE IV

EFFECT OF STANNOUS CHLORIDE CONCENTRATION ON THE REDUCTION OF 112-NITROCHLOROBENZENE

Run	t, min.	a	x	$a - x$	$3b - x$	K
I	15	0.0125	0.0072	0.0053	0.0428	− 3.75
II	15	.0250	.0133	.0117	.0368	3.59
III	15	.0500	.0247	.0253	.0253	3.90
IV	15.	.0625	.0286	.0339	.0215	3.76
V	15	.0750	.0315	.0435	.0186	3.59
VI	15	.1125	.0384	.0741	.0117	3.31
VII	15	.1250	.0401	.0849	.0100	3.28

Summary

1. **A** table is given of the relative rates of reduction to amines of twenty-eight aromatic nitro compounds by an acid stannous chloride solution.
2. An increase in the hydrogen-ion concentration of the stannous chloride solution increases the speed of the reduction.
3. Water has an inhibitory effect upon the speed of the reduction.
4. When the stannous chloride concentration is varied ten-fold, constants calculated for a second order reaction hold well for such a complex system.

THE POLARITY OF THE CARBON–HALOGEN BOND. III. THE INHIBITORY EFFECT OF WATER ON THE ACID HYDROLYSIS OF HALOGEN NAPHTHOLS[1]

BY JOHN R. SAMPEY

RECEIVED JULY 16, 1929 PUBLISHED JANUARY 8, 1930

The inhibitory effect of water upon reactions catalyzed by hydrogen ions has been studied intensively, although the number of different types of reactions investigated has been limited. The theories postulated to explain the phenomenon are almost as numerous as the number of investigators working in the field. A comprehensive review of the literature has appeared recently.[2] In the present investigation data are presented to show the inhibitory effect of water on another type of reaction catalyzed by hydrogen ions.

1-Iodo-2-hydroxynaphthalene was the compound selected for the determination of the effect of moisture on the rate of removal of the iodine by hydrogen ions. The method of hydrolysis was the same as that developed for the study of the relative rates of reduction of aromatic nitro compounds.[3] The alcoholic hydrochloric acid solutions used in Table I were prepared as follows.

Solution A	37% HCl, 10.00 cc.	....	Abs. alc. to 500.00 cc.
Solution B	37% HCl, 10.00 cc.	Water, 50.00 cc.	Abs. alc. to 500.00 cc.
Solution C	37% HCl, 10.00 cc.	Water, 190.00 cc.	Abs. alc. to 500.00 cc.

The insoluble nature of $SnCl_2 \cdot 2H_2O$ in absolute alcohol did not permit us to make a more anhydrous solution than Solution A; 0.3375 g. of the iodonaphthol and 0.3000 g. of $SnCl_2 \cdot 2H_2O$ (equivalent to 25.00 cc. of $N/10$ iodine solution) were added to each 50.00-cc. portion of the above solutions in the hydrolyses. The constants reported in Table I were obtained when the data were substituted in the equation for a first order reaction.[4]

TABLE I

EFFECT OF WATER ON THE HYDROLYSIS OF 1-IODO-2-HYDROXYNAPHTHALENE IN ALCOHOLIC HYDROCHLORIC ACID SOLUTION

	Soln. A		Soln. B		Soln C	
0.1 N iodine used in titrn., cc.	15.2	15.0	20.3	20.5	21.7	21.7
$k \times 10^{-2}$	3.32	3.40	1.38	1.32	0.94	0.94

---

[3] Sampey, THIS JOURNAL, 52, 88 (1930).

[4] Sampey, *ibid.*, 49, 2853 (1927).

When acetic acid was used as the solvent in place of the alcohol the inhibitory effect of water was even more pronounced. The acetic acid solutions were made as follows

Solution A	37% HCl, 5.00 cc.	. . . .	Gl. HAc, to 500.00 cc.
Solution B	37% HCl, 5.00 cc.	Water, 10.00 cc.	Gl. HAc, to 500.00 cc.
Solution C	37% HCl, 5.00 cc.	Water, 30.00 cc.	Gl. HAc, to 500.00 cc.
Solution D	37% HCl, 5.00 cc.	Water, 50.00 cc.	Gl. HAc, to 500.00 cc.
Solution E	37% HCl, 5.00 cc.	Water, 100.00 cc.	Gl. HAc, to 500.00 cc.

The same weights of iodonaphthol and stannous chloride were used as in the previous hydrolyses.

TABLE II

EFFECT OF WATER ON THE HYDROLYSIS OF 1-IODO-2-HYDROXYNAPHTHALENE IN ACETIC ACID SOLUTION

	Soln. A		Soln. B		Soln. C		Soln. D		Soln. E	
Time, minutes	5	5	5	5	5	5	10	10	10	10
$0.1\ N\ I_2$, cc.	11.0	11.1	8.0	8.3	12.4	12.4	11.1	11.2	20.3	20.0
$k \times 10^{-1}$	1.64	1.62	2.27	2.20	1.40	1.40	0.81	0.80	0.20	0.22

It will be noted that in Solution B the rate of removal of the iodine is faster than in Solution A, although the former contains more water. This may be explained by the observation that at the end of the five-minute period Solution A was strongly colored by iodine; this color disappeared *immediately* upon the addition of ten cubic centimeters of water. Presumably the iodine was removed more rapidly in Solution A than in Solution B, but because of the nearly anhydrous conditions existing in the former, the stannous chloride was unable to react with the liberated iodine, with the result that part of the iodine resubstituted in the naphthol. When iodine and stannous chloride were dissolved in glacial acetic acid containing a small amount of hydrochloric acid, the iodine color did not disappear until more water was added. This phenomenon made it impossible to determine the effect of small amounts of water on the rate of removal of the iodine from the iodonaphthol.

Neutral Salt Effect.—The effects of neutral salts on the reactions catalyzed by hydrogen ions have received considerable attention. In Table III some observations are recorded of the action of several inorganic salts upon the rate of hydrolysis of the positive halogen in 1-iodo-2-hydroxynaphthalene. The alcoholic solution used had to contain a large proportion of water in order to dissolve the salts, and also a large amount of hydrochloric acid to bring about the removal of the halogen from the aqueous solution; after a considerable number of solubility determinations, the solution that was used was prepared by making up 100.00 cc. of **37%** hydrochloric acid and 475.00 cc. of water to exactly one liter with 95% alcohol. The amounts of iodonaphthol and stannous chloride were the same as in the previous tables. Sufficient quantities of the dry salts were added to give a half molar concentration.

TABLE III

EFFECT OF NEUTRAL SALTS ON THE HYDROLYSIS OF 1-IODO-2-HYDROXYNAPHTHALENE

Salt	Time, min.	0.1 N I_2, cc.	$k \times 10^{-2}$	Time, min.	0.1 N I_2, cc.	$k \times 10^{-2}$
...	15	12.7	4.51	15	12.7	4.51
KCl	15	11.3	5.29	15	11.2	5.35
NaCl	15	10.8	5.59	15	10.8	5.59
KBr	15	10.5	5.78	15	10.6	5.72
NaBr	15	10.1	6.04	15	10.2	5.98
LiCl	15	10.0	6.10	15	10.2	5.98
$SnCl_4$	15	10.4	5.84	15	10.2	5.98

Stannic chloride is not a neutral salt but it was added to the list because in the former method of preparing standard solutions of stannous chloride[3] there were always appreciable quantities of this salt present due to the oxidation of the stannous chloride during storage. We were not able to include sodium or potassium iodide in Table III, because they decomposed quite rapidly with the liberation of free iodine.

Summary

1. Water decreases the rate of hydrolysis of 1-iodo-2-hydroxynaphthalene in alcoholic and acetic acid solutions of hydrochloric acid.
2. Stannous chloride and iodine do not react appreciably in hydrochloric acid solutions of acetic acid containing little moisture.
3. Neutral salts increase the rate of hydrolysis of positive halogens.

THE TEMPERATURE COEFFICIENT OF REACTIONS IN SOLUTION

BY F. O. RICE AND H. C. UREY

RECEIVED JULY 17, 1929 PUBLISHED JANUARY 8, 1930

The generally accepted explanation for the temperature coefficient of reactions in general is essentially the Arrhenius hypothesis of activated molecules. This has been worked out rather completely for gaseous reactions on the assumption that there is a whole series of such active molecules in statistical equilibrium with the inactive molecules and that the active molecules differ from the inactive molecules only in their energy content; each of these active molecules has a finite probability of reacting which depends upon this energy content. On this hypothesis the energy of activation is the difference of the mean energy of the molecules which react and the mean energy of all the molecules.[1] It is generally supposed that the temperature coefficients of reactions occurring in solution has a similar explanation but so far there has been no theory generally

---

[1] Tolman, THIS JOURNAL, **47**, 2652 (1925).

accepted which accounts for the experimental facts observed in the study of the temperature coefficient of reactions in solution.[2] It is the purpose of this paper to discuss an application of the temperature coefficient of gaseous reactions to reactions in solution.

Bronsted's Theory.—Bronsted[3] has obtained formulas accounting for many of the apparently anomalous facts in the field of reaction kinetics involving ions. It may be assumed that the first reaction between two molecules in a solution is to form a fugitive reactive complex which is in statistical equilibrium with the reacting molecules and it is this reactive complex which decomposes spontaneously and unimolecularly or reacts with another molecule in the system. The equations representing the change may be given as

$$A + B \leftrightarrows A{\cdot}B$$
$$A{\cdot}B = C + D + \ldots.$$

or

$$A{\cdot}B + C = D + E + \ldots.$$

The velocity of the reaction is assumed to be proportional to the concentration of the fugitive reactive complex A·B. The concentration of this complex is related to its activity by the equation

$$C_{A\cdot B} = \frac{C_A C_B f_A f_B}{f_{A\cdot B}}$$

where the f's are the activity coefficients.

The success of this theory lies in its ability to predict the changes in the velocity of such reactions due to the addition of electrolytes to the solution. These additions of salts will change the activity of the ions present in accordance with the principles first proposed by Lewis and by Brönsted.[4] The theory predicts the general nature of the change in velocity due to the addition of such salts; in some cases it gives correctly the sign and magnitude of the change, which is a remarkable contribution to our knowledge of these reactions when we consider the confusion in this field before the theory was developed.

An extension of the theory has been proposed to account for the phenomenon of acid and basic catalysis. It is only necessary to replace the fugitive complex between two reacting molecules by a fugitive complex between a molecule and the hydrogen ion or the molecule and a basic ion. The reaction rate is again assumed to be proportional to the *concentmtion* of the reactive complex and this concentration is again calcu-

[4] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, **1923**; Bronsted, THIS JOURNAL, 42, 761 (1920).

lated in the same way. Bronsted[5] was led to this concept of acid and basic catalysis from his previous proposal of a new definition of acids and bases according to which an acid is defined as a substance that can give up a proton to another molecule, while a base is one which can accept a proton from another molecule. Acid catalysis consists then in the addition of a hydrogen ion to a molecule with the subsequent reaction to give the final products and the final liberation of the proton, and basic catalysis in the addition of a basic ion to a molecule with the subsequent reaction and removal of a proton by the basic ion. Bronsted[6] has found some interesting empirical relationships between the acid and basic strength as determined from the ordinary dissociation constants of the acids and bases involved and the velocity of the reaction.

In all of this development, however, there has been a notable lack of any suggestions to account for the observed facts in connection with the temperature coefficients of these reactions. Moreover, in spite of the enormous amount of work done in support of Bronsted's theory, this work has mostly been done at only one temperature and in consequence there are comparatively few experimental data to test any theory.

Observed Temperature Coefficients.—A comprehensive review of the experimental facts has been given by Rice and his co-workers,[7] and in addition they have made the most accurate measurements of the rate of reaction between halogens and ketones in dilute aqueous solutions. They also studied the effect of adding various amounts of electrolytes and non-electrolytes. The essential observed facts are that the temperature coefficients of all these reactions are the same; when catalyzed by strong acids, the addition of salts of strong acids or non-electrolytes does not change the temperature coefficient even when present at high concentrations, though the absolute values of the reaction rate change considerably and follow the prediction of Bronsted's theory. These same reactions have a lower temperature coefficient when catalyzed by weak acids and the temperature coefficient is diminished still more by the addition of salts of these weak acids. The available data for sulfuric acid have been collected and are shown in Table I, from which it appears that there is first a rapid decrease in the energy of activation which finally approaches a constant value.

The small amount of experimental data available show that the change in temperature coefficient by changing the conditions in the solution is in general small, so that only high precision work is useful for any theory of the effect.

.097 N H_2SO_4	1.69 M $(NH_4)_2SO_4$	17,150

Theoretical

The Debye–Hückel theory predicts that the activity coefficient of an ion of a strong electrolyte will approach in the limit for zero concentration[8]

$$-\ln f_i = Z_i^2 \frac{e^3}{4k}\sqrt{\frac{\pi}{k}}\frac{1}{(DT)^{3/2}}\sqrt{\sum_1^s n_i Z_i^2}$$

where Z_i is the valence of the ion, e the atomic charge, K the Boltzmann constant, D the dielectric constant and N_i the number of ions of the i^{th} kind per cc. The rate of change of the In f_i with temperature is easily shown to be of the order of $2 \times 10^{-4}\sqrt{\mu}$, where μ is the ionic strength. This formula is only a limiting law and does not apply in the range of concentrations used in the experiments discussed in this paper, but it seems improbable that the change of the activities of strong electrolytes with temperature can account for more than a small part of the observed temperature coefficients of these reactions and some other hypothesis must be developed.

It has occurred to the authors that the following mechanism provides a means of accounting for the observed facts discussed in the previous section. The reactive complex postulated by Bronsted undoubtedly consists of a whole series of molecules which differ from each other only in energy content. It is only necessary to assume that the probability of a molecule (AH+) reacting is a function of its energy content and that it increases with increasing energy content. This is the generally accepted hypothesis in gaseous reactions and leads to the conclusion that the energy of activation as determined from the measured temperature coefficient of the reaction is equal to the difference of the mean energy of the molecules that react and the mean energy of all the molecules. The reaction scheme which we propose is then

$$\begin{aligned}&A + H^+ \rightleftarrows AH^+\\&AH^+ \rightleftarrows (AH^+)'\\&(AH^+)' + B = H^+ + C + D + \dots\end{aligned}$$

where $(AH^+)'$ represents a whole series of high energy molecules of the variety (AH^+). This differs from the usual scheme used by Bronsted only in the introduction of an additional step. Its extension to other

---

[8] La Mer, *Trans. Am. Electrochem. Soc.*, *51*, 530 (1927).

cases besides hydrogen-ion catalysis is obvious. It remains now to show that this scheme does agree with the experimental facts.

The addition of salts to such a reaction catalyzed by a strong acid changes the velocity of the reaction by changing the concentration of the reactive complex and this change in the concentration of the critical complex is characteristic of the charges of A, (AH^+) and $(AH^+)'$ to a first approximation and is not due to any other specific properties which they may have. It, therefore, affects the whole series of molecules of the (AH+) type regardless of their energy contents. The energy distribution of these molecules will therefore not be disturbed. There is the possibility that the addition of the salt will change the probability of reaction of a given member of this series of (AH+)' molecules. However, if this were true, it would change the velocity of the reaction and it would not be possible, therefore, to predict the general nature of the primary salt effect. We conclude, therefore, that the distribution of molecules with different energy contents and their probabilities of reaction do not change with the addition of salt and, therefore, the temperature coefficient should be independent of the concentration of salts of strong acids, which is in agreement with experimental results. Rice and Lemkin[7] showed that the temperature coefficient is unchanged even when the reaction between acetone and iodine occurs in solutions of salt concentrations up to saturation, *i.* e., at concentrations far beyond the range in which Bronsted's theory for the salt effect can be applied. The addition of non-electrolytes such as methyl acetate or acetic acid did not change the velocity of the reaction, while cane sugar increased the velocity of the reaction; in no case was the temperature coefficient changed, which on our theory means that the relative concentrations of high energy and low energy (AH^+) molecules were unchanged.

We will now consider catalysis by weak acids. We have now present two acids, one being the (H_3O^+) and the other the undissociated acid molecule; the reaction will be catalyzed by both these acids and it is possible that it may also be catalyzed by the basic anion of the weak acid. Each of these simultaneous reactions will have its own characteristic temperature coefficient and in addition there may be an effect upon the measured temperature coefficient due to side equilibria changing the relative amounts of these catalysts. Rice and Lemkin[7] investigated the catalysis of the acetone–iodine reaction by weak acids and found in all cases that the temperature coefficient was decreased. The temperature coefficient of this same reaction when catalyzed by sulfuric acid is less than when catalyzed by hydrochloric acid and the addition of sulfates lowers the temperature coefficient still further; the experimental facts have been summarized in Table I.

We shall try to give a general interpretation of this behavior by considering the catalysis by sulfuric acid in detail. In this case we must consider the two simultaneous reaction schemes

$$\begin{aligned}&A + H_3O \rightleftharpoons (A\cdot H_3O^+)\\&(A\cdot H_3O^+) \rightleftharpoons (A\cdot H_3O^+)'\\&(A\cdot H_3O^+)' \longrightarrow H_3O^+ + B + C + \ldots\end{aligned}$$

and

$$\begin{aligned}&A + HSO_4^- \rightleftharpoons (A\cdot HSO_4^-)\\&(A\cdot HSO_4^-) \rightleftharpoons (A\cdot HSO_4^-)'\\&(A\cdot HSO_4^-)' \longrightarrow HSO_4^- + B + C + \ldots\end{aligned}$$

We assume that these are the only catalysts present since basic catalysis by the SO_4^{--} ion is negligible. The observed velocity is due, therefore, to the joint catalytic effect of the (H_3O^+) and (HSO_4^-) and the observed temperature coefficient will depend upon the heats of activation of $(A\cdot H_3O^+)$ and $(A\cdot HSO_4^-)$ and their relative amounts.

The observed velocity constant of the reaction k will be

$$k = \frac{k_1c_1 + k_2c_2}{c_1 + c_2}$$

where c_1 and c_2 are the concentrations of H_3O^+ and HSO_4^-, respectively, and k_1 and k_2 are the velocity constants for the reaction catalyzed by these ions at unit concentration. Since $(c_1 + c_2)$ is the total acidity we can rewrite this in the form

$$k = k_1F + k_2(1 - F)$$

where F is the fraction of the total hydrogen present as (H_3O^+). Using the values for the concentration of hydrogen ion and hydrogen-sulfate ion secured by Sherrill and Noyes[9] and the measured values for the velocity constant of the reaction as catalyzed by strong acids which we assume gives k_1 together with the measured velocity constant catalyzed by 0.08060 N sulfuric acid, it is possible to calculate k_2. Interpolating Sherrill and Noyes' data for this concentration, we secure 0.0547 and 0.02525 for the normalities of H_3O^+ and HSO_4^-, respectively. Using these values and the observed values of k and k_1, namely, 15.55 X 10^{-4} and 17.1 X 10^{-4}, we secure 12.6 X 10^{-4} for the value of k_2. Further, by extrapolating Sherrill and Noyes' data to 0.15 N sulfuric acid, we find 0.0982 and 0.0520 for the normalities of H_3O^+ and HSO_4^-, respectively. Using these values, the observed value of k_1, and the value of k_2 calculated above, we find the value of k for this higher concentration to be 15.5 X 10^{-4}. This shows that the specific velocity constant should not change with a variation of the concentration of the sulfuric acid, in agreement with observation.

The observed temperature coefficient of the reaction is given by the equation

$$\frac{d\ln k}{dT} = \frac{1}{k}\frac{d}{dT}[k_1F + k_2(1 - F)]$$

---

[9] Sherrill and Noyes, THIS JOURNAL, 48, 1870 (1926).

There are two limiting cases for this relationship. In the case of strong acids $F = 1$, $k = k_1$ and the heat of activation is that for the reaction scheme I; in the case of the reaction catalyzed by sulfuric acid in *the* presence of a high concentration of sulfate, there will be only a very low concentration of hydrogen ion, and thus $F = 0$ and $k = k_2$, so that the measured heat of activation is that of scheme II. These two heats of activation are 20,540 and 17,100 cal., respectively. Without knowing the way F changes with temperature, it is impossible to calculate the intermediate values, but we can expect that there will be a gradual transition in agreement with Table I.

Similar considerations will apply to basic catalysis and ionic reactions in general but we must emphasize the point that it does not seem possible to make any sweeping generalization as to the magnitude of the temperature coefficient, since each reaction is a special case.

Summary

1. Up to the present there has been no satisfactory explanation developed for the temperature coefficient of reactions in solution. The present paper proposes such an explanation based on Bronsted's theory and current theories for the temperature coefficient of reactions in the gaseous state.

2. It is suggested that there is a whole series of fugitive complexes of the type postulated by Bronsted which differ from each other only in energy content. The energy of activation is defined as the difference between the mean energy of the critical complexes which react and the mean energy of all the molecules.

3. When there is only a primary salt effect the temperature coefficient should be independent of the addition of salt.

4. In the case of catalysis by weak acids we may expect that there will be several simultaneous reactions, each with its own characteristic energy of activation. This has been discussed for the catalysis of the acetone–iodine reaction by sulfuric acid and the experimental results are shown to be in agreement with theory.

PHOTOCHEMICAL DECOMPOSITION OF NITROSYL CHLORIDE

BY GEORGE B. KISTIAKOWSKY

RECEIVED JULY 22, 1929 PUBLISHED JANUARY 8, 1930

The decomposition of nitrosyl chloride under action of light has been in the past an object of some study. Kiss[1] has shown that visible light produced decomposition, but that since the nitric oxide and chlorine formed recombined in the dark, the decomposition was incomplete, a stationary state being finally reached. The temperature coefficient of the photochemical reaction was determined by him to 1.0 over the temperature range 0–78°. Bowen and Sharp[2] have carried out a determination of the quantum yield which led them to believe that 0.5 molecule was decomposed per light energy quantum absorbed. The light was used from a carbon arc and the spectral regions 4380–5000 and 4480–5200 Å. were isolated by means of filters. These authors found also that the quantum yield was unaffected by the degree of decomposition, which was followed up to 10%. They failed to notice any action of "red" light and attributed this failure to a very weak absorption by nitrosyl chloride in this spectral region. The reaction mechanism offered in explanation of their results included a primary dissociation of a nitrosyl chloride molecule into nitric oxide and a chlorine atom, followed by some secondary reactions of the chlorine atom resulting in a partial recombination of nitric oxide and chlorine. Such a mechanism, while accounting formally for the deficiency of the quantum yield from the value two, is quite unsatisfactory on closer consideration because it fails to account for the independence of the quantum yield from the degree of decomposition, thus from the concentrations of nitric oxide and chlorine present, as observed by these authors.

The absorption spectrum of nitrosyl chloride has also received some attention. Magnanini[3] finds that it consists of weak bands in the region 5300–6200 Å. with a strong absorption setting in below 5300 Å. Dr. G. Cario[4] and the writer carried out some time ago[5] a preliminary investigation of the absorption spectrum of nitrosyl chloride. It was found to have a banded structure, bands being observed even below 4000 Å., although no definite information with respect to the existence of fine structure in these bands was obtained.

The behavior of nitrosyl chloride seemed thus to offer a striking simi-

larity to the decomposition of ammonia,[6] both substances having banded spectra and showing on illumination a deficient quantum yield unaffected by the presence of the reaction products and only very slightly (NH_3) or not at all (NOCl) affected by temperature. The deficiency of the quantum yield in both reactions, although receiving some consideration, has never been satisfactorily explained and further work in this direction seemed desirable. The nitrosyl chloride decomposition was chosen here because it has been less fully investigated and offers fewer experimental difficulties.

Experimental Details

Decomposition of nitrosyl chloride was measured manometrically. The pressure changes were followed by means of a quartz spiral manometer of the Bodenstein type, used as a zero instrument and connected to a differential manometer filled with α-bromonaphthalene. With this system pressure changes of less than 0.1 mm. of mercury could be measured. As the reaction vessel a pyrex tube **35** X 120 mm. with sealed-on polished pyrex plates was used. Nitrosyl chloride was prepared from nitrosylsulfonic acid and dry sodium chloride. It was dried over phosphorus pentoxide and purified by repeated vacuum distillations. Before an experiment the reaction vessel was evacuated by a high vacuum mercury pump, was then filled with nitrosyl chloride and finally sealed off. The details of the apparatus and of the optical system will be seen from Fig. 1. The second diaphragm separated a parallel beam of light narrow enough so that all light passing through the reaction vessel fell on the light-sensitive surface of a Moll surface thermopile placed immediately behind the vessel. Two light sources were used in the present work: a 1000-watt tungsten projection lamp and a horizontal mercury quartz lamp. The thermopile–galvanometer system was calibrated by means of a standard carbon filament lamp furnished by the Bureau of Standards. Various spectral regions were isolated by means of light filters composed of Corning colored glasses and suitable solutions. The "red filter consisted of the "H. R. Red 100 per cent." glass and a ferro-ammonium sulfate solution. The "orange" filter was of the "Heat Resisting Yellow" glass and the same solution as the red filter. The "green" filter contained a didymium "G 55 P" glass, a "Sextant Green" glass and a solution containing ferric and nickel chlorides:

the “blue” filter a "Purple G 55" glass, a cuprammonium sulfate solution and a quinine sulfate solution. The "u. v." filter was a nickel oxide glass.

Results

To determine the average wave length transmitted through the filters and absorbed by nitrosyl chloride, the transmission curves of the filters as well as the absorption curve of nitrosyl chloride (at 620-mm. pressure) have been measured with a Koenig–Martens spectrophotometer. The light energy distribution in the spectrum of the tungsten lamp has been calculated assuming that the filament is at 2800° and that it emits as a gray body. By combining these three curves, the curves of Fig. 2 have been obtained which represent (in arbitrary units, not the same for different filters) the spectral distribution of light energy absorbed by nitrosyl chloride. These curves served to determine the average wave lengths used in calculations of the quantum yield. In conjunction with the mercury lamp the "blue" and the "green" filters are better than 99% monochromatic (4358 and 5461 Å., respectively), whereas in the light transmitted by the "orange" filter and absorbed by nitrosyl chloride about 90% belongs to the yellow lines 5769 and 5790 Å., 10% to the green line 5461 Å. and only very little to the red mercury lines. The ultraviolet filter, according to photographs taken with a quartz spectrograph, transmits an essentially monochromatic light of the 3650 Å. mercury line. With these filters

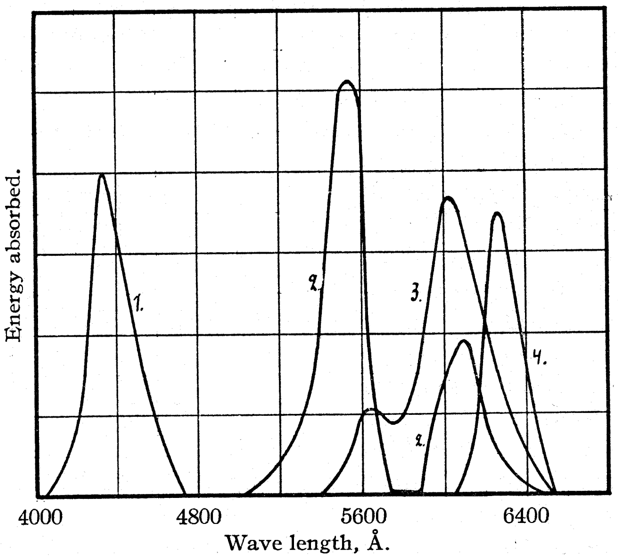

Fig. 2.—Light energy transmitted through filters and absorbed by nitrosyl chloride. 1, “Blue” filter; 2, “Green” filter; 3, “Orange” filter; 4, “Red” filter.

measurements of the quantum yield have been made and are reproduced in a summarized form in Table I. Each of the values for the decomposition rate there presented is a mean of 4 to 8 independent runs, the average deviation of the single runs from the mean amounting to about 8%. Since, in order to obtain as good a monochromasy as possible, the transmissions of the filters have been sacrificed to a considerable extent and the resulting decomposition rates were very slow, it was not possible to neglect the rate of the opposed dark reaction as Bowen and Sharp have done. Instead, the thermal reaction was measured before and after each illumination and the mean was used to correct the rate obtained on illumination. The taking of an arithmetic mean involves here an error since the thermal reaction is of the third order,[7] but the whole correction being small, this error can be neglected.

The light energy absorbed by nitrosyl chloride was determined by measuring the thermopile deflections while the vessel was alternately filled with nitrosyl chloride and emptied, the reactant being frozen out by liquid air. Considerable difficulty was experienced in the beginning since the absorption with the red filter amounted to only about 3% of the transmitted energy while the fluctuations in the lamp intensity exceeded 5% on account of the line voltage variations. This was overcome by introducing a second thermopile (a linear one of the Coblentz type) placed at some distance from the lamp and taking simultaneous readings with both thermopiles. The readings of the linear thermopile were assumed to be proportional to the lamp intensity and served to reduce the readings of the Moll thermopile to a constant lamp intensity. The values presented in Table I are the

means of some 15 readings each, the average deviation from the mean being about 10% with the red and less with other filters. In calculations of the absorbed light energy a correction of 20% was introduced which took care of the reflection losses on the rear plate of the reaction vessel and on a quartz plate protecting the surface of the thermopile.

The absorption spectrum of nitrosyl chloride was further investigated,[8] using a Hilger E2 quartz spectrograph and a plane grating with glass optics giving a dispersion of about 3.5 Å. per mm. in the first order.

The absorption by nitrosyl chloride was found to begin above 6300 Å. and to increase gradually toward the ultraviolet. Several fairly distinct maxima of absorption, however, have been observed. They are situated at about 5990, 4690, 3300 Å. and in the extreme ultraviolet (<2500 Å.). The spectrum consists on the long wave length side of numerous fairly distinct bands which gradually fade out, the appearance of the spectrum toward the shorter wave lengths becoming more and more continuous. In the region 4000–4500 Å., only using contrast photographic plates and particularly favorable concentration of nitrosyl chloride, the existence of bands could be established. In the ultraviolet below the absorption maximum at 3300 Å. no banded structure could be detected at all.

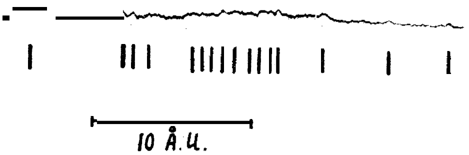

Fig. 3.

The spectrum of nitrosyl chloride thus seemed to offer the same peculiarities as the "predissociation" spectra discussed by Henri.[9] In order to ascertain this, a section of the spectrum between 4100 and 4350 Å. has been photographed in the third order of the grating, thus with a dispersion of 1.17 Å. per mm. Figure 3 is a small section of the photometer record of the plate[10] which shows that the absorption spectrum in this region has distinct line structure, although the latter is very faint. Figure 3 shows as well a reproduction of the same section of the spectrum made by hand from visual study of the plate.

Table I shows that the quantum yield observed is very near to two molecules per quantum. Indeed, if the value for the wave length 3650 Å. be excluded—we shall return to it later—the mean quantum yield is calculated to 2.1, thus a value within 5% of the theoretical 2.0. The experimental values show a slight trend to increase toward the shorter wave lengths. This is due undoubtedly to the circumstance that the correction

---

[8] The author is greatly indebted to Dr. Joseph C. Elgin of this Laboratory for his valuable assistance in this part of the work.

[9] V. Henri, "Structure des Molecules," Paris, 1925.

[10] A Siegbahn microphotometer of the E. I. du Pont de Nemours and Co. Experimental Station, Wilmington, Delaware, has been used for the purpose.

for reflection on the glass has been applied uniformly to all values, whereas in reality the losses by reflection and scattering increase toward the ultraviolet. The value 2.7 for the 3650 Å. wave length is the only one which deviates considerably from two. Most likely this is partially due to light of this wave length being already appreciably absorbed in the thick pyrex plates forming the ends of the reaction vessel, partially to a still further increased correction for reflection and scattering. Table I further shows that the presence with nitrosyl chloride of nitrogen in a seven-fold concentration does not in the least affect the quantum yield—neither with the blue nor with the red light.

The quantum yield obtained, 2.1, is in considerable disagreement with the value 0.48 of Bowen and Sharp. The cause of this discrepancy cannot he definitely established. The neglect to take into account the dark rate could hardly account for such a large error in Bowen and Sharp's measurements and it is more likely that either in the calibration of the thermopile by Leslie cubes some mistake was made, or that the total light energy absorbed by nitrosyl chloride was determined incorrectly.

The finding of the quantum yield of two removes the necessity of introducing into the mechanism of the reaction some secondary processes reforming nitrosyl chloride. The decision must be made between the two alternate possibilities

$$\mathrm{NOCl} + h\nu \longrightarrow \mathrm{NO} + \mathrm{Cl}$$
$$\mathrm{Cl} + \mathrm{NOCl} \longrightarrow \mathrm{NO} + \mathrm{Cl_2}$$

and

$$\mathrm{NOCl} + h\nu \longrightarrow \mathrm{NOCl}^{*} \text{ (excited)}$$
$$\mathrm{NOCl}^{*} + \mathrm{NOCl} \longrightarrow 2\mathrm{NO} + \mathrm{Cl_2}$$

The observed absence of influence of nitrogen on the reaction velocity could be interpreted as favoring the first possibility but two other facts decidedly support the second scheme. The first is the indication that nitrosyl chioride can be decomposed by light energy quanta smaller than its heat of dissociation. The latter is calculated from the heat of dissociation of chlorine, 56.9 cal.,[11] and the heat of formation of nitrosyl chloride, 18 cal.,[12] to be 46.4 cal., thus corresponding to a wave length of 6130 Å., whereas in experiments wave lengths up to 6400 Å. (<44.3 cal.) were found to be effective (see Fig. *2*). More important is the evidence offered by the observations of the absorption spectrum of nitrosyl chloride. There is no doubt that this spectrum consists in the region 5500–6500 Å. of bands with line structure due to quantization of rotation. Furthermore, the plate here reproduced shows that such a structure is retained in bands of much shorter wave length. Thus, for the wave lengths employed in the present work the spectral evidence favors the formation of excited nitrosyl chloride molecules as the primary process or absorption of light energy quanta.

[11] **Kuhn,** *Naturwissenschaften,* **14,** 600 (1926).

[12] Trautz and **Hinck,** *Z. anorg. Chem.,* *97,* 127 (1916).

The excited molecule must collide with another nitrosyl chloride molecule to yield the decomposition products.

The presence of structure in the visible absorption bands of nitrosyl chloride of course does not preclude that at shorter wave lengths the phenomenon of predissociation may not show itself. The observations recorded here rather support this supposition, although indicating that the "predissociation" state of a molecule is not necessary for its chemical activation.

Summary

1. Quantum yield measurements in the nitrosyl chloride decomposition show that the quantum yield is constant and is equal to two with wave lengths from 6300 to 3650 Å.
2. Study of the absorption spectrum of nitrosyl chloride indicates that it has banded structure throughout the visible part of the spectrum.
3. It is concluded that the mechanism of nitrosyl chloride decomposition consists in formation of an excited molecule and in a subsequent decomposition on collision.

THE SPECIFIC HEATS OF GASES AT HIGH PRESSURES. I. METHOD AND APPARATUS AT ROOM TEMPERATURE[1]

BY NORMAN W. KRASE AND B. H. MACKEY[2]

RECEIVED JULY 22, 1929 PUBLISHED JANUARY 8, 1930

Introduction

An obvious need for data regarding the properties of gases at high pressures has made it desirable to develop a method for measuring specific heats. This is the first of a series of papers from this Laboratory reporting methods and measurements. It is confined to a description of a continuous flow, adiabatic gas calorimeter suitable for measuring specific heats up to 1000 atmospheres at ordinary temperature.

The literature contains practically no data on this important property of gases above 200 atmospheres. Holborn and Jacob[3] have published results on air but their apparatus could not be used over the entire range of pressures. An excellent review of the existing data and methods has recently been published.[4]

Experimental Method and Apparatus.—The principle of the adiabatic constant temperature flow calorimeter is well known. The present apparatus differs from previous ones particularly in the methods of measuring the several heat loss corrections.

Figure 1 is a simplified flow diagram of the method as used for nitrogen. High pressure gas storage cylinders, I, II and III are connected through a copper deoxidizer and soda lime scrubber to a thermostat. A long coil of steel tubing immersed in the liquid of the thermostat brings the temperature of the flowing gas to a constant value. Passing through a short, well-insulated tube to the calorimeter, the gas flows through the coil immersed in the calorimeter liquid. Since the temperature of the calorimeter is maintained about 6° higher than that of the thermostat, the flowing gas is heated during passage. To compensate for this continuous removal of heat by the flowing gas and for the heat losses by conduction along the steel tubing and the usual calorimeter losses, a carefully measured quantity of electrical energy is introduced into the calorimeter liquid to maintain its temperature constant. The rise in temperature of the flowing gas due to its heat absorption is measured by thermojunctions placed in the gas stream. After leaving the calorimeter the gas is expanded to about atmospheric pressure, the rate of flow being indicated by a sensitive capillary flowmeter. After humidifying the gas, the rate of flow is measured in a calibrated wet meter and the gas then is collected in a water-sealed gas holder. As needed the gas is recompressed by means of a three stage gas compressor into cylinder I and, for work at 300 atmospheres or more, is further compressed above a water piston formed by the hydraulic pump. The usual method of maintaining a constant pressure on the calorimeter was to pump cylinder III to the desired calorimeter pressure and cylinder II to a higher pressure. By adjustment of the pressure regulating valve between the two, the calorimeter pressure was held constant.

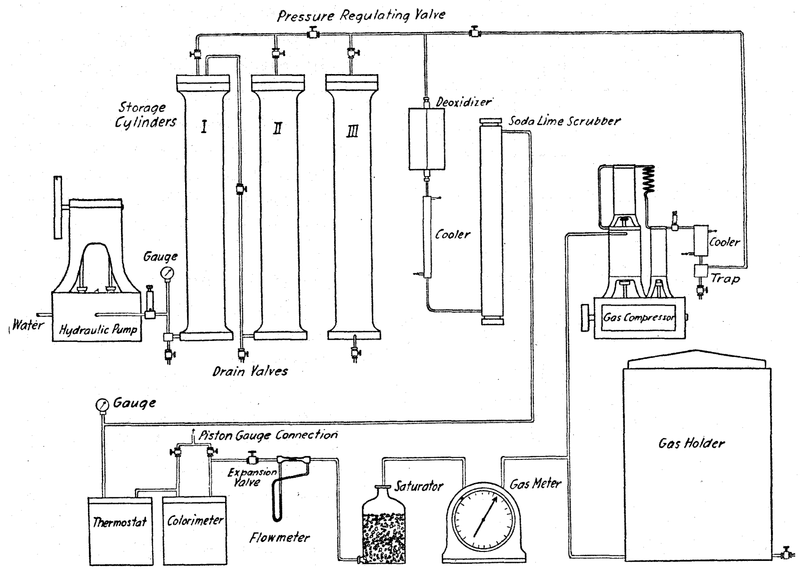

Fig. 1.

The actual manipulation during an experiment, in addition to that just described, consisted in adjusting the electrical energy input to the calorimeter so that its temperature remained constant. With a constant rate of gas flow at a constant pressure, a steady calorimeter temperature indicated that the energy input exactly equaled the energy absorbed by the gas and the energy lost by conduction, radiation, etc. Measurements of the several losses and subtraction from the total gave the energy absorbed by the gas in its passage through the calorimeter. Measurement of the gas temperature rise corresponding to this heat gives directly the heat capacity at the pressure used.

The Calorimeter.—Because the requirements to be met in this problem were radically different from any recorded in the literature, the final calorimeter as used was the result of experience and trial. An exact evaluation of the conduction losses and the measurement of the gas temperature rise offered the principal difficulties. The essential features of the calorimeter are shown in Fig. 2. A Parr adiabatic calorimeter was modified in several ways. The water jacket and cover together with the circulating pump were retained. A small resistance heater was placed in the jacket and the heat input controlled by an external resistance. The inside compartment consisted of a small copper can containing 1000 cc. of kerosene. Four feet of steel tubing, one-quarter inch in outside diameter and one-sixteenth inch bore, was coiled inside the can. By leaving a turn of tubing above the liquid the temperature gradient along the tubes leading out was reduced. The kerosene was stirred in the usual way and a resistance coil immersed in it and controlled by a sensitive external resistance furnished temperature regulation. A twelve-volt storage battery supplied a steady source of current. The jacket and calorimeter temperatures were measured by means of Beckmann thennometers.

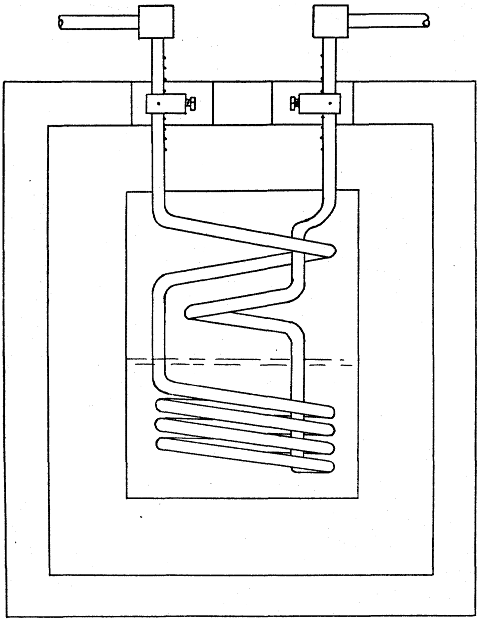

Fig. 2.—High pressure calorimeter.

The connections between the ends of the calorimeter tubing and the external tubing carrying gas into and out of the calorimeter were made by means of specially designed "gradient" tubes. These are shown in Fig. 3. The purpose of these tubes is two-fold. Since they connect the inside of the calorimeter with the outside, it is necessary to measure their temperature gradient in order to evaluate the heat conduction loss along them. They also contain the thermocouples that indicate the incoming and outgoing gas temperatures. Since the tubes are well insulated so that no heat is lost to or gained from the surroundings, any diierence in the amount of heat carried by.conduction along different sections may be accounted for as having gone into the gas. Consequently the amount of heat passing the section where the gas temperature is read is the true conduction loss. In order to introduce the "gas" couples into the stream, it was necessary to enlarge the gradient tubes at this point. The thermocouples were made from No. 40 copper and No. 36 constantan wire, double silk insulated and coated with paraffin. These wires were threaded through a small Bakelite compression cone, a steel conical disk and a nut as shown. On assembling and tightening the nut, the Bakelite was crushed around the wires, keeping them electrically insulated and sealing the opening. By connecting the constantan wires of the two gas couples together, the difference between the temperatures of the incoming and outgoing gas was read directly. This is the "rise" desired.

The temperature gradient on each side of the enlarged section was measured by similar junctions placed at the dots shown on Fig. 2. A constantan wire was placed along the outside of the tube with copper wires soldered on at known intervals. These junctions were electrically insulated from the steel by lacquer. *By* plotting the temperatures of the thermocouple points against their distance from one end, a smooth curve is obtained. The slope at any point gives the amount of heat passing that point; the heat quantity desired, however, is that passing the enlarged section containing the gas couple. The slope at one side gives the heat entering this section and the slope at the other gives that leaving; their average is taken as very close to the true value for the section.

All thermocouple readings were made using a low resistance Type HS Leeds and Northrup galvanometer and a White ten thousand microvolt single potentiometer. It was possible to estimate tenths of a microvolt from the galvanometer deflection. All switches and connections were copper and all junctions soldered. The galvanometer was mounted on a concrete pier set through the floor to eliminate vibration. The scale distance was one and one-half meters.

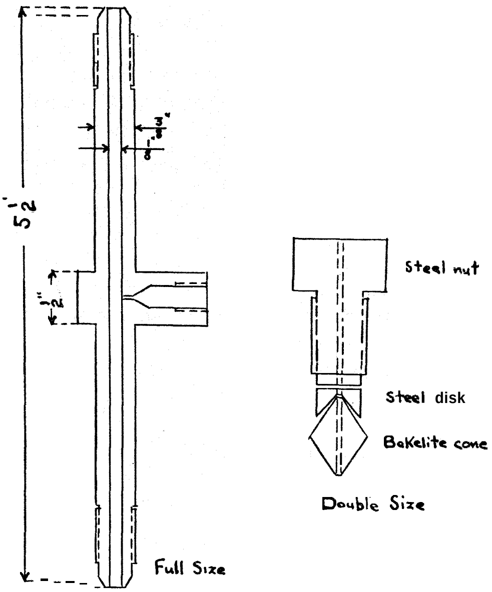

Fig. 3.—Gradient tube.

Auxiliary Measurements.—Other quantities measured during an experiment were (a) the pressure of the gas in the calorimeter tubing, (b) the pressure drop across the calorimeter, (c) the rate of flow of gas, (d) the heat of stirring and miscellaneous calorimetric loss. These measurements will be described in order.

A dead weight piston gage[5] was used as a standard and all Bourdon gages were frequently calibrated against it. Such calibrated gages were then used during experiments. The connections in the tubing at the upper end of each gradient tube permitted direct measurement of the gas pressure in the calorimeter. The piston gage is too sensitive for measurement of the flowing gas pressure and indicating gages are perfectly satisfactory. The change of C_p with pressure is greatest at low pressure and is of the order of 0.1% per atmosphere. Regulation to this accuracy is easily accomplished.

In order to measure the pressure drop of the flowing gas, a glass U-tube was connected to the two tee outlets. The use of glass is safe up to about 200 atmospheres. According to the laws of fluid flow the pressure drop for a given rate of flow of expanded

---

[5] Publications from the Massachusetts Institute of Technology, *63,* No. 28, July, **1929.**

gas should decrease with pressure; the measured drop at low pressures therefore permits a calculation of the Joule–Thomson effect due to expansion in the calorimeter. The measured pressure difference at 100 atmospheres is less than one-fourth of an atmosphere. The error due to this is discussed later.

The rate of flow of gas is determined by measurements after expansion. In order to increase the sensitivity of control of the rate, a special valve was used having an extended handle. This valve was heated to counteract the cooling due to expansion since this seemed to improve the regulation. The gas then passed through a capillary flowmeter having an inclined tube to magnify small changes in head of the indicating liquid. This meter served merely to indicate constancy of rate. After humidification the gas passed through a wet meter. The rate was read with an accurate stop watch. The wet meter was calibrated immediately after each experiment under exactly the same temperature and rate conditions as obtained during the experiment. The calibration consisted in weighing a small steel cylinder containing compressed gas, expanding this gas at the same rate used during the experiment, reading the indicated volume and time interval, and re-weighing the cylinder. The weight of gas was usually about 500 grams and readily could be weighed to one gram.

The heat of stirring and the losses due to radiation, convection, evaporation, etc., are determined by making measurements with no gas flowing but with all other conditions exactly as during a regular experiment. The heat put into the calorimeter as electrical energy plus the heat put in by the stirrer exactly equal the losses due to conduction along the steel tubing and all other losses. Since the electrical energy input and the conduction loss are accurately measured, their difference is equal to the difference between the heat of stirring and the other losses. This last difference varies only slightly with room temperature and may be used as a constant of the calorimeter under normal conditions.

Typical Results

Data taken from duplicate experiments at 200 atmospheres are shown in Table I.

TABLE I

RESULTS OF TYPICAL EXPERIMENTS

			Expt. 11	Expt. 12
Absolute pressure, atm.			200	200
Room temperature, °C.			24	20
Calorimeter temperature, °C.			29.8	29.6
Thermostat temperature, °C.			22.4	21.8
Gas temperature, rise, °C.			6.80	7.60
Voltmeter reading			11.2	11.0
Ammeter reading			0.569	0.562
Wet meter reading, cu. ft. per minute			1.418	1.183
Wt. of gas passed in calibration, g.			590	674
Vol. of gas passed in calibration, cu. ft.			18	20.0
Gas flow, moles per minute, corrected			1.66	1.422
Gradient tube temp. dences °C. (enlarged section)	Inlet	Above	0.37	0.83
		Below	0.32	0.72
	Outlet	Above	0.44	0.99
		Below	0.38	0.85
Conductivity loss, calories per minute			0.4	0.9
Power input, corrected			93.2	89.9
Value of MC_p			8.25	8.31

A typical set of data for the evaluation of the heat of stirring and other corrections is given in Table **11.** The result, 2.20 calories per minute, is used to correct the power input in Table I.

TABLE II

TYPICAL SET OF DATA

Room temp., °C.	23.00
Calorimeter temp, °C.	29.80
Voltmeter reading	0.40
Ammeter reading	0.02
Power input, calories per minute	0.115
Temp. difference along inlet tube, °C.	0.86
Temp. difference along outlet tube, °C.	0.99
Cross sectional area of tubing, sq. cm.	0.633
Conductivity of tubing metal	0.110
Conduction loss inlet tube = (0.86 X 0.633 X 0.11 X 60)/3.33 =	1.08
Conduction loss outlet tube = (0.99 X 0.633 X 0.11 X 60)/3.33 =	1.24
Conduction loss (total), calories per minute	2.32
Net correction, calories per minute = 2.32 − 0.115 = 2.20	

Discussion of Errors

The reduction of the size of the errors in a problem such as this is of prime importance because approximate results have comparatively little value. A constant error would not change the relative value of the results but relative values as determined by this method would probably be inferior to those obtained from compressibility data.

The nitrogen used in these experiments was purchased from the Linde Air Products Company and was their regular grade of atmospheric nitrogen guaranteed to be better than 99% pure. The deoxidation by heated copper and drying should leave only a trace of argon present as an impurity. No analysis was made to determine the purity.

The pressure regulation was accurate to about an atmosphere during an experiment. This is about the order of the sensitivity of the gages used. These gages were calibrated frequently against the piston gage so no large error due to change in calibration was possible. The change of C_p with pressure is somewhat less than 0.1% per atmosphere change between one and two hundred atmospheres. The change is greater here than in any other interval so this error may be taken as less than 0.1%.

The voltmeter and ammeter used to measure the power input were calibrated against a Leeds and Northrup Type K potentiometer using Leeds and Northrup resistance boxes. The calibrations should be reliable to 0.1% of the full scale reading. The ammeter readings were taken at about half the scale value so an error of 0.2% might be introduced here. The voltmeter readings were usually close to the maximum scale value, so the error here would be of the order of 0.1%.

The error in the gas flow measurement can be reduced to the order of the power input error. The flowmeter reading can be held constant to 0.05% as checked against the wet meter with a stop watch. It is unlikely that any appreciable error is ever introduced due to the change in calibration of the wet meter during the experiment or between the experiments and the subsequent calibration. The flowmeter reading always has checked the wet meter reading when timed during the run and during the calibration. The weight of gas passed during calibration is usually about 500 g., accurate to one gram, so this error may be 0.2%.

The thermocouples have already been described in connection with the temperature measurements in the calorimeter. The calibration of the difference couples after being sealed into the tubes presented some difficulty. This was done by calibrating similar couples made at the same time as the difference couples. This calibration held to a tenth of a per cent. for several sets of couples, so all calculations have been made using the value found in this manner. The accuracy of the couples reading the temperature gradient along the tubes is not so important, as the quantities involved are small.

The errors introduced by the potentiometer circuit are probably small. All connecting wires are of insulated copper and the thermocouple switches are also of copper, so large parasitic thermal e.m.f.'s are improbable. The White potentiometer has an arrangement to correct for the e.m.f.'s in the potentiometer and galvanometer circuits. All difference readings can be read to a tenth of a microvolt, which is usually about 0.04% of the reading.

Conduction losses have been discussed also in connection with the calorimeter. They should introduce no larger error than 0.1 to 0.2% in the final result. The conduction losses during a run are rarely greater than 0.5 calorie per minute and it is not likely that the correction should be in error by more than 20% of this. The correction, called heat of stirring, depends for the most part on the conduction loss during a static calibration. The actual heat of stirring should be very constant, as the stirrer speed and liquid level are always the same. This correction has always been found to be 2.2 calories per minute with a variation of not more than ±0.1 calorie. If the largest variation is considered, the total result is affected by slightly over 0.1%.

A discussion of the errors in a flow gas calorimeter would be incomplete without some mention of the size of the Joule–Thomson effect due to the pressure drop in the calorimeter. At 100 atmospheres the pressure difference was less than one-fourth atmosphere for the largest flow used in regular experiments, *i.* e., 1.45 cubic feet per minute. The pressure difference decreased with an increase in total pressure when the flow remained constant and increased when the total pressure was decreased. Using Bartlett's[6] value for $-(\mathrm{d}T)/(\mathrm{d}p)H$ of 0.14 calculated from his com-

---

[6] Private communication.

pressibility data at 100 atmospheres, the temperature drop in expanding through the calorimeter would be slightly less than 0.04'. When the total temperature rise is 6°, this factor causes the final result to be too high by about 0.6%. This correction is less as the pressure is increased because $-(\mathrm{d}T/\mathrm{d}p)H$ approaches zero and finally changes sign.

Faulty technic in operating the apparatus is probably the main cause for errors in the final result. An average experiment takes about four hours and all conditions should be very constant for at least half an hour before the readings are taken. This is rather difficult to do since quite frequent gas compression is necessary with the high rates used.

During a satisfactory experiment the temperature of the calorimeter does not change more than 0.01' in half an hour. A correction can be applied for a slight temperature change by taking into account the water equivalent of the calorimeter and the rate of temperature change. The water equivalent is roughly one kilogram. A 0.01' rise indicates that 10 calories have been absorbed and if the rise takes place in 30 minutes, 0.3 calorie is being absorbed per minute. This correction is usually less than 0.5%. The results are reproducible to something better than 0.5% under good conditions.

Summary

A constant temperature continuous flow adiabatic calorimeter has been described. The apparatus for measurement of the specific heats of gases at ordinary temperatures and up to 1000 atmospheres pressure is described. Typical results for nitrogen at 200 atmospheres are given together with the method of calculation.

THE HEATS OF COMBUSTION AND FORMATION OF AROMATIC NITRO COMPOUNDS

BY WM. H. RINKENBACH[1]

RECEIVED JULY 24, 1929 PUBLISHED JANUARY 8, 1930

Although numerous investigators have studied the relationship existing between the constitution and thermochemical constants of organic compounds and particular attention has been paid to this relationship as regards nitro explosives, stereoisomers, homologs, etc., there still exist gaps in the values available for series of compounds and their derivatives. As the availability of such physico-chemical constants is of increasing importance and certain data of this nature were desired for use in connection with other work, it was considered desirable to make accurate determinations of the heats of combustion of a number of aromatic nitro com-

---

[1] Chief Chemist, Picatinny Arsenal, U. S. War Department.

pounds and to calculate their heats of formation. For purposes of comparison and confirmation, it was decided to make similar determinations with compounds for which values have already been published.

Accordingly, calorimetric studies were made of fourteen nitro compounds

TABLE I

THERMOCHEMICAL CONSTANTS OF NITRO COMPOUNDS. HEAT OF COMBUSTION

Compound	G. cal. per g. at const. vol.	G. cal per g. mole At const. vol.	G. cal per g. mole At const. press.	Heat of formation at const. press.	Heat of nitration at const. press.

for which no values were found in the literature, as well as of seven similar compounds of importance which had been studied by previous investigators. The data obtained are considered as serving to close a number of gaps in series of values available and hence of importance in determining the relationship between the constitutions and physical constants of chemical compounds.

Materials.—All materials used were of the highest purity, being purified by recrystallization until constant melting points agreeing with accepted values were obtained. Each compound was then kept in a sulfuric acid desiccator in a dark place until required for use.

Experimental Procedure.—A calorimeter of the Parr type was used in determining the values for heats of combustion given. This was equipped with a calibrated Beckmann thermometer and a cathetometer permitting the accurate estimation of 0.001°. The calorimeter was calibrated by means of pure benzoic acid furnished by the U. S. Bureau of Standards and found to give results accurate to ±11 calories per gram.

Duplicate or triplicate determinations were made with each material, the average value being reported. The initial temperature of the system in each case was 22 to **23°**. Combustions were carried out with the oxygen in the bomb at a pressure of 400 lbs./sq. in. **At** the completion of each combustion the bomb was rinsed out and the nitric acid formed was determined by titration, the proper correction for this being applied to the calorimetric results.

Results.—The values for heats of combustion at constant volume were determined. From these the heats of combustion at constant pressure and the heats of formation were calculated. Table I gives the constants so determined and calculated, as well as a number of corresponding values reported by other investigators.

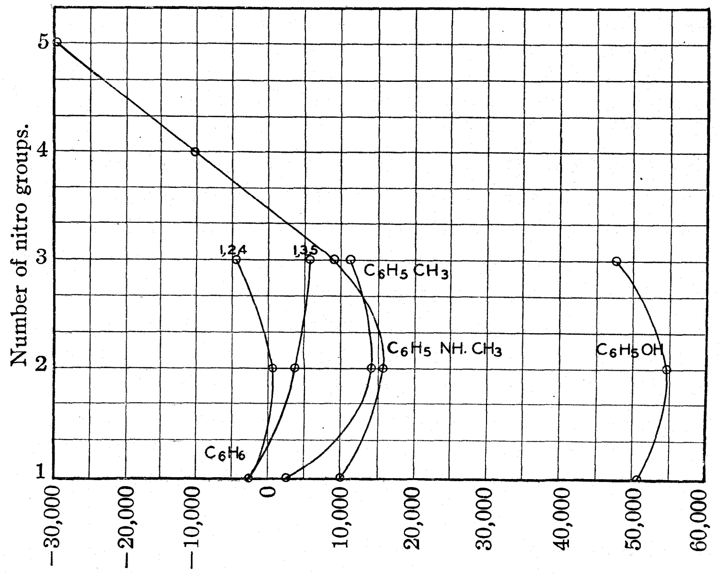
In making the calculations, the following constants were used: R = 1.9885; T = 295°K.; H_F of H_2O (liq.) = 68,400 cal./g. mole; H_F of CO_2 = 04,400 cal./g. mole; H_F of HNO_3 = 41,500 cal./g. mole.

A comparison of the values for heats of combustion determined with those previously recorded for some of the compounds would indicate a probable accuracy of about 1%. Standardization of the calorimeter indicated an accuracy of ±0.18%.

The possible error of 1% is based largely on the fact that Garner and Abernethy[3] give values from 0.2 to 1.3% (av. 0.7) higher for six compounds than those found by the writer. However, the value found for picric acid is 0.2% higher than that given by Roth and Macheleldt,[4] who also carried out their investigations quite recently. Rubtzov and Sever'yanov,[7] the only other recent investigators who have reported on two of these compounds, give results which apparently are much too high, being 2.5 and 3.1% higher than those determined by the writer and 1.9 and 2.6% higher than those reported by Garner and Abernethy. The work of the last-mentioned investigators having been done with great care, the results given by Rubtzov and Sever'yanov are at least open to question and do not form the basis of a fair comparison.

A similar comparison with values reported by other investigators shows that the determinations on check compounds herein reported are lower than those given by Swarts,[2] Matignon and Deligny[5] and Bertholet and Matignon[6] by 1.6, 1.4 and 0.1%, respectively.

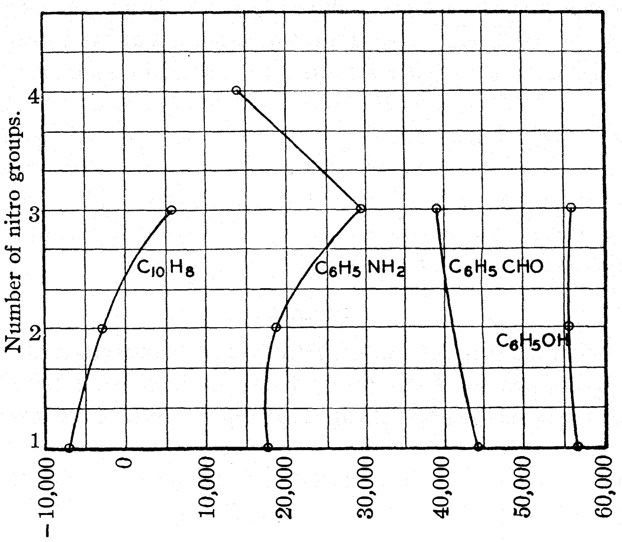
From these facts it may be concluded that the new values for heats of combustion now reported have a possible error of −0.7%, though the existence of this percentage of error instead of the ±0.18% indicated by the calibration experiments cannot be considered as proved. The insufficiency of data giving direct comparisons with at least several other investigators for individual compounds renders doubtful any rigid conclusion that the results reported in this paper contain a consistent error approximating −0.70%. This lack of comparisons is due to the fact that the filling of gaps in existent data was the prime objective of this study.



Heat of formation at constant pressure in cal./g. mole.

Fig. 1.

As is to be expected, when values for the heat of combustion of a compound determined by other investigators and the writer are used for calculating the heats of formation, the difference in results will be numerically equal but proportionally much greater than the difference in heat of combustion values. When the values for heats of formation of the compounds in each series of nitro derivatives, as calculated from the determinations of Garner and Abernethy[3] (Fig. 1) and of the writer (Fig. 2), are plotted against the number of nitro groups present in each compound, it is noted that the effect of the divergences is to produce curves having quite different orientations with respect to the reference axes.



Heat of formation at constant pressure in cal./g. mole.

Fig. 2.

If the heat of formation be used to calculate the heat of nitration (reaction) evolved when each member of a nitro compound series is prepared by nitrating the next lower nitro compound or the hydrocarbon itself in the case of the mononitro compounds, comparative results having *a* bearing on the accuracy of the combustion values determined by the writer are obtained.

TABLE II

THERMOCHEMICAL DATA

	Heat of combustion at const. press.[3], cal./g. mole	Heat of formation at const. press.. cal./g. mole	Heat of nitration, cal./g. mole
Nitrobenzene	739,700	−2,300	37,300
m-Dinitrobenzene	699,400	+3,800	33,000
1,3,5-Trinitrobenzene	663,400	+5,600	28,700
o-Dinitrobenzene	702,600	+ 600	29,800
1,2,4-Trinitrobenzene	673,700	−4,700	21,600
o-Nitrotoluene	897,200	+3,000	32,700
2,4-Dinitrotoluene	852,800	+13,200	37,100
2,4,6-Trinitrotoluene (TNT)	820,700	+11,100	24,000
p-Nitromethylaniline	924,300	+10,100	43,200
2,4-Dinitromethylaniline	884,500	+15,700	32,500
2,4,6-Trinitromethylaniline	857,900	+ 8,100	19,300
Tetryl	842,300	−10,500	8,300
p-Nitrophenol	686,500	+50,900	41,400
2,4-Dinitrophenol	648,700	+54,500	30,500
2,4,6-Trinitrophenol (picric acid)	621,200	+47,800	20,200

Values given by Garner and Abernethy (Table 11), with one exception, indicate a rather regular rate of decrease in the amount of heat given off with the introduction of each successive nitro group into the ring. In no one of the several series covered by the writer (Table I) was this found to be true, the entrance of the second nitro group in each case causing the liberation of less heat than the third. This is contrary to both theory and observed fact and is ascribable to variation in the errors in determining heats of combustion, small variations in the percentage of error causing much larger variations in derived values. This would indicate that the new determinations of heats of combustion reported in this paper are probably low to the extent of 0.7%.

Summary

1. The heats of combustion of twenty-one compounds have been determined, no values for fourteen of these having been previously published. From these, heats of formation and of nitration have been calculated.

2. Study of the values determined and calculated indicate that those determined have a probable error of −0.7%.

THE EFFECT OF PH UPON THE PRECIPITATION OF ZINC AMMONIUM PHOSPHATE

BY T. R. BALL AND MEYER S. AGRUSS

RECEIVED JULY 24, 1929 PUBLISHED JANUARY 8, 1930

The well-known method of determining zinc as zinc ammonium phosphate was first introduced by Tamm.[1] It has been studied by several investigators[2] with the final result that the precipitation is carried out in neutral or faintly acid solution, using diammonium phosphate as the precipitant. From five to twenty grams of ammonium chloride is present in the solution and the amount of precipitant may vary from ten to twenty times that of the weight of zinc estimated to be present. The precipitate formed at first is assumed by Olsen[3] to be amorphous $Zn_3(PO_4)_2$, which in the presence of ammonium salts is changed into crystalline Zn-

NH_4PO_4 by hot digestion. Practice varies as to the method of washing the precipitate, some authors using a 1% solution of diammonium phosphate followed by a mixture of water and alcohol. Langley[2] finds that washing with cold water gives satisfactory results.

While the accepted procedure calls for precipitation in a neutral or faintly acid solution, none of the previous investigators has determined the optimum PH. Fales[4] states that "the exact value of Pa for which zinc ammonium phosphate is least soluble has not been definitely ascertained, but apparently is around a value of Pa = 7.5." The present work has to do with the determination of the optimum PH.

Materials and Procedure

A high grade of zinc sulfate was mixed with C. P. ammonium sulfate mole for mole, dissolved in boiling water and twice recrystallized from hot water. The crystals were air-dried and analyzed by gentle ignition to $ZnSO_4$ in a large platinum crucible. The percentage of $ZnSO_4$ was found to be 40.19, 40.15 and 40.18% in three determinations; average, 40.173%; calcd. for $ZnSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ = 40.193%. A standard was made by dissolving the salt in a weighed amount of water and all samples were taken by weighing the solution. In general, 5 g. of ammonium chloride and 10 cc. of 2 N sodium acetate were added to each zinc solution, followed by dilution to 140 cc. The solutions were then placed on a water-bath and when hot 10 cc. of 10% diammonium phosphate was slowly added from a pipet. The diammonium phosphate used conformed to the specifications of the Committee on Analytical Reagents of the American Chemical Society.[5] A solution of 1 g. in 10 cc. of water was colored pink by the addition of 2 drops of phenolphthalein solution. After two hours on the water-bath in a covered beaker, the precipitates were filtered onto Gooch crucibles, washed with about 150 cc. of cold water, 5 cc. of 95% alcohol and dried in the oven for one hour at 105°. The amount of zinc was then calculated on the assumption that the precipitate was $ZnNH_4PO_4$. In some cases larger amounts of ammonium chloride were added, as shown in the notes to Table I.

Where low Pa values were desired, varying amounts of 1.0 N HCl were added just before the addition of the precipitant. To produce high PH values, 1.0 *N* NaOH or 10% NH_3 was added. All of these reagents were carefully tested and found to yield no precipitate with phosphate under the range of conditions used.

The PH values of the undiluted filtrates were determined with a hydrogen electrode against a normal calomel. This was the method followed for all the results shown in Table I which were obtained by Ball. Mr. Agruss followed much the same procedure except that he used an equivalent amount of ammonium acetate in place of sodium acetate and determined the PH by the Gillespie drop ratio method, using the Clark and Lubs indicators. The results of Mr. Agruss, forty-seven in number, are not given in the table since they are so consistent with those of the senior author that their inclusion would add nothing to the interpretation. They simply show that the presence of sodium salts, in the concentrations used,

[5] *Ind. Eng. Chem.*, 19, 645 (1927).

are without effect. The object of adding the sodium acetate was to increase the buffer action.

Experimental

The results are given in Table I, which is self-explanatory. Unless otherwise stated each solution contained 5 g. of ammonium chloride. The average error for each PH value is plotted against the *P*H in Fig. 1.

TABLE I

EFFECT OF *P*H ON THE PRECIPITATION OF ZINC AMMONIUM PHOSPHATE

[a] HCl added. [b] 10 g. of NH_4Cl. [c] 8 g. of NH_4Cl. [d] NaOH added. [e] 10% NH_3 added.

Discussion

Determinations 1 to 8 of Table I show that all results are low up to a PH of 6.2 and fall off very rapidly below 5.1. From a PH of 6.4 to 6.9 (Nos. 9 to 24) seven results show *a* zero error, five show slightly high results and four are low. The mean deviation from the theoretical over this range is zero. From a PH of 7.1 to 7.7 all results are high, with the exception of No. 25, but the error is not large. It should be noted, however, that whenever the PH exceeds **7.0,** the precipitates are removed from the beaker with great difficulty and do not have the definite crystalline structure characteristic of those precipitated from the more acid solutions. Above **a** PH of 7.7 the zinc error is negative and very large. This is obviously due to the formation of a complex ion of zinc with free ammonia. Even at PH values as low as 6.6 the odor of ammonia is distinct from the hot solution.

A study of Fig. 1 shows that the curve crosses the zero axis at 6.6. This obviously is the optimum *Ph* at which to make the determination. The results of Mr. Agruss, using ammonium acetate in place of the sodium salt, when similarly plotted, lead to the same conclusion.

The filtrates of Expts. 9 to 15, Table I, all showed a *Ph* of 6.4 regardless of the fact that Nos. 9 to 12 contained twice as much ammonium chloride as the others. The range of 6.4 to 6.9 in **Ph** shown in Nos. 13 to 24, which were all run with identical reagents, is doubtless due to variations in air circulation resulting in unequal volatilization of ammonia during the heating. However, all fall within a safe *Ph* range, so that the conclusion seems justified that the two-hour heating period in a covered beaker automatically adjusts the acidity to the proper range. This was further investigated by preparing a solution containing 5 g. of NH_4Cl, 10 cc. of 2 N NaAc and 10 cc. of 10% $(NH_4)_2HPO_4$ in a total volume of 150 cc. The *Ph* of this solution was 7.5 but it dropped to 6.9 after two hours of heating on the bath. Ten minutes of vigorous boiling, followed by dilution to the original volume with water, reduced the *Ph* to 5.6. Obviously the solution should not be boiled.

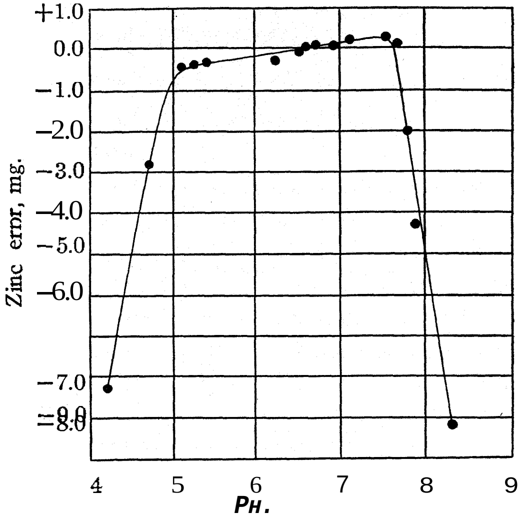

Fig. 1.—The effect of *Ph* upon the precipitation of zinc ammonium phosphate.

Justification for the addition of sodium acetate to improve the buffer action is shown by the fact that the original solution referred to above was changed from a *Ph* of 7.5 to 6.5 by the addition of 5 cc. of 1.0 N HCl. When the sodium acetate was left out the *Ph* changed to 6.3, which is dangerously low (see Nos. 7 and 8 of Table I).

Summary

1. Satisfactory results may be obtained for the determination of zinc as zinc ammonium phosphate over a Ph range of 6.4 to 6.9.
2. The optimum Ph is 6.6.
3. The concentration of ammonium chloride between five and ten grams per 150 cc. is without appreciable effect.
4. The precipitate is not crystalline at Ph values above 7.0 and is removed from the beaker with difficulty.

5. Below a PH of 5.1 and above 7.7 the results are much too low.

6. Solutions containing 5 to 10 g. of NH_4Cl, 10 cc. of 2 N $NaC_2H_3O_2$ and 10 cc. of 10% $(NH_4)_2HPO_4$ in 150 cc. have a PH of 7.5 but automatically fall to a range of 6.4 to 6.9 on the water-bath when heated for two hours.

7. Washing of the precipitate with cold water seems to yield satisfactory results.

THE QUANTUM YIELD IN THE PHOTOCHEMICAL DECOMPOSITION OF HYDROGEN AZIDE

BY ARNOLD O. BECKMAN AND ROSCOE G. DICKINSON

RECEIVED JULY 27, 1929 PUBLISHED JANUARY 8, 1930

Introduction

In a previous paper[1] it has been shown that gaseous hydrogen azide, HN_3, is decomposed by ultraviolet radiation of wave length less than 2200 Å. The products of the reaction were found to be hydrogen, nitrogen and ammonia (ammonium azide); no hydrazine was found.

The decompositions of aqueous solutions of HN_3 by ultraviolet radiation has been studied by Gleu[2] who found that here the products were largely hydroxylamine and nitrogen with small amounts of ammonia and traces of hydrazine.

The present paper is concerned with the quantum yields in the decomposition of gaseous HN3 produced by monochromatic radiation, and with the effect of pressure on these yields.

Apparatus and Procedure

A diagram of the apparatus is shown in Fig. 1. Anhydrous gaseous HN_3, prepared as before' from sulfuric acid and NaN_3, was stored in the 1-liter bulb, A, which was attached to a vacuum system. Attached to the same system were a quartz reaction vessel, N, in which the HN_3 was irradiated, a McLeod gage, and a quartz fiber gage, H. With the mercury cut-off, C, and the cock K closed and with the cut-off M open, a desired quantity of HN_3 was admitted to the system with the aid of the doser, B. The HN_3 was frozen out by applying liquid air at P and any traces of non-condensable gas were pumped off. The cut-off M was then closed and the liquid air removed from P allowing the HN_3 to vaporize into the reaction cell, N. The pressure of the HN_3 was read from the difference in the mercury levels in the two arms of M. In those cases where the pressure of HN_3 was too small to be measured satisfactorily in this manner, this procedure was slightly modified to permit the measurement of the HN_3 pressure on the McLeod gage. The reaction cell, N, was a quartz cylinder 2.5 cm. in diameter and

---

[1] Beckman and Dickinson, THIS JOURNAL, 50, 1870 (1928).

[2] Karl Gleu, Ber., 61, 702 (1928).

4.8 cm. long with flat windows fused on each end; it was attached to the rest of the apparatus through a graded seal.

After irradiation liquid air was again applied at P, the cut-off M opened and the non-condensed gas allowed to expand into the evacuated McLeod gage and quartz fiber gage. The McLeod gage reading gave the total pressure of hydrogen and nitrogen produced and this combined with the known volume of the gases (all mercury levels were held at definite marks) gave the total number of moles of nitrogen and hydrogen produced. The fiber gage readings were used to determine the mole fraction of hydrogen in the gas in the way already described.'

The source of radiation was an aluminum spark. Aluminum was used because it gives quite intense lines which are widely separated in the desired region, permitting the use of wide slits in the monochromator. The electrodes were 0.25 inch aluminum rods with the ends turned down to a diameter of 0.1 inch for a distance of $^3/_{16}$ of an inch. The small ends were essential to keep the spark from drifting about; the larger shanks were necessary to keep the tips from melting. As the electrodes eroded their separation was adjusted to a constant value of about 6 mm. during operation with the aid of an image of the spark projected upon a screen by a lens, in a manner similar to that described by Warburg.[3] The spark was operated from the 13,000 volt secondary winding of a transformer, the primary current being 40–60 amperes at 220 volts. A 0.1 mf. condenser was placed in parallel with the spark.

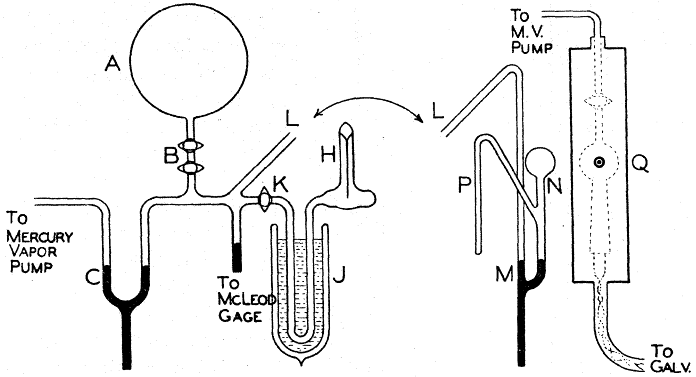

Fig. 1.—Schematic diagram of vacuum system.

The spark was placed close to the entrance slit of a Bausch and Lomb quartz monochromator. To permit this, the regular slit mechanism was replaced by a more compact one covered by a micarta cap with a rectangular hole in front of the slit. Provision was also made for blowing the spark by a blast of air issuing from the hole in the micarta cap. A shutter was also built into the monochromator.

The flux of radiation was measured by the vacuum thermocouple Q (Fig. 1), which is shown in greater detail in Fig. 2. The thermo-elements were pure bismuth and an alloy of 95% bismuth with 5% tin. The junctions were cemented to the rear faces of two circular vanes of aluminum foil. The vanes were 5.5 mm. in diameter, just large enough to receive the entire beam of radiation which was converged onto the receiving vane by a quartz lens of 2.5 cm. focal length fastened to the monochromator just outside the rear slit. The front surfaces of the vanes were coated with lampblack from a sooty flame. To aid in alignment, a piece of fluorescent uranium glass was placed imme-

---

[3] Warburg, *Sitz. Ber. Preuss. Akad.*, 216 (1912).

diately behind the vanes. When in use, the thermocouple vessel was continuously evacuated with a liquid-air trap placed between it and the pump. The thermocouple was connected with a Leeds and Northrup high sensitivity galvanometer; the thermocouple, galvanometer and leads were carefully shielded in a grounded metallic covering. The front windows of the thermocouple vessel and reaction cell were aligned horizontally and both located in a plane perpendicular to the exit beam of the monochromator. The monochromator, with the spark rigidly attached to it, was arranged to slide horizontally in V-grooves provided with stops so adjusted that when the monochromator was in one extreme position, the light was focused exactly on one receiving vane of the thermocouple and when in the other extreme position, the light was centered on the reaction cell. Reaction exposures were usually about fifteen minutes long. Ordinarily measurements of the energy flux were alternated with the reaction exposures and carried over about the same time interval; during this interval a number of galvanometer readings were made with the shutter open and closed and the deflections averaged. The mean values of several such sets of readings taken successively fluctuated about 10%. It would evidently be better so to arrange the apparatus that thermocouple readings could be made simultaneously with the reaction; apparatus is now being constructed which will permit this in the study of other reactions.

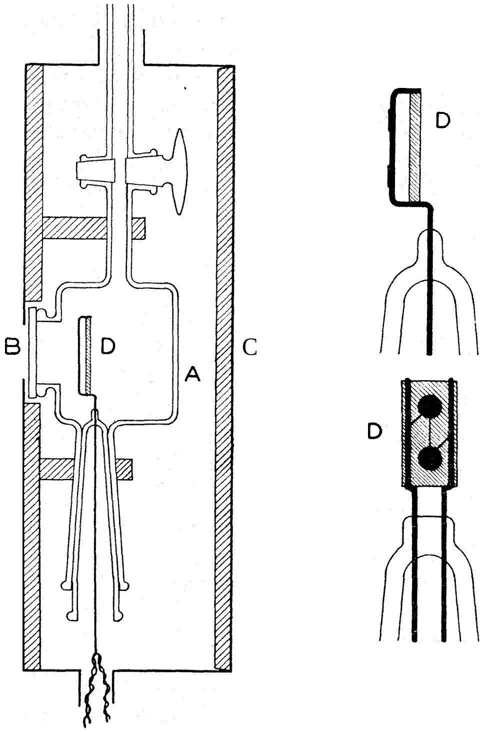

Fig. 2.—Side view of vacuum thermocouple. The thermocouple vessel, A, was of pyrex with a quartz window, B, fastened on with sealing wax. The rear side, C, of the metal-covered housing was removable for aligning. The thermocouple assembly and fluorescent screen, D, are shown in greater detail on the right.

The thermocouple–galvanometer combination was calibrated with the aid of a carbon lamp which had itself been calibrated by the Bureau of Standards. The procedure was as follows: with the aid of a Moll thermopile the transparency of a quartz plate for radiation from the standard lamp was measured and found to be 90.6%. The vacuum thermocouple was then assembled using this quartz plate as a window, and evacuated. A hole 4.50 mm. in diameter (area, 15.87 mm.^{2}) was made in a thin sheet of metal. The hole was placed in front of the thermocouple window in such a position that light from the standard lamp passing through the hole was entirely intercepted by the receiving vane; the scale deflection was 4.766 cm. (average). From the calibration of the standard lamp, the intensity of radiation at the hole was known to be 7.04 ergs per mm.^{2} per sec. Accordingly 1 cm. of scale deflection corresponded to $7.04 \times 15.87 \times 0.906/4.766 = 21.25$ ergs per second of radiation falling on the receiving vane. An exactly similar plate of quartz was used for the front window of the reaction cell. Hence, in using the thermocouple to measure ultraviolet radiation, no correction for the transmission loss at the front window of the reaction cell was necessary, *i. e.*, **1** cm. of scale deflection was taken to indicate **21.25** ergs per second entering the reacting substance To test the integrating ability of the thermocouple vane, a beam of light about **0.5** mm. in diameter was directed onto the center and then onto regions near the edge of the vane, and the deflections were noted. The deflections differed from each other by less than 1%.

Light Absorption Coefficients.—In the determination of the quantum yields it was necessary to know the absorption coefficient of HN_3 for the radiation used. Absorption coefficients were determined photographically by a method substantially the same as that described by Winther.[4] This consisted in photographing on the same plate with a quartz spectrograph a series of exposures of the radiation from the aluminum spark. **The** exposures were all of the same length and in every case the radiation passed through the reaction vessel. In half the exposures the reaction vessel contained HN_3 at a measured pressure; in the alternate exposures, the reaction vessel was empty, and calibrated wire screens of known transmission were interposed in the optical path. The plates were photometered using the microphotometer of the Mount Wilson Observatory. The resulting absorption coefficients, a, defined by the equation $I/I_0 = e^{-\alpha l}$ where I/I_0 is the fraction of radiation transmitted by a thickness of 1 cm. of gas at 0° and 1 atm., are shown in Pig. **3.** The absence of any systematic variation of a with the pressure is evidence that Beer's law holds here at least approximately.

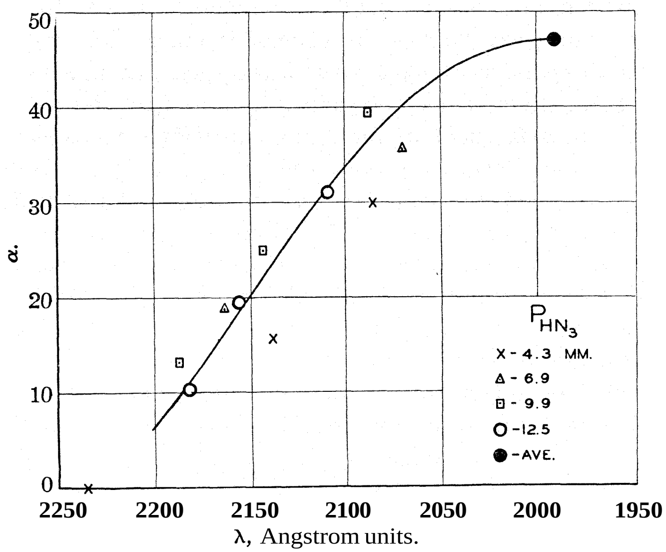

Fig. 3.—Light absorption coefficients, α, of HN_3 at various wave lengths, λ.

[4] Winther, Z. *wiss.* **Phot., 22, 125 (1923).**

Experimental Results

The results of the quantum yield determinations made with the aluminum line λ1990 are given in Table I. In the first column is given the initial pressure of HN_3 in the reaction chamber; in no case was more than 1.7% of the HN_3 decomposed. In the second column is A, the fraction of the incident radiation absorbed, calculated from the absorption coefficient $\alpha = 47.0$, assuming Beer's law to hold and allowing for reflection at the rear window of the reaction cell. The exposure time, t, is given in seconds in the third column. The variability of the galvanometer deflection, d, given in the fourth column arises in part from the fact that the slit widths and spark lengths were not the same in all experiments. The volume of the gas during the reaction was **25.3** cc. in all experiments. The volume of the products when expanded into the gages was larger, and is given in Col. 6; this volume is an effective one determined by air expansion with liquid air at P as in the measurement of the non-condensable gas pressures. The pressure of the non-condensed products given in Col. 7 came directly from McLeod gage readings. From these and the values of $\Sigma p \sqrt{M}$ determined with the quartz fiber gage, the mole fractions of hydrogen given in Col. 8 were computed. These mole fractions are, in the present case, very sensitive toward small errors in the readings of either gage. Since the measured pressures are small, we do not feel certain that the rather considerable variability of these mole fractions is real; fortunately, the quantum yields are not sharply dependent upon them. In the ninth column, the number of quanta of radiation absorbed by the HN_3 was computed from the relation

$$N_Q = \frac{21.25 \cdot d \cdot t \cdot A}{hc/\lambda} = 2.150 \cdot 10^{12} \cdot d \cdot t \cdot A$$

the factor 21.25 being the number of ergs per second of radiation entering the gas for a galvanometer deflection of 1 cm. In the tenth column is given N_{HN_3}, the number of molecules of HN_3 decomposed; this was calculated from the following equation which may be simply obtained from the perfect gas law and the consideration that the number of gram atoms of hydrogen and nitrogen in the products (H_2, N_2 and HN_3) must equal the number of gram atoms of hydrogen and nitrogen in the decomposed HN_3

$$N_{HN_3} = \frac{N \cdot p_{H_2 + N_2} v}{760RT} (3/4 - x_{H_2})$$

Here N is the Avogadro number, and R has the value 82.1-cc. atm. per degree.

The quantum yield tabulated in the last column is the ratio of the number of molecules of HN_3 decomposed to the number of quanta absorbed, *i.* e., N_{HN_3}/N_Q. The yield at the lowest pressure is regarded as less reliable than the others, partly on account of the comparatively small pressure of the products; any uncertainty in the absorption coefficient would also have its greatest effect in this run. If this run be left out of account, there remains certainly no considerable variation of yield with pressure over the range from 2 to **130** mm. The mean of all the yields excluding the first is **2.97 ± 0.45.**

The conclusion that the quantum yield is largely independent of the pressure is borne out by the results of some rate experiments made at lower pressures. In these experiments the monochromator was removed. The cell was exposed to the full radiation of the spark which was placed at a distance of 40 cm. from the cell. The spark length was controlled as before. A series of 2-minute exposures was made at various HN_3 pressures of from 0.06 to **0.5** mm. The HN_3 pressures were measured on the McLeod gage. It was found that the manipulation of the gage produced traces of decomposition; consequently, after HN_3 had been admitted to the McLeod gage and the reaction cell, the trap M (Fig. 1) was just closed and the gas in the McLeod gage pumped off after the HN_3 pressure measurement. After exposure, liquid air was applied at P, and the pressure of the non-condensed gas measured with the McLeod gage. It was also found that illumination of the reaction cell with the full radiation of the spark produced gas pressure at the rate of 6×10^{-5} mm. per minute even when the cell was empty. Consequently 12×10^{-5} mm. was subtracted from the measured pressures. The results are shown in Fig. **4** in which the abscissas are the HN_3 pressures and the ordinates the total corrected pressures of non-condensed gas. The curve has been drawn as a straight line through the origin and is evidently reasonably representative of the points.

In these rate experiments the absorption of λ1990 was sufficiently low **(13%)** at even the highest pressure, so that it could be taken as proportional to the pressure. If this is true also of such shorter wave-length radiations from the spark as may have reached the reaction cell, then the linearity of rate with pressure is evidence in favor of constancy of quantum yield down to those lower pressures.

Discussion

The first question involved in the consideration of the mechanism of photochemical HN_3 decomposition is the nature of the primary process, *i. e.*, whether light absorption is accompanied by the production of an HN_3 molecule in an excited electronic state or is accompanied by dissociation of the absorbing molecule. Unless we have to deal here with unusually large molecular diameters or with an electronic state of considerably longer life than that usually assumed ($\sim 10^{-7}$ sec.), the experiments are decidedly in favor of primary dissociation; taking a collision diameter of 5 X 10^{-8} cm., the mean time between collisions is readily calculated from the usual kinetic theory formula to be about 7 X 10^{-7} sec. at a pressure of 0.1 mm. so that a decided falling off in rate could be expected at even higher pressures, were the primary process one of excitation.

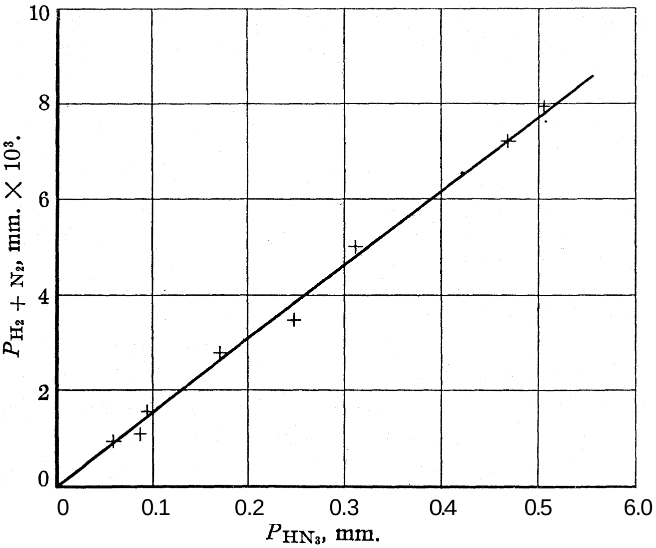

Fig. 4.—Rate of production of non-condensable gas at low HN_3 pressures.

The energy available for primary dissociation is large; a quantum of wave length λ1990 corresponds to 143,000 cal. per mole and in addition HN_3 is itself endothermal to the extent of 54,500 cal. per mole.[5] Because of the high heat of dissociation of nitrogen,[6] 219,000 cal. per mole, the

---

[5] According to Mellor, "Treatise on Inorganic and Theoretical Chemistry," Vol. VIII, p. 334, the heat of formation of HN_3 in aqueous solution is –61,600 cal. while the heat of solution is –7080 cal.

[6] R. T. Birge, *Nature*, 122, 842 (1928).

available energy is not sufficient for complete dissociation of HN_3 into atoms, but is sufficient for dissociation into H, N and N_2 or, it seems reasonable to suppose, into other configurations such as HN and N_2.

The fact that NH_3 is produced from HN_3 seems to require either (1) the occurrence of multiple collisions involving an active configuration (such as a collision of $2HN_3$ with one H), or (2) the transient occurrence of intermediate compounds. In the first case we should expect the amount of ammonia produced (as compared with the amount of hydrogen produced) to fall off greatly with decreasing pressure. As this appears not to be the case, we are disposed to accept the second alternative.

A possible mechanism of the reaction is the following, the first step of which is identical with that assumed by Gleu[2] to account for the formation of hydroxylamine in aqueous solution.

$$h\nu + HN_3 = HN + N_2 \qquad (1)$$
$$HN + HN_3 = H_2N_2 + N_2 \qquad (2a)$$
$$HN + HN_3 = H_2 + 2N_2 \qquad (2b)$$
$$H_2N_2 + HN_3 = NH_3 + N_2 \qquad (3)$$

If Reaction 2a went three times as often as Reaction 2b the quantum yield would be 2.75 HN_3 decomposed per quantum and the mole fraction of hydrogen in the non-condensed gas would be 0.08; the averages of the observed values are 2.97 ± 0.45 and 0.111 ± 0.036, respectively. However, we do not care to stress this particular mechanism; indeed, we regard the ad *hoc* invention of intermediate compounds as a pastime usually indulged in with more entertainment than profit.

We would finally draw attention to the fact that in spite of the very high concentration of energy involved in the primary process and the highly explosive character of HN_3, there is no discernible tendency toward chain reaction even at a pressure of 130 mm. This behavior is, however, not entirely unprecedented, for low quantum yields have been found in the decomposition of the gaseous compounds chlorine monoxide[7] and azomethane,[8] both of which are explosive.

Summary

Using monochromatic radiation of wave length λ1990, quantum yields in the decomposition of gaseous HN_3 have been measured over a pressure range of from 2 to 130 mm.; the quantum yield was found to be substantially constant over this range with the average value **3.0** ± 0.5 molecules of HN_3 decomposed per quantum absorbed. At pressures of from 0.06 to 0.5 mm., the rate of decomposition produced by the full radiation from an aluminum spark was found to be proportional to the HN_3 pressure, indicat-

CERIC SULFATE AS A VOLUMETRIC OXIDIZING AGENT. XI. THE OXIDATION OF ORGANIC ACIDS

BY H. H. WILLARD AND PHILENA YOUNG

RECEIVED AUGUST 10, 1929 PUBLISHED JANUARY 8, 1930

Introduction

The permanganate oxidation method for a number of organic acids[1] such as tartaric, malic, malonic, etc., is not entirely satisfactory, due to the fact that formic acid, which is one of the oxidation products, is, in turn, slowly oxidized by permanganate in acid solution. If a direct titration of any of these acids with standard permanganate in hot solution is attempted, the end-point is unsatisfactory, and if even a slight excess of standard permanganate is added, followed by excess of standard oxalic acid and back titration with permanganate, some formic acid is oxidized, the amount depending on such factors as concentration of the formic acid, amount of permanganate in excess and time of its action, temperature and acidity of solution. Therefore, even fairly accurate results can be obtained only when experimental conditions are closely controlled. To avoid the error caused by oxidation of formic acid, the complete oxidation of a number of these acids to carbon dioxide and water has been proposed, first in acid, then in alkaline solution, using standard permanganate, followed by addition of sulfuric acid, excess of standard oxalate and back titration with permanganate.

Hatcher and West[2] found that formic acid was an intermediate oxidation product in the oxidation of complex organic acids and that the rate of its oxidation by permanganate was inversely proportional to the hydrogen-ion concentration of the solution.

Benrath and Ruland[3] studied the velocity of reaction of ceric sulfate with a number of organic compounds. They were interested in determining the course of the reactions, however, rather than in an analytical method for these acids. They stated that sulfuric acid retarded the velocity of oxidation by ceric sulfate, and that a solution containing ceric

---

[1] Representative references are given under the individual acids. It is obvious, however, that space is not available for complete lists of oxidation methods for determining these acids. The authors have made no attempt to prepare such a bibliography, which would be beyond the scope of the present paper.

[2] Hatcher and West, *Trans. Roy. Soc.*, 21, 269 (1927).

[3] Benrath and Ruland, *Z. anorg. allgem. Chem.*, 114, 267 (1920).

sulfate and a large excess of formic acid, if kept at 100° for a day, showed no change in the ceric ion content, as determined colorimetrically.

The present authors have studied the oxidation of oxalic acid with ceric sulfate[4] and have based an accurate method for the standardization of ceric sulfate solutions on this reaction.

It seemed probable that ceric sulfate, if its action on formic acid was negligible, could be used with much greater accuracy and under a much wider range of experimental conditions, than could permanganate or other oxidizing agents to determine such acids as tartaric, malic, malonic, etc. In the experimental work which follows such is shown to be the case. Obviously quantitative data can be given for only a few representative acids but the cases listed below will serve to illustrate the possibilities of ceric sulfate as a volumetric oxidizing agent in the determination of organic acids.

Experimental

The ceric sulfate solution was prepared by the method described by the authors[5] from high-grade ceric oxide and was 0.5 M in sulfuric acid. It was standardized against sodium oxalate.[4] The ferrous sulfate solution was standardized electrometrically against standard ceric sulfate.[4] A silver chloride–platinum electrode system was used and a thermionic voltmeter, Type DP-2, from the General Electric Company.

Formic Acid, HCOOH.—In five experiments 15–50 cc. of very pure formic acid 0.1 N as a reducing agent was taken, then 20–60 cc. of sulfuric acid, sp. gr. 1.5, and 25 cc. of 0.1 N ceric sulfate. After diluting to 200 cc. the solution was held just below the boiling point for thirty or sixty minutes. The volume of ceric sulfate used varied from 0.03 cc. at the shorter time and low acidity to 0.21 cc. at the longer time and highest acidity. The average error of 0.12 cc. would correspond to 0.28 mg. of formic acid. Thus formic acid is not appreciably oxidized in hot acid solution by ceric sulfate, a result scarcely to be expected when one considers the ease with which it is oxidized by many oxidizing agents. Its presence as an oxidation product from other organic acids should cause no interference in oxidations with ceric sulfate.

Corrections of 0.03–0.05 cc. have been applied to the above figures, for it was found that in blank experiments in which formic acid was omitted the oxidizing power of ceric sulfate decreased to this extent. In previous experiments[5] using a reflux condenser no change whatever was observed, but in this work a beaker was used.

Acetic Acid, CH_3COOH.—Acetic acid distilled from chromic acid was diluted to a 0.1 *N* acid solution. Two 50-cc. samples of this, after dilu-

[4] Willard and Young, THIS JOURNAL, 50, 1322 (1928); see also Furman, *ibid.*, 50, 755 (1928).

[5] Willard and Young, *ibid.*, 51, 149 (1929).

tion with 20 cc. of sulfuric acid, sp. gr. 1.5, 25 cc. of ceric sulfate, 0.1020 N, and water to 200 cc., were heated to boiling and held just below the boiling point over a free flame for thirty and sixty minutes, respectively. After cooling and determining the excess ceric salt in the usual way, it was found that 0.05 cc. and 0.10 cc. of the ceric sulfate had been used up in the two experiments. Therefore, acetic acid is not oxidized in hot solution by ceric sulfate.

Tartaric Acid, HOOCCH(OH)CH(OH)COOH.—Mestrezat[6] added a slight excess of permanganate to a hot sulfuric acid solution containing tartaric acid, then an excess of standard oxalic acid, and determined the excess of the latter by back titration with standard permanganate. He gave as the reaction

$$H_2C_4H_4O_6 + 3O = 2HCOOH + 2CO_2 + H_2O \qquad (1)$$

but obtained in this method an oxygen equivalent of 6.86 instead of 6, due to slow oxidation of formic acid. To avoid this error he attempted the complete oxidation of tartaric acid, first in acid, then in alkaline medium, to carbon dioxide and water.

$$H_2C_4H_4O_6 + 5O = 4CO_2 + 3H_2O \qquad (2)$$

and obtained an oxygen equivalent of 9.80 instead of 10. A number of other oxidation methods for tartaric acid have been described.[7]

Benrath and Ruland[3] stated that the velocity of the reaction of tartaric acid with excess ceric sulfate was retarded by the presence of sulfuric acid (their work was carried out at 0 and 20°). This was, therefore, the first matter to be investigated.

Very pure potassium acid tartrate was recrystallized from water, dried at 100° for a short time and used to prepare a standard solution. The tartrate, checked further by titrating three 1-g. samples of it with 0.1 N sodium hydroxide which had been standardized against Bureau of Standards potassium acid phthalate, was found to be 99.91% pure.

Twenty-five cc. portions of potassium acid tartrate solution containing 0.06916 g. of $KHC_4H_4O_6$ or 0.05439 g. of $H_2C_4H_4O_6$ were diluted with water, sulfuric acid, sp. gr. 1.5 and 40 cc. of 0.1020 N ceric sulfate to 200 cc., heated to 90–95° and kept at this temperature on a low temperature hotplate for thirty minutes. The solutions were cooled to 30–35° and the excess ceric sulfate titrated electrometrically with standard ferrous sulfate.

With all factors but the acid concentration at time of oxidation held constant, the extent of oxidation of tartaric acid decreased at first and

[7] For example—iodimetric, Strebinger and Wolfram, *Oesterr. Chem.-Ztg.*, 26, 156 (1923); Cuny, *J. pharm. chim.*, [8] 3, 112 (1926); Pirrone, *Riv. ital. essenze e profumi*, 101 (1928)—dichromate, Taufel and Wagner, *Z. anal. Chem.*, 67, 16 (1925).

then increased to a constant value as the acid concentration was steadily increased. In the last four experiments in which the volume of sulfuric acid added varied from 30 to 60 cc., there was a deviation of 0.19 cc. of 0.1020 *N* ceric sulfate, which corresponds to 0.4 mg. of tartaric acid. In the following experiments, therefore, these conditions were used.

Measured volumes of a standard potassium acid tartrate solution (25 cc. = 0.06678 g. of $KHC_4H_4O_6$ or 0.05326 g. of $H_2C_4H_4O_6$) were taken, diluted with water, acid and 0.1020 N ceric sulfate to the volume indicated in Table I, and treated in the same way as the solutions for the experiments described above. The results obtained are shown in Table I.

TABLE I

THE OXIDATION OF TARTARIC ACID WITH CERIC SULFATE IN ACID SOLUTION

H_2SO_4 sp. gr. 1.5, before ox, cc.	Time of standing at 90–95°, min.	Vol. during ox., cc.	0.1020 *N* $Ce(SO_4)_2$ added, cc.	0.1 *N* $Ce(SO_4)_2$ used, cc.	$H_2C_4H_4O_6$ taken, g.	$H_2C_4H_4O_6$ found, g.
30	30	200	40	25.54	0.0533	0.0532
30	60	200	40	25.55	.0533	.0533
30	30	200	30	25.49	.0533	.0531
30	60	200	60	25.55	.0533	.0533
30	10	200	40	25.54	.0533	.0532
30	30	200	100	76.91	.1598	.1603
30	30	200	40	10.21	.0213	.0213
15	30	100	40	25.47	.0533	.0531
45	30	300	40	25.63	.0533	.0534

The amount of tartaric acid oxidized by 1 cc. of 0.1 N ceric sulfate is 0.002084 g. When this factor is used the values in the last column are obtained, the results agreeing very closely with those in the preceding column. Three other series of experiments similar to those in Table I were carried out, in which the sulfuric acid, sp. gr. 1.5, added before oxidation amounted in turn to 40, 50 and 60 cc. per 200 cc. of solution, and the results obtained were of the same degree of accuracy as those above. Thus it is seen that the amount of tartaric acid oxidized by 1 cc. of 0.1 N ceric sulfate remains constant over wide variations in acid concentration, excess of oxidizing agent and time of its action, volume of solution in which the oxidation is carried out and tartaric acid content. According to Table I, 1 mole of tartaric acid requires 7.2 equivalents of oxygen for oxidation; that is, the oxidation reaction, under the conditions used above, cannot be expressed by Equation 1.[8]

Succinic Acid, $HOOCCH_2CH_2COOH$.—Very pure succinic acid which had been recrystallized twice from nitric acid and once from water was used to prepare a 0.05 M solution. Twenty-five cc. portions of this so-

---

[8] After this paper had been submitted for publication, Berry [Analyst, 54, 46 (1929)] published some work in which he obtained an oxygen equivalent of 7.02 by the use of ceric sulfate, apparently by direct titration, a reaction too slow to be practicable.

lution were diluted with water, acid and 25 cc. of 0.1020 N ceric sulfate to 200 cc., and treated in the same way as the solutions for the experiments in Table I. The volume of ceric sulfate used varied from 0.06 cc. in half an hour to 0.17 cc. in two hours, indicating that succinic acid is not appreciably oxidized under these conditions.

Malonic Acid, $HOOCCH_2COOH$.—Malonic acid has been titrated directly in hot acid solution with permanganate,[9] the reaction being

$$H_2C_3H_2O_4 + 3O = H_2O + HCOOH + 2CO_2 \tag{3}$$

Later investigators[10] found the method very irregular, due to appreciable oxidation of formic acid, and developed an accurate procedure for malonic acid, based on its complete oxidation, first in acid, then in alkaline medium

$$H_2C_3H_2O_4 + 4O = 2H_2O + 3CO_2 \tag{4}$$

Pure malonic acid was recrystallized from ether and the first fraction of crystals used to prepare a standard solution. Titrations of three samples of this material with 0.1 N sodium hydroxide indicated a purity of 99.59%. Measured volumes of a standard solution (25 cc. = 0.04337 g. of $H_2C_3H_2O_4$) were diluted with water, 0.1020 N ceric sulfate and acid to the volume indicated in Table II, and treated in the same way as the solutions for the experiments with tartaric acid. With malonic acid it was important to add the ceric sulfate before the acid; otherwise, a slight error was introduced, due possibly to decomposition of the malonic acid by the sulfuric acid. The results obtained are shown in Table II.

[9] Durand, *Ann. chim.* anal., 8, 330 (1903).

[10] Cameron and McEwan, *Proc.* Chem. *Soc.*, 26, 144 (1910).

Thus, an average of 0.001563 g. of malonic acid is oxidized by 1 cc. of 0.1 *N* ceric sulfate. By the use of this factor the values in the last column are obtained. Experiments 1 to 5 show that the extent of oxidation of a given amount of malonic acid is constant in a solution containing 40–60 cc. of sulfuric acid, sp. gr. 1.5, per 200 cc.; Expts. 3 to 13 show that the results are accurate for a given concentration of malonic acid over wide variations in acid concentration, excess of oxidizing agent and time of its action, and volume of solution in which the oxidation is carried out; Expts. 14 to 17 show that the results become less accurate as the concentration of malonic acid is changed. Because of this effect, the approximate strength of the solution, if unknown, should be determined by a preliminary experiment, that volume which will contain 40–50 mg. of malonic acid taken for the final analyses and the oxidation carried out in a volume of 200 cc. These experiments show that 1 mole of malonic acid requires 6.66 equivalents of oxygen for oxidation.

Glycolic Acid, $CH_2(OH)COOH$.—The acid was purified by recrystallizing from ether, and the first fraction of crystals used to prepare a standard solution. Titrations of three samples of acid with 0.1 N sodium hydroxide indicated *a* purity of 99.75%. Preliminary experiments showed that glycolic acid was not as easily oxidized by ceric sulfate as tartaric or malonic acid, a steady increase in oxidation being evident over a five-hour period with solutions kept at 90–95°. Therefore, measured portions of the standard solution (25 cc. = 0.05131 g. of $HC_2H_3O_3$) were diluted with water, 0.1020 *N* ceric sulfate and acid to the volume indicated in Table III, heated to boiling, held just below the boiling point over a small flame for the time indicated, then cooled to 30–35° and titrated electrometrically with standard ferrous sulfate. The results are shown in Table III.

TABLE III

THE OXIDATION OF GLYCOLIC ACID WITH CERIC SULFATE IN ACID SOLUTIONS

9	60	60	300	50	25.13	.0513	.0483
10	60	60	300	75	26.95	.0513	.0518
11	40	60	200	75	26.93	.0513	.0518
12	60	60	200	75	26.75	.0513	.0515

The amount of glycolic acid oxidized by 1 cc. of 0.1 N ceric sulfate, according to these experiments, is 0.001923 *g.* Experiment 1 shows that the extent of oxidation of glycolic acid is not constant after contact with excess ceric sulfate for thirty minutes in hot solution and Expt. 9 that the excess of ceric sulfate used there is not sufficient for the larger volume of solution. The other experiments indicate that an accurate determination of glycolic acid may be made within a wide range of conditions. According to Table VI 1 mole of glycolic acid requires 3.95 equivalents of oxygen for oxidation, that is, the reaction may be

$$HC_2H_3O_3 + 2O = HCOOH + CO_2 + H2O \qquad (5)$$

Malic **Acid,** $HOOCCH_2CH(OH)COOH$.—Mestrezat[6] used procedures for malic acid similar to those developed for tartaric acid. By oxidation with permanganate in acid solution

$$H_2C_4H_4O_5 + 4O = 2HCOOH + 2CO_2 + H_2O \qquad (6)$$

he obtained an oxygen equivalent of 8.81 instead of 8, and by oxidation first in acid, and finally in alkaline solution

$$H_2C_4H_4O_5 + 6O = 4CO_2 + 3H_2O \qquad (7)$$

his oxygen equivalent was 11.40 instead of 12. Lange and Kline[11] did not obtain satisfactory results in titrating malic acid in hot solution with permanganate.

Malic acid was purified by dissolving in hot acetone, filtering and adding carbon tetrachloride to the hot solution and allowing the acid to crystallize on cooling. Three samples, dried at 100–110°, indicated a purity of 99.59% when titrated against 0.1 N sodium hydroxide. The treatment of measured portions of a standard solution of malic acid was similar to that described for the experiments in Table III. The volume at the time of oxidation was always 200 *cc.* Results obtained are given in Table IV.

Thus, 0.001449 g. of malic acid is oxidized by 1 cc. of 0.1 N ceric sulfate. Using this factor, the values in the last column are obtained. Experiments 1 to 5 show that the extent of oxidation of malic acid is constant in a solution containing 40–60 cc. of sulfuric acid, sp. gr. 1.5, per 200 cc.; Expts. 4 to 13 show that the results are accurate for a given concentration of malic acid over wide variations in acid concentration, excess of oxidizing agent and time of its action; Expts. 14 to 16 show that the results become less accurate as the concentration of malic acid is changed. With variations in the volume the results were not satisfactory. Therefore, it is necessary to determine the approximate concentration of the solution and to use a volume which will contain 40–60 mg. of malic acid, carrying out the oxidation in a volume of 200 cc. In these experiments 1 mole of malic acid requires 9.25 equivalents of oxygen for oxidation.

---

Citric Acid, $HOOCCH_2C(OH)COOHCH_2COOH$.—From a study of the oxidation of citric acid by permanganate, Wöhlk[12] found that these substances reacted with each other, with or without the addition of mineral acid. In a direct titration with permanganate in hot dilute sulfuric acid solution, he considered that acetone-dicarboxylic acid, a primary oxidation product, split up quickly into acetone and carbon dioxide, these being the chief products of the oxidation. In a secondary oxidation reaction, the acetone was further split up to some extent into acetic and formic acids.

$$H_3C_6H_5O_7 + O = C_3H_6O + 3CO_2 + H_2O \qquad (8)$$

$$C_3H_6O + 3O = HC_2H_3O_2 + HCOOH \qquad (9)$$

Pratt's method[13] for citric acid, depending upon its fractional oxidation by permanganate to acetone, removal of the acetone as fast as formed by distillation, formation of an insoluble mercury–acetone complex and the weighing of this precipitate, has been modified by Willaman[14] to give more satisfactory results. Cuny[7] has described an iodimetric method for citric acid, complete oxidation to carbon dioxide being effected.

$$5H_3C_6H_5O_7\cdot H_2O + 9I_2O_5 = 9I_2 + 30CO_2 + 25H_2O \qquad (10)$$

A solution of citric acid was prepared from pure material and standardized by titrating three 100-cc. samples with 0.1 N sodium hydroxide. The treatment of measured portions of this standard acid solution (25

---

15	25	30	110	60	42.38	.0500	.0513
16	75	30	300	75	40.59	.0500	.0492

Thus, 0.001211 g. of citric acid is oxidized by 1 cc. of 0.1 N ceric sulfate. Experiment 1 indicates that there was not enough sulfuric acid added. The results are somewhat less accurate in Expts. 12 to 14, as the citric acid content is changed and in Expts. 15–16 the volume is changed. The other experiments indicate that an accurate determination of citric acid may be made within a wide range of conditions. To use the conversion factor given above, the approximate strength of the solution if unknown should be determined by a preliminary experiment, that volume which will contain 40–60 mg. of citric acid taken for the final analyses, and the oxidation carried out in a volume of 200 cc. According to Table V, 1 mole of citric acid requires 15.85 equivalents of oxygen for oxidation, an indication that the oxidation of the acetone is very extensive.

Maleic and Fumaric Acids, HOOCCH=CHCOOH.—Lange and Kline[11] stated that maleic or fumaric acid could be titrated with permanganate in hot acid solution and assumed that the reaction was

$$H_2C_4H_2O_4 + 5O = 3CO_2 + HCOOH + H_2O \qquad (11)$$

Their results were not altogether satisfactory and they did not recommend the method. Sabalitschka and Tietz[15] reported that accurate results could be obtained if excess permanganate was added to the hot acid solution, followed by oxalate, and the excess of the latter determined by titration with permanganate. They gave as the reaction

$$H_2C_4H_2O_4 + 30O = 20CO_2 + 10H_2O \qquad (12)$$

---

[15] Sabalitschka and Tietz, *Continental Met. and Chem. Eng.*, 2, 232 (1927).

It was thought that both of these acids would be easily oxidized by ceric sulfate, but such did not prove to be the case. Several 31-mg. samples of each acid, in volumes of 200 cc. containing 20–60 cc. of sulfuric acid, sp. gr. 1.5, and 50 cc. of 0.1020 N ceric sulfate, reacted at 95° with 0.68–0.98 cc. (fumaric acid) or 0.35–0.61 cc. (maleic acid) of 0.1 *N* ceric sulfate in a half hour. In an hour with a 62-mg. sample of either acid, less than 2 cc. of 0.1 *N* ceric sulfate was used.

Benzoic Acid, C_6H_5COOH.—Benzoic acid, though resistant in general to oxidizing agents, was oxidized to a considerable extent by ceric sulfate. For example, a 0.0987-g. sample of the acid was dissolved, diluted with water, 60 cc. of sulfuric acid, sp. gr. 1.5, and 50 cc. of 0.1020 *N* ceric sulfate to 200 cc., heated to boiling and kept just below the boiling point for two hours. After cooling the solution and determining the excess ceric sulfate in the usual way, it was found that 29.10 cc. of 0.1 *N* ceric sulfate had been used for oxidation. Another sample of the same weight was dissolved, diluted with 40 cc. of sulfuric acid, sp. gr. 1.5, and 100 cc. of 0.1020 N ceric sulfate to 200 cc., and held just below the boiling point for three hours. In this case 39.63 cc. of 0.1 N ceric sulfate was used for oxidation. Other experiments covering a wide range of conditions indicated that the extent of oxidation of benzoic acid was not definite.

Phthalic **Acid,** *o*-$C_6H_4(COOH)_2$.—Several 43-mg. samples of phthalic acid, in volumes of 200 cc. containing 30–50 cc. of sulfuric acid, sp. gr. 1.5, and 25 cc. of 0.1020 *N* ceric sulfate, reacted at 95° with only 1.49–1.98 cc. of 0.1 *N* ceric sulfate in a period of one hour. The oxidation of phthalic acid by ceric sulfate was, therefore, very slight.

Salicylic **Acid,** $C_6H_4(OH)COOH$.—Several 19-mg. samples of salicylic acid, in volumes of 200 cc. containing 20–60 cc. of sulfuric acid, sp. gr. 1.5, and 50 cc. of 0.1020 *N* ceric sulfate, reacted at 95° with 28.50–32.18 cc. of 0.1 N ceric sulfate over periods of one-half to two hours. The oxidation of salicylic acid was very extensive but not constant.

Discussion

These results prove that the oxidizing action of ceric sulfate on organic materials may be very different from that of potassium permanganate or chromic acid. For this reason ceric sulfate may be of use in certain organic oxidations where permanganate or chromic acid either do not act or do not bring about the reaction desired—possibly, for example, in some oxidations to determine structure. The fact that formic acid, which is an aldehyde as well as an acid, is not oxidized by ceric salt but is slowly attacked by permanganate suggests the possibility of oxidizing alcohols quantitatively to aldehydes with ceric salt. The authors intend to investigate this matter as well as the action of ceric sulfate on other types of organic compounds. Preliminary experiments indicate that some organic substances can be oxidized by direct titration with ceric sulfate.

Though none of the acids listed above can compare in accuracy with oxalic acid (used as sodium oxalate) as primary standards in oxidimetry reactions, a number of them have been suggested as primary standards in acidimetry reactions, notably maleic, fumaric, malic and tartaric in the form of potassium acid tartrate. The authors found potassium acid tartrate to be by far the most satisfactory of these four. It is obtained in very pure form by one recrystallization, and compares favorably in accuracy with potassium acid phthalate, an accepted primary standard in acidimetry.

Summary

1. Formic, acetic, succinic, fumaric and maleic acids are not oxidized by ceric sulfate in hot sulfuric acid solution.

2. Tartaric, malonic, malic, glycolic and citric acids are oxidized under the same conditions, the products being, usually, formic acid and carbon dioxide. Because the formic acid is not oxidized by ceric sulfate, it has been possible to develop accurate analytical procedures for each of this last group of acids, based on their oxidation in hot sulfuric acid solution by excess standard ceric sulfate and titration of the excess with standard ferrous sulfate.

3. Benzoic, phthalic and salicylic acids are oxidized to a variable extent by ceric sulfate in hot sulfuric acid solution.

4. Attention is called to the possibility of using ceric sulfate in certain organic oxidations where the usual reagents, such as permanganate or dichromate, either do not act or do not produce the result desired.

PYROPHORIC IRON. I. PREPARATION AND PROPERTIES[1]

BY T. G. FINZEL

RECEIVED AUGUST 16, 1929 PUBLISHED JANUARY 8, 1930

The pyrophoric property of properly prepared finely divided iron reacting with air at room temperatures is a well-known phenomenon.[2] It has been definitely established, moreover, that such material becomes non-pyrophoric when subjected to a high temperature.

---

[1] The subject of this research was suggested by Professor James H. Walton and the investigation was conducted under his direction. (Manuscript first received August 30, 1928.)

[2] Magnus, *Pogg. Ann.*, 3, 81 (1825); Moissan, *Ann. chim. phys.*, [5] *21*, 199–256 (1880); Birnie, *Rec. trao. chim.*, *2*, 273–294 (1883); Smits, Kettner and de Gee, *Verslag. Akad. Wetenschappen*, Amsterdam, [II] *16*, 999 (1913); Tammann and Nikitin, *Z. anorg. allgem. Chem.*, *135*, 201–204 (1924).

Pyrophoric iron has been prepared in many ways, among which may be enumerated the thermal decomposition of ferrous oxalate, reduction of ferrous oxalate by hydrogen, reduction of ferric oxide or a mixture of ferric oxide and aluminum oxide by either hydrogen or carbon monoxide and the reduction of ferrous oxide or carbonate by hydrogen. In most cases definite conditions for the preparation of the pyrophoric materials are not mentioned in the literature nor are the pyrophoric products properly identified. Consequently the term pyrophoric iron includes any pyrophoric ferrous material containing any amount of metallic iron. The references on the preparation of pyrophoric iron indicate that such factors as temperature, length of time of heating or reduction and the condition of the starting material are exceedingly important in obtaining concordant results. To explain pyrophoric action and the inactivation of pyrophoric materials, several theories have been proposed, among which may be named Magnus'[2] theory of fineness of division; that of Moissan,[2] who believed that, in general, so-called pyrophoric iron owes its pyrophoric activity to finely divided FeO; the metastable equilibrium theory of Smits;[2] and the surface theory of Tammann and Nikitin.[2]

According to Hofmann,[3] the smaller the oxide particle, the greater will be the rate and the extent of reduction, and the greater will be the tendency for the iron particles to adhere to each other so as to diminish the surface. If pyrophoric activity is dependent upon the extent of the surface of the individual particles, the degree of dispersion of the iron oxide from which the pyrophoric iron is to be prepared should have an effect on the pyrophoric activity and also on the inactivation of the resulting iron.

To prepare the true metallic pyrophoric iron in the highest state of purity, it is advisable to avoid all organic compounds. Oxalates or carbonates upon heating or reduction tend to form finely divided carbon. Even carbon dioxide will react with finely divided iron at 500° as shown by Herschkowitsch,[4]

The present paper deals chiefly with the preparation of pyrophoric iron with the highest possible metallic iron content, the effect of the condition of the starting material and the effect of various gases on the inactivation of pyrophoric iron.

Experimental

Ferric oxide precipitated from a ferric nitrate solution by ammonia was used as a starting material in this work. Ferric nitrate was chosen in preference to ferric chloride as it was found that chlorides inhibit the formation of pyrophoric iron while the oxides of nitrogen apparently do not. It has been shown by von Weimarn[5] that if substances

[5] Von Weimarn, *Chem. Rev.*, 2, 228 (1925).

are precipitated from solutions of different concentrations, a difference in the degree of dispersion of the precipitate will result. Thus, in two samples of ferric oxide, the degree of dispersion should be greater in the one precipitated from the more concentrated solution of ferric nitrate. Ferric oxide as a colloidal sol would also be in a state of high dispersion. With this principle in mind, the ferric oxide used in this work was prepared in three ways. *Ferric oxide A* was prepared by precipitation from a hot ferric nitrate solution containing 100 g. of $Fe(NO_3)_3 \cdot 9H_2O$ per liter of water, using an excess of NH_4OH (sp. gr. 0.90). The oxide was freed from salts and ammonia by decantation and washing, dried at 110–120° and ground to a fine powder in an agate mortar. *Ferric oxide* B was prepared in a manner similar to the preparation of oxide A with the exception that the concentration of the ferric nitrate solution was 25 g. per liter. *Ferric oxide C* was obtained by hydrolysis of 10 g. of ferric nitrate per liter of boiling water, so as to produce a colloidal sol. It was subsequently dialyzed in collodion bags at 90–95° for approximately one week, after which time the sol was almost free from the nitrate ion. This method for preparation of the sol is similar to that described by Sorum.[6] The sol was slowly evaporated to dryness in an electric oven held at about 140". Oxides A-11, B-II, etc., represent different samples of the oxides prepared in the same manner as A and B, respectively.

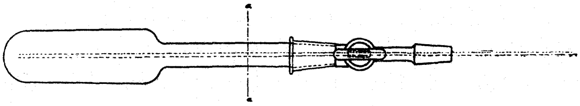

Fig. 1.—Reduction tube.

Preparation of Pyrophoric Iron.—The pyrophoric iron was prepared by hydrogen reduction of approximately two grams of iron oxide placed either in a drawn-out test-tube or in a container similar to that shown in Fig. 1. The latter consisted of a tube fitted with a stopcock and ground-glass joints which permitted it to be attached to a high vacuum apparatus for subsequent degassing of the iron. The hydrogen, previously carefully purified by passage through hot copper, soda lime and phosphorus pentoxide, was passed into the tube through a small capillary. In each case reduction was continued for three hours at 500°, using a gas flow of approximately 80 cc. per minute.

Inactivation of Pyrophoric Iron by Heating in Hydrogen, Nitrogen or Helium.—It is known that pyrophoric iron becomes inactive when heated ior an extended length of time. Consequently, experiments were carried out to determine the effect of the following factors upon the pyrophoric property of iron: the length of time of heating, the method of preparation of the oxide from which the iron was reduced and the gaseous medium in which the pyrophoric iron was heated. Samples of pyrophoric iron prepared in drawn-out test-tubes as described above were placed in a furnace held at 600° for various lengths of time, after which the tubes were removed from the furnace and allowed to cool, hydrogen passing through the capsules continually. When cool, the contents of the tubes were thrown into the air and their pyrophoric or non-pyrophoric property noted.

In preparing the samples of iron to be heated in nitrogen or helium, all samples were reduced in the manner described above. After reduction, these samples were degassed at 500° for approximately one hour until the pressure dropped to at least 5×10^{-5} mm. of mercury. The

---

bulb was then filled with dry oxygen-free nitrogen or helium at approximately atmospheric pressure and heated for various lengths of time as indicated in Table I.

TABLE I

EFFECT OF HEATING PYROPHORIC IRON IN HYDROGEN, NITROGEN OR HELIUM

Oxide sample	Condition	Time of heating, hours			
		H_2 (600°)	N_2(600°)	He (600°)	He (625°)
A	Pyrophoric	1.5	6	70	..
	Non-pyrophoric	2.5–3	..	156	42
A-I1	Pyro.	1	5–9	144	..
	Non-pyro.	3	11	...	..
B	Pyro.	12.5	45	...	..
	Non-pyro.	17	..	...	..
13-11	Pyro.	....	..	73.5	..
	Non-pyro.	....	..	160	..
B-III	Pyro.	....	..	...	48.5
	Non-pyro.	....	..	...	..
C	Non-pyro.	1	1	1	1

In every case the pyrophoric iron was black while the non-pyrophoric form was gray-black or decidedly gray From the results obtained by heating in nitrogen and hydrogen, it is evident that iron C loses its pyrophoric property the most rapidly, A and B following next in order. The time for inactivation was greater for heating in nitrogen or helium than in pure hydrogen. Helium required the greatest length of time.

The difference between Samples A, B and C is one of preparation or, as previously pointed out, one of dispersion. It thus appears that the oxide of the lowest degree of dispersion yields pyrophoric iron which is the most difficult to inactivate. As previously mentioned, Hofmann[3] found that the smaller the oxide particles the greater will be the extent of reduction and the greater will be the tendency for the iron covered oxide particles to adhere to each other so as to diminish the total surface. It thus appears that inactivation of pyrophoric iron consists in a decrease of the total surface. This is also in accord with Tammann's views. From Table I, it can also be seen that iron from any particular oxide sample can be more easily inactivated in hydrogen than in nitrogen or helium, the latter taking the longest time. One possible explanation for this difference is that at 600° hydrogen and nitrogen are absorbed and combine to form hydrides and nitrides with the active iron, thus causing it to become inactive, while helium is non-reactive with the iron and consequently allows it to remain pyrophoric for a greater length of time. However, it is known that iron reduced at 500° contains an abundance of absorbed hydrogen and is still pyrophoric; also, iron heated at **500** or 600° gives the a-iron x-ray diagram with no indication of swelling of crystal lattice or evidence for any new lines. Inasmuch as oxide B has the lowest degree of dispersion on the basis of von Weimarn's theory and is also the most difficult to inactivate, it might seem probable that the pyrophoric iron particle contains a small core of oxide which hinders recrystallization of the iron. Heating in hydrogen at a temperature higher than its reduction temperature (500") should then cause further reduction and also facilitate the removal of the water vapor thus formed so as to increase coalescence of the iron atoms. The larger the oxide particle, the larger the residual oxide core and consequently the longer will be the time necessary for inactivation. On this basis, however, it seems impossible to explain the large difference found in the inactivation in nitrogen and helium.

Analysis of the Samples of Iron.—The metallic iron content of the pyrophoric and non-pyrophoric samples of iron was determined by measuring the amount of hydrogen liberated from dilute sulfuric acid solution. Approximately 0.4 g. of iron was prepared by reducing the desired oxide in hydrogen in a small tared capsule, the neck of which was slightly constricted. After reduction, the capillary, through which hydrogen was introduced into the capsule, was withdrawn and the neck of the capsule quickly sealed off while still hot, thus causing a partial vacuum upon cooling. The weight of the iron was obtained as the difference between the gross and tare weights of the capsule. The determination was carried out by breaking the capsule under pure water, which was later acidified with sulfuric acid. The hydrogen liberated was collected and measured in a buret, reduced to standard conditions of temperature and pressure and the metallic iron equivalent calculated. To check the accuracy of the results a determination was made on a sample of pure iron wire the analysis of which was known. The results are given in Table II.

TABLE II

METALLIC IRON CONTENT OF PYROPHORIC AND NON-PYROPHORIC IRON

Oxide reduced	Temp., °C.	Time, hrs.	Yield, %	Condition
B	500	3	98.5	Pyrophoric
B	500	14	98.4	Pyrophoric
B (Constantly agitated)	500	10.5	99.1	Pyrophoric
B	400	24	97.6	Pyrophoric
C	500	12.5	99.0	Pyrophoric
A	625	4	98.5	Non-pyrophoric
Standard iron wire, 99.7% Fe	...	...	99.4	....

From these results it is evident that with the sample used reduction at 500° in hydrogen for three hours is practically the optimum condition for the preparation of pyrophoric iron. It is further shown that there is no essential difference in the iron content of the various samples reduced at 500" and above, whether they be pyrophoric or not.

Microscopic examination of the pyrophoric and non-pyrophoric forms of the most easily inactivated iron, Sample C, was carried out by breaking sealed capsules of both forms of iron under paraffin oil and examining the suspension. The difference in the samples (see Figs. 2 and 3) is in the sizes of the respective clusters or lumps of iron, suggesting that adhesional forces were at play during the heating of the iron. Both photographs are of the same magnification, the distance between the two small lines in Fig. 3 representing 0.1 mm.

Fig. 2.—Pyrophoric iron.

X-Ray examination of pyrophoric iron prepared by reducing oxide C at 400° for twenty-four hours in a special tube (Fig. 4) to prevent entrance of air was carried out as follows: the reduction tube (Fig. 4) was constructed so that it could be sealed off at a-a and b-b after reducing the oxide in the bulb. The active iron was shaken into the capillary, which was then sealed off at c-c. The diffraction lines showed the iron to be of the a-variety with the same pattern as the non-pyrophoric iron which was heated to 650°. Those due to the pyrophoric material appeared slightly more diffused than those shown by iron heated at 650° in hydrogen, indicating a smaller particle size for the pyrophoric iron. Similar results have been obtained by Wyckoff and Crittenden[7] in their studies of ammonia catalysts.

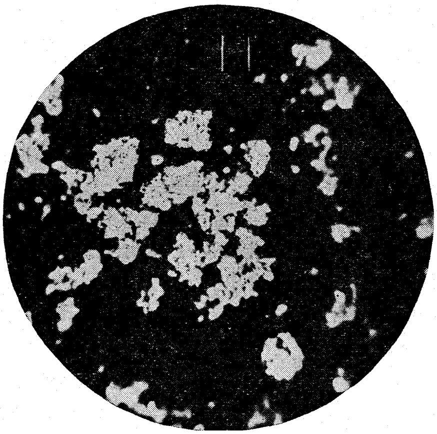

Fig. 3.—Non-pyrophoric iron.

Method for Determining the Degree of **Pyrophoric** Activity.—A measure of the relative pyrophoric activities of the samples of iron was obtained by determining the limiting concentration of oxygen in an oxygen–nitrogen mixture which would just cause pyrophoric action when a sample of the iron was dropped through the gaseous mixture. A gaseous mixture of the desired composition was prepared in a glass tube **30** cm. in length, one end of which was fitted with a rubber stopper through which passed a glass tube. The sealed capsule containing the prepared sample of iron was attached to this glass tube by means of a tough

[7] Wyckoff and Crittenden, THIS JOURNAL, 47, 2866 (1925).

rubber tube which could be squeezed with a pair of pliers, thereby breaking the neck of the capsule and allowing the iron to drop through the gaseous mixture. The observations were made in the dark so that the slightest indications of pyrophoric activity could be noticed. One-gram samples of iron were prepared by hydrogen reduction at 500°, the reduction being carried out until 1.0 mg. or less of water was liberated per hour. As a check on the preparation of the sample, the iron after being dropped through the tube, was thrown into the air. In all cases, the samples which failed to ignite in the prepared oxygen–nitrogen mixture afterward took fire when dropped into the air. The results obtained by this method are given in Table III.

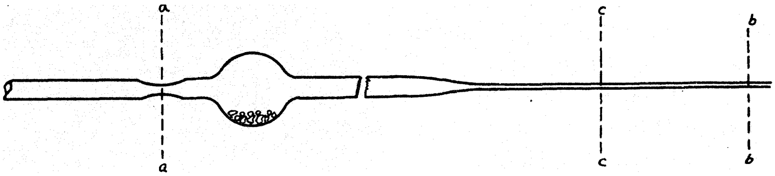

Fig. 4.—Preparation tube for x-ray sample.

TABLE III

LIMITING CONCENTRATION OF OXYGEN IN WHICH PYROPHORIC IRON IS ACTIVE

Oxide sample	A-I1			B			C		
Oxygen concn., %	5	3	5	10	3	1	9.4	5	3
Condition	Pyro.	Non-pyro.	Pyro.	Pyro.	Pyro	Non-pyro.	Pyro.	Non-pyro.	Non-pyro.

From these data, it is evident that the limiting oxygen concentrations for the various samples of iron are as follows: C, between 5 and 9.4%; A, between 3 and 5%; B, between 1 and 3%. This would put the oxides in the order of their increasing pyrophoric activity as C, A, B, an order which is just the reverse of what one would predict from a consideration of a method for preparation of the three oxides. The colloidal oxide, being the most finely divided, should yield the iron having the greatest surface per unit mass, the surface factor, according to Tammann being the criterion for pyrophoric activity. However, referring to the results obtained in heating the pyrophoric iron in hydrogen and also in nitrogen, it will be seen that C became non-pyrophoric in the shortest length of time, A followed and B remained active the longest, probably due to the degree of incompleteness of reduction of the oxides. It is very probable that the inactivation process caused by adhesion or recrystallization is operative at temperatures as low as 500°, the iron containing the most residual oxide remaining pyrophoric the greatest length of time and also being the most pyrophoric when tested by this method. In the following paper it is shown that the adsorptive capacities of the samples of iron for ammonia and carbon dioxide also increase in the order C, A, B.

Reaction of Pyrophoric Iron at −78° and with Dried Air.—A sample of oxide B was reduced in a capsule at 500° in hydrogen for three hours, after which time the neck of the capsule was sealed. The sample was allowed to drop into a glass tube 18 inches long, the sample, tube and air within the tube being cooled to −78° for one-half hour by means of carbon dioxide, snow and ether. A trigger was placed in a side-arm of the 18-inch tube to break the capsule and allow the iron to drop through the cold air. No precautions were taken to prevent the diffusion of the carbon dioxide through the side-arm and into the tube. The iron falling through the tube was exceedingly pyrophoric, heating the air in the tube to such an extent that some of the finely divided iron was blown out of the side-arm.

It was also found that properly prepared iron was pyrophoric when allowed to drop through air dried for two to three months over phosphorus pentoxide. The iron samples were prepared from oxide A, reduced at 500° by hydrogen. The capsules containing the iron were evacuated to 10^{-3} mm. pressure at 500°, filled with nitrogen and sealed.

Summary

1. Pyrophoric iron can best be prepared by reducing precipitated ferric oxide by hydrogen at 500°.
2. Ferric nitrate is a suitable starting material for the preparation of the ferric oxide. Chlorides are to be avoided as they destroy the pyrophoric property of the iron.
3. For pyrophoric iron prepared from a definite sample of oxide, inactivation is dependent not only upon the temperature and time of heating but also upon the gaseous medium in which it is heated.
4. Accepting von Weimarn's precipitation law, the time necessary for inactivation of pyrophoric iron is dependent upon the degree of dispersion of the oxide from which it is reduced.
5. Iron was found to be pyrophoric in dried air and also in air cooled to −78°.
6. A method was devised for the determination of the degree of pyrophoric activity of iron.

PROPERTIES OF PYROPHORIC IRON. II. ADSORPTION OF CARBON DIOXIDE AND AMMONIA AND THE USE OF PYROPHORIC IRON IN THE AMMONIA SYNTHESIS[1]

BY T. G. FINZEL

RECEIVED AUGUST 16, 1929 PUBLISHED JANUARY 8, 1930

In a previous paper,[2] it was shown that the pyrophoric activity of iron prepared by the reduction of ferric oxide in hydrogen was influenced by the method of preparation of the oxide. The greater the degree of dispersion of the ferric oxide, the more easily was pyrophoric iron converted into the non-pyrophoric form when heated to a temperature higher than the reduction temperature.

This investigation is an attempt to find any relationship between the differences in the ease of inactivation of the three samples of pyrophoric iron and their adsorptive and catalytic properties.

Materials for Adsorption

Gases.—Carbon dioxide was prepared by dropping sulfuric acid into a saturated solution of sodium bicarbonate, previously boiled to remove any dissolved air. The gas was dried by concentrated sulfuric acid and phosphorus pentoxide. Pure ammonia was prepared by heating a concentrated solution of ammonium hydroxide, passing the gas through a strongly alkaline solution of pyrogallol and finally over soda lime and flaked caustic soda. Nitrogen, used to determine the free volume of the adsorption bulb, was obtained from a cylinder of the gas. It was passed through concentrated sulfuric acid, over hot copper and finally dried over phosphorus pentoxide. Hydrogen for the reduction of ferric oxide was commercial gas produced by the electrolysis of caustic soda solution. It was purified by passing through concentrated sulfuric acid, soda lime, hot copper, soda lime and phosphorus pentoxide in the order named.

Iron Oxides.—Ferric oxides A and B were precipitated from a ferric nitrate solution by ammonium hydroxide, while ferric oxide C was prepared from a colloidal sol, using ferric nitrate and in one case ferric chloride as a starting material. The preparation of these oxides has been described in Part I.[2]

Preparation of the Iron for Adsorption

The reduction of the iron oxide was carried out in the adsorption bulb, illustrated in Fig. 1 of the previous paper.[2] In all cases pyrophoric iron was prepared by hydrogen reduction at 500°, the hydrogen being passed into the bulb by means of a small capillary tube at a rate approximating 80 cc. per minute. During the reduction the bulb was removed several

---

[1] The work in this paper and Part I is from the thesis presented in partial fulfilment of the requirements for the degree of Doctor of Philosophy at the University of Wisconsin. The subject of this research was suggested by Professor James H. Walton and the investigation was carried out under his direction. (Manuscript first received November **13, 1928.)**

[2] Finzel, THIS JOURNAL, 52, **142 (1930).**

times from the furnace and the material shaken to break up any lumps of material formed during the early stages of the reduction. After about ten hours of reduction a T-tube to which was connected a U-tube containing phosphorus pentoxide was attached to the adsorption bulb. Reduction was stopped when the gain in weight of this U-tube showed that the water liberation had dropped to approximately 0.5 to 1.5 mg. per hour. The iron was degassed at 500° by means of a mercury vapor and oil pump until the pressure dropped to at least 5×10^{-5} mm. pressure. Three to five hours was the usual time for degassing, depending upon the kind of iron in the bulb.

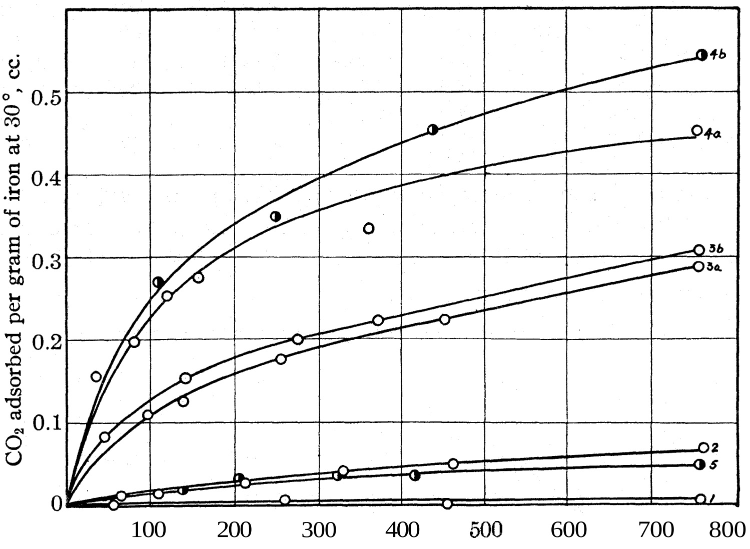

Fig. 1.—Adsorption of carbon dioxide by pyrophoric iron.

Adsorption Results.—The free volume of the adsorption bulb was determined by two methods; in the first the volume of the iron in the bulb was subtracted from the volume of the empty bulb while in the second the volume of nitrogen necessary to fill the bulb containing the iron was determined. Since it was found that the two methods agreed within experimental error, the former was generally used. The adsorptive capacities of the pyrophoric and non-pyrophoric iron samples for carbon dioxide and ammonia at the highest equilibrium pressure and at 30° are given in Table I, the complete isotherms being illustrated graphically in Figs. 1 and 2.

By comparing Curves 2 and 5 (Fig. 1), it is evident that the pyrophoric iron reduced at 500° from oxide C adsorbed less carbon dioxide than the non-pyrophoric iron reduced at 625° from oxide A. It is evident that

TABLE I

ADSORPTION OF CARBON DIOXIDE AND AMMONIA BY PYROPHORIC AND NON-PYROPHORIC IRON AT 30°

adsorption of this particular gas is not a criterion for judging pyrophoric activity. For the pyrophoric samples, adsorption of both carbon dioxide and ammonia increased in the order C, A, B, the last showing the largest adsorption in each case.

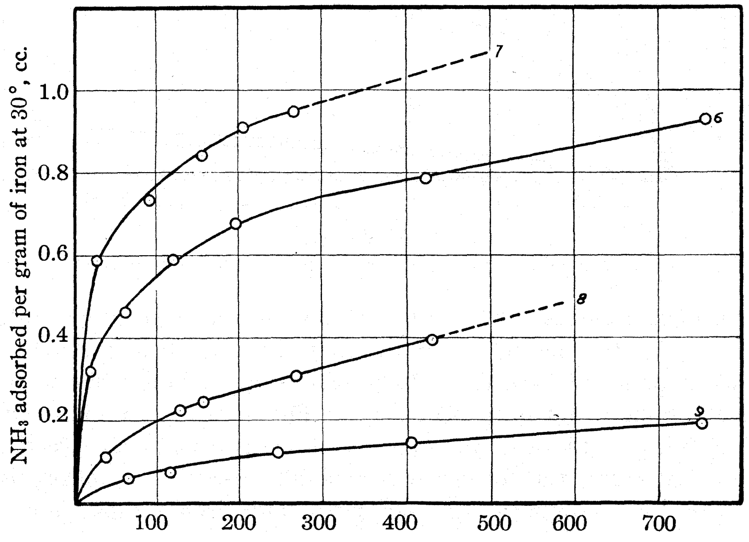

Fig. 2.—Adsorption of ammonia by pyrophoric iron.

It was previously[2] shown that samples of pyrophoric iron reduced from these oxides become non-pyrophoric when heated in nitrogen, hydrogen or helium at 600°. It was found that C became inactive the most rapidly, A next, B taking the longest time. On the basis of von Weimarn's precipitation rule, oxides C and A should have a greater degree of dispersion than oxide B. It was shown by Hofmann[3] that the extent of reduction of iron oxide depends among other factors upon the particle size of the oxide. From these considerations it seemed probable that the reason for the order of pyrophoric inactivation of the iron samples lay in the degree of incomplete reduction of the oxide, so that each particle or cluster contained a residual oxide core varying with the size of the original oxide particle. On this basis it seemed that pyrophoric iron B contained the largest oxide core while C contained the smallest. The definite order for adsorption of carbon dioxide and ammonia could thus be attributed to small amounts of oxide remaining as a core in the iron particles. Taylor and Burns[4] found that finely divided iron reduced from the calcined nitrate for twenty-six hours at 450° in hydrogen adsorbed only 0.25 cc. of carbon dioxide per cubic centimeter of iron. Nikitin[5] reports nearly 4 cc. of carbon dioxide adsorbed per gram of pyrophoric iron at 18° and 732 mm. Since the latter investigator prepared this iron by reducing ferrous carbonate in hydrogen at 515°, this high adsorption value may be attributed to residual oxide or carbon formed by the reaction of the carbon dioxide and iron. Pyrophoric iron produced from the carbonate, moreover, may contain more elementary spaces or fine capillaries[6] especially suitable for carbon dioxide adsorption.

Ammonia Synthesis

Since the iron prepared from oxide C was found to be very sensitive toward heating, becoming thereby non-pyrophoric very readily, and was also found to be inactive with' respect to adsorption, it was of especial interest to investigate the behavior of this particular iron in the synthesis of ammonia.

Materials

Gases.—Nitrogen and hydrogen were prepared by the thermal decomposition of ammonia by a method somewhat similar to that described by Larson, Newton and Hawkins,[7] the ammonia being passed over steel wool in a porcelain tube held at a red heat. The gases were purified by the method recommended by Larson and his co-workers.

Ferric Oxide B.—In addition to oxide B, previously described, "Oxide B-dialyzed" was prepared by precipitating oxide B, washing partially, dialyzing the precipitate in collodion bags for one week at 90–95° and finally drying.

Ferric Oxide C.—Together with the colloidal oxide C prepared by the method of Sorum[8] by hydrolyzing ferric nitrate and dialyzing the oxide so formed in collodion

bags, an oxide C was dialyzed in parchment bags. Oxide C *ex* $Fe(NO_3)_3$–$Al(NO_3)_3$ was also prepared by hydrolyzing 10 g. of ferric nitrate and 1 g, of aluminum nitrate in boiling water, dialyzing in collodion bags and treating subsequently like oxide C. The ignited oxide C *ex* $Fe(NO_3)_3$–$Al(NO_3)_3$ contained 95.4% of Fe_2O_3, the remainder being Al_2O_3. All oxides were ground to 5- to 12-mesh.

Method and Results.—The catalyst was prepared by reducing the desired iron oxide in the hydrogen–nitrogen mixture at 400–450° at one atmosphere pressure. The type of catalyst tube used was similar to that described by Almquist and Black.[9] All experiments were carried out at atmospheric pressure with 5000, 11,000 and 16,000 space velocities, 2 cc. of catalyst being used. The ammonia was absorbed in 0.1 N sulfuric acid and the excess acid titrated with 0.1 N sodium hydroxide, using methyl orange as an indicator.

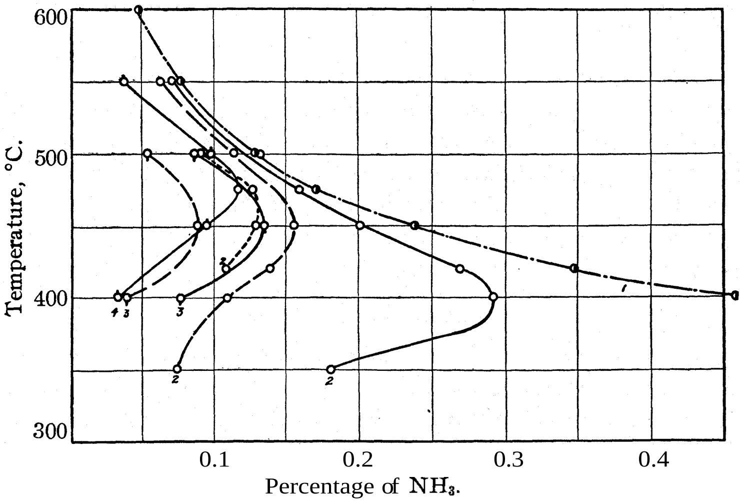

Fig. 3.—Curve **1**, equilibrium; **2**, oxide B; **3**, oxide B dialyzed; **4**, C *ex* $Fe(NO_3)_3 \cdot Al(NO_3)_3$: 5000 S. V.————, 11,000 S. V.— — —, 16,000 S. V.– – – – – –.

Oxide C was reduced at 400° for thirty-six hours and finally at 500°. This oxide proved to be absolutely worthless as a catalyst, no ammonia being formed. Upon examining the reduced oxide microscopically the granules of iron appeared not in the least porous but had a distinctly metallic luster, indistinguishable under a low power microscope from a piece of white cast iron. From the appearance of the iron, an extremely rapid recrystallization must have taken place; however, some poison from the collodion bags may have caused its inertness as a catalyst. To test the probability of poisoning, oxide B and oxide B-dialyzed were used as catalysts. The results obtained are presented in Fig. 3, showing that a cer-

---

[9] Almquist and Black, This Journal, 48, **2814** (1926).

tain amount of inactivation was caused by dialysis since the curves for B-dialyzed lie a greater distance from the theoretical curve than those for catalyst B. With the view that collodion may have had a poisoning effect on iron C, oxide C was dialyzed in parchment bags. Here again no ammonia was produced, the iron after reduction having a decidedly metallic luster. If recrystallization forces caused the inertness of iron C, the incorporation of an oxide of the Al_2O_3 type in the catalyst should prevent such an occurrence. Wyckoff and Crittenden[10] have shown that such an oxide acts as a "guard," inhibiting sintering of the iron. Such a mixed oxide, C ex $Fe(NO_3)_3$–$Al(NO_3)_3$, was prepared and reduced in the same manner as oxide C. The mixture showed catalytic properties although it was not as active as iron B. The results are given in Table II and shown graphically in Fig. 3. After being in use for more than a day, the catalyst had a bulky black appearance in contrast to the metallic gray of iron C. The material was decidedly pyrophoric when thrown into the air. These experiments, together with the fact that pyrophoric iron C is easily caused to become non-pyrophoric upon heating, point to the fact that the sensitivity and ease of inactivation of iron C is due to extremely rapid recrystallization. The superior catalytic property of iron B could be attributed to the lower degree of dispersion of oxide B. Oxide B would be more difficultly reduced and the resulting iron particles no doubt would contain small oxide cores which tend to hinder coalescence of the iron in a manner similar to the action of aluminum oxide.

phoric iron prepared seems to be dependent primarily upon the amount of residual oxide contained in the iron.

3. Iron prepared from colloidal iron oxide by Sorum's method was worthless as an ammonia catalyst. The incorporation of colloidal aluminum oxide in this colloidal iron oxide produced an active catalyst.

4. It appears as though inactivation of an iron catalyst through processes of recrystallization is hindered by an iron oxide core within the iron particles.

THE EQUILIBRIUM OF THE REACTION BETWEEN NITROGEN AND CARBON DIOXIDE IN THE ELECTRIC ARC

BY H. V. TARTAR AND J. L. HOARD

RECEIVED AUGUST 30, 1929 PUBLISHED JANUARY 8, 1930

This study was undertaken as a natural consequence of former work performed in this Laboratory on the equilibrium of gaseous reactions in the electric arc.[1] The reaction between nitrogen and carbon dioxide seemed to offer a very interesting problem because of the appearance of *a* recent article[2] which indicated that a much higher concentration of nitric oxide could be obtained with a mixture of these gases than could be realized with a mixture of nitrogen and oxygen. The earlier work of Muthmann and Schaidhauf[3] seemed to indicate that this view is erroneous; for they obtained concentrations of nitric oxide from carbon dioxide and nitrogen mixtures which compare unfavorably with those obtainable from air. However, it seemed desirable to collect a more complete series of data in which conditions were varied and in which equilibrium was known to be realized.

Description of Apparatus.—The power supply available was 110-volt, SO-cycle alternating current. The high voltage necessary to maintain the arc was obtained by means of an oil-cooled, closed core transformer of 3.5 kilowatts capacity. Reactance coils in the primary circuit served to stabilize the arc and to give the desired value of secondary current. A milliammeter in the secondary circuit indicated the value of the current. The line voltage varied somewhat, but the current through the arc was substantially constant.

The arc furnace was that used by Colin and Tartar[4] in their study of the equilibrium of the reaction of nitrogen and oxygen in air and other mixtures, to form nitric oxide. It consisted of a 5-liter pyrex flask with platinum electrodes sealed into the neck of the flask. The electrodes were originally of the horn-gap type, and were about 0.8

[4] Ref. 1b, see Fig. 2, p. 1544.

cm. apart, but at the temperature of the arc the platinum was gradually volatilized and fused down, so that only small hooks remained upon the ends. The neck of the flask was drawn out and sealed to a two-way stopcock, and another outlet was provided in the bottom of the flask. To each side of the two-way stopcock (a in Fig. **1)** was sealed a T-tube; one side of each T-tube was joined to a manometer and the other to a tube containing phosphorus pentoxide (b in Fig. 1). Nitrogen was admitted to the furnace through one of these drying tubes after having passed successively through alkaline pyrogallol, concentrated sulfuric acid and a tube containing heated metallic copper. This latter tube was closely packed with alternate layers of copper gauze, tightly wound into rolls, and of granulated copper. The copper was heated to a dull red during the passage of nitrogen; the oxide formed was periodically reduced with hydrogen.

The tube (e) was filled with carbon dioxide snow and by means of the by-pass (d-g) leading directly to a Cenco Hivac pump was subjected to direct evacuation until nearly one-half of it was gone. This served to purify the carbon dioxide by removal of the gaseous impurities. The purified gas was then admitted to the furnace after passing through the drying tube (b).

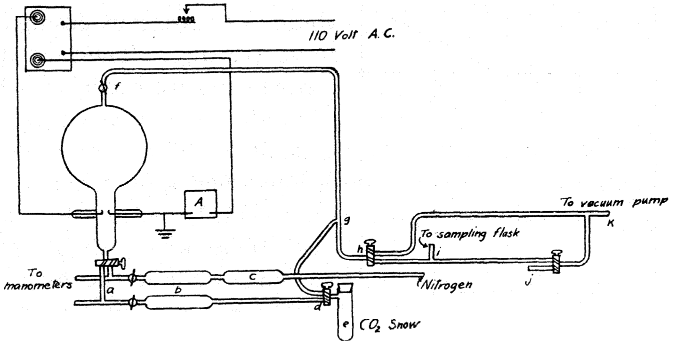

Fig. 1.

Between the points (h) and **(k)** (Fig. **1)** were two lines leading to the pump; one was used for evacuation; the other for sampling the reaction products. The sampling flask was connected in the line by means of a T (i in Fig. **1)** and was evacuated down to the limit of the pump when preparing for use. The sampling flask consisted of a 5-liter pyrex flask with a stopcock sealed into the bottom. An absorption train between (i) and (j) served to absorb residual gases after the sampling had been accomplished. Air was first admitted to oxidize the nitric oxide and the gases were then drawn through towers containing hydrogen peroxide and caustic soda solutions (in separate towers).

Method of Procedure

The furnace was evacuated by means of the direct line to the pump. It was then flushed out four times with the oxygen-free nitrogen and with the aid of the manometer in that line was filled to the desired pressure. Carbon dioxide snow was then introduced into the tube (e) and purified as described heretofore. The furnace was filled to the desired total pressure with carbon dioxide. The arc was started and allowed to run for at least three hours, although tests indicated that equilibrium essentially was attained in a somewhat shorter period. At the end of this time a sample of the reaction gases was drawn for analysis. The sampling flask was evacuated and the gases were allowed to distribute themselves through the system, When constant pressure and temperature had been attained, the flask was withdrawn, sodium hydroxide solution was drawn into it (since it was still under reduced pressure) and air was admitted to oxidize the nitric oxide. The flask was allowed to stand with occasional vigorous shaking until the nitrous gases were completely absorbed. The solution was then washed into a 500-cc. Kjeldahl flask and the nitrogen compounds reduced with Devarda's alloy to ammonia, which finally was distilled into standard sulfuric acid. In order to avoid carrying over alkali spray during the distillation, an apparatus was used which was quite similar to that of Mitscherlich.[5] This method was found to be quite reliable. All results were calculated as percentage of nitric oxide by volume of the actual amount of gas present in the furnace.

Discussion

The equation for the reaction of nitrogen and carbon dioxide to form nitric oxide may be written

$$N_2 + 2CO_2 = 2NO + 2CO$$

Thus a two-to-one mixture of carbon dioxide to nitrogen should, theoretically, give the best yield of nitric oxide. Also, it is apparent that three volumes of reacting gases give four volumes of reaction products at constant pressure. The fact that these experiments were performed at substantially constant volume made it difficult to obtain exactly similar conditions when approaching the equilibrium from both sides for, in the one case, there was a slight increase in pressure, while in the other there was a slight decrease. Furthermore, when equilibrium was attained, starting with a nitrogen–carbon dioxide mixture, there was undoubtedly some excess of oxygen and of carbon monoxide present, resulting, of course. from the decomposition of some carbon dioxide not taking part in the reaction with nitrogen; this amount was not precisely known. However, starting with 5% of nitric oxide and 5% of carbon monoxide, with 60% of carbon dioxide and 30% of nitrogen, it was possible to arrive at an equilibrium mixture differing by but 0.1–0.2% from that reached when starting with the theoretical mixture of carbon dioxide and nitrogen. Carbon monoxide was generated by dropping formic acid into concentrated sulfuric acid; nitric oxide by dropping dilute nitric acid through copper gauze so as to keep the nitrate solution formed out of contact with the metal.

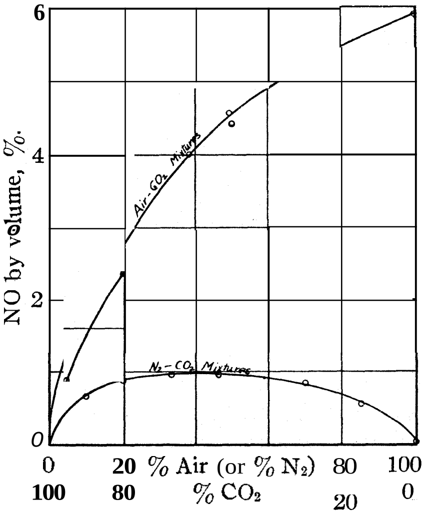

Fig. 2.

A series of runs was made with a current of 65–67 milliamperes and at 760 mm. pressure, in which mixtures of air and carbon dioxide ranging

---

[5] Scott, "Standard Methods of Chemical Analysis," D. Van Nostrand Co., New York, 1922.

from 100% of the former to 95% of the latter were used. The results are reported in Table I and are shown graphically in Fig. 2. These data indicate that carbon dioxide acts largely as a diluent under these circumstances, for the concentrations of nitric oxide obtained range from 1.3% in a mixture containing 95% of carbon dioxide, to 5.9% for pure air. This view is substantiated for the most part by the results obtained from nitrogen–carbon dioxide mixtures under similar conditions of current and pressure. The data are given in Table II and are plotted in Fig. 2. Here a maximum of about 1% of nitric oxide was obtained, or only one-sixth the concentration resulting from air alone. In all runs but those having

Since Colin and Tartar[1b] had shown that high concentrations of nitric oxide could be attained at reduced pressures from air and other nitrogen–oxygen mixtures, it was decided to try a similar proceeding with nitrogen and carbon dioxide. Series of runs were made, therefore, at 500, 300 and 150 mm. pressure. The results are given in Table II and the first two are compared graphically with the atmospheric runs made with the same current in Fig. 3. The values determined at 150 mm. are altogether too uncertain to more than indicate the order under those conditions. The effect of pressure upon the equilibrium between nitrogen and carbon dioxide seems to be rather slight; in fact, there is scarcely more than 0.1% variation, and this almost comes within the limits of experimental error. As a matter of fact, the two values obtained at 500 mm. pressure with original concentrations of nitrogen of 70 and 85% are, perhaps, a little high for the reason given in the next paragraph. Pressures above atmospheric were not tried, but it seems improbable that the reaction would be much favored, if at all, by such a procedure.

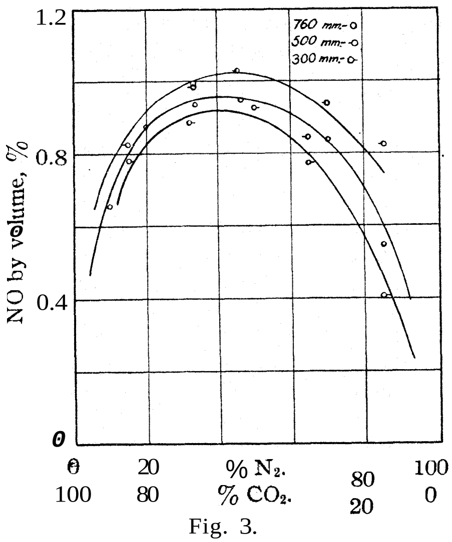

Fig. 3.

Finally, a series of runs was made at atmospheric pressure with a somewhat larger current. Unfortunately this increased current (about 98–100 milliamperes, or approximately a 50% increase) proved to be more than the electrodes could conveniently handle, and the "horn-gap" was completely fused down into stubs. This, of course, had the effect of increasing the current density for the same current. Therefore, this last series is not quite so consistent as those made with the lower current. (The two values made at 500 mm. and 65 milliamperes referred to above as being somewhat high were made after this change in the electrodes.) It was found, however (Table 111), that 50% increase in current caused 30–40% increase in the concentration of nitric oxide.

The natural inference from the foregoing results is that not nearly as high a concentration of nitric oxide can be produced by the high tension electric arc from carbon dioxide and nitrogen as can be produced from air or other nitrogen-oxygen mixtures. Krase and Mackey[3] have recently published some thermodynamic calculations which seem to indicate that the very opposite is true, *e.* g., that four times as high a concentration of nitric oxide could be produced from carbon dioxide and nitrogen mixtures at 3500°, as would be obtained from air. They gave (at 3500°) 5.52% nitric oxide for air, and the present work shows 5.9%, corresponding to some unknown temperature; but where their calculations for nitrogen–carbon dioxide mixtures indicate 23.75% (at 3500°) and 10.88 (at 3000°), the present work shows not more than 1.4%. Now the matter is somewhat complicated by two factors: first, the temperature of the arc (or of the region at the edge just outside the arc where a thermal equilibrium is attained),[6] and, second, the rapidity with which the equilibrium is "frozen." The work of Colin and Tartar[1b] showed that such an equilibrium is "frozen" with almost incredible rapidity. It appears, therefore, that if an equilibrium be attained at some high temperature, say 3000°, it should be little changed during cooling. With this fact established, only the question of the temperature to which the equilibrium corresponds remains to be considered.

In the case of air, it is seen from a comparison with the data of Nernst, Finckh and Jellinek[7] for a purely thermal equilibrium that the concentration of nitric oxide here obtained must correspond to a very high temperature. At 2675° they found 2.23% of nitric oxide (although it appears from the more recent data of Briner, Boner and Rothen[8] that this value may be somewhat low). As a matter of fact, Nernst, Finckh and Jellinek, by extrapolation from their experimental data, estimate that the temperature corresponding to a thermal equilibrium concentration of 6% nitric oxide

---

[6] Daniels, Keene and Manning, Trans. Am. Electrochem. *Soc.*, 44,247 (1923).

[7] Nernst, Finckh and Jellinek, Z. *anorg. Chem.*, 45, 116–126 (1905); 49, 213–229 (1906).

[8] Briner, Boner and Rothen, J. *chim. phys.*, 23, 788 (1926).

is approximately 3500 Å.; and about 6% was obtained in the present work. It seems justifiable, furthermore, to assume that the equilibrium with carbon dioxide–nitrogen mixtures corresponds to a temperature comparable with that in the case of air, particularly in the cases where the current was increased by 50% over that used for air. Moreover, Colin and Tartar[1b] found, in the case of air, that the highest concentrations of nitric oxide were obtained at relatively low values of current, that is, 40 milliamperes or less, so it is improbable that the yield of nitric oxide from nitrogen–carbon dioxide mixtures could be improved by indefinitely increasing the current. The conclusion is, therefore, that only small concentrations of nitric oxide, as compared with air, may be produced from nitrogen–carbon dioxide mixtures in the high tension arc.

The validity of the calculations of Krase and Mackey[2] appears to be in question. One objection to their procedure is the empirical equations used for expressing heat capacity as a function of the temperature. The equations for the heat capacities of nitrogen, oxygen, nitirc oxide, carbon monoxide and carbon dioxide apparently were taken from Lewis and Randall[9] who had formulated them upon the basis of data collected from various sources.[10] These equations, admittedly of a grossly empirical character, and based upon a minimum of reliable experimental data, have been used in the calculations of Krase and Mackey over a temperature range which amounts to an extrapolation of 1000–1500". This is, no doubt, an unjustifiable procedure; for it is the opinion of Partington and Shilling,[11] who have recently collected data on the heat capacity of gases, that practically no reliable information exists for the region above 2000°. They state: "It will be seen, too, that the tables do not extend above 2000". This is admittedly a drawback, but reliable tables cannot be constructed for the region where practically no accurate data exist. For approximate estimations in the region 2000–3000°C., several indications may be given, but that is all. For example, the molecular heats of the so-called permanent gases probably reach a maximum value, and continue for some considerable temperature range at that value. . . . It must be emphasized, however, that the final equations given for these tables apply only over the temperature range stated. Extrapolation will not give accurate results. . . ."

Summary

1. Only small concentrations of nitric acid were produced from nitrogen–carbon dioxide mixtures in the electric arc.

2. With a current of 65 milliamperes only one-sixth (1%) the concentra-

THE ORIGIN OF PROTOACTINIUM

BY JAMES E. WILDISH

RECEIVED SEPTEMBER 9, 1929 PUBLISHED JANUARY 8, 1930

The major part of this investigation grew out of work started several years ago to separate protoactinium from America's most important uranium ore, carnotite. As expected, after much preliminary work, the presence of protoactinium was established. From the standpoint of radioactivity, it is generally considered as being the parent of actinium and hence takes its place at the head of the actinium series. The fact has long been established that the radioactive elements allow themselves to be arranged in three great divisions, the uranium, the thorium and the actinium series. The exact relation of the actinium series to the uranium and thorium series of radioactive elements is as yet not definitely known. This investigation was undertaken with the hope of throwing some light on this very important relationship.

The uranium disintegration series, as it is now generally represented, shows the actinium series as springing from uranium II, by the way of uranium Y, although it is generally indicated that this is uncertain.[1] According to this scheme, the actinium series is formed in a dual a-ray change from uranium II, the remainder of the uranium II atoms forming the ionium–radium series. At present the most widely accepted percentages for the numbers of uranium atoms forming the ionium–radium and actinium series are ninety-seven and three per cent., respectively. Obviously, if a definite percentage of the uranium atoms disintegrates to form the actinium series, the ratio between this series, or any member of it, to uranium, should be a constant in uranium bearing minerals, just as the radium–uranium ratio is constant.

[1] Meyer and Schweidler, "Radioaktivitat," **1927,** p. **347;** also Kohlrausch, "Radioaktivitat," **1928,** p. 8.

If, on the other hand, protoactinium exists in a series independent of uranium, the protoactinium–uranium ratio should show some variation in different minerals used as sources of protoactinium. While it is true that the proportion of the isotopes of stable elements, such as chlorine, is relatively constant in nature, it does not follow that constancy of proportion holds for radioactive isotopes, since their disintegration constants are generally quite different.

Boltwood[2] showed that the actinium content of minerals is roughly proportional to their uranium content. Fussler[3] measured the same relation for three different samples of carnotite and obtained values that are in the ratio 1.261 : 1.644 : 1.00. Meyer and Hess[4] made similar determinations on different uranium minerals and came to the conclusion that the actinium–uranium ratio is constant. Others[5] have made similar determinations on the uranium Y–uranium and the actinium series–uranium relations and report values ranging all the way from two to five per cent. When the results of all these investigations concerning this ratio are compared, the degree of variation is so marked that we cannot, even today, say with certainty that the ratio between the actinium series, or any member of it, and uranium, is constant.

The results of this investigation indicate that the protoactinium–uranium ratio is far from constant, and consequently strengthens the view advocated in recent years by several investigators that the actinium series is not a direct offspring of the uranium series. This conclusion is based upon the quantitative determination of the protoactinium–uranium ratio of different uranium minerals from widely separated localities. A rich carnotite from Colorado, two pitchblendes from Bohemia, a soddite from the Belgian Congo, and a thorianite from Ceylon, were analyzed for their protoactinium and uranium contents.

Preliminary Work.——First a method had to be developed for the quantitative separation and recovery of tantalum from carnotite, since tantalum is the nearest homolog of protoactinium and must be added to protect the minute quantities of protoactinium to be extracted. After obtaining confidence in the technique involved, an extensive amount of work still remained to be done on simplifying and standardizing a method, applicable not only to carnotite but, with little modification, to other uranium minerals as well.

In attacking a problem of this sort one naturally begins with methods which earlier investigators have followed in extracting protoactinium from uranium minerals. Hahn and Meitner[6] in their extended study of proto-

actinium, confined themselves to pitchblende as a source of the element. They used three different methods of extraction: (1) decomposition of the ore with sodium bisulfate, which leaves the protoactinium in the insoluble residue; (2) treatment with fifty per cent. hydrofluoric acid plus sulfuric acid, which puts the protoactinium into solution; and (3) the nitric acid treatment, which leaves most of the protoactinium in the insoluble residue.

For the preliminary work of separating protoactinium from carnotite the bisulfate method of Hahn and Meitncr seemed best adapted because, in their hands, better results were more readily obtained by it than with the other two methods.

The bisulfate method is, briefly, as follows: A few milligrams of tantalic oxide is added to the sample of mineral and the whole thoroughly fused with sodium bisulfate. The fused mass is then thoroughly lixiviated with boiling water, to which sulfur dioxide is added to aid in the quantitative precipitation of the tantalum. Upon filtering, radium, radio-lead, tantalum, protoactinium and small quantities of radium E, polonium, ionium and uranium X remain in the residue and uranium, ionium plus uranium X, actinium, radium E and polonium in the filtrate. The residue is now ignited in a porcelain crucible and then transferred to a platinum dish. Hydrofluoric acid, a few drops of sulfuric acid and a few drops of thorium nitrate solution are now added and the solution warmed on a water-bath. The tantalum and protoactinium are brought into solution in from one to two hours. Filtering through a paraffined funnel leaves radium, radio-lead, and traces of ionium plus uranium X in the residue, and tantalum, protoactinium and traces of radium E and polonium in the filtrate. The filtrate is now brought to the fuming point of the sulfuric acid and the residue treated with aqua regia to remove the last traces of radioactive impurities. The insoluble material left after the aqua regia treatment consists of the oxides of tantalum and protoactinium.

Hahn and Meitner refer to the fact that they had great difficulty in removing the tantalum from the platinum dish after bringing the solution to the fuming point of sulfuric acid, just before the aqua regia treatment. They solved the problem by adding a small quantity of an iron salt to the solution just before bringing it to the fuming point. This put the residue in a form less difficult to remove from the dish. The writer found that the tantalum, in the absence of an iron salt, is not only difficult to remove, but tends to form a glaze, especially around the side of the dish, which because of its transparency makes most of the residue invisible; but if water is added at this point and the surface of the dish carefully rubbed with a horn spatula, the glaze of tantalum comes off and forms a white suspension of tantalic acid. With a little patience all of the tantalum may be removed from the dish without the addition of an iron salt. In some cases as high as ninety-five per cent. of the tantalum was recovered from the pitchblende samples in this way.

Carnotite.—Carnotite is a potassium urano vanadate and even high grade material is very rich in silica. Consequently it was found very difficult to apply this method satisfactorily, for when the bisulfate fusion is made, the tantalum remains with the silica in the insoluble residue. After sufficient hydrofluoric acid had been added to remove all of the silica and put the tantalum in solution, nothing like quantitative returns could be made on the tantalum, because a considerable quantity of the tantalum is volatilized in the hydrofluoric acid treatment.[7] It was found in later experiments with other minerals, where much less silica was involved and hence much less hydrofluoric acid used, that the recovery on tantalum increased. However, the tantalum recovered from the carnotite by this method showed an increase in activity characteristic of protoactinium.

In the earlier experiments the recovered tantalum was badly contaminated with radium, which persisted very strongly. The barium in the carnotite remained in the insoluble residue, and a relatively large amount of it would be carried through with the hydrofluoric acid, since barium fluoride is far more soluble than barium sulfate.

Tantalum can be freed from radium by a procedure based on two findings: one is that freshly precipitated tantalic acid is very soluble in very dilute hydrofluoric acid, and the other is that tantalum is readily precipitated, even from solutions of hydrofluoric acid, by means of ammonium hydroxide.[8] The writer found that quantitative recoveries could be made in this way, especially in the presence of the small amount of hydrofluoric acid used in these separations. The mineral sample, to which the tantalic oxide had been added, was fused as before, boiled in a large excess of water and the solution filtered through a paraffined funnel. A beaker containing ammonium hydroxide was placed under it and some very dilute hydrofluoric acid poured through the precipitate. The tantalum, some silica and perhaps a little barium fluoride were carried through into the ammonium hydroxide. The tantalum immediately precipitated, and if much silica is present, it is precipitated at this point. Under any condition, much of the silica is carried into the filtrate, and the amount of hydrofluoric acid necessary to remove it will cause the yield of tantalum to be low. The operation of dissolving the tantalic acid from the residue on the filter paper with dilute hydrofluoric acid and precipitating it with ammonium hydroxide must, therefore, be repeated several times. This procedure has the advantage of not precipitating any of the barium and

---

[8] Hopkins, "Chemistry of the Rarer Elements," D. C. Heath and Co., 1923, p. 235.

radium along with the tantalum, because ammonium hydroxide will not precipitate barium from dilute solutions of barium salts.

By several repetitions of the above operation, the tantalum precipitate is completely freed from traces of barium and radium salts. The tantalum precipitate is finally filtered, washed and ignited. Traces of silica are removed with hydrofluoric acid. For final purification, and to give the precipitate a good texture, it is fused with potassium bisulfate and the melt dissolved in boiling water. After filtering, washing and igniting, the tantalic oxide comes out as a fine, white powder which is easily brushed from the crucible.

With these modifications, the recoveries from carnotite were much better than those obtained by the Hahn and Meitner method, and the separations, in the main, less difficult to carry out. Even with all of the above precautions, it is difficult to remove the last traces of radium. This was verified time and time again during the course of this investigation. Since the amount of protoactinium is determined by the activities of these tantalum preparations, it is very important to rid them entirely of other active material. Because of the generally low recoveries made on the tantalum by fusion with bisulfate, it was reluctantly abandoned.

The procedure finally employed for the extraction of protoactinium from carnotite was developed from a method used by Russell and Widdowson[9] for the extraction of protoactinium from pitchblende. By introducing some modifications, the Russell and Widdowson method can be applied not only to carnotite, but to other uranium minerals as well. Their method is, briefly, as follows. The mineral sample is boiled vigorously for an hour in dilute nitric acid and then filtered. The residue is active. A few milligrams of tantalic oxide is added to this residue and the whole mass fused with potassium hydroxide in a nickel crucible. The melt is dissolved in cold water and the residue, which is inactive, is filtered out. The alkaline solution is now added to the nitric acid solution, then a few cubic centimeters of dilute sulfuric acid and the solution is neutralized with ammonium hydroxide. Upon boiling, the tantalum separates out as a flaky precipitate. The precipitate is filtered out, washed, and then fused with potassium bisulfate to remove elements other than those of atomic number ninety-one. Naturally, some modification must be made here for minerals such as carnotite, which contains considerable barium, and at the same time have a high silica content.

In this procedure the silica is all changed to the soluble silicate in the potassium hydroxide fusion and then when the alkaline solution is added to the nitric acid solution, great quantities of silicic acid are precipitated, from which it is very difficult to separate the small amount of tantalum. In fact, it is almost impossible to separate quantitatively the small amounts of tantalum, if there is much silica present.

---

[9] Russell and Widdowson, *Phil. Mag.*, 46, **925 (1923).**

It was found in the course of this work, that in order to get quantitative returns on the tantalum, it was necessary to add ammonium hydroxide until a small amount of the uranium, and perhaps a little vanadium, were precipitated along with the tantalum. The uranium and vanadium were removed later. As to final fusion with bisulfate, carnotite presents a problem because of the presence of barium. It is obvious that barium cannot be removed by fusion with bisulfate.

In order to utilize the fusion with potassium hydroxide for the extraction of tantalum from carnotite, it is evident from all the preceding work that most of the silica must be first removed from the mineral sample. To this end, the radioactive constituents of the mineral were concentrated, before adding the tantalum to protect the protoactinium in carnotite, by sliming with dilute nitric or sulfuric acid, which leaves the bulk of the sand in an inactive residue. It was found that the sand was inactive only after sliming off about six times and only the coarsest sand remained. Small quantities of silica carried over in this operation gave no particular trouble in the precipitation of the tantalum and they were finally removed with hydrofluoric acid. In fairness to the bisulfate method of Hahn and Meitner, it may be said that great quantities of silica in all methods investigated gave serious trouble.

The best results were obtained when carnotite was dissolved in about twenty per cent. sulfuric acid instead of dilute nitric acid, using about ten cubic centimeters of the acid per gram of sample and sliming off as indicated above. The main advantage of using sulfuric instead of nitric acid lies in the fact that sulfur dioxide reduces vanadic salts very readily in the presence of sulfuric acid, but not in the presence of nitric acid. It was found that tantalum precipitates much more readily and in better form in the presence of the reduced vanadium salts. The solution was filtered and the tantalic oxide added to the dried residue and fused with potassium hydroxide in a nickel crucible. After the fusion was dissolved in cold water, there was practically no evidence of a precipitate and it was not filtered. The alkaline solution was then added to the acid solution and sulfur dioxide passed in until the vanadium was reduced to a lower state of valence, as indicated by the change in color. Ammonium hydroxide was added to incipient precipitation of uranium and perhaps some vanadium, and the solution boiled to precipitate the tantalum. Traces of barium sulfate and other insoluble sulfates appear immediately and later on the tantalum precipitates in a form which settles readily.

A difficulty here is apparent, that is, the barium–radium sulfates are brought down with the tantalum. Any number of bisulfate fusions would not remove the barium, The problem of separating the radium from the tantalum here offered one of the greatest difficulties of all in the work on carnotite. At first an attempt was made to remove most of the barium sulfate by letting it settle out before boiling the solution to precipitate the tantalum. After the solution had stood for forty-eight hours, it was decanted and filtered from the insoluble sulfates and the tantalum precipitated in the filtrate. This, on six different samples, showed that even in the cold about four-fifths of the tantalum was carried down with the barium sulfate.

Since the barium sulfate carries down most of the tantalum, even in the cold, there is no gain in trying to remove most of it by letting it settle out prior to boiling to precipitate the tantalum. On the contrary, it is best to boil the solution and precipitate the tantalum immediately after adding the ammonium hydroxide. The precipitate, consisting of tantalic acid, barium sulfate, some silica and so forth, may be allowed to settle and most of the supernatant liquor decanted before filtering, or it may be filtered through paraffined funnels as soon as it is cool, and treated with dilute hydrofluoric acid and ammonium hydroxide, as described under the bisulfate method.

In order to determine how many precipitations by the ammonium hydroxide would be necessary to remove the radium, the following experiment was carried out. Three ten-gram samples of carnotite were carried through the above procedures and filtered into paper cartons lined with paraffin. These filtrates were each diluted to about one hundred cubic centimeters and a little barium chloride solution was added to each. Since the sulfate is much more insoluble than the fluoride, a few drops of dilute sulfuric acid was added to each of them, and then each solution stirred with a platinum wire. The precipitate of barium sulfate and barium fluoride was allowed to settle for at least forty-eight hours, and then the solution was filtered through a good quality of filter paper and thoroughly washed. These papers were flattened out, dried and then placed in the chamber of an α-ray electroscope. In this particular instrument they had an average activity of 169.5 divisions per minute, and all ran very closely the same. The solutions were again treated with barium chloride and sulfuric acid, as before, and again allowed to stand for forty-eight hours. After filtering, washing and drying, the residues had the following activities in divisions per minute: No. 1, 0.13; No. 2, 3.35 and No. 3, 8.66. These divergencies are to be expected since no special care was used in the preparation of the films. They would normally, under the conditions, vary in concentration, area and thickness. After a third treatment, as outlined above, except that this time they were filtered through two thicknesses of filter paper, they had the following activities, in divisions per minute: No. 3, practically no activity on either filter paper; No. 2, 0.75 on the upper paper and 0.087 on the lower paper and No. 3, practically no activity on either filter paper. After a fourth treatment there was negligible activity in all three samples. The solutions were now made ammoniacal and the tantalum precipitated. This clearly indicates that if the tantalum is precipitated in the presence of the barium and radium carried through by the hydrofluoric acid treatment of the original residues, it is contaminated, and would certainly give untrustworthy results. In all of the experiments the results of which are recorded in this paper, the above operation was carried out from four to five times, depending on the mineral. By careful work, it is easy to recover upwards of ninety per cent. of the tantalum.

Thorianite.—The method of Russell and Widdowson, modified as indicated above, readily lends itself to thorianite. After grinding the mineral, it is treated with about forty per cent. nitric acid, using fifteen cubic centimeters of the acid per gram of sample. By gentle heating it is easily put into solution in less than a half hour. The solution is diluted, filtered and the residue dried and fused with potassium hydroxide in a nickel crucible. The tantalic oxide is added to the potassium hydroxide fusion. When quantitative results are desired, it is best to fuse the potassium hydroxide until vigorous action ceases and then drop the tantalic oxide into the crucible. It may be carefully brushed in, or put into a small piece of paper and dropped in. This procedure lessens the danger of losing any of the tantalum during the vigorous part of the reaction. The heating is continued until there is complete fusion, and since this tantalum is to bring out all of the protoactinium, it is best to keep it in a state of fusion at least fifteen minutes. The melt, after it has cooled, is dissolved in cold water. In the case of thorianite, the precipitate formed when the potassium hydroxide fusion was dissolved in water was very small, and since it was found to be very soluble in nitric acid, it was not removed. The potassium hydroxide solution is now added to the original nitric acid solution, then a few cubic centimeters of dilute sulfuric acid, and ammonium hydroxide to incipient precipitation of the uranium and thorium. The tantalum readily precipitates after boiling the solution for a few minutes. Since this particular mineral was relatively rich in radium, the tantalum precipitate was dissolved in hydrofluoric acid and precipitated with ammonium hydroxide, and this operation repeated four times in order to remove the last traces of radium. The final precipitate of tantalum was dried and fused with potassium bisulfate and the silica removed with hydrofluoric acid. The residue was finally weighed as tantalic oxide.

Soddite.—Soddite is a combination of uranic oxide, silica and water of hydration. It was treated in precisely the same way as thorianite. It required about three quarters of an hour to bring it into solution. In order to get the tantalum to precipitate, ammonium hydroxide must be added until considerable uranium is brought down and the precipitate is quite bulky. This precipitate is filtered out, ignited and then treated with nitric acid. The reason for igniting it is to change the tantalic acid to tantalic oxide, as freshly precipitated tantalic acid is quite soluble in mineral acids. The greater part of this ignited precipitate went into solution in the nitric acid. The residue remaining from the nitric acid treatment was filtered, washed and fused with potassium bisulfate, mainly to bring the tantalum into **a** condition in which it is readily soluble in dilute hydrofluoric acid. Upon boiling the bisulfate fusion in water, the tantalum readily separates out. This solution was filtered through a paraffined funnel, the precipitate washed and repeatedly treated with hydrofluoric acid and ammonium hydroxide as in the case of other minerals. The precipitate was finally thoroughly washed, dried and the silica removed in the regular way. To obtain a better texture, it was fused with potassium bisulfate, leached out and finally ignited to tantalic oxide.

Pitchblende.—The pitchblendes were treated in precisely the same way as the thorianite. The lead sulfate was more marked in the pitchblende than in the other minerals, because of their much higher uranium content. In all cases, the repeated treatment of the precipitates with dilute hydrofluoric acid and ammonium hydroxide removes the lead. This treatment also puts the tantalum through the same chemical processes as were followed with the other minerals. As with the other minerals, the tantalum precipitate was finally fused with potassium bisulfate, not only to purify it, but to put it into better form. In all this work samples ranging from three grams, in the case of pitchblendes, to ten grams in the case of carnotite, were used.

With all the minerals studied, the method outlined above gave excellent quantitative results when one considers the great number of chemical manipulations involved and the recovery of the twenty milligrams of tantalic oxide which was added in each case. In most cases upwards of ninety per cent. of the tantalum was recovered, and in many cases the recoveries were considerably higher than this. While it is important to obtain good quantitative results, it is more important to see to it that the samples have been fused long enough to bring the tantalum in contact with all of the protoactinium. Fundamentally, a quantitative return on the tantalic oxide added to the sample is unnecessary, if the recovered oxide is pure. The activities of the films made from the tantalic oxide recovered depends on the amount of protoactinium present in the sample, hence the activity due to all of the protoactinium in the sample of mineral can be computed from films of known weight, provided the weight of the tantalum added to the original sample is known. The total activity, divided by the weight of the sample in grams, gives the activity due to the protoactinium in one gram of the mineral.

To prove that the activities of the protoactinium films furnish a true measure of the quantity of the protoactinium in minerals, the following sets of separations were carried out. The protoactinium was separated from three different minerals, using samples of different weight, but adding the same weight of tantalic oxide to each sample. Uraninite, thorianite and carnotite were used in these tests. For uraninite and thorianite, three three-gram and three six-gram samples were used. For carnotite, three five- and three ten-gram samples were taken. Twenty milligrams of tantalic oxide was added to each of the eighteen samples and then the samples were processed as described.

Films of the tantalic oxide recovered from each sample were made, weighed and their activities measured. From the weight of the film and its activity, the activity of twenty milligrams of film was computed. This value represents the a-ray activity of all the protoactinium in the sample of mineral taken.

Normally the tantalic oxide recovered from the larger samples should be twice that from the smaller samples and the activity per gram of mineral should be constant for each mineral, but different for the different minerals.

The averages of the total activities, in divisions per minute, and the ratio of the two activities, are given in the following tabulation.

Mineral	Av. small samples	Av. large samples	Ratio
Uraninite	7.46	15.32	2.05
Thorianite	4.31	9.40	2.18
Carnotite	8.73	17.66	2.02

The individual readings vary from 3.6 to 12.9% from the average readings given above. The eighteen samples were put through the same chemical processes as nearly as possible. Except in the case of the inactive sand from carnotite, the tantalum was precipitated in the presence of the whole sample in solution, that is, there was no chance for the division of the protoactinium between residue and solution in any stage of the analysis. The double quantity of protoactinium extracted when the mineral samples were doubled clearly established the reliability of the method followed for the quantitative separation of protoactinium from different types of uranium minerals.

The activities of the numerous protoactinium preparations obtained in this investigation were measured in an a-electroscope. The general idea for the use of the films was taken from Boltwood.[10] The material to be measured was painted on thin aluminum disks eight centimeters in diameter. These disks were turned in such a way as to have a rim about one millimeter high. The rim not only protects the film to some extent, but it keeps the very thin disk perfectly flat. The rims were so low that no correction was made for a-particles that may have encountered them. Before shaping the disks, one surface of the thin sheet aluminum was thoroughly rubbed with steel wool. This surface was then rubbed with

---

[10] Boltwood, Am. J. *Sci.,* [4] **25,** 176 (1908).

clean cotton until all free particles of aluminum were removed. This treatment produced a very slightly roughened surface upon which films can be painted more uniformly than on smooth aluminum. Material to be painted on these disks was ground very fine in an agate mortar and a suspension formed by adding a few drops of acetone. After trying different methods for painting films on these disks, it was found that small tufts of cotton, tightly rolled and held with small tweezers, were as good as anything tried. A small camel's hair brush works fairly well, except that in using the very small amount of material necessary in this work, practically all of it would be drawn up into the brush. Then too, a new brush would be required for each new preparation because of the possibility of contamination. The use of small pieces of cotton avoids both these difficulties.

In making measurements, one of these clean disks was placed in the chamber of the electroscope, in each case, before the natural drift was taken, to screen off any activity that might be in the chamber floor, as constant use of the instrument is liable to leave traces of active material on the bottom of the chamber. To reduce absorption of the radiations by the material to a negligible value, the films were made very thin, never containing over 0.2 mg. of material per square centimeter and in most cases less than this amount. Experiments showed that for thicker films there is a rapid falling off of activity with increase in weight.

The chamber of the electroscope used in all of these measurements was of such dimensions that the full range of the particles was utilized except for a negligible fraction. The activities were measured from time to time over a period of a year or more, and the activities, in divisions per minute, were computed on the basis of a gram of mineral in each case. A typical example: a 5.7-mg. film made from the tantalic oxide recovered from a ten-gram sample of carnotite gave a reading of 6.52 divisions per minute. Twenty milligrams of tantalic oxide had been previously added. The activity of all the protoactinium in the sample is $20/5.7 \times 6.52$ or 22.0 divisions per minute, and for one gram of the mineral the activity due to the protoactinium is 2.29 divisions per minute.

The initial activity due to the protoactinium in one gram of each of the minerals was obtained by plotting the activities, in divisions per minute, obtained as above, on the axis of ordinates, and the time, in days, on the axis of abscissas, and extending backward the growth curve to the axis of ordinates. The values obtained and their probable errors are given in Col. 4, Table I. The probable errors shown are based on at least six initial activities for each mineral.

To convert these initial activities due to the protoactinium in the different minerals, into atom for atom relations between protoactinium and uranium, it is necessary to know the α-ray activity of a gram of pure uranium, the percentage of uranium in the mineral and the a-ray activity due to the uranium in one gram of mineral.

In order to determine the α-ray activity of one gram of pure uranium, seven films of pure urano-uranic oxide, of the same dimensions as those above, were prepared and measured. The urano-uranic oxide used had been carefully freed from radioactivity by the method of McCoy.[11] The films varied in weight from 4.1 to 7.2 milligrams, and gave an average activity of 359.7 divisions per minute, per gram of oxide, or 423.9 divisions per minute, per gram of uranium element. The value 415.4 was obtained after deducting two per cent. due to the ionization of uranium X and uranium Y.[12] The average weight of the seven films was 4.9 milligrams, and since they had an area of 50.3 sq. cm., the average weight per square centimeter was approximately 1 X 10^{-4} grams. Johnstone and Boltwood[13] found that for films of approximately the same diameter as these, and weighing not more than ten milligrams, the absorption of the a-radiation was negligible. The probable error for the a-ray activities of the seven films was ±9.1 or about 2.2 per cent., when computed on the basis of one gram of uranium element.

The uranium content of the pitchblendes, soddite and carnotite were determined by the writer, using the emanation method. The value for the uranium content of thorianite was one made gravimetrically by Moore and Schlundt.[14]

Furthermore, the uranium content of the pitchblendes and soddite was very carefully determined, gravimetrically, by Mr. Fred Kavanagh, using the Randall[15] modification of the Boltwood[16] method for the determination of uranium in uranium minerals. The method used for the analysis of carnotite was that described in Bulletin 212, U. S. Bureau of Mines.[17] The value for carnotite was duplicated by an analysis made by Le Doux and Co.

The analytical results which follow give the percentage of uranium element in the different minerals.

Mineral	Emanation method	Gravimetric method
Carnotite, Colorado	20.43	18.65
Pitchblende, Bohemia	58.83	60.71
Pitchblende, Bohemia	62.22	62.98
Soddite, Belgian Congo	43.98	44.70
Thorianite, Ceylon	...	26.75

[16] Boltwood, *Phil. Mag.*, 9, 603 (1905).

[17] Bulletin 212, U. S. Bureau of Mines, pp. 225–226.

The gravimetric values given above were used in all the calculations. The a-ray activity, Col. **3**, Table I, due to the uranium in one gram of mineral was obtained in each case by multiplying the arbitrary constant 413.4 by the percentage of uranium in the mineral.

In order to reduce the measured protoactinium activities, Col. 4, Table I, to values corresponding to an equal number of uranium atoms, the protoactinium activities were multiplied by 61/72. This factor was determined as follows. According to Meyer and Schweidler[18] one α-particle from uranium I produces 1.16×10^5 pairs of ions in air over its entire range, and one a-particle from uranium II produces 1.27×10^5 pairs, the average being 1.22×10^5 pairs. One a-particle from protoactinium produces 1.44×10^5 pairs of ions in air over its entire range, hence the ionization due to the protoactinium is about fifteen per cent. greater atom for atom disintegrating than the average of that from uranium I and uranium II. To convert the protoactinium values to corresponding uranium values, they must be multiplied by the ratio $1.22 \times 10^5/1.44 \times 10^5$ or 61/72. These reduced values are given in Col. 5, Table I.

To illustrate the method of calculating the atom for atom relation, let us consider the sample of carnotite containing 18.65% of uranium element. The a-ray activity due to the uranium in one gram of the mineral is 415.4×0.1866 or 77.5 divisions per minute. The initial a-ray activity of the protoactinium in one gram of this mineral is 2.36 divisions per minute, and this times 61/72 equals 2.00 divisions per minute, which is the activity it would have if the a-particles from protoactinium had the same range as the average of those from uranium I and uranium II. Dividing 2.00 by 77.5 gives 0.0258, which is the ratio between the number of protoactinium atoms and atoms of uranium I and uranium II disintegrating in unit time. Multiplying 0.0258 by 2 gives 0.0516, or the ratio between the number of protoactinium atoms and atoms of uranium I or uranium II disintegrating. Multiplying 0.0516 by 100 gives 5.16, which is the number of atoms of protoactinium disintegrating per one hundred atoms of uranium I or uranium II. The values obtained for the different minerals are given in Col. 6, Table I.

TABLE I

VALUES FOR DIFFERENT MINERALS

Mineral	Uranium element, %	U activity per gram of mineral	Pa activity per gram of mineral	Pa activities reduced	Atoms of Pa per 100 atoms of U I and U II disintegrating
Carnotite, Colorado	18.65	77.5	2.36 ± 0.053	2.00	5.16
Pitchblende, Bohemia	60.71	252.2	4.16 ± .063	3.52	2.79
Pitchblende, Bohemia	62.98	261.6	2.26 ± .088	1.92	1.47
Soddite, Belgian Congo	44.70	185.7	4.03 ± .080	3.41	3.67
Thorianite, Ceylon	26.75	111.1	1.64 ± .031	1.39	2.50

Discussion

It is seen that the ratio of protoactinium to uranium in the five minerals studied is by no means constant. The result is not entirely contradicted by the investigations of others, who have concluded that the ratio between protoactinium and uranium is constant in different minerals, for their experimental results show considerable variation in this ratio.

Largely on other evidence, many writers[19] of recent years have advocated the theory that the actinium series springs from an unknown isotope of uranium. The values they have variously assigned for the atomic weight of this isotope of uranium are 235, 237, 239 and 240.

The arguments in favor of an independent origin of the actinium series have centered around one or more of the following considerations: (1) the atomic weight of uranium being 238.18 has been taken as evidence of the existence of a higher isotope of uranium. However, this apparent excess weight of 0.18 has been explained on the basis of the "packing effect" by Plotnikow.[20] (2) There is no parallel to the formation of a branched series featuring a dual a-ray change. The other cases of branching, as in the "C" members of the uranium, thorium and actinium series, form one branch in an a-ray change and the other branch in a β-ray change. (3) The assumption of an independent origin of the actinium series seems to be more nearly in accord with the Geiger–Nuttall relation. (4) The discovery of certain rings in some pleochroic haloes can be explained on such an assumption.

Of all the suggested atomic weights for this independent source of the actinium series, the value 235 at present seems to be the most probable. Aston[21] found a faint line in the mass spectrum of some lead tetramethyl made from uranium lead obtained from Norwegian broggerite. He states that it cannot be due to lead as an impurity, because in ordinary lead 208 is about twice as strong as 207; neither can it be due to the products of radium or thorium. As he states, it is difficult to resist the conclusion that it is the end-product of the only other disintegration family, that of actinium.

Rutherford[22] likewise speculates regarding this isotope of lead, atomic weight 207, and concludes that it is highly probable that the mass 207 is mainly due to actinium lead and that the actinium series has its origin

in an isotope of uranium which he calls "actino-uranium." He states that it is simplest to suppose that its mass is 235 and that it undergoes first an α- and then a β-ray transformation into protoactinium. The β-ray body is probably to be identified with uranium Y discovered by Antonoff.[23] On this view the successive transformations follow the order alpha, beta, alpha, beta, and differ in this respect from the main uranium series, which follows the order alpha, beta, beta, alpha. He states that it is possible for it to follow the uranium mode of disintegration, if it is assumed that the "actino-uranium" has an atomic weight of 239, atomic number 92 and disintegrates in an α-ray change followed by two β-rays. No evidence of such β-ray bodies has been found.

If it is true that 207 represents the mass of actinium lead, then it represents the first accurate determination of the atomic weight of a member of the actinium series and indicates that the atomic weight of protoactinium is 231. Thus it seems very probable that the origin of the actinium series is, as yet, an undiscovered isotope of uranium and the series is independent of the main uranium series. The results of this investigation lend support to this view.

Acknowledgments.—The writer wishes to express his sincere appreciation to Dr. Herman Schlundt, at whose suggestion this work was undertaken, for his personal interest and very helpful advice, throughout the investigation, and to Mr. Fred Kavanagh, whose very careful gravimetric determinations of the uranium content of some of the minerals added materially to the paper.

Summary

1. Since tantalum is the nearest homolog of protoactinium, extensive work was done on simplifying and standardizing a method which, with slight modifications, was used for the quantitative separation of tantalum from different uranium ores.

2. The uranium and protoactinium contents of five uranium ores from widely separated localities were determined and the atom for atom relation between uranium and protoactinium was computed in each case.

3. The results show that the protoactinium–uranium ratio in the different ores is far from constant, and consequently strengthens the view, now held by some, that the actinium series springs from a source other than uranium II.

EQUILIBRIA INVOLVING SOME COMPLEX IONS OF SILVER AND THE FREE ENERGY OF SOME SILVER COMPOUNDS[1]

BY MERLE RANDALL AND J. O. HALFORD

RECEIVED SEPTEMBER 19, 1929 PUBLISHED JANUARY 8, 1930

Complex ions of silver are formed by the combination of silver ion with ammonia, cyanide, sulfite, thiosulfate, nitrite, thiocyanate, chloride, bromide, iodide and a few other substances. They fall into two classes: those formed from the ions of strong acids, including the halides and thiocyanates, in which case no one complex predominates, and those formed by the combination of silver ion with neutral, weakly basic, or weakly acidic substances in which only a single complex is predominantly present. The equilibria involving the latter class may be treated in a manner comparable to the treatment of simple ion equilibria. The latter class includes the ammonia and cyanide complexes, and it is with these that this paper is chiefly concerned.

When silver chloride is added to aqueous ammonia, silver ammonia complex is formed in accordance with the equation

$$\mathrm{AgCl(s)} + 2\mathrm{NH_4OH(aq.)} = \mathrm{Ag(NH_3)_2}^+ + \mathrm{Cl}^- + 2\mathrm{H_2O(l)} \qquad (1)$$

If we define K_m' by the equation[2]

$$K_m' = m(\mathrm{Ag(NH_3)_2}^+)m(\mathrm{Cl}^-)a^2\,(\mathrm{H_2O})/a^2\,(\mathrm{NH_4OH(aq.)}) \qquad (2)$$

it is obvious from the definition of the activity coefficient that the true equilibrium constant, K, is equal to $\gamma_\pm{}^2 K_m'$, where $\gamma_\pm$ is the activity coefficient of the complex salt. The activity of the water is included in the activity of the aqueous ammonia by definition and it will be found in the following article[3] that the activity coefficient of the ammonia in aqueous silver ammonia chloride is equal to the molality of the ammonia. If, then, we plot the logarithm of the reciprocal square root of K_m' against a function of the ionic strength, or its square root ($\mu^{1/2}$), the curve is similar to that obtained by plotting the logarithm of the activity coefficient (log $\gamma_\pm$) of a simple univalent salt against the same function of the ionic strength. The extrapolation to infinite dilution is made by superimposing our plot upon the similar plot for a suitable strong electrolyte.[2a] The logarithm of the reciprocal square root of K then coincides with the origin of the reference plot. From the value of log $(1/K^{1/2})$ and the measured values of

---

[1] Abridged paper; original received December 22, 1927.

[2] The method of extrapolation is a modification of that adopted by (a) Randall and Vietti, THIS JOURNAL, 50, 1526 (1928). Reference to the present work was made by (b) Randall, Trans. *Faraday Soc.*, 23, 502 (1927). See also (c) Randall, *ibid.*, 23, 498 (1927); (d) Bray and MacKay, THIS JOURNAL, 32, 1207 (1910), and (e) Johnston, *ibid.*, 37, 2001 (1915), used similar equilibrium constants.

[3] Randall and Halford, *ibid.*, 52, 192 (1930).

log $(1/K_m'^{1/2})$ the activity coefficient of the complex salt may be obtained for a given ionic strength, for by definition

$$\log \gamma_{\pm} = \log (1/K_m'^{1/2}) - \log (1/K^{1/2}) \tag{3}$$

In a reaction in which the complex is formed by the addition of an ion as cyanide or sulfite, rather than by reaction with a neutral molecule as ammonia or hydrocyanic acid, another method of extrapolation must be employed. For example, in the reaction

$$AgI(s) + 2CN^- = Ag(CN)_2^- + I^-;\ K = a(Ag(CN)_2^-)a(I^-)/a^2(CN^-) \tag{4}$$

the value of K is probably not far different from the stoichiometrical equilibrium constant K_m; and if log K_m is plotted against the square root of the ionic strength, a straight line will be obtained if the activity coefficients of the cyanide complex and iodide ion are not far different from that of cyanide ion. In many cases K is obtained with sufficient accuracy by taking the numerical average of K_m.

The Solubility of Silver Chloride in Aqueous **Ammonia.**—$AgCl(s) + 2NH_4OH(aq.) = Ag(NH_3)_2^+ + Cl^- + 2H_2O(l)$.—Silver chloride was prepared by adding silver nitrate (0.5 M) to a slight excess of ammonium chloride (0.1 M) in the presence of very dilute nitric acid. After filtering and washing thoroughly, the precipitate was dried at 100°. At all times care was taken to avoid prolonged exposure to light. Aqueous ammonia was prepared by diluting U. S. P. ammonium hydroxide to the desired strength. The resulting solutions were found to be free from carbonate. Toluene was distilled before use, about 20% being discarded in the initial and final fractions.

Silver chloride, aqueous ammonia and toluene were placed in bottles with ground glass stoppers secured by small rubber caps and rotated in a thermostat at 25° for a period exceeding twenty-four hours. The mixtures were allowed to settle for several hours before analysis. To prevent loss of ammonia by evaporation, samples were forced by pressure from the reaction bottles through absorbent cotton filters into flasks containing a known weight of 0.1 M hydrochloric acid (standardized against sodium carbonate) in excess. The ammonia was extracted from the toluene by excess of standard acid, with methyl orange as the indicator since methyl red was found to dissolve in the toluene. The excess acid was titrated (methyl red, weight buret against sodium hydroxide). Samples for the determination of silver were received in excess of nitric acid and the silver was weighed as silver chloride.

The concentration of free ammonium hydroxide was calculated by subtracting twice the silver concentration plus the calculated ammonium ion from the total ammonia concentration (moles per 1000 g. of water in vacuum).

Experiments by Reychler[4] on the freezing points of solutions of the nitrate and sulfate of silver ammonia complex led to the formula $Ag(NH_3)_2^+$. Konowalow[5] and later Gaus,[6] from vapor pressure, and Berthelot and Delépine,[7] from the heat effects attending the addition of silver nitrate in excess to aqueous ammonia and of aqueous ammonia in excess to silver nitrate, obtained the same formula. The work of Whitney and Mel-

[7] Berthelot and Delépine, *Compt. rend.*, 129,326 (1899).

cher,[8] which included transference, freezing point and conductivity experiments, led to a similar result. More recently, de Wijs[9] has presented evidence that in saturated solutions of the base $Ag(NH_3)_2OH$ the average number of ammonia molecules per silver molecule is slightly greater than two. Our experiments with silver chloride solutions, in which the ratio of free ammonia is high in comparison to the complex ion concentration, suggest the presence of small amounts of the higher forms, but at present we are unable to present definite evidence as to the constitution of the complex. Our treatment is independent of the existence of small amounts of the higher forms.

The results of our measurements are given in Table I. Cols. 1 and 2 give the total molality of ammonia and silver constituents, Cols. 3 and 4 the molality of ammonium ion and of undissociated ammonium hydroxide as calculated[10] by the method of approximations, on the basis that the formula of the complex ion is $Ag(NH_3)_2^+$, and Cols. 5 and 6 the functions log $(1/K_m'^{1/2})$ and $\mu^{1/2}$.

TABLE I

SOLUBILITY OF SILVER CHLORIDE IN AQUEOUS AMMONIA AT 25°

Total $m(NH_3)$	Total $m(Ag)$	Calcd. $m(NH_4^+)$	Calcd. $m(NH_4OH)$	Log $(1/K_m'^{1/2})$	$\mu^{1/2}$
0.1089	0.005665	0.0015	0.0960	1.229	0.0835
1.3039	.0895	.0051	1.1198	1.097	.307
1.710	.1256	.0065	1.4525	1.063	.363
1.8782	.1379	.0068	1.5956	1,064	.380
2.1339	.1628	.0074	1.8009	1.054	.413
2.6400	.2151	.0085	2.2014	1.010	.473
2.9091	.2395	.0090	2.4211	1.005	.498

The values of log $(1/K_m'^{1/2})$ are plotted in Fig. 1 against the square root of the ionic strength. We also show the values of this constant as calculated from the data of other authors.[11]

By superimposition of the plot of Pig. 1 upon the standard activity coefficient curve,[2a] we find that the activity coefficient of the aqueous silver ammonia chloride is slightly less than that given by the limiting curve[2a]

---

Chem.*, **39, 597 (1901);** (b) Straub, *ibid.*, 77, **332 (1911);** (c) Whitney and Melcher, **Ref. 8.** The values given by Whitney and Melcher are in concentration units. More weight should be given to their values in the dilute solutions as the data for converting concentrations to molalities is not known. (d) The data and calculations are given by Randall in the section on Free Energy, "International Critical Tables," Vol. VII, McGraw-Hill Book Co., New York, **1930.**

of the Debye–Hückel equation. We take $\log (1/K'^{1/2})$ equal to 1.272 ± 0.002, hence

$$AgCl(s) + 2NH_4OH(aq.) = Ag(NH_3)_2^+ + Cl^- + 2H_2O(l);\ K_{298.1} = 2.858 \times 10^{-3};\ \Delta F^\circ_{298.1} = 3472 \text{ cal.} \quad (5)$$

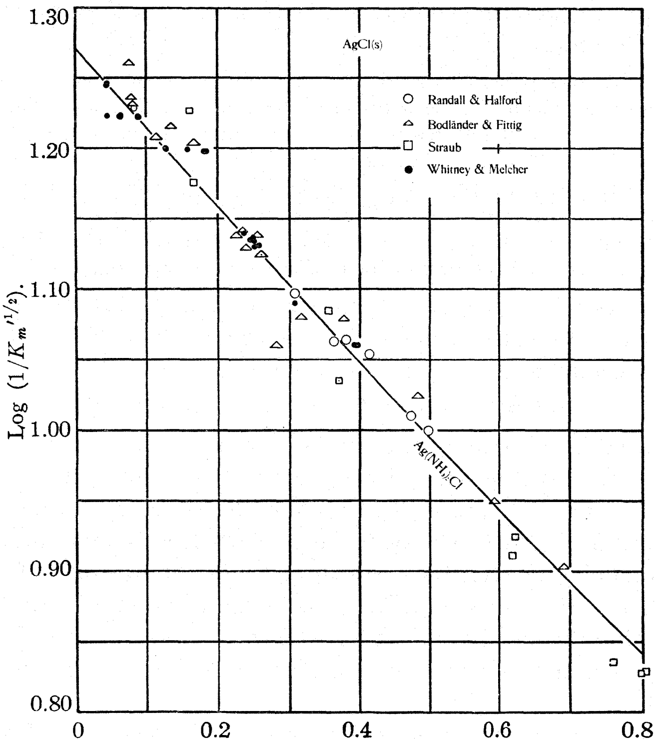
The values of the logarithm of activity coefficient of the silver ammonia chloride at round molalities are given in Table II.

Table II

Activity Coefficient of Silver Ammonia Chloride

m	0.001	0.002	0.005	0.01	0.02	0.05	0.1	0.2	0.5
Log γ	−0.017	−0.024	−0.040	−0.056	−0.080	−0.126	−0.176	−0.248	−0.382

The Solubility of Silver Oxide in Aqueous Ammonia.—$^1/_2Ag_2O(s) + 2NH_4OH(aq.) = Ag(NH_3)_2^+ + OH^- + {^3/_2}H_2O(l)$. In this reaction



Square root of ionic strength.

Fig. 1.—Solubility of silver chloride in aqueous ammonium hydroxide at 25°.

the values of K_m' calculated from the distribution ratios of ammonia between toluene and water do not correct completely for the activity of the water since the reaction of two moles of ammonia produces only 1.5 moles of water. The reciprocal square root of the equilibrium constant is given by

$$1/K^{1/2} = a(\mathrm{NH_4OH(aq.)})/[a(\mathrm{Ag(NH_3)_2}^+)a(\mathrm{OH})^-a^{3/2}(\mathrm{H_2O})]^{1/2} \qquad (6)$$

Since by definition

$$a(\mathrm{NH_4OH(aq.)}) = \gamma' m(\mathrm{NH_4OH})a(\mathrm{H_2O}) \qquad (7)$$

then

$$1/K_m'^{1/2} = \gamma' m(\mathrm{NH_4OH})a^{1/4}(\mathrm{H_2O})/m(\mathrm{Ag(NH_3)_2}^+)m(\mathrm{OH})^- \qquad (8)$$

The activity of the water is involved in Equation 8 only as the fourth root. In our measurements the activity of the water does not differ from unity by more than 10% at the highest concentration investigated. Therefore, if we include the fourth root of the activity coefficient of the water in that of the complex base, the maximum error introduced is 2.5% and this only at the highest concentrations. The equilibrium at ionic strengths, 0.01 to 0.27, was determined in the same manner as in the case of the silver ammonia chloride.

Silver oxide was prepared by adding 0.5 N silver nitrate to an excess of 0.1 N barium hydroxide which had been found to be free from halides. The precipitate was washed thoroughly and heated to boiling in distilled water to decompose any silver carbonate. This method of preparation did not exclude small quantities of barium carbonate but the presence of that substance should have no effect on the measurements.

The silver was determined by the method of Volhard. In a few cases the equilibrium was approached from supersaturation by diluting mixtures which had already come to equilibrium and rotating for more than twenty-four hours in the thermostat.

In the more dilute solutions, the distribution experiments were omitted because of the difficulty of measuring accurately the concentration of ammonia in the toluene layer. The average value[3]

$$\mathrm{NH_4OH(aq.\ in\ Ag(NH_3)_2OH)};\ (\log \gamma')/\mu = 0.136 \qquad (9)$$

has been used in calculating the values of $1/K_m'^{1/2}$ from those of $1/K_m^{1/2}$.

The results of our measurements are given in Table III. Col. 1 gives molality of the total base, Col. 2 that of the silver constituent which is also the ionic strength, Col. 3 the molality of the free ammonium hydroxide, equal to molality of total base less three times the molality of silver constituent, Col. 4 the value of $1/K_m^{1/2}$, Col. 5 the value of the same function after changing the molality of the NH_4OH to activity by means of Equation 9, and Cols. 6 and 7 have the same significance as the corresponding columns in Table I.

The values of Col. 6 are plotted against $\mu^{1/2}$ in Fig. 2. This plot also shows the values of $\log(1/K_c'^{1/2})$ calculated from the results of similar measurements (moles per liter) by Whitney and Melcher.[8,11c,d] Olmer[12] also studied this reaction at room temperature, and at ionic strengths from 0.1 to 1.4. His results are qualitatively in agreement with those of Fig. 2 and show that the activity coefficient of the silver ammonia hydroxide

[12] Olmer, Bull. *soc. chim.*, **35, 333 (1924).**

rapidly increases in the more concentrated solutions, thus offering additional evidence that this substance is a strong base.

Noyes and Kohr and later Newton[13] have determined the ratio of potassium chloride and potassium hydroxide shaken with an excess of silver

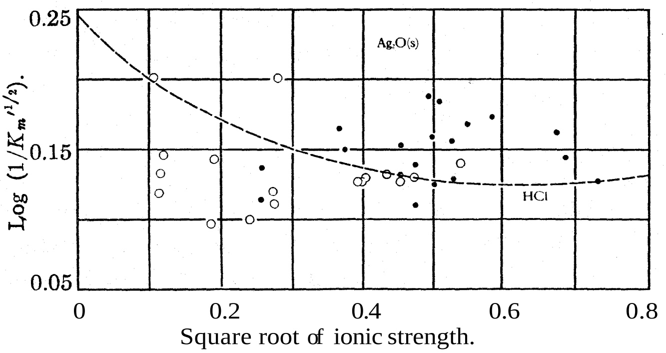

Fig. 2.—Solubility of silver oxide in aqueous ammonium hydroxide at 25°.

oxide and silver chloride. When their values of K_c and K_m are plotted against $\mu^{1/2}$ they appear to be in agreement. An extrapolation to $\mu^{1/2} = 0$ gives

$$AgCl(s) + OH^- = {}^1/_2Ag_2O(s) + Cl^-;\ \log K_{298.1} = -2.050 \pm 0.003;$$
$$\Delta F^\circ_{298.1} = 2798 \pm 5 \text{ cal.} \quad (10)$$

---

[13] (a) Noyes and Kohr, Z. *physik.* Chem., 42,336 (1902); (b) Newton, THIS JOURNAL, 50,3258 (1928).

and this value gives a reasonable ratio between the activity coefficients of $OH-$ and Cl^- in the more concentrated solutions.[14]

Combining Equations 5 and 10 we find

$$^1/_2Ag_2O(s) + 2NH_4OH(aq.) = Ag(NH_3)_2^+ + OH^- + ^3/_2H_2O(l); \log K_{298\cdot 1} = -0.494 \pm 0.005; \quad \Delta F^\circ_{298\cdot 1} = 674 \text{ cal.} \quad (11)$$

whence we find log $(1/K^{1/2}) = 0.247$ and this point is shown on Fig. 2 as the intersection of the dotted curve with the ordinate $\mu^{1/2} = 0$. The dotted curve is that of the logarithm of activity coefficient of hydrochloric acid plus 0.247. In general, the activity coefficient of strong bases is slightly less than that of hydrochloric acid. Our results show agreement with the assumption that the complex hydroxide is an approximately normal strong base in the region of $\mu^{1/2}$ = about 0.4. If we were to attempt to superimpose Fig. 2 upon the plot of log γ for strong bases so as to pass through the points at about $\mu^{1/2} = 0.2$, then we should find the activity coefficient of silver ammonia hydroxide much higher than that of any other substance at 0.2 M, and we should need to explain a discrepancy between the free energy as given by Equation 10 and the difference between Equations 5 and 11. A possible explanation of the anomalous activity coefficient of the hydroxide of silver ammonia complex is a change in the fineness of subdivision of the solid phase with the concentration and nature of the electrolyte. The probable analytical errors are not of the right sign to explain the unusual results.

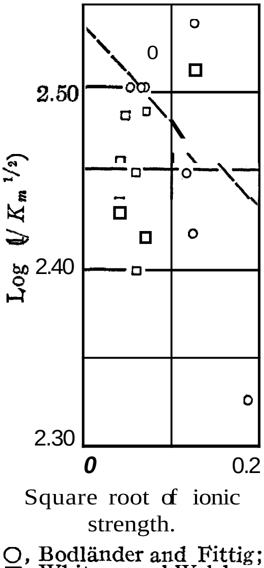

Fig. 3.—Solubility of silver bromide in aqueous ammonia.

$AgBr(s) + 2NH_4OH(aq.) = Ag(NH_3)^+ + Br^- + 2H_2O(l)$.—We show in Pig. 3 the values of log $(1/K_m'^{1/2})$ and log $(1/K_c'^{1/2})$ as calculated from the measurements of Bodländer and Fittig[11a,d] and of Whitney and Melcher[8,11c,d] plotted against $\mu^{1/2}$ or $\mu_c^{1/2}$. Account was taken of the amount of NH_4^+ present. The limiting value, log $(1/K^{1/2})$, was calculated from Equation 5 and the free energies of silver chloride, silver bromide, chloride and bromide ions,[15] and found to be 2.537. The experimental values are found to be in agreement with this value, and show that the activity coefficient of silver ammonia bromide is somewhat lower than that of the complex chloride. We thus write

$$AgBr(s) + 2NH_4OH(aq.) = Ag(NH_3)_2^+ + Br^- + 2H_2O(l); \log K_{298\cdot 1} = -5.074 \pm 0.005; \quad \Delta F^\circ_{298\cdot 1} = 6926 \text{ cal.} \quad (12)$$

Solubility **of** Silver Cyanide in **Hydrocyanic Acid.** $AgCN(s) + HCN(aq.) = H^+ + Ag(CN)_2^-$.—We have studied this reaction in solutions of

---

[15] Randall and Spencer, unpublished calculations.

hydrocyanic acid from 0.1 to 0.5 *M*. When silver cyanide is allowed to come to equilibrium with aqueous hydrogen cyanide, a small concentration of a strong acid is produced. A measurement of this acid concentration and the concentration of hydrocyanic acid permits the calculation of the equilibrium constant. The fugacity of the hydrogen cyanide is proportional to its molality.[3]

Hydrocyanic acid was prepared by the method used by Perry and Porter,[16] who investigated the vapor pressures of solid and liquid hydrogen cyanide. A solution of 18 N sulfuric acid was added slowly to powdered potassium cyanide in a distilling flask and the vapors were collected in water. The production of cyanogen by oxidation is not probable because of the slow rate of oxidation exhibited by sulfuric acid of the strength used. Perry and Porter had no difficulty with the cyanogen impurity. Silver cyanide was precipitated in dilute solution by the addition of silver nitrate to a slight excess of potassium cyanide. Some of the experiments were carried out in glass stoppered bottles, others in sealed flasks.'' In a few cases equilibrium was approached from supersaturation by maintaining the mixtures at a temperature of about 35" for several hours before rotating in the thermostat. The mixtures of silver cyanide, benzene and aqueous hydrocyanic acid were rotated in the thermostat at 25° for several days. To prevent loss of hydrogen cyanide by evaporation, samples were forced by pressure from the reaction bottles. The acid concentration was determined by titration with 0 01 N sodium hydroxide. Samples for the determination of cyanide were received in excess of sodium hydroxide and titrated by the method of Liebig to an endpoint with potassium iodide.

In Table IV we have summarized the results of the solubility measurements. Column 1 gives the molality of hydrocyanic acid, Col. 2 that of the complex acid, Col. 3 the reciprocal square root of the stoichiometrical constant, Col. 4 its logarithm and Col. 5 the square root of the ionic strength. The acid concentration produced in these equilibria is so small that an accurate determination of the equilibrium constant is difficult. We have plotted, in Fig. 4, $1/K_m^{1/2}$ against the sauare root of the ionic strength and for the purpose of making the very slight extrapolation to zero molality have taken the point determined by the mean value of $1/K_m^{1/2}$ and the mean value of . From this point we have extrapolated to zero ionic strength with the aid of the curve for hydrochloric acid and have obtained for log $(1/K^{1/2})$ the value 2.212.

aqueous hydrocyanic acid has been treated in the same manner as that of silver cyanide.

Our analysis determines only the molality of the strong acid and the molality of the hydrocyanic acid. In the simplest interpretation the complex cyanide and the chloride would have the same molality equal to half that of the acid. From the equilibrium constant of the solubility of silver cyanide in aqueous hydrogen cyanide, it is evident that if in our solutions the complex ion concentration were half that of the acid, the solutions would be supersaturated with respect to silver cyanide. Therefore, we must introduce a correction to account for the reaction

$$\mathrm{AgCl(s)} + \mathrm{HCN(aq.)} = \mathrm{AgCN(s)} + \mathrm{H^+} + \mathrm{Cl^-} \qquad (14)$$

The chloride ion concentration is greater than that of the silver cyanide complex.

Columns 1 to 4 of Table V give the molality of the hydrogen cyanide, the hydrogen ion, the complex and of the chloride, Col. 5 the reciprocal fourth root of K_m, Col. 6 its logarithm and the last the square root of the ionic strength. To determine the equilibrium constant we have plotted log $(1/K_m^{1/4})$ against the square root of the ionic strength and have extrapolated to zero ionic strength with the aid of the curve for hydrochloric acid. This gives us log $K_m^{-0.25} = 2.180$ and

$$\mathrm{AgCl(s)} + \mathrm{2HCN(aq.)} = \mathrm{Ag(CN)_2^-} + \mathrm{2H^+} + \mathrm{Cl^-};\ K_{298.1} = 1.9 \times 10^{-9};\ \Delta F^\circ_{298.1} = 11{,}902\ \mathrm{cal.} \qquad (15)$$

TABLE V

SOLUBILITY OF SILVER CHLORIDE IN AQUEOUS HYDROCYANIC ACID AT 25°

m(HCN(aq.))	m(Acid)	m(Complex)	m(Chloride)	Log $(1/K_m^{1/4})$	$\mu^{1/2}$
0.0938	0.00303	0.00132	0.00161	2.163	0.0552
.1831	.00430	.00182	.00258	2.146	.0652
.2292	.00493	.00199	.00294	2.141	.0702

Solubility of Silver Iodide in Potassium Cyanide. $\mathrm{AgI(s)} + \mathrm{2CN^-} = \mathrm{Ag(CN)_2^-} + \mathrm{I^-}$.—Measurements were made with "precipitated" silver iodide and also with a crystalline form. The precipitated silver iodide was prepared by adding 0.5 N silver nitrate to an excess of 0.1 *N* potassium iodide. The precipitate was separated and dried at 100°. The preparation of hexagonal crystals of silver iodide involved a digestion of mercuric iodide with 0.1 M silver nitrate at the boiling point. This method does not exclude mercury salts but these should have no effect on the reaction other than to cause a slight increase of ionic strength,

The silver iodide was rotated in a thermostat in contact with a potassium cyanide solution of known strength for several days. Sufficient sodium hydroxide was added to repress the hydrolysis of the cyanide. To determine the silver content a sample was acidified with nitric acid and heated to remove hydrogen cyanide; this precipitated the silver iodide, which was collected on a filter, dried at 100° and weighed.

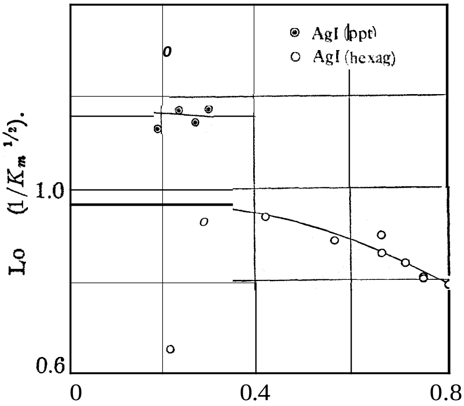

Fig. 5.—Solubility of silver iodide in aqueous potassium cyanide at 25°.

The measurements of the solubility of the precipitated and crystalline forms are summarized in Tables VI and VII and the results are plotted in Fig. 5. The limiting value of log $K^{1/2}$ in the case of precipitated silver iodide was calculated by combining Equation 15 with the free energy of ionization of aqueous hydrogen cyanide[17] and the standard free energies of the silver chloride[18] and silver iodide electrodes.[15] We thus find

$$AgI(ppt.) + 2CN^- = Ag(CN)_2^- + I^-;\ K_{298.1} = 221;\ \Delta F°_{298.1} = -3201 \text{ cal.} \quad (16)$$

The greatest uncertainty is in the value for the free energy of ionization of the hydrogen cyanide. The value of log $K^{1/2} = 1.172$ is shown in Fig. 5 as the limit of the extrapolated curve. This extrapolation appears to be reasonable. In the extrapolation of the curve for the hexagonal silver iodide, it was made parallel to the curve for the precipitated variety, whence log $K^{1/2} = 0.978$, and

$$AgI(hexag.) + 2CN^- = Ag(CN)_2^- + I^-;\ K_{298.1} = 90.4;\ \Delta F°_{298.1} = -2670 \text{ cal.} \quad (17)$$

From the difference of Equations 16 and 17

$$AgI(ppt.) = AgI(hexag.);\ \Delta F°_{298.1} = -531 \text{ cal.} \quad (18)$$

Solubility of Silver Thiocyanate, Silver Iodide and Silver Bromide in Potassium **Thiocyanate.**—Bodländer and Fittig[11a] have given the formula and free energy of the silver thiocyanate complex. Their data suggested that the free energies of silver bromide and silver iodide might be linked through their solubility in potassium thiocyanate. We have measured the solubility of silver thiocyanate, silver bromide and silver iodide in solutions of potassium thiocyanate.

Silver bromide was made by precipitating potassium bromide in dilute solution with silver nitrate in the presence of dilute nitric acid; silver thiocyanate was prepared in an analogous manner. Potassium thiccyanate of known strength was rotated in bottles in the thermostat in contact with the solid phase at 25° for several days. The silver content of the sample selected for analysis was determined gravimetrically by precipitating the dissolved solid and weighing. The thiocyanate was oxidized by heating with 2 N nitric acid, the solid precipitating during the oxidation. When the solid phase was silver thiocyanate, a small concentration of potassium thiocyanate was added to the solution before filtering to replace any silver thiocyanate which had been oxidized.

In the silver bromide equilibria agreement was obtained in two sets of experiments in which rotation was continued respectively for two days and three weeks. This eliminates the time factor in the explanation of the results. In the silver thiocyanate equilibria a few rough measurements were made in which the equilibrium was approached from supersaturation. They were consistent with the others.

Table VIII gives the results of the solubilities of silver bromide. The first column gives the total molality of potassium thiocyanate, the second of the dissolved silver bromide, the third the free thiocyanate if the formula of the complex is $Ag(CNS)_2^-$, and the fourth a function of the equilibrium constant.

Table IX gives similar results for the solubility of precipitated silver iodide in potassium thiocyanate, while Table X summarizes the silver thiocyanate equilibria.

TABLE VIII

SOLUBILITY OF SILVER BROMIDE IN POTASSIUM THIOCYANATE AT 25°

1.009	1.63	1.008	−3.80

TABLE X

SOLUBILITY OF SILVER THIOCYANATE IN POTASSIUM THIOCYANATE AT 25°

$AgCNS(s) + CNS^- = Ag(CNS)_2^-$

Original m(KCNS)	m(AgCNS)	m(KCNS(free))	Log (K_m)
0.312	0.00202	0.310	−2.187
.564	.0121	.512	−1.627
.870	.0458	.824	−1.255
1.124	.0985	1.026	−1.018

Evidently we cannot account for the solubility of these solids in potassium thiocyanate by the formation of a single complex ion $Ag(CNS)_2^-$. Attempts to interpret these results by other simple assumptions have been unsuccessful. The reactions here studied are analogous to those of the silver halides in halide ion solutions. By assuming a sufficient number of complexes, and determining the equilibrium constants among these by the method of approximations, one should be able to satisfy the experimental data, but it is doubtful if such a calculation would be of more than academic interest.

The Solubility of Silver Chloride in Sulfite Solutions.—From the measurements of Luther and Leubner,[19] the details of which are found in another place,[11d] we find on extrapolation to infinite dilution

$$AgCl(s) + 2SO_3^{--} = Ag(SO_3)_2^{---} + Cl^-; K_{298.1} = 0.0578; \Delta F^\circ_{298.1} = 1690 \text{ cal.} \quad (19)$$

The Solubility of Silver Bromide in Sulfite Solutions.—Likewise from the solubility measurements of Luther and Leubner,[11d,19] we find on extrap-

---

[19] **Luther** and Leubner, Z. anorg. *Chem.*, 74, 393 (1911).

olating to zero ionic strength along a line parallel to the curve of log K_c against $\mu_c^{1/2}$ for Reaction 19, the value log K = 3.754, whence

$$AgBr(s) + 2SO_3^{--} = Ag(SO_3)_2^{---} + Br^-;\ K_{298\cdot1} = 1.76 \times 10^{-4};\ \Delta F^\circ_{298\cdot1} = 5124\text{ cal.} \quad (20)$$

The difference in the values of the free energy from Equations 19 and 20 is —3434 cal. while the corresponding difference between Equations 5 and 12 is −3454 cal. which is a very satisfactory check upon the accuracy of the measurements and the assumptions made in the various extrapolations.

The Equilibrium of Silver Chloride and Silver Bromide with Silver **Thiocyanate.**—From the measurements of Hill,[20,11d] we find by extrapolation

$$AgCl(s) + CNS^- = AgCNS(s) + Cl^-;\ K_{298\cdot1} = 161;\ \Delta F^\circ_{298\cdot1} = -3012\text{ cal.} \quad (21)$$

$$AgBr(s) + CNS^- = AgCNS(s) + Br^-;\ K_{298\cdot1} = 0.505;\ \Delta F^\circ_{298\cdot1} = 404\text{ cal.} \quad (22)$$

The difference between Equations 21 and 22 is —3416 cal., which is also in satisfactory agreement with the difference between Equations 5 and 12.

The Free Energy of Some Silver Complexes

Silver Ammonia Complex.—The free energy of the silver ammonia complex ion is best calculated from Equation 5, which is based upon the solubility of silver chloride. We have already shown that the results based upon the solubility of silver oxide (Equation 11) and of silver bromide (Equation 12) in aqueous ammonia are in agreement with Equation 5. Hence combining with the values for the free energy of formation of silver chloride,[15] aqueous ammonia,[11d,17] chloride ion,[18] and liquid water,[11d,17] we find

$$Ag(s) + N_2(g) + 3H_2(g) = Ag(NH_3)_2^+ + E^-;\ \Delta F^\circ_{298\cdot1} = -4003\text{ cal.} \quad (23)$$

Dissociation Constant of Silver Ammonia Complex.—By combination of Equation 23 with the free energy of silver ion,[11d,17] liquid water and ammonia we find

$$Ag(NH_3)_2^+ + 2H_2O(l) = Ag^+ + 2NH_4OH(aq.);\ \Delta F^\circ_{298\cdot1} = 9851\text{ cal.};\ K_{298\cdot1} = 7.86 \times 10^{-8} \quad (24)$$

Silver Cyanide Complex.—We calculate the free energy of formation of silver cyanide complex from Equation 15 and the free energies of silver chloride,[15] aqueous hydrogen cyanide[11d,17] (27,510) and chloride ion,[18] whence

$$Ag(s) + 2C(graph.) + N_2(g) + E^- = Ag(CN)_2^-;\ \Delta F^\circ_{298\cdot1} = 72{,}047\text{ cal.} \quad (25)$$

As in the case of the silver ammonia complex, this value has already been shown to be in agreement with that calculated from other reactions. (Equation 16.)

Silver Cyanide.—From Equations **13** and *25* with the free energy of aqueous hydrogen cyanide we find for the free energy of formation of silver cyanide.

$$Ag(s) + C(graph.) + \tfrac{1}{2}N_2(g) = AgCN(s);\ \Delta F^\circ_{298\cdot1} = 38{,}499\text{ cal.} \quad (26)$$

Dissociation Constant of **Silver Cyandie** Complex.—Prom Equation

---

[20] Hill, THIS JOURNAL, 30, 68 (1908).

15, the free energy of chloride ion, silver chloride and the free energy of dissociation of aqueous hydrogen cyanide,[11d,17] we find

$$Ag(CN)_2^- = Ag^+ + 2CN^-;\ \Delta F^\circ_{298.1} = 25{,}141\ \text{cal.};\ K_{298.1} = 3.81 \times 10^{-19} \quad (27)$$

Solubility Product of Silver Cyanide.—From Equations 13 and 27 we find

$$AgCN(s) = Ag^+ + CN^-;\ \Delta F^\circ_{298.1} = 19{,}319\ \text{cal.};\ K_{298.1} = 7 \times 10^{-15} \quad (28)$$

Hydrogen Silver Cyanide.—Since the results of Table IV and Fig. 4 show the hydrogen silver cyanide to be a strong acid, we may write from Equation 25

$$Ag(s) + 2C(\text{graph.}) + N_2(g) + {}^1/_2H_2(g) = HAg(CN)_2;\ \Delta F^\circ_{298.1} = 72{,}047\ \text{cal.} \quad (29)$$

Silver Sulfite Complex.—From Equation 19 and the free energy of silver chloride,[15] chloride ion[18] and sulfite ion,[11d,17] we find

$$Ag(s) + 2S(\text{rhomb.}) + 3O_2(g) + 3E^- = Ag(SO_3)_2^{---};\ \Delta F^\circ_{298.1} = -226{,}545\ \text{cal.} \quad (30)$$

We may consider this result verified by Equation 20. The largest uncertainty in the value lies in the uncertainty in the free energy of sulfite ion.

Dissociation Constant of Silver Sulfite Complex.—From Equation 30 and the free energies of silver and sulfite ion,[11d,17] we find

$$Ag(SO_3)_2^{---} = Ag^+ + 2SO_3^{--};\ \Delta F^\circ_{298.1} = 11{,}633\ \text{cal.};\ K_{298.1} = 3.00 \times 10^{-9} \quad (31)$$

Summary

A method has been presented for the treatment of equilibria involving the solution of difficultly soluble compounds in weak acids or bases to form complex ions. The method has been applied to new data for the solubility of silver chloride and silver oxide in ammonium hydroxide and of silver chloride and silver cyanide in aqueous hydrogen cyanide.

The solubility of precipitated and crystalline silver iodide in potassium cyanide, and the solubility of silver bromide, silver iodide and silver thiocyanate in potassium thiocyanate has been determined.

The activity coefficient of silver ammonia chloride, of silver ammonia bromide, of silver ammonia hydroxide and of complex silver cyanide acid has been determined.

The data for the solubility of silver salts in weak acids have been reviewed and the free energy of several complex ions calculated.

The data for the free energy of several silver salts have been considered and the free energies of some of the silver compounds are presented in the following table.

TABLE XI

THE DISTRIBUTION OF AMMONIA BETWEEN TOLUENE AND AQUEOUS SILVER AMMONIA CHLORIDE AND HYDROXIDE, AND OF HYDROGEN CYANIDE BETWEEN BENZENE AND AQUEOUS HYDROGEN SILVER CYANIDE[1]

BY MERLE RANDALL AND J. O. HALFORD

RECEIVED SEPTEMBER 19, 1929 PUBLISHED JANUARY 8, 1930

Incidental to the experiments described in the previous paper,[2] we present the following values of the distribution ratio of ammonia between toluene and aqueous silver ammonia chloride and hydroxide at 25°. Column 1 gives the nature of the silver salt, Col. 2 its molality (mole per 1000 g. of water in vacuum), Col. 3 the molality of the total ammonia, Col. 4 the molality of the free NH_4OH based upon the formula $Ag(NH_3)_2^+$ for the complex ion (calculated molality of NH^+ deducted), and Col. 5 the mole fraction of NH_3 in the toluene layer.

TABLE I

DISTRIBUTION OF AMMONIA BETWEEN TOLUENE AND AQUEOUS SILVER AMMONIA CHLORIDE AND HYDROXIDE AT 25°

[a] Not saturated with $Ag_2O(s)$.

If we assume the activity of the solvent as unity,[3] the constant of the reaction

$$NH_3(g) + H20\ (\text{in } NH_4OH\ (aq.)) = NH_4OH\ \textbf{(aq.)} \qquad (1)$$

---

[1] Abridged paper; original received December 22, 1927.

[2] Randall and Halford, THIS JOURNAL, 52, 178 (1930).

[3] See Lewis and Randall, "Thermodynamics and the Free Energy of **Chemical** Substances," McGraw-Hill Book Co., New York, 1923, p. 558.

is independent of the concentration of the ammonium hydroxide up to molal. At the small mole fractions of ammonia in the toluene layer, no great error can be made if we assume the activity of the NH_3 (in toluene) equal to its mole fraction. We therefore write

$$NH_3 \text{ (in toluene)} + H_2O \text{ (in } NH_4OH \text{ (aq.))} = NH_4OH\text{(aq.)}; \; K_D = \gamma' m(NH_4OH\text{(aq.)})/N(NH_3 \text{ in toluene}) = \gamma' K_{mD} \quad (2)$$

where K_D, K_{mD} and γ' are the equilibrium constant, the ratio m/N and the combined activity coefficient of the aqueous ammonia and the water.

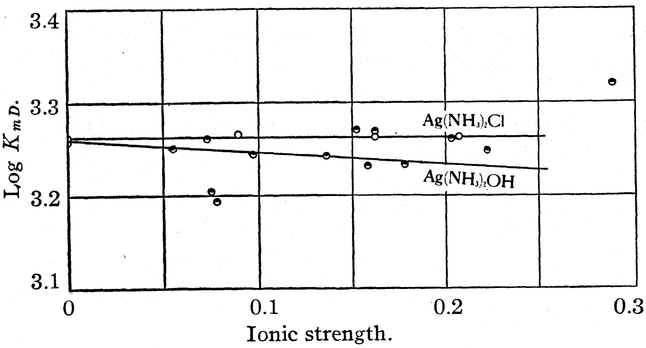

Fig. 1.—Distribution of ammonia between toluene and aqueous silver ammonia chloride or hydroxide.

The values of K_{mD} and of $\log K_{mD}$ are given in Cols. 6 and 7 of Table I. The values of $\log K_{mD}$ are plotted in Fig. 1 against the ionic strength, μ, which is taken as the molality of the silver salt. The values with silver ammonia hydroxide are less concordant than the others because of difficulty of determining the small amount of ammonia in the toluene layer.

From Equation 2

$$\log \gamma' = \log K_D - \log K_{mD} \quad (3)$$

Since the curves of Fig. 1 are approximately straight lines, the logarithm of the activity coefficient of the ammonia is approximately proportional[4] to the ionic strength.

In the case of ammonia in the presence of silver ammonia chloride, we may take $\log \gamma'$ equal to zero. In the case of the silver ammonia hydroxide, the value of $(\log \gamma')/\mu = \mathbf{0.136}$ is about that which would be predicted from that of the chloride and of other substances as given by Randall and Failey.[4]

The assumption that $\log \gamma'$ is a measure of the combined effect of salting out of the ammonia and the lowering of the activity of the water implies that ammonia in the toluene layer is not hydrated. Complete hydration in the toluene layer would eliminate the activity coefficient of the water from the constant of Equation 1. By combining the data of Hantzsch and

---

[4] See Randall and Failey, *Chem. Reviews*, 4, 271, 285, 291 (1927).

Vogt[5] on the distribution of ammonia between air and toluene with data on the vapor pressure of aqueous ammonia, the distribution ratio K_{mD} has been calculated for the case in which hydration is impossible. The distribution ratio obtained in this manner is in agreement with our own as given in Table I, and justifies the assumption that the activity coefficient of the water is included in γ'.

If in calculating the distribution coefficient, we employ the mole fraction of ammonium hydroxide in the aqueous phase instead of the molality, we find a positive salting out effect. The calculation of an activity coefficient based on these quantities would not be significant since the activity coefficient is defined as the ratio of the activity to the molality rather than to the mole fraction. Since the activity of the ammonium hydroxide is determined by the mole fraction of ammonia in the toluene layer, it is, of course, independent of the units of concentration employed in the aqueous phase.

The values for the distribution of hydrogen cyanide between benzene and aqueous hydrogen silver cyanide are given in Table II. There is no trend in the values of the distribution coefficient and we may assume that at these low concentrations of the complex acid the activity coefficient of the aqueous hydrogen cyanide may be taken as unity.

TABLE II

DISTRIBUTION OF HYDROGEN CYANIDE BETWEEN BENZENE AND AQUEOUS HYDROGEN SILVER CYANIDE AT 25°

Summary

The activity coefficient of ammonia in aqueous silver ammonia chloride and of hydrogen cyanide in aqueous hydrogen silver cyanide is unity at 25°. The quotient (log γ')/μ for ammonia in aqueous silver ammonia hydroxide is 0.136 at 25°.

[CONTRIBUTION FROM THE AMERICAN CYANAMID COMPANY]

THE HYDROLYSIS AND POLYMERIZATION OF CYANAMIDE IN ALKALINE SOLUTIONS

BY G. H. BUCHANAN AND GEORGE BARSKY

RECEIVED FEBRUARY 8, 1929 PUBLISHED JANUARY 8, 1930

When calcium cyanamide is added to water, hydrolysis of the normal cyanamide occurs, with production of a solution of calcium acid cyanamide and precipitation of calcium hydroxide.[1]

$$2CaCN_2 + 2H_2O \rightleftharpoons Ca(HCN_2)_2 + Ca(OH)_2 \qquad (1)$$

Following the formation of calcium acid cyanamide, a number of reactions may occur, of which the two most important are hydrolysis of the acid cyanamide with production of urea, as represented by

$$Ca(HCN_2)_2 + 4H_2O \rightleftharpoons 2NH_2CONH_2 + Ca(OH)_2 \qquad (2)$$

and polymerization to produce dicyandiamide, as represented by

$$Ca(HCN_2)_2 + 2H_2O \rightleftharpoons NH_2C{=}NHNHCN + Ca(OH)_2 \qquad (3)$$

Secondary reactions also may occur, dicyandiamide being hydrolyzed to guanylurea or to cyanurea, and urea to ammonium carbonate.

It has long been known that the reactions of cyanamide in alkaline solutions are dependent upon the nature of the base present. The facts have been summarized as follows:[2] "The strong alkalies KOH or NaOH in aqueous solutions produce almost entirely urea with no trace of dicyandiamide; weak alkalies, NH_4OH or MgO, produce dicyandiamide almost exclusively at first, and then ammonia. CaO, however, produces a mixture of urea, dicyandiamide, ammeline, amidodicyanic acid, ammonia and other bodies."

It must be carefully emphasized that the reactions occurring in soil solutions are not necessarily the same as those in ordinary aqueous solutions. In the former such variables as colloids, bacteria and the like have important effects upon the course of the reactions. It remains true, however, that one cannot expect fully to understand the reactions of cyanamide in a system as complex as is the soil unless he first understands its reactions in water alone.

That cyanamide is readily converted to other products was noted long before the development of the modern Cyanamid industry. Cloëz and Cannizzaro[3] observed that a compound of the same empirical formula but with markedly different properties was spontaneously formed when

solutions of cyanamide were allowed to evaporate. They named this new product cyanuramin—it was undoubtedly dicyandiamide. The same observers reported that alkalies decomposed cyanamide, although they did not mention the products formed. Other early observers were aware of the formation of polymerized products, variously styled, and of urea.[4]

The first attempt at a quantitative study of the reactions of calcium cyanamide in alkaline solutions was made by Grube and his co-workers.[5] They found that the concentration of the alkali had a marked effect upon the velocity of decomposition of cyanamide, the velocity increasing and then decreasing with increasing alkali concentration. As a result of their work a process for the manufacture of dicyandiamide was worked out, styled by the inventors the "Process of Optimum Lime Concentration."[6] According to their procedure a solution of calcium acid cyanamide was first prepared, and to this solution sulfuric acid was added in varying amounts and at varying time intervals. The additions were to be made in accordance with the theory that there should always be present in the solution four moles of cyanamide for each mole of lime, this ratio being considered the "optimum" for dicyandiamide formation. The mechanism of the reaction, according to these workers, is that dicyandiamide is formed by reaction between an undissociated cyanamide molecule and *a* cyanamide ion, as represented by the equation

$$(\mathrm{NHCN})^- + \mathrm{H_2NCN} = (\mathrm{NHC{=\!=}NHNHCN})^-$$

Morrel and Burgen[7] also studied the kinetics of the formation of dicyandiamide from cyanamide and arrived at the same conclusion, namely, that the reaction is ionic. This theory, announced almost simultaneously by Grube and Krüger and by Morrell and Burgen, is discussed more fully in a later section of the present paper where we have shown that our own data are consistent with and confirmatory to the ionic theory.

Hetherington and Braham[8] studied the polymerization and hydrolysis of cyanamide in aqueous alkaline solutions. Earlier investigators had assumed that the cyanamide disappearing was completely transformed to dicyandiamide, an assumption which our data show to be true only under special conditions. Hetherington and Braham determined cyanamide disappearing and urea formed. Dicyandiamide formed was arrived at by difference. A summary of their results is shown below.

[a] Dicyandiamide obtained by difference.

Hetherington and Braham's results show that in alkaline solution urea is formed as well as dicyandiamide, increased concentrations of alkali resulting in increased urea formation. Hetherington and Braham concluded that their results with respect to dicyandiamide formation could be explained by the theory of Grube and Krüger. The formation of urea was attributed to the catalytic effect of hydroxyl ions.

Although it seems readily apparent that effects such as those reported by the previous investigators are controlled by hydrogen-ion concentration, the problem had not heretofore been studied from this point of view. It therefore became the purpose of the work which is here reported to study the influence of hydrogen-ion concentration upon the fate of cyanamide in alkaline solutions. In the experiments, the details of which are recorded below, the course of cyanamide disappearance and urea and dicyandiamide formation was observed in solutions whose hydrogen-ion concentration was maintained at constant values.

Dicyandiamide Formation

Experimental Method

Cyanamide Solutions.—Commercial calcium cyanamide was agitated for one hour with three times its weight of water at 30° and filtered. To the filtrate dilute sulfuric acid was added carefully and with vigorous stirring, the temperature being maintained below 30°. The sulfuric acid addition was continued until the solution was just acid to methyl red indicator (about PH 5), and the precipitated calcium sulfate was filtered off. Solutions of cyanamide prepared in this way and kept at ordinary room temperature suffer practically no change in cyanamide concentration over a period of several months.

Buffer Solutions.—For the measurements at PH 6 sodium dihydrogen phosphate and sodium hydroxide were employed as the buffer combination. For *P*H 8 to *P*H 10 sodium hydroxide–boric acid solutions were used. The buffer solutions used were all more concentrated than those usually employed (0.5 molal phosphate or borate instead of 0.2 molal). As will appear from the data the buffering was very good throughout this range. For hydrogen-ion concentrations lower than PH 10, sodium hydroxide was used because suitable buffer combinations were not available. Alkalinity control was consequently poor.

Methods of Analysis.—Cyanamide was determined by precipitating it as silver cyanamide from an ammoniacal solution, filtering, washing and determining nitrogen in the precipitate by the Kjeldahl method.

Urea was determined by the urease method.

Dicyandiamide was determined by hydrolyzing to guanylurea under carefully controlled conditions, precipitating guanylurea picrate by the addition of picric acid and weighing. Details of the method are as follows. A 10-cc. sample is pipetted into a 150-cc. beaker and 25 cc. of hydrochloric acid solution (one volume of sp. gr. 1.18 mixed with two volumes of water) added. The beaker is suspended over a gently boiling water-bath so that the bottom of the beaker almost touches the water and is held there for fifteen minutes. The solution is then cooled, made slightly alkaline to phenolphthalein with 10% sodium hydroxide solution, and made up to 100 cc. in a volumetric flask. To a 25-cc. aliquot of this solution, 5 cc. of an alcoholic solution of picric acid (6 g. of picric acid in 100 cc. of 95% ethyl alcohol) is added. The solution is allowed to stand for one hour with occasional stirring and is then filtered through a tared Gooch crucible. A saturated solution of guanylurea picrate is used for washing. The precipitate is dried at 105° for one hour. A solubility correction of 0.0044 g. is added to the weight of the precipitate. The factor for conversion of the weight of guanylurea picrate to dicyandiamide nitrogen is 0.169. The quantity of picric acid recommended is sufficient for about 0.2 g. of guanylurea picrate.

Melamine, guanylurea and guanidine were tested for by means of picric acid with negative results in all of the experiments.

Measurement of the Hydrogen-Ion Concentration.—Hydrogen-ion concentrations were determined by potentiometer measurements with a hydrogen electrode immersed in the solution. A saturated potassium chloride calomel cell was used as the other electrode. The chain was at 50°. The value of the chain

$$\text{Hg–HgCl} - \text{satd. KCl} - \text{satd. KCl} - 0.1\ M\ \text{HCl} - \text{H}_2\text{(Pt)}$$

was checked at intervals and found to agree with the value reported by Fales and Mudge for 50°.[9] The hydrogen-ion concentration was calculated from the e.m.f. measurement by means of the Nernst equation, which for this temperature and chain is

$$P_{\text{H}^+} = 15.60E - 3.61$$

Procedure.—In a water-bath at 50 ± 0.1° were placed bottles containing the necessary buffer solutions, a wash bottle containing distilled water and, in a standard 200-cc. flask, exactly enough cyanamide solution to contain 2.80 g. of cyanamide nitrogen. When all had reached the temperature of the bath, the proper amounts of buffer solutions were pipetted into the cyanamide solutions, distilled water was added to make the volume up to 200 cc. (0.5 molal) and the contents of the flasks were mixed as quickly as possible. The initial time was taken at the moment when the additions of buffer solutions had been completed. Samples were withdrawn immediately for analysis and subsequently at various time intervals as indicated in the tables. Immediately after samples were withdrawn, they were made neutral to methyl red to prevent further reaction.

In the tables the velocity constants, k_{D}, for the polymerization of cyanamide to dicyandiamide are calculated by means of the formula for a reaction of the second order

$$k_{\text{D}} = \frac{1}{t}\frac{x}{c(c-x)}$$

where c is the initial concentration of cyanamide, in grams of nitrogen

---

[9] Fales and Mudge, This Journal, 42,2434 (1920).

per 100 cc., and x is the change in concentration occurring in the time interval, t, in hours.

For the hydrolysis to urea and for the decomposition of dicyandiamide the velocity constants k_U and k_D1 are calculated for a reaction of the first order

$$k = \frac{1}{t} \log \frac{c}{c - x}$$

Table I summarizes the results of this study over the range PH 6 to **PH 12.** The relation between the velocity constants and the hydrogen-ion concentrations is shown graphically in Fig. 1.

						Average for P_H 11.4,		3.1×10^{-2}

The data of Table I may be summarized as follows: (1) At constant hydrogen-ion concentration the polymerization of cyanamide to dicyandiamide proceeds as a reaction of the second order. *(2)* The velocity of the reaction is a function of the hydrogen-ion concentration. **(3)** The velocity of formation of dicyandiamide is at a maximum at P_H 9.6 and decreases rapidly at hydrogen-ion concentrations above or below this point. (4) Urea formation is negligible throughout this range of hydrogen-ion concentration. (5) Cyanamide disappearing is quantitatively accounted for by dicyandiamide produced up to about P_H 10. Above P_H 10, nitrogen accounted for as dicyandiamide and urea is significantly less than the cyanamide disappearing. That this is due to dicyandiamide destruction is shown in a later section of this paper.

It is of interest to attempt a correlation of the velocity constants of dicyandiamide formation shown in our table with the theory of Grube and Krüger,[5] which, it will be recalled, states that dicyandiamide is formed by reaction between a cyanamide molecule and a cyanamide ion.

$$(\mathrm{NHCN})^- + \mathrm{H_2CN_2} \rightleftarrows (\mathrm{NHCNHNHCN})^-$$

According to this theory

$$\frac{dx}{dt} = g(\mathrm{H\ Cy})(\mathrm{Cy}^-) \qquad (1)$$

where g is the velocity constant of the reaction.

The ionization constant, K, of cyanamide is given by

$$\frac{\mathrm{H}^+ \times \mathrm{Cy}^-}{\mathrm{H\ Cy}} = K \quad \text{or} \qquad (2)$$

$$\frac{\mathrm{Cy}^-}{\mathrm{H\ Cy}} = \frac{\mathrm{K}}{\mathrm{H}^+} \qquad (3)$$

Adding one (1) to both sides of this equation, we have

$$\frac{\mathrm{Cy}^- + \mathrm{H\ Cy}}{\mathrm{H\ Cy}} = \frac{\mathrm{K} + \mathrm{H}^+}{\mathrm{H}^+} \qquad (4)$$

Since

$$Cy^- + H\,Cy = (c - x) \tag{5}$$

$$H\,Cy = (c - x)\frac{H^+}{K + H^+} \tag{6}$$

In a similar manner it can be shown that

$$Cy^- = (c - x)\frac{K}{K + H^+} \tag{7}$$

On substitution of values given by (6) and (7), Equation 1 becomes

$$\frac{dx}{dt} = (c - x)^2 g \frac{K\,H^+}{(K + H^+)^2} \tag{8}$$

Our experimental work has shown that

$$\frac{dx}{dt} = k_D(c - x)^2 \tag{9}$$

where k_D is a function of H^+

Therefore

$$k_D = g\frac{K\,H^+}{(K + H^+)^2} \tag{10}$$

The ionization constant, K, of cyanamide is given by Kamayama[10] as 20.1×10^{-11} at 50°. Thus

$$K = 20.1 \times 10^{-11} = 10^{-9.7} \tag{11}$$

Using this value of K in (10) we have the equation giving k_D as a function of H

$$k_D = g\frac{10^{-9.7}\,H^+}{(10^{-9.7} + H^+)^2} \tag{12}$$

From Equation 12 it may be seen that, knowing the value of k_D for any value of H^+, we may calculate the constant g. Then knowing **g,** we may calculate k_D for any value of H^+. In other words, if we know the velocity constant at any one hydrogen-ion concentration, it is possible to calculate it for any other hydrogen-ion concentration. In the following table we have taken the value of k_D for PH 8.4, and from it have calculated the velocity constants for the hydrogen-ion concentrations at which our experiments were conducted.

TABLE II

Formation of Urea in Highly Alkaline Solutions.—We have seen from the data already presented that dicyandiamide is practically the only product obtained from solutions of cyanamide up to about PH 10. Above PH 10 the rate of dicyandiamide formation became slower and at the highest PH studied, PH 12, small amounts of urea were being formed. This

---

[10] Kamayama, *Trans. Am. Electrochem. Soc.*, *40*, 131 (1921).

suggested a few experiments on the fate of cyanamide in highly alkaline solutions. The data of this work are shown in Table III.

168	..	13.6	.11	.00	1.23	....

The conclusions which may be derived from these data are as follows. (1) Cyanamide disappearing is quantitatively accounted for by urea formed. (2) The hydrolysis of cyanamide to urea in alkaline solutions is a reaction of the first order. (3) In the range studied the reaction velocity is independent of the alkali concentration.

We conclude from the data of Tables III and I that the hydrolysis of cyanamide in alkaline solutions is a reaction of cyanamide ion, and that the velocity of the hydrolysis is proportional to the concentration of this ion. When sufficient alkali is present to convert all the cyanamide into the salt, further addition of alkali has no further effect on the rate of hydrolysis.

Dicyandiamide Destruction.—The data of Table I show that at the higher alkalinities the cyanamide disappearing cannot be accounted for by urea and dicyandiamide produced. That this is in part at least due to destruction of dicyandiamide is indicated by the dicyandiamide analyses of the solution maintained at PH 11, where it was found that the dicyandiamide content of the solution was reduced by one-half between the twenty-fourth and the forty-eighth hours.

This led to an investigation of the stability of dicyandiamide at various hydrogen-ion concentrations. The methods were the same as those employed in the previous work. Pure dicyandiamide was dissolved in the buffered solutions and its concentration determined after various intervals of time. The data are shown in Table IV and graphically in Fig. 1.

It will be seen that dicyandiamide is relatively stable up to PH 10. Above *P*H 10 dicyandiamide is destroyed, the rate increasing with increasing *P*H. The nature of the products thus formed was not studied; cyanurea is known to be formed under these conditions.[11]

Effect of Temperature on Hydrogen-Ion Concentration **Optimum** for Polymerization.—On page 196 we considered the Optimum Lime Process of Grube, which was based upon the maintenance of equal concentrations of cyanamide ions and undissociated cyanamide. That this condition necessitates maintenance of the hydrogen-ion concentration at a constant value is proved as follows. In any solution containing cyanamide

$$\frac{H^+ (Cy)^-}{H\ Cy} = K$$

$$\text{If } (Cy)^- = H\ Cy \text{ then } H^+ = K$$

This relation may also be derived from Equation 10.

The value of K at 50°, as was noted above, was found by Kamayama to be $10^{-9.7}$, which our work has shown to be the optimum hydrogen-ion concentration for the polymerization of cyanamide to dicyandiamide. This relationship between H^+ and K holds regardless of the temperature. Since Kamayama has reported the ionization constants for cyanamide at various temperatures, we may adopt his values as the optimum hydro-

Reactions of Cyanamide in **the** Soil.—In view of the fact that the *P*H of soil solutions in humid regions is usually less than 7, it will be evident

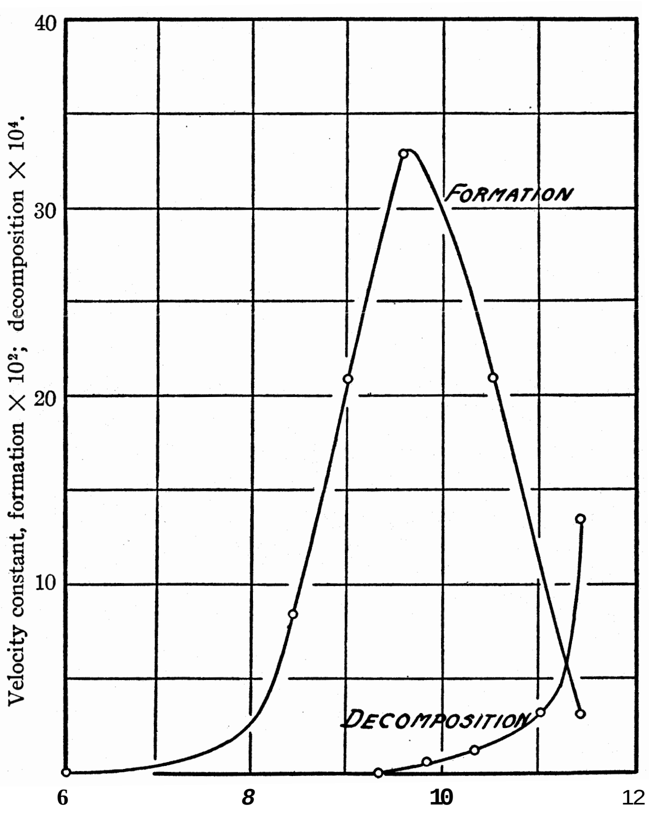

Fig. 1.—Effect of *P*H on velocities of formation and decomposition of dicyandiamide.

from the data which we have presented that dicyandiamide cannot normally be formed when calcium cyanamide is applied to the soil. Even at 50° our results show negligible dicyandiamide formation at this PH, while at lower temperatures not only is the reaction velocity greatly reduced but the limiting PH for dicyandiamide formation is raised.

The occasional finding of dicyandiamide reported by some investigators is clearly attributable to improper conditions of application. Calcium cyanamide is an alkaline material and should be applied is such a manner that its alkalinity does not exceed the buffering capacity of the soil. This necessitates proper distribution so that local high concentrations of alkalinity are avoided and suggests special care when calcium cyanamide is applied to sandy soils deficient in humus and other colloidal materials.

Many studies of the fate of calcium cyanamide in the soil are reported in the literature and the conclusion reached that cyanamide is converted to urea.[12] In our experiments urea formation was negligible in solutions of low PH. This difference between ordinary aqueous solutions and soil solutions is to be ascribed to the catalytic effect of the soil colloids. That the conversion of cyanamide to urea is catalyzed by such substances has been shown by many investigators. Kappen in particular in his elaborate "Dissertation" (Die Katalyse des Cyanamids und ihre Bedeutung für die Landwirtschaft) has called attention to the catalytic action of soil colloids, metallic oxides and hydroxides, and has, in fact, obtained a long series of patents on the production of urea from calcium cyanamide by agitating it with water in the presence of such catalytic materials.[13]

Addendum.—Subsequent to the preparation of the above paper, our attention was called to an article by Cochet on the polymerization of cyanamide to dicyandiamide as a function of hydrogen-ion concentration.[14] Cochet did not buffer his solutions and very marked changes in hydrogen-ion concentration occurred during the course of the experiments, a fact to which attention is called by the author. His results are in entire accord with our own, when the increasing PH observed in his experiments is taken into account. Cochet concludes that the polymerization reaction reaches an equilibrium at the end of 165 hours. We are of the opinion that the equilibrium is only an apparent one and that the reaction velocity has been reduced by the rise in the *P*H.

Cochet reports that cyanamide in the soil is rapidly transformed into urea.

The authors wish to express their thanks to Mr. P. W. Griffith for valuable assistance.

Summary

1. The influence of hydrogen-ion concentration on the reactions of cyanamide in aqueous solution has been studied from PH 6 to PH 13 at 50°.

[14] Cochet, Congrès des Engrais Azotés de Synthèse, May, 1927, p. 34.

2. Polymerization to dicyandiamide takes place quantitatively in alkaline solution up to PH 10.

3. The velocity of dicyandiamide formation is a function of the hydrogen-ion concentration. It reaches a maximum at PH 9.6 and decreases rapidly below or above this PH.

4. Above PH 12 cyanamide is hydrolyzed quantitatively to urea.

5. The rate of hydrolysis is independent of alkalinity in the range studied.

THE POLARITIES AND THE ORIENTING INFLUENCES OF SUBSTITUTES IN THE BENZENE RING

BY WENDELL M. LATIMER AND C. W. PORTER

RECEIVED JUNE 5, 1929 PUBLISHED JANUARY 8, 1930

More than fifty years ago it was observed that certain groups, when substituted for hydrogen in benzene, direct the next entering group to the meta position and that other groups direct to the ortho and para positions. There have been many attempts to classify atoms and groups on the basis of this behavior.[1] The most successful theory (proposed by Lapworth[2] and Stieglitz[3] and supported and amplified by many others) assumes alternate polarities in the carbon atoms of the benzene ring, induced by the electronegative or electropositive character of the first substituted group. The theory is based upon arbitrary qualitative estimates of polarity.

We wish to present in this paper a system which gives at least a semi-quantitative basis for determining polarity and which may, therefore, serve as a means of classifying groups exerting different orienting influences.

Our plan is to estimate, from considerations of electronic configurations, the residual charge on the atom attached to the ring. When a pair of electrons is shared between two atoms, we assume, except in the case of hydrogen, that the electrons are quantized in respect to the field between the atoms and that the effect of their charges is distributed between the atoms in the ratio of the positive charges on the two kernels. Thus we consider a pair of electrons between carbon and nitrogen as contributing 2 X 4/9 electron charges to the carbon atom and 2 X 5/9 electron charges to the nitrogen.

The bond between hydrogen and another atom cannot be so treated, as

[3] Stieglitz, THIS JOURNAL, 44, 1299 (1922).

the moments of inertia of hydrides, obtained from band spectra, indicate that the hydrogen ion is within the electron shell or at least very close to the position of maximum electron density. Hence in this case we consider that two electrons and one proton are so close together that their resultant charge is minus one.

On this basis we may calculate, as an example, the resultant charge on the nitrogen of aniline  $C_6H_5:\overset{\cdot\cdot}{\underset{H}{\overset{H}{N}}}:$ The positive charge on the nitrogen kernel is five. This is reduced by two unshared electrons, four electrons shared with hydrogen and two shared with carbon. The residual charge then is

$$+5 - 2 - (4 \times 1/2) - (2 \times 5/9) = -0.11$$

Dealing with nitrobenzene,  $C_6H_5:\underset{:\underset{\cdot\cdot}{O}:}{\overset{:\overset{\cdot\cdot}{O}:}{N}}.$, in the same way, we have for the residual charge

$$+5 - (4 \times 5/11) - (2 \times 5/9) = 4\text{-}2.07$$

Similar calculations for a large number of groups and atoms are summarized in Table I.

TABLE I

[a] p and o in chlorinations and m in nitrations.

It will be observed that if the residual charge on the atom attached to the ring has a high positive value, the substituent directs to the meta position.

If the value is negative or zero, the group directs to the ortho and para positions. As the rule represepts only a first approximation to a true solution of the problem, the line of division is not sharp and in general values between +0.1 and +0.6 lead to mixtures of para, ortho and meta compounds with large percentages of each.

An obvious inaccuracy in the method is the failure to take into account the decrease in the effective positive charge of the kernels by distortion or shielding effects of the orbits of electrons not directly involved in the bond. Thus actually there must be a difference between the residual carbon charges in CF_3, CCl_3, CBr_3 and CI_3: the distortion of the electron shells in the larger ions will tend to decrease the effective positive charge on their kernels making the carbon in CI_3 more negative than in CF_3, though in the case of the lighter elements such effects are probably not large.

In the case of unsaturated compounds it is especially arbitrary to assign positions to the electrons since we do not know how many electrons are in the bonds. In Table I we have used the ordinary symbol for double bond, =, as indicating four electrons shared; in all other cases the bond is considered as a single pair. In the so-called carbon–oxygen double bonds of carboxyl, aldehyde, etc., we have assumed a single electron pair in the belief that the large difference in the electronegative character of oxygen and carbon renders it unlikely that the carbon can pull four electrons into the bond. This is also in agreement with the symmetrical arrangement of the oxygen atoms about carbon in solid carbonates. Por the same reason we assume for the structure of the cyanide ion, $:C::\overset{\cdot\cdot}{\underset{\cdot\cdot}{N}}$, rather than a six electron bond. However, the nature of an unsaturated nitrogen—xygen bond is more uncertain, as oxygen is not much more electronegative than nitrogen. In these cases we have assumed a double electron bond in the NO_2 group where there are two oxygen atoms competing with a single nitrogen atom, but a four electron bond in the NO group. Actually these represent limiting conditions and our values for nitro, carboxyl, aldehyde, etc., are probably somewhat too positive and for the nitroso group too negative.

The system used in the calculations does not take into account atoms beyond those directly connected with the key atom, though these may in certain cases have considerable influence. An example of this, discussed by Fliirscheim and Holmes,[4] is COOH which, in benzoic acid, directs meta, and COO– which, in the benzoate ion, directs ortho and para, the latter being an exception to our rule. In the free acid the resultant field acting upon the benzene ring is positive, as determined by the residual charge upon the carbon of the carbonyl group. In the ion the negative field due to the unneutralized charge is superimposed to such an extent that the sign of the

---

[4] Flürscheim and Holmes, *J. Chem. Soc.*, **128,1562** (1926).

resultant field is changed. Likewise the positive charges on NH_3^+ and on NR_3^+ probably render them more strongly meta orienting than indicated by our figures.

Ingold's[5] observation that the group $CH_3{-}O{-}\overset{|}{C}{=}CH_2$ directs to the ortho and para positions is in harmony with our system of classification. This was regarded as an exceptional case when the oxygen atom was used as the key atom in determining the position of induced positive charges in the ring; and in general the results obtained clearly indicated that the actual orienting influence of a group is determined by its positive or negative character, as given by this semi-quantitative treatment.

Holleman lists certain groups in the order of their meta directing capacities as follows:[6] $COOH > SO_3H > NO_2$. The order was determined with reference to the position taken by a third group in a ring containing two of these radicals. The presence of two groups complicates the problem by destroying the balance which normally exists in the benzene ring (see later discussion of this point). The more direct evidence based upon the percentages of ortho, meta and para derivatives formed from monosubstitution products is given below. The figures indicate the percentage of meta derivative obtained from each by treatment with nitric acid.

	C_6H_5COOH[7]	$C_6H_5SO_3H$[8]	$C_6H_5NO_2$[9]
% meta	82%	90%	93%
Charge (Table I)	+1.4	+1.8	+2.1

These values substantiate our order, although it is not to be expected that this type of evidence will in every case give agreement, especially when derived from very different experimental conditions.

While the effect of polarity upon orientation may be accepted as an experimental observation, the explanation of this behavior obviously depends upon a knowledge of the structure of the benzene ring. The theory proposed by Lapworth and by Stieglitz of induced polarity of opposite signs on alternate carbon atoms appears to make a satisfactory start. Thus the action of chlorine upon aniline was pictured as indicated. The chlorine molecule splits to give a negative chloride ion, which combines with a hydrogen ion. The positive chlorine combines with a negative carbon, in this case para and ortho, to the negative nitrogen. The same mechanism applies to all the other types of direct substitution, i. e., Br, NO_2 or SO_3H, since all of these involve the

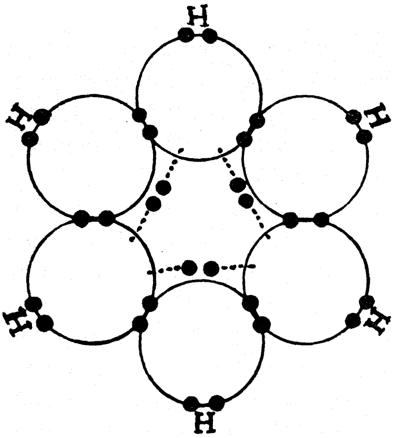
[9] "Annual Reports on the Progress of Chemistry," London, 1926, p. 132.

splitting of the oxidizing agent into a negative ion which joins with a hydrogen ion and a positive ion which combines with a negative carbon.



One interpretation of this picture in terms of an electronic structure of the benzene ring would be that alternate carbon atoms of the ring possess or share six and eight electrons, respectively. This, doubtless, is a limiting condition, the actual polarity being very much less.. It appears probable in terms of our present ideas of molecular structure that the electrons not directly held in the bonds between carbon and carbon and between carbon and hydrogen are quantized in respect to the field of the molecule as a whole. For each atom the direction of this resultant field is a line drawn through the center of the atom and the center of the ring. A pair of electrons rotating about this line might be thought of as binding one atom to all the other atoms of the ring, especially those in the ortho and para positions, as indicated in the diagram.

It is not especially profitable to speculate in terms of hypothetical benzene models; still, we believe that attempts to explain these orienting effects should be based upon some such electronic picture. In the above model unsubstituted benzene would be very nearly non-polar as on an average the three pairs of unshared electrons would be distributed equally among the six carbons. The substitution of a polar group would upset this balance. If the group is negative, the carbons in the ortho and para positions become slightly more negative. If the group is positive, the carbon atoms in the meta positions become relatively negative.

It is then only necessary to assume that the hydrogen ion is more readily displaced by the positive ion of the oxidizing agent from its electron pair on the negative carbon than from the pair on the positive carbon. Whether this is a matter of energy or of rate, depending upon the ease of activation, is not easily determined. The fact that varying amounts of all of the products are obtained seems to indicate that the rate of some step in the process is the determinative factor and that the ratio of the quantities of the products formed is not a good measure of their relative energies of formation.

Summary

A semi-quantitative measure of the polarity of a group attached to the benzene ring has been proposed which correlates the directing influence of various substituents. The polarity is discussed in terms of the electronic structure of benzene.

ELECTROMETRIC STUDIES ON THE 2-HYDROXYNAPHTHALENE SULFONIC ACIDS. PREPARATION OF PURE 2-HYDROXYNAPHTHALENE-6-SULFONIC ACID

BY KARL H. ENGEL AND A. WITT HUTCHISON

RECEIVED JUNE 7, 1929 PUBLISHED JANUARY 8, 1930

The purpose of the investigation was to study the neutralization curves, as obtained by electrometric titrations, of the 2-hydroxynaphthalenesulfonic acids in order to characterize them as acids and to determine especially the effect on the second dissociation constant of the position of the sulfonic acid group.

Preparation of Pure 2-Hydroxynaphthalene-6-sulfonic Acid.—In the study of this acid an especially pure material was desired. Though the preparation of metallic salts of the acid in a pure state may be accomplished by repeated recrystallization from their solutions, this cannot be done with the free acid because of its extreme solubility in water, alcohol, acetone, ether, etc.

It was found that the free acid may be precipitated from its aqueous solution by the addition of hydrogen chloride. This permitted a complete separation of the acid from excess sulfuric acid remaining in the sulfonation mass and from any isomeric compounds that may have been formed.

Schaeffer[1] first prepared the free acid from the lead salt by means of hydrogen sulfide. He obtained a crystalline compound which, when dried over concentrated sulfuric acid, melted at 125°. Later Ebert and Merz[2] used the same method of isolation and found a melting point of 122° but accepted Schaeffer's higher value as the correct one. Analyses of the compounds were not given in either case.

Preparation of the Free Acid from Hydrogen Chloride Solutions.—A mixture of 100 g. of 2-hydroxynaphthalene (Merck's resublimed) and 100 g. of sulfuric acid (100%) was stirred for seventy-five minutes at a temperature of 85°. The sulfonation mass, which had begun to solidify, was poured into a mixture of 500 g. of ice and water.

An aliquot portion of the solution was made alkaline with sodium carbonate and titrated with a standard solution of 1-diazo-2-methylbenzene hydrochloride. It was found that the solution contained 70% of the theoretically possible amount of the 2-hydroxynaphthalene-6-sulfonic acid.

---

[1] Schaeffer, *Ann.*, 152, 296 (1869).

[2] Ebert and Merz, *Ber.*, 9, 609 (1876).

Traces of insoluble substances were removed by filtration from the solution of the sulfonation mass. The filtered solution was saturated with dry hydrogen chloride and a crystalline precipitate of the 2-hydroxynaphthalene-6-sulfonic acid appeared. Previous tests had shown that neither the isomeric 2-hydroxynaphthalene-8-sulfonic acid, nor the two 2-hydroxynaphthalenedisulfonic acids, 3,6- and 6,8-, which might have been formed during the sulfonation, could be precipitated in this way. The crystals were removed from the mother liquor by filtration and washed with hydrochloric acid (30%). They were redissolved in water and reprecipitated with hydrogen chloride until, after four such recrystallizations, a test with barium chloride showed the absence of sulfuric acid.

Analytical.—The purified crystals were allowed to stand for four weeks in a desiccator over potassium hydroxide sticks (Baker's Analyzed). A sample tested at this time with silver nitrate solution showed the absence of chloride ions.

Anal. Calcd. for $C_{10}H_6OH{\cdot}SO_3H{\cdot}2H_2O$: S, 12.32. Found: S, 12.23.

Melting point determinations were made by means of capillary tubes in a bath of sulfuric acid. The dihydrate melted sharply and without apparent decomposition at 118° corr. The dihydrate was stable at the water vapor tension of air at room temperatures. When placed in a desiccator over concentrated sulfuric acid or phosphorus pentoxide at 20°, a loss in weight corresponding to one mole of water occurred.

Anal. Loss calcd. for one mole of H_2O: 6.915%. Found over P_2O_5, 6.96%; over H_2SO_4, 6.92%. Samples regained their original weights when exposed to the air. The monohydrate melted sharply without decomposition at 129° corr.

A sample of the dihydrate when dried over phosphorus pentoxide in an atmosphere of dry nitrogen at 65° showed a loss corresponding to two moles of water.

Anal. Loss calcd. for two moles of H_2O: 13.83%. Found: 13.79%.

Samples regained their original weights when exposed to the air. The anhydrous acid melted sharply without decomposition at 167° corr.

It should be noted that the melting point of 125° given by Schaeffer agrees best with the value the authors have found for the monohydrate. Undoubtedly this was the compound he had prepared since he had dried the acid over concentrated sulfuric acid.

Materials and Apparatus.—The potassium salt of the 2-hydroxynaphthalene-6-sulfonic acid was prepared as suggested by Schaeffer.[1] The potassium salt of the 2-hydroxynaphthalene-1-sulfonic acid was prepared according to the method of Nietzki.[3] The 2-hydroxynaphthalene-6-sulfonic acid was prepared as described above.

The standard sodium hydroxide solution used in the titrations was prepared free from carbonates by diluting the required amount of a saturated sodium hydroxide solution with recently boiled distilled water. Fused benzoic acid was used as a standard.

The materials used in the calomel cells were reagents prepared by Leeds and Northrup Company especially for electromotive force measurements.

Experimental.—Fifteen-cc. portions of 0.1 molar solutions of the acids were titrated with 0.1 molar sodium hydroxide solution. The progress of the titrations was followed by measuring potential differences between a hydrogen electrode and a saturated calomel half-cell by means of a Leeds and Northrup Type K potentiometer. A suspended coil galvanometer with a sensitivity of 126 megohms was used as a null point instrument.

Data and Calculations.—The data obtained are listed in the tables. PH values were calculated from the equation.

---

[3] Nietzki, Ber., 15, 305 (1882).

$$\frac{E(\text{obs.}) - E(\text{calcd.})}{0.00019837\ T} = \log \frac{1}{(\text{H})} = P_{\text{H}}$$

Values for pK and, from these, values for the usual dissociation constants were obtained from the equation

$$pK = P_{\text{H}} + \log \frac{\text{moles acid—moles base}}{\text{moles salt}}$$

as suggested by Clark.[4]

These values have been plotted in the curve of Fig. 3.

Discussion of Results.—The value of 1.1×10^{-11} determined for the dissociation constant of the hydroxy group of the 2-hydroxynaphthalene-1-sulfonic acid shows it to be an exceedingly weak acid. This is evident from the curve (Fig. 1) in which no break appears at the end-point of the titration. It is perhaps of interest to note that the value assigned to the constant for phenol is **1.3** $\times 10^{-10}$.[5]

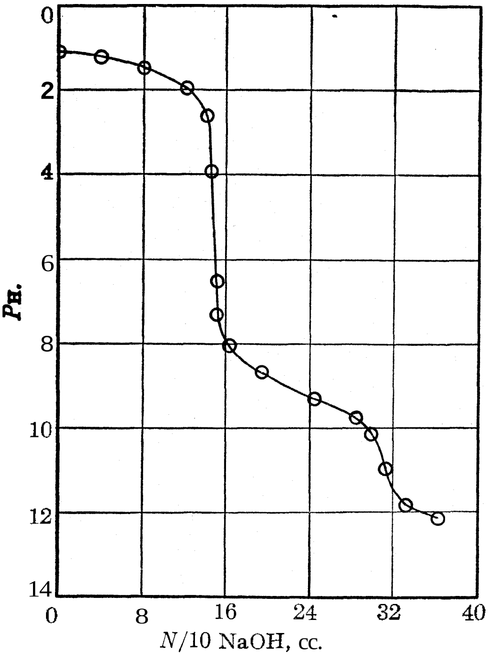

Fig. 3.—Titration of 15 cc. of $M/10$ 2-hydroxynaphthalene-6-sulfonic acid.

In the case of the constant for the hydroxy group of the 2-hydroxy-naphthalene-6-sulfonic acid the value 1×10^{-9} obtained both from the titration of the free acid and from that of its potassium salt is larger. Inspection of the curves (Fig. 2 and Fig. 3) shows that a definite break does occur at the end of the titration. It may be classed with the weak acids such as hydrogen sulfide, $K = 5.7 \times 10^{-8}$, or hydrocyanic acid, $K = 7.2 \times 10^{-10}$.[6] The break occurring in the curve of this acid makes possible its quantitative estimation in the presence of the 2-hydroxynaphthalene-1-sulfonic acid or of neutral salts.

The value of **3.3** $\times 10^{-2}$ found for the first dissociation constant of the 2-hydroxynaphthalene-6-sulfonic acid places it with the fairly strong

[6] Kolthoff and Furman, "Potentiometric Titrations," John Wiley and Sons, Inc., New York, **1926,** Tables.

acids, the value for the second hydrogen of sulfuric acid being 3×10^{-2}; for the first constant of oxalic acid, 3.8×10^{-2}.[6] The very sharp break occurring at the end-point of the curve of the free acid (Fig. 3) lends itself well to the quantitative estimation of the acid.

Summary

1. 2-Hydroxynaphthalene-6-sulfonic acid has been purified by recrystallization of the acid from aqueous solutions by means of the addition of hydrogen chloride. The identity of a monohydrate and a dihydrate has been established. Melting points for these three compounds have been determined.

2. The 2-hydroxynaphthalene sulfonic acids have been studied electrometrically and values determined for their acid dissociation constants. The nature of the curve obtained for the 2-hydroxynaphthalene-6-sulfonic acid shows that the quantitative estimation of the acid or of its salts might be possible in the presence of the isomeric 2-hydroxynaphthalene-1-sulfonic acid, or of neutral salts.

RESEARCHES ON CYCLIC ACETALS. I. FORMATION OF CYCLIC ACETALS OF 4,5-DIHYDROXY-2,6-OCTADIENE[1]

BY C. PAULINE BURT AND FRANCES HOWLAND

RECEIVED JUNE 18, 1929 PUBLISHED JANUARY 8, 1930

The tendencies toward formation of cyclic acetals have been investigated by Hibbert and co-workers.[2] In the majority of these investigations both the aldehyde and the glycol used were of the saturated type. More recently[3] work has been published on the tendencies of unsaturated glycols. The present investigation deals with a saturated glycol to form acetals with both the saturated and unsaturated type of aldehyde.

Experiments were carried out on the condensation of 4,5-dihydroxy-2,6-octadiene (dipropenyl glycol), $CH_3CH{=}CHCHOHCHOHCH{=}CHCH_3$, with acetaldehyde, paraldehyde, propionaldehyde, butyraldehyde, heptaldehyde, acetone, benzaldehyde, crotonaldehyde, cinnamaldehyde and chloral, using sulfuric acid as a catalyst. The yields of cyclic acetals obtained were taken as a basis of comparison for the tendencies of the aldehydes toward cyclic acetal formation.

---

[1] This paper is constructed from a dissertation submitted in partial fulfilment of the requirements for the degree of Master of Arts at Smith College.

[2] Hibbert and co-workers, J. Ind. Eng. Chem., 13, 256, 334 (1921); THIS JOURNAL, 45, 734, 2433, 3108, 3117, 3124 (1923); 46, 1283 (1924); 50, 1411, 2235, 2242 (1928).

[3] Hibbert, Houghton and Taylor, ibid., 51, 611 (1929).

The saturated carbonyl derivatives, acetaldehyde, paraldehyde, acetone, propionaldehyde, butyraldehyde and heptaldehyde all readily formed acetals of dipropenyl glycol with yields of 90, 83, 71, 90, 92 and 85%, respectively, acetaldehyde and paraldehyde forming the same acetal. Hibbert[4] has shown that acetaldehyde, butyraldehyde and heptaldehyde form acetals of ethylene glycol with yields of 87, 50 and 50%, respectively. It can, therefore, be concluded that unsaturation of the type in dipropenyl glycol does not decrease the tendency toward cyclic acetal formation, but instead seems to increase such a tendency. In attempting to condense chloral with dipropenyl glycol, a mixture of products was obtained but none could be identified as the acetal. It should not be concluded, however, that a cyclic acetal of chloral cannot be formed. Reaction apparently took place in all cases, but resulted in the original or resinous substances when attempts were made to isolate the products.

According to Hibbert,[3] substitution of hydrogen by chlorine atoms in the aldehyde residue of saturated aldehydes results in the formation of acetals of ethylene glycol in two cases. β-Phenyl-α,β-dichloropropylidene ethylene glycol was formed with a yield of 37%, and dichlorobutylidene ethylene glycol was formed with a yield of 50%. Experiments are now in progress on the condensation of several other saturated chloroaldehydes with dipropenyl glycol.

Negative results were also obtained when benzaldehyde was used with dipropenyl glycol. It has been shown that benzaldehyde with ethylene glycol[4] gives a yield of 80–85% of the acetal. The tendency of dipropenyl glycol to form an acetal with benzaldehyde is, therefore, much less than in the case of ethylene glycol.

The unsaturated aldehydes, crotonaldehyde and cinnamaldehyde, also showed little tendency to form the acetals of dipropenyl glycol; this is in agreement with the results of Hibbert,[3] who showed that the amount of reaction of ethylene glycol with these aldehydes was negligible.

Experimental Part

In all cases one part of dipropenyl glycol and about twice the calculated quantity of the aldehyde or ketone were heated in a bath at about 70° for four hours with a few drops (4–6) of 40% sulfuric acid for each tenth mole of the glycol used. At the end of the reacting period an equal volume of ether and sufficient 5% sodium carbonate solution for neutralization were added. The ether solution was washed, dried and distilled. Acetals were obtained as slightly yellow oils in high yield (71–92%) from acetaldehyde, paraldehyde, propionaldehyde, butyraldehyde, heptaldehyde and acetone, as shown in the table, while no product could be obtained when using crotonaldehyde, cinnamaldehydc, chloral and benzaldehyde.

6	72.47	9.96	72.57, 72.37	10.25, 9.97

Summary

1. A comparison has been made of the tendency of saturated, chloro-saturated and unsaturated aldehydes to form acetals of dipropenyl glycol.

2. The saturated aliphatic carbonyl derivatives, acetaldehyde, paraldehyde, propionaldehyde, butyraldehyde, heptaldehyde and acetone showed a marked tendency to form acetals with yields of 90, 83, 90, 92, 85 and 71%, respectively, indicating that the length of the hydrocarbon chain of the carbonyl compound has practically no effect on the yield. The saturated chloro derivative, chloral, does not give an acetal as a product. The acetal of benzaldehyde was not formed under the conditions used.

3. The unsaturated aldehydes, cinnamaldehyde and crotonaldehyde show practically no tendency to form acetals.

MIXED BENZOINS. I

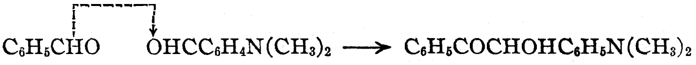
BY JOHANNES S. BUCK AND WALTER S. IDE

RECEIVED JUNE 21, 1929 PUBLISHED JANUARY 8, 1930

By mixed benzoins is understood unsymmetrical benzoins, that is, benzoins formed from two different aldehydes, or, in other words, containing different substituents in the two rings. A considerable amount of theory has been written on simple benzoin formation but there is little of practical value. Staudinger[1] is one of the few authors to speculate on the question of mixed benzoins. To support his views he prepared two mixed benzoins. Fischer[2] also prepared two mixed benzoins but made no speculations. These four compounds, together with one prepared by Ekecrantz and Ahlqvist,[3] represent the total number of mixed benzoins prepared heretofore by the condensation method.

Staudinger regards benzoin formation as due to the migration of a hydrogen atom from one aldehyde group to the carbonyl group of the other aldehyde, and hence he divides aldehydes into two main types—Type A having a reactive carbonyl group and a non-mobile hydrogen atom, and Type B, which has a mobile hydrogen atom but does not possess an active carbonyl group. The criterion for Type A is not stated; presumably it is the ability of the aldehyde to react with the usual aldehyde reagents. Type B is characterized by the rate of auto-oxidation. There are necessarily many intermediate aldehydes possessing both an active carbonyl group and a mobile hydrogen atom (although in varying degrees). Benzaldehyde, which forms a benzoin, belongs to this class.

On Staudinger's views the aldehydes of Type B donate the hydrogen atom and hence the nucleus of this aldehyde appears in the resulting benzoin next to the carbonyl group of the CHOH-CO chain. This may be illustrated by an example.



$$C_6H_5CHO \quad OHCC_6H_4N(CH_3)_2 \longrightarrow C_6H_5COCHOHC_6H_5N(CH_3)_2$$

The method used by Staudinger was to heat two selected aldehydes, one each of Types A and B, in alcoholic potassium cyanide solution. Clearly, since neither aldehyde can form its own simple benzoin, and since only one mixed benzoin can be formed, the method will give excellent yields, provided always that the aldehydes are typical.

The case of the majority of aldehydes, which are not exclusively of either type, presents serious difficulties, since both simple benzoins and two

---

[1] Staudinger, Ber., 46, 3535 (1913).

[2] Fischer, Ann., 211, 214 (1882).

[3] Ekecrantz and Ahlqvist, *Arkiv Kemi, Mineral. Geol.*, 3, Nr. 13, 26 S (1908–1910).

mixed benzoins may all be formed simultaneously. Their separation would then be a matter of chance depending on their relative solubilities. Fischer's two mixed benzoins were evidently obtained only because of their favorable solubilities.

The authors sought to make the production of mixed benzoins a more general process by considering the reaction from a dynamic point of view. They consider that the speed of formation of the simple benzoin is a rough index either of the mobility of the hydrogen atom or of the reactivity of the carbonyl group (without, at this stage, making any distinction). Aldehydes forming simple benzoins, and therefore possessing to some extent both a reactive carbonyl group and mobile hydrogen atom, are henceforth referred to as Group I. Aldehydes which form no simple benzoin, and therefore possess only a mobile hydrogen atom or a reactive carbonyl group (but not both), are classed as Group 2. The speed of formation of a simple benzoin may be roughly indicated by primes, thus $1''''$ signifies that the aldehyde forms a simple benzoin very rapidly. The relation between Staudinger's and the authors' grouping is simply that Group 1 possesses in varying degree the properties of both Types A and B. Group 2 is either of Type A or of Type B.

By adding the aldehydes at different speeds to the reaction mixture and by varying the time of heating, the authors have been able to isolate a number of new mixed benzoins and to improve the yields of some already known. Doubtless a considerable number of others could be prepared by similar methods. The rates of addition and the times of heating have to be determined by trial, since data on the speed of formation of benzoins are practically non-existent.

To illustrate the argument, consider one mole of an aldehyde of Group 2 in boiling alcoholic potassium cyanide solution. No reaction will take place. If now one mole of an aldehyde of Group 1 is run in at such a rate that it does not accumulate in the reaction mixture, it will form little of its own simple benzoin, being at high dilution, but will (on mass action considerations) form large amounts of one mixed benzoin. The formation of one mixed benzoin is also necessitated by the aldehyde of Group 2 possessing only a mobile hydrogen atom or a reactive carbonyl group, but not both.

Three other cases remain to be considered. If both aldehydes are of Group 2, but one of Type A and the other of Type B, a single mixed benzoin will be formed under any conditions. This is Staudinger's case. If both aldehydes are of Group 2 and both of Type A or both of Type B, then no mixed, or simple, benzoin will be formed. Lastly, as is usually the case, if both aldehydes are of Group I, then necessarily four products will be formed, two simple and two mixed benzoins. However, by adding both aldehydes, say $1'$ and $1'''$ at such rates that aldehyde $1'$ is always present in relatively great excess to $1'''$ (but usually at small concentration) and adjusting the rate of addition so that neither aldehyde accumulates, the formation of the simple benzoin from 1" is largely suppressed, while the simple benzoin from 1' (slow aldehyde) has not had time to form to any extent. The conditions then favor the formation of the mixed benzoins, but the fact that aldehyde 1' must nearly approach either Type A or B will cause one mixed benzoin to preponderate. The present paper largely deals with reactions of this type. In the limiting case, where both aldehydes are of Group 1 and have about the same speeds of formation of simple benzoins, both simple and mixed benzoins are necessarily formed, whatever conditions are used. In one case of this type the authors have succeeded in isolating both of the mixed benzoins.

The position of the CHOH group in the mixed benzoin could only be definitely settled by synthesizing the compound in some other way which would leave no doubt as to its position. However, as previously explained, when one aldehyde belongs to Type A or to Type B, the position of the CHOH group can be assigned with fair certainty, for it will be next to the nucleus of the Type A aldehyde or furthest from the nucleus of the Type B aldehyde. The possibility of assigning a correct structure when both aldehydes belong to Group 1 depends upon which type (A or B) the aldehydes are most nearly related to.

It has been shown by Lachman[4] that in the ordinary benzoin reaction a number of side-products are formed. The amount, however, is not serious if the heating be not too prolonged. In the present work the side-products were avoided as much as possible, but they undoubtedly render the separation of mixed benzoin more difficult.

Nomenclature.—In the literature mixed benzoins are named from the two aldehydes, with the termination -oin. The authors suggest placing this termination after the aldehyde with the reactive carbonyl group, or, which is the same thing, after the aldehyde whose CHO becomes CHOH. Thus, $CH_2O_2C_6H_3COCHOHC_6H_5$ is piperbenzoin and $CH_2O_2C_6H_3CHOHCOC_6H_5$ is benzpiperoin. If the structure is doubtful a query mark is placed after the name.

Experimental

The experimental procedure, in general, is very simple. A three-necked flask contains the alcoholic potassium cyanide solution, which is kept boiling briskly on a steam-bath. Two burets and a reflux condenser are fitted to the three necks. The time of addition and the amount of one aldehyde first added have been determined by trial from a number of experiments. In general both aldehydes were added at the same rate after the preparation was begun. The amounts of water, alcohol and potassium cyanide were also varied—the optimum values are given.

Furo-*p*-dimethylaminobenzoin.—To a boiling solution of 7.5 g. of *p*-dimethylaminobenzaldehyde and 3.0 g. of potassium cyanide in 55 cc. of 65% alcohol was added 5.0 g. of furfural over a period of forty-five minutes. On standing overnight a crystalline product separated. After recrystallization from alcohol the compound forms buff plates melting at 168° and is very soluble in chloroform, moderately soluble in benzene and alcohol and slightly soluble in ether and ligroin; yield, 30%.

Anal. Calcd. for $C_{14}H_{15}O_3N$: N, 5.71. Found: N, 5.99.

***o*-Chloro-*p*-dimethylaminobenzoin.**—A solution of 7.5 g. of *p*-dimethylaminobenzaldehyde, 7.5 g. of o-chlorobenzaldehyde and 2.0 g. of potassium cyanide in 45 cc. of 65% alcohol was refluxed for one hour. On addition of ice water, a solid separated and was recrystallized from alcohol; yield, 36%.

It forms white needles melting at 166° and is very soluble in chloroform, moderately soluble in benzene and alcohol, slightly soluble in ligroin and ether.

Anal. Calcd. for $C_{16}H_{16}O_2ClN$: N, 4.83. Found (Kjeldahl): N, 4.77, 4.69.

***m*-Bromo-*p*-dimethylaminobenzoin.**—This compound was prepared by heating a solution of 7.5 g. of p-dimethylaminobenzaldehyde, 9.0 g. of m-bromobenzaldehyde and 3.0 g. of potassium cyanide in 45 cc. of 65% alcohol for an hour. On adding ice water a solid product separated and was recrystallized from alcohol; yield, 50%. It forms buff prisms melting at 145° and is very soluble in chloroform, moderately soluble in alcohol and benzene and slightly soluble in ether and ligroin. Analyses were made by the Kjeldahl method.

Anal. Calcd. for $C_{16}H_{16}O_2NBr$: N, 4.19. Found: N, 4.01, 4.13.

Benzpiperoin.—Fifteen grams of piperonal in saturated alcoholic solution are added during one and three-fourths hours to a boiling solution of 10.6 g. of benzaldehyde in 120 cc. of 50% alcohol containing 5.0 g. of potassium cyanide. The oil which separated on cooling was removed and dissolved in alcohol. The product crystallized in a few hours and was recrystallized from alcohol; yield, 28%. It forms white needles, m. p. 120°, very soluble in chloroform, moderately soluble in alcohol, ether, ligroin and benzene.

Anal. Calcd. for $C_{15}H_{12}O_4$: C, 70.30; H, 4.70. Found: C, 69.93; H, 4.97.

Piperbenzoin.—The mother liquors from the preparation of benzpiperoin sometimes deposit, on standing for several days, an isomer, melting at 112°, in a yield of about 16%. It forms white needles, rather more soluble than benzpiperoin, especially in ether.

Anal. Calcd. for $C_{15}H_{12}O_4$: C, 70.30; H, 4.70. Found: C, 70.06; H, 4.87.

Benz-m-bromobenzoin (?).—This compound is best prepared by dissolving 18.5 g. of m-bromobenzaldehyde in 140 cc. of 50% alcohol containing 5.0 g. of potassium cyanide and boiling for two hours while 15.0 g. of benzaldehyde is run in. An oil separated on cooling and was sludged with benzene. The crystals which formed were recrystallized from alcohol; yield, 32%.

Benz-*m*-bromobenzoin forms white prisms, m. p. 129–130°, very soluble in chloroform and moderately soluble in benzene, alcohol, ether and ligroin.

Anal. Calcd. for $C_{14}H_{11}O_2Br$: C, 57.73; H, 3.77. Found: C, 58.00; H, 4.08.

Piper-m-bromobenzoin (?).—Eighteen and one-half grams of m-bromobenzaldehyde dissolved in 160 cc. of 50% alcohol containing 5.0 g. of potassium cyanide was treated over one and a half hours with 15.0 g. of piperonal in saturated alcohol solution. The mixture was kept boiling and the piperonal was added at a steady rate. On cooling, the oil which separated was removed and kept in a refrigerator, where it gradually crystallized. The product was recrystallized from ether and then alcohol; yield, 33%.

Piper-m-bromobenzoin forms white needles, m. p. 106°, very soluble in benzene and chloroform, moderately soluble in ether, ligroin and alcohol.

Anal. Calcd. for $C_{15}H_{11}O_4Br$: C, 53.73; H, 3.28. Found: C, 53.68; H, 3.38.

Piper-o-chlorobenzoin (?).—Three and sixty-five one-hundredths grams of *o*-chlorobenzaldehyde was dissolved in 50 cc. of 50% alcohol containing 3.0 g. of potassium cyanide and the whole was boiled briskly; 3.75 g. of piperonal in saturated alcoholic solution was added at a steady rate over one and three-fourths hours. On cooling, an oil separated which was removed and sludged with ligroin. After twenty-four hours the crystalline product was filtered off and recrystallized from alcohol; yield, 50%.

Piper-o-chlorobenzoin forms white needles, m. p. 115°, very soluble in benzene and chloroform, moderately soluble in alcohol, ether and ligroin.

Anal. Calcd. for $C_{15}H_{11}O_4Cl$: C, 61.94; H, 3.78. Found: C, 61.84; H, 4.14.

Summary

By considering the reactivity of aldehydes in the simple benzoin reaction, a method has been worked out whereby mixed benzoins may be obtained from the large majority of aromatic aldehydes. Eight new mixed benzoins have been prepared by the method.

DURHAM, NORTH CAROLINA

SUBSTITUTED PHENYLETHYLBARBITURIC ACIDS[1]

BY E. W. BOUSQUET AND ROGER ADAMS

RECEIVED JUNE 27, 1929 PUBLISHED JANUARY 8, 1930

Of the numerous 5,5-disubstituted barbituric acids that have been prepared and offered to the physician as hypnotics, the one which is of peculiar interest is the phenylethyl derivative.[2] This substance is generally accepted by the clinician as having, in addition to the usual soporific value, a specific sedative action toward epileptics, much more marked than appears in the various dialkylbarbituric acids. Phenylethylbarbituric acid (phenobarbital) is more toxic than most of the important dialkyl derivatives, though the ratio of effective dosage and toxicity is not so very different from that of barbital[3] itself. The phenylmethyl[4] and the phenylallyl[5] barbituric acids have also been prepared, but appear to be of less interest than the better-known phenylethyl derivative.

In spite of the importance of phenobarbital, derivatives containing substituents in the benzene ring, with the exception of the *p*-methoxyphenylethylbarbituric acid,[2] which was mentioned in the original patent, have never been prepared. Numerous investigators have obtained barbituric acid derivatives isomeric with phenylalkyl- or phenylallylbarbituric

---

[5] U. S. Patent 1,056,793 (1912).

acid, such as benzylalkyl,[6] benzylallyl[7] or ethylphenethyl.[8] None, however, proved to be of any value. The dibenzyl-,[9] the 5,5-di-(*p*-hydroxyphenyl)-[10] and the 5,5-di-(3-methyl-4-hydroxyphenyl)-[10] barbituric acids have also been described and were shown to have no soporific effect.

This investigation had as its object the preparation of substituted phenylalkylbarbituric acids, in order, if possible, to obtain a compound with lower toxicity and possibly higher soporific value than phenobarbital.

The method commonly used for preparing phenylethylbarbituric acid is condensation of phenylacetic ester and oxalic ester to phenyloxalacetic ester, elimination of carbon monoxide by heating to give phenylmalonic ester, condensation with an alkyl halide to give phenylalkylmalonic esters and, finally, condensation to the corresponding barbituric acid. The application of this procedure is of questionable value on account of the difficulty of obtaining substituted phenylacetic esters, and also because such substitution products do not enter readily into the subsequent reactions. No directions were given in the original patent for preparing the *p*-methoxyphenylethylbarbituric acid but, presumably, the method just mentioned was the one used.

The procedure first attempted in this research was to nitrate phenylethylmalonic ester and to obtain through the nitro group a variety of substituted phenylethylmalonic esters which could be condensed in the usual way to the barbituric acids. Conditions were found for nitration which gave the p-nitro derivative in good yields. The position of the substituting group was proved by oxidation to p-nitrobenzoic acid. The nitro compound was reduced to the corresponding amino and the amino, in turn, further substituted or replaced. However, proper conditions were not found for the condensation of any of the substituted phenylethylmalonic esters to the corresponding barbituric acids.

Attention was next given to the nitration of phenylethylbarbituric acid itself. A very satisfactory yield of product was obtained (I), and through this substance a series of derivatives was produced: the amino, the bromo-amino, the acetamino, the bromo-acetamino, the nitro-acetamino, the nitroamino and the chloro. The nitro, the amino, the acetamino, the bromo-acetamino, the bromoamino, and the chloro derivatives were kindly tested for their soporific value and toxicity by H. C. Spruth of the Abbott Laboratories, for whose help the authors are grateful. With the exception of the chloro, each was

found to be less toxic than phenobarbital itself, but, as so frequently happens in the study of the relation between pharmacological action and chemical constitution in organic compounds, the substitution of these groups caused the hypnotic property to disappear entirely. The chloro compound possessed hypnotic power of almost the same order as the parent substance, phenobarbital, but was slightly more toxic.

Experimental

Preparation of the Substituted Aryl-alkyl-malonates

Methyl Ethyl *p*-Nitrophenylethylmalonate.—Fifteen grams of the pure methylethyl ester of phenylethylmalonic acid, b. p. 142–147" (5 mm.), was dissolved in 15 cc. of ice-cold concentrated sulfuric acid. The temperature of the ester–sulfuric acid mixture was brought down to −10° and a cold nitrating mixture consisting of 0.072 mole of fuming nitric acid (sp. gr. 1.50) in 5 cc. of concentrated sulfuric acid was added very slowly, while stirring and keeping the temperature of the reaction between −10 and 0°. Stirring was continued for two hours after the nitrating mixture had been added. The reaction mixture was added to ice-water mixture and the oily mass extracted with ether. After washing and drying, the solvent was removed and a crude yellow oil weighing 16 g. (90.4%) was obtained. Several runs using twice the molecular proportions of the above experiment gave consistent yields of 87.5% of the theoretical of purified product.

Oxidation of Methyl Ethyl *p*-Nitrophenylethylmalonate.—Five grams of the nitro ester was dissolved in 20 cc. of 95% alcohol and 3.5 g. of solid potassium hydroxide was added. After refluxing for two hours on the steam-bath, the alcohol was evaporated off, and a hot solution of 15 g. of potassium permanganate in 100 cc. of water was added all at once with stirring. The solution was allowed to stand for two hours and then filtered from the manganese dioxide. Upon acidification of the filtrate with concentrated hydrochloric acid, 0.5 g. of a white product precipitated. Two recrystallizations from dilute alcohol gave a product melting at 235–237° (uncorr.). Several mixed melting points containing various percentages of *p*-nitrobenzoic acid with the oxidation product showed no depression of the original melting point.

Methyl Ethyl *p*-Aminophenylethylmalonate.—A solution of 30 g. of methyl ethyl *p*-nitrophenylethylmalonate, b. p. 180–185° (4 mm.), in 50 cc. of 95% alcohol was reduced with hydrogen and 0.2 g. of platinum-oxide catalyst.[11] At 2–3 atm. pressure after half an hour, the theoretical amount of hydrogen had been absorbed, and the spent catalyst was filtered off and the alcohol evaporated. The resulting dark red oil amounted to 25 g. (92.7%). When pure it was a very viscous, heavy, yellow oil. Attempts to form a solid hydrochloride or benzoyl derivative were unsuccessful.

Methyl Ethyl *p*-Acetaminophenylethylmalonate.—Fifteen grams of the crude amino ester was slowly mixed with 17.5 g. of pure acetic anhydride. The reaction mixture was heated over the steam-bath for four hours and then distilled. The pure product was a very viscous, yellow oil. Crystallization could not be induced.

Methyl Ethyl *p*-Hydroxyphenylethylmalonate.—Fifteen grams of the crude amine was dissolved in a cold dilute acid mixture consisting of 20.5 g. of concentrated sulfuric acid and 15 g. of water. Twenty-eight grams of ice was then added to the sulfate. When cooled down to 0°, it was treated with a solution of 3.8 g. of sodium nitrite in 10 cc. of water, while maintaining the temperature between 0 and 5°. The diazonium mixture was then poured into a boiling solution of 35 cc. of concentrated sulfuric acid

---

[11] Adams and Shriner, THIS JOURNAL, 45, 2171 (1923).

and 30 cc. of water and stirred until the evolution of gases had subsided. The black oily layer was extracted with ether and the ether extracts washed with 5% sodium hydroxide solution to take up the phenolic ester. The phenolic ester was then regenerated by treatment with dilute hydrochloric acid and extracted with ether. Six and one-half grams of a very viscous, yellow oil was obtained.

Methyl Ethyl *p*-Methoxyphenylethylmalonate.—Fifteen grams of freshly distilled phenolic ester was dissolved in a 20% excess of 5% sodium hydroxide solution and to this alkaline solution 8 g. of freshly distilled dimethyl sulfate was added with vigorous shaking, keeping the temperature below 60°. The reaction mixture was heated at 60–70° for an hour and when cool was extracted with ether, Ten and one-half grams of a lemon-yellow oil was obtained.

p-Aminophenyl	182–185 (4 mm.)	63.36	7.22	63.40	7.22
		(N, 5.28)		(N, 5.02)	
p-Acetaminophenyl	192–197 (3 mm)	62.50	6.89	62.23	6.82
p-Hydroxyphenyl	180–185 (4 mm.)	63.12	6.87	64.13	6.85
p-Methoxyphenyl	152–156 (4 mm.)	64.24	7.19	64.25	7.13

Preparation of Substituted Aryl-alkylbarbituric Acids

5-Nitrophenyl-5-ethylbarbituric Acid.—Five grams of phenylethylbarbituric acid, m. p. 169–170°, was added to 20 cc. of ice-cold concentrated sulfuric acid. A nitrating mixture of 1.1 cc. of fuming nitric acid (sp. gr. 1.50) in 5 cc. of concentrated sulfuric acid was added slowly to the rapidly stirred mixture, while maintaining the temperature between −10 and 3°. Stirring was continued for an hour after the nitrating mixture was added. The nitration mixture was added to 300 cc. of ice-water mixture and filtered when cold. The white precipitate was washed with water until almost neutral to litmus and then dried at 100°. Two crystallizations gave 2 g. of pure material. Recrystallizations of material in the mother liquors gave average yields of 60–65% of the pure product.

5-Aminophenyl-5-ethylbarbituric Acid.—Ten grams of the nitro compound, m. p. 276–277" (uncorr.), was suspended in 125 cc. of 95% ethyl alcohol with 0.2 g. of platinum-oxide catalyst. The reduction was carried out at 40–50° at a pressure of 2–3 atm., and the theoretical amount of hydrogen was absorbed in twenty to thirty minutes

5-Acetaminophenyl-5-ethylbarbituric Acid.—Nine grams of the amino compound was poured slowly into 11 g. of freshly distilled acetic anhydride, keeping the temperature below 50°. The hard, crystalline mass was heated at 70° for half an hour, after which 20 cc. of glacial acetic acid was added and the solution refluxed until a test portion with sodium nitrite solution and β-naphthol showed that acetylation was complete. The reaction was diluted with 100 cc. of water and filtered, washed and dried at 100°. Two recrystallizations gave 6 g. of pure product. It contained one molecule of water of crystallization.

5-(Bromo-acetaminopheny1)-5-ethylbarbituric Acid.—Two grams of the acetamino compound was brominated with 10% excess of dry bromine in 10 cc. of glacial acetic acid at 60–70°. Evolution of hydrogen bromide had ceased in an hour and the cold brominated product was precipitated by adding 50 cc. of cold water, filtered, washed and dried. Three recrystallizations gave pure material, 5-(Nitro-acetaminophenyl)-5-ethylbarbituric Acid.—Twenty cc. of concentrated sulfuric acid was cooled to −10° and 5 g. of acetamino compound was added with rapid stirring, keeping the temperature below 0°. A nitrating mixture containing 1.15 cc. (20% excess) of nitric acid (sp. gr. 1.42) and 5 cc. of concentrated sulfuric acid was then added, keeping the temperature between —10 and 3° during the addition. Stirring was continued for fifteen minutes after the nitrating agent had been added. The reaction mixture was poured into 150 cc. of ice water and a light yellow product separated out. The product, after two crystallizations was pure.

5-(Bromo-aminophenyl)-5-ethylbarbituric Acid.—Ten grams of the brominated acetamino compound was refluxed for five hours with 70 cc. of 95% alcohol and 30 cc. of 30% sulfuric acid. The alcohol was distilled off and just enough 10% sodium hydroxide solution was added to neutralize the sulfuric acid present.

5-(Nitro-aminophenyl)-5-ethylbarbituric Acid.—Fifteen grams of the nitrated product was refluxed for five hours with 150 cc. of 95% ethyl alcohol and 40 cc. of 20% sulfuric acid. The cold solution was filtered and 95.2% of the theoretical amount of fine yellow needles which did not melt below 320° was obtained. Purification was accomplished by taking up the product in a slight excess of cold 5% sodium hydroxide solution, filtering and precipitating by slow addition of dilute hydrochloric acid while stirring the solution rapidly. The precipitate was filtered, washed with alcohol and dried.

5-Chlorophenyl-5-ethylbarbituric Acid.—A solution of cuprous chloride was made by adding a mixture of 2.7 g. of sodium acid sulfite and 1.8 g. of solid sodium hydroxide in 20 cc. of water to a solution of 12.6 g. of copper sulfate and 2.3 g. of sodium chloride in 40 cc. of hot water. The white precipitate of cuprous chloride after filtration was treated with 8 cc. of concentrated hydrochloric acid and 40 cc. of water.

A diazonium salt solution was made by dissolving 10 g. of the amine in 35.5 cc. of concentrated hydrochloric acid, 20 cc. of water and 37 g. of ice. After cooling to 0°, a solution of 2.86 g. of pure sodium nitrite in 15 cc. of water was added to the amine hydrochloride. To the cuprous chloride solution was added as rapidly as possible the above diazonium salt solution, keeping the temperature between 0 and 5° for twenty minutes after addition of the solutions, when the reaction mixture was allowed to come to room temperature in the course of two hours. It was then heated to 60° for a short time.

The crude yellow product from 10 g. of the amine was washed thoroughly with 5% ammonium chloride solution, followed by water to remove all traces of insoluble copper salts; the yellow dry powder weighed 9.5 g. (83.5%) and melted with decomposition at 239–243° (uncorr.). The crude yellow powder after three recrystallizations from methyl alcohol, acetone and glacial acetic acid was pure.

TABLE II

DERIVATIVES OF PHENYLETHYLBARBITURIC ACID

( )-Phenyl-5-ethyl-barbituric acid	M. p., °C. (uncorr.)	Cryst. solvent	Needles	Carbon, %		Hydrogen, %	
				Calcd.	Found	Calcd.	Found

[a] Calcd.: H_2O, 5.86. Found: H_2O, 5.84.

Several attempts at replacing the amino group by hydroxyl were unsuccessful and only a reddish brown dye melting with decomposition between 260–270° was isolated but not identified.

Summary

1. 5-Phenyl-5-ethylbarbituric acid has been nitrated.

2. The following groups have been introduced into the phenyl ring through the nitro group: amino-, acetamino-, bromo-acetamino-, bromo-amino-, nitro-amino-, nitro-acetamino-, chloro-.

3. Methyl ethyl phenylethylmalonate has been nitrated and the nitro group shown to be in the para position in the benzene ring. In addition the following groups have been introduced into the phenyl ring of methyl ethyl phenylethylmalonate: 4-amino-, 4-hydroxy-, 4-acetamino-, 4-methoxy-.

4. None of the substituted phenylethylmalonates could be condensed with urea to form the corresponding barbituric acids.

5. Preliminary physiological tests which have been carried out on a majority of the 5,5-substituted phenylalkylbarbituric acids show that these compounds with the exception of the 4-chlorophenylethylbarbituric acid are inert. The sedative properties of the chloro derivative are of the same order as those of phenylethylbarbituric acid but the substance is slightly more toxic.

CONDENSATION PRODUCTS OF AMINO-ARSANILIC AND ARSANWC ACIDS[1]

BY P. L. CRAMER WITH W. LEE LEWIS

RECEIVED JUNE 28,1829 PUBLISHED JANUARY 8, 1930

This paper is a continuation of the study[2] of condensation products of amino-arsanilic acid with 1,2-diketones to yield arsenated quinoxalines and with monocarbonyl compounds to form arsenated Schiff's bases. In the present study arsanilic acid as well as amino-arsanilic acid has been employed.

Glyoxal sodium bisulfite condenses with amino-arsanilic acid to give 6-arsono-quinoxaline-2,3-sodium bisulfite. This compound when treated with hydrochloric acid gives 6-arsono-quinoxaline, parent substance of this series.

Maltosone and lactosone, prepared according to the method of Emil

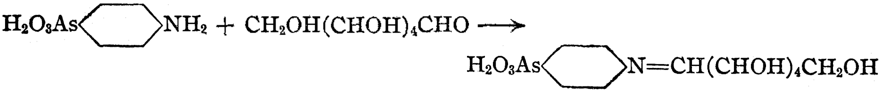
---

[1] This research was carried out under a grant from the Public Health Institute of Chicago. Some of the compounds are being studied for possible therapeutic value at the University of Wisconsin in the Department of Pharmacology.

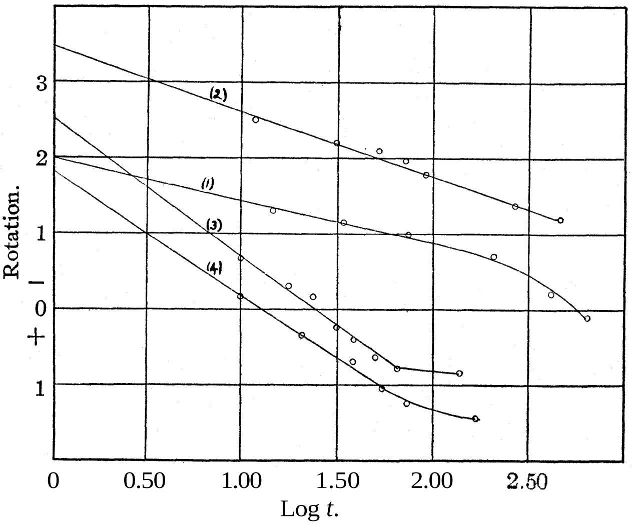
[2] W. Lee Lewis, P. L. Cramer and R. S. Bly, THIS JOURNAL, 46,2058 (1924).

Fischer,[3] condense with amino-arsanilic acid to give substituted quinoxalines. These compounds are readily hydrolyzed by water.

Aldoses condense with arsanilic acid to form Schiff bases containing an aromatic arsonic acid group and a carbohydrate residue. The reaction of glucose is typical of these reactions.



Similar products were obtained with mannose, galactose, arabinose and xylose. These compounds are also very soluble in water and readily hydrolyzed. The rotations of the sugars are inverted by the aromatic arsonic acid group. Due to the fact that these compounds are insoluble in organic solvents and decompose rapidly in water, no definite rotation data could be obtained. The data given indicate the degree and rate of hydrolysis.



Pig. 1.—Curves showing the rate of hydrolysis and the approximate initial rotations of **4-aldo-aminophenylarsonic** acids. Data from Table II.

Aromatic sulfone chlorides react with arsanilic and amino-arsanilic acids to give substituted phenylsulfone-aminophenylarsonic acids. These were prepared by the Schotten–Baumann reaction. Of this series, 4-phenylsulfone-aminophenylarsonic acid,[4] 4-p-tolylsulfone-aminophenylarsonic acid,[5] 4-*m*-nitrophenylsulfone-aminophenylarsonic acid[6] and 4-m-nitro-p-tolylsulfone-arninophenylarsonic acid[6] have previously been described.

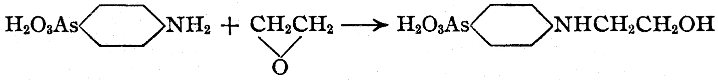
. The present study includes compounds prepared from benzenesulfone chloride and *p*-tolylsulfone chloride with amino-arsanilic acid, and also p-bromobenzene-sulfone chloride with both arsanilic and amino-arsanilic acids. In the case of amino-arsanilic acid only one amino group is involved in the reaction. Judging from the comparative reactivities of the two groups, it is assumed that the amino group in the para position to the arsonic acid is the reactive group.

Highly colored compounds were obtained by condensing picryl chloride with both arsanilic and amino-arsanilic acids in absolute ethyl alcohol, namely, 4-(2,4,6-trinitrophenylamino)-phenylarsonic acid and 4-(2,4,6-trinitrophenylamino)-3-aminophenylarsonic acid.

p-Arsono-anilino-ethanol-2[7] is readily prepared in good yields by the reaction of ethylene oxide and arsanilic acid in the cold.



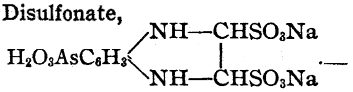
By refluxing arsanilic acid with an excess of o-bromoacetophenone, 4-di-(phenacylamino)-phenylarsonic acid is formed.

$$H_2O_3AsC_6H_4NH_2 + 2BrCH_2COC_6H_5 \longrightarrow H_2O_3AsC_6H_4N(CH_2COC_6H_5)_2 + 2HBr$$

4-Phenacylaminophenylarsonic acid has been prepared by Jacobs and Heidelberger.[8]

Experimental Part

Preparation of 6-Arsonoquinoxaline-2,3-sodium Disulfonate,



$$H_2O_3AsC_6H_3\begin{cases}NH-CHSO_3Na\\ \quad\ \ | \\ NH-CHSO_3Na\end{cases}.—$$

Five grams of amino-arsanilic acid was dissolved in 25 cc. of N sodium hydroxide solution and 6 g. of powdered glyoxal sodium bisulfite added. The reaction mixture was heated to 60° with stirring until the bisulfite compound had dissolved. The solution was filtered and acidified slightly to congo paper with concentrated hydrochloric acid. An equal volume of ethyl alcohol was added to the solution and after standing for a few minutes in the cold a bulky mass of grayish white needles was formed. The product was purified by dissolving in a small amount of water and precipitating with ethyl alcohol as previously described. The yield was 6 g. The product is insoluble in organic solvents but very soluble in water.

Anal. Subs., 0.1583, 0.1615; 0.5631, 0.6250; 0.3861, 0.3144; 14.05, 14.35 cc. of 0.04810 N iodine solution; $BaSO_4$, 0.5686, 0.6470; Na_2SO_4, 0.1202, 0.0984. Calcd. for $C_8H_9O_9N_2S_2Na_2As$: As, 16.22; S, 13.88; Na, 9.95. Found: As, 16.01, 16.02; S, 13.87, 14.22; Na, 10.08, 10.13.

6-Arsonoquinoxaline,  $H_2O_3AsC_6H_3\begin{cases}N=C-H\\ \quad\ \ | \\ N=C-H\end{cases}$.—Five grams of 6-arsonoquinoxaline-2,3-sodium bisulfite was dissolved in 20 cc. of water. After filtering, the solution was heated to boiling and made strongly acid to congo paper with concentrated hydrochloric acid. The solution was boiled with stirring until no mote sulfur dioxide was given off.

---

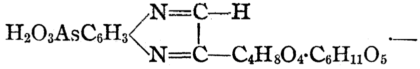
[7] Hamilton, This journal, 45, 2751 (1923).

[8] Jacobs and Heidelberger, *ibid.*, 41, 1590 (1919).

The resulting dark colored precipitate was washed with hot water and purified further by refluxing with water. The green colored product was dried to constant weight by heating at 100" under reduced pressure. The compound is slightly soluble in water and insoluble in organic solvents. It does not melt below 250°.

Anal. Subs., 0.1548, 0.1692; 24.90, 27.35 cc. of 0.04810 N iodine solution. Calcd. for $C_8H_7O_3N_2As$: As, 29.51. Found: As, 29.01, 29.14.

3-Glucosido-erythrityl-quinoxaline-6-arson Acid,

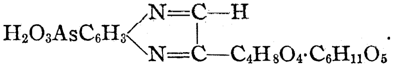


$$H_2O_3AsC_6H_3\begin{cases}N{=}C{-}H\\ \quad\;\; |\\ N{=}C{-}C_4H_8O_4{\cdot}C_6H_{11}O_5\end{cases}.{-}$$

Five grams of maltosone was dissolved in 159 cc. of absolute methyl alcohol and to this was added 3.5 g. of amino-arsanilic acid in 50 cc. of methyl alcohol. The solution was refluxed for three hours and the resulting purple precipitate removed and refluxed with absolute methyl alcohol for purification. The product weighed 4 g. or 60% of the theoretical and did not melt below 250". It is quite soluble in water but is easily hydrolyzed. The red color of its aqueous solution disappears on slight warming and the solution reduces Fehling's solution in the cold, showing the presence of a free osone. The product was heated to constant weight under reduced pressure at 139°.

Anal. Subs., 0.1292, 0.1177; 9.98, 9.00 cc. of 0.04892 N iodine solution. Calcd. for $C_{18}H_{25}O_{12}N_2As$: As, 13.88. Found: As, 14.16, 14.02.

3-Galactosido-erythrityl-quinoxaline-6-arsonc Acid,



$$H_2O_3AsC_6H_3\begin{cases}N{=}C{-}H\\ \quad\;\; |\\ N{=}C{-}C_4H_8O_4{\cdot}C_6H_{11}O_5\end{cases}.$$

One gram of lactosone was dissolved in 25 cc. of hot ethylene glycol and 0.8 g. of amino-arsanilic acid dissolved in 50 cc. of absolute methyl alcohol added. The solution was refluxed for five hours. A light brown substance was precipitated during the heating. The product was filtered from the hot solution and washed with methyl alcohol. The yield was 1.0 g. or 66% of the theoretical. It was purified by working and refluxing with absolure methyl alcohol. The product was dried to constant weight at 100° under reduced pressure.

Anal. Subs., 0.1240, 0 1000; 10.40, 8.40 cc. of 0.04591 *N* iodine solution. Calcd. for $C_{18}H_{25}O_{22}N_2As$: As, 13.88. Found: As, 14.43, 14.45.

Condensation Products of Certain Aldoses with **Arsanilic** Acid.—These reactions were carried out in absolute methyl alcohol. The sugar was dissolved in the least amount of alcohol, filtered and one molecular equivalent of arsanilic acid dissolved in methyl alcohol added. The solution was refluxed from one to four hours, during which time the condensation product was precipitated. They were worked and refluxed with small amounts of methyl alcohol for purification. These compounds are insoluble in organic solvents but quite soluble in water, in which they are readily hydrolyzed. They were dried to constant weight at 45° under reduced pressure.

TABLE I

CONDENSATION PRODUCTS OR ARSANILIC ACID AND ALDOSES

	( )-Aminophenylarsonic acid	Yield, %	Subs.	0 04869 *N* I, cc.	Arsenic, % Calcd.	Arsenic, % Found
1	4-Gluco-, $CH_2OH(CHOH)_4CH{=}NC_6H_4AsO_3H_2$	54	0.1166	12.70	19.83	19.88

Preparation of Substituted Phenylsulfone-aminophenylarsonic Acids.—The arsonic acids were dissolved in the theoretical amount of N sodium hydroxide and one molecular equivalent of the aromatic sulfone chlorides added. The reaction mixture was heated to boiling with stirring and the mixture refluxed until all of the sulfone chloride had dissolved. The solution was filtered and allowed to cool, the product crystallizing from the cold solution. These compounds were purified by dissolving in *N* sodium hydroxide and precipitating with a slight excess of hydrochloric acid to dissolve any unchanged arsonic acid. The compounds are slightly colored and melt with decomposition. The yields are poor but may be increased by carrying out the reactions in sodium carbonate solution, rather than sodium hydroxide.

TABLE III

SUBSTITUTED PHENYLSULFONE-AMINOPHENYLARSONIC ACIDS

( )-Sulfone-amino-3-aminophenylarsonic acid	Yield, %	M. p., °C. (dec.)	Analysis			
			Subs.	0.05571 *N* I, cc.	Arsenic, % Calcd.	Arsenic, % Pound
4-Phenyl-, $C_6H_5SO_2HN(NH_2)C_6H_3AsO_3H_2$	31	205-7	0.1439	13.80	20.14	20.02
4-*p*-Tolyl-, $CH_3C_6H_4SO_2HN(NH_2)C_6H_3AsO_3H_2$	60	160-5	.1297	12.05	19.41	19.40
4-*p*-Bromophenyl-, $BrC_6H_4SO_2HN(NH_2)C_6H_3AsO_3H_2$	18	180-5	.1244	9.75	16.62	16.33
(4-*p*-Bromophenylsulfone-aminophenylarsonic acid) $BrC_6H_4SO_2HNC_6H_4AsO_3H_2$	33	210-12	.1470	11.82	17.19	16.80

Preparation of 4-(2,4,6-Trinitrophenylamino)-phenylarsonic Acid, $H_2O_3AsC_6H_4NHC_6H_2(NO_2)_3$.—Two grams of arsanilic acid was dissolved in 80 cc. of absolute ethyl alcohol and 3 g. of picryl chloride added. The solution was refluxed for three hours, filtered and cooled to room temperature. Beautiful yellow crystals formed on the sides of the container. The yield was 2 g. or 50% of the theoretical. The substance does not melt below 260°. The product was recrystallized from ethyl alcohol until it gave no test for chlorine.

Anal. Subs., 0.1303, 0.1364; 10.75, 11.35 cc. of 0.05571 *N* iodine solution. Calcd. for $C_{12}H_9O_9N_4As$: As, 17.59. Found: As, 17.22, 17.41.

4-(2,4,6-Trinitrophenylamino)-3-aminophenylarsonic Acid, $H_2O_3AsC_6H_3(NH_2)NHC_6H_2(NO_2)_3$.—This compound was prepared from picryl chloride and amino-arsanilic acid according to the preceding method. It is a deep red colored product and chars at 165°.

Anal. Subs., 0.1040, 0.1261; 8.32, 10.02 cc. of 0.05571 *N* iodine solution. Calcd. for $C_{12}H_{10}O_9N_5As$: As, 16.91. Found: As, 16.70, 16.58.

p-Arsono-anilino-ethanol-2, $H_2O_3AsC_6H_4NHCH_2CH_2OH$.—Forty grams of arsanilic acid was dissolved in 174 cc. of N sodium hydroxide solution and 10 g. of ethylene oxide added. The solution was allowed to stand in a closed container for twenty-four hours at room temperature. The solution was filtered and acidified to congo paper, the white product precipitating immediately. The yield was 24 g. or 50% of the theoretical and the substance melted at 168°. The product was purified by dissolving in N sodium hydroxide solution and precipitating with an excess of concentrated hydrochloric acid.

Anal. Subs., 0.1081, 0.1097; 15.20, 15.30 cc. of 0.05493 N iodine solution. Calcd. for $C_8H_{12}O_4NAs$: As, 28.72. Found: As, 28.95, 28.72.

4-Di-(phenacylamino)-phenylarsonic Acid, $H_2O_3AsC_6H_4N(CH_2COC_6H_5)_2$.—Three grams of arsanilic acid was dissolved in the calculated amount of N sodium hydroxide solution and refluxed with 6 g. of brorno-acetophenone. A yellow colored mass separated after heating the solution for about fifteen minutes; a sufficient amount of N sodium hydroxide solution was added to dissolve the reaction product and the heating continued for ten minutes. The solution was filtered and the excess of bromo-acetophenone extracted by washing with small amounts of ether. The product was precipitated by adding an excess of concentrated hydrochloric acid. The yield was 1.5 g. and the substance melted at 162.5°.

Anal. Subs., 0.1229, 0.1674; 10.90, 14.65 cc. of 0.05240 N iodine solution. Calcd. for $C_{22}H_{20}O_5NAs$: As, 16.73. Found: As, 17.42, 17.20.

Summary

1. Maltosone and lactosone were condensed with amino-arsanilic acid to produce certain new types of arsenated quinoxalines. These compounds are very soluble in water but hydrolyze rapidly.

2. Aldoses condense readily with arsanilic acid to form Schiff bases containing an aromatic arsonic acid and a carbohydrate residue.

3. Further condensation products of arsanilic and amino-arsanilic acids with substituted sulfone chlorides, etc., are given.

LOCAL ANESTHETICS IN THE PYRROLE SERIES. I[1,2]

BY F. F. BLICKE AND E. S. BLAKE

RECEIVED JUNE 28, 1929 PUBLISHED JANUARY 8, 1930

The pyrrole or modified pyrrole nucleus is found in a number of naturally occurring compounds—hemoglobin, chlorophyll, proteins, bile and urinary pigments and certain alkaloids. Because of the presence of this nucleus in so many normal physiological products, we decided to introduce it into certain synthetic drugs by the substitution of this group for other cyclic radicals such as phenyl.[3]

Investigations in the chemistry of pyrrole compounds have been retarded by the high cost of pyrrole in this country and by the fact that practical laboratory methods have not been developed for the preparation of relatively large amounts of the simpler pyrrole derivatives.

Recently[4] it was found possible in this Laboratory to prepare pyrrole in fairly large quantities at moderate expense. We began, then, a detailed study of the preparation of pyrrole-carboxylic acids from pyrrole itself[6] and during the investigation of pyrrole-2-carboxylic acid the discovery was made that the ethyl ester of this substance possesses decided local anesthetic action when placed on the tip of the tongue. Although local anesthetic action is a property common to many esters of aromatic acids, especially those of aminobenzoic acids, this type of action, with one exception, has not been noticed hitherto in the case of the esters of the

---

[1] This paper represents the first part of a dissertation to be submitted to the Graduate School by Mr. Blake in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the University of Michigan.

[2] We wish to take this opportunity to acknowledge our indebtedness to Frederick Steams and Company who have made this investigation possible by the grant of a fellowship.

[3] In a few instances comparisons have been made between pyrrole, thiophene and furan compounds and the corresponding benzene derivatives. Because of the close chemical relationship between thiophene and benzene it is not surprising that a number of thiophene derivatives resemble their benzene analogs in taste and odor (Cohn, "Die organischen Geschmacksstoffe," Siemenroth, Berlin, 1914, p. 78). Steinkopf and Ohse have prepared several synthetic drugs in which the thienyl group has been used in place of phenyl. Thiophene-cocaine hydrochloride [*Ann.*, 437, 14 (1924)] and the thiophene analogs of eucaine-A and stovaine [*ibid.*, 448, 205 (1926)] all proved to be strong anesthetics. Diethylamino-ethyl-2-thiophene-carboxylate and diethylamino-ethyl-2-furan-carboxylate [Gilman and Pickens, THIS JOURNAL, 47, 252 (1925)] were found to be poor local anesthetics compared to procaine.

[4] Blicke and Powers, *Ind. Eng. Chem.*, **19**, 1334 (1927).

[5] A number of substituted pyrrole-carboxylic acids have been prepared from aliphatic compounds by ring closure. However, in many instances the yields obtained by this process are poor; furthermore, the method is applicable only for the preparation of certain definite types of pyrrole derivatives.

simpler pyrrole-carboxylic acids. Gilman and Pickens[6] prepared the diethylamino-ethyl ester of pyrrole-2-carboxylic acid and according to Kamm[7] this substance is about one-third as active as procaine.

In addition to the ethyl ester[8] of pyrrole-2-carboxylic acid, we investigated the action of the methyl,[8, 9] propyl,[10] *iso*propyl,[10] butyl,[10] *iso*butyl[10] and *iso*-amyl[10] homologs. It seemed from the rough test on the tip of the tongue that the propyl ester possessed the most decided action. The phenyl ester also possessed some activity. Preliminary pharmacological tests[11] indicate that the ethyl ester is a compound of comparatively low toxicity.

The ethyl esters of pyrrole-1-carboxylic acid, 2-methylpyrrole-3-carboxylic acid[12] and of 2,4-dimethylpyrrole-3-carboxylic acid[13] possessed marked action, but the ethyl esters of the following acids were inactive: 2,5-dimethylpyrrole-3-carboxylic acid,[14] 2,5-diphenyl-pyrrole-3-carboxylic acid,[15] 1,2,5-triphenylpyrrole-3-carboxylic acid,[15] 1,5-diphenyl-2-methylpyrrole-3-carboxylic acid,[16] 1-phenyl-2,5-dimethylpyrrole-3-carboxylic acid,[17] 3-phenyl-5-methylpyrrole-4-carboxylic acid,[13] 2,4-dimethylpyrrole-3,5-dicarboxylic acid,[18] 2,5-dimethylpyrrole-3,4-dicarboxylic acid,[19] 2-pyrrolidone-5-carboxylic acid[20] and 3,4,5-tribromopyrrole-2-carboxylic acid.

Mannich and co-workers[21] found, unexpectedly, that β-N-piperidinoethyl phenyl ketone, $C_6H_5COCH_2CH_2NC_5H_{10}$, a substance obtained readily from acetophenone, piperidine hydrochloride and paraformaldehyde, possesses local anesthetic action. Furthermore, the benzoyl derivative of the corresponding secondary carbinol, $C_6H_5CH(OCOC_6H_5)CH_2CH_2NC_5H_{10}$, was shown to be a strong anesthetic. We prepared the above ketone by another process, a method which indicates definitely the structure of the substance, namely, by the action of β-bromopropiophenone on piperidine

$$C_6H_5COCH_2CH_2Br + 2HNC_5H_{10} \longrightarrow C_6H_5COCH_2CH_2NC_5H_{10} + HNC_5H_{10}\cdot HBr$$

From bromo-acetophenone and piperidine we obtained N-piperidinomethyl phenyl ketone, $C_6H_5COCH_2NC_5H_{10}$, the lower homolog of the above ketone. This latter compound, as well as the benzoate of the corresponding secondary alcohol, $C_6H_5CH(OCOC_6H_5)CH_2NC_5H_{10}$, was found to possess anesthetic activity.

2-Acetylpyrrole, piperidine hydrochloride and paraformaldehyde react readily to form a substance which possesses marked anesthetic action. Based on analogy the compound should have the structure $C_4H_4NCOCH_2CH_2NC_5H_{10}$. Unfortunately, we were unable to obtain this material in crystalline condition.

Experimental Part

Pyrrole.—We wish to add the following notes to the information published previously[4] concerning the preparation of pyrrole.

For the preparation of ammonium mucate on a large scale about three and one-half times the amount of ammonia water (technical) required theoretically was added to mucic acid which had been put into a large crock. The mixture was stirred thoroughly from time to time. After several weeks, through evaporation of the water, the ammonium salt was obtained in the form of a thick paste. The latter was transferred to galvanized iron trays and allowed to dry thoroughly. The material was then milled to a flour-like powder.

It was found advantageous to replace the metal coil condenser by two ordinary glass bulb condensers.

As soon as the mixture of pyrrole, water and ammonium carbonate begins to distil from the apparatus at a fairly rapid rate, the Fletcher burner should be replaced by a micro burner. If the bottom of the apparatus is heated too strongly at this stage of the operation the reaction mixture invariably foams over into the condenser.

After 200–250 cc. of pyrrole (this refers to experiments in which 5.5 pounds of ammonium mucate have been used) has been collected, the formation of pyrrole becomes so slow that it seems that the process is complete. The micro burner should now be replaced by a Fletcher burner. The distillation of pyrrole then begins again and at least 100 cc. more of pyrrole is obtained.

The crude pyrrole contains considerable ammonia and this should be removed by treatment of the material with a small amount of water.

Contrary to the statements in the literature,[22] we found that pyrrole is appreciably soluble in water and in a saturated solution of ammonium carbonate. One hundred cc. of water dissolves about 5 cc. of pyrrole at ordinary temperature. The aqueous ammonium carbonate layer obtained in the preparation of pyrrole should be extracted with ether.

To obtain pyrrole in a colorless state it should be distilled in a stream of dry nitrogen and kept in sealed ampules, under nitrogen, protected from light.

Ethyl Ester of Pyrrole-1-carboxylic Acid.[23]—This compound was prepared from

[23] Ciamician and Dennstedt, *Ber.*, **15**, 2579 (1882); *Ann.*, **210**, 400 (1881); Tschelinseff and Maxoroff, *J. Russ. Phys.-Chem. Soc.*, **1**, 161 (1915); Tschelinseff and Maxoroff, *Ber.*, **60**, 196 (1927). The latter investigators (*ibid.*, p. 195) were able to isolate the unstable pyrrole-1-carboxylic acid and studied a number of its derivatives.

potassium pyrrole and ethyl chloroformate. The potassium pyrrole can be prepared rapidly by the use of excess pyrrole as a solvent as described in a later experiment. The potassium compound, which precipitates when the hot concentrated solution is cooled, is filtered and washed with absolute ether.

In an attempt to rearrange the ester into the ethyl ester of pyrrole-2-carboxylic acid, the material was passed through a hot combustion tube. The only products which we were able to identify were ethylene and a very small amount of pyrocoll. The ethylene was isolated as ethylene bromide; b. p. 128".

Esters of Pyrrole-2-carboxylic Acid.—Pyrrole-2-carboxylic acid was obtained from pyrrylmagnesium bromide and carbon dioxide.[24] The dark colored acid was purified in the following manner. The substance was dissolved in somewhat more than the required amount of ammonium hydroxide. The solution was diluted and then boiled for a short time with "nuchar." The mixture was filtered and the filtrate cooled with ice. After the addition of ether the colorless solution was stirred and dilute sulfuric acid added in small amounts. The carboxylic acid was obtained from the ether solution in a practically colorless state. It was found that in some instances the acid did not dissolve readily in ether if it had been precipitated completely and then treated with a solvent.

In order to prepare the alkyl esters an excess of the alkyl halide was heated in a pressure bottle, immersed in a bath of boiling water, with the silver salt of pyrrole-2-carboxylic acid; in some instances, however, we refluxed a mixture of the alkyl bromide, the silver salt of the acid and toluene. The crude esters boiled over a considerable range of temperature and the distillate was collected in several portions. The fractions used in our tests boiled as follows: methyl ester, 220–223° (m. p. 72–73'); ethyl ester, 227–230° (m. p. 38–40°); n-butyl ester, 255–260° (m. p. 36–38°); *iso*butyl ester, 250–255° (m. p. 68-69"); iso-amyl ester, 263–267°. The barometric pressure was 740 mm.

According to Ciamician and Silber[8a] bromination of the methyl ester of pyrrole-2-carboxylic acid yields a tribromo derivative. We brominated the ethyl ester in the presence of water according to the method described by the above-mentioned investigators. A tribromo substitution product was formed which, after recrystallization from acetic acid and then from alcohol, melted at 195–196°. Anal. Calcd. for $C_7H_6O_2NBr$: Br, 63.79. Found: Br, 63.75. The following preparative method was found to be much more satisfactory. To 1.4 g. of the ester, dissolved in 5 cc. of acetic acid, there was added slowly, with cooling, 1.6 cc. (3 molecular equivalents) of bromine dissolved in 5 cc. of acetic acid. The bromine was decolorized almost instantly with the evolution of hydrogen bromide and the greater part of the bromo ester separated from the solution. The product was recrystallized twice from acetic acid and then from alcohol; m. p. 195–196°. The compound dissolves in warm, aqueous sodium hydroxide. Upon acidification of the solution a gelatinous precipitate was obtained. The latter melted at 195° after recrystallization from acetic acid. In view of the fact that the compound can be recovered unchanged from an alkaline solution and that the methyl ester of tribromopyrrole-2-carboxylic acid yields a tribromopyrrole-2-carboxylic acid upon hydrolysis,"' it seems certain that the bromine atoms in the bromo esters occupy the nuclear positions 3, 4 and 5.

The phenyl ester was obtained in the following manner. The acid chloride obtained from 3 g. of pyrrole-2-carboxylic acid was dissolved in ether and heated for two hours on a steam-bath with sodium phenolate which had been prepared from 2.5 g. of phenol, 0.62 g. of sodium and 70 cc. of absolute ether. The mixture was treated

---

[24] Oddo, *Gazz.* chim. ital., I, 39, 649 (1909); I, **44**, 482 (1914); *Ber.*, **43**, 1012 (1910); McCay and Schmidt, THIS JOURNAL, **48**, 1935 (1926).

with dilute sodium hydroxide, then with water, and the ether layer dried over fused sodium sulfate. After removal of the ether a dark colored, oily residue was obtained. The material was dissolved in hot petroleum ether (30–60°). When the solution was cooled crystals were obtained which melted at 44–45°. The yield was **2.8** g.

Anal. Subs., **0.2350;** CO_2, **0.6089;** H_2O, **0.1035.** Calcd. for $C_{11}H_9O_2N$: C, **70.56;** H, **4.85.** Found: C, **70.66;** H, **4.93.**

β-*n*-Piperidino-ethyl Phenyl **Ketone.**—β-Bromopropionic acid was mixed with three times the calculated amount of thionyl chloride. After two days the excess thionyl chloride was removed under diminished pressure. The acid chloride of β-bromopropionic acid was then distilled; b. p. **69–71"** under **23** mm. pressure.[25]

Thirty grams of the acid chloride **(0.17** mole) was dissolved in **150** cc. of dry benzene and **28** g. of aluminum chloride **(0.21** mole) was added in small portions.[26] After twenty-four hours the reaction mixture was decomposed with ice and hydrochloric acid. Upon removal of the excess benzene under diminished pressure the residue became crystalline. The β-bromopropiophenone melted at **59–60**° after recrystallization from alcohol. The yield was **29** g. or 80% of the calculated amount. The halogen is removed rapidly from the bromo ketone when the latter is heated with alcoholic sodium hydroxide.

Anal. Calcd. for C_9H_9OBr: Br, **37.51.** Found: Br, **37.62.**

Ten cc. of piperidine **(0.1** mole) dissolved in **50** cc. of absolute ether was added slowly to **10.6** g. **(0.05** mole) of β-bromopropiophenone, dissolved in **70** cc. of the same solvent. Eight and one-tenth grams of piperidine hydrobromide precipitated immediately. The calculated amount of piperidine hydrobromide is **8.2** g. After removal of the piperidine salt the ether layer was washed with water and then dried thoroughly with fused sodium sulfate. The solution was filtered and then treated with dry hydrogen chloride. There precipitated **8.3** g. of the hydrochloride of β-*n*-piperidino-ethyl phenyl ketone. The calculated yield of the hydrochloride is **12.6** g. The salt melted at 187–188°.[27] The melting point was unchanged after recrystallization from ethyl acetate to which a few drops of alcohol had been added. We prepared the ketone hydrochloride by the method of Mannich and Lammering;[27] the material melted at **182–183°.**

The ketone was reduced to the secondary carbinol in the following manner. The hydrochloride described above was dissolved in water and the free base liberated by the addition of sodium hydroxide. Five g. of the oily base, dissolved in **50** cc. of absolute alcohol, was reduced with hydrogen in the presence of **0.35** g. of platinum oxide catalyst[28] under an initial pressure of four atmospheres. The calculated amount of hydrogen was absorbed in about twenty minutes. The carbinol was obtained in solid form after removal of the alcohol; m. p. **64–65"** after recrystallization from petroleum ether (30–60°).[29] The hydrochloride precipitated immediately when hydrogen chlo-

---

[25] The acid chloride would probably distil without decomposition under ordinary pressure.

[26] Collet, Bull. *soc. chim.*, **[3] 17, 66** (1897), studied the interaction of a number of halogenated acid chlorides and benzene in the presence of aluminum chloride. He found that only the acyl halogen reacts readily with the benzene.

[27] Mannich and Lammering, *Ber.*, **55, 3515** (1922), recorded the melting point as 192–193° and stated that the hydrochloride can be recrystallized from a mixture of dilute alcohol and acetone.

[28] "Organic Syntheses," John Wiley and Sons, Inc., New York, **1928,** Vol. VIII, p. **92.**

[29] Mannich and Lammering, *Ber.*, **55, 3517** (1922), state the melting point to be 68–69°. They reduced the amino-ketone hydrochloride with hydrogen in the presence of palladium-charcoal.

ride was passed into an ether solution of the carbinol; m. p. 139–140°. Upon benzoylation of the carbinol in chloroform the benzoate described by Mannich and Lammering was obtained. Hydrolysis of the benzoate with alcoholic sodium hydroxide yielded the secondary carbinol which melted at 64–65° after recrystallization from petroleum ether.

n-Pipefidinomethyl Phenyl Ketone.—To 16 g. of bromo-acetophenone[30] dissolved in 100 cc. of absolute ether there was added 16 cc. of piperidine dissolved in 50 cc. of the same solvent. The calculated amount of piperidine hydrobromide precipitated at once. The piperidino ketone was obtained in the form of an oil which exhibited marked local anesthetic action on the tongue. The hydrochloride was obtained in crystalline form from an ether solution of the ketone and hydrogen chloride. It can be recrystallized from ethyl acetate to which a few drops of alcohol have been added; m. p. 210–211°. The hydrochloride possesses anesthetic action.

In order to prepare the secondary carbinol 10.5 g. of the ketone was dissolved in 50 cc. of absolute alcohol and reduced with hydrogen in the presence of 0.5 g. of platinum oxide catalyst. The initial pressure was four atmospheres. After thirty minutes the reduction seemed to be complete. A solid material was obtained which, after recrystallization from petroleum ether, melted at 69–70'. The hydrochloride melts at 193–194°.

Anal. Subs., 0.2201: CO_2, 0.6143; H_2O, 0.1854. Calcd. for $C_{13}H_{19}OH$: C, 76.02; H, 9.33. Found: C, 76.11; H, 9.42.

The secondary carbinol was benzoylated in the following manner. One gram of the carbinol was dissolved in 25 cc. of absolute ether. The required amount of benzoyl chloride, dissolved in ether, was added. Seven-tenths of a gram of the hydrochloride of the benzoate precipitated; m. p. 193–194°. The free base was obtained in the form of an oil. The hydrochloride and the free base both possess anesthetic action. The melting point of the carbinol, obtained by hydrolysis of the benzoate, was 69–70°.

n-Piperidinomethyl 2-Pyrryl Ketone.—Twelve and one-tenth grams of piperidine hydrochloride, 30 cc. of absolute alcohol and 4.5 g. of paraformaldehyde were heated and 10.9 g. of 2-acetylpyrrole was added during the course of half an hour. An additional 3 g. of paraformaldehyde was then added and the mixture heated for fifteen minutes longer. After evaporation of the alcohol the ketone was obtained in the form of an oily hydrochloride. The latter was dissolved in water and the free base precipitated by the addition of sodium hydroxide. The oily base possessed anesthetic action.

Summary

It has been found that a number of esters of pyrrole-carboxylic acids, especially the alkyl esters of pyrrole-2-carboxylic acid, possess marked local anesthetic action on the tongue.

n-Piperidinomethyl phenyl ketone, n-piperidinomethyl 2-pyrryl ketone and the benzoate of *n*-piperidinomethylphenylcarbinol were found to possess local anesthetic action.

THE MOLECULAR WEIGHT OF CASEIN. I[1]

BY T. SVEDBERG, L. M. CARPENTER AND D. C. CARPENTER[2]

RECEIVED JUNE 29, 1929 PUBLISHED JANUARY 8, 1930

The molecular weight of casein was first estimated by Van Slyke and Bosworth[3] from the sulfur and phosphorus content. These workers found 0.72% of sulfur and 0.71% of phosphorus in a sample of casein, and assuming one atom of each of these elements in the original protein arrived at the value 4444. For no clear reason they doubled this value and set down the probable molecular weight as *8888.* As to their method of preparing casein, which involves heating for some time in alkaline solution, Harden and Macallum[4] have called attention to the fact that no doubt hydrolytic cleavage of part of the sulfur and phosphorus of the protein has taken place during the preparation. Experiments by one of the writers,[5] while not bearing directly on the matter of sulfur and phosphorus cleavage, show that there is considerable cleavage of nitrogen of the casein molecule under the conditions which Van Slyke and Bosworth imposed on their material. This substantiates the claims of Harden and Macallum and shows that Van Slyke and Bosworth's material and calculations based thereon cannot be seriously considered.

Pauli and Matula[6] ingeniously attempted to evaluate the valency of casein through application of the Ostwald dilution rule. Using this rule they concluded that the valency of casein was 3. Since they found the combining weight of casein for base was about 1000, they concluded that the molecular weight was 3000.

Yamakami[7] examined the molecular weight of casein by Barger's method, which compares solutions of equal vapor pressure. He concluded that for the simplest alkali caseinates which he could prepare, the mean weight of the ions was about 2000, which would mean for a caseinate dissociating into only two ions a molecular weight of about 4000. This figure would then necessarily represent only a minimum value for the molecular weight.

More recently Cohn, Hendry and Prentiss[8] have attempted to evaluate

the molecular weight of several proteins from their amino acid content. With considerable reluctance they placed the molecular weight of casein at 192,000. On the basis of one molecule of cystine per molecule of casein, the minimal molecular weight of casein was calculated to be 96,000. However, largely on account of the difficulty of fitting the tryptophan content to this latter value, they decided in favor of the value 192,000.

Researches on casein in late years have usually started with preparations made either by the method of Hammarsten[9] or by the method of Van Slyke and Baker.[10] We have examined casein made by each of these methods, by means of the ultracentrifuge, and in this paper will report experiments based on Hammarsten casein.

The recent experiments of Kondo,[11] Linderstrorn-Lang and Kodama,[12] and Linderström-Lang[13] seem to show that Hammarsten casein is a mixture of substances, inasmuch as they found the solubility in dilute hydrochloric acid to be dependent on the casein content of the solution.

Gortner[14] criticized these workers on the ground that they had not removed an alcohol-soluble protein from their material, which had previously been separated and identified by Osborne and Wakeman.[15] Although Gortner may have been right in part, Osborne and Wakeman reported a yield of their alcohol-soluble protein entirely too low to account for the results obtained by the workers in the Carlsberg laboratory.

In view of the discordant state of the literature relating to casein, it was considered advisable to undertake an investigation of this important protein by means of the centrifugal methods developed in this Laboratory[16] and already used for the determination of the molecular weights of hemoglobin,[17] egg albumin,[18] phycocyan, phycoerythrin,[19] hemocyanin,[20] serum albumin and serum globulin[21] and edestin.[22]

Experimental

The casein used in this investigation has in every instance been prepared from cow's milk and in so far as possible was obtained from the same dairy herd. As casein is practically insoluble at its isoelectric point, PH 4.7, we have carried out our centrifuging experiments in phosphate buffer solutions of *PH* 6.8, this *PH* value closely approximating that of freshly drawn milk.

Preparation of Material.—Milk was drawn from the animal into flasks containing toluene, brought to the laboratory at once and cooled to 5° as rapidly as possible. Butter fat was removed from the cold milk by slow passage through a milk separator operated at *13,200* r.p m. In this operation practically all the fat was removed from the milk and clung firmly to the center shaft and disks of the separator. Some "separator slime" collected on the sides of the bowl and was discarded.

The separated milk was diluted with 4 volumes of cold water and the casein precipitated by the Hammarsten method[9] through the slow addition of diluted (1:100) acetic acid, the diluted milk being mechanically stirred meanwhile. This operation required the equivalent of 7.5 cc. of glacial acetic acid per liter of milk. The precipitated casein settled rapidly and after washing by decantation several times with water, the precipitate was centrifuged from the wash water and several additional washings made, separating the casein each time centrifugally.

The moist precipitate was then dissolved in dilute ammonia, adding the ammonia slowly during mechanical agitation so as to have no pronounced alkalinity at any time in any part of the solution. (The PH of the solution was kept below 7.0.) The ammonium caseinate solution was then passed slowly through the separator and after diluting with water the casein was precipitated by the calculated amount of dilute acetic acid as before. The precipitate was washed with water, redissolved in ammonia and again reprecipitated with dilute acetic acid and washed repeatedly. Hammarsten[23] showed that further reprecipitation does not improve the purity of the product.

A portion of the moist casein (2 g., dry basis) was then dissolved in *25* cc. of $M/15$ mixed phosphate buffer solution (PH *6.8)* in the cold and diluted to 100 cc., thereby making the buffer salt concentration $M/60$. The solution was stored at 5° with toluene as preservative. This is hereinafter referred to as Hamrnarsten casein.

Another portion of the moist casein *(13* g., dry basis) was extracted at 40° for one hour with two liters of 70% ethyl alcohol containing 1 cc. of normal hydrochloric acid per liter, after the manner of Linderström-Lang.[12,13] The solution was separated from undissolved casein in a centrifuge. (The extraction was continued with a second two-liter portion of acidified alcohol which was separated again in the centrifuge from undissolved material.) From the first extraction with 2 liters of acidified alcohol. 2.15 g. of material (dry basis) was reclaimed by precipitation with dilute sodium hydroxide and from the second extraction 2.19 g. was reclaimed in the same manner. These fractions were dissolved separately in 25-cc. portions of $M/15$ mixed phosphate buffer solution (PH *6.8)* in the cold, diluted to 100 cc. and stored at 5° with toluene. This is hereinafter referred to as acid–alcohol soluble casein, and would probably correspond to fractions K_3, K_4 and K_5 of Linderstrom-Lang's nomenclature. The undissolved casein residue from the above treatment was not further extracted or examined.

Specific Volume.—The partial specific volume was determined pycnometrically **at** 19.8". The amount of protein in solution was found by drying a sample of the stock solution to constant weight at 105° and corrected for the amount of residue due to the

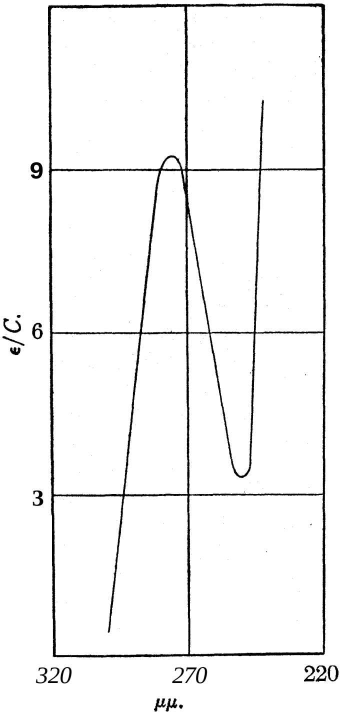
---

[23] Hammarsten, *Z. physiol.* Chem., 7,227 *(1883).*

buffer salts themselves. This method has been shown to give results identical with those obtained by removing the protein by some precipitation process and weighing directly.

The partial specific volume was found to be 0.750 and was independent of concentration, within the limits of experimental error, for protein concentrations between 1.0 and 2.0%. This value closely approximates similar values for several proteins already examined.

Light Absorption.—Experiments were carried out by means of the Judd–Lewis spectrophotometer to determine the absorption in the short-waved ultraviolet part of the spectrum. The toluene used as preservative in the protein solutions was first removed by bubbling moist nitrogen gas through the solution before measuring the light absorption. The solutions were examined at PH 5.9, 6.8 and 8.0 in 20-mm. cells with protein contents, respectively, of 0.02, 0.05 and 0.10%. The specific extinction coefficient $\epsilon/C = 1/Cd \log I_0/I$, where C is the protein concentration in per cent., I_0 the intensity of the light beam after passing a layer of solvent d cm. in thickness and I the intensity after passing the same thickness of protein solution. The extinction coefficient is plotted against wave length in Fig. 1.



Pig. 1.

The absorption curve has a maximum at 276μμ and a minimum at 250μμ. The values of the extinction coefficient fall somewhat below those reported for serum globulin but are higher than for the other proteins thus far examined in this Laboratory. This order is to be expected if the extinction coefficient in this region is due to the tryptophan content of the protein molecule. Differences in extinction coefficient due to differences in PH of the solutions fell within the experimental error.

Hammarsten Casein.—Several runs were made by the sedimentation velocity method with solutions containing various concentrations of Hammarsten casein. In Tables I and II are recorded data of a representative sedimentation series at an initial protein content of 0.75%. The sedimentation curves for this run are shown in Fig. 2.

The unusual shape of the sedimentation curves (Fig. 2) suggests at once that we are not dealing with a monomolecular substance, but rather with a substance containing several different kinds of molecules. Similar curves have been obtained for other proteins which were in a state of change. To arrive at an approximation, we have assumed that the upper break in the successive curves occurs at about their respective points of intersection with the line AB. On this basis we have calculated the specific sedimentation velocity and the "apparent" diffusion constant as shown in Tables I and II.

[b] "Mean Z" represents the mean of the distances from C = **25%** to **C** = **50%** and from C = **50%** to **C** = 75%, see THIS JOURNAL, **49,2922 (1927).**

It will be noted that the "apparent" diffusion constant is not at all constant and that the value increases as the experiment proceeds. This is evidence that we are dealing with a mixture of substances.

If we assume a spherical particle and apply Stokes' Law

$$r = \sqrt{\frac{9\eta s}{2(\rho_1 - \rho_2)}}$$

in which r is the radius of the particle, η the viscosity of the solvent, s the specific sedimentation velocity and $(\rho_1 - \rho_2)$ the difference in density between particle and solvent, we find that the particle radius is 2.85×10^{-7} cm. From Einstein's equation

$$D = \frac{RT}{N} \times \frac{1}{6\pi r\eta}$$

we calculate that a spherical particle of this radius will have a diffusion constant equal to 7.48×10^{-7}. This will distinctly be a limiting case and one in which the frictional force opposing the motion of the sphere will be a minimum. In other words, the maximum diffusion constant we can possibly expect would be 7.48×10^{-7}. That we find higher values than this shows that the "apparent" diffusion must be due to a spreading out of the boundary on account of the presence of molecules of more than one size.

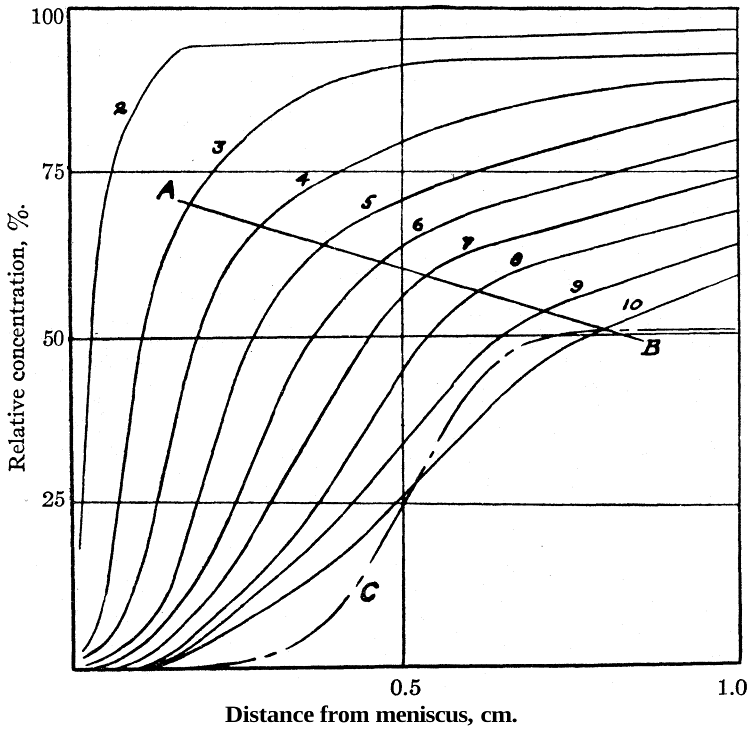

Fig. 2.

The broken line C in Fig. 2 represents how a monomolecular system having $S_{20^\circ} = 5.97 \times 10^{-13}$ and $D_{20^\circ} = 7.48 \times 10^{-7}$ would have been distributed under the same conditions as in Curve 10.

From these experiments we are forced to conclude that Hammarsten casein is a mixture of protein molecules of different weight.

Acid–Alcohol Soluble Casein.—The protein material extracted from Hammarsten casein by warm 70% ethyl alcohol containing 1 cc. of hydrochloric acid per liter[12,13] was examined in the ultracentrifuge by both the sedimentation velocity and the equilibrium methods.

Sedimentation Velocity Method.—Sedimentation velocity runs were made at various protein concentrations between **0.32** and 1.50%. A summary of these runs is given in Table III. A graph showing the relationship between concentration and specific sedimentation velocity is to be found in Fig. 3. It is to be noted that as the protein solution is progressively diluted with $M/60$ phosphate buffer the specific sedimentation velocity is found to increase rapidly until the concentration 0.45% is reached, below which concentration the sedimentation velocity remains practically constant. It is inferred that in concentrations of this protein above 0.45% the protein particles in the solutions are sufficiently close together to have an interfering effect on the free movement of one another and hence the normal diffusion and sedimentation rates are lowered.

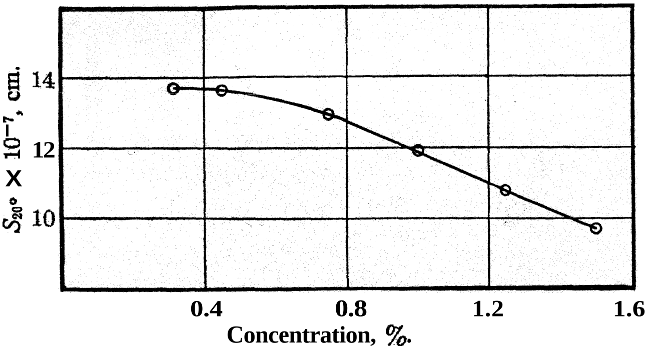

Fig. 3.

TABLE III

ACID–ALCOHOL SOLUBLE CASEIN. SUMMARY OF SPECIFIC SEDIMENTATION VELOCITY VALUES

	9.74	11.05	12.22	12.66	13.06	13.32
	9.76	11.64	12.51	13.10	14.38	13.88
	9.79	12.01[a]	13.60[a]	12.59	14.60	13.68
	9.70				13.62	
Mean $S_{20°}$........	9.68	10.79	11.92	12.83	13.64	13.72

[a] Value discarded in calculating mean.

As we are primarily interested in the more dilute solutions, for this reason we will direct attention to those solutions in which the protein concentration is sufficiently low to eliminate inter-particle forces tending to disturb the free motion of the individual particle.

In Fig. 4 is shown the photographic record of a sedimentation run at 43,600 r.p.m. on a solution containing 0.45% of protein. The progress of sedimentation as the experiment proceeds is shown in the upper row of photographs, while the lower row represents the concentration scale from pure buffer solution (left side) by successive increases to the initial concentration of the protein solution centrifuged (right side). In Fig. 5 are shown the sedimentation curves representing the distribution in a series of photographs obtained in a duplicate run to Fig. 4, at a speed of about 25,000 r.p.m.

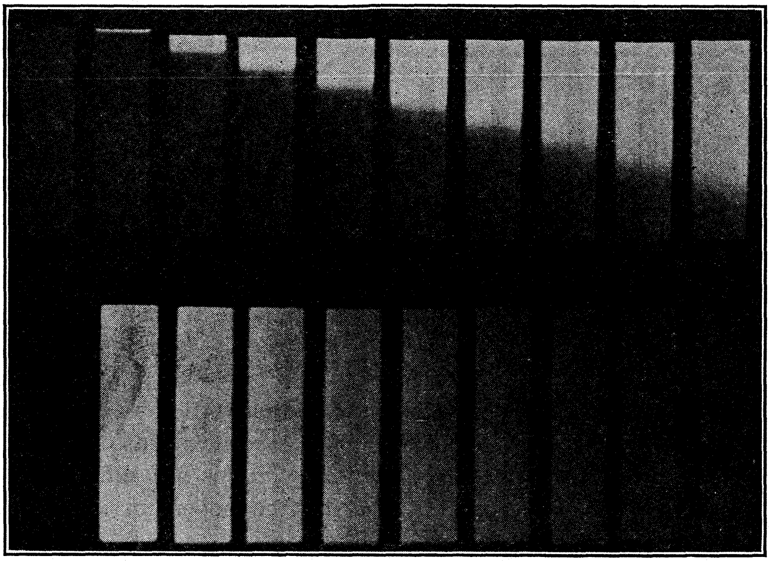

Fig. 4.

The diffusion constant for this protein was found to be 3.56 X 10^{-7} at concentrations below 0.45%. This value represents a mean of several well-agreeing determinations. In Fig. 5 the circles represent the theoretical distribution after three hours at the boundary of a monomolecular substance having a diffusion constant of 3.56 X 10^{-7}. The excellent agreement between theory and experiment is all that can be asked of the experimental method.

In Table IV are recorded the sedimentation data on the above run, showing that the mean specific sedimentation velocity at 20° equals 13.64 X 10^{-13} when the concentration is 0.45% protein. Another run at 0.32% protein concentration gives $S_{20^\circ} = 13.72 \times 10^{-13}$.

Using the above data for S_{20° and D_{20° we have calculated the molecular weight of this protein from the equation $M = RTS/D(1 - V_\rho)$ where M = molecular weight, S = specific sedimentation velocity, V = partial specific volume of the protein, ρ = density of solvent, and R, T and D have the usual significance. In the solutions of 0.32% and 0.45% the molecular weight was found to be 375,000 and 373,420, respectively, the former number being perhaps preferable to the latter.

Table IV

Acid–Alcohol Soluble Casein. Specific Sedimentation Velocity Method

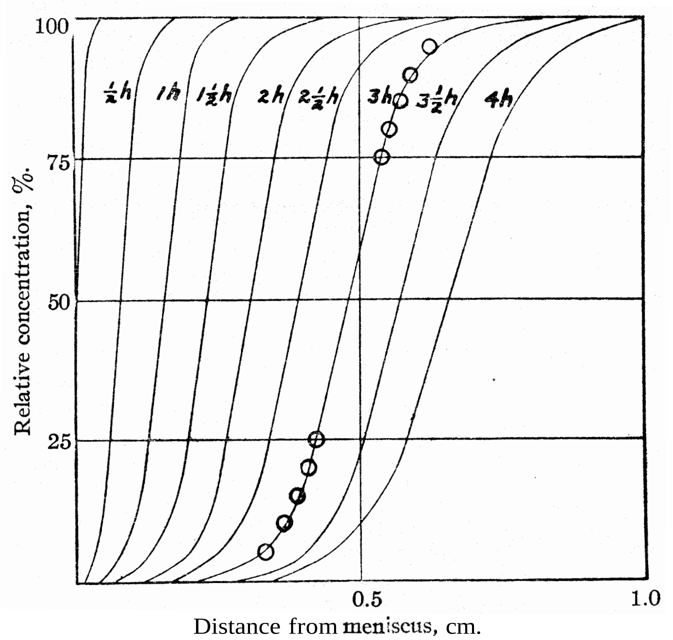
[a] Sedimentation curves bear the same number in Fig. 5 as in these data.



$S = 13.64 \times 10^{-13}$; $D = 3.56 \times 10^{-7}$; $M = 373,400$.

Fig. 5.

Sedimentation Equilibrium Method.—In this method the molecular weight is given by the relation

$$M = \frac{2RT \ln (C_2/C_1)}{(1 - V\rho)\omega^2(X_2^2 - X_1^2)}$$

where C_1 and C_2 represent the protein concentrations at the distances X_1 and X_2, respectively, from the center of rotation. The other symbols have the usual significance.

The optical system as regards light source, filters, photographic plates, developer, etc., was the same as previously used. Photographs were taken with three different lengths of exposure time in order to obtain suitable photographic densities at all concentration levels within the cell for comparisons in the microphotometer. Changes in the intensity of illumination were corrected for by photographing a potassium chromate solution of suitable concentration at the same time as the protein solution. The potassium chromate solution was contained in a cell counterbalancing the cell containing the protein solution, and was masked off from the light source by a brass disk, except for a small window cut in the disk at an appropriate height above the level of the protein solution in the opposite cell.

In Table V are given data on a typical sedimentation equilibrium run with the acid–alcohol soluble protein. The mean molecular weight as shown by this run was 374,210. A duplicate run gave a mean value of 377,795.

TABLE V

ACID–ALCOHOL SOLUBLE CASEIN. SEDIMENTATION EQUILIBRIUM METHOD

Discussion of Results

The experiments described in this paper with casein precipitated from cow's milk by Hammarsten's method have shown that this material is a mixture of several protein molecules of different weight, From 13 g. of this mixture we have separated and reclaimed 4.34 g. of protein by extraction with warm acidified 70% alcohol. This represented at least 33% of the original material and was found to be a definite chemical entity having a molecular weight of 375,000. It might be possible to obtain more than 33% of this protein from Hammarsten casein, as we have only performed the extraction twice, each time removing about the same amount of protein. On the other hand, the shape of the curves in Fig. 2, compared with the curves of other proteins studied in this Laboratory, indicates that, provided the extinction coefficient is the same for all of the protein molecules in Hammarsten casein, there can hardly be present as much as 33% of a protein possessing a molecular weight of 375,000 in Hammarsten casein. If this were the case, one would expect to find two distinct breaks in the upper parts of these sedimentation curves.

It might be argued that by the extraction process we have definitely changed the casein into some polymerized substance which was not originally present in the Hammarsten casein. In support of this argument we find the experiments of Robertson,[24] who concluded from ionic mobility experiments that potassium caseinate polymerized in the presence of 70% alcohol. It is quite possible, however, that compounds of casein with acid would behave differently with respect to alcohol than compounds of casein with base.

According to the experiments of Linderström-Lang[12,13] the polymerization argument seems to be untenable, for continued extractions eventually reach a point where no great amount of protein is further dissolved. This would not be the case were we dealing with a progressive polymerization.

Our own experiments were not designed to show which of the above views was correct. Our only aim was to ascertain whether a definite chemical entity was obtained by the extraction process. The matter would seem to hinge on whether, after continued extractions, the remaining product possessed the same solubility in fresh solvent as it exhibited in the beginning.

The particle size of the acid–alcohol soluble casein may be calculated from the specific sedimentation velocity data using Stokes' Law, under the assumption that the particle is spherical. This gives the value $r = 4.177 \times 10^{-7}$ cm. Using the diffusion constant, we can also calculate the particle size from Einstein's Law without making any assumption as to the shape of the particle. This gives the value $r = 5.994 \times 10^{-7}$ cm. From these values we conclude that the protein particle must be of some other shape

---

[24] Robertson, "Physical Chemistry of the Proteins," T. B. Robertson, New York and London, 1918, p. 268.

than spherical. The ratio between the two values for the particle radius given by the two laws (r_E/r_S) is 1.43. This compares well with similar ratios already obtained in the cases of hemoglobin, serum albumin, serum globulin and phycocyan. This probably means that the departure of the particle from a spherical shape is about the same amount for all of these proteins.

Summary

1. Casein prepared by the Hammarsten method has been examined at Ph 6.8 in phosphate buffer solution by the centrifugal sedimentation velocity method and found to consist of a mixture of protein molecules of different weight.

2. Hammarsten casein was extracted with hot acidified 70% alcohol and the soluble protein precipitated out with dilute sodium hydroxide. This protein after washing was dissolved in phosphate buffer solution of Ph 6.8. Various concentrations were examined by both the sedimentation velocity and sedimentation equilibrium methods.

3. It was found that within the limits of experimental error the acid–alcohol soluble protein was homogeneous with regard to molecular weight and that it therefore probably was a pure chemical individual.

4. The molecular weight was found to be 375,000 ± 11,000.

5. The molecule was not spherical and deviated from the spherical shape by about the same amount that has been found for several other proteins.

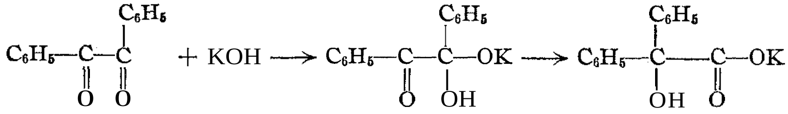
THE BENZILIC ACID REARRANGEMENT

BY THEODORE W. EVANS AND WILLIAM M. DEHN

RECEIVED JULY 1, 1929 PUBLISHED JANUARY 8, 1930

It seems probable that the benzilic acid rearrangement is best formulated as follows



$$C_6H_5-\underset{\overset{\|}{O}}{C}-\overset{C_6H_5}{\underset{\overset{\|}{O}}{C}} + KOH \longrightarrow C_6H_5-\underset{\overset{\|}{O}}{C}-\overset{C_6H_5}{\underset{OH}{C}}-OK \longrightarrow C_6H_5-\overset{C_6H_5}{\underset{OH}{C}}-\underset{\overset{\|}{O}}{C}-OK$$

The addition of one molecule of potash was postulated by Hoogewerff and van Dorp;[1] the migration of both C_6H_5 and H, by Michael;[2] ex-

---

[1] Hoogewerff and van Dorp, *Rec. trav. chim.*, **9**, **225 (1890)**. These authors assumed that Ph and OK migrate from one carbon atom to the other.

[2] Michael, THIS JOURNAL, 42, **814 (1920)**. Michael assumes the addition of one mole of potassium hydroxide, and this forms a system which "may now completely convert itself, by the transmigration of phenyl and hydrogen, into a salt of the relatively strong benzilic acid."

perimental indication of $C_{14}H_{10}O_2 \cdot KOH$ was given by Scheuing.[3] It has been assumed that benzil adds to H_2O,[4] to $2H_2O$,[5] to 2KOH,[6] or to KOH.[7] Since it is possible to avoid water[8] and to limit the alkali to one molecule, it is possible to obtain definite proof not only that water is not necessary but that the intermediate additive[9] compound is formed.

All experiments directed toward increasing the yield of the acid have involved large excesses[10] of alkali. Experiments of only theoretical interest have always involved either water alone, or alkali alcoholate alone, or alcoholic potash, or mixtures of these. In no case has only one molecule of benzil, one molecule of potash and an indifferent solvent such as ether, benzene, etc., been employed. We have treated equivalents of benzil, furil and diacetyl with potash in anhydrous ether and have found that only one molecule of potash is necessary for the transformation.

A single lump of potassium hydroxide weighing 1.4 g., placed in absolute ether with 5.4 g. of benzil and shaken occasionally during four days, was replaced by 5.6 g. of a powdery, light yellow solid; the ether yielded 1 g. of unchanged benzil, melting at 95°. The solid was analyzed.

Anal. Calcd. for $C_{14}H_{10}O_2 \cdot KOH$: K, 14.68. Found: K, 15.04.

[3] Scheuing, *Ber.*, 56, 252 (1923); 57, 1963 (1924). Schonberg, *ibid.*, 58, 235 (1925), criticizes Scheuing's product as affording no proof of an intermediate compound, "da das Anlagerungsproduct weder analysiert noch sein molekular gewicht bestimmt worden ist."

[4] Nef, *Ann.*, 298, 372 (1897). For a criticism of Nef's interpretation see Michael, THIS JOURNAL, 42, 812 (1920).

[5] Lachman first assumed the addition of two molecules of water but later assumed only one molecule of water. *Cf.* THIS JOURNAL, 44, 330 (1922), and 45, 1509, 1522, 1529 (1923); 46, 779 (1924). His contention that a mobile hydroxyl group shifts, that water is necessary for the benzilic acid rearrangement and his use of the word "metakliny," involving intramolecular oxidation and reduction, seem unjustified.

[6] Tiffeneau, *Rev. gen. sci.*, 585 (1907). Staudinger and Binkert, *Helv. Chim. Acta*, 5, 703 (1922).

[7] Schroeter, *Ber.*, 42, 2336 (1909), also assumed initial addition of one mole of potassium hydroxide, but his theory of rearrangement, involving the intermediate formation of diphenylketene was disproved by Nicolet and Pelc, THIS JOURNAL, 43, 935 (1921); see also Schonberg and Keller, *Ber.*, 56, 1638 (1923).

[8] Lachman states unequivocally that water is necessary for the benzilic acid rearrangement; see especially THIS JOURNAL, 46, 781 (1924). Others who have observed the effects of water are Jena, *Ann.*, 155, 78 (1870); Klinger, *Ber.*, 19, 1868 (1886).

[9] Scheuing used equivalents of alcoholic potash and benzil in ether solution and obtained a light yellow solid which he claimed was changed gradually at 0° and rapidly at 80° to potassium benzilate.

[10] From 3 to 8 equivalents of potassium hydroxide have been used. Liebig, *Ann.*, 25, 27 (1838); Zinin, *ibid.*, 31, 329 (1839); Limpricht and Schwandert, *Ber*, 2, 134 (1869); Jena, *Ann.*, 155, 79 (1870); Fischer, *Ber.*, 14, 326 (1881); Klinger, *ibid.*, 22, 1212 (1889); H. v. Liebig, *ibid.*, 41, 1644 (1908); Staudinger, *Ann.*, 356, 71 (1907); "Organic Syntheses," Vol. I, 1921, p. 29; Scheuing, *Ber.*, 56, 255 (1923); Schonberg and Keller, *ibid.*, 56, 1640 (1923).

Some of this salt, treated with concentrated sulfuric acid, gave the characteristic red color which benzilic acid does.[11] Upon acidifying 4.64 g. of this potassium benzilate, 3.71 g. (94%) of white needles of benzilic acid melting at 150° were obtained. Since no benzaldehyde or benzoic acid was detected, the precipitate represented an 81% transformation to potassium benzilate. The transformation was effected in the absence of water and while the additive compound was in the solid state. In another experiment equivalents of materials were ground up in a mortar under dry ether, but owing to rise of temperature or unavoidable contact with atmospheric moisture and oxygen, the yield was poor and contained benzaldehyde and benzoic acid.

From anhydrous ammonia, benzil and toluene was obtained a white solid, which proved to be benzilam,[12] melting point at 110°. With anhydrous ammonia, benzil and ether a white solid melting at 158° was obtained. With potash, it yielded ammonia and a white solid, insoluble in water, and melting at 203°. It will be further investigated.

When 5 g. of furil and 1 g. of sodium hydroxide in dry ether were shaken during twenty-four hours, 5.33 g. (88%) of a dark brown powdery mass was obtained.

Anal. Calcd. for $C_{10}H_6O_4 \cdot NaOH$: Na, 10.00. Found: Na, 10.27.

Acidification of the salt and extraction with ether yielded white needles of furilic acid agreeing in all properties with Fischer's product.[13]

With 10 g. of diacetyl and 6.5 g. of potassium hydroxide in dry ether, an immediate blackening of the potash resulted; the final sticky mass was brown-black, and though it contained acetaldehyde, resin, acetic acid and other products, it could not be made to yield dimethylglycolic acid.

Summary

One molecule of potash transforms benzil to benzilic acid; water is not necessary for this reaction. An additive compound is first formed which undergoes molecular rearrangement while in the solid phase.

THE KINETICS OF THE REACTION OF HEXAPHENYLETHANE WITH OXYGEN

BY R. C. MITHOFF AND G. E. K. BRANCH

RECEIVED JULY 3, 1929 PUBLISHED JANUARY 8, 1930

Introduction

Gomberg and others have shown that hexaphenylethane when dissolved in non-ionizing solvents such as ether, benzene, toluene and carbon tetrachloride exists in at least two forms, undissociated hexaphenylethane and the free radical triphenylmethyl. The solutions are amber-colored, and it appears to be proved conclusively that the color is due to the free radical, part or all of which may be colored. When the amber-colored solution of hexaphenylethane in these solvents is shaken with air or oxygen, the color decreases very rapidly, the solution becoming colorless if the hexaphenylethane is sufficiently pure. A few moments after the shaking is stopped, the color reappears, but much more slowly than it disappeared. The over-all reaction in this process is

$$(C_6H_5)_3C—C(C_6H_5)_3 + O_2 \longrightarrow (C_6H_5)_3C—O—O—C(C_6H_5)_3$$

This simple experiment suggests that there is some colored substance in the solution before the addition of oxygen which is in equilibrium with hexaphenylethane, and that this substance reacts with oxygen to form triphenylmethyl peroxide at a much faster rate than that of the reaction through which it is in equilibrium with hexaphenylethane.

Again, the color of hexaphenylethane solutions decreases on dilution to a less extent than that predicted by Beer's law.[1] Hence the colored substance is formed by a reversible dissociation.

These two experiments together show that hexaphenylethane dissociates to form a colored substance, triphenylmethyl, whose reaction with oxygen can be much faster than its recombination. When such a condition exists, the kinetics of the over-all reaction are those of the preliminary slower step. Thus in this case the rate of oxidation of hexaphenylethane by this mechanism has to be that of its dissociation and is independent of the concentration of oxygen. That the necessary condition of rapid reaction of triphenylmethyl with oxygen can be achieved may be seen from the following considerations. The color of a hexaphenylethane solution can easily be reduced to less than one-tenth of its original depth by shaking with air or oxygen. Under these conditions the rate of re-combination, a bimolecular reaction, is reduced to less than 1% of its value in the oxygen-free solution, while that of dissociation is presumably unchanged. Consequently, practically all of the molecules which dissociate react with oxygen and very few of them return to the original hexaphenylethane. This failure of the

---

[1] J. Piccard, *Ann. chim.*, **381**, **347** (1911).

intermediate to return to the original state is the necessary condition that a preliminary step shall be the rate-determining reaction.

It is, therefore, of interest to study the kinetics of the absorption of oxygen by hexaphenylethane solutions, for in this way the rate of the dissociation will be measured, or it will be possible to show that there is some other mechanism for the reaction.

In such measurements it will be necessary that the passage of oxygen from the gas phase to the liquid does not delay the reaction. Therefore, the solutions must be shaken sufficiently vigorously to permit this transfer of oxygen to occur at a rate much faster than that of the oxidation. In our measurements concordant results were obtained over periods during which the rate of passage of oxygen from the gas to the liquid varied thirty-fold. Again, in the beginning of each experiment, while the solvent was being saturated with oxygen and the free radical was being reduced below its equilibrium concentration, the rate of transfer of oxygen across the gas–liquid interface was often two hundred times as fast as the rate of absorption of oxygen at stages of the run during which significant measurements were being made. These two observations, which can be seen by an inspection of the curves in Fig. 1, show that a sufficiently rapid solution of oxygen was achieved. Attempts were made to measure the rate of solution of oxygen in carbon tetrachloride under the conditions of the experiment, but it was found to dissolve too rapidly.

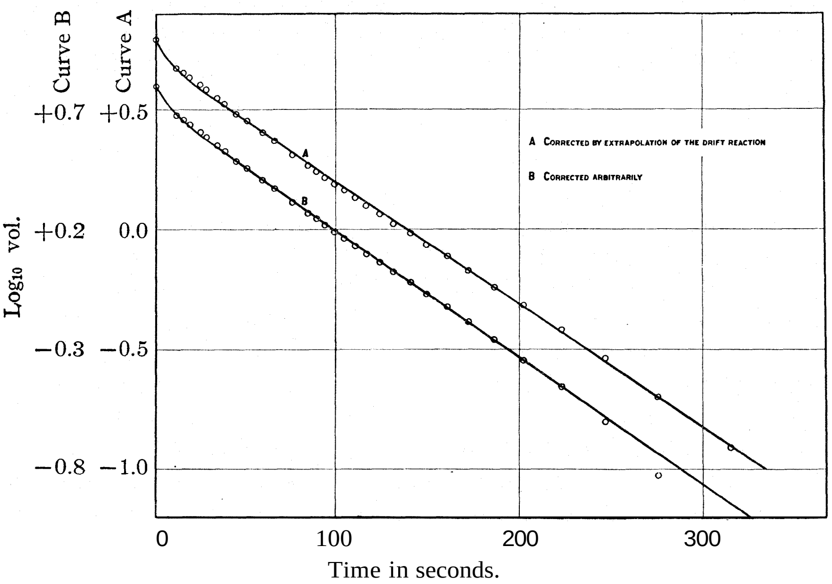

Fig. 1.—The logarithm of the volume of oxygen yet to be absorbed by hexaphenylethane plotted against the time.

The kinetics of the reaction was studied over ranges of temperature, of concentrations of hexaphenylethane and of partial pressures of oxygen. During any one run only the second variable changed. The solvent was carbon tetrachloride throughout. A few experiments were carried out in the presence of some of Bäckström's oxidation inhibitors.

Experimental Method

The method consisted of shaking hexaphenylethane solutions in the presence of oxygen gas mixed with nitrogen and measuring the rate of absorption of the gas.

The reaction was carried out in a vessel connected to a powerful automatic shaker, the whole being immersed in a thermostat. The volume of the containing vessel was so large, compared to that of the gas absorbed, that the composition of the oxygen and nitrogen mixtures used did not change significantly during an individual experiment.

The reaction vessel was attached by a rubber connection to a long calibrated horizontal tube which was bent at the end and dipped into a basin of liquid. This tube served as a constant pressure gas buret.

During an experiment the liquid meniscus advanced along the buret, and as it passed the calibration marks the time was registered. This was done by pressing a key which sent sparks through a paper tape moving at a known and constant rate. After the run had been made, the times were calculated from the distances between the marks burned through the tape.

Owing to its length, the buret was not immersed in the thermostat, but was surrounded by a jacket through which water flowed. In order to have an evenly moving meniscus, water was used as the buret liquid.

A certain amount of difficulty was encountered owing to the violent shaking which caused vibrations of the meniscus in the buret. This trouble was entirely overcome. In its final construction the apparatus could be shaken without causing any appreciable fluctuations of the meniscus in the buret.

A temperature of 0° was maintained in the thermostat by a mixture of ice and water. On account of the excellent stirring no variation in temperature as large as a tenth of a degree could be observed. For temperatures below 0° alcohol was added to the above mixture. In such experiments the temperatures increased a couple of tenths of a degree during the runs. These variations of temperature were measured. The observed volumes of gas were then corrected for this change of temperature from the known volume of gas in the reaction vessel and on the assumption that the change of temperature was proportional to the elapsed time. A few measurements were made above 0°. In these cases no device except insulation was used to keep the temperature of the thermostat constant. The rate of change of the temperature was observed and the necessary corrections to the volumes applied.

The solutions of hexaphenylethane were made by shaking solutions of triphenylchloromethane with molecular silver. The whole process of preparation and siphoning away from the silver chloride into containers was done in an atmosphere of inert gas. These containers were sealed and put into the reaction vessel. The required mixture of oxygen and nitrogen could then be introduced and the whole apparatus allowed to come to temperature equilibrium. When the shaker was started the sealed container was broken and the solution came into contact with the gas. A forward motion of the meniscus showed when this occurred.

Results at Constant Oxygen Pressure and Temperature.—The motion of the meniscus in the gas buret presented three phases, which appeared clearly differentiated to an observer of the experiment. The initial phase was a very rapid advance, that is, absorption of gas, starting the moment the sample tube broke and lasting about ten seconds. The second phase was a slower advance of the meniscus, decreasing in rate as the time increased. The second phase merged gradually into the final phase, which was a very slow advance continuing for more than an hour.

The interpretation of the rapid gas absorption during the initial phase was the process of saturating the carbon tetrachloride with oxygen as well as the reaction of the gas with that portion of the hexaphenylethane which existed at the start as the free radical.

The major portion of gas absorption takes place during the second phase, which represents the main reaction, the oxidation of hexaphenylethane.

The last phase is evidently not due to any reaction of hexaphenylethane, for the apparent half time of the second or main phase is about one minute, so that after ten minutes there should be practically no hexaphenylethane left; but the third phase continues noticeably for over an hour. Further, there is no combination of reactions of different orders but of the same substance which can account for both the second and final phases in the oxygen absorption, if reactions having ridiculous orders are excluded. On the other hand, the entire advance of the meniscus from twenty seconds after the start to the finish can be accounted for on the assumption that there are two substances present, one of which absorbs oxygen by a first order reaction whose half time is a little less than a minute, while the other compound is present in comparatively small quantities and reacts at a much slower rate, the half time of the second reaction being about a quarter of an hour.

In order to be sure that the main reaction is first order with respect to hexaphenylethane, it is necessary to correct for the side reaction. This may be done by extrapolating the measurements obtained during the latter part of the experiment, in order to calculate the absorption of gas by the impurity during the main part of the run.

The procedure is as follows: the experiment is continued until no more oxygen is absorbed, so that the volumes of oxygen yet to be absorbed may be obtained for any time at which a reading is made. The values of the logarithm of this quantity are plotted against the times and the best straight line is drawn through the points obtained ten minutes or more after the start. From the extension of this line to earlier times, the amount of oxygen which will be absorbed by the impurity may be read off. By subtracting this value from the total amount of oxygen yet to be absorbed, the volume of the gas yet to be absorbed by hexaphenylethane is obtained. This quantity is proportional to the concentration of hexaphenylethane. It may be noted that it is assumed that the side reaction is first order. The volumes involved are too small to decide this point, but for that very reason the assumed order is unimportant.

This method may be illustrated by a typical experiment, which was carried out at 0° and with 0.93 atmosphere of oxygen. The absorption of oxygen by the impurity near the end of the run is shown in Table I.

TABLE I

ABSORPTION OF OXYGEN BY THE IMPURITY

Time in minutes	0	10	15	20	25	30	35	40
Vol. to absorb, cc.	0.670	0.250	0.155	0.147	0.141	0.140	0.135	0.100
Time in minutes	45	50	55	60	65	70	75	80
Vol. to absorb, cc.	0.054	0.043	0.054	0.052	0.052	0.025	0.020	0.011
Time in minutes	85	90	95	100	105	110	115	120
Vol. to absorb, cc.	0.013	0.010	..	...	...	...	...	...

The volumes given in the second and fourth lines are calculated on the basis that the final reading is 6.770. The straight line which was drawn through the plot of the logarithms of these values against time corresponded to a total volume of 0.49 cc. absorbed by the impurity and a rate constant of 0.044 reciprocal minutes.

Other experiments agreed approximately with this one, that is, somewhere between 5 to 15% of the oxygen taken up was absorbed by a reaction whose half-time was approximately a quarter of an hour.

In Table II the first two columns show the times and the volumes of oxygen yet to be absorbed. Column 3 is the extrapolation of lines two and four of Table I. The volumes of oxygen yet to be absorbed by hexaphenylethane are exhibited in the fourth column.

TABLE II

ABSORPTION OF OXYGEN BY HEXAPHENYLETHANE

Time, sec.	Total cc. to be abs.	To be abs. by impurity, cc.	To be abs. by hexaphenylethane, cc.	Same as Col. 4 but obt. by appros. method

275.3	.60	.40	.20	.15
315.0	.50	.376	.124	.05

In Pig. 1, Curve A, the logarithms of the volumes of oxygen yet to be absorbed by hexaphenylethane are plotted against the times. In this figure the curve from twenty-five seconds onward is a ruled line whose slope corresponds to a rate constant equal to 0.0118 reciprocal seconds. It can thus be seen that the reaction is quite strictly first order with respect to hexaphenylethane over a thirty-fold change of the concentration of that substance.

This method of calculating the rate constant was carried out for several runs at 0°, but it could not be used at other temperatures, because the thermostat could not be held sufficiently constant in temperature to permit an approximate evaluation of the effect of the side reaction; therefore, another method of correction was used. This was based on the knowledge previously obtained that the main reaction is strictly first order with respect to hexaphenylethane.

This second way of correcting for the side reaction consists of subtracting such a constant amount from the observed values of oxygen yet to be absorbed, that their logarithms fall on a straight line when plotted against the time. Thus in the experiment shown in Tables I and II, if 0.45 cc. is subtracted from the amounts of oxygen yet to be absorbed, the resulting values, which are shown in Col. 5 of Table II, are such that their logarithms when plotted against the time fall on a straight line from about 25 to 220 seconds. This can be seen on inspection of Curve B of Fig. 1. In this drawing the curve from twenty-five seconds onward is a ruled line whose slope corresponds to a rate constant of 0.0122 reciprocal seconds. This value agrees fairly well with 0.0118, obtained by the logically more correct first method.

The second method is only applicable when the drift reaction contributes only a small fraction to the rate of absorption of oxygen. Thus in the present experiment between the times 50.5 and 160.9 seconds 0.04 cc. of oxygen was absorbed by the impurity and 2.06 cc. by the hexaphenylethane. As this proviso will not hold near the end of the reaction, the approximate method cannot be extended over as great a range as the other. This can be seen by comparing Curves A and B of Fig. 1.

The approximate method introduces an uncertainty of about 10% into a measurement, owing to the fact that it is possible to choose a range of values for the correcting volume which will make the significant measurements correspond to a first-order reaction. This uncertainty increases as the accuracy in the determined volumes of gas decreases. The uncertainties introduced by extrapolation of the side reaction are less.

Owing to the somewhat large errors introduced in the way described above, a great many experiments were performed. All the chief points discussed in the text are based on averages of more than forty individual experiments.

Throughout the rest of the text the rate of change of the logarithm of the concentration of the hexaphenylethane under otherwise constant conditions will be referred to as the rate constant for those conditions, and will be represented by the letter K. The actual values given will be those obtained by the approximate method of correction. The units are reciprocal seconds.

Variation of Rate Constant **with** Oxygen Pressure.—The results obtained by changing the partial pressure of oxygen but keeping the temperature constant at 0° are shown in Table III.

It will be noticed that K changes considerably with change of the partial pressure of oxygen. Conant and Evans[2] have published measurements of the rate of the reactions of several dixanthyls with oxygen. They have shown that the rate of absorption of oxygen by these substances is inde-

---

[2] Conant and Evans, THIS JOURNAL, 51, 1925 (1929).

TABLE III

VARIATION OF KATE CONSTANT WITH OXYGEN PRESSURE

Partial pressure of oxygen, atm.	No. of observations	Rate constant Av., 1/sec.	Rate constant Av. dev., 1/sec.
0.93	17	0.0124	±0.00071
.80	4	.0118	.00005
.60	4	.0105	.0003
.55	5	.0104	,0003
.43	3	.00989	.0003
.31	3	.00837	.00029
.20	11	.00735	.00017

pendent of the oxygen pressure. This difference in the kinetics of the oxidation of hexaphenylethane and of the related dixanthyl is not surprising as it is accompanied by a thousand-fold change in the rate constants and more than 10,000 calorie change in the heat of activation.

It has been shown in the introduction that hexaphenylethane can absorb oxygen by a reaction whose rate is independent of the oxygen pressure. Consequently there must be a second mechanism for the oxidation of hexaphenylethane.

The alternatives for this mechanism are either a reaction of an undissociated but active form of hexaphenylethane, or a dissociation into an isomer of triphenylmethyl, followed by a combination with oxygen. This second form must, however, be colorless, and it must recombine more rapidly than it reacts with oxygen. This latter alternative agrees with the suggestion of Gomberg and Sullivan[3] that triphenylmethyl exists in two forms, which differ in color. However, the authors favor the first alternative on account of its greater simplicity. The experimental results can be equally well explained, whether the oxygen combines with a colorless free radical or with an active but undissociated form of hexaphenylethane. We shall in future refer to the second mechanism as the direct oxidation.

If the values of K are plotted against the pressure of oxygen the points seem to fall on a curved line. This is shown in Fig. 2, in which Curve A is the best parabola and Curve B is the best straight line.[4]

The equation for the straight line is $K = 0.00628 + 0.00678\ P_{O_2}$. This equation means that there are two independent mechanisms. One of these is independent of the oxygen pressure, and has a rate constant equal to 0.00628 reciprocal seconds. Its rate is that of the dissociation into free radicals. The rate of the other reaction is proportional to the oxygen pressure. Its rate constant is 0.00678 in reciprocal seconds and reciprocal atmospheres.

The equation of the parabola is $K = 0.00511 + 0.01225 P_{O_2} - 0.004715 P_{O_2}^2$. The probable percentage error calculated for the coefficient of $P_{O_2}^2$

---

[3] Gomberg and Sullivan, THIS JOURNAL, 44, 1822 (1922).

[4] These curves are the most probable of their respective types, taking all the values given in Table III into consideration, but the circles represent mean values.

is 23.3%. The value of this coefficient is, therefore, more than four times the probable error, which formally means that the curvature is real. However, the calculation of probable error does not take into account any consistent error. Thus although the passage of oxygen across the gas–liquid interface was sufficiently rapid to eliminate any large errors, it is possible that the small curvature of the plot may be due to a slight delay involved in this process. However, having given this warning, we shall treat the curvature as significant.

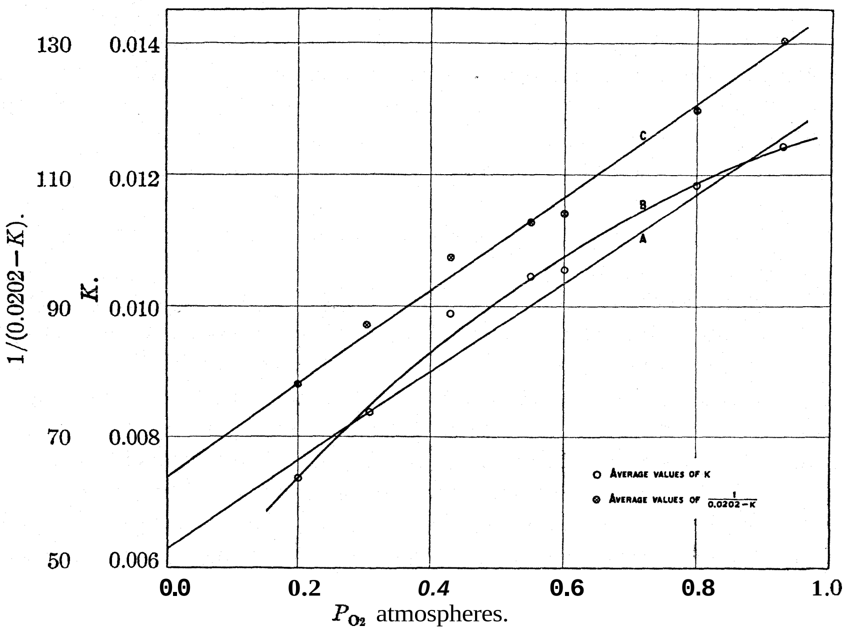

Fig. 2.—Variation of the rate constant with oxygen pressure.

This curvature could be explained by assuming that there are two independent mechanisms. One of which has a rate independent of the oxygen pressure and the other has a rate proportional to a fractional power of the oxygen pressure. The measurements would indicate that this fractional power is the square root. However, it would be necessary to assume an unlikely mechanism in order to account for the proportionality between the reaction rate and the square root of the oxygen pressure.

It is more probable that the direct oxidation is first order with respect to oxygen. The curvature may then be due to the formation of an active intermediate whose rate of return to the normal form is near that of its oxidation. In such a case the intermediate reaches a steady state during the reaction, and its concentration depends, not only on the concentration of hexaphenylethane, but also on the rate of oxidation. If the dissociation depends on the same active intermediate, the steady state depends on the summed effects of the two mechanisms. In both cases the mathematical expression for the kinetics is $K = K_0 - 1/(a + bP_{O_2})$. In the next paragraph we have derived this equation for the more complex case.

Let P_1, P_2 and P_3 represent the specific rate constants of the reactions of active hexaphenylethane to normal hexaphenylethane, of dissociation, and of reacting directly with oxygen, respectively. The probabilities that the life of an individual among these active forms is eventually terminated by each of these processes are, respectively

$$\frac{P_1}{P_1 + P_2 + P_3P_{O_2}} \qquad \frac{P_2}{P_1 + P_2 + P_3P_{O_2}} \qquad \frac{P_3P_{O_2}}{P_1 + P_2 + P_3P_{O_2}}$$

The sum of these probabilities is unity.

$$\frac{P_1}{P_1 + P_2 + P_3P_{O_2}} + \frac{P_2 + P_3P_{O_2}}{P_1 + P_2 + P_3P_{O_2}} = 1$$

If the steady state concentration of the active form is small compared to the concentration of the normal form, the rate of formation of the intermediate is equal to that of its decay. If K_0 is the rate constant for its formation

$$K = K_0\left(\frac{p_2 + p_3P_{O_2}}{p_1 + p_2 + p_3P_{O_2}}\right) = K_0 - \frac{p_1}{p_1 + p_2 + p_3P_{O_2}}K_0$$

Replacing $p_1 + p_2/(p_1K_0)$ and $p_3/(p_1K_0)$ by the constants a and b, respectively, $K = K_0 - 1/(a + bP_{O_2})$.

The constants in this equation can be obtained from the experimental values by a graphical method. The equation is expressed in the form $1/(K_0 - K) = a + bP_{O_2}$. Various values are assumed for K_0, in order to find the range of values for which the quantity $1/(K_0 - K)$ is a linear function of P_{O_2}, within the experimental accuracy of the determinations of K and P_{O_2}. The range of values found was not very great, and the mean value, 0.0202 reciprocal seconds, was chosen for K_0. Curve C in Fig. 2 is this graph. The slope of the line $1/(K_0 - K)$ is b, and its intercept with the ordinate is a. The values found are $a = 64$ seconds and $b = 71$ seconds times reciprocal atmospheres.

The rate of the dissociation reaction is $K_1 - (1/a)$, whether or not the two mechanisms depend on the same intermediate. The value = 0.0046 reciprocal seconds. This compares favorably with 0.0051, the value obtained by extrapolating the parabola to $P_{O_2} = 0$. If the two mechanisms depend on the same intermediate, its rate constant of formation is K_0; but if this substance is only involved in the direct oxidation, the constant is equal to $1/a$.

There are thus three possible theories of the kinetics of the mechanism of the reaction which we have called the direct oxidation. The first is that this reaction is strictly first order with respect to oxygen. The second is that it depends on an intermediate form of hexaphenylethane whose concentration is kept below its equilibrium value. The third is that the substance which is held in a steady state is an intermediate in both the dissociation and direct oxidation. The actual results favor the second and third hypotheses, but these two are not experimentally distinguishable, as they correspond to the same mathematical expression for the variation of K with P_{O_2}.

No matter which theory of the kinetics is correct, a considerable fraction of the reactions occurs through the mechanism of direct oxidation, when oxygen at one atmosphere is used. These fractions may be calculated. They are approximately $^1/_2$, $^3/_4$ and $^5/_6$ on the first, second and third assumptions, respectively.

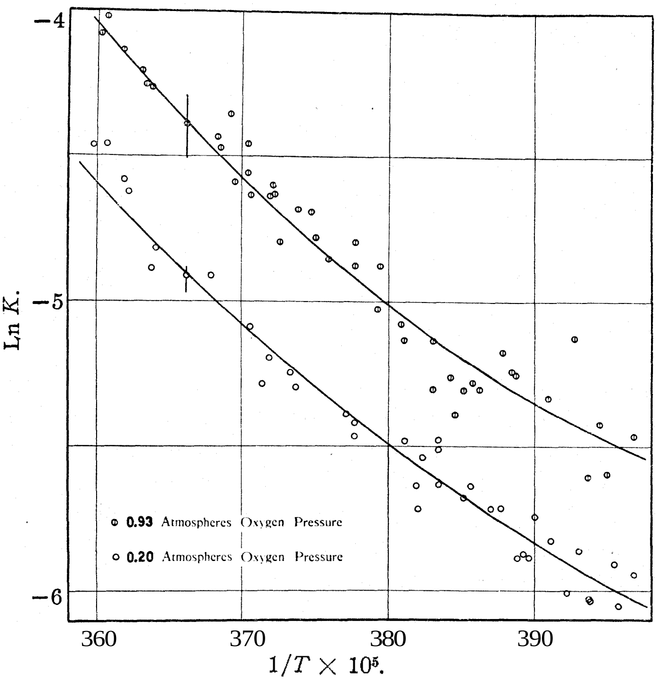

Fig. 3.—Variation of the natural logarithm of the rate constant with the reciprocal of the absolute temperature.

Variation **of** K with **Temperature.**—The rate constants with 0.93 and 0.20 atmospheres of oxygen were measured from 5 to −21°. **A** large number of experiments were performed, and the logarithms of the results were plotted against the reciprocal of the temperature. By means of a least square method of reduction of the data the most probable parabolas were calculated. These parabolas and the individual data are shown in Fig. **3.** Only the average values of ln K at 0° are shown, as the complete data for K at 0° may be found in Table III. The complete data are given in Tables IV and V.

The equations for these parabolas are $Y = -0.03415 - 5890X + 4.98 \times 10^6X^2$ for 93% oxygen, and $Y = -0.5851 - 5220X + 3.45 \times 10^6X^2$ for 20% oxygen. In these equations $Y = \ln K + 4$, and $X = 1/T - 0.0036$. These curves are approximately parallel, almost to within the probable errors. Thus the probable errors in the coefficients of X are 207 and 261, respectively, while the difference between the coefficients is 670. The probable errors in the coefficients of X^2 are 0.569×10^6 and 0.707×10^6, respectively, and the difference between the coefficients is 1.53×10^6. The curvature appears to be real, for in the first equation the coefficient of X^2 is nearly nine times the probable error, and in the second the coefficient of X^2 is nearly five times the probable error. The curve for 93% oxygen was based on sixty-two measurements and that for 20% oxygen on fifty-two. The values of K at 0° calculated from these equations both differ by less than 2% from the average values obtained at this temperature.

The heat of activation of a reaction may be calculated from the rate of change of the logarithm of the velocity constant with the reciprocal of the temperature. The equation is blog, $K/\partial(1/T) = -E/R$. If such an equation is applied to the reaction of oxygen with hexaphenylethane, the calculated value of the heat of activation will depend on the temperature. Thus with 93% oxygen the apparent heat of activation is 10,500 calories at 0°, 8900 calories at $-6°$ and 4800 calories at $-20°$. With 20% oxygen the heats of activation at these temperatures are 9500, 8400 and 5500 calories, respectively. Since the changes of the heat of activation with temperature depend on the curvature of the plot of log K against $1/T$, this dependence of E on the temperature is presumably real.

Such a variation of the value of blog $K/\partial(1/T)$ with the temperature could be explained by the double mechanism of the reaction; but this would necessitate that the dissociation and direct oxidation have very different heats of activation. In this case the values of blog $K/\partial(1/T)$ would change markedly when the percentage of oxygen is varied, but the differences between the values for 93 and 20% of oxygen are only slightly in excess of the probable errors. One is, therefore, forced to the conclusion that this anomalous change of blog $K/\partial(1/T)$ with the temperature has nothing to do with the double mechanism of the reaction, but is a characteristic of both the dissociation and the direct oxidation, or that the result is due to some consistent experimental error. Of course, this is not the first time that the logarithm of a reaction rate has been found not to be a linear function of the reciprocal of the temperature.

It is not strictly correct on the activation theory of reactions to use the same equation for calculating the change of K with the temperature for both the dissociation and direct oxidation, for the latter is a bimolecular reaction. The proper equation for second-order rate constants is $\frac{\partial(\ln K - \frac{1}{2}\ln T)}{\partial(1/T)} = -\frac{E}{R}$, but the value of $\frac{1}{2}\frac{\partial \ln T}{\partial(1/T)}$ is smaller than the prabable errors. Also the variation of the rate of the direct oxidation with temperature is dependent on the rate of change of solubility of oxygen in carbon tetrachloride with temperature. This effect is also negligible.

It may be noted that the parallelism of the curves obtained with 93 and 20% of oxygen shows that the heats of activation of the dissociation and direct oxidation have nearly the same magnitudes.[5] This would suggest that little or no energy is needed to activate the oxygen. This to some extent confirms the view of G. N. Lewis that the electronic structure of oxygen is $:\underset{\cdot\cdot}{\overset{\cdot}{O}}:\underset{\cdot\cdot}{\overset{\cdot}{O}}:$, and as such does not require activation in order to react.

The Effect of Inhibitors.—Bäckström[6] has found that the absorption of oxygen by benzaldehyde in the dark is slowed down to a great extent by many substances. Diphenylamine, anthracene and phenol are notable examples of these inhibitors. The effects of these substances were tried. The inhibitors were used in concentrations of 0.005 molal, which is about one-fifth of the concentration of the hexaphenylethane. The two substances did not mix until the experiments were started by the breaking of the container for the hexaphenylethane. The experiments were carried out at 0° and at an oxygen pressure of 0.20 atmosphere. The diphenylamine and anthracene had no appreciable effect; with the former substance $K = 0.00693$ reciprocal seconds was the average of two experiments, and with the latter 0.00725 reciprocal seconds was the average of two experiments. The mean value of K obtained with pure carbon tetrachloride was 0.00735 reciprocal seconds. The value $K = 0.00693$ in the presence of diphenylamine is perhaps a little lower than what might be expected on pure chance; but in this case the diphenylamine was attacked, and much color developed in the solution. The absorption of any oxygen by the diphenylamine would tend to lower K on account of the approximate character of the method used to estimate the total volume of oxygen absorbed by the hexaphenylethane. For this reason it is best to consider the difference between 0.00735 and 0.00693 as experimental error.

With phenol an appreciable increase in the rate was observed. The average of two measurements was $K = 0.0110$ reciprocal seconds. This is more than a 50% increase in the rate, which is much greater than the probable experimental error.

Summary

Measurements were made on the rate of oxygen pressure by carbon tetrachloride solutions of hexaphenylethane under the conditions of constant temperature, of constant oxygen pressure and of vigorous shaking.

The experiments were carried out at many temperatures from 5 to $-21°$, and with several partial pressures of oxygen from 0.93 to 0.20 atmosphere.

The reaction rate was found to be proportional to the concentration of hexaphenylethane, and to a somewhat complicated function of the oxygen

---

[5] Calculations which separate the two heats of activation greatly enhance the experimental error, so that "nearly" may be taken as equivalent to "within 3000 calories."

[6] Backstrom, THIS JOURNAL, 49, 1460 (1927).

pressure. This function could be best expressed as $K_0 - 1/(a + bP_{O_2})$, in which K_0, a and b are constants.

The character of this function was explained on the assumption that there are two mechanisms, for the reaction. One of these is a dissociation into free radicals followed by a very rapid oxidation. The other is a direct oxidation. On these assumptions alone the function would be $a + bP_{O_2}$; its more complicated form was assumed to be due either to a consistent error, or to the formation of an active intermediate which is held in a steady state other than its true equilibrium ratio with normal hexaphenylethane.

The logarithm of the rate constant was found not to be a linear function of $1/T$. The calculated heats of activation increase with temperature, but are approximately constant to change of the oxygen pressure.

The reaction was not inhibited by diphenylamine, anthracene nor phenol. The last substance increased the rate.

THE RATE OF REACTION OF CERTAIN ALCOHOLS WITH PARA-NITROBENZOYL CHLORIDE IN ANHYDROUS ETHER SOLUTION

BY AVERY ALLEN ASHDOWN[1]

RECEIVED JULY 10, 1929 PUBLISHED JANUARY 8, 1930

The speed of ester formation from alcohols and p-nitrobenzoyl chloride, in ether solution, has been studied in this Laboratory as a means for measuring the relative reactivity of the hydroxyl hydrogen of the alcohols. In two earlier papers,[2] the influence of the structure of the alcohols on the rate of the reaction has been discussed.

Although the net result of the reaction consists in the formation of a molecule of hydrogen chloride and one of an ester, from one molecule each of alcohol and acid chloride, the second-order velocity constants decrease steadily as the reaction proceeds. This peculiarity was observed with all of the twenty-nine alcohols studied, and it is not dependent on the type of alcohol, whether primary, secondary or tertiary. Furthermore, if the original molal solutions are replaced by half-molal ones, the second-order constants are much smaller and, as before, decrease with the progress of the reaction. If the drop in the value of the second-order reaction constants were attributable to the non-ideality of solution alone,

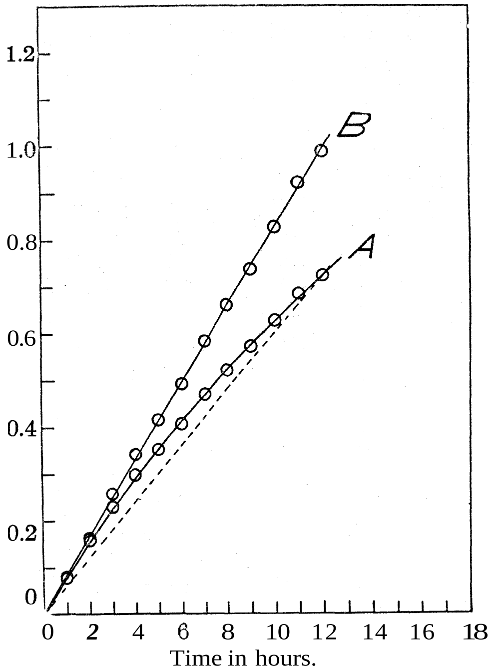
then the half-molal solutions would be expected to give both a higher and a more steady value for the constant. The very reverse of this, found by experiment, led to a study of the law of the reaction rate as a possible means of throwing light on the mechanism involved,

At the outset, a graphical analysis of the data for methyl and ethyl alcohols showed that the reaction was of an order higher than second, probably of the third order. The integrated form of the second-order equation for equal molal concentrations, $KtC_0 = x/(1 - x)$, in terms of the fraction, x, of reactant transformed, is linear. Plotting values of $x/(1 - x)$ against t should give a straight line. In all cases, however, the data led to a smooth curve, bending toward the t-axis (Fig. 1, Curve A, n-butyl alcohol). The slopes of this curve, corresponding to values of the constant, K, are steadily decreasing. The following considerations show how the graphically observed change in K indicates a third-order reaction. For a second-order reaction between two compounds at equal concentrations



Pig. I.—Rate of reaction of *n*-butyl alcohol with *p*-nitrobenzoyl chloride. Curve **A**, data calculated as a second-order reaction. $x/(1 - x)$ plotted against t in hours. Curve B, data calculated as a third-order reaction. $x(2-x)/2(1 - x)^2$ plotted against t in hours.

$$dx/dt = k(1 - x)^2 \text{ or } dx/(1 - x)^2 = kdt$$

but

$$d\frac{(x)}{(1 - x)} = dx/(1 - x)^2 = kdt$$

In the case of a third-order reaction (equal concentrations), however

$$dx/dt = k(1 - x)^3 = k(1 - x)^2(1 - x)$$

In other words, for a third-order reaction

$$d(x/1 - x) = k(1 - x)dt$$

This equation obviously satisfies the condition observed graphically and strongly suggests a reaction of the third order.

In the light of this indication, the data on all twenty-nine alcohols were calculated using the third-order equation for equal molal concentrations. For all cases throughout a given run the constants thus obtained were steady, not decreasing as did the second-order constants. Furthermore, the half-molal solutions yielded third-order constants which were higher than those for molal solutions, a consequence to be expected if the reactions were of the third order, and the solutions not ideal. In Table I the second- and third-order constants for n-butyl alcohol are given as an example.

TABLE I

n-BUTYL ALCOHOL AND *p*-NITROBENZOYL CHLORIDE AT EQUAL MOLAL CONCENTRATIONS

Molal					Half molal				
t	x	K_2^1	K_3^1	K_3^0	t	x	$K_2^{0.5}$	$K_3^{0.5}$	K_3^0
1	0.0717	0.0772	0.080	0.119	1	0.0266	0.055	0.110	0.138
2	.1366	.0791	.085	.125	2	.0452	.047	.097	.121
3	.1877	.0770	.086	.124	3	.0727	.052	.107	.134
4	.2302	.0747	.086	.123	4	.0854	.047	.098	.121
5	.2614	.0708	.083	.119	5	.1035	.046	.098	.121
6	.2895	.0679	.082	.116	6	.1146	.043	.092	.114
7	.3212	.0675	.084	.117	7	.1366	.045	.098	.120
8	.3439	.0654	.083	.115	8	.1506	.044	.097	.117
9	.3663	.0638	.082	.113	9	.1632	.043	.095	.115
10	.3862	.0630	.083	.114	10	.1736	.042	.093	.114
11	.4071	.0624	.084	.115	11	.1840	.041	.091	.112
					12	.1963	.041	.091	.112

K_2^1 and $K_2^{0.5}$ are second-order and K_3^1 and $K_3^{0.5}$ are third-order constants at molal- and half-molal concentrations. K_3^0 is the third-order constant at infinite dilution, computed analytically. t = time in hours.

Curve B, Fig. 1, also shows how the data from n-butyl alcohol conform to a third-order reaction. The integrated form of the third-order equation, equal molal concentrations, in terms of the fraction, x, of reactant used is

$$KtC_0^2 = \frac{x(2-x)}{2(1-x)^2}$$

It should yield a straight line if the numerical value of the right-hand member of the equation be plotted against t.

Description of Experiments

When the calculation of the third-order constants was completed, the reaction rate was tested by a series of experiments. The method for measuring the rates and the details for purifying the compounds have been described rather completely in two previous papers.[2] The procedure consisted in dissolving the acid chloride in anhydrous ether contained in a glass-stoppered Erlenmeyer flask, placing the flask in a thermostat at 25°, adding alcohol equivalent to the acid chloride and following the rate by titrating the hydrogen chloride produced. All concentrations were in moles per thousand grams of ether.

In a modification of the method, equal volumes of the reaction mixture, measured from a buret, were sealed in small glass vials. These were placed in the thermostat and at appropriate intervals a vial was taken out and the entire contents titrated for hydrogen chloride. This modified method was tested with n-butyl alcohol and found to give results like those obtained in the earlier procedure. The sealed vials were particularly advantageous where dry hydrogen chloride was added to the reaction mixture at the start.

The reversibility of the reaction was tested by dissolving equal molal quantities of ethyl *p*-nitrobenzoate and dry hydrogen chloride in anhydrous ether. The mixture was kept at 25° in the thermostat for forty-three hours. The hydrogen chloride was not absorbed, showing that the tendency to reverse must be very small under the conditions at which the reaction rates were measured. Dry hydrogen chloride was prepared by dropping pure concentrated sulfuric acid onto C. P. sodium chloride, passing the gas through two wash bottles containing pure concentrated sulfuric acid and finally through a 50-cm. column of phosphorus pentoxide.

In two trials the products of the reaction were shown to have no effect on the rate. Equal molal quantities of n-butyl alcohol, the acid chloride and dry hydrogen chloride were dissolved in anhydrous ether. The usual rate for n-butyl alcohol was observed, showing, in this case, that the decrease in the second-order constants could not be due to the influence of the hydrogen chloride evolved. A similar result was obtained for ethyl alcohol when a mole of ethyl p-nitrobenzoate was added to the reaction mixture at the start. The rate was unaffected by the presence of the ester in this instance.

Two experiments were carried out with n-butyl alcohol to test the effect on the rate of changing the concentrations of the reactants with respect to each other. If the reactions were of the second order, then the same rate would be observed whether the alcohol concentration were twice that of the acid chloride or *vice versa.* If, however, the reactions were of the third order, then the rate would be much greater in one case than in the other.[3]

It was found that the speed of the reaction was much faster when the concentration of the alcohol was twice that of the acid chloride than when the reverse relations were tried. Table II shows these differences. After ten hours 0.23 mole of the acid chloride had reacted when the concentrations were one mole of alcohol to half a mole of acid chloride. With the conditions reversed, however, only 0.16 mole of the acid chloride had reacted after ten hours

TABLE II

n-BUTYL ALCOHOL WITH *p*-NITROBENZOYL CHLORIDE IN ANHYDROUS ETHER SOLUTION

Alcohol, moles per 1000 g. of ether	1.0	0.5
Acid chloride, moles per 1000 g. of ether	0.5	1.0
Moles of chloride reacted in ten hours	0.229	0.163

Development of an Equation for Calculating the Velocity Constants for the Reaction of Alcohols with *p*-Nitrobenzoyl Chloride in Ether Solution at Infinite Dilution.—The experiments just described, showing the great influence on the speed of the reaction conditioned by changing the concentration of the alcohol, both strengthened the earlier conviction that the reaction was of the third order and suggested the notion that two

---

[3] This excellent method for testing the order of a reaction was employed first by van't Hoff over forty-five years ago, "Etudes de dynamique chimique," Amsterdam, 1884. Its usefulness was emphasized by A. A. Noyes in the course of an investigation of the rate of reaction of ferric chloride with stannous chloride, Noyes, *Z. physik.* Chem., 16, 554 (1895).

molecules of alcohol might be required for each molecule of chloride used. Such a process would be in harmony with certain general views[4] concerning the mechanism of organic chemical reactions. The first step could be taken to be the addition of a molecule of alcohol to the acid chloride. The unstable complex could then react with another molecule of alcohol, splitting out the ester and hydrogen chloride and giving back a molecule of alcohol.[5]

The equation for the reaction may be symbolized as follows[6]

$$A + 2B = E + F + B$$

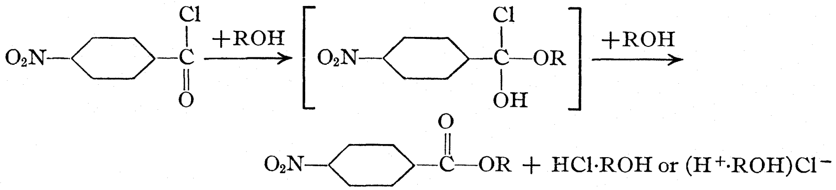
where A = acid chloride and B = alcohol. By using the ideas of the activity theory as applied to reaction rates,[7] and Bronsted's assumption of the critical complex,[8] an equation has been developed on the basis of this mechanism for calculating the velocity constants of these esterification reactions at infinite dilution.

---

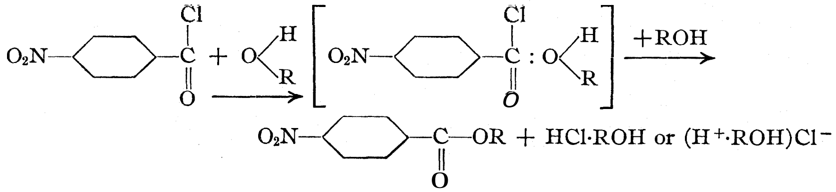
[4] See, for example, Stieglitz, *Am. Chem. J.*, **39**, *60* (1908); THIS JOURNAL, 32, 221 (1910).

[5] It is conceivable that the reaction might be formulated either on the basis of the ordinary conception of valency (a) or by making use of the electronic theory of valence (b).

(a)



(b)



Actually by rates of reaction studies, it cannot be determined whether or not the mechanism takes any one of the following courses, all of which lead to the same "complex," AB_2.

$$\begin{cases} A + B \rightleftharpoons AB \\ AB + B \rightleftharpoons (AB_2) \longrightarrow E + F + B \end{cases}$$

$$\begin{cases} B + B \rightleftharpoons B_2 \\ A + B_2 \rightleftharpoons (AB_2) \longrightarrow E + F + B \end{cases}$$

$$A + 2B \rightleftharpoons (AB_2) \longrightarrow E + F + B$$

[6] The integration of this equation and its use for chemical reactions of the third order under ideal conditions has been considered in detail by F. E. E. Germann, *J. Phys. Chem.*, 32,1748 (1928).

[7] An excellent survey of the activity theory and a bibliography have been published by Harned and Seltz, THIS JOURNAL, 44, 1475 (1922).

[8] J. N. Bronsted, *Z. physik. Chem.*, 102,169 (1922); 115,337 (1925).

According to Bronsted

$$\frac{-\mathrm{d}C_{\mathrm{A}}}{\mathrm{d}t} = \frac{-\mathrm{d}C_{\mathrm{B}}}{\mathrm{d}t} = KC_{\mathrm{B}}^2C_{\mathrm{A}}\frac{f_{\mathrm{B}}^2f_{\mathrm{A}}}{fx} \qquad (1)$$

where C's are concentrations, *f*'s are activity coefficients, and *fx* refers to the critical complex, AB_2. The activity theory differs from this formulation only in replacing *fx* by unity.

The alcohols give rise to very abnormal solutions, as shown by molecular weight determinations from freezing-point measurements in non-polar solvents? Unquestionably these solutions differ enough from ideality to warrant consideration. Experiments already mentioned have shown in two cases that the acid and ester formed have practically no effect on the rate of the reaction. Even greatly changing the concentration of the acid chloride does not produce a very marked influence on the rate. It appeared reasonable, therefore, to assume that the substances, other than the alcohols, did not give wide deviations from ideal solutions. Nothing could be known, of course, of the values for the critical complex, but it seemed reasonable to assume (f_{A}/fx) constant for all the solutions considered, or, in other words, that these two activity coefficients varied in the same way. This was equivalent to assuming f_{A} constant, if the activity theory be used. For simplicity it was further assumed that f_{B} depended on C_{B} only.

In accordance with the general method for dealing with rates of reactions in a changing environment, developed in the preceding paper,[10] the following equation may be written to express the realtion between the activity coefficients of the alcohols and their concentrations

$$f^2 = \frac{1}{1 - 2gC} \qquad (2)$$

where *g* is a constant dependent on the alcohol and the solvent in which it is dissolved and C is concentration expressed in moles per thousand grams of solvent.[11]

Auwers, Z. *physik. Chem.*, *12*, 689 (1893); Wilhelm Biltz, *ibid.*, **29**, 249 (1899); C. R. Bury and F. S. Brown, *J. Phys. Chem.*, 30,694 (1926).

[10] Scatchard, THIS JOURNAL, 52, 52 (1930).

[11] The following equations may be used to express empirically the relation between activity coefficient and concentrations. The last of the series was chosen because it leads to the fewest complications.

$$f = e^{gC}$$

$$f = 1 + gC \qquad \left\{\begin{array}{l} f = \sqrt{\dfrac{1}{1 - 2gC}} \\[2ex] f^2 = \dfrac{1}{1 - 2gC} \end{array}\right.$$

$$f = \frac{1}{1 - gC}$$

Substituting this value for f^2 in the Bronsted Equation 1 above

$$\frac{-\mathrm{d}C_B}{\mathrm{d}t} = K_3^0 \frac{C_B^2 C_A}{(1 - 2gC)} \tag{3}$$

where K_3^0 is the third-order constant at infinite dilution.

If x is the fraction of B transformed

$$C_B = C_0 (1 - x)$$
$$C_{A_0} = C_0 D,\ C_A = C_0 (D - x)$$

Substituting these values in Equation 3

$$\frac{-\mathrm{d}(C_0)(1 - x)}{\mathrm{d}t} = K_3^0 \frac{C_0^3(1 - x)^2(D - x)}{1 - 2gC_0(1 - x)} \text{ or } \tag{4}$$

$$C_0 \frac{\mathrm{d}x}{\mathrm{d}t} = K_3^0 \frac{C_0^3(1 - x)^2(D - x)}{1 - 2gC_0(1 - x)} \tag{5}$$

$$K_3^0 \mathrm{d}t = \frac{\mathrm{d}x}{C_0^2(1 - x)^2(D - x)} - 2g \frac{\mathrm{d}x}{C_0(1 - x)(D - x)} \tag{6}$$

For the case where D = 1

$$K_3^0 \mathrm{d}t = \left(\frac{1}{C_0^2} \frac{\mathrm{d}x}{(1 - x)^3}\right) - \left(\frac{2g}{C_0} \frac{\mathrm{d}x}{(1 - x)^2}\right) \tag{7}$$

Integrating, evaluating the integration constant by the condition $x = 0$, when $t = 0$, and combining terms

$$K_3^0 t = \frac{x(2 - x)}{2C_0^2(1 - x)^2} - \frac{2g}{C_0} \frac{(x)}{(1 - x)} \tag{8}$$

For the case where $D \neq 1$

$$K_3^0 \mathrm{d}t = \frac{\mathrm{d}x}{C_0^2(1 - x)^2(D - x)} - \frac{2g}{C_0} \frac{\mathrm{d}x}{(1 - x)(D - x)} \tag{9}$$

Integrating, evaluating the integration constant by the condition $x = 0$ when $t = 0$, and combining terms

$$K_3^0 t = \frac{x}{C_0^2(D - 1)(1 - x)} - \frac{1}{C_0^2(D - 1)^2} \ln \frac{D - x}{D(1 - x)} - \frac{2g}{C_0(D - 1)} \ln \frac{D - x}{D(1 - x)} \tag{10}$$

For the special case where $C_0 = 1$ and D = $^1/_2$

$$K_3^0 t = -\frac{2x}{1 - x} - 4 \ln \frac{(1 - 2x)}{(1 - x)} + 4g \ln \frac{(1 - 2x)}{(1 - x)} \tag{11}$$

Or, in terms of y, the fraction of A transformed

$$y = 2x \text{ or } x = y/2$$

$$K_3^0 t = -\frac{2y}{2 - y} - 4 \ln \frac{2(1 - y)}{2 - y} + 4g \ln \frac{2(1 - y)}{2 - y} \tag{12}$$

For the special case where $C_0 = {}^1/_2$ and D = 2

$$K_3^0 t = 4 \frac{x}{1 - x} - 4 \ln \frac{2 - x}{2(1 - x)} - 4g \ln \frac{2 - x}{2(1 - x)} \tag{13}$$

Or, in terms of y, the fraction of A transformed, $x = 2y$

$$K_3^0 t = \frac{8y}{1 - 2y} - 4 \ln \frac{(1 - y)}{(1 - 2y)} - 4g \ln \frac{(1 - y)}{(1 - 2y)} \tag{14}$$

These new equations, (7), (12) and (14), exhibit the peculiarity that the first part of each corresponds to the usual integrated form of equations for reactions of the third order. The second part is the integrated form of the equation for a second-order reaction, multiplied by the constant, *g*. In using the new equation for obtaining values of K_3^0, the constant, g, was evaluated from the data of the last observations in experiments at molal and half molal concentrations. In one case, that of n-amyl alcohol, where data on but a single run at half-molal concentration were available, using the last observation of this half-molal run led to an absurd value for g. By taking the point next to the last, the value for *g* was much more reasonable. As a check, in this case, both *g* and K_3^0 were recalculated by the method of least squares, using all thirty available observations. The value of *g* thus obtained was —0.12, against —0.13 obtained by the first method. The value for K_3^0, found in this way, was 0.106 instead of 0.108. For inactive amyl alcohol the value of g was very small, —0.01. In other words, the deviation from ideality of solutions of this alcohol in anhydrous ether apparently is very small. In all cases except *iso*-amyl alcohol the sign of the constant, g, is negative. The reason for the positive sign in this single instance is not quite clear. Considerably more study ought to be given to this alcohol.

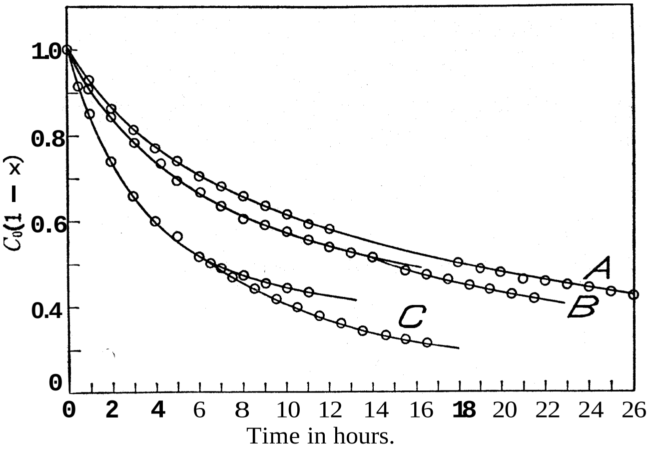

Fig. 2.—Plot of $C_0(1 - x)$ against *t* in hours for three alcohols. A, n-butyl alcohol, molal and half molal; B, ethyl alcohol, molal and half molal; C, methyl alcohol, molal and half molal.

With methyl and ethyl alcohols, the method adopted for calculating values of g gave very absurd results (—9.58 and —1.23, respectively). This circumstance led to the surmise that in these cases the hydrogen chloride evolved was producing a marked effect. Such a conclusion was borne out by the experiment showing that ethyl p-nitrobenzoate had no appreciable effect on the rate with which ethyl alcohol reacted with *p*-nitrobenzoyl chloride. This view was substantiated further by plotting the values of $C_0(1 - x)$ against t in the case of three alcohols, for molal and half-molal concentrations. For methyl alcohol the curves were markedly divergent; for ethyl alcohol the agreement was much better. With butyl alcohol, where experiment had shown the effect of added hydrogen chloride to be negligible, the curves were continuous (see Fig. 2).

If the assumption be made, in the cases of methyl and ethyl alcohols, that the effect of hydrogen chloride is equal to that attributable to the abnormality of the alcohol solutions, a reasonable value for g may be calculated by the following method.

For the third-order reaction, equal molal concentrations, the rate may be expressed by the equation

$$dx/dt = K_3^0 C_0^2 (1 - x)^3 f^2_{\mathrm{B}} \tag{15}$$

In accordance with the assumption that the effect of hydrogen chloride on the rate be equal to that of the alcohol

$$f_{\mathrm{B}}^2 = \frac{1}{1 - 2g(C_{\mathrm{B}} + C_{\mathrm{HCl}})} = \frac{1}{1 - 2gC_0} \tag{16}$$

Equation 15 may now be written

$$\frac{dx}{C_0^2(1 - x)^3} = \frac{K_3^0 dt}{(1 - 2gC_0)} \tag{17}$$

but

$$\frac{dx}{C_0^2(1 - x)^3} = K_3 dt$$

Therefore, Equation 17 may be written as follows

$$K_3 = \frac{K_3^0}{(1 - 2gC_0)} \text{ or } K_3^0 = K_3 (1 - 2gC_0) \tag{18}$$

In accordance with Equation 18 the relation between the third-order constants at molal and half-molal concentrations may be expressed in terms of g, as follows

$$K_3^1(1 - 2g) = K_3^{0.5}(1 - g) \tag{19}$$

Using the third-order constants at molal and half-molal concentrations, K_3^1 and K_3^0, the calculated values of g were -0.65 for methyl alcohol and -0.21 for ethyl alcohol. These values, in turn, gave the constants, K_3^0 0.497 and 0.144, respectively, for the two alcohols.

In the cases of five other alcohols, where data were available on experiments made with at least two different concentrations, the new equation gave results accurate within the limits of experimental error.

The deviations of the data from the equations for second- and third-order reactions and from the third-order equations for non-ideal solutions were determined by the following method. For each of the equations t was calculated, using the values of K and x or K, x and g in the case of the third-order equation for non-ideal solutions. The calculated values of t were plotted against observed values of x, on a large scale. Values of x were read off the plot at the times of observation. The differences between observed and calculated values of x were plotted against t, in hours. For *n*-butyl alcohol, to take an example, it was found that the

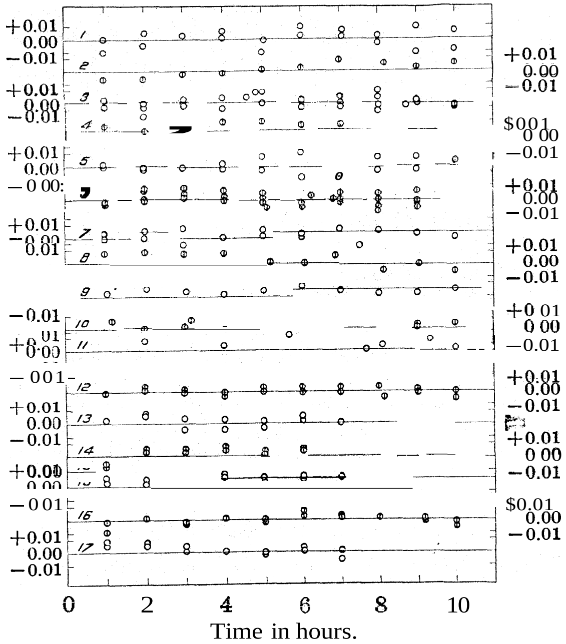

Fig. 3.—Deviations of observed values of the fraction of alcohol transformed in time, t, from the values calculated by the equation for third-order reactions. Methyl alcohol, molal (1), half molal (2); ethyl alcohol, molal (3), half molal (4); n-propyl alcohol, molal (5); n-butyl alcohol, molal (6), half molal (7), molal in alcohol, half molal in acid chloride (8), half molal in alcohol, molal in acid chloride (9); n-amyl alcohol, molal (10), half molal (11); inactive amyl alcohol, molal (12), half molal (13); iso-amyl alcohol, molal (14), half molal (15); *n*-hexyl alcohol, molal (16), half molal (17).

deviations reached as high as 7% for the second-order equation. On the other hand, they were only 2% for the third-order equation, formulated either for ideal or non-ideal solutions. Similar results were found for the other alcohols. In Fig. 3 the deviations of the observed from the calculated values of x are presented graphically. The constants obtained for the eight alcohols considered in this paper are summarized in Table III.

TABLE III

SUMMARY OF THE VELOCITY CONSTANTS FOR THE REACTION BETWEEN ALCOHOLS AND *p*-NITROBENZOYL CHLORIDE IN ANHYDROUS ETHER SOLUTION

Alcohol	K_2^1	$K_2^{0.5}$	K_3^1	$K_3^{0.5}$		g
Methyl	0.184	0.141	0.215	0.300	0.497	-0.65
Ethyl	.0853	.057	.103	.121	.144	− .21
n-Propyl	.0658	...	.0731	...	...	...
n-Butyl	.0739	.046	.0826	.0944	.118	− .25
	.0824[a]	.053[b]	.0827[a]	.1066[b]		
n-Amyl	.077	.048	.0895	.0919	.108	− .13
Inactive amyl	.035	.0195	.0373	.0386	.0387	− .01
Iso-amyl	.0695	.0325	.0751	.0668	.0571	+ .16
n-Hexyl	.0815	.053	.0940	.111	.1375	− .28

[a] Concentrations were molal in alcohol and half molal in acid chloride.

[b] Concentrations were molal in acid chloride and half molal in alcohol.

The values of these constants are averages, weighted for time. They were obtained from the ratio $\Sigma Kt/\Sigma t$. In connection with the two earlier papers, to which reference has been made,[2] it should be noted that the relative order in which the constants stand is the same, with one exception, whichever equation be used in calculating these constants. The order of n-butyl and *n*-amyl alcohols is reversed, if the third-order constants at half-molal concentration or at infinite dilution be used in making the comparison. It should be said, in all fairness, that, however, the constants for these two alcohols are calculated, they are very close together.

The writer is profoundly grateful to Professor George Scatchard of this Institute for unstinted help in developing the theoretical aspects of the problem, to Professor James F. Norris for his long-sustained interest in the work, and to many other associates at the Massachusetts Institute of Technology for significant suggestions. The data used were obtained partly by Dr. F. Cortese ("Thesis," Ph.D., Massachusetts Institute of Technology, 1926) and partly by the writer.

Summary

The reaction of alcohols with *p*-nitrobenzoyl chloride in anhydrous ether solution is of the third order, instead of the expected second order.

The mechanism of the reaction requires two molecules of the alcohol to one of the acid chloride. In other words, the reaction is second order with respect to the alcohol and first order with respect to the acid chloride.

Taking into account the well-known abnormality of alcohol solutions, an equation has been developed for calculating the third-order constants at infinite dilution,

THE MOLECULAR WEIGHTS OF AMANDIN AND OF EXCELSIN

BY THE SVEDBERG AND BERTIL SJÖGREN

RECEIVED JULY 15, 1929 PUBLISHED JANUARY 8, 1930

In a recent communication from this Laboratory[1] it was shown that the edestin molecule has a weight of 212,000 in a PH region from the isoelectric point *P*H 5.5 to about PH 10. At a *P*H of 11.3 definite dissociation takes place. Molecules of one-half and one-third of the normal are formed at this alkalinity. On the acid side of the isoelectric point the edestin molecule was found to be quite unstable.

Chiefly thanks to the fundamental work done by Osborne[2] a considerable number of vegetable proteins are known. Especially those which like edestin belong to the globulin group seem to be very stable and are easy to prepare in a pure state. It was thought to be of interest to study some more representatives of this important class of proteins by means of the ultracentrifuge analysis. Amandin and excelsin were first worked with because of their widely differing elementary composition. Amandin has the lowest (0.44%) and excelsin the highest (1.08%) sulfur content of the oil-seed proteins so far analyzed.

Preparation of Material

Amandin was prepared in the following way. Almonds were soaked in cold water for some hours and freed from skins. The material was then ground in a mill, and 1000 g. of the paste suspended in 5000 cc. of 10% sodium chloride solution. Toluene was added as a preservative and the mixture was digested with stirring at room temperature for twenty-four hours. After settling the solution was siphoned off and the residue treated again in the same way with 2000 cc. of 10% sodium chloride solution and after that with 1000 cc. of the same solution. By means of centrifuging the collected liquid extracts were freed from oil and fat which had been partly dissolved in the toluene. To the protein solution was then added an equal volume of saturated ammonium sulfate and some more toluene. After standing for two days at 0° the precipitate was filtered off and washed with half saturated ammonium sulfate solution. The amandin was then dissolved in a phosphate buffer 0.095 M in KH_2PO_4 and 0.005 M in Na_2HPO_4 and further containing 1% of sodium chloride in order to increase the solubility of the amandin. The solution was dialyzed against the same buffer; the final volume was 50 cc. and the concentration 2.89%.

Excelsin was isolated in the following manner. Brazil nuts were freed from the shells and ground in a mill (without removing the skins from the kernels), and 1000 g. of the paste was suspended in 5000 cc. of a 3% ammonium sulfate solution. Toluene was added as a preservative and the mixture shaken at room temperature for twenty-four hours. It was then filtered and to the solution was added ammonium sulfate to 60% saturation. The precipitate formed was dissolved in 6% ammonium sulfate, the solution was filtered and reprecipitated with ammonium sulfate to the same degree of saturation. The excelsin precipitate was washed with ammonium sulfate solution of

[2] Osborne, "Vegetable Proteins," Longmans, Green and Co., London, 1909.

the same strength. One portion of the excelsin precipitate was dissolved in phosphate buffer of *P*H 5.5 (0.182 *M* in KH_2PO_4 and 0.018 M in Na_2HPO_4) and containing 1% ammonium sulfate and dialyzed at 0° against the same buffer. No precipitation occurred; volume of solution, 35 cc. and concentration, 3.79% (Material I). A second portion of the excelsin was dialyzed against pure water. The excelsin was precipitated in crystalline form and the crystals were dissolved as in the case of Material I: volume of solution, 50 cc.; concentration, 2.26% (Material II). The isoelectric points of these proteins are difficult to determine accurately, because of the high salt content necessary to keep them in solution. A value of *P*H 5.5–5.7 was assumed as the most probable one.[3]

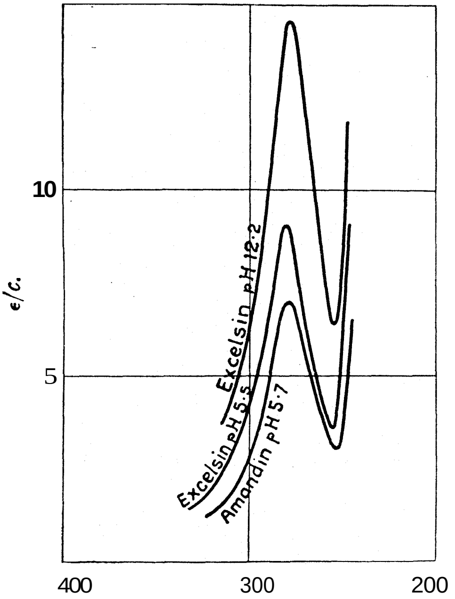

Fig. 1.

Specific Volume.—The partial specific volume was determined pycnometrically at 19.8° as described in previous communications.[4] For amandin the value 0.746 was obtained. The protein concentration was 1.4%, the solvent was 0.095 *M* in KH_2PO_4, 0.005 M in Na_2HPO_4 and contained 1% NaCl, giving a *P*H of 5.7. For excelsin the value found was 0.743. The protein concentration was 1% and the solvent was 0.182 M in KH_2PO_4, 0.018 *M* in Na_2HPO_4 and contained 1% of ammonium sulfate, giving a *P*H of 5.5.

The specific volumes for these two proteins are identical within the limits of error and also identical with the specific volumes of egg albumin, Bence–Jones protein, hemoglobin, serum albumin, serum globulin, phycocyan, phycoerythrin and edestin.

Light Absorption.—The light absorption of amandin and excelsin solutions were studied by means of the Judd–Lewis spectrophotometer. The solutions were brought to the desired concentration and *P*H directly before measuring the light absorption. Amandin was measured in 0.2 and 0.1% solutions and with a thickness of layer of 2.0 cm. The solvent was 0.095 M in KH_2PO_4 and 0.005 M in Na_2HPO_4 with 1% of NaCl, giving a *P*H of 5.5. The absorption maximum was found to be 280μμ and the minimum 253μμ. At high *P*H values where the centrifugal analysis showed that splitting up of the molecule occurs, the light absorption was found to increase.

Excelsin was measured at two different *P*H values, at 5.5 and at 12.2. In the first case two excelsin concentrations 0.10 and 0.05% made up from Material II were used in 2.0-cm. layer. The solvent was 0.182 M in KH_2PO_4 and 0.018 M in Na_2HPO_4 with 1% of ammonium sulfate. The absorption maximum was 279μμ and the minimum 253μμ. In the second case the solution was 0.06% with regard to excelsin. The solvent was 0.021 M in KH_2PO_4, 0.013 M in Na_2HPO_4, 0.030 M in NaOH and 0.12% in ammonium sulfate. The maximum was 279μμ and the minimum 253μμ. The position

[4] Svedberg and Chirnoaga, *ibid.*, 50, 1401 (1928).

of the absorption band therefore is not shifted by the change in PH, but on the other hand the values of the extinction constant were much higher at the higher PH. The centrifugal analysis showed that the excelsin molecule, which at the isoelectric point is built up of six units of weight 35,000, is at a PH of 12.2 completely split up into the unit 35,000. This together with a slight formation of non-centrifugal substance accounts for the increase in light absorption at the high PH. In Fig. 1 the specific extinction coefficient, $\epsilon/c = 1/cd \times \log I_0/I$ (where c is the concentration, d the thickness of the solution, I_0 the intensity of the light beam after passing through the solvent and I the intensity after passing through the same thickness of solution), is plotted against wave length. As shown by the diagram the excelsin has a stronger light absorption than amandin. This is probably caused by the higher tryptophane content of excelsin.[5]

Determination of Molecular Weight

Sedimentation Equilibrium Method.—As shown in previous communication~ the molecular weight is given by the relation

$$M = \frac{2RT \ln (c_2/c_1)}{(1 - V\rho)\omega^2(x_2^2 - x_1^2)}$$

where R is the gas constant, T the absolute temperature, V the partial specific volume of the solute, ρ the density of solvent, w the angular velocity and c_2 and c_1 are the concentrations at the distances x_2 and x_1 from the center of rotation.

Two different types of ultracentrifuges for medium speed previously described[8,9] were used.

In Table I the result of a typical run with amandin is given and in Table II are collected the data of the five equilibrium runs made on amandin and excelsin.

.1	.1	$(NH_4)_2SO_4$	6.5	Excelsin, 0.20	4,800	210,500

As mean values for the molecular weights we find for amandin 208,000 ± 5000 and for excelsin 212,000 ± 5000.

Sedimentation Velocity Method.—For the sedimentation velocity runs the high-speed oil-turbine ultracentrifuge was used.[10] The cells were of the type described in the previous paper.[9] In most of the runs the wave length region was 290–240 μμ isolated from the mercury arc by means of chlorine and bromine filters. For the study of extremely low protein concentrations the wave length region 231–214μμ produced by means of a cadmium spark-lamp as described in the previous paper was used.[9]

In the case of amandin and excelsin the same kind of irregularities with regard to diffusion constant were observed as in the case of the Bence-Jones protein.[9] The measurement of the sedimentation constant on the other hand presented no difficulties. In the following, therefore, only a report of the latter determination will be given.

The behavior of amandin was studied within the PH region 4.3–12.2. Excelsin was investigated from PH 5.5 to PH 11.9. The solutions were

[a] Cadmium light was used. [b] 0.005 M in sodium hydroxide. [c] 0.040 M in sodium hydroxide.

As shown by Table III amandin is stable within the *PH* range 4.3–9.4. The mean value of the sedimentation constant is 11.4 X 10^{-13}. A non-centrifugible substance was not present in the solutions studied. In Fig. 2 a diagram of the microphotometer curves from the run at PH 12.16 is given. The diagram shows that at this PH the solution contains two different centrifugible substances (together with a small amount of a non-centrifugible substance). In Fig. 3 the last curve corresponding to the state of the solution after two hours of centrifuging is given after being reduced to represent relative concentrations (Curve D) instead of merely galvanometer deflections as in Fig. 2. In the same diagram are given (in dotted lines) the curves for the undecomposed amandin (A), for a protein of molecular weight one-sixth of the normal amandin (B) and for a mixture of 59% normal amandin and 41% of amandin of weight one-sixth of the normal substance (C). The closeness of the two curves C and D makes it very probable that the normal amandin at a *PH* of 12.16 is to a large extent split up into molecules of one-sixth of

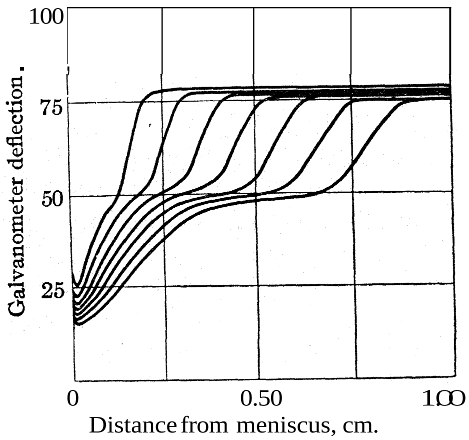

Fig. 2.

the normal weight. Because of the difficulty of taking into account the difference in light absorption between the normal and the decomposed amandin, the calculation of the relative amounts of the two components in the mixture should be regarded only as a first approximation.

Table IV shows that excelsin is stable within the PH range 5.5–9.81, with *a* mean corrected sedimentation constant of 11.8×10^{-13}. A small amount of a non-centrifugible substance was present. At a PH of 11.88 the protein was completely broken up into a substance possessing a sedimentation constant of 3.54×10^{-13}. Now this is, within the limit of error, the same value as that found for egg albumin (**3.32** $\times 10^{-13}$) and for Bence-Jones protein (3.55×10^{-13}), which have been shown to have a molecular weight of one-sixth of that of normal excelsin. It is therefore extremely probable that in the solution of *P*H 11.88 the excelsin is broken up into molecules of one-sixth the weight of normal excelsin.

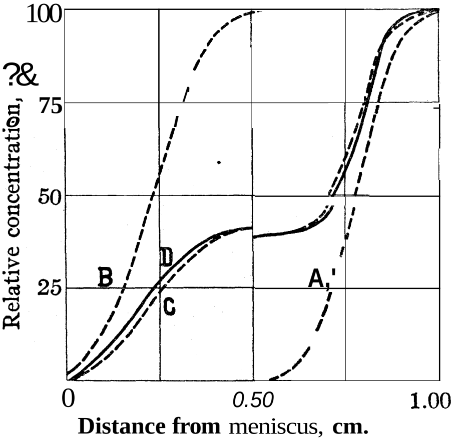

Fig. 3.

A test of the reversibility of the disaggregation of the excelsin molecule was performed. A solution identical with the one used for Run 10 (of PH 11.88) which had been shown to possess a sedimentation constant of 3.54×10^{-13}, indicating a molecular weight of one-sixth of normal excelsin, was dialyzed for seven days against a phosphate buffer of PH 6.5 (0.1 M in KH_2PO_4, 0.1 M in Na_2HPO_4 and 1% in ammonium sulfate). As shown by Table IV, excelsin has its normal molecular weight at the PH of 6.5. During the dialysis a small amount of insoluble substance appeared and was filtered off. The determination of the sedimentation constant gave 11.7×10^{-13} (corrected value). A small amount of non-centrifugible substance was present and also traces of a centrifugible substance of lower sedimentation constant. The light absorption had very nearly assumed the value corresponding to undecomposed excelsin (compare Fig. 1). The disaggregation of the excelsin molecule into molecules one-sixth of **normal** excelsin is therefore practically reversible.

Discussion of Results

The sedimentation equilibrium measurements have shown that amandin has a molecular weight of 208,000 ± 5000 and excelsin a weight of 212,000 ± 5000 near their isoelectric points. These values are, within the limits of error, identical with those previously found for edestin,[1] R-phycoerythrin,[12,13] R-phycocyan and C-phycocyan[13] near their isoelectric points. At higher PH values the molecules of all these proteins have been found to break up into simple sub-multiples of the isoelectric molecule. With regard to PH stability R-phycoerythrin resembles amandin inasmuch as at a PH of 11.0 its molecules are to an amount of about 25% disaggregated into molecules of the weight one-sixth of that of the normal molecule. The sedimentation velocity measurements have shown that at a PH of 12.2 the amandin molecule is to an extent of about 41% disaggregated into molecules of weight one-sixth of the normal.

Excelsin seems to be somewhat less stable than amandin. Its PH stability region is smaller and it shows a tendency to form a non-centrifugible decomposition product, which is not the case with amandin.

The values of the sedimentation constants 11.41×10^{-13} for normal amandin and 11.78×10^{-13} for normal excelsin are within the limits of error identical with the values found for the proteins just mentioned in the vicinity of their isoelectric points. A calculation of the molar frictional constants f at 20° by means of the formula, $f = [M(1 - V\rho)]/s$, gives for amandin 4.63×10^{16} and for excelsin 4.63×10^{16}, while the values of f_s to be expected for spherical molecules of the same weight and specific volume, calculated by means of the formula $f_s = 6\pi\eta N(3MV/4\pi N)^{1/3}$, are for amandin 4.50×10^{16} and for excelsin 4.52×10^{16}. The ratio f/f_s, which for a spherical molecule should be unity, is for amandin 1.03 and for excelsin 1.02. The radius of the molecule, derived from the formula $r = (3MV/4\pi N)^{1/3}$, is for amandin 3.94 $\mu\mu$ and for excelsin 3.96 $\mu\mu$.

It seems to be of interest to be able to compare the values for the frictional constant and the radii of edestin, R-phycoerythrin, R-phycocyan, and C-phycocyan with the values for amandin and excelsin. Those other values have therefore been calculated. In order to give a more complete review of the data of the six proteins with molecular weights near 208,000, Table V has been arranged so as to contain molecular weight, M, sedimentation constant, s, molar frictional constant, f, molar frictional constant for a spherical molecule, f_s, dissymmetry ratio f/f_s and radius r.

TABLE V

COLLECTED VALUES

Protein	Molecular weight	$s \times 10^{13}$	$f \times 10^{-16}$	$f_s \times 10^{-16}$	f/f_s	r, $\mu\mu$
Amandin	208,000 = 6.04 × 34,500	11.4	4.63	4.50	1.03	3.94
Excelsin	212,000 = 6.15 × 34,500	11.8	4.63	4.52	1.02	3.96
Edestin	208,000 = 6.04 × 34,500	12.8	4.16	4.50	0.93	3.94
R-Phycoerythrin	209,000 = 6.06 × 34,500	11.5	4.61	4.51	1.02	3.95
R-Phycocyan	206,000 = 5.97 × 34,500	11.1	4.51	4.51	1.00	3.95
C-Phycocyan	208,000 = 6.04 × 34,500	11.2	4.74	4.50	1.05	3.94

[13] Svedberg and Katsurai, *ibid.*, 51, 3573 (1929).

Within the limit of error all the corresponding data of Table V are equal for the six proteins in question.[14] Thus it is obvious that the mass and the shape of the molecules of these proteins are almost identical. The six proteins in question have different chemical composition, different isoelectric points and different light absorption. Their P_H stability ranges are also different but the molecular weights of the products of alkaline disaggregation are simple sub-multiples of the normal molecule. So far only the sub-multiples $^1/_2$, $^1/_3$, $^1/_6$ have been observed. It is very remarkable that these sub-multiples are identical with the normal molecular weights of other proteins. Thus all the 12 native and stable proteins so far investigated in this Laboratory as well as their disaggregation products—with the possible exception of the hemocyanins, which have molecular weights of the order of millions—can all as a first approximation be derived from the unit 34,500 by multiplying with the integers *two,* three and *six.*

The expenses connected with these experiments have been defrayed by grants from the foundation "Therese och Johan Anderssons Minne" and from the Nobel Fund of Chemistry.

Summary

1. The molecular weights and P_H stability regions of amandin and excelsin have been studied by means of the ultracentrifugal methods.

2. Amandin is stable from P_H 4.3 to about 10 with a molecular weight of 208,000 ± 5000. At a P_H of 12.2 it is partly disaggregated, forming molecules with a weight one-sixth of the normal ones. The sedimentation constant is 11.41×10^{-13} and the molar frictional constant 4.63×10^{16} for the normal molecules. The molecules of normal amandin are spherical with a radius of 3.94 $\mu\mu$.

3. Excelsin is stable from P_H 5.5 to about 10, possessing a molecular weight of 212,000 ± 5000. At a P_H of 11.9 excelsin is completely disaggregated into molecules of one-sixth of the molecular weight of normal excelsin. The sedimentation constant is 11.78×10^{-13} and the molar frictional constant 4.63×10^{16} for the normal molecules. The sedimentation constant is 3.54×10^{-13} for the disaggregated molecules. The aggregation and disaggregation processes are reversible. The normal excelsin molecules are spherical with a radius of 3.96 $\mu\mu$.

4. The molecular weight, sedimentation constant, molar frictional constant and molecular radius of amandin and excelsin have been compared with the corresponding constants of edestin, R-phycoerythrin, R-phycocyan and C-phycocyan and have been found to be identical within the limits of error.

5. The disaggregation products of these six proteins have been found

---

[14] The sedimentation constant for edestin and the other data containing this constant are uncertain because of the high salt content of the solution.

to belong to one or more than one of the sub-multiples $^1/_2$, $^1/_3$ or $^1/_6$ of the normal molecule. The molecular weights of these sub-multiples correspond to normal molecular weights of other proteins.

CYCLIC QUATERNARY AMMONIUM SALTS FROM HALOGENATED ALIPHATIC TERTIARY AMINES

BY E. R. LITTMANN AND C. S. MARVEL

RECEIVED JULY 17, 1929 PUBLISHED JANUARY 8, 1930

The formation of rings from open-chain compounds of various types has been the subject of many recent investigations. The work of Ruzicka[1] and his collaborators on the large carbon rings has led to this study of the nitrogen compounds in the hope of obtaining large rings containing a nitrogen atom in place of one of the carbon atoms. The largest simple ring containing a nitrogen atom heretofore described is the seven-membered ring, hexamethylene-imine, which has recently been characterized by Müller and Sauerwald.[2]

In a recent study of bromo tertiary amines[3] it was observed that 4-bromobutyldiethylamine on standing changed into a quaternary ammonium salt, which was thought to be a pyrrolidine derivative. The ease with which this reaction occurred suggested that other brominated tertiary amines might give the desired larger rings containing nitrogen.

Knorr and Roth[4] have studied bromo-ethyldimethylamine and chloropropyldimethylamine and have found that they reacted to give six- and eight-membered rings containing two nitrogen atoms, according to the general reaction

$$2Br(CH_2)_nNR_2 \longrightarrow \underset{Br}{R_2N}\langle\begin{smallmatrix}(CH_2)_n\\(CH_2)_n\end{smallmatrix}\rangle\underset{Br}{NR_2}$$

Von Braun and his students[5] have studied bromo-alkyl primary amines of the type $Br(CH_2)_nNH_2$ and have found that when $n = 4$, 5 or 6 some of the cyclic nitrogen compound was obtained, although the yields were low and by-products due to secondary reactions formed the greater part of the final product. When $n = 7$, they were unable to obtain a reaction product that could be identified as the cyclic amine. In addition to these

---

[1] The fourteenth paper on large carbocyclic rings by Ruzicka and his co-workers was published in *Helv. Chim. Acta*, 11, 1174 (1928).

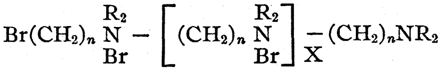
[2] Muller and Sauerwald, *Monatsh.*, 48, 527, 731 (1927).

[3] Marvel, Zartman and Bluthardt, THIS JOURNAL, 49, 2299 (1927).

[4] Knorr and Roth, *Ber.*, 39, 1425 (1906).

[5] Von Braun and Steindorff, *ibid.*, 38, 173, 3089 (1905); Von Braun and Müller, *ibid.*, 39, 4116 (1906); Von Braun and Beschke, *ibid.*, 39, 4121 (1906).

two types of reactions, bromo-alkylamines of this general type might be expected to unite to form long-chain molecules of the type



$$Br(CH_2)_n\overset{R_2}{\underset{Br}{N}} - \left[(CH_2)_n\overset{R_2}{\underset{Br}{N}}\right]_X - (CH_2)_nNR_2$$

According to the views recently expressed by Carothers,[6] ring formation would be the main reaction to be expected when n has the value 4 or 5. When n has a value greater than 5, the reaction would be expected to give the long open-chain polymeric type of compound.

The present paper describes the preparation and reactions of bromoamines of the general type $Br(CH_2)_nN(CH_3)_2$, where n has a value of 4, 5, 6 and 7. All of these amines react with themselves to give cyclic quaternary ammonium salts to a greater or less degree. Where n has the value 4, 5 or 6, ring formation proceeds as the major reaction and yields of more than 50% of the cyclic salt have been isolated. When n has the value 7, the yield of cyclic compound is lowered to less than 50% but still represents a fairly large amount of the final product. These results are shown in Table I, where they are compared with the yields of the cyclic ketones which Ruzicka[7] has obtained by the distillation of the salts of dibasic acids.

TABLE I

COMPARISON OF THE YIELDS OF CYCLIC KETONES AND CYCLIC QUATERNARY AMMONIUM SALTS

Ketone	Yield, %	Quaternary ammonium salt	Yield, %
$(CH_2)_4{>}CO$	45	$(CH_2)_4{>}N(CH_3)_2Br$	76
$(CH_2)_5{>}CO$	70	$(CH_2)_5{>}N(CH_3)_2Br$	63
$(CH_2)_6{>}CO$	50	$(CH_2)_6{>}N(CH_3)_2Br$	56
$(CH_2)_7{>}CO$	20	$(CH_2)_7{>}N(CH_3)_2Br$	37

That the products isolated in this work were really rings was determined by comparing the five- and six-membered rings with known pyrrolidine and piperidine derivatives. The seven-membered ring was found to be identical with the corresponding derivative of Müller and Sauerwald's[2] hexamethylene-imine. The molecular weights of these salts were determined by freezing point depression in water. They showed the behavior of typical uni-univalent salts in that the values obtained were slightly over one-half the calculated value. No eight-membered ring containing nitrogen was available for comparison with the compound which was obtained from bromoheptyldimethylamine. However, its molecular weight from freezing point depression data checks with the value expected for the simple cyclic salt.

Attempts to determine the rate of the ring closing reaction quantitatively

[6] Carothers, THIS JOURNAL, 51, 2548 (1929).

[7] The figures in the table are the highest reported in the paper of Ruzicka, Brugger, Pfeiffer, Schinz and Stoll, *Helv. Chim. Acta*, 9, 505 (1926).

by titration of ionic halogen and thus make it possible to compare the ease of formation of rings of different sizes were not successful. The side reactions proceeded to a sufficient extent to invalidate reaction rate studies,

Experimental Part

4-Phenoxybutyldimethylamine.—To 180 cc. of a solution of dimethylamine (0.2 g. of amine per cc.) in absolute alcohol was added 46 g. of 4-phenoxybutyl bromide. The solution was allowed to stand overnight and then heated on a steam-bath for about one-half hour. The alcohol and excess dimethylamine were removed by distillation, the residue was treated with a 25% aqueous solution of sodium hydroxide and the amine was extracted with ether. The ether was evaporated and the amine was distilled under reduced pressure. The yield was 30 g. (77% of the theoretical amount) of a product, b. p. 122–124" (5 mm.); sp. gr. $^{20}_{20}$ 0.951; n^{20}_{D} 1.5017. This compound has previously been described by von Braun,[8] who prepared it by the distillation of 5-phenoxybutyltrimethylammonium hydroxide. The chloroplatinate was prepared and recrystallized from dilute alcohol; m. p. 104".

Anal. Subs., 0.1382: Pt, 0.0338. Calcd. for $(C_{12}H_{19}ON)_2 \cdot H_2PtCl_6$: Pt, 24.52. Found: Pt, 24.45.

5-Phenoxyamyldimethylamine.—A solution of 163 g. of 5-phenoxyvaleric acid in 250 cc. of absolute alcohol containing 10 cc. of concentrated sulfuric acid was refluxed for about five hours. The ester was isolated in the usual way. The yield was 169 g. (90% of the theoretical amount) of ethyl 5-phenoxyvalerate; b. p. 151° (6 mm.); sp. gr. $^{20}_{20}$ 1.041; n^{20}_{D} 1.4982.

Anal. Subs., 0.2130: CO_2, 0.5025; H_2O, 0.1557. Calcd. for $C_{13}H_{18}O_3$: C, 64.48; H, 8.11. Found: C, 64.39; H, 8.10.

This ester was reduced to 5-phenoxyamyl alcohol by the method described by Marvel and Tanenbaum[9] for the preparation of 4-phenoxybutyl alcohol. From 110 g. of ester, 110 g. of sodium and 1 liter of absolute alcohol there was obtained 45 g. (50% of the theoretical amount) of 5-phenoxyamyl alcohol; b. p. 152–155° (5 mm.); m. p. 36°. This compound was previously described by von Braun, Deutsch and Schmatloch,[10] who prepared it by the action of oxygen on 5-phenoxyamylmagnesium iodide.

5-Phenoxyamyl bromide was prepared by mixing 55 g. of phosphorus tribromide and 90 g. of the alcohol at 0° and gradually allowing the mixture to come to room temperature. Water was added to the mixture and the product was separated and distilled. The yield was 63 g. (52% of the theoretical amount) of product; b. p. 154–155° (5 mm.); sp. gr. $^{20}_{20}$ 1.199; n^{20}_{D} 1.5240. Von Braun and Steindorff[11] have previously prepared this compound from sodium phenolate and pentamethylene bromide.

5-Phenoxyamyldimethylamine was prepared from 25 g. of the bromide and 18 g. of dimethylamine in alcohol solution. The yield was 15.5 g. (74% of the theoretical amount) of a product, b. p. 132–134° (5 mm.); sp. gr. $^{20}_{20}$ 0.945; n^{20}_{D} 1.4997. Von Braun[12] has previously prepared this amine by the distillation of 5-phenoxyamyltrimethylammonium hydroxide. The chloroplatinate was prepared. After crystallization from dilute alcohol it melted at 112°.

Anal. Subs., 0.2032: Pt, 0.0481. Calcd. for $(C_{13}H_{21}ON)_2 \cdot H_2PtCl_6$: Pt, 23.69. Found: Pt, 23.70.

6-Phenoxyhexyldimethylamine.—Ethyl 6-phenoxycaproate was prepared by esterifying with ethyl alcohol the crude 6-phenoxycaproic acid obtained from 147 g. of diethyl 4-phenoxybutylmalonate. The yield was 75 g. (63% of the theoretical amount) of a product, b. p. 157–159° (3 mm.); sp. gr. $^{20}_{20}$ 1.031; n^{20}_{D} 1.4928.

Anal. Subs., 0.2103: CO_2, 0.5461; H_2O, 0.1592. Calcd. for $C_{14}H_{20}O_3$: C, 71.18; H, 8.46. Found: 70.86; H, 8.41.

By reduction of 70 g. of this ester with sodium and absolute alcohol, there was obtained 32 g. (55% of the theoretical amount) of 6-phenoxyhexyl alcohol; b. p. 152–154° (3 mm.); m. p, 31°. Von Eraun, Deutsch and Schmatloch[10] have previously prepared this alcohol by the action of oxygen on 6-phenoxyhexylmagnesium bromide.

6-Phenoxyhexyl bromide was prepared by the action of 18 g. of phosphorus tribromide on 30 g. of the alcohol. The yield was 23 g. (54% of the theoretical amount) of a product; b. p. 155–156° (3 mm.); sp. gr. $^{20}_{20}$ 1.248; n^{20}_{D} 1.5361.

Anal. Subs., 0.2376: 16.3 cc. of 0.0549 *N* $AgNO_3$. Calcd. for $C_{12}H_{17}OBr$: Br, 31.1. Found: Br, 30.8.

6-Phenoxyhexyldimethylamine was prepared from 22 g. of the bromide and 60 cc. of a 33% alcoholic dimethylamine solution. The yield was 14 g. (74% of the theoretical amount) of a product, b. p. 132–134° (3 mm.); sp. gr. $^{20}_{20}$ 0.942; n^{20}_{D} 1.4988.

The chloroplatinate was prepared and after recrystallization from dilute alcohol melted at 126°.

Anal. Subs., 0.1920: Pt, 0.0438. Calcd. for $(C_{14}H_{23}ON)_2 \cdot H_2PtCl_6$: Pt, 22.91. Found: Pt, 22.86.

7-Phenoxyheptyldimethylamine.—Diethyl 5-phenoxyamylmalonate was prepared from 81 g. of 5-phenoxyamyl bromide. The yield was 67 g. (63% of the theoretical amount) of a product, b. p. 202–204° (4–5 mm.); sp. gr. $^{20}_{20}$ 1.508; n^{20}_{D} 1.4882. The ester was impure and contained some unchanged bromide. It was not purified further but was used directly to give 7-phenoxyheptoic acid.

The crude malonic ester (65 g.) was saponified with boiling aqueous potassium hydroxide solution and the mixture was acidified. The malonic acid was separated and heated to drive out carbon dioxide. The crude 7-phenoxyheptoic acid thus obtained was esterified with ethyl alcohol. The yield was 31.5 g. (61% of the theoretical amount) of ethyl 7-phenoxyheptoate; b. p. 161–163° (3 mm.); sp. gr. $^{20}_{20}$ 1.015; n^{20}_{D} 1.4932.

Anal. Subs., 0.1345: CO_2, 0.3524; H_2O, 0.1066. Calcd. for $C_{15}H_{22}O_3$: C, 72.00; H, 8.80. Found: C, 71.48; H, 8.87.

Reduction of 30 g. of this ester with sodium and absolute alcohol gave 16 g. (60% of the theoretical amount) of phenoxyheptyl alcohol; b. p. 157–158° (3 mm.); m. p. 34°.

Anal. Subs., 0.2545: CO_2, 0.6985; H_2O, 0.2214. Calcd. for $C_{13}H_{20}O_2$: C, 75.00; H, 9.62. Found: C, 74.81; H, 9.68.

The bromide was prepared by treating 13 g. of the alcohol with 13 g. of phosphorus tribromide. The yield was 13.5 g. (80% of the theoretical amount) of a product, b. p. 154–157° (3 mm.); sp. gr. $^{20}_{20}$ 1.199; n^{20}_{D} 1.5240.

Anal. Subs., 0.1421: AgBr, 0.0981. Calcd. for $C_{13}H_{19}OBr$: Br, 29.52. Found: Br, 29.39.

7-Phenoxyheptyldimethylamine was obtained by treating 15 g. of the bromide with 4 cc. of 30% alcoholic dimethylamine solution. The yield was 12 g. (82% of the theoretical amount) of a product, b. p. 158–160° (8 mm.); sp. gr. $^{20}_{20}$ 0.939; n^{20}_{D} 1.4980.

The chloroplatinate was prepared and after recrystallization from dilute alcohol melted at 162°.

Anal. Subs.. 0.2029: Pt, 0.0446. Calcd. for $(C_{16}H_{25}ON)_2 \cdot H_2PtCl_6$: Pt, 22.20. Found: Pt, 22 00.

ω-Bromo-alkyl Dimethylamines.—The bromo-amines were prepared from the corresponding phenoxy derivatives by the action of hot 48% hydrobromic acid. The general procedure was to prepare a solution of 20 g. of the phenoxyamine in 100 cc. of 48% hydrobromic acid. This solution was distilled until the temperature of the vapors reached 123–125°. Then a second 100-cc. portion of 48% acid was added and the distillation was continued until the total distillate amounted to about 175 cc. This operation was carried out in all-glass apparatus to avoid contamination from the stoppers.

The residue in the distilling flask was evaporated to dryness under reduced pressure on a steam-bath. The crude bromo-amine hydrobromide was dissolved in about 30–35 cc. of water and the free amine was liberated by the addition of a 28% solution of sodium hydroxide. The solution was cooled in an ice-bath during the decomposition of the salt with the alkali. The amine was collected in ether and the ether then removed by evaporation under reduced pressure. If possible the amine was distilled under reduced pressure.

4-Bromobutyldimethylamine.—This amine was never definitely isolated due to too rapid formation of cyclic quaternary salt. Attempts were made at −10° and in a carbon dioxide–ether bath but no pure product could be obtained.

5-Bromo-amyldimethylamine.—This amine was obtained in ether solution at low temperatures, but attempts at distillation always resulted in the formation of the quaternary salt. The ether solution was extracted with dilute hydrochloric acid and the acid solution treated with an excess of gold chloride. The crystalline chloro-aurate was recrystallized from dilute alcohol and then melted at 57°.

Anal. Subs., 0.1943: Au, 0.0715. Calcd. for $C_7H_{16}NBr \cdot HAuCl_4$: Au, 36.95. Found: Au, 36.75.

6-Bromohexyldimethylamine.—This amine was distilled under reduced pressure without the formation of very large quantities of cyclic quaternary salt. It boiled at 78–80" (6 mm.). Attempts to determine the density and index of refraction gave very poor results since enough salt formed during the work to prevent any degree of accuracy. The chloro-aurate of some freshly distilled amine was prepared and crystallized from dilute alcohol. It melted at 111°.

Anal. Subs., 0.1199: Au, 0.0423. Calcd. for $C_8H_{18}NBr \cdot HAuCl_4$: Au, 35.98. Found: Au, 35.52.

7-Bromoheptyldimethylamine.—This amine was distilled under reduced pressure. Very little material was lost due to salt formation during the distillation. It boiled at 85–87° (7 mm.); sp. gr. $^{20}_{20}$ 1.029; n^{20}_{D} 1.4695. The chloro-aurate was prepared and after crystallization from dilute alcohol it melted at 126°.

Anal. Subs., 0.1021: Au, 0.0361. Calcd. for $C_9H_{20}NBr \cdot HAuCl_4$: Au, 35.10. Found: Au, 34.96.

Cyclic Quaternary Ammonium Salts

N-Dimethylpyrrolidinium Bromide.—Upon the addition of an excess of strong sodium hydroxide solution to 30–35 cc. of a solution of 4-bromobutyldimethylamine hydrobromide in water, prepared as described for the preparation of the bromo-amines from the corresponding phenoxy derivatives, the quaternary salt was precipitated as a crystalline mass. After filtration the product was crystallized from a mixture of 80% ethyl acetate and 20% absolute alcohol. There was obtained 13–14 g. of product (72–76% of the theoretical amount). The salt did not melt below 325° (uncorr.).

Anal. Subs., 0.0870: 8.36 cc. of 0.0549 N $AgNO_3$. Calcd. for $C_6H_{14}NBr$: Br. 43.5. Found: Br, 43.7.

The molecular weight of the N-dimethylpyrrolidinium bromide was determined cryoscopically. Subs., 0.6922: H_2O, 24.905; At, 0.556°. Calcd. for $C_6H_{14}NBr$: mol. wt., 180. Found: mol. wt., 92.6. A further check on the identity of this compound was made by converting it to the chloro-aurate of N-dimethylpyrrolidinium chloride, previously described by Willstatter and Huebner.[13]

Approximately 1 g. of the dimethylpyrrolidinium bromide was treated with an excess of an aqueous suspension of silver oxide. After shaking for one to two hours, all of the halogen was removed from the aqueous solution and the mixture filtered. The filtrate was then acidified with hydrochloric acid and to this solution was added an excess of gold chloride. The chloro-aurate so prepared melted at 282° (uncorr.) after recrystallization from water. Willstätter and Huebner have recorded the melting point as 286° (uncorr.), with decomposition. A second sample of the chloro-aurate showed no depression upon taking a mixed melting point with the chloro-aurate prepared from N-dimethylpyrrolidinium chloride which in turn had been prepared from pure pyrrolidine by the following method. Two to three g. of pyrrolidine was treated with an excess of methyl iodide in the presence of an excess of aqueous 20% sodium hydroxide solution. The insoluble N-dimethylpyrrolidinium iodide was removed by filtration, treated with an excess of an aqueous suspension of silver oxide, and converted to the chloro-aurate with hydrochloric acid and gold chloride as described above.

N-Dimethylpiperidinium Bromide.—This salt was obtained in two ways. A portion of a solution of 5-bromo-amyldimethylamine in alcohol was evaporated and the product purified by crystallization. The same product was obtained when an ether solution of the bromo-amine was evaporated and the residue allowed to solidify at room temperature. The crude salt was recrystallized from a mixture of 50% ethyl acetate and 50% absolute alcohol. The pure salt melted at 324° (uncorr.).

Anal. Subs., 0.1110: 10.14 cc. of 0.0549 N $AgNO_3$. Calcd. for $C_7H_{16}NBr$: Br, 41.3. Found: Br, 41.2. The molecular weight was determined cryoscopically. Subs., 0.6166; H_2O, 24.904; At, 0.448°. Calcd. for $C_7H_{16}NBr$: Mol. wt., 194. Found: mol. wt., 100.

The structure of the N-dimethylpiperidinium bromide was confirmed by converting it to the chloroplatinate of N-dimethylpiperidinium chloride, which has been described by von Braun[14] as melting at 209–210°. The bromide was converted to the chloride as described under the pyrrolidinium salts. The chloroplatinate was prepared by the addition of chloroplatinic acid to the aqueous solution of dimethylpiperidinium chloride. It melted at 243° (uncorr.), with decomposition, after crystallization from water. Since this melting point did not agree with the one recorded by von Braun, a sample of the piperidine derivative was made for comparison.

Approximately 5 g. of piperidine was converted to N-dimethylpiperidinium chloride by the method used for the corresponding pyrrolidinium derivative. The aqueous, acid solution so obtained was treated with an excess of chloroplatinic acid and the salt crystallized from water. The chloroplatinate melted at 241° (uncorr.).

Anal. Subs., 0.1219: Pt, 0.0371. Calcd. for $(C_7H_{16}N)_2 \cdot PtCl_6$: Pt, 30.6. Found: Pt, 30.4.

Since pure 5-bromo-amyldimethylamine could not be isolated except in ether, the amount of ring compound formed was determined on a sample of amine which had been allowed to stand in alcohol for two months. About 5 cc. of bromo-amyldimethylamine hydrobromide solution which was equivalent to approximately 3 g. of bromo-amine was neutralized and extracted with ether as indicated in the general method. The

---

[14] Von Braun, *ibid.*, 33, 2735 (1900).

ether solution was transferred to a flask containing about 50 cc. of alcohol and the mixture allowed to stand. The quantity of bromo-amine lost during the neutralization as quaternary salt was not determined, although it was considerable. After standing the solvent was evaporated from the bromo-amine solution and the residue (0.65 *g.)* separated by fractional crystallization. The crude product thus obtained was dissolved in the minimum quantity of boiling solvent, composed of equal parts of ethyl acetate and absolute alcohol, and the solution cooled. After filtration, the filtrate was concentrated to incipient crystallization and again cooled. This process was repeated until the fractions became too small to handle, when the soluble end was mixed with all the previously used filter papers, extracted with alcohol, evaporated to dryness and the mixture again crystallized from the ethyl acetate–alcohol mixture. From the 0.65 g. of crude product there were obtained 0.413 *g.* of pure dimethylpiperidinium bromide and 0.23 g. of material that was slightly less pure.

N-Dimethylhexamethylene-iminium Bromide.—In one experiment a portion of the solution of 6-bromohexyldimethylamine in alcohol was evaporated and in another the pure distilled amine was allowed to solidify in the absence of a solvent. In either case the same product was obtained. Without a solvent the formation of quaternary salt seemed to take place more rapidly. The crude salt was crystallized from absolute alcohol, after which it melted at 289° (uncorr.).

Anal. Subs., 0.0940: 7.81 cc. of 0.0549 N $AgNO_3$. Calcd. for $C_8H_{18}NBr$: Br, 38.45. Found: Br, 38.70.

The molecular weight of N-dimethylhexamethylene-iminium bromide was determined cryoscopically. Subs., 0.2873: H_2O, 24.904; *At,* 0.165°. Calcd. for $C_8H_{18}NBr$: mol. wt., 208. Found: mol. wt., 130.

The structure of the N-dimethylhexamethylene-iminium bromide was determined by converting to a known derivative. Müller and Sauerwald[2] prepared the corresponding iodide and found it to melt at 265° (corr.).

About 1 *g.* of the dimethylhexamethylene-iminium bromide was shaken with an excess of an aqueous supension of silver oxide for one to two hours. After filtration the filtrate was acidified with hydriodic acid and evaporated to dryness. After crystallization from absolute alcohol the iodide thus obtained melted at 255° (uncorr.).

A sample of distilled 6-bromoheuyldimethylamine was allowed to stand at room temperature until the mass solidified. The product was then dissolved in the minimum quantity of boiling solvent composed of 80% ethyl acetate and 20% absolute alcohol. The fractionation was carried out in the same way as for the corresponding piperidine derivative. From 10 *g.* of the distilled amine there was obtained 5.6 *g.* of the pure quaternary ammonium salt.

N-Dimethylheptamethylene-iminium Bromide.—This salt could be obtained in appreciable quantity only by reaction of the bromo-amine with itself in the absence of a solvent. The formation of quaternary ammonium salt in alcohol was so slow that practically no material could be isolated during a reaction period of several weeks. A sample of distilled 7-bromoheptyldimethylamine was allowed to stand overnight. The solid mixture which formed was crystallized from the minimum quantity of a mixture of equal parts of ethyl acetate and absolute alcohol. The pure N-dimethylheptamethylene-iminium bromide melted at 268° (uncorr.).

Anal. Subs., 0.1326: AgBr, 0.1114. Calcd. for $C_9H_{20}NBr$: Br, 36.02. Found: Br, 35.86.

The molecular weight of N-dimethylheptamethylene-iminium bromide was determined cryoscopically. Subs., 0.2433: H_2O, 24.890; *At,* 0.165°. Calcd. for $C_9H_{20}NBr$: mol. wt., 222. Found: mol. wt., 111.

A second sample of bromo-amine was allowed to solidify overnight and the ring compound separated by crystallization from the above ethyl acetate–alcohol mixture in the same way as the dimethylpiperidinium bromide. There was thus obtained 0.59 g. of pure quaternary ammonium salt from 1.57 g. of the amine.

Summary

1. Halogenated aliphatic tertiary amines of the type $Br(CH_2)_nN(CH_3)_2$, in which n has the values 4, 5, 6 and 7 have been prepared.

2. These amines react with themselves to form cyclic quaternary ammonium salts in yields which indicate that ring formation is the principal reaction.

THE MECHANISM OF CARBOHYDRATE OXIDATION. XI. THE ACTION OF POTASSIUM HYDROXIDE ON MALTOSE

BY WILLIAM LLOYD EVANS AND MARJORIE PICKARD BENOY

RECEIVED JULY 22, 1929 PUBLISHED JANUARY 8, 1930

The fact that maltose is a disaccharide makes a study of its behavior toward aqueous solutions of potassium hydroxide a much more complex problem than is the case with the monosaccharides for the reason that it may react in any one or all of three general ways. (a) The molecule of maltose may undergo hydrolysis[1] into two molecules of glucose. In this case one should expect the experimental data obtained from equivalent solutions of glucose and maltose to be quantitatively the same. (b) Since maltose is a reducing sugar like glucose, there exists the possibility of the disaccharide molecule undergoing enolization[2] and subsequent decomposition without hydrolysis having taken place previously. (c) It is evident that both reactions may take place simultaneously, the extent to which the maltose is changed in either direction being probably dependent on such experimental factors as alkali concentration and temperature. To obtain data with reference to the behavior of maltose in alkaline solutions, when examined from this general standpoint, was the first objective of these experiments.

If maltose is found to react in accordance with possibility (b) or (c), the mechanism of the alkaline decomposition of the disaccharide might depend upon the presence of an equilibrated mixture of six glucosido-hexoses, maltose and its isomers, analogs of the sugars in the well-known de Bruyn and van Ekenstein systems. These would be maltose (4-glucosido-d-glucose), 4-glucosido-d-mannose, 4-glucosido-*d*-fructose, 4-glucosido-pseudo-*d*-fructose, 4-glucosido-d-a-glutose and 4-glucosido-*d*-β-glutose.[3] Under the

[3] Nef, *ibid.*, 403, 382 (1914).

conditions employed in our experiments, these glucosido sugars should react to give a series of 4-glucosido-hexose enediols. It is conceivable that these maltose isomers together with the 4-glucosido-hexose enediols and also the hexose sugars arising from any possible hydrolysis of the 4-hexosido-hexose sugars might form in these reaction mixtures a more general equilibrated condition which could be influenced by such experimental factors as the alkali concentration and the temperature.[4] To obtain some experimental data with reference to this latter point of view was the second objective of this study.

Experimental Part

The general procedures used in these experiments were exactly the same as those described in previous reports[5] from this Laboratory concerning the action of aqueous solutions of potassium hydroxide on the trioses and certain hexoses.

Materials. (a) Carbohydrates.—Maltose-monohydrate, d-glucose and *d*-mannose were purchased on the market and were found to be of the highest degree of purity.

(b) Reagents.—All reagents used in the various experimental operations were examined by the usual laboratory procedures as to their fitness for this study.

Manipulations. (a) Maltose and Potassium Hydroxide.—A 0.25 molar solution of maltose monohydrate was made by dissolving 2.251 g. of the disaccharide in 25 cc. of potassium hydroxide solution of the desired normality. This was agitated for forty-eight hours in a thermostat at the desired temperature. During this time the flask was kept closed with a well-fitting rubber stopper. At the end of the reaction period the solution was worked up for formic, acetic and lactic acids.

(b) Analytical Methods.—The necessary qualitative and quantitative methods have been described previously.

(c) Determination of Mannose Phenylhydrazone.—A portion of mannose weighing 2.251 g. was dissolved in a mixture of 25 cc. of potassium hydroxide solution of such strength as to give the final desired normality, 17.5 cc. of 95% alcohol and 5 cc. of phenylhydrazine. After this reaction mixture had been agitated in a thermostat at 25° for two hours, a light-colored precipitate was observed to separate out. At the end of forty-eight hours the solid was filtered, washed with acetone to remove any pyruvic aldehyde osazone, dried *in vacuo* at 55° and then weighed. The product was of a pale buff color. Samples were also similarly prepared using an equivalent weight of *d*-glucose. These were arranged into two groups: (1) the first group consisted of samples all of the same alkalinity (0.105 N), which were used as a time run, specimens being removed at intervals of several days, filtered, washed and weighed; (b) the second group of samples of varying alkali normalities was removed from the thermostat at the end of fourteen days, filtered, washed with acetone, dried and weighed. An exactly similar procedure was carried out with maltose, the time being twenty-six days.

The material was identified as mannose hydrazone by the known solubility of the compound in various reagents and by a comparison of its

[5] (a) Evans, Edgar and Hoff, *ibid.*, 48, 2665 (1926); (b) Evans and Hass, *ibid.*, 48, 2703 (1926); (c) Evans and Cornthwaite, *ibid.*, 50, 486 (1928); (d) Evans and Hutchman, *ibid.*, 50, 1496 (1928); (e) Evans and O'Donnell, *ibid.*, 50, 2543 (1928); (f) Evans, ***Chem. Reviews,*** 6, 281 (1929).

melting point with that of mannose hydrazone prepared from pure d-mannose in cold acetic acid solution. Our results on the latter method of identification are the following.

Mannose hydrazone from glucose	178–180°
Mannose hydrazone from mannose	178–180°
Mixture of the above two	182°
Mannose hydrazone from mannose	181°
Mixture of mannose hydrazone from both mannose and maltose	192°
Mannose hydrazone from mannose	190°

The brackets indicate that the samples were heated simultaneously. Because of the known variation in melting points of hydrazones and osazones with a change in the rate of heating, all such determinations recorded in our experiments were made by direct comparison with known material. The agreement between these two was considered much more significant than that with values recorded in the literature.[6] The melting point of mannose hydrazone recorded by Reiss, Tollens and Gans[7] is 186–188°, and that by Fischer is 196–200°.

The effect of varying the rate of heating is clearly shown in the following test carried out on some pure mannose-hydrazone used as a standard of comparison.

Rate of heating, degrees/minute	4	7	8
Melting point, °C.	178–180	183–186	190

The mannose hydrazone was a pale cream color when first precipitated, a pale buff after one crystallization from water and a decided yellow after a second crystallization. The color deepened to an orange if the material was allowed to stand overnight in contact with water. It came out of alcohol solution much lighter in color. Corrections were made for the solubility of the mannose phenylhydrazone in the data given in Fig. 6.

(d) **Pyruvic** Aldehyde.—Pyruvic aldehyde was determined as an osazone by the general method described by Evans and Hass.[5b]

Experimental Results.—The quantitative data obtained from our reaction mixtures are shown in graphical form in Figs. 1–6.

Theoretical Part

In attempting to outline the decomposition mechanism of maltose in alkaline solutions, one is confronted with an appalling lack of knowledge with reference to the possible complex reaction products. More particularly, the difficulties in dealing with the experimental data obtained from the action of aqueous solutions of potassium hydroxide on maltose lie in the following facts: (a) the five theoretically possible 4-glucosido-hexoses,

---

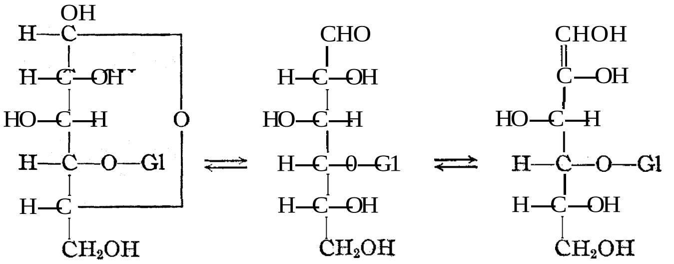
[6] Fischer, Ber., 21, 987 (1888); 22, 1156 (1889).

[7] Reiss, Tollens and Gans, *ibid.*, 22,610 (1889).

isomers of maltose, are unknown; (b) there is also much work to be done in the development of sharp methods for the quantitative separation of many known organic products which are obtained by the action of alkalies on the sugars. The recently established proof[8] that maltose is 4-glucosido-d-glucose increases the complexity of the problem. Maltose can no longer be regarded as glucose with an inactive glucosido section attached in such a way as not to interfere with the activity of the glucose portion of the molecule. The attachment at the fourth carbon atom makes a vital difference because it limits the extent of the enediolization. The yields of pyruvic aldehyde osazone, mannose hydrazone, lactic and acetic acids obtained by the interaction of maltose and potassium hydroxide at 25 and 50° are smaller than those obtained from equivalent solutions of glucose under exactly the same experimental conditions, while those of formic acid are greater. An[8a] examination of these facts seems to show that their quantitative aspects are best understood on the assumption that maltose, in alkaline solution, reacts to form a series of 4-glucosido-glucose enediols which may rupture at the double bond. The products obtained by such a fission may then react with the alkali present much after the well-known behavior of the hexose sugars under similar experimental conditions.

The following explanation is offered to account for the relative yields of reaction products found in our experiments on the alkaline decomposition of maltose when compared to those from glucose.

(a) Maltose-1,2-enediol (4-Glucosido-glucose-1,2-enediol).—The formation of maltose-1,2-enediol may be shown by the following equation



(1)

Maltose Maltose, aldehydo form[a] Maltose-1,2-enediol
Gl = Glucosido

A rupture of the maltose-1,2-enediol **(4-glucosido-glucose-1,2-enediol)** would result in the formation of 3-glucosido-arabinose and hydroxymethylene, as is shown in the reaction

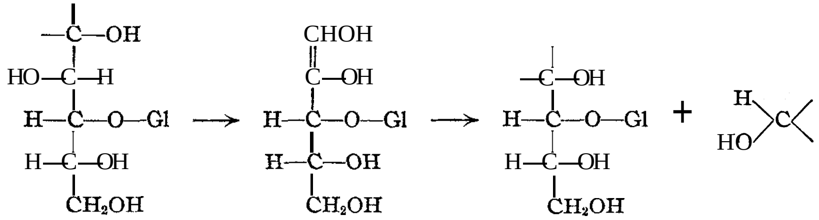
Maltose-1,2-enediol 3-Glucosido-arabinose, active form Hydroxy-methylene (2)

If sufficiently mild oxidizing agents were present, it is clear that 3-glucosido-arabonic and formic acids would be the reaction products. In the presence of potassium hydroxide maltose is oxidized by potassium permanganate to oxalic acid and carbon dioxide together with traces of acetic acid. The general relationship of the quantities of reaction products to the alkali concentration in the oxidation is in general similar to that of glucose.[10]

The 3-glucosido-arabinose thus formed may then in turn undergo an enediol formation with subsequent splitting into hydroxymethylene and 2-glucosido-erythrose. This change is shown in the equation



3-Glucosido-arabinose, active form 3-Glucosido-arabinose-1,2-enediol 2-Glucosido-erythrose, active form Hydroxy-methylene (3)

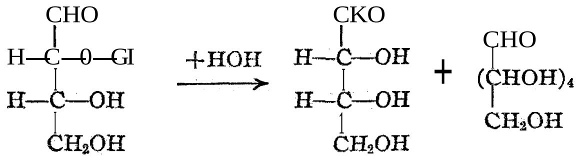
Under appropriate oxidizing conditions 2-glucosido-erythronic acid should be formed at this point. In connection with the possible formation of the 3-glucosido-arabinose and 2-glucosido-erythrose, it is of much interest to point out that Glattfeld and Hanke[11] oxidized maltose in an alkaline solution with air and with hydrogen peroxide. When the glucosido acids which they obtained as reaction products were hydrolyzed, they identified erythronic acid lactone and arabonic acid, the latter being recognized by means of its phenylhydrazide.

If the enediol formation can proceed no further, *i. e.*, if the CHO-Gl group remains intact, then it is possible for the 2-glucosido-erythrose to undergo hydrolysis with the formation of erythrose and glucose. This change is shown in the equation

---

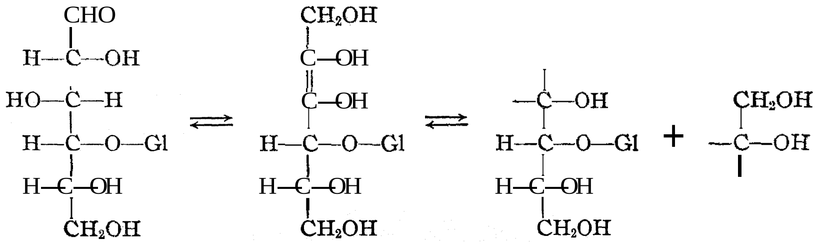
[10] Unpublished results.

[11] Glattfeld and Hanke, THIS JOURNAL, 40, 992 (1918).



2-Glucosidoerythrose Erythrose Glucose (4)

(b) **Maltose-2,3-enediol (4-Glucosido-glucose-2,3-enediol).**—As the temperature of the reaction and the concentration of the alkali are increased, there should be mote of a tendency for the general equilibrated condition present in the maltose solution to shift in the direction of forming a maltose-2,3-enediol, *i. e.*, **4-glucosido-glucose-2,3-enediol.** Its behavior in this respect would be represented by the reaction



Maltose, aldehydo form Maltose-2,3-enediol 2-Glucosido-erythrose, active form Glycol-aldehyde, active form (5)

Then it is clear that the 2-glucosido-erythrose thus formed would also yield glucose and erythrose as shown in Equation 4. If the mechanism of the alkaline decomposition of maltose is correctly set forth in these equations, then it is possible to offer a satisfying explanation for the relative amounts of lactic, acetic and formic acids and pyruvic aldehyde when this disaccharide is treated with aqueous solutions of potassium hydroxide under the same conditions of alkali normality and temperature as the monosaccharide, glucose.

Lactic Acid.—From the above-outlined decomposition of the maltose molecule it is seen that one molecule of the disaccharide may yield the following general results: (a) two molecules of hydroxymethylene, one molecule of erythrose and one molecule of glucose (Equations 1, 2, 3 and 4); (b) or it may yield one molecule of glycol aldehyde, one molecule of erythrose and one molecule of glucose (Equations 5 and 4). From a study of these possibilities it may be shown that only one-half of the maltose molecule yields lactic acid and that that portion of the disaccharide molecule is the glucosido section.[11a]

It has been established recently that the yields of lactic acid obtained from alkaline solutions of glucose are a function of both the alkali concentration and the temperature of the reacting system. An examination of

[11a] *Cf.* H. Wolff, *Biochem. Z.*, 210, 459 (1929).

Fig. 1 will show that the general characteristics of lactic acid formation in alkaline solutions of maltose are also practically the same as those obtained from glucose except that the yield is less in the case of the disaccharide, *i. e.*, it tends to be somewhat less than one-half at both temperatures.

Nef reached the conclusion that the tetroses in alkaline solutions did not give rise to the formation of a 1,2-enediol, *i. e.*, $CH_2OHCHOHC(OH)=CHOH$. The formation of this enediol would be essential because on fission it would yield glyceric aldehyde, a necessary intermediate in the production of lactic acid in alkaline solutions of the sugars. It is quite possible that the speed of rearrangement of the 1,2-enediol to the corresponding saccharinic acid is too rapid when compared to that of glyceric aldehyde formation. Nef came to his point of view because he found that *glycol aldehyde*[12] *did not yield the least trace of lactic acid* **when** it was *treated with S N potassium hydroxide solution.* However, he did obtain significant amounts of four carbon atom saccharinic acid (1,3-dihydroxybutyric acid), a fact which shows that a tetrose sugar had formed under the conditions of his experiments.[13] These general findings were confirmed in this Laboratory, although alkaline solutions were employed of lesser normality than those used by Nef.

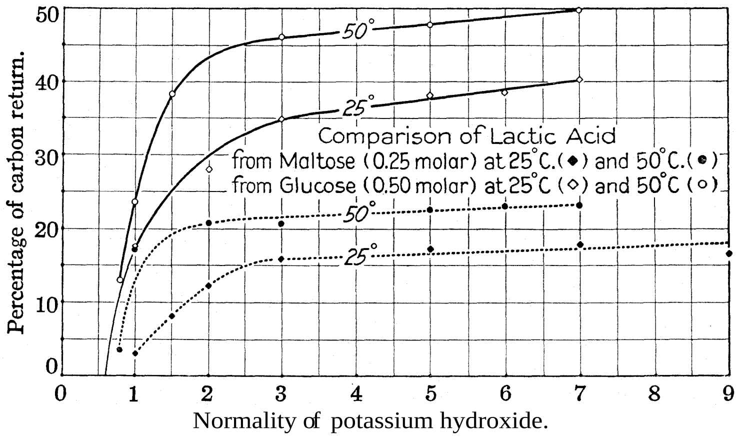


Fig. 1.

By reason of the facts pointed out in the two preceding paragraphs, namely, that glucose in alkaline solution will yield lactic acid and that erythrose under the same conditions will not do so, it is clear that on the basis of the above-outlined decomposition of maltose the conclusion must be reached that the source of the lactic acid in this reaction is the glucosido section of the disaccharide molecule and not the glucose section.

---

[12] Nef, *Ann.*, 376, 40 (1910).

[13] *Cf.* Fischer and Landsteiner, *Ber.*, 25,2553 (1892).

Since 0.25 molar maltose (equivalent to 0.50 molar glucose) and 0.50 molar glucose solutions were used, it is now evident that the lactic acid yields from maltose should tend to be one-half those which could be obtained from glucose. On the basis that the lactose molecule is 4-galactosido-glucose, it may be predicted safely that this well-known sugar will not yield much lactic acid when treated with aqueous solutions of potassium hydroxide under the same conditions that were used in our maltose study. This arises from the fact that the hexosido section of the milk sugar molecule[3] does not give rise to much lactic acid in alkaline solutions, while the hesose seticon of this sugar gives rise to a tetrose which, as is pointed out above, does not give the 1,2-enediol which is necessary for lactic acid formation. Mr. Robert C. Hockett of this Laboratory is at present studying the behavior of the disaccharides toward aqueous solutions of potassium hydroxide.

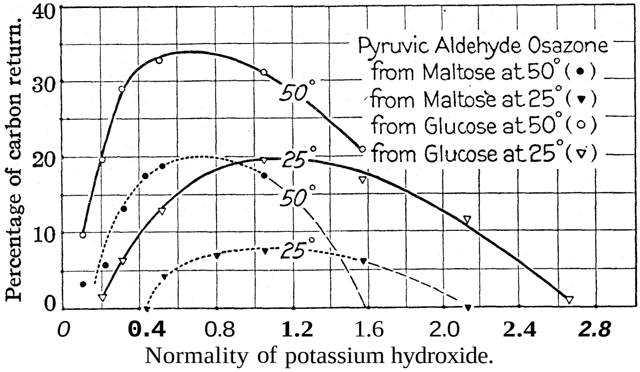

Fig. 2.

Should 3-glucosido-arabinose hydrolyze to any great degree, the yields of lactic acid should tend to be greater than those which we found, because Mr. Rollin F. Conaway of this Laboratory has shown recently that arabinose in alkaline solutions will yield pyruvic aldehyde, which changes under these conditions to lactic acid.

Pyruvic Aldehyde Osazone.—If the above reactions of maltose take place, then the disaccharide in alkaline solution should give rise to yields of pyruvic aldehyde osazone in amounts which approximate one-half those obtained from equivalent solutions of glucose. By our experimental methods this was shown in general to be true (Fig. 2). Pyruvic aldehyde is the forerunner of lactic acid. It is derived from the glyceric aldehyde obtained through a splitting of the 3,4-enediol of the glucosido section of the maltose molecule. Alkaline solutions of glycol aldehyde do not give rise to pyruvic aldehyde osazone when the experiment is carried out under the same conditions as are used with sugars that do so react. Hence, any tetrose formed from glycol aldehyde will not give a 1,2-enediol, a reaction necessary for the production of glyceric aldehyde, which, in turn, is the forerunner of pyruvic aldehyde.

Formic Acid.—It has been pointed out previously that formic acid may arise from the action of alkalies on hydroxymethylene. In the above equations it is seen that the glucose section of the maltose molecule yields at least two molecules of hydroxymethylene. Since erythrose forms a 2,3-enediol in preference to a 1,2-enediol, then two molecules of glycol aldehyde (active form) will form according to the equation

$$\mathrm{CH_2OHC(OH){=}C(OH)CH_2OH \rightleftharpoons 2CH_2OH\overset{\diagdown\diagup}{C}(OH)} \qquad (6)$$

It has been shown in this Laboratory that alkaline solutions of glycol aldehyde will yield formic acid. Since the glucosido section of the maltose molecule will yield formic acid also, then it becomes clear from all of these facts that alkaline solutions of maltose should produce more formic acid than do equivalent alkaline solutions of glucose. From the data in Fig. 3 this comparison is found to be true.

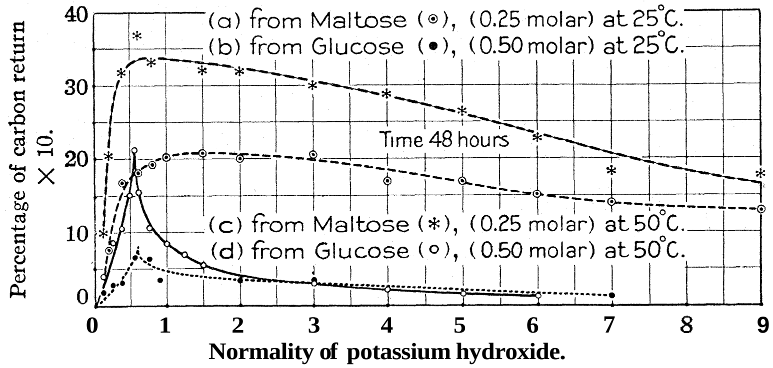

Fig. 3.—Comparison of formic acid.

Acetic Acid.—Our data, Fig. 4, with reference to acetic acid production in alkaline solutions of maltose show that this acid is found in smaller amounts than it is in alkaline solutions of glucose. The possible sources of acetic acid arising from the alkaline decomposition of maltose as given by the above equations may be these: (a) pyruvic aldehyde formed in the alkaline decomposition of the glucosido section of the maltose molecule; (b) the glycol aldehyde obtained in Equation 5 and also that arising from the splitting of the tetrose-2,3-enediol in Equations 4 and 5. Since not over 1% of glycol aldehyde carbon is returned as acetic acid under the conditions of these experiments, then from our data it may be fairly concluded that the principal source of acetic acid in these maltose reactions must be the glucosido section of the disaccharide molecule. From these statements it is clear that the amounts of acetic acid obtained from maltose must be less than those arising from equivalent solutions of glucose. Whether 2,3-dihydroxybutyric acid formed from the action of potassium hydroxide on the tetrose present will yield acetic acid has not yet been established.

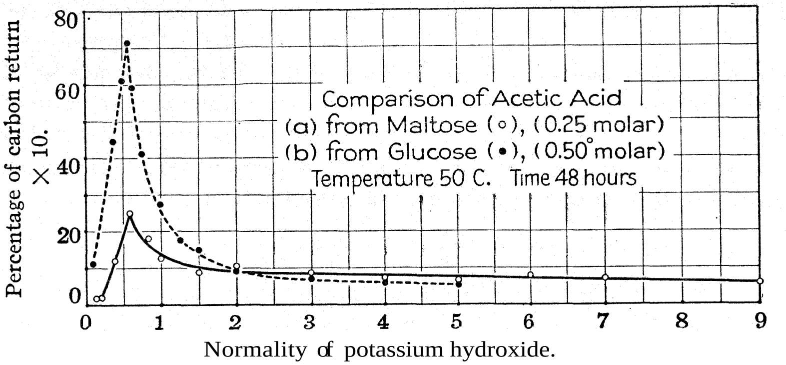

Fig. 4.

Production Relation of Reaction Products.—From Fig. 5 it is seen that the data obtained for pyruvic aldehyde osazone, lactic, acetic and formic acids from alkaline solutions of maltose are of the same general character as those which have been obtained previously in this Laboratory from glucose, mannose and fructose, a fact which would seem to support the points of view set forth in the above explanation of the mechanism involved in the alkaline decomposition of maltose.

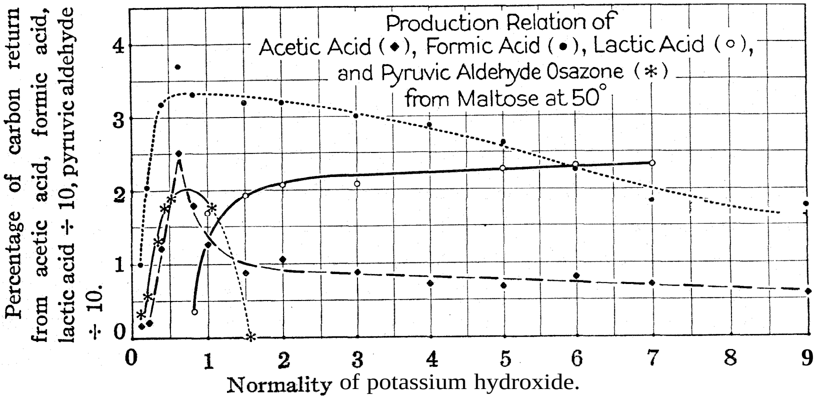

Fig. 5.

Effect of Temperature and Alkali Concentration.—Our data on the alkaline decomposition of maltose show that the effects of alkali concentration and increased temperature are of the same general type as those obtained with the hexose sugars.

The Hydrolysis of Maltose. (a) **Mannose Hydrazone.**—De Bruyn and van Ekenstein[14] obtained d-mannose phenylhydrazone from maltose after boiling it for three hours in a **0.166** N potassium hydroxide solution. Kolb[15] also obtained it at room temperature after the sugar had stood with a dilute barium hydroxide solution for a long period. It is clear that the mannose in these two cases might have arisen from the following sources. (1) Glucose arising from the possible hydrolysis of maltose would be converted into the well-known series of hexose sugars, one of which is mannose. (2) The theoretically possible 4-glucosido-mannose might be hydrolyzed into its possible monosaccharide units. The possibility of the existence of the 4-glucosido-mannose in an alkaline solution seems to be borne out by the fact that Lewis[16] obtained mannonic acid lactone from the hydrolysis of the glucosido products resulting from the oxidation of maltose with alkaline copper hydroxide. To *obtain mannose as its hydrazone from an alkaline solution of maltose would therefore seem to be proof that an hydrolysis of a 4-glucosido-hexose compound had occurred.* The results of our experiments are shown in Fig. **6.** The first formation of a noticeable precipitate of mannose phenylhydrazonefrom maltose in **0.105** N potassium hydroxide solution occurred after eleven days at 25°. A corresponding sample of d-glucose under similar conditions showed some precipitate in five days, thus making it appear that the conversion of maltose into its monosaccharide

units by either Mechanism 1 or 2 required about the same length of time as the formation of the mannose phenylhydrazone from glucose. The formation of the hydrazone directly from mannose is very rapid since precipitation began within two hours. In the long periods during which these sugars were exposed to the action of alkaline solutions, longer for maltose than for d-glucose, the mannose hydrazone was no doubt being decomposed, so that sharp comparisons between the curves cannot be made nor far-reaching conclusions drawn, but some interesting suggestions are contained in the data. (1) A comparison of corresponding points on the two curves shows that the maltose values are approaching those for d-glucose, and also that the hydrolysis of maltose or its glucosido isomers is a function of the alkalinity.[17] (2) The rise in the two curves shows that the de Bruyn and van Ekenstein equilibrium is disturbed by changes in the alkali normality. (3) The downward trend of these curves is thought to be due to the fact that the hexose enediols are beginning to undergo splitting at their double bonds, a reaction which would result in lowering the available concentration of the hexose sugars. It is a noteworthy fact in this connection that the maxima are between 0.15–0.20 N alkali, a value slightly above that (0.05 N) which Nef[18] indicated as the point where enediolic splitting first begins for the hexoses. The only significance of the mannose curve is that it marks off the regional limits in which we might hope to find the hydrazone in the case of the other sugars. This curve is taken as a measure of the decrease in the concentration of the aldehydo form of this sugar in the presence of an increase in the alkali normality. This seems to be in harmony with the point of view expressed by Wohl and Neuberg[19] and Fischer with reference to the non-formation of the hydrazones from the salts of the enediols.

(b) Pyruvic Aldehyde **Osazone.**—A comparison of the mannose phenylhydrazone curves from maltose and glucose with those of pyruvic aldehyde osazone obtained from these sugars seems to indicate very strongly that an increase in the concentration of the alkali causes a change in the equilibrium present which favors a splitting of the maltose enediols. Such *a* change should result in a decrease in the yields of derivatives obtained from 4-glucosido-hexose sugars and an increase in the products arising from the fission of glucosido sugars containing less than 12 carbon atoms. Attention is directed to the fact that the mannose hydrazone formation from both glucose and maltose ceases at approximately the same alkalinity (0.42 N) as that at which pyruvic aldehyde formation begins at 25°.

Summary

1. Objectives of these experiments were as follows: (a) to determine whether maltose in alkaline solutions reacts in accordance with the views that postulate the presence of hexosido-hexose-enediols or whether it undergoes hydrolysis at the glucosido union; (b) to ascertain whether temperature and the concentration of the alkali used influence the character of the reaction products.

2. (a) Maltose was dissolved in aqueous solutions of potassium hydroxide of various normalities (0.1–9.0), the sugar concentration being 0.25 molar. After forty-eight hours of agitation at 25 and 50°, the reaction mixtures were quantitatively examined for acetic, lactic and formic acid. (b) Similar aqueous-alcoholic solutions of maltose, phenylhydrazine and potassium hydroxide were examined for pyruvic aldehyde osazone.

3. Maltose yields larger amounts of formic acid than glucose does under exactly the same conditions, while smaller amounts of pyruvic aldehyde osazone, lactic and acetic acids are obtained than from the hexose sugar.

4. These quantitative differences between maltose and glucose have been explained on the assumption that the disaccharide forms two enediols, namely, maltose-1,2-enediol (4-glucosido-glucose-1,2-enediol) and maltose-2,3-enediol (4-glucosido-glucose-2,3-enediol)). Since the glucosido linkage is on the fourth carbon atom, it is further assumed that the 4-glucosido-glucose-3,4-enediol does not rupture, if formed.

5. Maltose-1,2-enediol (4-glucosido-glucose-1,2-enediol) may split into hydroxymethylene and 3-glucosido-arabinose, and this latter product in turn may yield 2-glucosido-erythrose and hydroxymethylene. Maltose-2,3-enediol (4-glucosido-glucose-2,3-enediol) may split into 2-glucosido-erythrose and glycol aldehyde. The 2-glucosido-erythrose formed in both cases may undergo hydrolysis into erythrose and glucose.

6. In its alkaline decomposition by the above mechanism the maltose molecule tends to form one molecule of glucose (*i.e.*, one-half of the maltose molecule), one molecule of erythrose and two molecules of hydroxymethylene. Under these experimental conditions glucose is the only one of these products which will form lactic acid in alkaline solution. As shown experimentally the yields of this acid should tend toward a value one-half that of an equivalent solution of glucose.

7. Pyruvic aldehyde is derived from glyceric aldehyde, which must be derived from glucose or any possibly formed arabinose. Since erythrose and hydroxymethylene do not yield pyruvic aldehyde, the experimental yields of pyruvic aldehyde osazone may be less than those of equivalent solutions of glucose, *i. e.*, should tend toward one-half the values obtained from the hexose. This was found to be the case.

8. Formic acid may be obtained from the two molecules of hydroxymethylene, erythrose (the alkaline glycol aldehyde of these experiments)

and glucose. These combined sources should yield more formic acid than an equivalent solution of glucose. This was found to be true.

9. Acetic acid is obtained in much smaller amounts from glucose than it is from erythrose. On the basis of the above-outlined decomposition of maltose, less acetic acid should be obtained from it than from glucose. Our data are in harmony with this point of view.

10. An experiment was made with maltose in the presence of phenylhydrazine at the lower alkalinities, seeking mannose hydrazone as an index of hydrolysis, a control being run with glucose. Mannose hydrazone was first obtained from maltose in eleven days, at 25°; after nineteen days the production reached a constant value. The hydrazone was obtained between 0.05–0.42 N potassium hydroxide. The presence of mannose is thought to be due to its formation from the glucose obtained by the hydrolysis of maltose or of 4-glucosido-mannose at the lower alkalinities.

11. The assumption of the presence of glucosido-hexose enediols and their degradation products in alkaline solutions of maltose seems to be in harmony not only with our experimental data, but also with those of Lewis and Buckborough,[1] and Glattfdd and Hanke.

12. Our data seem to be in harmony with the view that the two kinds of decomposition open to the maltose molecule—enediolic splitting and hydrolysis—go on simultaneously in alkaline solution, but whereas the former is a rapid function of the time, the latter is a very slow one.

ACETYL CHOLINE CHLORIDE

BY LAUDER W. JONES AND RANDOLPH T. MAJOR

RECEIVED JULY 23, 1929 PUBLISHED JANUARY 8, 1930

Choline and its esters have achieved considerable importance in recent years due to their property of producing a marked vasodilation[1] and also because it has been shown that they are normally present in the serous coat of the intestine and probably are the normal peristaltic hormones.[2] The acetyl derivative is especially interesting since it has been found that it possesses a depressor effect 100,000 times as great as that produced by choline itself and yet it is only three times as toxic as this substance.[3]

Salts of acetyl choline have been found in certain natural products.[4] Baeyer and later Nothnagel synthesized the chloride by acetylating

choline chloride with acetyl chloride.[5] Fourneau and Page have made acetyl choline chloride by treating trimethylamine with chloro-ethyl acetate,[6] and recently Abderhalden and Paffrath have obtained small yields of acetyl choline by the action of sodium acetate on choline in the presence of an enzyme.[7]

However, none of these investigators seem to have isolated pure acetyl choline chloride, analyzed it and determined its physical properties. Fourneau and Page unsuccessfully attempted to obtain the pure salt by recrystallizing the product formed by the interaction of trimethylamine and chloro-ethyl acetate. They used a methanol-acetone solution as a crystallizing medium, but found that acetyl choline chloride was hydrolyzed in this process.[6] Later Hunt reported that a solution of acetyl choline chloride in ethyl alcohol decomposed extremely slowly.[8]

Due to the rather widespread use of acetyl choline chloride in pharmacological investigations, it was thought that it might be of interest to isolate the pure salt, to determine its melting point and its other properties. This has been done and it has been possible to corroborate the statement made by Hunt that the compound is not appreciably hydrolyzed when it is dissolved for a short time in ethyl alcohol. Also because of the interest in this substance it was thought that another method of synthesizing it would be of value.

Accordingly, the hydrochloride of dimethylamino-ethyl acetate has been prepared from dimethylamino-ethyl alcohol and acetyl chloride, according to the equation

$$(CH_3)_2NC_2H_4OH + CH_3COCl \longrightarrow (CH_3)_2NHClC_2H_4OCOCH_3$$

Alkali converted this into its free base. This compound had previously been prepared by methylating amino-ethyl acetate, but only its physiological properties were described.[9] Treatment of dimethylamino ethyl acetate with methyl iodide gave acetyl choline iodide

$$(CH_3)_2NC_2H_4OCOCH_3 + CH_3I \longrightarrow (CH_3)_3NIC_2H_4OCOCH_3$$

from which the chloride was obtained by shaking a solution of the iodide in alcohol with silver chloride. Acetyl choline chloride was found to be a white hygroscopic solid melting at 151°. Prom this the chloroplatinate was prepared; the temperature at which decomposition occurred, 227°, corresponded rather closely to the temperature of decomposition, 223–224°, assigned by Nothnagel[5] to the chloroplatinate of acetyl choline,

hut differed markedly from the value 256–257° given to this compound by Ewins.[10] A chloro-aurate of acetyl choline was also prepared by the method described by Baeyer[6] and later by Nothnagel.[5] The analysis of this compound agreed with that of acetyl choline chloro-aurate and all of its properties corresponded with those ascribed to this substance by Baeyer and Nothnagel except that our acetyl choline chloro-aurate melted at 168–169° while Nothnagel[6] found the melting point to be 154–155°. The reason for this difference in the melting points of these apparently otherwise identical chloro-aurates is not clear but it is well known that, due to different physical modifications, the melting point often is a criterion of little significance when one is investigating salts such as chloro-aurates and chloroplatinates.[11]

Experimental Part

Preparation of Dimethylamino-ethyl Acetate, $(CH_3)_2NC_2H_4OCOCH_3$.—To a solution of 0.2 of a mole of acetyl chloride in dry ether was slowly added, under a reflux condenser, 0.2 of a mole of dimethylamino-ethyl alcohol (Eastman Kodak Company). There was a vigorous reaction and a white solid formed at once. The solid was collected on a filter and dissolved in water. This solution was extracted with ether to remove any excess of acetyl chloride, after it had been made slightly more acidic with a little hydrochloric acid, in order more readily to hold all of the amine in the aqueous layer. More ether was then added and, while it was kept cold and stirred, the solution was made basic to phenolphthalein with solid potassium carbonate and a little caustic soda. The ether layer was separated and the aqueous solution was repeatedly extracted with ether. The ether extracts were combined and dried with anhydrous potassium carbonate. Fractional distillation yielded dimethylamino-ethyl acetate as a colorless oil; b. p. (80 mm.) 86–88"; yield, 47%.

Hydrochloride.—Dry hydrogen chloride was passed into a solution of dimethylamino-ethyl acetate in anhydrous ether. A white solid precipitated. It was recrystallized by dissolving it in absolute alcohol and reprecipitating it with ether; m. p. 129–130". It was very hygroscopic.

Anal. Subs., 0.2038: AgCl, 0.1752. Calcd. for $C_6H_{14}O_2NCl$; Cl, 21.18. Found: Cl, 21.31.

Preparation of Acetyl Choline Iodide, $(CH_3)_3NC_2H_4OCOCH_3$.—To a solution of 0.02 of a mole of dimethylamino-ethyl acetate in dry ether was added 0.02 of a mole of methyl iodide. A white solid at once formed. This solid was recrystallized from hot absolute alcohol; m. p. 160–162°; yield, 90%.

Anal. Subs., 0.2297: AgI, 0.1962. Calcd. for $C_7H_{16}O_2NI$: I, 46.40. Found: I, 46.25.

Preparation of Acetyl Choline Chloride, $(CH_3)_3NClC_2H_4OCOCH_3$.—A concentrated solution of acetyl choline iodide in warm absolute alcohol was shaken with a slight excess of silver chloride until the solution gave no further test for the iodide ion. The silver salts were removed by filtration and acetyl choline chloride was precipitated as a white solid by adding dry ether to the filtrate. In order to rid this solid of a trace of silver chloride it was added to some absolute alcohol which had previously been saturated

---

[10] Ewins, *Biochem. J.*, 8, 48 (1914).

[11] F. Beilstein, "Handbuch der organischen Chemie," Julius Springer, 1922, 4th ed., Vol. 4, pp. 204, 280; Willstatter, *Ber.*, 35, 2700 (1902).

with hydrogen sulfide. The silver precipitated as silver sulfide but the acetyl choline chloride readily dissolved. In order to separate the silver sulfide more easily, activated charcoal which previously had been washed with absolute alcohol was added. The mixture was shaken for a few minutes and then filtered. Acetyl choline chloride was reprecipitated from the filtrate by the addition of dry ether; m. p. 151°; yield, 65%. It was very soluble in water and alcohol, but insoluble in ether. It was extremely hygroscopic.

Anal. Subs., 0.2344: AgCl, 0.1867. Calcd. for $C_7H_{16}O_2NCl$; Cl, 19.53. Found: Cl, 19.70.

Chloroplatinate.—The calculated amount of a concentrated solution of chloroplatinic acid in absolute alcohol was added to 0.1 g. of acetyl choline chloride in absolute alcohol. An orange-colored precipitate soon formed. It was recrystallized from hot water and then washed with water and alcohol; m. p. 227° with decomposition.

Anal. Subs., 0.1296: Pt, 0.0362. Calcd. for $C_{14}H_{34}O_4N_2PtCl_6$: Pt, 27.81. Found: Pt, 27.93.

Chloro-aurate.—To 0.46 g. of acetyl choline chloride dissolved in water was added the calculated amount of a concentrated solution of auric chloride in water. An orange-colored solid at once precipitated. It was recrystallized from hot water; m. p. 168–169°.

Anal. Subs., 0.2212: Au, 0.0894. Calcd. for $C_7H_{16}O_2NAuCl_4$: Au, 40.55. Found: Au, 40.42.

Summary

1. Dimethylamino-ethyl acetate has been prepared by adding alkali to the product formed by the interaction of acetyl chloride and dimethylamino-ethyl alcohol.

2. Acetyl choline iodide was formed when dimethylamino-ethyl acetate was treated with methyl iodide. From the iodide the corresponding chloride, chloroplatinate and chloro-aurate were made.

PAPAVERINE: AN ATTEMPTED RÜGHEIMER SYNTHESIS

BY IVEY ALLEN, JR., AND JOHANNES S. BUCK

RECEIVED JULY 23, 1929 PUBLISHED JANUARY 8, 1930

A simple general synthesis of the papaverine type of alkaloid is for many reasons of great importance, particularly so as it would offer a possible means of synthesizing the tetrahydroberberine type of alkaloid.[1] The two methods[2] for synthesizing papaverine which have been worked out are probably only of scientific interest on account of the inaccessibility of the starting materials. An ideal starting point for the synthesis of isoquinoline alkaloids would be a benzoin or a benzil. Such a synthesis was attempted by Fritsch,[3] who condensed desoxyveratroin with amino-acetal and at-

---

[2] Pictet and Gams, *Ber.*, 42, 2943 (1909); Buck, Haworth and Perkin, *J. Chem. Soc.*, 125,2176 (1924).

[3] Fritsch, *Ann.*, 329, 37 (1903).

tempted to cyclize the product after the method of Pomeranz.[4] No papaverine was obtained. Fritsch obtained his desoxyveratroin by a rather involved series of reactions from veratrole and dichloro-acetaldehyde, while the authors prepared this material from veratric aldehyde, via veratril.

Rugheimer and Schön[5] prepared dimethoxyisoquinoline by condensing veratrylamine with chloro-acetal and cyclizing the product, using sulfuric acid and arsenic pentoxide as cyclizing agents. In a similar manner tetramethoxydiphenylethylamine should condense with chloro-acetal to tetramethoxystilbylainino-acetaland this product be capable of cyclization to papaverine.[6] The authors undertook to investigate this possibility. It was realized at the outset that the chances were against success, as many failures of the Rugheimer synthesis are recorded, among them the failure of Salway[7] and later Rügheimer[8] to cyclize myristicylamino-acetal. In addition, it is known that papaverine is unstable to sulfuric acid above about 80%, even without the presence of oxidizing agents? However, the importance of the issue was considered to justify the attempt. The expected result was obtained, namely, that tetramethoxystilbylamino-acetal cannot be cyclized to papaverine and that, therefore, the Riigheimer synthesis is not applicable to the benzylisoquinoline alkaloids such as papaverine.

As a check on the work, the same process was carried out with the corresponding methylenedioxy derivatives, starting with piperonal in place of veratric aldehyde. Exactly parallel results were obtained, the stilbylamino-acetal being destroyed and not cyclized at the last stage.

The stages in the attempted synthesis are as follows

$(CH_3O)_2C_6H_3CHO \longrightarrow (CH_3O)_2C_6H_3CHOHCOC_6H_3(OCH_3)_2 \longrightarrow$

Veratric aldehyde Veratroin

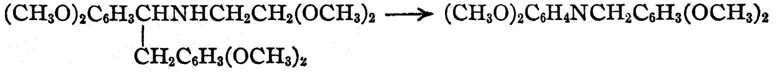
$(CH_3O)_2C_6H_3COCOC_6H_3(CH_3O)_2 \longrightarrow (CH_3O)_2C_6H_3CH_2COC_6H_3(OCH_3)_2 \longrightarrow$

Veratril Desoxyveratroin

$(CH_3O)_2C_6H_2CH_2C(NOH)C_6H_3(OCH_3)_2 \longrightarrow (CH_3O)_2C_6H_3CH_2CHNH_2C_6H_3(OCH_3)_2$

Desoxyveratroin oxime Tetramethoxydiphenylethylamine (Tetramethoxystilbylamine)

Sym.-diphenylethane is an unsuitable root for the naming of side-chain derivatives. It was, therefore, re-named "stilbane" (by analogy with stilbene) in this paper. The radical stilbyl is then $C_6H_5CH_2CHC_6H_5$ and the radical stilbylidene, $C_6H_5CH_2CC_6H_5$.



$$\underset{\textstyle CH_2C_6H_3(OCH_3)_2}{(CH_3O)_2C_6H_3CHNHCH_2CH_2(OCH_3)_2} \longrightarrow (CH_3O)_2C_6H_4NCH_2C_6H_3(OCH_3)_2$$

Experimental

Veratril.—Veratric aldehyde, prepared by the method of Buck and Perkin[10] was converted into veratril substantially as described by Vanzetti.[11]

Desoxyveratroin. First Method.[12]—Twenty grams of veratril, 200 cc. of alcohol, 40 g. of granulated tin and 5 cc. of saturated copper sulfate solution were heated on the water-bath for four hours, during which time 200 cc. of concentrated hydrochloric acid containing 15 cc. of copper sulfate solution was gradually added. The mixture was filtered, diluted with an equal volume of water and allowed to stand. The product which separated was filtered off and recrystallized from alcohol. It forms colorless needles melting at 107°.

Anal. Calcd. for $C_{18}H_{20}O_5$: C, 68.36; H, 6.33. Found: C, 68.31; H, 6.29.

Second Method.[13]—Seven grams of homoveratric acid (prepared by the method of Haworth and co-workers)[14] was dissolved in 20 cc. of chloroform and 5.0 g. of thionyl chloride added. The mixture was refluxed for forty minutes on the water-bath, the chloroform then distilled off and 30 cc. of carbon disulfide and 11 g. of veratrole (prepared from guaiacol and methyl sulfate) added; 12 g. of anhydrous aluminum chloride was introduced in portions through the condenser and the whole refluxed for two hours, allowed to stand for a further two hours and then treated with water. The carbon disulfide layer was separated and water added, after which steam was passed through to remove the solvent and excess veratrole. After purification from dilute alcohol, the product melted at 107° and was identical with the desoxyveratroin prepared by the first method. It corresponded exactly with the description given by Fritsch.[3]

Desoxypiperoin.—Fifty grams of piperoin (prepared after the method of Perkin),[15] 40 g. of granulated tin and 200 cc. of alcohol were heated on a steam-bath under a reflux condenser, 73 cc. of concentrated hydrochloric acid containing a little copper sulfate was added and the whole refluxed for three hours. A further 50 cc. of alcohol and 20 cc. of acid with a little copper sulfate were then added and the heating continued for one and one-half hours. On cooling, the product crystallized out. A further amount separated on diluting the liquor; yield, 23 g. Desoxypiperoin forms small white needles melting at 114° when crystallized from alcohol, in which it is sparingly soluble.

Anal. Calcd. for $C_{16}H_{12}O_5$: C, 67.61; H, 4.24. Found: C, 67.48; H, 4.40.

Desoxyveratroin **Oxime.**—Fifty grams of desoxyveratroin and 12.5 g. of hydroxylamine hydrochloride were heated with 125 cc. of pyridine on a boiling water-bath for five hours. The solution was then diluted with water to 500 cc. and allowed to stand. The oil which separated became crystalline on standing; yield, 38 g. The oxime forms fine white needles melting at 128° when crystallized from alcohol.

Anal. Calcd. for $C_{18}H_{21}O_5N$: C, 65.27; H, 6.34; N, 4.2. Found: C, 65.03; H. 6.26; N, 4.5.

Desoxypiperoin Oxhe.—Twenty grams of desoxypiperoin was heated on a water-bath for two hours with 50 cc. of pyridiie and 5 g. of hydroxylamine hydrochloride. On adding water to incipient precipitation and allowing the mixture to stand, the oxime crystallized out; yield, 19 g. Desoxypiperoin oxime crystallizes from alcohol, in which it is sparingly soluble, in colorless needles melting at 158°.

Anal. Calcd. for $C_{16}H_{13}O_5N$: C, 64.21; H, 4.35; N, 4.7. Found: C, 64.40; H, 4.51; N, 4.7.

Tetramethoxystilbylamine.[16]—Twenty grams of desoxyveratroin oxime dissolved in 200 cc. of alcohol was treated while hot with 800 g. of 3.5% sodium amalgam, and 100 cc. of glacial acetic acid added in portions during one hour, the mixture being kept hot and water being added as required to keep the sodium acetate formed in solution. When cool, the mixture was diluted to 400 cc. with water and allowed to stand overnight to permit the separation of unchanged oxime. After removing the mercury and filtering, a slight excess of ammonia was added. The resulting precipitate was filtered off and recrystallized; yield, 15 g. Tetramethoxystilbylamine forms glistening plates melting at 107° when crystallized from water, in which it is sparingly soluble. It is soluble in cold alcohol and benzene, sparingly soluble in ether and insoluble in petrol ether. The hydrochloride forms white crystals melting at 195°. The hydrobromide is pale yellow and melts at 241°.

Anal. Calcd. for $C_{18}H_{23}O_4N$: C, 68.14; H, 7.25; N, 4.4. Found: C, 68.06; H, 7.48; N, 4.5.

Acetyl Derivative.—Acetylation by means of acetic anhydride gave the acetyl compound, which crystallized from alcohol in a felted mass of colorless needles melting at 160–162°.

Anal. Calcd. for $C_{20}H_{25}O_5N$: N, 3.9. Found: N, 4.0.

Dimethylenedioxystilbylamine.—This compound was prepared in the same manner as the foregoing tetramethoxy compound, the same quantities being used; yield, 17 g. It is best purified by recrystallizing the hydrochloride from alcohol and then suspending the salt in hot water and adding an excess of ammonia. The base is readily soluble in cold alcohol and benzene and sparingly soluble in ether and petrol ether. Recrystallized from water, in which it is sparingly soluble, it forms long shining needles melting at 111°. The hydrochloride forms colorless needles melting at 245".

Anal. Calcd. for $C_{16}H_{15}O_4N$: C, 67.38; H, 5.26; N, 4.9. Found: C, 67.79; H, 5.44; N, 5.2.

Acetyl Derivative.—The acetyl derivative prepared by acetylation of the base with acetic anhydride crystallizes from dilute acetic acid in small clusters of tiny colorless needles melting at 141°.

Anal. Calcd. for $C_{18}H_{17}O_5N$: N, 4.3. Found: N, 4.1.

Tetramethoxystilbylamino-acetal.—Three grams (1 mole) of tetramethoxystilbylamine and 1.0 g. (0.5 mole) of bromo-acetal were heated slowly in an oil-bath until the temperature reached 150° (forty-five minutes). After cooling, the mixture was sludged with ether and filtered. The precipitate of tetrarnethoxystilbylamine hydrobromide was filtered off with suction and washed with ether. The filtrate and washings were united and the ether was evaporated. The product, like practically all compounds of this class, formed a reddish oil which could not be crystallized and which gave no crystalline derivatives. In the presence of reagents it gave back the original amine by fission with rather unusual ease. The material obtained was used directly for subsequent experiments.

Dimethylenedioxystilbylamino-acetal.—This was prepared in the same manner as the foregoing tetramethoxy compound except that the heating was carried out at 125°. It also forms a reddish oil, uncrystallizable and giving no crystalline derivatives.

Action of **Cyclizing** Agents on **Tetramethoxystilbylamino-acetal.**—The method of

---

[16] *Cf.* Goldschmidt and Polonowska, Ber., 20, 492 (1887); Strandmark. *Svensk Kem. Tid.*, 18, 3 (1906).

investigation was to take 1.5 g. of tetramethoxystilbylamino-acetal and 2.0 g. of arsenic pentoxide, together with 20 cc. of sulfuric acid, and to heat the mixture on the water-bath for thirty minutes. The reaction mixture was poured into water and neutralized. Nothing but black amorphous material which could not be purified and from which no derivatives were obtainable was ever found. The starting material was evidently completely destroyed. Acid of 30, 50, 65 and 75% strength was tried in the hot as well as 65 and 75% acid in the cold. Dimethylenedioxystilbylamino-acetal was completely destroyed by 75% sulfuric acid and arsenic pentoxide in the cold.

It is, therefore, evident that the stilbylamino-acetals are unstable under the rather drastic treatment required to produce a Riigheimer cyclization and that further, work along these lines would be profitless.

Summary

Tetramethoxystilbylamino-acetal and dimethylenedioxystilbylamino-acetal were prepared from veratric aldehyde and piperonal, respectively, in an attempt to synthesize papaverine and the corresponding dimethylenedioxybenzylisoquinoline. The stilbylamino-acetals were found to be unstable to the usual cyclizing agents, thus precluding the synthesis of papaverine and its homologs by this method.

STUDIES ON POLYMERIZATION AND RING FORMATION.
III. GLYCOL ESTERS OF CARBONIC ACID

BY WALLACE H. CAROTHERS AND F. J. VAN NATTA

RECEIVED JULY 24, 1929 PUBLISHED JANUARY 8, 1930

The glycol esters of dibasic acids described in a previous paper[1] are all highly polymeric. This was expected from the generalization[2] that bifunctional reactions which, if intramolecular, could lead only to larger-than-6 rings proceed intermolecularly. It seemed desirable to examine an homologous series of similar compounds in which the length of the structural unit might be as short as 5 or 6 atoms, since in these cases reaction should be intramolecular and the products monomeric, and in the longer chains of the same series reaction should be intermolecular and the products polymeric.

Such a series is found in the glycol esters of carbonic acid. The first member of this series, ethylene carbonate, , has long been known.[3] It is a crystalline solid which boils at 238° and it is definitely

established to be the monomeric 5-ring by both cryoscopic and vapor density data.[4]

We have now prepared the trimethylene, tetramethylene, hexamethylene, decamethylene, diethylene and p-xylylene esters of carbonic acid. The properties of these esters, together with the apparent mean molecular weights determined by cryoscopic and ebullioscopic methods, are indicated in Table I. The analytical compositions of all these esters correspond with the formulas of their structural units $—O—(CH_2)_n—CO—$, but where the length of the chain of this unit is 5 or 6, only one such unit is present in a molecule of the ester. On the other hand, where the length of the chain of the structural unit is 7, 8, 9 or 13, eight to twenty-two structural units are present in each molecule. The method of preparation and the analytical compositions of the polymeric esters indicate a structure which may be represented by the general formula $—O—(CH_2)_n—O—CO—O—(CH_2)_n—O—CO—O—(CH_2)_n—O—CO—O—(CH_2)_n—O—CO—$, etc. To complete this formula, it is necessary to discover whether the valences at the ends of the chains are saturated mutually with the formation of a ring, or are saturated by univalent groups to give open chains. The 7-, 8-, 9- and 13-membered rings which might be formed in this reaction are not found, and there is no reason to suppose that much larger rings would be formed more readily. For some poly-esters similar to those described here we have direct experimental proof of the open-chain structure. It seems quite certain, therefore, that these polycarbonates are also open chains. From the method of preparation it follows that the ends of the chains must bear hydroxyl groups (from an extra molecule of glycol) or carbethoxy groups (from an extra molecule of ethyl carbonate). In this connection it is interesting to observe that when an excess of ethyl carbonate was used in the preparation of hexamethylene carbonate, pure dicarbethoxyhexane, $C_2H_5O—CO—O(CH_2)_6O—CO—OC_2H_5$, was isolated, and an oil which, judging by its composition, was composed chiefly of $C_2H_5-O—CO—O(CH_2)_6O—CO—O(CH_2)_6O—CO—O(CH_2)_6O—CO—OC_2H_5$.

Properties of the **Polycarbonates.**—The physical properties of these polycarbonates again illustrate the fact that neither melting points nor solubilities offer any general criteria of molecular size.

In this connection trimethylene carbonate is of especial interest since it has been obtained in both the monomeric form and a form in which the degree of polymerization is 38–45. The monomeric form is hygroscopic and is soluble in water, benzene and alcohol, but only slightly soluble in ether and ligroin. The polymeric form is not soluble in water and alcohol, but is still soluble in benzene. Solubility here diminishes with considerable increase in molecular size, but it does not disappear. Practically all the polymeric esters described in this and the previous paper

[a] The analyses were carried out by the Pregl micro method

[b] Vorländer, *Ann.*, 280, 187 (1894).

are insoluble in water and alcohol, but soluble in chloroform and somewhat soluble in acetone. Those poly-esters in which the structural units contain polymethylene chains, $(CH_2)_x$, in which x is greater than 3–5, show great solubility in benzene.

Poly-esters of high molecular weight may be either liquid (diethylene carbonate, ethylene malonate,[1] decamethylene phthalate[1]) or solids. Most of the solid poly-esters are *crystalline.* These crystalline poly-esters differ from analogously constituted crystalline esters of low molecular weight in that the crystals are always microscopic. In some cases it is not possible to decide even by microscopic examination whether these solid polymers are crystalline, but x-ray examination always shows definite crystallinity. Thus hexamethylene carbonate was an opaque, tough, horny material with considerable elasticity. Nevertheless, it had a fairly definite melting point and it gave a quite sharp x-ray diffraction pattern (Fig. 3).

The following generalizations concerning the influence of the structure of the structural units of poly-esters on their physical properties can now be offered. As the lengths of the poly-methylene chains, $(CH_2)_x$, which separate the ester groups increase, solubility in organic solvents increases and viscosity of the molten ester diminishes. This would be expected from the fact that carbonyl groups contribute much more heavily to intermolecular association forces than do methylene groups. With one exception (ethylene malonate[1]) all of the linear poly-esters in which the ester groups are separated only by polymethylene chains, $(CH_2)_x$, are solids. Less symmetrical linear polyesters such as the alkylene phthalates are resins (transparent glasses or sirups). The solid poly-esters when melted and then cooled yield opaque masses. These may be brittle and porcelain-like or soft and waxy. The waxy quality increases with the lengths of the polymethylene chains just as it does in the glycols and the acids from which the poly esters are derived.

The problem of the more precise expression of the relationship between the structure and the properties of high polymers is complicated by the fact that some of the properties of this class of substances which are of the greatest practical importance and which distinguish them most sharply from simple compounds cannot be accurately measured and indeed are not precisely defined. Examples of such properties are toughness and elasticity. We have found these two properties in only one of the poly-esters which we have prepared. This poly-ester is hexamethylene carbonate. Like pentamethylene and decamethylene carbonates, this material is crystalline; it has a fairly definite melting point (55–60°) and it gives a sharp x-ray diffraction pattern (see Fig. 3). But the higher and lower members of this series separate from solution as powders, while hexamethylene carbonate separates in the form of rubbery flakes. It is not yet certain that this peculiar combination of properties is inherently associated with the molecular structure of this particular ester (*i. e.*, with the linear union of a large number of the structural units —CO—O—$(CH_2)_6$—O—) rather than with some accidental features of its formation which may have been absent in the preparation of other members of the series, but the important problem of the relationship between chemical or physical structure and rubber-like properties is so poorly provided with material suitable for inductive argument that the discovery of a new synthetic and analytically homogeneous material exhibiting these properties is of some significance. So far as we are aware there is nothing in current theories which would lead one to expect that polymeric hexamethylene carbonate would be elastic.

As indicated above, high polymers, like materials of low molecular weight, may show great variety in certain physical properties—they may be either liquids or high-melting solids; they may show slight or very great solubility. The following properties, however, are inherently associated with the highly polymeric state.

(1) Lack of Volatility.—None of the poly-esters which we have prepared can be volatilized as such even at very low pressures and high temperatures. Volatility diminishes continuously with increase in molecular size due to the increase in intermolecular forces. It is probably true in general that compounds whose molecular cohesions lie above 75,000 cal. (the heat of separation of a carbon–carbon bond) cannot be distilled. The calculated molecular cohesion (about 250,000 cal.),[5] of our poly-esters lie far above this value.

(2) Viscosity in Liquid State.—This would be expected to increase with the intermolecular forces and so with molecular size. All of the poly-esters which we have studied are extremely viscous in the molten state.

(3) Micro-crystallinity in the Solid State.—This has been referred to above. In this connection it is interesting to observe that considerable difficulty was experienced in preparing and keeping crystals of monomeric trimethylene carbonate sufficiently small to yield a powder diagram in an x-ray diffraction experiment. On the other hand, it has not been possible to prepare macroscopic crystals of any polymeric ester.

Trimethylene Carbonate.—Among all the esters formed from bifunctional reactions which we have studied, trimethylene carbonate and ethylene oxalate[6] present the peculiar property of exhibiting reversible transformation between a monomeric and a polymeric form. These monomeric esters contain 6-membered rings. The polymerization of trimethylene carbonate is brought about by heating and is catalyzed by a trace of potassium carbonate. The polymer is a perfectly colorless, transparent

glass, which on long standing becomes opaque (crystallization). X-ray diffraction patterns of the monomeric and polymeric forms are shown in Figs. 1 and 2. The polymer has the same apparent analytical composition as the monomer. Its degree of polymerization as measured by molecular weight determinations in boiling benzene is 3845. On heating *in vacuo,* it distils and the distillate is found to be the monomeric form. Examination of the literature shows that the property of undergoing reversible polymerization is common to many 6-rings containing ester linkages. Thus, the lactones of δ-hydroxyvaleric acid and of the hydroxyethyl ether of glycolic acid polymerize on heating[7] and so does glycolide.[8] The action of heat on lactic acid leads to polylactyl lactic acids, and these on further heating are converted to the 6-ring lactide.[9]

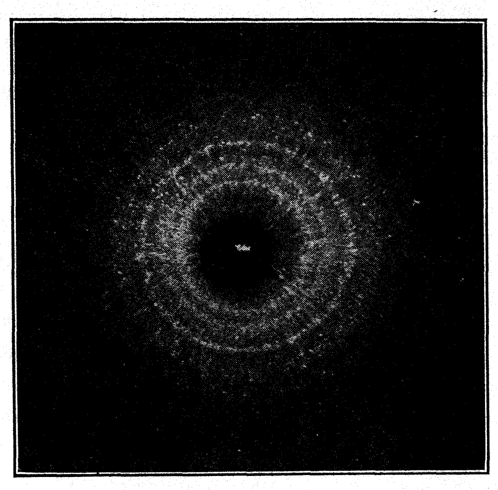

Fig. 1.—Monomeric trimethylene carbonate (Mo radiation). The intensity of the numerous outer rings is weak and these do not appear in the reproductions.

The unique position occupied in this respect by 6-rings containing an ester linkage is indicated by the following facts. No record of the polymerization of *a* γ-lactone (5-ring) is found. Our own attempts to polymerize ethylene carbonate (5-ring) were unsuccessful. The polyesters which we have prepared and in which the length of the chain of the structural unit is greater than 7 are not depolymerized on heating. The monomeric form of none of these esters is known.

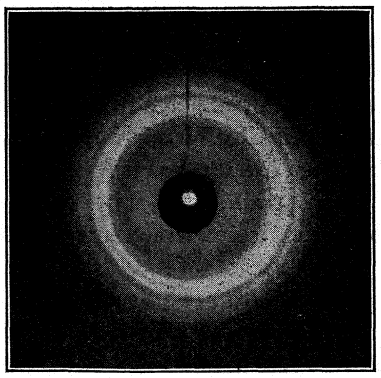

Fig. 2.—Polymeric trimethylene carbonate (Cu radiation).

In an attempt to force the depolymerization of tetramethylene carbonate, it was heated above 300° at 0.9 mm. This caused it to decompose with the evolution of considerable gas. From the dis-

[7] Hollo, *Ber.,* 61, 895 (1928).

[8] Bischoff and Walden, *Ann.,* **279,** 45 (1894).

[9] Dietzel and Krug, *Ber.,* 58, 1307 *(1925).*

tillate was isolated a very small amount (about 1% of the calculated) of a crystalline solid having the analytical composition of tetramethylene carbonate. Molecular weight determinations indicated that it is a dimer: $\overline{COO(CH_2)_4OCOO(CH_2)_4O}$. The absence of a monomer was not definitely established, but it could only have been present in very small amount. Thus, the behavior of polymeric tetramethylene carbonate is very different from that of its next lower homolog.

In the self-esters of some of the higher ω-hydroxy fatty acids, $HO(CH_2)_x$-COOH, both the monomeric lactones and the poly-esters are known.[10] The poly-esters, however, are not depolymerized on heating, and the poly-esters, not the lactones, are formed on heating the acids.

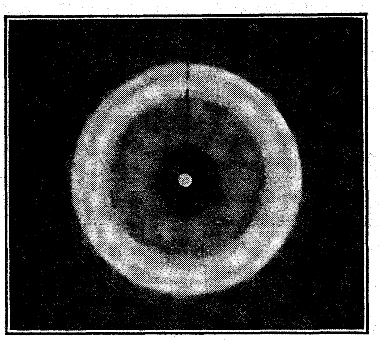

Fig. 3.—Hexamethylene carbonate (Cu radiation).

These facts, together with others which will be discussed later, indicate clearly that poly-esters formed by bifunctional reactions in which the length of the structural unit is greater than 6 atoms are the direct result of intermolecular condensation (C polymerization).[2] The formation of polymeric trimethylene carbonate from its monomer is obviously A polymerization, and the same is true of the polymerization of lactides and of 6-lactones.

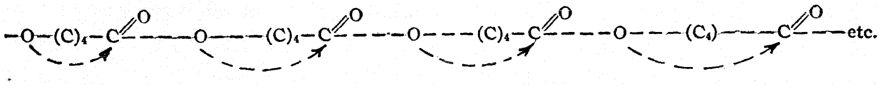
A fairly satisfactory explanation of these peculiarities may be found in the Mohr theory,'' which has proved adequate to explain all of the previously observed influences of structural features on the course of bifunctional reactions.[2] In accordance with the terms of this theory, 5-rings will be readily formed and very stable since they are free from strain. The formation of seven-membered and larger rings by bifunctional reactions is very improbable, but such rings once they are formed will be quite stable, since they too are practically free from strain. Six-rings will be readily formed, but they present the possibility of strains which are absent or present only to a diminished degree in larger rings. Thus, the Mohr theory predicts the possible existence of two cyclohexanes (cis and *trans)* but only one is known, However, where structural features would preclude the possibility of the interconversion of these two forms, as in decalin, both forms are known. It is concluded, therefore, that in simple 6-rings, such as cyclohexane, equilibrium with reversible interconversion

---

[10] Ruzicka and Stoll, *Helv. Chim. Acta,* 11, 1159 (1928); Lycan and Adams, THIS JOURNAL, 51, 625 (1929); Chuit and Hausser, *Helv. Chim. Acta, 12,* 463 (1929); Lycan and Adams, THIS JOURNAL, 51, 3450 (1929).

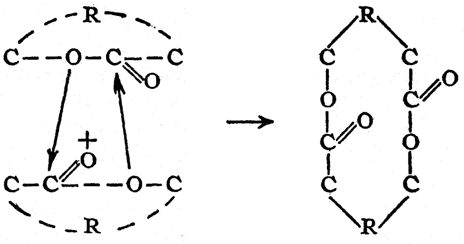
[11] Mohr, *J. prakt. Chem.,* 98,348 (1918).

of the two forms exists. At every such interconversion the molecule must pass through a position of considerable strain. This picture presents the features necessary to rationalize the peculiar position of 6-membered ester rings. A poly-ester in which the recurring structural unit is a chain of six atoms would be readily converted into the corresponding monomeric 6-ring by a process of ester interchange, as indicated below:



If the chain of the structural unit were longer than 6 atoms, this reaction would be less probable for the same reason that the higher ω-hydroxy fatty acids do not yield lactones, *i.* e., the number of points of rotation in the chain between carbonyl and alcoholic oxygen are so numerous that the probability of close intramolecular approach of these groups is very low.

The polymerization of the 6-ring esters seems also to involve ester interchange. This process may involve the coalescence of two such rings, as indicated below



The resulting 12-ring might then coalesce with another six-ring, and so on, with the formation of very large rings. It is possible also that traces of water may intervene at some stage in the process and that the large molecules produced are open rather than closed chains. In any event the peculiar mobility of the 6-ring esters may be ascribed to the fact that these rings are subject to strains, and that the strains may be relieved by an ester interchange resulting in an enlargement of the molecule.

The precise mechanism of the polymerization of the 6-membered ester rings shares to a certain extent the obscurity which is common to most cases of A polymerization, but further attention is being devoted to this problem and the study is being extended to the corresponding amides. In this connection the analogy which exists between lactides and diketopiperazines on the one hand, and poly-esters and polypeptides on the other hand, is of especial interest because of its possible relationship to the structure of proteins.

Dimeric Tetramethylene Carbonate.—The dimeric tetramethylene carbonate referred to above deserves special mention. There can be little doubt that it is a 14-membered cyclic ester, and as such it represents a class of compounds of which few members are known. Other dimeric cyclic esters have been obtained and will be described in later papers.

Previous Work on the Carbonates of **Dihydric** Alcohols.—Reference to ethylene carbonate has already been made. Carbonates of the three dihydroxybenzenes were prepared by Bischoff and v. Hedenström.[12] The carbonate of catechol is apparently monomeric since it can be distilled. The *m*-phenylene carbonate is a non-volatile, brown, glassy material of uncertain melting point (197–202°) and low solubility, and the corresponding para compound shows similar properties. These two compounds are evidently polymeric.

Experimental Part

Preparation of Carbonates.—The carbonates here described were all prepared by ester interchange (alcoholysis) between the glycol and ethyl carbonate. This reaction proceeds very smoothly in the presence of an alkaline catalyst and may be forced to completion; the process need not be modified to take into account the solubility of the resulting ester, as is necessary when phosgene and the glycol are used as starting materials.

Trimethylene Carbonate.—A mixture of **60.8** g. **(0.8** mole) of trimethylene glycol, **114 g. (16%** excess) of ethyl carbonate and a small cube of sodium was warmed in a Claisen flask until the sodium had completely dissolved. The flask was then immersed in an oil-bath at 130°. During three hours the temperature was allowed to rise to 170°. The evolved alcohol condensed and collected weighed 69.1 g. or 94% of the calculated.

The oily residue was dissolved in benzene, washed twice with 20-cc. portions of water and dried over calcium chloride. After removal of the solvent, the residue was subjected to vacuum distillation. **A** small initial fraction, b. p. 120–135° at **20 mm.,** was unchanged glycol. The pure trimethylene carbonate then distilled fairly constantly; b. p. 160–165° at **6 mm.**; 135° at **4 mm.,** 105° at **0.2** mm.; weight **53** g., or **65%** of the calculated. It completely crystallized in the receiver; recrystallization from absolute ether produced colorless needles, m. p. 47–48°. This hygroscopic ester is very soluble in benzene, alcohol and water and slightly soluble in ether and ligroin. It decomposes on distillation at ordinary pressure. This ester gave a sharp x-ray powder diagram (Fig. **1)** slightly scattered due to the difficulty of obtaining sufficiently small crystals. For analysis, see Table I.

Polymerization of Trimethylene Carbonate.—In the distillation of trimethylene carbonate it was frequently observed that the distilling residue was very thick and viscous while the warm distillate was comparatively thin and mobile. The distillation of **53** g. of trimethylene carbonate was interrupted while still incomplete. The distillate was monomeric trimethylene carbonate, m. p. 48°. The undistilled residue **(15.6** g.) was very viscous even when hot and it cooled to a colorless sticky resin. Molecular weight determinations showed it to be polymeric; molecular weight in boiling benzene, found: **2390,2320.**

This residue was distilled at **10 mm.** It yielded **13.6** g. of monomeric trimethylene carbonate (observed b. p. 150–190") which completely crystallized on cooling; mol. wt., calcd. for monomeric trimethylene carbonate: **102.** Found: (in boiling benzene) **115, 118.**

---

[12] Bischoff and v. Hedenstrom, **Ber., 35,3431** (1902).

The tarry residue (1.7 g.) remaining in the flask was insoluble in the common organic solvents.

A trace (0.1%) of finely powdered anhydrous potassium carbonate was added to a sample of the pure crystalline monomeric ester and the mixture was heated at 130°. After shaking and heating for ten minutes the mixture suddenly became very viscous and a slight amount of gas was evolved. After five hours of heating the colorless product formed a clear glassy mass on cooling; mol. wt., found: (in boiling benzene) 9670, 3880. For analysis see Table I. After standing for a week, this glassy polymer became opaque and x-ray examination showed it to be crystalline (Fig. 2).

Under similar conditions (temp. 130°; time of reaction, four hours) ethylene carbonate did not polymerize.

When polymeric trimethylene carbonate was heated to 210° at ordinary pressure, it was decomposed. Allyl alcohol was identified as one of the products of this reaction by its boiling point and by the melting point of its phenylurethan. This fact indicated decomposition according to the scheme

$$-O-CH_2-CH_2-CH_2-O-C{=}O \longrightarrow CH_2{=}CH-CH_2OH + CO_2$$

The allyl alcohol isolated accounted for only about 25% of the ester decomposed. Higher boiling unsaturated materials present in the products of this reaction were not identified.

Tetramethylene Carbonate.—This was prepared from 9.0 g. of tetramethylene glycol, to which a small piece ($2\ mm.^3$) of sodium had been added and 11.8 g. of ethyl carbonate. The mixture was heated to 120° and then the temperature was allowed gradually to rise to 160° during seven hours. The distillate was poured back several times to insure complete reaction of the ethyl carbonate. From the distillate was isolated 5.7 g. or 62% of the calculated amount of ethyl alcohol.

The non-volatile reaction product was dissolved in benzene and the solution washed with water, dilute hydrochloric acid and water. It was dried with calcium chloride and the solvent was removed by distillation. On heating the residue in *vacuo* there was obtained a very small amount of distillate boiling at 100–110° at 1 mm. This was chiefly unchanged tetramethylene glycol since it gave a di-*p*-nitrobenzoate, m. p. 175°. No further distillation could be effected when the bath was heated to 250° and the pressure reduced to 0.2 mm.

The residue was purified by dissolving it in chloroform and precipitating it with absolute alcohol while cold. The oily precipitate soon crystallized to a cream-colored powder; weight 6.3 g. or 54% of the calculated; m. p. 55–59°; very soluble in cold benzene, chloroform, acetone, and acetic acid; insoluble in ether, alcohol and petroleum ether. It gave a sharp x-ray diffraction pattern. Before analysis it was dried for four days at 80° in high vacuum. For analytical data see Table I.

Di-*p*-nitrobenzoate of Tetramethylene Glycol.—Prepared from the glycol and the acid chloride in pyridine; crystallized from boiling acetic acid; m. p. 175°.

Anal. Calcd. for $C_{18}H_{16}O_8N_2$: C, 55.67; H, 4.12. Found: C, 56.19, 56.00; H, 4.31, 4.14.

Thermal Decomposition of Tetramethylene Carbonate.—An attempt was made to bring about the depolymerization of tetramethylene carbonate by heating it to high temperature in *vacuo*. The tetramethylene carbonate was prepared from 9.0 g. of glycol and 11.8 g. of ethyl carbonate in the same manner as described above. It was heated at 0.9 mm. in a small Claisen flask by means of a metal-bath. Very slight distillation occurred as the temperature of the bath was raised from 270 to 300°. Between 300 and 325° evolution of gas occurred and the pressure increased. From the distillate were isolated 0.1 g. of crystalline solid and 2.8 g. of oil. The residue remaining in the distilling flask weighed 3 g. and was apparently identical with the polymeric tetramethylene carbonate described above; it melted at 55° and had the same physical appearance and solubility behavior.

The crystalline distillate separated from alcohol in minute prisms melting at 175–176°. Analysis and molecular weight determinations showed it to be dimeric tetramethylene carbonate,

$CO—O(CH_2)_4O—CO—O(CH_2)_4O$.

Anal. Calcd. for $(C_5H_8O_3)_2$: C, 51.71; H, 6.94; mol. wt., 232. Found: C, 51.77; 51.80; H, 6.95; 7.02; mol. wt., in boiling ethylene chloride, 194,231; mol. wt., in freezing benzene, 204.

The liquid distillate had a pungent mint-like odor and readily absorbed bromine in acetic acid solution. It is a mixture and no chemical individuals have as yet been isolated from it.

Pentamethylene Carbonate.—This was prepared from 5.9 g. of ethyl carbonate and 5.2 *g*. of pentamethylene glycol to which a small amount of sodium had been added. The mixture was heated for twelve hours at 120–160°; 76% of the calculated amount of alcohol was found in the distillate. The residue after it had been freed from sodium was heated at 250° under 0.15 mm. The distillate (1.1 g.) boiled at 110–130" and consisted chiefly of unchanged glycol; di-$-nitrobenzoate, m. p., 104–105°. The non-volatile sirupy residue crystallized on standing to a hard waxy material; weight, 4.1 g. or 63% of the theoretical. It was purified by precipitation with absolute alcohol from a cold chloroform solution as a granular and slightly colored powder; m. p., 44–46°; very soluble in benzene, chloroform, acetone and acetic acid; insoluble in ether, alcohol and petroleum ether. Before analysis it was dried to constant weight in high *vacuo*. For analysis see Table I.

Di-p-nitrobenzoate of Pentamethylene Glycol.—From the glycol and the acid chloride in pyridine; crystallized from a mixture of benzene and alcohol; m. p., 104–105°.

Anal. Calcd. for $C_{19}H_{18}O_8N_2$: C, 56.71; H, 4.51. Found: C, 56.95, 57.02; H, 4.59, 4.69.

Hexamethylene Carbonate.—This was prepared from 12 *g*. of ethyl carbonate and 12 g, of hexamethylene glycol to which a small piece of sodium had been added. The mixture was heated from 130 to 170° during two hours; 86% of the calculated amount of alcohol was found in the distillate. The residue after the removal of the sodium was subjected to distillation in high vacuum. A very small amount of distillate was found to consist of unchanged glycol. The residue, which amounted to 10 g. or 67% of the calculated, solidified on cooling to a light colored, horny, tough mass. It was soluble in benzene, acetone and chloroform; insoluble in ether and alcohol; m. p. 55–60°. A sharply defined x-ray diffraction pattern (Fig. 3) showed it to be crystalline. For analysis see Table I.

Dicarbethoxyhexane.—In an experiment similar to the above, ethyl carbonate and glycol were used in the ratio of 2 moles to 1 (24 *g*. of ester and 12 *g*. of glycol). The calculated amount (9.2 g.) of alcohol was collected. The residue after removal of sodium was subjected to vacuum distillation. It yielded 5.5 g. of distillate, b. p. 130–140° at 0.8 mm. The residue could not be distilled, and neither the distillate nor the residue could be induced to crystallize. No ethyl carbonate was found in the distillate. The distillate was dicarbethoxyhexane; n_D^{20} 1.4310; d_{20}^{20} 1.065; d_{20}^{25} 1.056.

Anal. Calcd. for $C_{12}H_{22}O_6$: C, 54.94; H, 8.41; mol. wt., 262. Pound: C, 55.00; H, 8.41; mol. wt. in boiling benzene, 236,240,245.

The oily residue was very soluble in alcohol and ether. Its analytical composition corresponded with the formula $C_2H_5O—CO—O(CH_2)_6O—CO—O(CH_2)_6O—CO—O(CH_2)_6O—CO—OC_2H_5$.

And. Calcd. for $C_{26}H_{46}O_{12}$: C, 56.73; H, 8.36; CO_2 on hydrolysis, 33.1%; mol. wt., 532. Found: C, 56.77, 57.00; *H,* 8.41, 8.53; CO_2, 34.15; mol. wt. in boiling benzene, 573, 549, 528. The CO_2 was determined by saponifying with alcoholic sodium hydroxide and weighing the sodium carbonate formed.

Carbonate of **Diethylene** Glycol.—This was prepared in 43% yield by the method used in the preparation of the other carbonates. It was a light colored sirup which could not be induced to crystallize; insoluble in alcohol and ether, quite soluble in acetone and benzene, very soluble in chloroform and hot ethyl acetate. On standing it appeared to decompose to some extent into acetaldehyde and carbon dioxide and for this season it could not be dried to constant weight. For analysis see Table I.

Decamethylene Carbonate.—This was prepared in 75% yield by the method used for the preparation of the other carbonates. It was soluble in benzene and chloroform but insoluble in alcohol. It was purified by precipitation from chloroform with alcohol in the cold. The oily product gradually solidified to a cream-colored powder; m. p. 55°; very soluble in chloroform, slightly soluble in ether, benzene, acetone and acetic acid; insoluble in alcohol and petroleum ether. This powder gave a sharply defined x-ray diffraction pattern. Before analysis it was dried to constant weight in high vacuum at 90°. For analysis see Table I.

p-**Xylylene** Carbonate.—This was prepared from *p*-xylylene glycol and ethyl carbonate as in the preparation of the other carbonates. The residue after completion of the ester interchange was insoluble in hot benzene, absolute alcohol, chloroform and carbon tetrachloride; slightly soluble in acetic acid. It dissolved more or less completely in ethylene chloride, anisole and dioxane. It was thoroughly triturated with water and with cold alcohol to remove sodium and excess glycol and ethyl carbonate. The amount of the white solid remaining corresponded to 82% of the calculated. It was separated into two fractions by extraction with ethylene chloride.

(a) Soluble Fraction.—This was precipitated with ether from ethylene chloride in the form of white flocks; m. p. 137–138°. For analysis see Table I.

(b) Fraction Insoluble in Ethylene Chloride.—This was insoluble in the common organic solvents; m. p. 177–185° (rather indefinite). For analysis see Table I.

Attempted Preparation of Methylene Carbonate.—Silver carbonate (81 g.) was heated with methylene bromide (51 g.) in dry toluene solution. Formaldehyde and carbon dioxide were formed and free silver was produced. From the reaction mixture there was isolated only a small amount of oil with a sweet odor—probably methylene carbonate. This liberated formaldehyde on heating: $CH_2CO_3 \longrightarrow H_2CO + CO_2$.

We are indebted to Dr. A. W. Kenney and Mr. Henry Aughey for the x-ray diffraction pictures, to Mr. W. H. Taylor for many molecular-weight determinations and to Mr. G. A. Jones for determinations of carbon and hydrogen.

Summary

The following compounds have been prepared by the action of the appropriate glycols on ethyl carbonate: trimethylene carbonate, tetramethylene carbonate, pentamethylene carbonate, hexamethylene carbonate, decamethylene carbonate, diethylene carbonate and p-xylylene carbonate. Their properties are described. In accordance with a generalization already set forth, ethylene carbonate and trimethylene carbonate are monomeric and the other carbonates are polymeric. Trimethylene carbonate undergoes reversible A polymerization. A stable dimeric form. of tetra-

methylene carbonate has been prepared by thermal decomposition of its usual polymeric form. Hexamethylene carbonate is tough and elastic.

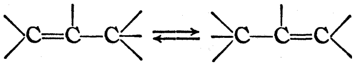
STUDIES OF CONJUGATED SYSTEMS
II. THE BROMINATION OF VINYLACRYLIC ACID

BY IRVING E. MUSKAT, BRUNNER C. BECKER AND JOEL S. LOWENSTEIN

RECEIVED JULY 25, 1929 PUBLISHED JANUARY 8, 1930

The abnormal addition reactions of conjugated systems have been the subject of a great deal of experimental work ever since Fittig[1] and Baeyer[2] found that compounds containing two double bonds in conjugation were reduced in the 1,4- rather than in the 1,2- or 3,4-positions, and did not exhibit the properties common to ordinary ethylenic double bonds. In 1899 Thiele[3] proposed his "partial valence" theory to interpret these 1,4-addition reactions to conjugated systems and brought a great deal of experimental evidence in its favor. According to this theory the type of addition taking place in a conjugated system depends solely on the valence relations of that system. Later work[4] proved this general theory to be incorrect, and it was modified by Hinrichsen[4] to take into consideration the electrochemical nature of the entering atoms or groups, as well as the nature of the original unsaturated compound in which the addition is taking place, More recent work,[5] carried out with greater precision and more refined technique, has shown that in many addition reactions where 1,4-addition is found, it is not due primarily to 1,4-addition but rather to an isomerization of the 1,2- or 3,4-addition compounds. Such isomerizations are common in three-carbon systems containing a double bond



Because of the theoretical importance of the addition reactions of conjugated systems, it was considered desirable to make a thorough investigation of such addition processes, particularly in simple conjugated systems. It was hoped that such studies would also throw some light on the mecha-

nism of addition reactions and directive influence in the aromatic series. The present paper, the second of the series, contains the results of an investigation on the bromination of vinylacrylic acid.

Thiele[6] proved that vinylacrylic acid adds hydrogen in the 1,4 (or 1,6)-position. Kohler and Butler,[7] while studying the relative ease of 1,4- and 1,6-addition, showed that sodium malonic ester combines with the esters of vinylacrylic and sorbic acids to give 1,6-addition products, while phenylmagnesium bromide reacts with the same esters to give first the corresponding ketones, which react further to give 1,4-addition products.

In a recent publication by Farmer and Healy[8] on "Addition to Butadiene Esters," the authors also report the bromination of vinylacrylic acid. They found that bromine adds to vinylacrylic acid in the 3,4-position to give a liquid dibromide from which they were able to separate a solid dibromide melting at 47°. They treated the dibromide with diethylamine and obtained a monobromide which polymerized so rapidly that they were unable to determine its structure or even its melting point. Quite independent of this work we have studied the bromination of vinylacrylic acid but have carried the work much further and proved the structures of our products.

Vinylacrylic acid was prepared according to a modification of Nottbohm's[9] method. The pure acid melted at 72°, the same melting point reported by Nottbohm. Doebner,[10] using a somewhat different method, had previously prepared vinylacrylic acid, reporting its melting point as 80°. Auwers[11] and Kohler[7] repeated the preparation of vinylacrylic acid: the former used Nottbohm's method while the latter used Doebner's method; both reported its melting point as 72°. Recently Farmer[8] reported the preparation of vinylacrylic acid according to Doebner's method, confirming his melting point as 80°. We prepared vinylacrylic acid according to both methods. Both preparations melted at 72° as did a mixture of the two. It is possible that there are two vinylacrylic acids which are either physical or geometric isomers of each other.

The bromination of vinylacrylic acid was then studied. It was found that vinylacrylic acid absorbed two atoms of bromine to give a dibromide which distilled at 156° under 3-mm. pressure. On standing it partially solidified to a solid melting at 47°. Farmer[8] apparently obtained the same dibromide (but does not give its boiling point) starting with the vinylacrylic acid melting at 80°. He proved its structure, 3,4-dibromo-Δ^1-pentenic

acid, by ozonization. We confirmed his structure in every particular. Thus we see that vinylacrylic acid adds bromine in the 3,4-position and not in the 1,4-position as postulated by Thiele. This stands in variance with the hydrogenation of vinylacrylic acid, which takes place in the 1,4-position.[6]

Vinylacrylic acid dibromide readily absorbed two atoms of bromine to give the tetrabromide. It melted at 156° and was identical with the tetrabromide described by Nottbohm.[9] The vinylacrylic acid dibromide was reduced with zinc dust to give the original vinylacrylic acid melting at 72°.

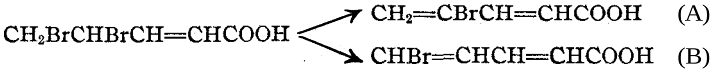
On distilling the dibromide under reduced pressure, decomposition occurred with the liberation of hydrogen bromide. A lower-boiling fraction distilled over and solidified partially on standing. The solid was removed; it melted at 143° and solidified again at 162°. Its structure was finally proved by converting it into aceto-acrylic acid. This, with its analysis ($C_5H_4O_2$), showed that it was a γ-lactone having the structure

$CH_2{=}CCH{=}CHC{=}O$ (O bridging)

When vinylacrylic acid dibromide was treated with two molar equivalents of sodium hydroxide, the temperature being kept at about zero degrees, the soluble sodium salt of monobromo-vinylacrylic acid was formed in almost theoretical yield. The free acid was obtained by acidifying the alkaline solution with cold dilute acids.

Bromovinylacrylic acid is a white crystalline compound, very soluble in all ordinary organic solvents and very unstable. It readily polymerizes to a white solid which is insoluble in all ordinary organic solvents with the exception of acetone. Due to its ease of polymerization it was not possible to obtain a sharp melting point. It melted at about 106°.

It may be seen readily from the structure of the vinylacrylic acid dibromide that hydrogen bromide may be eliminated in either of two ways



$CH_2BrCHBrCH{=}CHCOOH \rightarrow CH_2{=}CBrCH{=}CHCOOH$ (A)

$CH_2BrCHBrCH{=}CHCOOH \rightarrow CHBr{=}CHCH{=}CHCOOH$ (B)

The structure of the monobromide was proved by further brominating it to the bromovinylacrylic acid dibromide and studying the oxidation products of the tribromide formed.

Bromovinylacrylic acid readily absorbed a molecule of bromine to give a tribromo derivative boiling at about 172° under 10-mm. pressure. There are six tribromides theoretically possible depending on the A or B structure of the monobromide and the 1,2-, 1,4- or 3,4-type of addition taking place

(A) $CH_2{=}CBrCH{=}CHCOOH$	(B) $CHBr{=}CHCH{=}CHCOOH$
(1–2) $CH_2{=}CBrCHBrCHBrCOOH$	(1–2) $CHBr{=}CHCHBrCHBrCOOH$
(1–4) $CH_2BrCBr{=}CHCHBrCOOH$	(1–4) $CHBr_2CH{=}CHCHBrCOOH$
(34) $CH_2BrCBr_2CH{=}CHCOOH$	(34) $CHBr_2CHBrCH{=}CHCOOH$

The bromovinylacrylic acid dibromide was ozonized in the usual manner. It was possible to recover oxalic acid (40% yield), which was identified by its melting point and a melting point of a mixture with a sample of known origin; and also α,α,β-tribromopropionic aldehyde, which was identified by the melting point of the α,α,β-tribromopropionic aldehyde hydrate and a melting point of a mixture with the synthesized product. This proves that 3,4-addition of bromine had again taken place, giving rise to a tribromide of structure $CH_2BrCBr_2CH{=\!=}CHCOOH$, and therefore the structure of the monobromide must be as represented by **(A).**

The experimental results recorded here lend support to the Hinrichsen view of addition to conjugated systems as contrasted to the Thiele view; that is, the mode of addition to conjugated systems is a function not only of the conjugated system itself, but also of the nature of the addendum.

Experimental Part

The Preparation of Vinylacrylic Acid.—The method of preparation described here is a modification of Nottbohm's[9] method. Nottbohm's method gives 15–20% of pure acid, while the Kohler[7] modiication of Doebner's method gives 30% of pure acid. The following method gave about 55–65% of pure acid.

To a solution of 118 g. of potassium metabisulfite in about 200 cc. of water, cooled in a freezing mixture, 29 g. of acrolein was added, drop by drop, under continuous stirring. After all of the acrolein had been added, the stirring was continued for two hours at room temperature. Malonic acid (52 g.) was then added and the solution was refluxed for two hours. The solution was then concentrated to a thick, sirupy mass on the water-bath until the evolution of carbon dioxide gas had ceased. During this time the viscous mass was stirred in order to avoid excessive frothing. The residue was then dissolved in about 100 cc. of water, which is contained in an iron dish, and 300 g. of coarsely ground sodium hydroxide was gradually added with continuous stirring. It was then heated on the water-bath for four hours, after which it was allowed to cool. The semi-crystallized mass was placed in a large enamel dish to which was added about 500 g. of ice and 500 g. of chloroform. The mixture was then slowly neutralized with 25% hydrochloric acid under continuous stirring. During the neutralization ice was added to keep the temperature at about zero degrees. The chloroform layer was separated and the acidic layer was twice extracted with chloroform. The chloroform extract was dried and the chloroform removed under reduced pressure. The yellow residue (about 40 g.) was recrystallized from ligroin. The pure acid (about 30 *g.)* melted sharply at 72°.

Vinylacrylic acid was also prepared according to Doebner's method[10] by the direct condensation of acrolein and malonic acid in the presence of pyridine. The purified acid thus prepared also melted at 72°, as did a mixture of the acids prepared by each method.

Vinylacrylic Acid Dibromide.—Vinylacrylic acid dibromide was prepared by the addition of the theoretical amount of bromine dissolved in chloroform to a solution of vinylacrylic acid in chloroform. Absorption took place fairly readily and the reaction mixture became warm. The reaction mixture was distilled under reduced pressure; a light yellow oil distilled over at 156° under 3 mm. pressure. On standing it partially crystallized to a solid melting at 47°, which is the same melting point recorded by Farmer for his dibromide, which he obtained from vinylacrylic acid melting at 80°.

Anal. Calcd. for $C_5H_6O_2Br_2$: Br, 61.98. Found: Br, 61.91, 62.01.

The conditions under which the vinylacrylic acid was brominated were varied considerably. Various solvents such as ligroin, carbon tetrachloride, carbon bisulfide and glacial acetic acid were used besides chloroform, and the temperature was varied from about −20° to about 50°. However, in all cases only one dibromide was obtained, regardless of the experimental conditions employed. The dibromide is unstable, particularly toward heat and alkali, and loses hydrogen bromide easily.

The pure vinylacrylic acid dibromide (4.2 g.), dissolved in chloroform, was subjected to ozonization and the ozonide thus formed was decomposed with water. To assure the complete decomposition of the ozonide it was warmed on the water-bath for a short time. The mixture consisted of aldehydes and acids and was separated by extracting the aqueous solution several times with ether. The aqueous solution was carefully evaporated to dryness and further heated in the oven to 110° for several hours. The residue (1.10 g.) melted at 187°, the melting point of anhydrous oxalic acid. A mixture with pure oxalic acid also melted at 187°. This corresponds to a 75% yield of oxalic acid. The aldehyde portion was distilled under reduced pressure. An oil distilled over at 80° under 5–6 mm. pressure, the boiling point of α,β-dibromopropionic aldehyde. This was further identified by treating with sodium acetate according to the method of Piloty and Stock,[12] which converted the dibromide into a-bromo-acrolein. This distilled over at 49–50° under 30 mm. pressure, the recorded boiling point of α-bromo-acrolein. The a-bromo-acrolein gave a semicarbazone melting at 160° with decomposition. This proves beyond any doubt that bromine had added to vinylacrylic acid in the 3,4-position.

Vinylacrylic acid dibromide readily absorbed two atoms of bromine to give the tetrabromide. It melted at 156° and was identical with the tetrabromide described by Nottbohrn. The dibromide was reduced with zinc dust to the original vinylacrylic acid, which was identified by its melting point. 72°. The yield was low, due to the polymerization of the vinylacrylic acid.

If vinylacrylic acid dibromide was distilled under reduced pressure, a great deal of decomposition occurred at about 140° with the liberation of hydrogen bromide. A lower-boiling fraction distilled over which solidified on standing. The solid is characterized by a marked insolubility in ether and could thus be freed easily from impurities by washing with ether. It is insoluble in all ordinary organic solvents with the exception of acetone, from which it can be recrystallized in pure white crystals. It melts at 143° and solidifies again at 162°, which may indicate that polymerization has occurred. It contained no halogen and dissolved slowly in alkali to give a reddish colored solution.

Anal. Calcd. for $C_5H_4O_2$: C, 62.5; H, 4.2. Found: C, 62.6, 62.6; H, 4.4, 4.4.

The molecular weight was determined by the boiling point method in acetone, which was erratic under the conditions of the experiment. Subs., 0.3134 g.; acetone, 100 g.; *AT*, 0.063°. Calcd. for $C_5H_4O_2$: mol. wt., 96. Found: mol. wt., 86.

The titer value of the substance was then determined by dissolving it in pure acetone, diluting with water, and titrating in the usual manner with standard alkali. Subs., 0.1003: 9.8 cc. of 0.1063 *N* sodium hydroxide. Calcd. for $C_5H_4O_2$: mol. wt., 96. Found: mol. wt., 96.3.

This proved that the substance contained one carboxyl group, but its slow solubility in alkali indicated that it was a lactone. From the fact that it was formed as a result of the elimination of two molecules of hydrogen bromide from vinylacrylic acid dibromide, it is at once clear that it could be either a 6- or a γ-lactone. The 8-lactone is known. It melts at 5° and has entirely different properties from those shown by our

---

[12] Piloty and Stock, *Ber.*, 31, 1385 (1898).

compound. It was proved to be the γ-lactone,  $CH_2{=}CCH{=}CHC{=}O$ (bridged by O), by hydrolyzing it with alkali to the corresponding aceto-acrylic acid. The hydrazone of aceto-acrylic acid melts at 160° with decomposition; the hydrolysis product of our lactone also formed a hydrazone melting at 160° with decomposition. The isolation and proof of the structure of this lactone stand in good agreement with the proof of the structure of the monobromide that follows.

Bromovinylacrylic Acid.—When vinylacrylic acid dibromide was treated with one molar equivalent of aqueous sodium hydroxide, the soluble sodium salt of the dibromide was formed. If another molar equivalent of sodium hydroxide was added, the temperature being kept at about 0° during this operation, the dibromide easily lost a molecule of hydrogen bromide and was thus converted into the soluble sodium salt of the monobromovinylacrylic acid, with an almost theoretical yield. It is of the utmost importance to keep the temperature very low, otherwise the monobromide polymerizes. The free acid was precipitated as a voluminous crystalline mass by acidifying the alkaline solution with cold dilute acids.

Anal. Calcd. for $C_5H_5O_2Br$: Br, 45.16. Found: Br, 45.07, 45.15.

The bromovinylacrylic acid is a white, crystalline compound, very soluble in the ordinary organic solvents and very unstable. It readily polymerizes to a white solid which is insoluble in all ordinary organic solvents with the exception of acetone. Due to its ease of polymerization it was not possible to obtain a sharp melting point. It melted at about 106°. The structure of the monobromide was established by further brominating it to the bromovinylacrylic acid dibromide and determining the oxidation products of the tribromide formed.

Bromovinylacrylic Acid Dibromide.—Bromovinylacrylic acid dibromide was prepared by the addition of the theoretical amount of bromine dissolved in chloroform to a solution of bromovinylacrylic acid dissolved in chloroform. Absorption took place fairly readily and the mixture became warm. The reaction mixture was distilled under reduced pressure. A light yellow oil distilled over at about 172" under 10 mm. pressure.

Anal. Calcd. for $C_5H_5O_2Br_3$: Br, 71.19. Found: Br, 71.23, 70.58.

The pure bromovinylacrylic acid dibromide (1.1 g.) was subjected to ozonization and the ozonide thus formed was worked up in the manner previously described for the vinylacrylic acid dibromide. The acid and aldehyde portions were separated; the acid portion yielded 0.17 g. of calcium oxalate, which corresponds to a 40% yield, while the aldehyde was removed as such and distilled under reduced pressure. It distilled over at 104–106° under 30-mm. pressure, the boiling point of α,α,β-tribromopropionic aldehyde. We completely verified the α,α,β-structure of the tribromopropionic aldehyde by preparing the hydrate, which melted at 57° and did not lower the melting point of the synthesized α,α,β-tribromopropionic aldehyde hydrate when mixed with it. This proves that the brornovinylacrylic acid dibromide has the structure $CH_2BrCBr_2CH{=}CH$-COOH, and consequently the bromovinylacrylic acid has the structure $CH_2{=}CBr$-$CH{=}CHCOOH$.

Summary

1. By bromination of vinylacrylic acid a dibromide is formed whose structure was proved by ozonization to be a 3,4-derivative, rather than a 1,4-derivative as required by Thiele's theory of addition to conjugated systems.

2. 3,4-Dibromo-Δ^1-pentenic acid loses a molecule of hydrogen bromide to give 3-bromovinylacrylic acid.

3. 3-Bromovinylacrylic acid absorbs one molecule of bromine in the 3,4-position to give 3,3′,4-tribromo-A^1-pentenic acid. Its structure was proved by ozonization.

4. An improved method for the preparation of vinylacrylic acid is given which doubles the best yield heretofore obtained.

5. On distillation 3,4-dibromo-Δ^1-pentenic acid loses two molecules of hydrogen bromide to give a γ-lactone whose structure was proved to be

$$\underset{\diagdown O \diagup}{\mathrm{CH_2{=}CCH{=}CHCO}}$$

CARBITHIOIC ACID STUDIES. I. TOLYL-4-CARBITHIOIC ACID AND CERTAIN DERIVATIVES[1]

BY R. W. BOST AND W. J. MATTOX

RECEIVED JULY 25, 1929 PUBLISHED JANUARY 8, 1338

There are three methods by which the carbithioic acids are usually made, namely, hydrolysis of the corresponding thio esters with alcoholic potassium hydroxide,[2] the action of carbon disulfide on benzene in the presence of anhydrous aluminum chloride[3] and the Grignard reaction.[4,5]

Sakurada[2] first isolated tolyl-4-carbithioic acid by the hydrolysis of ethyl dithio-p-toluate with alcoholic potassium hydroxide, the ethyl dithio-p-toluate being prepared by passing dry hydrogen sulfide into an ethereal solution of the corresponding thio-imino ester. However, none of its properties was studied and no derivatives were prepared other than the ethyl ester.

In this paper is described the preparation of tolyl-4-carbithioic acid by the action of carbon disulfide on tolyl-4-magnesium bromide. The acid is a viscous red oil having a disagreeable odor. Attempts to distil the acid resulted in decomposition. The sodium salt was more stable and was used in the preparation of the derivatives

Tolyl-4-carbithioic acid readily forms salts with the chlorides and acetates of inorganic metals. It is easily converted into thio esters by alkyl sulfates and alkyl halides. The thio esters are susceptible to ammonolysis, whereupon thio amides are obtained. In these respects the —CSSH group is similar to the —COOH group.

---

[1] This paper is an abstract of a thesis submitted in June, 1929, to the Faculty of the University of North Carolina by W. J. Mattox in candidacy for the degree of Master of Arts.

[2] Sakurada, Mem. *Coll. Sci.* Kyoto, 10, 79-83 (1926).

[4] Houben, *ibid.*, 39, 3219 (1906).

[5] Wheeler and Thomas, THIS JOURNAL, 50,3106 (1928).

The acid differs from the carboxylic acids in that the —CSSH group is converted by oxidizing agents such as nitric acid and permanganate into the —COOH group. Attempts to prepare an acid chloride were negative.

Experimental Part

Tolyl-4-magnesium Bromide.—Thirteen grams of clean, dry magnesium shavings was placed in a liter balloon flask provided with a reflux condenser and a mixture of 200 ml. of absolute ether and **25** g. of *p*-bromotoluene added. A small crystal of iodine was allowed to dissolve on the bottom. The reaction usually started in a few minutes. p-Bromotoluene was then added in 10-ml. portions until **85** g. had been added. After the reaction was complete, the ether solution was decanted into a dry flask.

Tolyl-4-carbithioic Acid.—The flask containing the Grignard reagent was surrounded by a freezing mixture and cooled to 0°; **38** g. of carbon disulfide was added dropwise so that the temperature did not rise above 0°. This required about an hour. Precautions were taken to exclude all moisture. After all of the carbon disulfide had been added the stirring was continued for about three hours. The ice-bath was removed and the reaction product allowed to stand at room temperature for an hour or longer. The solution was poured into 500 g. of ice and dilute hydrochloric acid then added to dissolve the magnesium hydroxide. The deep red ether layer was removed by means of a separatory funnel and extracted with 100-ml. portions of 5% sodium hydroxide until the latter was only slightly colored. This aqueous solution of the sodium salt was covered with 200 ml. of ether and dilute hydrochloric acid added until the aqueous solution was slightly acid. The free acid which was then in solution in the ether was washed well with water. From three to four precipitations from the aqueous solution of the sodium salt were necessary to purify the acid. The ether was evaporated in a desiccator to obtain the free acid.

Tolyl-4-carbithioic acid is a dark red, viscous oil having a disagreeable odor. All attempts to distil it, even at 3-mm. pressure, resulted in decomposition. It solidifies at 27° into a mass of dark red crystals. It is very soluble in benzene, toluene, ether and acetone, slightly soluble in alcohol, carbon tetrachloride and chloroform and insoluble in water. The acid decomposes slowly on exposure to the atmosphere, but is much more stable in ether solution.

Zinc Salt of Tolyl-4-carbithioic Acid.—Five grams of zinc acetate dissolved in 150 ml. of water was added to 15 ml. of acetic acid. To this solution was slowly added, with stirring, a slight excess of the sodium salt of the acid and the stirring continued for three to four hours. It is necessary to keep the sodium salt in excess as otherwise complex products are formed. After the precipitate was washed and dried, the zinc salt was twice extracted with hot absolute alcohol. It is soluble in benzene, toluene and hot alcohol.

Lead Salt of Tolyl-4-carbithioic Acid.—This salt was prepared similarly to the zinc salt. It is practically insoluble in all the organic solvents.

Methyl Ester of Tolyl-4-carbithioic Acid.—An aqeuous solution of the sodium salt was treated with dimethyl sulfate, with shaking, until a dark red oil separated out and the red color had disappeared from the aqueous layer. The mixture was gently refluxed for thirty minutes to insure complete reaction. The ester was extracted with ether, the ethereal solution washed with water, dried and distilled in vacuum. It is a dark red oil having a disagreeable odor.

Ethyl Ester.—This ester was prepared similarly to the methyl ester, using the corresponding alkyl sulfate. It resembles the methyl ester in its physical properties.

n-Butyl Ester.—Ninety-five grams of the sodium salt of the acid dissolved in 300 ml. of water and 70 g. of *n*-butyl bromide were refluxed until a red oily layer separated out and the aqueous layer was colorless. When cooled, the ester was extracted with ether, washed, dried and distilled in vacuum. It is a red oily liquid of disagreeable odor and solidifies at 20°.

p-**Nitrobenzyl** Ester.—To 4 g. of *p*-nitrobenzyl bromide dissolved in 40 ml. of hot alcohol was slowly added, with stirring, a freshly prepared aqueous solution of the sodium salt in slight excess. Gentle boiling was continued for five minutes. After cooling the dilute alcohol was decanted off the thick oil which separated out. The oil was washed with 95% alcohol and placed on a porous plate to crystallize. The crude ester was purified by dissolving in hot absolute alcohol and heating with several portions of charcoal. The filtrate upon cooling yielded large red rectangular plates in the form of clusters. The ester is soluble in ether, hot toluene, alcohol and benzene.

Amide of Tolyl-4-carbithioic Acid.—Seven grams of the methyl ester and 20 ml. of concentrated ammonium hydroxide were placed in a 50-ml. glass-stoppered bottle for five or six days. The bottle was shaken occasionally during this time. The crude amide which separated out, was filtered off, washed with petroleum ether and crystallized from hot toluene. It is soluble in ether, hot alcohol and benzene. Methyl mercaptan is also formed in the reaction.

p-Toluide of Tolyl-4-carbithioic Acid.—Ten grams of *p*-toluidine, 6 g. of the dry sodium salt and 6 ml. of concentrated hydrochloric acid were placed in a small beaker and gently heated for thirty minutes. The product was cooled and extracted with 50 ml. of hot toluene. The toluene solution was boiled with several portions of charcoal, filtered and set aside to crystallize. Long yellow needles separated out when about one-third of the toluene had evaporated. It is soluble in hot alcohol, benzene and toluene.

Oxidation of Tolyl-4-carbithioic Acid.—To an ether solution of the acid cooled to 0° was added nitric acid (sp. gr. 1.42) dropwise, with stirring, until the red color of the acid changed to a light yellow. The mixture was removed from the ice-bath and stirring continued for an hour. The oxidation product was extracted with ether, purified through its sodium salt and finally recrystallized from dilute alcohol. The white crystalline product melted at 181°. Qualitative tests for sulfur were negative. Molecular-weight determinations and other tests proved the oxidation product to be *p*-toluic acid. Similar results were obtained with potassium permanganate at room temperature. At higher temperatures complex products are obtained.

Action of Phosphorus Pentachloride on Tolyl-4-carbithioic Acid.—Phosphorus pentachloride reacts with the acid, producing a viscous red liquid. All attempts to distil the product in a vacuum resulted in decomposition. Phosphorus trichloride and phosphorus oxychloride were used and similar results obtained.

Summary

1. Tolyl-4-carbithioic acid was prepared by the action of carbon disulfide on tolyl-4-magnesium bromide.
2. The acid readily forms salts and esters.
3. A thio amide and the p-toluide were prepared.
4. The acid is very sensitive to oxidizing agents.
5. Attempts to prepare the acid chloride were negative.

THE EFFECT OF HEAT UPON CROTONIC ACID

BY EVALD L. SKAU[1] AND BLAIR SAXTON

RECEIVED JULY 26, 1929 PUBLISHED JANUARY 8, 1930

In the course of a study of the mutual solubility relations of geometrical isomers, an unsuccessful attempt was made to prepare isocrotonic acid by a method based upon the work of Michael[2] and Schulthess and of Morrell and Hanson.[3] According to these investigators the product obtained upon heating crotonic acid or isocrotonic acid to a temperature above 100° is a binary mixture of these two acids. The latter authors made a more extensive study of the system and came to the conclusion that it afforded an example of "unstable" or "false equilibrium." Since there is considerable doubt whether such cases actually exist,[4] the system promised to be interesting from this point of view also.

Morrell and Hanson obtained their "equilibrium" values by heating a sample of each acid for successive six-hour periods at various temperatures and determining the primary freezing points of the solutions obtained at each temperature. (Their data are included in Table I.) The composition

[4] See Roozeboom, "Die Heterogenen Gleichgewichte," 1918, Vol. **11**, Part 3, p. 13; Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, p. 17.

in each case was then read from the freezing point-composition diagram of the binary system crotonic acid–isocrotonic acid (a system of the simple eutectic type) on the assumption that only these two acids were present. Their "equilibrium curves meet at 172°" at a composition corresponding to 24% isocrotonic acid and **76%** crotonic acid.[5]

On the basis of their work we proposed to prepare a quantity of isocrotonic acid for use in another investigation. By heating a sample of crotonic acid at 172° a mixture freezing at about 50" should be obtained, from which we hoped to get a 34% yield of liquid having the eutectic composition **(70%** isocrotonic acid) by filtering the crotonic acid separated just above the eutectic temperature, −3°. It seemed probable that the isocrotonic acid could be isolated from this solution since Wislicenus[6] was able to obtain it from Kahlbaum "Isocrotonic acid" which was found by him to be only **33%** pure.

Upon carrying out this procedure, the heating being at various temperatures ranging from 125 to 175°, a liquid was obtained by filtering at 0° which did not solidify completely at −3°, nor could isocrotonic acid be isolated from it by Wislicenus' method.

A study of the equilibrium mixtures showed that they are not simple binary but at least ternary mixtures containing crotonic acid, probably some isocrotonic acid and a third substance which has been isolated in 90–95% purity. The evidence seems to show that this third substance is a double molecule having one free carboxyl group and one double bond, the suggested formula being $CH_3CH{=}CHCOOCH(CH_3)CH_2COOH$.

It has also been shown that above **110"** the system does not exhibit the phenomenon of "false equilibrium" as Morrell and Hanson stated.

Effect of Heating Upon Certain Properties of Crotonic Acid

Materials.—The first part of the work was carried out on a sample of Kahlbaum crotonic acid obtained through the courtesy of the Bureau of Chemistry; later, samples were purchased from the Sylco Laboratories of Chicago. In all cases the acid was repeatedly crystallized from petroleum ether, the purified product giving a flat on its time–temperature curve at 71.4°.[7] Successive vacuum sublimation also proved to be an effective method of purification.

---

[5] They suggested the possibility of compound formation within the range 138–145° inasmuch as the sample of isocrotonic acids after being heated at 145° failed to solidify completely at −19°, whereas the eutectic temperature for the crotonic–isocrotonic acid system is −3° as determined by themselves. They state that with the possible exception of this temperature range, preliminary experiments on the equilibrium in the liquid phase seemed to indicate the absence of compound formation below 170".

[6] Wislicenus, *Vierteljahrsschrift der naturforschenden gesellschaft in Zurich*, **41**, *270* (1896); *Verh. d. Vers. deutsch. Ntf. u. Arzte*, (II) **1**, 78 (1895).

[7] It may be noted that this is 0.5° below the value given by Morrell and Hanson. On the basis of purity of material and accuracy of temperature measurement, we believe our value to be the more accurate. By means of heat content curves, Lynn, in this Laboratory, estimated that the impurity was less than 0.03 mole per cent.

Method of Heating.—Samples sealed in evacuated tubes were heated at different temperatures between 97 and 170° for various periods of time. The resulting mixtures, in some cases after the crotonic acid which separated on cooling had been removed by filtration, were examined with reference to the following properties.

Freezing Point.—The apparatus used has already been described.[8] Since it is difficult to control the supercooling of crotonic acid mixtures, it was impossible to use Andrews, Kohman and Johnston's[9] method of correction for the amount of solvent which separated. Instead, the surroundings (the copper shield) were set at various temperatures below the freezing point and the highest maximum after crystallization was taken as the freezing point. The values are, therefore, accurate for pure crotonic acid and the error increases with the increase in concentration of the other components up to probably 1.5' for the most concentrated solutions.[10]

We confirm the finding of Morrell and Hanson that the freezing point is lowered by previous heating and our results show fairly good agreement with theirs for equal periods of heating (see Table I). That these are not the equilibrium values at the respective temperatures, as these investigators evidently assumed, is shown by the fact that further heating at the same temperature caused additional lowering, as can be seen from this table. In fact, by heating a sample of crotonic acid for 165 days at 110° (±1°), a freezing point of 41° was attained, a value which was decidedly lower than any of theirs, even though in some cases they heated to 168°.

TABLE I

THE CHANGE IN FREEZING POINT UPON HEATING THE CROTONIC ACIDS

Morrell and Hanson				Skau and Saxton		
Duration of heating,* hours	Temp. of heating, °C.	Freezing point, Tube I (isocrotonic). °C.	Freezing point. Tube II (crotonic), °C.	Heating, hours	Temp. of heating (±1°), °C.	Freezing point, (crotonic), °C.
0	...	14.96	71.96	0	...	71.4
6	100	13.6	70.5	6	100	70.8
6[a] more	126	10.8	68.4	6.5 more	125	68.7
6 more	138	3.1	64.8	10 more	127	66.9
6 more	145	–3.1	60.3	56 more	123	*52*
6 more	152	21	55.8			
6[a] more	160	37.6	52.8			
6[a] more	168	46	51			

[a] The time of heating is not specifically stated, but it is to be implied that each period was six hours.

Acid Value and Bromination Value.—The acid value is taken as the number of grams of crotonic acid equivalent to the amount of standard alkali used per gram of sample. It was determined by direct titration in dilute alcohol solution using phenolphthalein as an indicator. The bromination value is taken as the number of grams of crotonic acid equivalent to the amount of bromine absorbed by one gram of sample. It was obtained by the method of Gaebel,[11] extending the time for absorption to exactly four hours.

The acid value and the bromination value were always numerically equal within

[10] For a discussion of the error due to this procedure see Andrews, Kohman and Johnston, Ref. **9**.

[11] Gaebel, *Arch. Pharm.*, 250, *72* (1912).

experimental accuracy and were always less than unity. For example, sixty-five hours at 110° gave 0.934; one hundred and twenty hours at 127° gave 0.816; and seven hours at 175° gave 0.891. Since the values for crotonic acid and isocrotonic acid are both unity, these results prove that there is some other substance or substances present in the heated product.

Saponification Value.—This seems to be unchanged by previous heating.

The Reversibility of the Reaction.—To test whether we were dealing with a case of true equilibrium, the final state was approached from two sides in the following manner. A sample of crotonic acid was heated at 160° for thirty-five hours and, after cooling to room temperature, the solid crotonic acid was removed by filtration. The remaining liquid gave a primary freezing point of 18.9° and an acid value of 0.750. Samples of this liquid, "Mixture I," and of pure crotonic acid were sealed in separate evacuated tubes and heated at constant temperature for a number of months. Their freezing points and acid values were then determined, as recorded in Table II.

TABLE II

EQUILIBRIUM VALUES REACHED FROM OPPOSITE SIDES

No.	Sample	Original freezing point, °C.	Duration of heating, months	Temp. of heating (*1°), °C.	Freezing point, °C.	Acid value
I	Crotonic	71.4	5.5	110	41.8	0.710
II	"Mixture I"	18.9	5.5	110	41.0	.703
III	Crotonic	71.4	6.5	125	48.2	.816[a]
IV	"Mixture I"	18.9	6.5	125	45.9	.772
V	"Mixture I"	18.9	5.0	(Room temp.)	19.1	.750

[a] Slight decomposition took place in this tube as was evidenced by the development of considerable pressure.

Besides indicating that above 110° we are dealing with a true and not a "false" equilibrium, these results afford evidence as to the effect of temperature on the equilibrium. This will be discussed more fully below. It should also be noted that while "Mixture I" showed substantially no change at room temperature during five months, heating at 110 and at 125° caused the freezing point to rise in both cases, whereas the acid value rose in one case and fell in the other. This points to the presence of at least three substances in the equilibrium mixtures.

Attempts to Isolate Isocrotonic Acid.—Michael's method was applied to a heated sample of crotonic acid from which considerable crotonic acid had been filtered at room temperature. Instead of isocrotonic acid, however, an oily liquid having an acid value of **0.608** was obtained.[12]

---

[12] Michael's method for the isolation of isocrotonic acid from the Kahlbaum "Isocrotonic acid" depends on the insolubility of the sodium salts of the foreign substances in alcohol. Wislicenus modified this by evaporating the alcoholic solution to a smaller volume and then precipitating a considerable amount of the remaining impurities by adding ether. He thus got a product which was nearly solid at 0°, whereas that obtained by Michael's method contained only a small amount of solid at that temperature.

The product obtained by the use of Wislicenus' modification on a similar sample had essentially the same properties, but undoubtedly contained less crotonic acid, It was a light brown liquid, not crystallizable at −78°, and was insoluble in water but very soluble in alcohol or ether. Its acid value was 0.535 and its bromination value approximately the same, 0.525. It appeared to be very readily hydrolyzed, for, after neutralizing, more acid seemed to be formed on heating, and if titrated back to neutrality occasionally the amount of alkali used approached a total corresponding to an acid value of unity. The saponification value was unity.[13]

From the depression of the freezing point of pure crotonic acid caused by the addition of various small amounts of this liquid, its apparent molecular weight was calculated[14] to be 144; that is, its molecular complexity was 1.67 times that of crotonic acid, thus corresponding to double molecules which are dissociated into single molecules to the extent of 20%.[15]

Distillation under diminished pressure of one of the samples of heated crotonic acid confirmed our conclusion that very little isocrotonic acid was present. We obtained a low-boiling fraction having an acid and a bromination value substantially of unity; a middle fraction rich in crotonic acid and, as the largest fraction, a high-boiling liquid (165–173° at 24 mm.)[16] which had an acid value of 0.679 and a bromination value of 0.671 and from which crotonic acid separated at room temperature.

Nature of the Products Formed.—All of the above data indicate that the system contains at least three substances: (1) crotonic acid; (2) a low-boiling constituent which comes over with the crotonic acid in a vacuum distillation; and (3) a high-boiling constituent which constitutes the major portion of the product obtained on applying the Michael–Wislicenus method for isolating isocrotonic acid.

---

[13] The low acid value, the high boiling point and the saponification value might be explained by the presence of an acid anhydride. To test this possibility, a sample from which the solid crotonic acid was filtered at 0° was treated in one case with a slight excess of alkali and in another with an excess of solid sodium carbonate in a small amount of water and then extracted thoroughly with ether. The ether extracts contained a slight amount of a brown resinous substance representing only a small fraction of a per cent. of the original heated mixture.

[14] From the ideal freezing point–solubility equation

$$\log N = \frac{-3100}{4.575(273.1 + 71.4)} \frac{\Delta t_F}{T_F} = -1.967 \frac{\Delta t_F}{T_F}$$

in which N is the mole fraction of crotonic acid, Δt_F the freezing point depression, T_F the freezing point of the solution on the absolute scale, 71.4 the freezing point of pure crotonic acid, and 3100 the molal heat of fusion of crotonic acid as determined by Lynn [Skau and Saxton, THIS JOURNAL, 50,2693 (1928)].

[15] From the relation $x = (2/1.67) - 1$.

[16] Wislicenus, Jr., ["Dissertation," Leipzig, 1892; *Chem.* Zentr., I, 413 (1893)] found that Kahlbaum's "Isocrotonic acid" distilled almost completely below 100° at this pressure, the impurity being essentially crotonic acid.

The low-boiling constituent is probably isocrotonic acid, for in the mixture with crotonic acid, as it was obtained, the acid and bromination values were approximately equal to unity, and, therefore, its molecular weight (within 2%) is equal to that of crotonic acid. If the low-boiling fractions are thus assumed to be binary mixtures of crotonic and isocrotonic acids, their compositions *can* be estimated from their freezing points and Morrell and Hanson's freezing point–composition diagram. By such an estimation it was found that the amount of isocrotonic acid in the original heated mixture was in the neighborhood of 7%.

The high-boiling constituent appears to be a dimolecular polymer of crotonic or isocrotonic acid or an addition compound of the two acids having one free carboxyl group and one double bond. This would require acid and bromination values of 0.5. The formula $CH_3CH{=}CHCOOCH(CH_3)CH_2COOH$ seems to agree with the properties best. This was the structure attributed by Thackrah[17] to a compound distilling at 163° (24–25 mm.) from a mixture obtained by heating crotonic acid at 190–200° for a few hours. His proof for this structure was based on the fact that the compound neutralized only one-half as much alkali as the same weight of crotonic acid, and that it was readily hydrolyzed on boiling or on heating with an excess of alkali, giving crotonic acid and β-hydroxybutyric acid salts. He also claimed that crotonic acid was formed practically quantitatively[18] by heating this product for a long time at 200°.

Thackrah came to the conclusion that the liquid condensation product cannot be prepared free from crotonic acid and his lowest neutralization value corresponds to an acid value of 0.57. We have been able, however, by taking advantage of the difference in the solubility of the sodium salts in a mixture of alcohol and ether, to obtain a product having an acid value of 0.535 and have attempted to purify it further by various methods. (1) Petrol ether extraction resulted in a lowering of the acid value of the residue but the change was relatively small. (2) By using the principle of steam distillation with benzene as the carrier, the acid value of a sample was reduced from 0.634 to 0.561, but the procedure was very slow. (3) The product obtained by the last method was heated in a vacuum distilling apparatus for about six hours at 104° and 20 mm. The residual liquid, which was now a deep brown, had an acid value of 0.455 and its saponification value was unity. Due to the smallness of the sample the determination of the bromination value was omitted. The apparent molecular weight was still less than twice that of crotonic acid, the mean value of x being 0.11. The fact that the acid value was less than 0.5 might seem to

---

[17] Thackrah, "Dissertation," Leipzig, 1891. To the best of our knowledge this work has never been otherwise published, the only reference to it being in another Leipzig dissertation by Wislicenus, Jr., in 1892.

[18] This seems rather doubtful, considering his method of preparation of the compound.

indicate the presence of a trimolecular compound, but it could be equally well explained by assuming the presence of a dimolecular form having no free carboxyl groups.

Effect of Temperature on the Equilibrium.—An examination of the acid values of I to IV in Table II indicates that the percentage of double molecules in the equilibrium mixtures decreases as the temperature of heating increases. This is to be expected since polymerization is, as a rule, exothermic. We have also noted indications that the percentage of the low-boiling constituent does not change proportionately to that of the double molecule. If it did, the separation of the crotonic acid at 0° would leave a liquid of the same acid value in all instances, but this was found not to be the case.

Summary

The effect of heating crotonic acid has been investigated. It has been proved that the resulting mixture is not a binary mixture, as is stated in the literature, but contains at least three compounds: crotonic acid, a low-boiling constituent (probably isocrotonic acid) and a high-boiling liquid from the properties of which its probable structure has been deduced. It has further been proved that above 110° the system does not show the phenomenon of "false equilibrium" as was previously supposed.

THE BROMINATION OF 2,4-DIMETHOXYCINNAMIC ACID

BY MARIE REIMER AND ELISE TOBIN

RECEIVED JULY 26, 1929 PUBLISHED JANUARY 8, 1930

In the study, in this Laboratory, of unsaturated a-ketonic acids, certain substituted cinnamic acids have been needed for purposes of identification. This has led to the study of the bromination products of 2,4-dimethoxycinnamic acid which are described in this paper. The acid was prepared by hydrolysis of ethyl 2,4-dimethoxycinnamate made by the Claisen condensation and was the stable form.

We have found that addition of bromine to 2,4-dimethoxycinnamic acid is invariably accompanied by bromination in the ring, the position of the nuclear bromine atom being established by oxidation of the tribromo acid thus formed to 2,4-dimethoxy-5-bromobenzoic acid.' The behavior of the dimethoxycinnamic acid on bromination is, therefore, similar to that of **the** corresponding dimethoxybenzoylacrylic acid.[1] It has not been possible to prepare an unsaturated acid by elimination of hydrogen bromide from the tribromo acid by the usual methods. Invariably saturated alkoxy acids result which are probably formed by direct replacement of bromine by an

---

[1] **Grace Potter Rice,** THIS JOURNAL, **48,3125** (1926).

alkoxyl group rather than by elimination of hydrogen bromide and addition of solvent. This is indicated by the fact that the tribromo acid is stable and does not lose hydrogen bromide below its melting point when heated alone nor when heated in high boiling solvents and that these same alkoxyl products are formed in alcoholic solution in the absence of an alkaline reagent. The ease of replacement of this bromine atom is comparable to that of the chlorine atom in unsaturated compounds containing the grouping $C_6H_5CHClCH{=}CH{-}{-}{-}{-}C_6H_5$. Straus[2] has found this chlorine atom to be increasingly labile with increasing unsaturation of the side chain and particularly with *p*-methoxy substituting groups. As it has been found during the course of previous work that such ease of replacement of bromine is not a characteristic of pmethoxy- nor of o-methoxycinnamic acid dibromide, with or without a bromine atom in the ring, this great lability of the bromine atom in the compounds under discussion must be ascribed to the presence of both para and ortho methoxyl groups, possibly also to the nuclear bromine atom. It is then, in all probability, the bromine atom adjacent to the ring that is replaced.

Since the usual esterification methods when used with the tribromo acid gave esters of alkoxy acids, the methyl ester of the tribromo acid was prepared by bromination of methyl 2,4-dimethoxycinnamate. Attempts to prepare the ethyl ester of the tribromo acid by bromination of ethyl 2,4-dimethoxycinnamate led to an interesting and unexpected result. Although the bromine and the solvent chloroform were the same as in the previous bromination reactions, the small amount of moisture evidently present hydrolyzed the product almost completely, the substance obtained in practically quantitative yield being 2,4-dimethoxy-5-bromobenzaldehyde. Even with dried reagents it has not as yet been possible to prepare a pure tribromo ethyl ester by this procedure. The crude product of the bromination gives the aldehyde when brought into contact with water. The tribromo acid and its methyl ester yield no trace of the aldehyde even on long boiling with water.

It seems reasonable to ascribe this difference in the behavior of the bromination product of the ethyl ester, on the one hand, and of the tribromo acid and its methyl ester on the other to a difference in space configuration. To test this assumption it would be necessary to prepare a tribromo ethyl ester, the diastereoisomer of the unstable one above postulated, which would be expected to have the characteristics of the tribromo acid and its methyl ester. It has been possible to prepare such an isomeric compound. Since the tribromo acid on treatment with diazomethane gave a tribromo methyl ester which, like the acid, was not hydrolyzed to the aldehyde, the tribromo acid was treated with diazoethane. As was expected, a tribromo ethyl ester resulted which behaved in all respects like the tribromo acid and

---

[2] Straus and Diitzmann, *J. prakt. Chem.*, [2] **103**, 1 (1921).

its methyl ester. This ester has then undoubtedly the same space configuration as that of the tribromo acid. It may be considered to be derived from an ethyl-dimethoxycinnamate geometrically isomeric with the one from which the acid used in this study was prepared, which was made by the Claisen condensation, is pale yellow, melts at 68–69' and is hydrolyzed on bromination. When this ester was distilled under diminished pressure, a colorless solid melting at 61° was obtained. This is the isomeric ester. It does give on bromination the same tribromo ethyl ester that was obtained by action of diazoethane on the tribromo acid. The space relations of these esters are now under investigation.

Experimental Part

2,4-Dimethoxycinnamic acid was prepared from its ethyl ester obtained by Claisen condensation of 2,4-dimethoxybenzaldehyde and ethyl acetate according to the method of Perkin and Schiess,[3] which gives much better yields of the acid than the Perkin synthesis described by the same authors. 2,4-Dimethoxybenzaldehyde was prepared by the method used by Freudenberg[4] for veratric aldehyde. It was obtained in 85% yield and used without further purification. The resorcyl aldehyde needed in its preparation was obtained in good yield by the Gatterman method as modified by Johnson and Lane.[5]

The ethyl ester of 2,4-dimethoxycinnamic acid, melting at 68–69', obtained in a yield of 70% was saponified by boiling for an hour with an excess of 10% sodium hydroxide. The cooled solution on acidification deposited an 85–90% yield of the stable form of the corresponding acid. It was purified by crystallization from glacial acetic acid, which proved to give the purest product, although there was considerable loss of substance with this solvent.

Reaction of Bromine on 2,4-Dimethoxycinnamic Acid

Since it was not found possible to prepare a dibromo addition product of the acid, as bromination in the ring invariably accompanied the addition reaction, the following brominations were carried out with two molecular proportions of bromine.

2,4-Dimethoxy-5-bromocinnamic Acid Dibromide, $(CH_3O)_2BrC_6H_2CHBrCHBr$-COOH (I).—Fifteen grams of 2,4-dimethoxycinnamic acid was suspended in 250 cc. of chloroform, the mixture cooled and 8.2 cc. of bromine added slowly; the acid dissolved readily and, toward the end of the reaction, the bromo compound separated out. The mixture was shaken for a few minutes, the solid product then filtered and washed repeatedly with small amounts of cooled chloroform until it was practically colorless. By evaporation of the mother liquor in a current of dry air, further small amounts separated. The substance, obtained in practically quantitative yield, is a granular solid melting at 228–229° with vigorous decomposition. It is readily soluble in acetone and glacial acetic acid, very slightly soluble in chloroform, benzene and ether. As it was not found possible to purify it further by crystallization from any solvent, the carefully washed crude product was analyzed.

Anal. Subs., 0.1944: CO_2, 0.2110; H_2O, 0.0437. Calcd. for $C_{11}H_{11}O_4Br_3$: C. 29.54; H, 2.48. Found: C, 29.60; H, 2.52.

To determine the position of the nuclear bromine atom, the acid was oxidized with potassium permanganate. The product of the oxidation was proved to be 2,4-dimeth-

[5] Johnson and Lane, THIS JOURNAL, 43,348 (1921).

oxy-5-bromobenzoic acid by a mixed melting point with a sample of that acid obtained from another source.

Esterification of the tribromo acid was at first attempted in alcoholic solution but in all such reactions one bromine atom was replaced by an alkoxyl group. The methyl ester of 2,4-dimethoxy-5-bromocinnamic acid dibromide (II) was obtained by the reaction of the acid in ethereal solution with a slight excess of diazomethane. The ester crystallizes from the ether and can be purified from benzene or from ether, from which it separates in large firm crystals melting, with decomposition, at 142°.

Anal. Subs., 5.605 mg.: CO_2, 6.47 mg.; H_2O, 1.59 mg. Calcd. for $C_{12}H_{13}O_4Br_3$: C, 31.25; H, 2.84. Found: C, 31.48; H, 3.17.

Methyl Ester of **α-Bromo-β-methoxy-2,4-dimethoxy-5-bromohydrocinnamic** Acid, $(CH_3O)_2BrC_6H_2CH(OCH_3)CHBrCOOCH_3$ **(III)**.—This ester crystallized out from solution when the tribromo acid was allowed to stand overnight in methyl alcohol saturated with hydrogen chloride. It separates in compact, colorless crystals melting, without decomposition, at 149°.

Anal. Subs., 0.1695: CO_2, 0.2359; H_2O, 0.0628. Calcd. for $C_{13}H_{16}O_5Br_2$: C, 37.87; H, 3.91. Found: C, 37.95; H, 4.15.

This ester was also formed by recrystallization of the tribromo methyl ester (II) from boiling methyl alcohol and from the tribromo acid by allowing the acid to stand for several hours in contact with methyl alcohol. In the latter case the corresponding acid was also obtained.

α-Bromo-β-methoxy-2,4-dimethoxy-5-bromohydrocinnamic Acid **(IV)**.—The methyl alcoholic solution of the tribromo acid on standing overnight deposited a considerable quantity of the methyl ester (III) just described. The alcoholic solution was poured into aqueous sodium carbonate, this extracted with ether and the alkaline solution acidified. The heavy white precipitate was crystallized from benzene from which the acid separates in tiny shining hard crystals melting at 171° with effervescence and charring. From 1.0 g. of tribromo acid 0.6 g. of acid and 0.3 g. of methyl ester were obtained. This acid readily gives the ester (III) by action of diazomethane.

Anal. Subs., 5.069 mg.: CO_2, 6.77 mg.; H_2O, 1.77 mg. Calcd. for $C_{12}H_{14}O_5Br_2$: C, 36.19; H, 3.55. Found: C, 36.42; H, 3.91.

The ethyl ester (V) of the methoxy acid (IV) was obtained by the reaction of the acid in ethereal solution with diazoethane. The substance crystallizes from ethyl alcohol or from absolute ether in characteristic bunches of hexagonal plates. It melts at 109°.

Anal. Subs., 5.125 mg.: CO_2, 7.37 mg.; H_2O, 2.00 mg. Calcd. for $C_{14}H_{18}O_5Br_2$: C, 39.44; H, 4.23. Found: C, 39.22; H, 4.37.

The Ethyl Ester of **2,4-Dimethoxy-5-bromocinnamic** Acid Dibromide **(VI)**.—Five grams of freshly prepared tribromo acid was moistened with ether and a slight excess of freshly prepared diazoethane in ethereal solution added slowly. The acid dissolved readily and the ester began almost at once to separate from the solution as a pure white granular solid. It was filtered and washed with dry ether. The substance melts with vigorous effervescence at 158°. It is soluble in boiling benzene, very slightly soluble in ether and methyl and ethyl alcohols. With the latter solvents it reacts readily. It is very slightly soluble in boiling water and does not appear to react with it.

Anal. Subs., 4.766 mg.: CO_2, 5.77 mg.; H_2O, 1.26 mg. Calcd. for $C_{13}H_{15}O_4Br_3$: C, 32.85; H, 3.18. Found: C, 33.02; H, 2.96.

When this tribromo ethyl ester was boiled with methyl alcohol, the ethyl ester (V) of the methoxy acid (IV) was obtained. From ethyl alcohol the ethyl ester (VII) of the ethoxy acid (VIII) crystallized. The substance has, therefore, undoubtedly, the same configuration as the tribromo acid and its methyl ester.

The ethyl ester of α-bromo-β-ethoxy-2,4-dimethoxy-5-bromohydrocinnamic acid, $(CH_3O)_2BrC_6H_2CH(OC_2H_5)CHBrCOOC_2H_5$ (VII), was formed when the tribromo acid was treated with ethyl alcohol saturated with hydrogen chloride. It separates from ethyl alcohol in fine needles melting at 105–107°.

Anal. Subs., 0.1588: CO_2, 0.2384; H_2O, 0.0722. Calcd. for $C_{15}H_{20}O_5Br_2$: C, 40.91; H, 4.58. Found: C, 40.94; H, 4.96.

This ester was also obtained in small quantity when the tribromo acid was allowed to stand overnight with ethyl alcohol. As in the parallel reaction with methyl alcohol, the corresponding acid was also formed and was separated in the way there described.

α-Bromo-β-ethoxy-2,4-dimethoxy-5-bromohydrocinnamic Acid (VIII) crystallizes from benzene in small thick prisms melting at 161–162° with decomposition. By action of diazoethane on this acid, the ethyl ester (VII) is readily formed.

Anal. Subs., 6.140 mg.: CO_2, 8.49 mg.; H_2O, 2.16 mg. Calcd. for $C_{13}H_{16}O_5Br_2$: C, 37.87; H, 3.91. Found: C, 37.70; H, 3.94.

The methyl ester (IX) of the ethoxy acid (VIII) was obtained by the action of diazomethane on that acid and by crystallization of the methyl ester of the tribromo acid (II) from ethyl alcohol. It crystallizes readily from methyl alcohol or ether in rosets of firm needles melting at 138" with preliminary softening at 134°.

Anal. Subs., 6.167 mg.: CO_2, 8.98 mg.; H_2O, 2.29 mg. Calcd. for $C_{14}H_{18}O_5Br_2$: C, 39.44; H, 4.23. Found: C, 39.71; H, 4.15.

In marked contrast to the behavior of the dibromides of unsaturatated α-ketonic acids, which readily lose hydrogen bromide on heating or even spontaneously,[6] the tribromo acid above described did not lose hydrogen bromide to form an unsaturated acid under the usual conditions. It was recovered unchanged after heating at 100° and also after long heating in high-boiling solvents such as toluene, xylene and cymene. Action of potassium hydroxide in methyl alcoholic solution gave two products, a styrene derivative, as was to have been expected, and a small quantity of an acid, not however the corresponding unsaturated acid but the methoxy acid (IV). This same acid was formed by reaction of potassium acetate in methyl alcoholic solution.

1-Bromo-2-(2,4-dimethoxy-5-bromophenyl)-ethylene, $(CH_3O)_2BrC_6H_2CH{=}CHBr$ (X).—Five grams of the tribromo acid was stirred rapidly into 15 cc. of a saturated solution of potassium hydroxide in methyl alcohol. There was vigorous effervescence and a pasty solid separated. This was filtered, washed with a trace of alcohol and then repeatedly with water. The substance is readily soluble in the usual organic solvents. It separates from diluted methyl alcohol in clumps of fine white crystals melting at 67-68°. The yield was 80%.

Anal. Subs., 5.096 mg.: CO_2, 6.98 mg.; H_2O, 1.51 mg. Calcd. for $C_{10}H_{10}O_2Br_2$: C, 37.26; H, 3.10. Found: C, 37.35; H, 3.32.

The compound is very readily affected by the light. It rapidly takes on a rose pink color in diffused light and becomes black in a short time in bright sunlight. The aqueous washings from this substance on acidification yielded a small amount of the methoxy acid (IV). The styrene derivative (X) readily reacted further with bromine.

1,1-Dibromo-2-bromo-2-(2,4-dimethoxy-5-bromophenyl)-ethane, $(CH_3O)_2BrC_6H_2$-$CHBrCHBr_2$ (XI).—The substance separated from chloroform in quantitative yield as a slightly yellow powder, which after washing repeatedly with small amounts of cold methyl alcohol was colorless. It melts at 146° with slight effervescence.

Anal. Subs., 4.825 mg.: CO_2, 4.45 mg.; H_2O, 0.98 mg. Calcd. for $C_{10}H_{10}O_2Br_4$: C, 24.91; H, 2.09. Found: C, 25.15; H, 2.27.

[6] Reimer, THIS JOURNAL, 48, 2454 (1926); Reimer and Howard, *ibid.*, 50, 2506 (1928).

This tetrabromo compound is perfectly stable when pure and does not change color on long standing. One of the four bromine atoms, presumably the one nearest the benzene ring, is very easily replaced by alkoxyl groups as in the case of the tribromo acid. On boiling the substance with methyl alcohol, in which it is only slightly soluble, a methoxy tribromo compound is formed.

1,1-Dibromo-2-methoxy-2-(2,4-dimethoxy-5-bromophenyl)-ethane, $(CH_3O)_2BrC_6H_2CH(OCH_3)CHBr_2$ **(XII)**.—The substance crystallizes from methyl alcohol or from ligroin in stiff prisms melting at 138–139°. The same substance was obtained by the action of potassium hydroxide in methyl alcoholic solution on the tetrabromo compound.

Anal. Subs., 4.965 mg.: CO_2, 5.55 mg.; H_2O, 1.27 mg. Calcd. for $C_{11}H_{13}O_3Br_3$: C, 30.48; H, 3.00. Found: C, 30.48; H, 2.86.

1,1-Dibromo-2-ethoxy-2-(2,4-dimethoxy-5-bromophenyl)-ethane, $(CH_3O)_2BrC_6H_2CH(OC_2H_5)CHBr_2$ **(XIII)**.—This substance is formed when the tetrabromo compound is boiled with ethyl alcohol. The product left after evaporation of the solvent was recrystallized from ligroin; melting point 117–120°.

Anal. Subs., 5.314 mg.: CO_2, 6.35 mg.; H_2O, 1.79 mg. Calcd. for $C_{12}H_{15}O_3Br_3$: C, 32.21; H, 3.36. Found: C, 32.59; H, 3.77.

Action of Bromine on the Esters of **2,4-Dimethoxycinnamic** Acid.—Methyl 2,4-dimethoxycinnamate was prepared by Claisen condensation by the same procedure as for the ethyl ester, and by the action of diazomethane on the acid. Either of these methods is simpler than that of Tiemann and Will.[7] It is most conveniently purified by distillation under diminished pressure. The pale yellow oil which distils at 216° (20 mm.) solidifies on cooling and, after one crystallization from methyl alcohol, is obtained in stiff colorless needles melting at 87°. Reaction of bromine on this ester gave, in quantitative yield, the tribromo ester (II) already described.

The ethyl ester of 2,4-dimethoxycinnamic acid behaved in an entirely different manner on treatment with bromine. The bromine was rapidly decolorized and on evaporation of the chloroform used as solvent, a yellow granular solid was left. This, after washing with benzene, was found to melt at 110–132°, showing it to be a mixture, and preliminary analysis gave 43.4% of carbon instead of 32.9% calculated for the expected tribromide. After purification, the product gave analytical results agreeing with those of an aldehyde, $(CH_3O)_2BrC_6H_2CHO$. That the product has this formula was proved by its ready oxidation with ammoniacal silver nitrate solution to 2,4-dimethoxy-5-bromobenzoic acid and by the preparation of its semicarbazone.

2,4-Dimethoxy-5-bromobenzaldehyde (XIV).—The substance is most readily obtained in pure condition by boiling the crude product of the bromination reaction with water. It separates from aqueous solution in a mass of very fine shining needles, from alcohol in sturdy needles or from benzene in branching clumps of fine thread-like crystals resembling a fungus growth. These after standing for some time crumble to small rhombic crystals. The substance melts without decomposition, 134–138°.

Anal. Subs., 5.468 mg.: CO_2, 8.90 mg.; H_2O, 1.74 mg. Calcd. for $C_9H_9O_3Br$: C, 44.08; H, 3.67. Found: C, 44.38; H, 3.56.

The semicarbazone is a fine white granular solid, very slightly soluble in methyl alcohol. It decomposes at about 275°.

Anal. Subs., 5.04 mg.: CO_2, 7.43 mg.; H_2O, 1.77 mg. Calcd. for $C_{10}H_{12}O_3N_3Br$: C, 39.74; H, 3.97. Found: C, 40.20; H, 3.93.

Since the preliminary analysis of the bromination product of ethyl 2,4-dimethoxycinnamate showed the product to be almost exclusively made up of the aldehyde, the

---

[7] Tiemann and Will, *Ber.*, 15, 2079 (1882).

presence of the latter was attributed to water in the reagents which had presumably hydrolyzed the tribromo ethyl ester first formed in the reaction. The experiment was, therefore, repeated with carefully dried chloroform and bromine which had been distilled from phosphorus pentoxide. The product melted with decomposition over a long range, showing it to be probably a bromo addition compound but very impure. Repeated trials have not as yet given a pure substance. When this crude product was treated with water, a copious yield of the aldehyde was obtained.

When ethyl 2,4-dimethoxycinnamate (68–69°), prepared by the Claisen condensation, was distilled under diminished pressure, a yellow oil boiling at 219° (22 mm.) was obtained. This distillate solidified on cooling and, on crystallization from low boiling petroleum ether, separated in perfectly colorless needles melting at 61°. A mixture of this ester and the one previously used (68–69°) melted from 45–55°. Analysis proved it to be an isomeric form.

Anal. Subs., 0.1148: CO_2, 0.2777; H_2O, 0.0730. Calcd. for $C_{13}H_{16}O_4$: C, 66.10; H, 6.78. Found: C, 65.97; H, 7.05.

This isomeric ester on bromination with the usual laboratory reagents or with those that had been carefully dried gave, in quantitative yield, the ethyl ester of 2,4-dimethoxy-5-bromocinnamic acid dibromide (VI) previously described.

Summary

The bromination of 2,4-dimethoxycinnamic acid and its methyl and ethyl esters has been described. The acid differs from p-methoxycinnamic acid and from o-methoxycinnamic acid in the fact that addition of bromine is invariably accompanied by bromination in the ring and in the extraordinary ease of replacement of the β-bromine atom in the bromination products by alkoxyl groups. The two isomeric ethyl esters of the acid give different products on bromination.

BENZYLPINACOLONES AND THEIR REDUCTION PRODUCTS. I

BY G. ALBERT HILL AND WILLIAM F. BRUCE

RECEIVED JULY 29, 1929 PUBLISHED JANUARY 8, 1930

Sodamide syntheses,[1] in ether, with pinacolone and benzyl chloride yielded mono- and dibenzylpinacolones, $C_6H_5CH_2CH_2COC(CH_3)_3$, $(C_6H_5CH_2)_2CHCOC(CH_3)_3$. Benzylpinacolone has been described by one of us[2] but an improved method of preparation is reported here.

Dibenzylpinacolone in toluene reacted with sodamide and benzyl chloride producing tribenzylpinacolone, $(C_6H_5CH_2)_3CCOC(CH_3)_3$. Good yields resulted in this synthesis only when the original ketone, a readily purified crystalline solid, was distilled just prior to the runs. Possibly this is due to a higher proportion of an enolic modification in the freshly distilled material.

[1] Haller and Bauer, *Ann. chim.*, [8] 29, 313 (1913).

[2] Hill, Spear and Lachowicz, THIS JOURNAL, 45, 1557 (1923).

Only the monobenzylpinacolone gave a crystalline oxime. Probably because of steric hindrance the more highly substituted ketones failed to react. All the ketones were reduced to the corresponding secondary alcohols by the action of sodium and absolute ethyl alcohol. Among the methods employed, which proved unattractive, were the use of sodium and amyl alcohol, sodium and moist ether, magnesium activated by mercuric chloride and absolute methyl alcohol, aluminum and solid potassium hydroxide in absolute ethyl alcohol and zinc and acetic acid.

Of the alcohols, only the tribenzyl derivative failed to give a crystalline phenylurethan.

The β-phenylethyl-*tert.*-butylcarbinol, $C_6H_5CH_2CH_2CHOHC(CH_3)_3$, is a liquid at room temperature. This is interesting because in the course of an earlier investigation of benzalpinacolone,[3] a compound was obtained which was thought to be this, then unknown, carbinol, but which melted at 142°. With the idea of reconciling these two reports, work on the substance melting at 142° has been resumed.

Attempts to reduce the ketones to the corresponding hydrocarbons by a wide variety of methods were unsuccessful save in the case of the monobenzyl compound. Heating with hydriodic acid and red phosphorus under pressure did, however, bring about reduction in this case. The Clemmensen method,[4] of which much was expected, gave only negative results.

Experiments with these ketones and alcohols, which it is hoped will yield the desired hydrocarbons, are being continued in this Laboratory.

It is a pleasure to acknowledge here the assistance in the preliminary work afforded by J. S. Lachowicz and E. W. Flosdorf, and gratefully to mention the material aid from the Atwater Fund.

Experimental Part

Pinacol Hydrate.—This was made according to Adams and Adams.[5]

Pinacolone.—The preparation was according to Hill and Flosdorf.[6]

The Ketones.—Mono-, di- and tribenzylpinacolones were prepared by methods essentially similar; therefore, the detailed procedure for the monobenzyl derivative only is given.

Monobenzylpinacolone.—A modification of the method of Hill and Lachowicz[3] was employed: 41 g. of finely ground friable sodamide was placed in a 2-liter, 3-necked flask provided with a reflux condenser, a mechanical stirrer with a mercury seal and a separatory funnel. A solution of 100 g. of pinacolone in 450 cc. of absolute ether was *slowly* introduced. The loss of ether and pinacolone swept out of the flask by the vigorous evolution of ammonia during the first half hour warranted the use of a trap bottle, im-

---

[4] Clemmensen, *Ber.*, 46, 1841 (1913).

[5] R. Adams and E. W. Adams, "Organic Syntheses," John Wiley and Sons, Inc., New York, Vol. V, 1925, p. 87.

[6] G. A. Hill and E. W. Flosdorf, *ibid.*, p. 91.

mersed in a freezing mixture, beyond the reflux condenser to collect the valuable pinacolone. The ether solution was boiled for from eight to ten hours, when evolution of ammonia had practically ceased; 132 g. of pure benzyl chloride was added very slowly, two or three drops a second, to avoid generation of too much ether vapor. The mixture was then warmed and stirred for twenty-four hours; 250 cc. of water was added and the ether layer removed, The latter was washed with water, dilute hydrochloric acid, and again with water, and dried with calcium chloride. After elimination of the ether, the residue was vacuum distilled: 106 g. of monobenzylpinacolone, a 56% yield, was obtained, accompanied by 60 g. of dibenzylpinacolone. These products account for 77.5% of the pinacolone used.

Monobenzylpinacolone is colorless when pure, and while insoluble in water dissolves readily in organic solvents; b. p. (10 mm.) 132"; (43 mm.) 155°; (760 mm.) 247°; d_{20}^{20} 0.95005; d_4^{20} 0.9483. The refractive index, n_D^{20}, is 1.4999. The dispersion factor found, $N_F - N_C$, is 0.01440. The molecular refraction, calculated by the Lorentz and Lorenz formula, is 58.8 while the values of Eisenlohr[7] give 58.6.

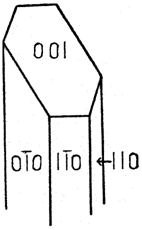
The oxime, prepared by Tanny's method,[8] melted at 95.5°, in agreement with the reported figure.

Dibenzylpinacolone.—The crude product was distilled, b. p. (9 mm.) 190–220°. The viscous yellow distillate solidified and after two crystallizations from ethyl alcohol melted at 49°. The yield of white crystalline material was 59%.

When pinacolone was treated with somewhat more than double the theoretical amount of sodamide and of benzyl chloride required for monosubstitution, a 66.6% yield of dibenzylpinacolone could be obtained without first isolating monobenzylpinacolone. An attempt to prepare an *oxime* was unsuccessful.

Anal. Subs., 0.1814, 0.1509: CO_2, 0.5691, 0.4743; H_2O, 0.1399, 0.1173. Calcd. for $C_{20}H_{24}O$: C, 85.66, H, 8.63. Found: C, 85.56, 85.69; H, 8.63, 8.70.

Crystal Structure of Dibenzylpinacolone.[9]—Triclinic system; prismatic habit. Positive unit prism 110; negative unit prism $1\bar{1}0$; side pinacoid 010. $110 > 1\bar{1}0 = 140° 33'$; $1\bar{1}0 > 010 = 97° 33'$; $110 > 0\bar{1}0 = 121° 52'$. Parameters: $a = 0.35735$; $b = 1.00000$; $c = 0.00000$. No good faces near 001 were obtained, but a conchoidal cleavage parallel to 001 was found.



Tribenzylpinacolone.—The apparatus used was similar to that previously described save that the stirrer passed through a close-fitting glass bearing tube, which extended into the solution, instead of through a mercury seal bearing. It was observed that when small amounts of mercury were prevented from passing into the reactants, the yields were better. Toluene was used as a solvent instead of ether. Pure tribenzylpinacolone was prepared by recrystallization from toluene, m. p. 161.5' (corr.). Yields as high as 73.4% were obtained.

Anal. Subs., 0.1983, 0.2372: CO_2, 0.6345, 0.7598; H_2O, 0.1442, 0.1721. Calcd. for $C_{27}H_{30}O$: C, 87.51; H, 8.17. Found: C, 87.26, 87.35; H, 8.14, 8.12.

The boiling point is (8 mm.) 268.9' (corr.). The calculated molecular weight is 370.2; found by Menzies' method, using benzene, 363.6, 365.2.[10]

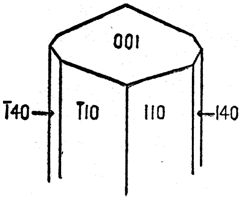
[9] Studies of the crystal structures were made with the assistance of Professor W. G. Foye.

[10] Determination by B. C. French.

This ketone dissolves in toluene, quite readily when hot, but is only soluble to the extent of somewhat over 1 g. in 100 cc. of boiling alcohol. Boiling ether dissolves twice as much. It dissolves easily in hot carbon tetrachloride. An attempt to prepare an *oxime* was not successful.

Crystal Structure of Tribenzylpinacolone.—Orthorhombic system; columnar habit. Base 001; unit prism 110; brachyprism 140. 140 > $\bar{1}40$ = 131° 08′; 110 > $1\bar{1}0$ = 132° 45′; 110>140 = 138° 22′. Parameters: *a* = 0.043741; b = 1.00000; *c* = 0.00000. Fair basal cleavage, very good prism cleavage.



The Secondary Alcohols.—The most successful method employed for the reduction of the ketones to the corresponding secondary alcohols was ultimately used with all three, and hence the preparation of but one will be given in detail.

β-Phenylethyl-*tert*.-butylcarbinol.—Thirty-eight grams of monobenzylpinacolone dissolved in 280 cc. of absolute ethyl alcohol was treated, with stirring and refluxing, with 51 g. of sodium. This required about twenty minutes and stirring was continued for three hours; 200 cc. of water was added, and the resulting two-layer system separated. The aqueous part was made acid with hydrochloric acid and a small amount of oily material separated. This was added to the non-aqueous layer, which was washed with water, dilute hydrochloric acid and water, and after the addition of a little ether, about 50 cc., dried with sodium sulfate. By vacuum fractionation at 15.5 mm., the corrected boiling point was found to be 145.5′. and 28.5 g. of the carbinol, a yield of 73%, was procured.

Anal. Subs., 0.47680, 0.17990,[11] 0.26575; CO_2, 1.4144, 0.53380, 0.78810; H_2O, 0.44310, 0.16720, 0.24720. Calcd. for $C_{13}H_{20}O$: C, 81.18; H, 10.42. Found: C, 80.90, 80.93, 80.88; H, 10.40, 10.40, 10.40.

The carbinol is a colorless oily liquid insoluble in water and readily soluble in organic solvents; d_{20}^{20} 0.9593; d_4^{20} 0.9578; n_D^{20} 1.5097; $N_F - N_C$, 0.01456; M_D, calculated from the refractive index, 60.16; calculated from the Eisenlohr values, 60.158.

Preparation of the **Phenylurethan.**—Ten grams of the carbinol was mixed with 6.5 g. of phenylisocyanate and set aside, in a closed flask, for two days; 20 cc. of ethyl alcohol was then added and the flask warmed to bring about complete solution. On cooling the filtered material, microscopic white crystals separated, m. p. 88.1° (corr.).

Anal. (Kjeldahl). Subs., 0.5788, 0.5403: acid used, 20.56 cc. of 0.09232 *N*, 20.08 cc. of 0.08351 *N* H_2SO_4. Calcd. for $C_{20}H_{25}O_2N$: N, 4.50. Found: N, 4.58, 4.33.

(Dibenzylmethyl)-*tert*.-butylcarbinol.—This carbinol, b. p. (15 mm.) 206–208°, was obtained in a 32% yield.

And. Subs., 0.1998, 0.2068: CO_2, 0.6219, 0.6438; H_2O, 0.1636, 0.1694. Calcd. for $C_{20}H_{26}O$: C, 85.05; H, 9.28. Found: C, 84.90, 84.88; H, 9.17, 9.16.

This alcohol is colorless when pure, and is extremely viscous. Whiie it could be solidified, apparently, at low temperatures, it was not obtainable crystalline despite numerous and various attempts; d_{20}^{20} 1.005; n^{20}, using daylight, 1.5422, 1.5440; $N_F - N_C$, 0.01755. The phenylurethan was deposited as fine, white needles, m. p. 148".

---

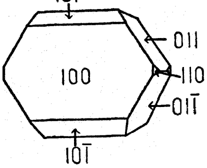
[11] Analysis by E. T. Dowling.

Anal. (Kjeldahl). Subs., 0.7512:[12] acid used, 18.34 cc. of 0.10372 N H_2SO_4. Calcd. for $C_{27}H_{31}O_2N$: N, 3.49. Found: N, 3.54.

(Tribenzylmethyl)-*tert.*-butylcarbinol.—Some of this carbinol was prepared by the action of sodium and amyl alcohol on the ketone, but the method was no better than the foregoing, which, in the presence of a little toluene, gave a yield of 45%, m. p. 156.5° (corr.). An attempt to form a phenylurethan was unsuccessful.

Anal. Subs., 0.2418, 0.2868: CO_2, 0.7723, 0.9137; H_2O, 0.1869, 0.2203. Calcd. for $C_{27}H_{32}O$: C, 87.03; H, 8.67. Found: C, 86.94, 86.88; H, 8.65, 8.60.

Crystal Structure of (Tribenzylmethyl)-*tert.*-butylcarbinol.—Orthorhombic system; tabular habit, Front pinacoid 100; brachydome 011; macrodome 101; indistinct unit prism 110. 011 > $01\bar{1}$ = 93° 15'; 011 > $0\bar{1}1$ = 86° 45'; 100 > 101 = 135° 33'; 101 > $\bar{1}01$ = 88° 46'. Parameters: a = 0.94482; *b* = 1.00000; c = 1.0218.



The Hydrocarbons.—Despite numerous and various attempts to reduce the ketones and carbinols to hydrocarbons, only that derived from the monobenzyl compound has been obtained.

2,2-Dimethyl-5-phenyl-pentane.—Nine and one-half grams of monobenzylpinacolone, 1.7 g. of red phosphorus and 25.6 g. of 57% hydriodic acid were heated to 180–190° in a sealed tube for twelve hours. The contents of the cooled tube was placed in 150 cc. of 1:15 sulfuric acid and mossy zinc was added. After one and one-half hours the product was removed by ether, the ether solution was washed with water, dilute sodium hydroxide, and water, and dried with calcium chloride. Upon repeated fractionation, after removal of the ether (4 g.) a 46% yield of hydrocarbon resulted; b. p. (9 mm.) 115".

Anal. Subs., 0.1701, 0.2218, 0.1592, 0.2030: CO_2, 0.5555, 0.7243, 0.5192, 0.6571; H_2O, 0.1584, 0.2063, 0.1479, 0.1882. Calcd. for $C_{13}H_{20}$: C, 88.55, H, 11.44. Found: C, 89.06, 89.06, 88.94, 88.28; H, 10.41, 10.43, 10.40, 10.40.

The pure substance was colorless and an acetone solution of potassium permanganate was only very slowly reduced when in contact with it. Molecular weight, calcd. for $C_{13}H_{20}$: 176.16; found, by Menzies' method, 189, 178; d^{20}_{20} 0.9460; d^{20}_{4} 0.9443; n^{20}, using daylight, 1.5281, 1.5267; $N_F - N_C$, 0.01615; M_D, from refractive index, 57.39; from Eisenlohr's values, 58.63.

Summary

1. Mono-, di- and tribenzylpinacolones, a series of highly substituted acetones, and their corresponding secondary alcohols have been prepared.
2. One hydrocarbon, 2,2-dimethyl-5-phenyl-pentane, related to the simplest of the ketones, has been produced.
3. Experiments leading to the other hydrocarbons are in progress.

THE MECHANISM AND APPLICATION OF THE FRIES REACTION[1]

BY EDWARD H. COX

RECEIVED JULY 29, 1929 PUBLISHED JANUARY 8, 1930

The rearrangement of the phenolic esters to hydroxy aromatic ketones by means of anhydrous aluminum chloride (the Fries reaction) has been observed by many workers.[2] Although aluminum chloride is the most effective reagent used in carrying out these rearrangements, anhydrous ferric chloride and, especially, zinc chloride are only slightly less efficient.[3]

Fries, Witt[4] and recently Auwers[5] have considered the reaction to be intramolecular. Skraup and Poller[6] prepared o-acetyl-m-cresol by the action of anhydrous zinc chloride on m-tolyl acetate and contended that the ester was first decomposed by the zinc chloride into acetyl chloride and m-cresol and that the acid chloride then reacted with the cresol to form the ketone. They repeated this reaction but added m-chlorobenzoyl chloride and observed that this acid chloride reacted with the cresol at the expense of the more volatile acetyl chloride. Only m-chlorobenzoyl-m-cresol (2-hydroxy-4-methyl-3'-chlorobenzophenone) was produced; no *o*-acetyl-*m*-cresol was isolated. Auwers and Mauss[7] have contrasted the Fries reaction with that of Friedel–Crafts when applied to phenols, and have drawn a distinction according to whether the acid residue is introduced from without the molecule or is originally present, as is the case in the Fries rearrangements. Since, according to these workers, the Friedel–Crafts reaction when applied to most phenols, in the preparation of aromatic hydroxy ketones, generally gives the *p*-acylphenols,[8] and with a few phenols of certain structure, the meta derivatives, and since on the other hand in the Fries reaction only ortho or para and never m-acylphenols are produced, then the Fries displacement according to them is considered to take place within the molecule (intramolecular).

Rosenmund and Schnurr[9] studied the conditions of the Fries transformation in order to improve upon the method. They have discussed

their experimental results and have disagreed with Auwers' statement that the reaction is intramolecular. They have found that when a mixture of o-chloro-p-tolyl acetate (2-chloro-4-methylphenyl acetate) and p-tolyl benzoate is acted upon by aluminum chloride, not only 2-acetyl-6-chloro-*p*-cresol (2-hydroxy-3-chloro-5-methylacetophenone) and *o*-benzoyl-*p*-cresol (2-hydroxy-5-methylbenzophenone) are formed, but also 2-benzoyl-6-chloro-p-cresol (2-hydroxy-3-chloro-5-methylbenzophenone) and *o*-acetyl-p-cresol (2-hydroxy-5-methylacetophenone). They state that if this reaction were strictly intramolecular, the latter two compounds should not have been formed. These authors have also taken exception to Skraup's explanation of the reaction, for they were unable to distil out any free acid chloride, even when working at reduced pressure and in a stream of hydrogen. They have interpreted the mechanism of the Fries change as one involving two molecules of the ester and have likened the reaction to that of Friedel–Crafts where acetic anhydride is the acetylating reagent. The possibility of free radical exchange is also indicated.

The experimental results given in this paper support the contention of Skraup and Poller, *viz.*, that, when phenolic esters are acted upon by anhydrous aluminum or zinc chlorides, the free acid chlorides are produced which then act upon the phenolic group, giving ketones. If the change were intramolecular there should be the possibility of the formation and isolation of some intermediate product. The failure to identify any such product and the results of Rosenmund and Schnurr's work are contrary to the interpretation that the transformation takes place within the ester molecule. That there is no exchange of free radicals is supported by the fact that a catalyst is necessary for the transformation.[10] That the Fries change is comparable to the Friedel–Crafts reaction when acetic anhydride is used is not untenable, since the action of aluminum chloride on acetic anhydride produces acetyl chloride.

In the first part of the experimental work recorded here the Fries reaction is carried out in the relatively inert solvent, diphenyl ether. When anhydrous aluminum or zinc chloride acts upon phenolic esters in the presence of this solvent, the acyl phenols and acyl diphenyl ether are both formed. It is difficult to interpret the formation of the acyl derivative of diphenyl ether other than that it is produced by the medium of the free acid chloride. Some free phenol is invariably recovered from the reaction mixture.

It has also been observed during the course of some experimental work that, if absolute alcohol was added during the reaction of anhydrous aluminum chloride on tolyl acetates, ethyl acetate was distilled from the re-

---

[10] Skraup [Skraup and co-workers, *Ber.*, 60, 942, 1070 (1927)] has carried out some pyrolytic reactions on special phenyl esters at high temperatures (350–420°) but the yields of the ketones were very low. When the reactions were carried out in the presence of anhydrous zinc chloride and halogen acids much lower temperatures were required and higher yields of ketones were obtained.

action mixture. Again, in an attempt to rearrange these acetates under pressure, using absolute alcohol containing hydrogen chloride as a solvent, ethyl acetate was found to be one of the reaction products. Finally, it was observed that some acetyl chloride was distilled out when aluminum chloride acted on 2,4,6-trichlorophenyl acetate. These observations support the conclusion that the free acid chloride is an intermediate in the Fries reaction.

That the reaction gives better yields of aromatic hydroxy ketones than are obtained by the Friedel–Crafts method may be explained by the fact that a less amount of aluminum chloride is necessary to effect the transformation and that the progressive splitting and resubstituting of the acyl group give rise to more ideal concentration of the reactants.

In the second part of the experimental work the Fries reaction is applied in the preparation of some acyl derivatives of salicylic acid. The esters of methyl salicylate are prepared by the action of acid chlorides on methyl salicylate, and are transformed by anhydrous aluminum chloride to the acyl salicylates. The acyl esters are then saponified and subsequently reduced to the alkyl salicylic acids by the Clemmensen method. In view of the general interest manifested in the relation of the alkyl phenolic substances to their antiseptic properties and because most of the substances are not given in the literature, it is considered of value to record them.

Experimental. Part I

A general statement of the experimental procedure is as follows: to 40 g. of anhydrous aluminum chloride was added 200 cc. of carbon disulfide. To these was added slowly with heating and stirring a mixture of 50 g. of the phenolic ester and 60 g. of diphenyl ether. After the addition, the reaction mixture was heated for a short time and the carbon disulfide was then distilled off. The temperature was raised from 100–175° for fifteen to forty-five minutes. The reaction melt was decomposed in water and the resulting oily layer separated, treated with a 15% solution of potassium hydroxide and extracted with ether. The aqueous portion was acidified with dilute hydrochloric acid solution and also extracted with ether. Both ether extracts were dried, evaporated and distilled in a vacuum.

Action of Aluminum Chloride on *m*-Tolyl Butyrate in Diphenyl Ether.—The reaction mixture was heated to 100–110° for fifteen to twenty minutes. The alkali-insoluble portion was distilled in a vacuum. Fraction one, boiling from 140–150° at 20 mm., was unchanged diphenyl ether (42 g.); fraction two, boiling from 200–208° at 12 mm., was *p*-butyryl diphenyl ether (24 g.). The second fraction solidified and was crystallized from petroleum ether (m. p. 50").

Anal. Subs., 0.1336: CO_2, 0.3931; H_2O, 0.0804. Calcd. for $C_{16}H_{16}O_2$: C, 80.00; H, 6.66. Found: C, 80.24; H, 6.73.

Fraction one of the alkali-soluble portion, distilling from 100–135° at 25–30 mm., was m-cresol (18 g.) and was identified as the benzoate (m. p. 54–55'). Fraction two, distilling from 175–200° at 15 mm., was *p*-butyryl-*m*-cresol, $C_6H_3(OH)(CH_3)(COC_3H_7)$ (1 3 4) The distillate soon solidified and was crystallized from a mixture of benzene and petroleum ether (m. p. 88°).

Anal. Subs., 0.1632: CO_2, 0.4422; H_2O, 0.1143. Calcd. for $C_{11}H_{14}O_2$: C, 74.15; H, 7.86. Found: C, 73.89; H, 7.84.

Action of Aluminum Chloride on *o*-Tolyl Acetate in Diphenyl Ether.—The reaction mixture was heated for thirty minutes at 175°. The alkali-insoluble portion yielded 54 g. of unchanged diphenyl ether and 14 g. of *p*-acetyl diphenyl ether, distilling from 180–190° at 7 mm. It was crystallized from petroleum ether and melted at 53°.[11]

Anal. Subs., 0.1254: CO_2, 0.3629; H_2O, 0.0764. Calcd. for $C_{14}H_{12}O_2$: C, 79.24; H, 5.66. Found: C, 78.91; H, 6.01.

The alkali-soluble portion yielded 18 g. of o-cresol, identified as the *p*-nitrobenzoate (m. p. 90–92°), and 27 g. of *p*-acetyl-*o*-cresol, $C_6H_3(OH)(CH_3)(COCH_3)(1,2,4)$, distilling from 170–175° at 5 mm. It was crystallized from a mixture of benzene and petroleum ether and melted at 110°.[12]

Anal. Subs., 0.2043: CO_2, 0.5380; H_2O, 0.1253. Calcd. for $C_9H_{10}O_2$: C, 72.00; H, 6.66. Found: C, 71.81; H, 6.86.

Action of Aluminum Chloride on *p*-Tolyl Acetate in Diphenyl Ether.—The reaction mixture was heated for fifteen minutes at 160°. The alkali-insoluble portion yielded 46 g. of unchanged diphenyl ether and 11 g. of p-acetyl diphenyl ether. The latter compound when mixed with the acetyl diphenyl ether from the above experiments showed a melting point of 52–53°.

The alkali-soluble portion yielded a small amount of *p*-cresol and 15 g. of *o*-acetyl-*p*-cresol, $C_6H_3(OH)(CH_3)(COCH_3)(1,4,2)$, distilling from 120–130° at 7 mm. After crystallization from petroleum ether it melted at 48–49°.[13] An alcoholic solution of the ketone gave a purple color with a few drops of ferric chloride solution.

Anal. Subs., 0.1674: CO_2, 0.4402; H_2O, 0.1025. Calcd. for $C_9H_{10}O_2$: C, 72.00; H, 6.66. Found: C, 71.71; H, 6.85.

Action of Aluminum Chloride on o-Tolyl Benzoate in Diphenyl Ether.—The reaction mixture was heated to 170° for thirty minutes. The ether extract from the alkali-insoluble portion was evaporated. The residue was treated with cold petroleum ether, which separated the diphenyl ether from the *p*-benzoyl diphenyl ether (34 g. of the former and 14 g. of the latter were recovered). The ketone was crystallized from ligroin and melted at 71–73°.[11]

Anal. Subs., 0.1192: CO_2, 0.3641; H_2O, 0.0575. Calcd. for $C_{19}H_{14}O_2$: C, 83.21; H, 5.11. Found: C, 83.01; H, 5.03.

The ether extract from the alkali-soluble portion was evaporated and yielded 34 g. of *p*-benzoyl-*o*-cresol, $C_6H_3(OH)(CH_3)(COC_6H_5)(1,2,4)$, and a small amount of o-cresol. The ketone was crystallized from benzene and melted at 173°.[14]

Anal. Subs., 0.1708: CO_2, 0.4949; H_2O, 0.0850. Calcd. for $C_{14}H_{12}O_2$: C, 79.24; H, 5.66. Found: C, 79.02; H, 5.57.

Experimental. Part II

All the fatty acid esters of methyl salicylate were made by treating the oil of wintergreen with the respective fatty acid chlorides. The reactions were carried out at about the boiling temperature of the acid chloride and over a period of about two hours, or until all the hydrogen chloride was

---

[11] Kipper, ***Ber.***, 38, 2491 (1905).

[12] Nencki and Stroeber, *ibid.*, 30, 1770 (1897).

[13] Auwers, *Ann.*, **364**, 166 (1908).

[14] Heller, ***Ber.***, **46**, 1502 (1913).

dispelled. The esters were purified by treatment with dilute sodium bicarbonate solution and distillation in a vacuum. They were considered pure when they showed no blue color with a few drops of ferric chloride solution. The yields averaged about 90%.

Since there were no essential variations in the experimental procedure used for the preparation of the members of these series, but one member of each series will be given in detail, *viz.*, hexylyl and hexylsalicylic acids. The melting points, boiling points and analyses of the different members will be shown in tabular review.

All of the ketones when dissolved in dilute alcohol gave a deep red coloration with a few drops of a solution of ferric chloride, while the reduced products showed a blue color. Reduction of the ketones was considered complete when the ferric chloride test showed a distinct blue color.

Methyl **Hexylyl-salicylate,** $C_6H_3(OH)(COOCH_3)(COC_5H_{11})(1,2,4)$.—To a suspension of 125 g. of anhydrous aluminum chloride in 200 cc. of boiling carbon disulfide was slowly added with stirring 150 g. of caproate of methylsalicylate (b. p. 204–210° at 20 mm.). After two hours of heating, the carbon disulfide was distilled off and the reaction mixture heated for a few minutes. The mass soon hardened and became impossible to stir (from 90–110°). The melt was decomposed in warm water and the resulting oily layer was washed with hot water, separated and distilled in a vacuum. After distilling off the water, two fractions were separated, one, boiling from 120–170° at 20 mm. (mostly unchanged material) and two, boiling from 210–230° at 20 mm. A small amount of residue remained in the flask. The distillate from fraction two soon solidified. A further recovery from fraction one gave a total yield of 123 g., or 82%. It was crystallized twice from petroleum ether and melted at 50–51°. It formed insoluble sodium and potassium salts. The ketone distilled from 202–205" at 20 mm.

TABLE I

METHYL ACYL-SALICYLATES

			M. p., °C.

[15] Swiss Patent 127,649 (1927).

Summary

The Fries reaction is discussed and an explanation of the mechanism is given based upon some experimental evidence. The reaction is shown not to be intramolecular. It has been applied to the production of some acyl salicylic esters and acids, many of which are new substances.

The alkyl salicylic acids are produced from the acyl salicylic acids by the Clemmensen reduction method. Although these acids show a higher toxicity than the parent substance, salicylic acid, they also possess by virtue of the alkyl group higher phenol coefficients.

SWARTHMORE, PENNA.

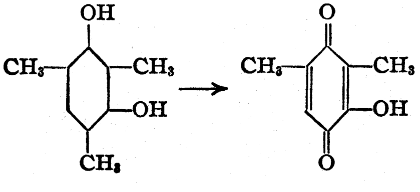
THE OXIDATION OF META-XYLORCINOL[1]

BY TENNEY L. DAVIS AND JOSEPH FREDERIC WALKER

RECEIVED JULY 30, 1929 PUBLISHED JANUARY 8, 1930

When tribromoresorcinol is oxidized with aqueous chromic acid[2] it does not yield a *m*-quinone, but loses a bromine atom from the position para to one of the hydroxyl groups and yields oxidized and brominated substances which are derivatives of diphenoquinone. We have wished to determine whether a methyl group in the para position would be similarly lost, and have accordingly studied the oxidation of m-xylorcinol in which both positions para to hydroxyl are occupied by methyl groups. A similar substance has been studied by Knecht,[3] who found that the action of hot ferric chloride solution on mesorcinol removed a methyl group from the para position and produced a derivative of benzoquinone, thus



It is apparent from Knecht's result that one of the methyl groups is more easily removed by oxidation than is the hydrogen of one of the hydroxyl groups. When tribromoresorcinol is oxidized, the bromine in one of the para positions is similarly removed and one of the hydroxyl groups remains unaffected. m-Xylorcinol differs from mesorcinol in having a hydrogen instead of a methyl in the position between the two hydroxyl groups, and it is to be expected that this particular hydrogen atom would be oxi-

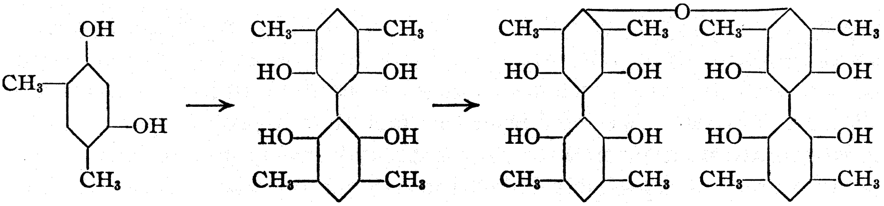
dized fairly easily, surely more easily than a methyl group. We find, in fact, that the methyl and hydroxyl groups of m-xylorcinol are not affected by dilute aqueous ferric chloride solution at laboratory temperature. One hydrogen atom, presumably the hydrogen which is present in m-xylorcinol but is lacking in mesorcinol, is, however, removed from the nucleus, and two nuclei combine to form di-m-xylorcinol. This product, soluble in water, is oxidized by the further action of ferric chloride to form an insoluble substance which appears to be di-(di-m-xylorcinol) ether.



m-Xylorcinol has been studied but little, probably because of the difficulty of its preparation. In the course of our work we have prepared from more than 2 kilos of m-xylene, a total of 15 g. of m-xylorcinol. We have checked the work of previous investigators and have substantiated the formula by determinations of molecular weight in benzene and in camphor. The substance is a vigorous reducing agent. If a 1% aqueous solution of m-xylorcinol is mixed with its own volume of 0.1 *N* silver nitrate, the liquid after about three minutes becomes colored from colloidal silver, and on longer standing deposits a silver mirror on the walls of the tube. Cresorcinol, in which there is a methyl group para to only one of the hydroxyl groups, under similar conditions shows no effect until about fifteen minutes have elapsed, and resorcinol itself shows none after twenty-four hours.

When a drop of ferric chloride solution is added to a dilute aqueous solution of m-xylorcinol a deep blue coloration is produced which disappears in a few minutes and leaves a pale green turbidity. On standing a voluminous greenish precipitate settles out. This behavior—similar to that observed by Dianin,[4] who reported that ferric chloride gave with solutions of α- and β-naphthol a color which vanished almost instantly with the appearance of a white precipitate—suggests that the hydrogen atom which is oxidized is that which occupies the position next to an hydroxyl group, or, in our case, between the hydroxyl groups, for Walder[5] and Fosse[6] later showed that the products from Dianin's experiments are dinaphthols in which the residues are linked through the position ortho to the hydroxyl group.

[6] Fosse, *Bull. soc. chim.*, [3] 21, 650 (1899).

The first product of the oxidation is a crystalline substance, soluble in water, and was obtained by extracting the filtered liquid with ether, or in better yields by shaking an ether solution of *m*-xylorcinol with an aqueous solution of ferric chloride. It is dinuclear and forms a tetra-acetate. It dissolves readily in sodium hydroxide solution, but not in sodium bicarbonate, and it gives Liebermann's nitroso reaction for *m*-diphenols. It precipitates metallic silver from ammoniacal silver nitrate, and with ferric chloride it yields the insoluble material which we believe to be di-(di-m-xylorcinol) ether. When distilled with zinc dust it yields a substance which is probably dixylyl. When di-m-xylorcinol is heated for three minutes at 160° with phthalic anhydride and a drop of concd. sulfuric acid, it gives a melt which dissolves in alkali to form a practically colorless solution. We infer from this fact that it probably contains no hydrogen atom either ortho or para to an hydroxyl group, and hence that the two nuclei are probably linked through the position between the two hydroxyl groups.

m-Xylorcinol contains one hydrogen atom which is readily replaceable by bromine, but this same atom appears to be lacking from di-m-xylorcinol and is evidently the atom through the removal of which the two nuclei are joined. m-Xylorcinol brominates easily in chloroform solution to form the monobromo-m-xylorcinol which was described by Luther.[7] When this substance is heated gently with a trace of sulfuric acid, it evolves hydrogen bromide vigorously—a fact which suggests that the bromine atom is in a position ortho to an hydroxyl group. Di-m-xylorcinol reacts with bromine in boiling chloroform solution to yield colorless needles of a product which analyses and molecular weight determinations show to be not a simple bromine substitution product. The product dissolves slowly in caustic alkali and reprecipitates on acidification; the solution after acidification contains no ionized bromine. It does not give Liebermann's reaction for m-diphenols. It reduces ammoniacal silver nitrate slowly in the cold, and rapidly when the liquid is heated. Its analysis, etc., correspond, unexpectedly and unexplainably, to di-m-xylorcinol in which two of the hydroxyl groups have been replaced by bromine atoms. In confirmation of the belief that the hydroxyl groups are involved in the reaction with bromine, we find that the tetra-acetate of di-m-xylorcinol does not react when boiled with two molecules of bromine in chloroform solution.

When a drop of ferric bromide solution is added to a dilute aqueous solution of monobromo-m-xylorcinol, a momentary violet coloration is produced which is followed by a white turbidity. After a few minutes a white precipitate settles out. The appearance of the reaction suggests that the changes are analogous to those which occur with m-xylorcinol,

---

[7] *Luther, Arch. Pharm., 244,561 (1906).*

but such is not the case. The crystalline product does not give Liebermann's reaction and does not yield an acetate by the usual procedure. It dissolves readily in dilute sodium hydroxide to form a solution which contains ionized bromine. It liberates a small amount of iodine from alcoholic potassium iodide to which a drop of hydrochloric acid has been added, and it reduces ammoniacal silver nitrate immediately in the cold. Analysis and molecular weight determinations show that it contains two bromine atoms, but it does not have the composition of dibromo-di-*m*-xylorcinol, and is not identical with the substance obtained by the action of bromine on di-*m*-xylorcinol.

Under the conditions in which m-xylorcinol is oxidized by ferric chloride to di-*m*-xylorcinol in maximum yield, cresorcinol yields no oxidation product and is recovered unchanged.

Experiments

Preparation of *m*-Xylorcinol.—*m*-Xylene was nitrated according to the method of Maltese and Errera[8] and the 4,6-dinitroxylene-1,3 was separated by fractional crystallization from alcohol as light yellow needles with a faint greenish glow, m. p. 93°. Maltese and Errera reported a yield of about one-third, but we were not able to obtain more than a 12% yield of the pure product. The other steps in the synthesis were slight modifications of the procedure originally employed by Pfaff.[9] Reduction in the usual way with hydrogen sulfide and alcoholic ammonia gave 4-nitro-6-aminoxylene-1,3, orange needles from alcohol, m. p. 122–123° (90%), and this by the diazo reaction gave 4-nitro-6-hydroxyxylene-1,3 as yellow needles from ligroin, m. p. 95° (65%). The nitrophenol was reduced with tin and hydrochloric acid and the 4-amino-6-hydroxyxylene-1,3 was isolated in the form of its hydrochloride (70%). In the diazo reaction for the replacement of the second amino group by hydroxyl it was found that the use of copper sulfate as a catalyst increased the yield from about 47 to 60%. The m-xylorcinol, obtained by extracting the boiled and filtered diazo solution with ether, decolorizing the product in water solution with decolorizing carbon and finally purifying by sublimation at 120" and 3 mm., consisted of colorless needles, m. p. 124.5–125.2". The yields indicated above are the yields in our best experiments and correspond to an over-all yield of 2.95% of the theoretical amount of m-xylorcinol from m-xylene. When the product was heated at 160° for three minutes with phthalic anhydride and a drop of sulfuric acid, it gave a melt which dissolved in alkali to give a dark brown solution possessing a deep green fluorescence. A similar experiment without phthalic anhydride gave, contrary to the report of Pfaff, a faint mauve-colored solution which showed only a very slight fluorescence.

Molecular weight. Subs., 0.0866, 0.1922 g.; benzene, 17.27, 17.27 g.; *AT*, 0.099°, 0.215". Calcd. for $C_8H_{10}O_2$: 138. Found: 135, 138. Subs., 0.0141 g.; camphor, 0.1158 g.; AT, 35.7°. Mol. wt. found: 136.

The Oxidation.—When ferric chloride was added to an aqueous solution of m-xylorcinol, a momentary blue color was followed by a turbidity which increased until a voluminous precipitate had settled out. The precipitate was very sparingly soluble in water, for a 0.01% solution of m-xylorcinol gave a distinct turbidity when a drop of ferric chloride was added, although the first blue color was not visible with so dilute

a solution. The precipitate had an olive-green color, evidently due to accidental traces of iron. Two samples, thoroughly washed and dried, contained, respectively, 0.24 and 0.56% of iron. The compound which might be formed from one atom of iron and three molecules of m-xylorcinol would contain 12% of the metal. By repeatedly dissolving in benzene and precipitating with ligroin, the pure substance was obtained as a faintly yellow amorphous powder which contained no iron. The aqueous filtrate from the original precipitate reduced many times as much permanganate as corresponded to the total possible ferrous chloride, a fact which suggested that it contained either m-xylorcinol or some water-soluble oxidation product of that substance. Extraction with ether gave di-m-xylorcinol. When an aqueous solution of this substance was treated with ferric chloride, it yielded the familiar olive-green precipitate.

Experiments in which known amounts of *m*-xylorcinol were treated in aqueous solution at laboratory temperature with ferric chloride in slight excess showed that the first product of the oxidation, the water-soluble di-m-xylorcinol, was formed rapidly but oxidized slowly and gradually decreased in amount, while the amorphous insoluble product of the further oxidation increased in amount as the solution was allowed to stand. Titration of an aqueous solution of m-xylorcinol with standard ferric chloride solution, ammonium thiocyanate on a spot plate being used as an indicator, showed that the reaction took place in two stages. The ferric chloride was at first reduced almost instantly until a fairly sharp change of rate occurred, after which the reduction proceeded slowly until finally no more ferric chloride was reduced. A fairly good end-point could be measured for the first stage of the reaction and was found to correspond to one molecule of ferric chloride per molecule of m-xylorcinol, 0.533 g. of m-xylorcinol (0.0039 mole) consuming 23 cc. of 0.16 M ferric chloride solution (0.0037 mole). The end-point, however, did not represent an abrupt boundary between the two stages of the oxidation, for a small amount of precipitate had already formed and a corresponding small amount of m-xylorcinol evidently remained unoxidized.

Since di-m-xylorcinol, the first product of the oxidation, was found to be soluble in ether as well as in water, it was hoped that it might be obtained in better yield if the oxidation was carried out in the presence of ether, by which it would be taken up and removed from the influence of the oxidizing agent. The expectation was verified. Ether solutions of m-xylorcinol were shaken in the shaking machine with aqueous solutions of ferric chloride in large excess, and after a known time interval the ether phase was removed and worked up for di-m-xylorcinol. Results were as shown in Table I.

TABLE I

TWO-PHASE OXIDATION, EFFECT OF TIME AND CONCENTRATION

m-Xylorcinol, g.	Ether, cc.	Ferric chloride, cc. 1 N	Time, hours	Di-*m*-xylorcinol, weight per cent.
1.000	150	100	2	32.9
1.000	150	100	2.5	35.5
1.000	150	100	3	34.0
0.619	200	50	2	17.6
.619	200	50	6	30.2
.502	50	50	1	33.0

The first three experiments show that the yield of di-m-xylorcinol increases with increasing duration of shaking until it drops off again after a maximum has been reached. The series shows that the best yields are probably to be obtained by the long shaking of dilute solutions.

In one experiment 0.533 g. of m-xylorcinol yielded 0.200 g. of di-m-xylorcinol and 0.326 g. of the amorphous oxidation product, a total of 0.526 g. or very nearly the weight of the original material which was oxidized.

Di-*m*-xylorcinol.—The ether solution from the two-phase oxidation was evaporated just to dryness and the residue, recrystallized from benzene, yielded colorless needles of di-m-xylorcinol, m. p. 242–243° with slight decomposition. The first mother liquors contained traces of m-xylorcinol and a small quantity of the amorphous oxidation product. Di-*m*-xylorcinol is much less soluble in water than m-xylorcinol. It is practically insoluble in cold benzene, but about 0.93 g. dissolves in 100 cc. of the boiling solvent. Small quantities were sublimed unchanged both at reduced and at atmospheric pressure. When distilled with zinc dust it yielded a substance which had an odor resembling that of diphenyl, and melted at 81–94", but was too small in amount for further examination. A chloroform solution of this material, which was evidently dixylyl, gave a violet coloration when poured upon a fresh sublimate of aluminum chloride.

Anal. Subs., 40.23, 40.95 mg.: CO_2, 104.19, 105.44 mg.; H_2O, 24.24, 24.43 mg. Calcd. for $C_{16}H_{18}O_4$: C, 70.04; H, 6.62. Found: C, 70.66, 70.24; H, 6.47, 6.68.

Molecular Weight. Subs., 0.0115, 0.0124 g.; camphor, 0.1045, 0.1161 g.; AT, 17.4°, 21.2°. Calcd. for $C_{16}H_{18}O_4$: 274. Found: 252, 249.

Di-m-xylorcinol tetra-acetate was prepared by refluxing di-m-xylorcinol with acetic anhydride and anhydrous sodium acetate, as colorless crystals from ligroin, m. p. 158–159°. It was not soluble in warm caustic soda solution, and was recovered unchanged after refluxing for several minutes with a chloroform solution of a large excess of bromine. It gave no color with ferric chloride solution.

Anal. Subs., 41.52, 33.18, 36.84 mg.: CO_2, 99 26, 79.38, 87.96 mg.; H_2O, 21.75, 17.52, mg. Calcd. for $C_{24}H_{26}O_8$: C, 64.99; H, 5.91. Found: C, 65.22, 65.27, 65.14; H, 5.86, 5.91.

Molecular Weight. Subs., 0.0241, 0.0211 g.; camphor, 0.1103, 0.0776 g.; AT, 20.7°, 24.5". Calcd. for $C_{24}H_{26}O_8$: 443. Found: 421, 431.

The Amorphous Oxidation Product, Probably Di-(di-m-xylorcinol) Ether.—This substance was prepared by adding an excess of ferric chloride to an aqueous solution of m-xylorcinol and allowing it to stand until precipitation was complete. The greenish precipitate, after washing and drying, was purified by repeatedly dissolving in benzene and precipitating with ligroin, and yielded the pure material in the form of a pale yellow amorphous powder which charred gradually when heated above 250". It dissolved readily in caustic alkali solution and was reprecipitated by acid. It reduced ammoniacal silver nitrate and did not liberate iodine from a solution of potassium iodide acidified with hydrochloric acid. It dissolved readily in benzene, chloroform, alcohol and ether, but was insoluble in cold ligroin and petroleum ether.

Anal. Subs., 38.81, 37.31 mg.: CO_2, 97.56, 93.64 mg.; H_2O, 20.87, 20.10 mg. Calcd. for $C_{32}H_{34}O_9$: C, 68.30; H, 6.09. Found: C, 68.58, 68.47; H, 6.02, 6.04.

Molecular Weight. Subs., 0.0186, 0.0109 g.; camphor, 0.1161, 0.0514 g.; AT, 12.6°, 16.0". Calcd. for $C_{32}H_{34}O_9$: 563. Found: 505, 530.

Bromination of *m*-**Xylorcinol.**—Two grams of m-xylorcinol was dissolved in 100 cc. of chloroform, 2.32 g. of bromine in 40 cc. of chloroform added and the mixture refluxed for an hour, at the end of which time hydrogen bromide was no longer given off. The residue from the evaporation was purified by sublimation at 110° and 1 mm. and yielded pure monobromo-*m*-xylorcinol in almost theoretical amount as colorless needles, m. p. 119–119.5". An excess of bromine was found to reduce the yield.

When bromine was added to a chloroform solution of monobromo-m-xylorcinol, hydrogen bromide was given off and a reddish-brown solution resulted which yielded a brown amorphous powder on evaporation. In one experiment, where a large excess of bromine was used, small dark blue crystals were deposited on the walls of the test-tube. These were too small in amount for further study but were notable because of their similarity in appearance to a substance which was produced by the action of an excess of bromine on di-m-xylorcinol.

Aqueous solutions of m-xylorcinol and of monobromo-m-xylorcinol both decolorized bromine water with the production of a white precipitate; both substances yielded the same products with an excess of bromine water. We have isolated three crystalline substances from the white precipitate, but all in insufficient quantity for analysis. They melted, respectively, at *71–72, 173* and 194°, and all decomposed above the melting point, giving off large quantities of gas in which bromine was detected by iodo–starch paper. The first, m. p. *71–72'*, liberated **iodine** from acidified alcoholic potassium iodide; the others did not.

Oxidation of Monobromo-*m*-xylorcinol.—The white precipitate produced by the action of an excess of ferric bromide on an aqueous solution of monobromo-m-xylorcinol was found to contain an amorphous substance, m. p. 128–135°, and a crystalline material, insoluble in water, sparingly soluble in cold benzene but readily in hot, as small faintly yellowish needles which did not melt but charred gradually between *265* and *278".* The yield of the crystalline product was *26.2–26.5%* of the weight of the original monobromo-*m*-xylorcinol.

Anal. Subs., *22.86, 25.12* mg.: CO_2, 41.43, 45.71 mg.; H_2O, *7.95, 8.57* mg. Subs., *18.98, 19.03* mg.: AgBr, *14.59, 14.50* mg. Found: C, *49.44, 49.64;* H, *3.89, 3.82;* Br, *32.40, 32.67.*

Molecular Weight. Subs., *0.0135, 0.0139, 0.0078 g.;* camphor, *0.1053, 0.0715,* 0.0541 g.; ΔT, 9.6°, 16.1°, 11.6°. Found: *531,480,497.*

If the substance contains one bromine atom, the molecular weight calculated from the found percentage of bromine would be *246;* if two atoms of bromine, *492;* if three, *738.* We conclude then that it contains two bromine atoms, but the corresponding calculated empirical formula, $C_{20}H_{19}Br_2O_4$ (corresponding to carbon 49.70%, hydrogen 3.96%, bromine 33.08%, and molecular weight 483.1), does not appear to represent any probable oxidation product of monobromo-m-xylorcinol.

Bromination of Di-*m*-xylorcinol.—When di-m-xylorcinol was treated with two moles of bromine in chloroform solution, there was no apparent action at room temperature, but hydrogen bromide was given off on boiling and, after a few minutes, fine silky colorless crystals appeared in the liquid. The solution was chilled and the crystals removed. The chloroform mother liquors were reddish colored and on evaporation gave a small amount of dark blue crystals. The colorless needle crystals, recrystallized from benzene, melted with decomposition at *274–277'* and amounted to 29–30% of the weight of the original di-m-xylorcinol. The simple introduction of two bromine atoms into di-m-xylorcinol would produce *161* weight per cent. of product. Analysis and molecular weight determinations gave results which correspond fairly closely to di-*m*-xylorcinol in which two of the hydroxyl groups have been replaced by bromine atoms.

Anal. Subs., 27.13, 23.29 mg.: CO_2, 46.96, 40.28 mg.; H_2O, 9.70, 7.06 mg. Subs., *18.65, 9.54* mg.: AgBr, *14.21,* 8.66 mg. Calcd. for $C_{16}H_{16}O_2Br_2$: C, *48.01;* H, *4.03;* Br, *39.95.* Found: C, *47.22, 47.18; H, 4.00, 3.39;* Br, 39.25, 38.63.

Molecular Weight. Subs., *14.21, 10.96* mg.: camphor, *63.26, 63.21* mg.; *AT,* 20.8°, 17.7°. Calcd. for $C_{16}H_{16}O_2Br_2$: 400. Found: 429,896.

Summary

m-Xylorcinol (4,6-dihydroxyxylene-1,3), when oxidized with ferric chloride in aqueous solution, first yields di-m-xylorcinol in which the two nuclei are evidently joined through the position between the hydroxyl groups. **The** further action of ferric chloride converts di-m-xylorcinol into an

insoluble amorphous tetranuclear substance which is probably di-(di-m-xylorcinol) ether.

The action of bromine on m-xylorcinol, on monobromo-m-xylorcinol and on di-m-xylorcinol, and the oxidation of monobromo-m-xylorcinol by means of ferric bromide in aqueous solutions have also been investigated.

SYNTHETIC GLYCERIDES. II. REFRACTIVE INDICES OF GLYCERIDES OF KNOWN CONSTITUTION

BY H. P. AVERILL, J. N. ROCHE AND C. G. KING

RECEIVED JULY 31, 1929 PUBLISHED JANUARY 8, 1930

In a previous paper,[1] methods for the synthesis of symmetrical and unsymmetrical triglycerides containing two fatty acids were given in detail and data for their melting points were included. It was pointed out that the melting point of the symmetrical isomer in each of the sets of isomeric triglycerides made was slightly higher than that of the unsymmetrical isomer. In continuing a study of the relation between their molecular structure and physical properties, a study of the refractive indices of these isomers has been made.

Although the refractive index is one of the most widely used physical constants for the identification of natural glycerides (oils and fats), very little is known of the relation of this property to the constitution of the component glycerides. Furthermore, as stated by Myddleton and Barry,[2] "at present it is not known whether the refractive index of a mixed triglyceride is the same as the corresponding mixture of simple glycerides." In this paper data are also given for the comparison of three sets of isomers with equivalent mixtures of the corresponding simple triglyeerides.

It was expected that any differences in the refractive indices of the isomers would be small. Apparatus was, therefore, devised by means of which a constant temperature could be held for a considerable length of time and which permitted the use of an immersion refractometer.

Apparatus.—The constant temperature bath was a round three-liter flask with the original neck shortened and three other necks, each one inch in diameter. These contained, respectively, the immersion refractometer, leads for the heating element, a standardized thermometer and a Liebig condenser.

A Zeiss immersion refractometer was used, fitted with an auxiliary prism and a metal beaker. The metal beaker made the enclosed sample air and water tight. As

---

[2] W. W. Myddleton and T. H. Barry, "Fats, Natural and Synthetic," Ernest Benn, Ltd., London, 1924, p. 93.

a further precaution a glass tip was placed over the end of the metal beaker and held in place by a tightly fitting rubber stopper protected with tin foil This stopper was about three-eighth of an inch thick, allowing uniform heating of the prisms and an uninterrupted transmission of heat into the metal case. Another rubber stopper in the shoulder of the flask held the refractometer in place. The lower end of the condenser was beveled so that the condensate could not form a seal and thus vary the pressure inside the flask. The whole apparatus was supported on a cork ring and held by a similar ring on top.

One degree variation in temperature would change the refractive index approximately 4 in the fourth place. By means of the vapor-bath it was possible to hold the temperature constant within ±0.02° as long as desired. By using liquids such as acetone, methyl alcohol and ethyl alcohol, the temperature inside the bath reached a maximum within five or six minutes, and thereafter remained practically constant. Several runs were recorded in which the temperature did not vary more than 0.01" during thirty minutes. By the use of sodium light the border line was sharp and could be checked repeatedly to ±0.02 scale divisions, which is equivalent to ±5 in the sixth place for the index of refraction.

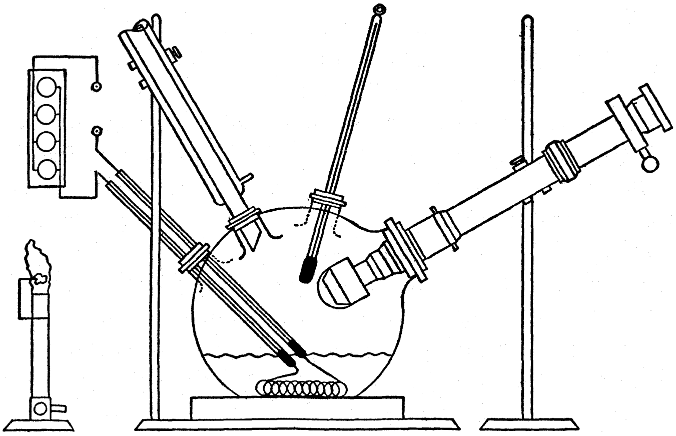

Fig. 1.—Constant temperature bath for refractometer.

Measurement of Refractive **Indices.**—Since there is some question as to the stability of a triglyceride when kept even at room temperature, the refractive indices were measured within a few days from the date of final crystallization. To remove any final traces of solvent, the crystalline compounds, already very dry, were placed in a vacuum desiccator at 40° and subjected to a vacuum of 8 mm. for a period of several hours. They were then carefully melted over a hot-plate and a few drops applied to the warm prisms. The metal beaker was then put in place and the refractometer inserted into the bath as shown in the accompanying diagram.

The values given in Table I for exact temperatures were obtained from readings near these points, corrected to the exact temperatures by use of the dn/dt factors obtained from a series of readings near those temperatures.

Discussion of Results.—It is evident from the data given in Table I that the symmetrical mixed triglycerides are characertized by a higher

TABLE I

index of refraction than that of their unsymmetrical isomers (average difference for five sets of isomers, 0.00062 at 75').

The index of refraction of equivalent mixtures of simple triglycerides may be expected to fall closely within the range covered by the respective isomers. From the constancy of readings over a period of an hour or more at 75°, it is evident that-the isomeric mixed triglycerides are comparatively stable at this temperature when isolated in pure form.

Summary

Apparatus was devised for using an immersion refractometer in a constant temperature bath at a range of 65–78'. The refractive indices of five sets of isomeric mixed triglycerides (two fatty acids) have been determined at 70 and 75°. In each case the symmetrical isomer had the higher value, the average difference being 0.00062 at 75°. The average dn/dt values over this temperature range are also given. Equivalent mixtures of simple triglycerides gave values lying within the range of the corresponding isomeric triglycerides.

THE SYNTHESIS OF DIMETHOXYPHTHALIMIDINE-ACETIC ACID

BY W. M. RODIONOW AND A. M. FEDOROVA

RECEIVED AUGUST 2, 1929 PUBLISHED JANUARY 8, 1930

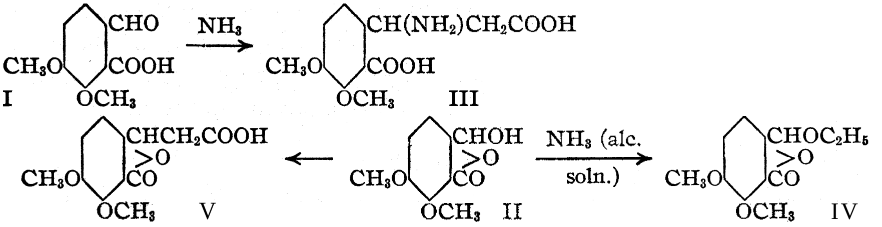
Some time ago[1] we announced a general method for the preparation of aryl-β-amino fatty acids by the condensation of aromatic aldehydes with malonic acid according to the equation

$$\mathrm{RCHO + NH_3 + CH_2(COOH)_2 = RCH(NH_2)CH_2COOH + CO_2 + H_2O}$$

The mechanism of this reaction was explained in the paper with E. A. Postovskaja[1d] as a condensation reaction between aldehyde-ammonia and malonic acid

$$\mathrm{RCH(OH)NH_2 + CH_2(COOH)_2 = RCH(NH_2)CH_2COOH + CO_2 + H_2O}$$

It was very interesting for many reasons to extend this reaction to an aldehyde carbonic acid. We have chosen for this purpose the most accessible substance of this type, opianic acid. This substance can react in two forms, as a true aldehyde, I, or in its ψ-form as an alcohol, II



Only the first form could give 3′,4′-dimethoxyphenyl-1′-β-alanine-2′-carbonic acid, III; the second form would give the #-ethyl ester of opianic acid, IV, and meconine-acetic acid, V.

Experiment showed that the condensation with opianic acid gave a mixture of the corresponding amino acid and meconine-acetic acid; the formation of the ψ-ethyl ester was not established. It is possible that this condensation takes place in the same course, as we have shown with benzaldehyde and piperonal[1e]

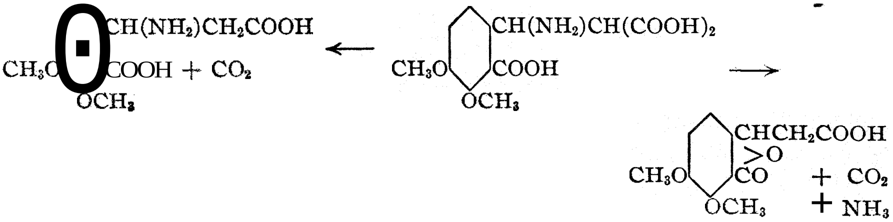
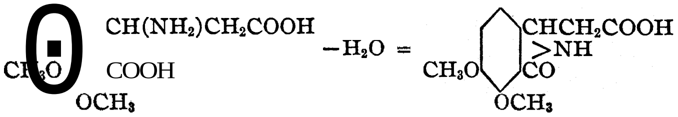
Rodionow and E. A. Postovskaja, THIS JOURNAL, 51, 841 (1929); (e) W. M. Rodionow, *ibid.*, 51, 847 (1929).



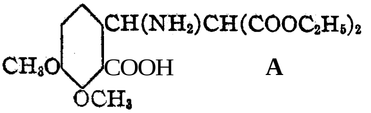
Until now we have not succeeded in isolating the tricarbonic acid and have obtained only the β-aryl-amino acid and meconine-acetic acid. The method of preparation of these substances is a very simple process. Equimolecular proportions of opianic and malonic acids and a slight excess of alcoholic ammonia solution are heated for two to three hours, then dissolved in soda solution, filtered off from small quantities of resinous matter and acidified. The precipitated mixture of both acids is separated with ether (see Experimental Part). The purified dimethoxyphenylalanine-carbonic acid melts over the range of 134–137° uncorr. Further crystallization from alcohol slowly changed the melting point; it became higher and nitrogen determinations gave larger percentages of nitrogen.

It seemed very probable that this acid would give a phthalimide derivative easily (with ring formation and loss of water) in accordance with the equation

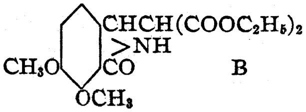


This supposition was proved experimentally. On heating the amino acid above its melting point for one to two hours, evolution of water takes place and the phthalimidine derivative is formed nearly quantitatively. When recrystallized from alcohol this substance melts at 174–175° and gives without difficulty a methyl ester and a nitrosamine derivative.

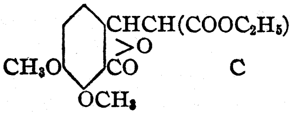
In our former investigation[1b] we showed that by replacing malonic acid by its ester, one could obtain the ester of β-aryl-β-amino-isosuccinic acid. It was expected that in the case of opianic acid either the derivative with the open chain, opianylmalonic ester (A) or the corresponding phthalimidine derivative (B) would be obtained. Both esters might be accompanied by the meconine-malonic ester (C).



A



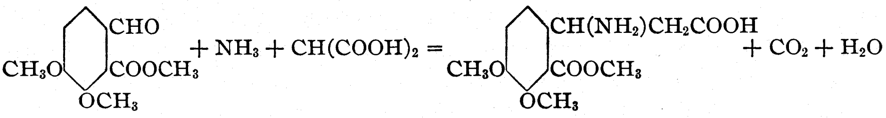
B



C

Our attempts to prepare these substances showed that only the meconine-malonic ester, not yet described, was obtained. It is a new confirmation of our former investigations, that the formation of esters of the β-aryl-β-amino-isosuccinic acid does not go with such good yield as the preparation of β-phenylalanine derivatives.

In order to avoid the ring formation we tried to condense the true esters (a-esters) of opianic acid with malonic acid in accordance with the equation



We have found, however, that methyl alcohol is split off and dimethoxyphthalimidine-acetic acid is formed exclusively.

Experimental Part

p-3′,4′-Dimethoxy-2′-carboxyphenyl-1′-β-aminopropionic Acid, $(CH_3O)_2C_6H_2(COOH)CH(NH_2)CH_2(COOH)$.—A mixture of 20 g. of opianic acid, 40 cc. of 10% alcoholic ammonia solution and 10 g. of malonic acid is heated for two hours on a boiling water-bath with a condenser set for distillation. The condensation product is dissolved in 10% soda solution, filtered from small quantities of tarry matter and acidified with hydrochloric acid. A heavy oil begins to separate from the solution and solidifies very slowly, but it is not advisable to allow it to crystallize as it is much more difficult to purify the solid substance. The acidified mixture of oil and water is immediately shaken with a large quantity of ether, whereby only the meconine-acetic acid goes into solution in the ether layer and gives, after recovery and recrystallization from water, 7.8 g. of substance melting at 165–167°. The yield is about 32.7% of the theoretical amount.

From the water solution the amino acid crystallizes after standing. Complete separation requires from ten to twelve hours, but the time is diminished considerably if mechanical stirring is used. The yield is 13.2 g. (about 55% of the theoretical). The filtrate gives after evaporation 3 g. of heavy oil, a mixture of opianic, meconine-acetic and β-amino acids.

The pure dimethoxyphenylalanine-carbonic acid crystallizes in thin plates from alcohol, is soluble in water and insoluble in ether. It melts at 132–134° with loss of water.

Anal. Calcd. for $C_{12}H_{15}O_6N$: N, 5.21. Found: N, 5.23, 5.28.

3,4-Dimethoxyphthalimidine-acetic Acid.—Three grams of dimethoxyphenylalanine-carbonic acid is heated for two hours on an oil-bath at 140–150°. The substance remaining is recrystallized from alcohol and then melts at 174–175°.

Anal. Calcd. for $C_{12}H_{13}O_5N$: N, 5.57. Found: N, 5.5, 5.6.

Methyl Dimethoxyphthalimidine-acetate, $(CH_3O)_2\overline{C_6H_2CONHC}HCOOCH_3$.—Two grams of dimethoxyphthalimidine-carbonic acid is dissolved in methyl alcohol and a current of dry hydrogen chloride is passed into the solution. This requires about two hours. After saturation the mixture is heated for two hours on the water-bath. When the temperature has dropped to 20–25°, the solution is poured into water and the substance which separates is filtered off and dried. The yield is 1.65 g. (about 80% of the theoretical). On recrystallizing from alcohol the ester gives lustrous prisms melting at 141–143°. The substance is easily soluble in alcohol and ether and is insoluble in water.

Anal. Calcd. for $C_{13}H_{15}O_5N$: N, 5.28. Found: N, 5.30.

Preparation of the Nitrosamine of Dimethoxyphthalimidine-carbonic Acid.—Two grams of dimethoxyphthalimidine-carbonic acid is dissolved in 40 cc. of water and mixed with 15 cc. of concd. hydrochloric acid. The solution is cooled with ice and treated little by little with 7 cc. of 10% sodium nitrite solution. After stirring for some time, the precipitated nitrosamine derivative is filtered by suction and crystallized from water. The yield is 1.9 g. (about 90% of the theoretical). The pure product melts at 167° with decomposition; it may be titrated with sodium hydroxide. Neutralization of 0.2 g. of the substance required 7.14 cc. of 0.1 *N* sodium hydroxide.

3,4-Dimethoxyphthalimidine-acetic acid from the α-Methyl Ester of Opianic Acid.—Two and one-half grams of α-ester and 1.2 g. of malonic acid are mixed with 5 cc. of 10% ammonia solution and heated for two hours on a boiling water-bath. The condensation product is dissolved in 10% soda solution and filtered. The filtrate is acidified with hydrochloric acid. The precipitate after crystallization from alcohol melts at 172–174". The yield is 1.7 g. (about 60% of the theoretical). The melting point of this substance mixed with the dimethoxyphthalimidine-acetic acid of other preparations did not show any depression.

Diethyl Meconine-malonate, $(CH_3O)_2\overline{C_6H_2COOC}HCH(COOC_2H_5)_2$.—A mixture of 20 g. of opianic acid, 15.3 g. of malonic ester and 25 cc. of 14% alcoholic ammonia solution is heated as usual for five hours. The condensation product, a heavy oil, is dissolved in ether and separated from a part of the oil which is not soluble in ether. The ethereal solution is treated with an alcoholic solution of hydrogen chloride and filtered again. The ether solution is then evaporated on the water-bath to a small volume. On cooling the diethyl meconine-malonate separates in large white prisms. The yield of unpurified substance is 26.5 g. (about 75% of the theoretical.) The product is very easily soluble in ether or alcohol and insoluble in water. The diethyl meconine-malonate melts at 74–75° after recrystallization from alcohol.

Anal. Subs., 0.1300: CO_2, 0.2756; H_2O, 0.0673. Calcd. for $C_{17}H_{20}O_8$: C, 57.95; H, 5.68. Found: C, 57.82; H, 5.75.

Summary

The reaction between opianic acid and malonic acid in the presence of alcoholic ammonia solution has been investigated and it was found that the primary condensation product, the β-phenylalanine derivative, forms dimethoxyphthalimidine-aceticacid very easily on heating, and that the condensation of opianic acid with malonic ester does not give an amino derivative but results in the corresponding meconine-malonic ester. The preparation and properties of these compounds are described.

STUDIES RELATING TO ORGANIC GERMANIUM DERIVATIVES. II. SOME TRIPHENYL GERMANIUM DERIVATIVES AND THEIR REACTIONS

Charles A. Kraus and Charles B. Wooster

Received August 2, 1929 Published January 8, 1930

In the development of the chemistry of germanium, certain simple triphenyl germanium derivatives have been prepared and some of their reactions have been studied. A comparison of the properties of such compounds with those of corresponding compounds of carbon presents interesting contrasts. Thus triphenyl germanium amine is extremely susceptible to hydrolysis, while the analogous organic amines are comparatively stable. Triphenyl germanium amine results from the action of gaseous ammonia upon solutions of triphenyl germanium bromide or other halides in organic solvents. The product is so sensitive toward moisture that it is largely hydrolyzed in the operations incident to its separation unless extreme precautions are taken. Even then this method does not serve in preparing a strictly pure compound.

Since the amine upon hydrolysis yields triphenyl germanium oxide and ammonia, the process, as a whole, is expressed by the equations

$$(C_6H_5)_3GeBr + 2NH_3 = NH_4Br + (C_6H_5)_3GeNH_2 \quad (1)$$
$$2(C_6H_5)_3GeNH_2 + H_2O = 2NH_3 + [(C_6H_5)_3Ge]_2O \quad (2)$$

Triphenyl germanium amine may also be prepared by the action of potassium amide on triphenyl germanium bromide in ammonia solution. In this case, reaction is facilitated by an excess of potassium amide, which forms a monopotassium salt of the amine. This behavior is similar to that of the simpler aromatic amines;[1] triphenylmethylamine, however, does not react with potassium amide.[2] The following equations represent the reactions

$$(C_6H_5)_3GeBr + KNH_2 = (C_6H_5)_3GeNH_2 + KBr \quad (3)$$
$$(C_6H_5)_3GeNH_2 + KNH_2 = (C_6H_5)_3GeNHK + NH_3 \quad (4)$$

The amine may be liberated from its salt by means of ammonium bromide. It appears as a fine white crystalline precipitate. The following reaction is involved

$$(C_6H_5)_3GeNHK + NH_4Br = KBr + NH_3 + (C_6H_5)_3GeNH_2 \quad (5)$$

The amine is further distinguished from its organic analogs by its marked tendency to lose ammonia with the formation of the imine, $[(C_6H_5)_3Ge]_2NH$. This sometimes occurs immediately upon precipitation. Attempts to recrystallize the amine invariably yielded mixtures of triphenyl germanium amine and imine and, perhaps, also the nitride.

---

[1] White, Morrison and Anderson, This Journal, 46,967 (1924).

[2] Kraus and Rosen, *ibid.*, 47,2739 (1925).

This tendency of the amine to lose ammonia is paralleled by that of the corresponding hydroxide, triphenyl germanol, to lose water. On hydrolyzing triphenyl germanium halides, the oxide is invariably obtained. Kraus and Foster[3] have shown that the germanol may be obtained indirectly from sodium triphenyl germanide by oxidation of this salt to the germanolate and subsequent hydrolysis of this compound. Although triphenyl germanol loses water at higher temperatures, it is comparatively stable under ordinary conditions, much more so, in fact, than the corresponding amine.

Complete conversion of the amide to the nitride may be effected by heating the primary amine above 200° under atmospheric pressure and then evacuating the containing tube. The nitride may be purified by fractional sublimation in *vacuo* or by recrystallization from dry petroleum ether. From the latter solvent it crystallizes in colorless needles which melt at 163–164° (corr.).

Analysis of the amine was first carried out by decomposing the compound with hydrochloric acid and separating the ammonium chloride from the triphenyl germanium chloride[4] formed in this reaction. The latter compound, which was also prepared from the oxide, was found to melt at 116° (corr.). It is interesting to note that neither a nitrate nor a sulfate could be prepared by a similar method. The triphenyl germanium oxide was recovered unchanged, showing that it is much more resistant to hydrolysis than its structural analog, bis-triphenylmethyl ether.[5] The oxide is readily attacked by sodium in liquid ammonia solution. Apparently the primary products of this reaction are sodium triphenyl germanide, $(C_6H_5)_3GeNa$, and sodium triphenyl germanolate, $(C_6H_5)_3GeONa$. These products are analogous to those obtained by the cleavage of aromatic ethers with sodium–potassium alloy.[6]

It is evident that the compounds of germanium with electronegative elements show a somewhat greater reactivity than do their carbon analogs.

Experimental Part

Action of Ammonia on Triphenyl Germanium Bromide.—Triphenyl germanium bromide was treated with liquid ammonia at its boiling point, −33.5°. Solutions of triphenyl germanium bromide in ether, petroleum ether and benzene were also treated with gaseous ammonia at ordinary temperatures. The reactions were carried out in tubes similar to those described by White[7] but ground-glass joints were employed throughout in place of rubber stoppers and inlet and outlet tubes were provided with

stopcocks so that the tube could readily be evacuated. The entire tube length was **40** cm. and it could be weighed on a 2-kilo balance.

When ammonia was passed through a solution of triphenyl germanium bromide in an organic solvent, a precipitate was formed immediately which, upon separation and analysis, proved to be ammonium bromide.

Anal. Subs., **0.2970, 0.3959:** AgBr, **0.5694, 0.7527.** NH_4Br recovered, **100.14,** 99.11%.

The organic residue was soluble in benzene and was crystallized therefrom and identified as triphenyl germanium oxide, m. p. 183–184° (corr.).[8]

The molecular weight of the oxide was determined in benzene at **its** boiling point by a modification of the Cottrell[9] method.

Mol. wt. Solvent, **32.57, 31.55;** solute, **1.370, 2.197;** At, 0.183°, 0.302'. **Calcd.** for $[(C_6H_5)_3Ge]_2$: mol. wt., **623.4.** Found: **620.6, 622.6,** mean, **621.6.**

The molecular weight of the oxide in benzene appears to be normal.

On treating the bromide with liquid ammonia, some unchanged triphenyl germanium bromide was usually recovered at the end of the experiment. The amount of ammonia absorbed in the reaction, as determined by weight increase, varied from **1.72** to **1.96** moles per mole of bromide. This indicates the preliminary formation of triphenyl germanium amine, but it was found impossible to obtain both a complete reaction and an oxide-free product.

Action of Potassium Amide on **Triphenyl** Germanium Bromide **in** Liquid Ammonia. **—A** quantity of metallic potassium more than equivalent to the triphenyl germanium bromide to be treated was converted to potassium amide in liquid ammonia solution by means of a bit of rusty iron as a catalyst. This catalyst was removed when the reaction was complete. The ammonia was then evaporated and the reaction tube evacuated. The tube was next filled with pure dry nitrogen and triphenyl germanium bromide **(1.302** g.) was introduced. This procedure was necessary, since ammonia vapor causes the bromide to cake on the walls of the reaction tube. The nitrogen was removed by means of a pump and ammonia was condensed on the materials in the tube. Reaction took place at once. It was accompanied by a decrease in the weight of the non-volatile contents of the tube amounting to **0.0605** g., which is equivalent to **1.113** moles of ammonia per mole of the original bromide used. The ammonia used in this reaction was dried by means of sodium in an auxiliary tube; the reaction tube was pre-dried by heating to **200'.**

The product obtained under these conditions was completely soluble in liquid ammonia and insoluble in ether. Upon hydrolysis the product became partially soluble in petroleum ether. When ammonium bromide was added equivalent to the excess of potassium amide, a precipitate was formed in the liquid ammonia solution. After evaporating the ammonia and exhausting the reaction tube, the gain in weight in two experiments corresponded to **15.42** and **16.92** g. per mole of the original bromide, **while** **16.00** g. is required for the formation of the amine, $(C_6H_5)_3GeNH_2$. Evidently triphenyl germanium bromide reacts with potassium amide according to Equation **3.**

The amount of free potassium amide was approximated by titrating the solution with ammonium bromide until a permanent precipitate began to appear. In two experiments the amount of potassium amide reacting with the bromide was found to be **1.842** and **1.879** moles, respectively. For the formation of the monopotassium salt two

---

[8] This oxide separates from benzene in the form of characteristic crystals containing two molecules of solvent which are slowly lost upon standing in the air at ordinary temperature. The benzene may be removed readily by heating the compound to **100°** in an oven.

[9] **Cottrell, THIS JOURNAL,** 41, **721 (1919).**

moles of potassium amide is required. The method of titration is not a precise one, since it is possible that the amine is appreciably soluble in liquid ammonia.

Triphenyl Germanium Nitride.—In order to obtain the amine, or its de-ammoniation products, in a pure state, reactions were carried out in a two-legged tube, which permitted the recrystallization of the products of reaction from petroleum ether in absence of air and moisture. When the initial reaction was completed, the ammonia was evaporated, the tube exhausted and petroleum ether introduced. The organic residue, being soluble in the ether, was decanted into the second leg, after which the solvent was recondensed in the first leg and the process repeated until the organic material was completely separated from the inorganic salts. Analysis of the product indicated that the amine lost ammonia during recrystallization. Accordingly, in later experiments, the product was heated to 200° and the tube was evacuated to facilitate the loss of ammonia. Under these conditions the product sublimed to the colder parts of the tube immediately above the bath. These crystals were then analyzed for nitrogen by dissolving in warm alcohol acidified with hydrochloric acid. The resulting solution was diluted with water and separated from precipitated triphenyl germanium chloride by filtration. Sodium hydroxide was added to the filtrate to liberate the ammonia, which was distilled and titrated with standard acid.

Anal. Subs., 0.3535, 0.6040, 0.3063: cc. of 0.0999 N HCl, 3.78, 7.28, 3.48. Calcd. for $[(C_6H_5)_3Ge]_3N$: N, 1.98. Found: N, 1.82, 2.05, 1.93; mean, 1.94.

Action of Sodium on Triphenyl Germanium Oxide in Liquid Ammonia.—A known weight of triphenyl germanium oxide was treated with metallic sodium in liquid ammonia. The first two equivalents of sodium, which were added slowly, reacted fairly rapidly. Thereafter reaction was quite slow and the reaction mixture was left for fifteen hours with a considerable excess of metal. At the end of that time the free metal was titrated back with ammonium bromide until the blue color, due to sodium, just disappeared. The solution exhibited a yellow color and a considerable quantity of a white precipitate was present. The yellow color was doubtless due to sodium triphenyl germanide, while the precipitate was taken to be sodium triphenyl germanolate. In three experiments, 2.42, 2.60 and 2.46 equivalents of metal reacted per mole of triphenyl germanium oxide. It was inferred that reaction takes place as follows

$$[(C_6H_5)_3Ge]_2O + 2Na = (C_6H_5)_3GeNa + (C_6H_5)_3GeONa \qquad (6)$$

While the sodium is capable of breaking down readily the first of the germanium–oxygen bonds, it attacks the second only with difficulty if at all. If the second bond had been completely broken down, four atoms of sodium should have been used up in the reaction.

The values found for the amount of sodium used are somewhat higher than required according to Equation 6. It is of course possible that a slow reduction of sodium triphenyl germanolate may have occurred. On the other hand, the reaction between the solvent and the metal may have been catalyzed by the presence of the germanium compounds. In the second experiment some sodium triphenyl germanide was evidently further reduced to disodium diphenyl germanide, as was indicated by the red color of the solution. In any case the reaction must have taken place initially according to Equation 6.

On passing dry air through the ammonia solution, on the completion of the initial reaction, the solution was decolorized and the amount of precipitate was increased. This was due to the oxidation of sodium triphenyl germanide to the corresponding germanolate, a reaction which is known to occur according to Kraus and Foster.

Summary

Ammonia reacts with triphenyl germanium bromide with the formation of ammonium bromide and triphenyl germanium amine. The amine

hydrolyzes with great ease in the presence of traces of moisture and loses ammonia readily, even at ordinary temperatures, with the formation of an imine and possibly some nitride.

Triphenyl germanium bromide is immediately and quantitatively ammonolyzed by potassium amide in liquid ammonia. In the presence of excess amide, the monopotassium salt, $(C_6H_5)_3GeNHK$, is formed. The amine is re-formed from the potassium salt on the addition of ammonium bromide.

Tritriphenyl germanium nitride was prepared by heating triphenyl germanium amine to 200° in *vacuo.* It crystallizes in the form of needles melting at 163–164°. It is soluble in petroleum ether and other common organic solvents and may be sublimed in *vacuo.*

Metallic sodium reacts with triphenyl germanium oxide in liquid ammonia with the formation of sodium triphenyl germanide and sodium triphenyl germanolate.

It is pointed out that the compounds of germanium are generally more reactive than are the analogous compounds of carbon.

THE REACTION BETWEEN ALKALI METAL ALKYLS AND QUATERNARY ARSONIUM COMPOUNDS

BY M. E. P. FRIEDRICH AND C. S. MARVEL

RECEIVED AUGUST 5, 1929 PUBLISHED JANUARY 8, 1930

In some of the early work on organic arsenic compounds Cahours[1] reported the preparation of pentamethylarsine by the action of zinc dimethyl on tetramethylarsonium iodide. The evidence for the existence of this penta-alkylarsine was slight and the work has never been confirmed. Previous attempts in this Laboratory to prepare the analogous penta-alkyl nitrogen[2] and phosphorus[3] compounds by the action of alkali metal alkyls on the corresponding -onium salts have not been successful. In view of Cahour's claim for the existence of pentamethylarsine, the work has been extended to the arsonium salts.

The methods used in the study of the reactions of alkali metal alkyls and arsonium salts were very similar to those used in the earlier work on nitrogen and phosphorus compounds. Lithium ethyl and lithium n-butyl were used in most of the experiments.

The first reaction studied was that between lithium n-butyl and tetraethylarsonium bromide. Low-boiling petroleum ether was used as a sol-

[1] Cahours, **Ann.,** 122, **337 (1862).**

[2] Hager with Marvel, THIS JOURNAL, **48,2689 (1926).**

[3] Coffman and Marvel, *ibid.,* 51, **3496 (1929).**

vent and the reaction mixture was carefully distilled out of contact with air or moisture in the hope of thus obtaining a high-boiling fraction that would prove to be the desired penta-alkyl arsenic compound. The only product that could be identified definitely was triethylarsine. Next an attempt was made to prepare a penta-alkyl arsenic compound from triethylarsine dibromide and lithium ethyl. Triethylarsine was the only product that was identified.

Since there seemed to be very little chance of isolating a pure stable penta-alkyl arsenic compound, it was decided to study some reactions that might lead to isomeric products of the type R_4AsR' and $R_3R'AsR$, as had been done before in the nitrogen series, and to determine whether or not their decomposition products would give any indication of the existence of penta-alkyl arsines in which the five valence bonds were equivalent. For this purpose the reactions between lithium n-butyl and tetra-ethylarsonium bromide and lithium ethyl and triethyl-n-butylarsonium bromide were investigated. The reaction products were worked up in such a manner as to make it possible to analyze the gaseous products. The reactions which occurred are shown by the following equations.

$$2LiC_4H_9 + 2(C_2H_5)_4AsBr \longrightarrow 2LiBr + 2(C_2H_5)_3As + C_2H_4 + C_2H_6 + C_4H_{10} + C_4H_2 \quad (1)$$

$$LiC_2H_5 + (C_2H_5)_3C_4H_9AsBr \longrightarrow LiBr + (C_2H_5)_2C_4H_9As + C_2H_4 + C_2H_6 \quad (2)$$

The fact that these two reactions give entirely different products shows that the arsenic atom did not at any stage of the reaction share five pairs of electrons with five hydrocarbon groups to give a penta-alkyl arsenic compound in which the alkyl groups were equivalent.

In working up these reaction mixtures it was found that the easiest way to identify the arsine was to allow it to undergo oxidation with air or oxygen. Instead of yielding the arsine oxides, it was found that triethylarsine gave diethylarsinic acid and diethyl-n-butylarsine gave ethyl-n-butylarsinic acid. These facts were checked by the use of the known arsines.

In analyzing the gaseous products of these reactions it was found that they were usually made up of less than 5% of unsaturated hydrocarbons and more than 95% of saturated hydrocarbons. This was the cause of considerable concern until it was found that ethylene was rather rapidly polymerized by a solution of a lithium alkyl to give non-gaseous products. Since the reaction mixtures containing in every case an excess of the lithium alkyl always stood for some two weeks under pressure it is not surprising that most of the olefins were polymerized before the tubes were opened.

One experiment was performed in which tetramethylarsonium iodide was treated with sodium triphenylmethyl in an attempt to isolate a compound analogous to the tetramethyltriphenylmethylammonium of Schlenk and Holtz.[4] There was some indication that a colored salt-like compound

---

[4] Schlenk and Holtz, *Ber.*, 49,603 (1916).

was produced. However, the only product fully identified was triphenylmethane. The odor of trimethylarsine was apparent. No definite conclusion can be drawn from this experiment.

Experimental Part

Triethylarsine.—In a 5-liter two-necked flask fitted with a reflux condenser, a mechanical stirrer and a 1-liter separatory funnel were placed 168 g. of magnesium turnings and 3.8 liters of dry ether. The Grignard reagent was prepared by adding 720 g. of ethyl bromide in the usual manner. The air was swept out of the flask with a current of dry nitrogen and to the Grignard solution thus prepared was then added a solution of 300 g. of arsenic trichloride in 600 cc. of dry ether. During the addition of this solution stirring was maintained and the solution was kept at a temperature of about 20°. Stirring was then discontinued and the mixture was boiled under the reflux for about twenty-four hours. The reaction mixture was decomposed with ice water acidified with hydrochloric acid. The ether layer was separated and the water layer was extracted three times with more ether. The combined ether layers were dried over calcium chloride and distilled. After the ether was removed at ordinary pressures, the residue was distilled under reduced pressure in a current of dry nitrogen or carbon dioxide. The triethylarsine boiled at 65–70° at 25–30-mm. pressure. The yield was 150–173 g. (54–62% of the theoretical amount). Steinkopf and Müller[5] obtained yields of 40% of the theoretical amount of triethylarsine without refluxing the mixture.

Tetra-ethylarsonium Bromide.—A solution of 15 g. of triethylarsine and 21 cc. of ethyl bromide in 20 cc. of dry ether was heated at 98° in a sealed tube for about eight hours. The tube was cooled and opened. The salt was dissolved in absolute alcohol, then precipitated with dry ether and filtered with suction. The yield was 18 g. (75% of the theoretical amount). The product melted at 298–300° (uncorr.).

Anal. Subs., 0.5518: 19.62 cc. of 0.1043 N $AgNO_3$. Calcd. for $C_8H_{20}AsBr$: Br, 29.51. Found: Br, 29.45.

Triethyl-n-butylarsonium Bromide.—A solution of 15 g. of triethylarsine and 18 g. of n-butyl bromide in 20 cc. of dry ether was heated at about 98° in a sealed tube for about two days. The salt was purified by dissolving in absolute alcohol and precipitating with dry ether. The yield was 19 g. (75% of the theoretical amount). The product melted at 227° (uncorr.).

Anal. Subs., 0.1213: 4.59 cc. of 0.0893 N $AgNO_3$. Calcd. for $C_{10}H_{24}AsBr$: Br, 26.74. Found: Br, 26.99.

Diethyl-*n*-butylarsine.—To the Grignard reagent prepared from 24 g. of magnesium and 110 g. of ethyl bromide in 200 cc. of dry ether was added a solution of 60 g. of n-butyldichloro-arsine in 70 cc. of dry ether. The mixture was stirred and boiled under a reflux condenser for about eighteen hours. The reaction mixture was decomposed with ice water acidified with hydrochloric acid. The ether layer was separated, dried over calcium chloride and distilled. After the ether was removed, the residue was distilled under reduced pressure. The arsine boiled at 78° at 28 mm. The yield was 25 g. (44% of the theoretical amount); sp. gr. d_{20}^{20} 1.0306; n_D^{20} 1.4745.

The compound was not analyzed but a 5-cc. sample was heated in a sealed tube overnight with 5 cc. of ethyl bromide in 10 cc. of dry ether. The product was identical with the triethyl-n-butylarsonium bromide obtained from triethylarsine and n-butyl bromide.

[5] Steinkopf and Müller, *Ber.*, 54B, 844 (1921).

Tetramethylarsonium Iodide.—A solution of methylmagnesium chloride was prepared by passing dry methyl chloride into a well-stirred suspension of magnesium turnings in dry ether. The strength of this solution was determined by titrating a portion with acid according to the method of Gilman, Wilkinson, Fishel and Meyers.[6] To 2 liters of this ether solution containing 3.02 moles of methylmagnesium chloride was added 165 g. of arsenic trichloride. Considerable solid separated and stirring was impossible. After standing overnight the mixture was decomposed with ice water acidified with hydrochloric acid. The mixture was distilled directly until the ether was removed and the distillate containing ether and trimethylarsine was dried over calcium chloride. To this solution an excess of methyl iodide was added. After several weeks the precipitated tetramethylarsonium iodide was filtered off and recrystallized from ethyl alcohol. The product seemed to sublime at 320–328°.

Anal. Subs., 0.2413: 9.78 cc. of 0.0893 *N* $AgNO_3$. Calcd. for $C_4H_{12}AsI$: I, 48.49. Found: I, 48.55.

Diethylarsinic Acid.—A sample of triethylarsine was allowed to stand in a loosely stoppered test-tube. The crust which formed on the surface was broken from time to time and the material gradually solidified. This solid product was recrystallized from ethyl acetate several times and it then melted sharply at 136–137°.[7] Some reddish oil was formed during the oxidation. This was entirely removed in the crystallization. The acid was titrated with standard alkali. Subs., 0.1275: 6.4 cc. of 0.1199 N NaOH. Neutral equivalent, calcd. for $C_4H_{10}AsO_2H$: 165.9. Found: 165.1. The same material was obtained by bubbling dry oxygen through a solution of triethylarsine in dry ether.

Ethyl-*n*-butylarsinic Acid.—This was first prepared by oxidizing diethyl-*n*-butylarsine with air in oxygen exactly as described above. The product was recrystallized from a mixture of benzene and finally melted at 93–96°.

To prove the structure of this product a sample was prepared by the general method for the synthesis of arsinic acids devised by Quick and Adams.[8]

To a well-stirred mixture of 20 g. of ethyl bromide and 70 cc. of 10 N sodium hydroxide was slowly added 34 g. of n-butyl dichloro-arsine. The mixture was stirred for a few hours, then filtered and evaporated to dryness. The residue was extracted with hot benzene and the arsinic acid was precipitated with petroleum ether. After several recrystallizations from a mixture of benzene and petroleum ether this product melted at 93–96°. A mixed melting point with the product obtained from the oxidation of diethyl-n-butylarsine showed that the two were identical. The product was titrated. Subs., 0.1229: 5.3 cc. of 0.1199 N NaOH. Calcd. for $C_6H_{14}AsO_2H$, neutral equivalent, 193.9. Found: 193.3.

General Procedure Followed in Studying the Reactions of the Lithium Alkyls and Quaternary Arsonium Salts

Lithium ethyl and lithium n-butyl were prepared and used in both petroleum ether (b. p. 40–45°) and a high-boiling paraffin oil in the manner previously described by Hager with Marvel.[2] The petroleum ether solutions were analyzed but no analysis was made on the solutions in the high-boiling oil. The arsonium salts were dried in a vacuum desiccator over sulfuric acid before use. When petroleum ether was used as a solvent for the reaction, the lithium alkyl was prepared exactly as described before and the reaction with the arsonium salt was carried out in a flask such as is shown in Fig. 1. The

---

[6] Gilman, Wilkinson, Fishel and Meyers, THIS JOURNAL, 45, 150 (1923).

[7] Wigren, *Ann.*, 437, 288 (1924), gives the melting point as 133–134°.

Quick and Adams, THIS JOURNAL, 44, 811 (1922).

dried salt was introduced into the small bulb (A), which was then sealed. The glass apparatus containing the lithium alkyl solution was sealed on at B and the apparatus was connected to a mercury vapor pump, all of the air exhausted and the apparatus was sealed. The valve on the reaction vessel containing the lithium alkyl was broken and the solution was allowed to flow into the large Bulb D. The reaction flask was then sealed at B. Some glass beads were placed in the large reaction flask so that shaking the flask prevented caking of the reaction mixture. The salt was introduced into the solution of the lithium alkyl by tilting the apparatus. Gas evolution was noted in all of the experiments. The reaction mixtures were allowed to stand for about two weeks with occasional shaking. After this time the flask was opened at C and the gas collected in an evacuated bulb of the type shown in Fig. 3.

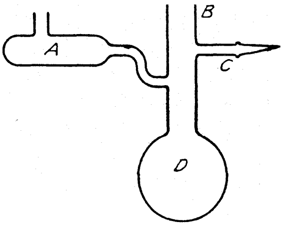

Fig. 1.

When the high-boiling paraffin oil was used as a solvent it was found more convenient to use the reaction vessel shown in Fig. 2. The dry salt was introduced in Bulb A (200 cc.). The solvent, mercury alkyl and lithium were placed in Bulb B (100 cc.). The system was evacuated with a mercury-vapor pump and sealed at C and D. E was a Gooch filter plate sealed into the apparatus. When the conversion of the mercury alkyl to the lithium alkyl was complete, as indicated by the settling of the lithium amalgam to the bottom of the solution, the oil solution was filtered over into the bulb containing the salt. These reaction mixtures were also allowed to stand for about two weeks and the gas was collected by opening at F.

The gas was collected by attaching the evacuated gas pipet (Fig. 3) to the side-arm of the reaction flask by means of heavy-walled pressure tubing. One stopcock of the gas pipet was opened and the tip on the reaction flask was broken inside the heavy tubing. The reaction flasks were heated to about 100° [illegible] of the gases when the high-boiling paraffin oil was used as a solvent. The gas in the pipet was brought to atmospheric pressure by introducing dry mercury until the pressure was equalized with atmospheric pressure.

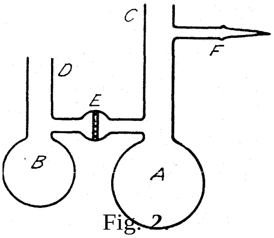

Fig. 2.

The first gas analyses were made by absorption and combustion methods. However, it was found much more satisfactory to determine the unsaturated hydrocarbons by absorption in bromine water and to determine the density of the remaining saturated hydrocarbons after drying with anhydrous magnesium perchlorate by means of an Edwards gas density balance.[9] A sample of each gas was burned to be sure that it was not air.

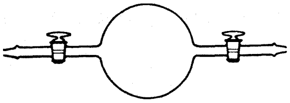

Fig. 3.

After removal of the gases in all of the later experiments, the flasks were opened. The odor of the arsine was always noticeable. From the high-boiling paraffin oil solutions it was impossible to isolate pure products of any sort. When petroleum ether was used as a solvent it was evaporated and the arsinic acids were obtained by allowing the residue to oxidize in the air.

Attempt to Prepare **Tetra-ethyl-n-butylarsenic.—After** a few preliminary trials the apparatus shown in Fig. 4 was used for this experiment. In Bulb A was placed 18 g. of carefully dried tetra-ethylarsonium bromide and some glass beads. The bulb was then

---

[9] Directions for using this balance are given in Bureau of Standards Paper No. 89.

sealed. The reaction flask containing the lithium *n*-butyl solution was sealed on to the apparatus at C. The entire apparatus was evacuated with a mercury-vapor pump and carefully sealed. Then 0.048 mole of lithium n-butyl in 60 cc. of petroleum ether was introduced into Bulb B and the apparatus was sealed at C. The salt was slowly poured over into the lithium alkyl solution. Vigorous gas evolution was noted. The petroleum ether solution was poured back and forth from Bulb A in order that all of the salt would come into contact with the lithium n-butyl. After about two days the reaction mixture was filtered through the filter sealed into the apparatus at D into Flask E. The petroleum ether was then partially distilled back into B to wash the salt and again filtered. The gas was then removed from the apparatus by opening the side-arm on Flask B and the apparatus was evacuated to a pressure of 30 mm. The apparatus was then sealed at F. The solid left in Flask B was found to be lithium bromide and some unchanged tetra-ethylarsonium bromide.

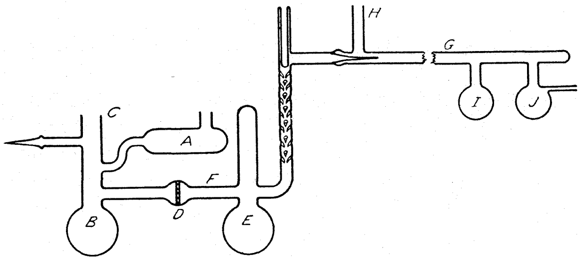

Fig. 4.

The petroleum ether solution in Flask E was then distilled. The two-bulb receiver was sealed onto the side-arm, evacuated and sealed. The valve at H was broken. The distillation flask was placed in an oil-bath and the receiver I was placed in an ice-bath. A first fraction was obtained up to about 54°. The bulb I was sealed off and a second fraction boiling up to 77° was collected in Bulb J. This bulb was sealed and about a half gram of liquid which boiled at 100–110° was collected in the tip of G. This was obtained by directly heating the bulb with a flame and the high-boiling temperature was undoubtedly due in part to superheating.

The first fraction was redistilled under atmospheric pressure and boiled at 40–65°. It did not have the characteristic arsine odor. The second fraction on redistillation in the air boiled at 65 to 140°. Most of the material came over at 139–140°, which indicated that it was nearly pure triethylarsine. A sample on standing in the air was oxidized to diethylarsinic acid. Another sample gave triethylarsine dibromide when treated with bromine. The small amount of high-boiling liquid was again distilled under atmospheric pressure and distilled below 150". It gave all of the tests for triethylarsine.

Lithium Ethyl and Tetraethylarsonium Bromide.—A solution of 0.095 mole of lithium ethyl in petroleum ether (b. p. 40–45°) was added to 25 g. (0.092 mole) of tetraethylarsonium bromide. A vigorous evolution of gas was noted but no color was produced. After two weeks the flask was cooled in an ice-bath, opened and the gas collected. It contained 1.4% of ethylene as shown by absorption in bromine water. The remaining gas was analyzed by combustion.

Anal. 60 cc. gas: 90 cc. of O_2. Vol. after combustion, 99.2 cc. Contraction, 50.8 cc. Vol. after absorption of CO_2 in alkali, 55.5 cc. CO_2, 43.7 cc. 48.7 cc. gas 89.9 cc. of O_2. Vol. after combustion, 94.5 cc. Contraction, 44.1 cc. Vol. after absorption of CO_2 in alkali, 58.3 cc. CO_2, 36.2 cc. (The gases were measured at the same temperatures and pressures.) Calcd. for ethane: contraction, CO_2: 1.25. Pound: 1.17, 1.22.

After the gas was collected, the reaction flask was opened, the reaction mixture filtered and the petroleum ether allowed to evaporate in the air. Diethylarsinic acid crystallized and after recrystallization melted at 136–137°.

For more accurate analysis of the gas the reaction was run in high-boiling paraffin oil. The reagents used were 2 g. of lithium, 20 g. of diethyl mercury and 23 g. of tetraethylarsonium bromide. The gas collected was analyzed by determining the density as mentioned in the general discussion.

Anal. (Gas density) bar. pressure, 742.00 mm.; gage readings with air, 705.9 mm.; 98.9 mm. Pressure, 607.0 mm. Total pressure, 135 mm. Gage readings with gas, 705.9 mm.; 98.9 mm. Pressure, 607.0 mm. Total pressure, 135 mm. Calcd. for C_2H_6: sp. gr., 1.049. Calcd. for C_2H_4; sp. gr., 0.978. Found: sp. gr., 1.00. (Absorption) 88.2 cc. of gas, 4.7 cc. lost by absorption in bromine water: 5.3% of unsaturated hydrocarbons.

The odor of the arsine was apparent in the paraffin oil solution but no arsinic acid was isolated.

Lithium n-Butyl and Tetraethylarsonium Bromide.—A solution of 0.04 mole of lithium n-butyl in petroleum ether was added to 11.11 g. (0.041 mole) of tetraethylarsonium bromide. A vigorous reaction occurred and gas evolution was noted. No attempt was made to collect this gas. The reaction flask was opened and the contents were filtered. On allowing the solution to stand in the air the petroleum ether evaporated and the arsine was oxidized to diethylarsinic acid, m. p. 136°.

A second reaction was carried out in high-boiling paraffin oil solution. The reagents used were 2 g. of lithium, 25 g. of di-n-butyl mercury and 23 g. of tetraethylarsonium bromide. After two weeks the reaction flask was opened and the gas collected.

Anal. (Gas density) bar. pressure, 742.3 mm.; gage readings with air, 713.5 mm.; 90.0 mm.; pressure, 623.5 mm.; total pressure, 118.8 mm. Gage readings with gas, 735.0 mm.; 66.1 mm.; pressure, 668.9 mm.; total pressure, 73.4 mm.; sp. gr. of gas, 1.62. (Absorption) 99.5 cc. of gas: 1.0 cc. lost by absorption in bromine water. 1.0% of unsaturated hydrocarbons. The density figures indicate that the gas is approximately 45% ethane and 55% butane. Such a mixture would have a specific gravity of 1.60.

Lithium Ethyl and Triethyl-*n*-butylarsonium Bromide.—A solution of 0.058 mole of lithium ethyl in petroleum ether was added to 175 g. (0.058 mole) of triethyl-*n*-butylarsonium bromide. After three weeks the mixture was cooled in ice, the reaction flask was opened and the gas collected. The gas density reported was determined after removal of the unsaturated hydrocarbons. Gas density: bar. pressure, 746.0 mm.; gage readings with air, 721.9 mm., 80.0 mm.; pressure, 641.9 mm.; total pressure, 104.1. Gage reading with gas: 725.8 mm., 76.1 mm.; pressure, 649.7 mm.; total pressure, 96.3: sp. gr., 1.08.

The specific gravity of this gas indicated that it was nearly pure ethane. It undoubtedly was contaminated with some petroleum ether vapors. After removal of the gas the reaction mixture was worked up as described before and ethyl-n-butylarsinic acid melting at 92" was obtained.

This reaction was run in paraffin oil using 2 g. of lithium, 20 g. of diethyl mercury and 25 g. of triethyl-n-butylarsonium bromide. The gas was collected and analyzed.

Anal. (Gas density) bar. pressure, 744 mm.; gage readings with air, 707.2 mm., 96.1 mm.; pressure, 611.1 mm.; total pressure, 132.9 mm.; gage reading with gas, 711.3 mm., 92.0 mm.; pressure, 619.3 mm.; total pressure, 124.7 mm.: sp. gr., 1.065. (Absorption) 96.5 cc. of gas: 2.4 cc. lost by absorption in bromine water: 2.5% of unsaturated hydrocarbons. These results indicated that the gas was nearly pure ethane with some ethylene and possibly a small amount of butane.

Lithium n-Butyl and Triethyl-n-butylarsonium Bromide.—A solution of 0.048 mole of lithium n-butyl in petroleum ether was added to 5 g. of triethyl-n-butylarsonium bromide. From the reaction mixture ethyl-n-butylarsinic acid, m. p. 87–89°, was isolated.

The reaction was repeated in paraffin oil using 2 g. of lithium, 25 g. of di-*n*-butyl mercury and 25 g. of triethyl-n-butylarsonium bromide. The gas was collected and analyzed. The unsaturated gases were removed after the density was taken on the original gas.

Anal. (absorption) 91.7 cc. of gas: 5.2 cc. lost by absorption in bromine water: 5.6% of unsaturated hydrocarbons. Gas density: bar. pressure, 743.4 mm.; gage readings with air, 715.0 mm., 88.5 mm.; pressure, 626.5 mm.; total pressure, 116.9 mm.; gage readings with gas, 735.0 mm., 66.0 mm.; pressure, 669.0 mm.; total pressure, 74.4 mm.; sp. gr., 1.57. This specific gravity indicated a mixture of about 47% of ethane and 53% of butane.

Lithium-n-Butyl and Triethylarsine Dibromide.—A solution of 0.047 mole of lithium n-butyl in petroleum ether was added to 7.8 g. (0.024 mole) of triethylarsine dibromide. A vigorous reaction occurred and gas was evolved. This gas was collected and by a gas density determination the specific gravity was found to be 1.801. Since petroleum ether vapors were present, this value was not very significant. However, not much ethane could have been present. The odor of an arsine was apparent when the flask was opened but not enough arsinic acid was isolated for positive identification.

Lithium Ethyl and Triethylarsine Dibromide.—A solution of 0.06 mole of lithium ethyl in petroleum ether was added to 9.5 g. of triethylarsine dibromide. No attempt was made to collect the gas. From the petroleum ether solution diethylarsinic acid, m. p. 136–137°, was isolated in the usual way.

Sodium Triphenylmethyl and Tetramethylarsonium Iodide.—A solution of 0.012 mole of sodium triphenylmethyl in dry ether was added with shaking to 5 g. of tetramethylarsonium iodide. The color of the solution faded and a solid of dull brick-red color remained in the flask. This solid was washed with anhydrous ether a few times. The red solid was not affected by dry carbon dioxide. When an attempt was made to recrystallize the solid from pyridine it appeared to decompose. The pyridine solution turned pale green. Triphenylmethane was isolated from the pyridine solution. If a compound related to the penta-alkyl ammonium of Schlenk and Holtz[4] had formed, it should have reacted with dry carbon dioxide to give tetramethylarsonium triphenylacetate.

Effect of Heat on Solutions of Lithium Alkyls in High-Boiling Paraffin Oil.—A solution of lithium ethyl in high-boiling paraffin oil did not give off gas when heated to 100°. Above this temperature gas was evolved. When such a solution was heated to 250° the gas obtained was about 75% unsaturated hydrocarbons. Gas density measurements indicated about 3% of hydrogen and 22% of ethane as the remaining constituents of the gas.

Lithium n-butyl in high-boiling paraffin oil solution did not liberate much gas until heated to about 173°. Gas evolution then became very marked. The gas collected was 94% unsaturated hydrocarbons. Gas density measurements indicated that the original gas was about 94% butylene, 3% butane and 3% hydrogen.

Effect of Lithium Alkyl Solutions on Ethylene.—A solution of lithium n-butyl was prepared from 1 g. of lithium and 10 g. of di-*n*-butyl mercury in 100 cc. of high-boiling paraffin oil. Ethylene from a tank of the commercial product was admitted under pressure. The pressure soon dropped and then more ethylene was introduced. In about two weeks 620 cc. of ethylene had been introduced. When an attempt was made to recover the ethylene, only 120 cc. of gas could be recovered on heating the solution to 100°. This gas was not pure ethylene but contained some inert material, probably air, which must have been present in the commercial gas. The ethylene did not remain in the oil as such because a similar experiment without the lithium alkyl showed that all of the gas could be recovered.

A similar experiment was tried with lithium ethyl instead of lithium n-butyl. The results were essentially the same. Only a small amount of gaseous hydrocarbons could be recovered by heating the paraffin oil solution.

Another experiment was made using *a* solution of 0.031 mole of lithium n-butyl in 50 *cc.* of petroleum ether (40–45°). Ethylene was absorbed readily and within two weeks a white solid began to appear on the surface of the solution. This solid has not been studied further.

The authors desire to express their thanks to Dr. G. F. Smith for help in some of the analytical problems met in this work.

Summary

1. Lithium alkyls have been found to react readily with tetra-alkyl arsonium bromides to give trialkylarsines and hydrocarbons which come from disproportionation of the alkyl groups. No evidence of the formation of a stable penta-alkyl arsenic compound was obtained.

2. Lithium alkyls have been found to cause polymerization of ethylene to give non-gaseous products.

3. It has been observed that trialkylarsines are oxidized by air to give dialkylarsinic acids.

4. Improved methods for the preparation of some trialkylarsines and tetra-alkyl arsonium salts have been reported.

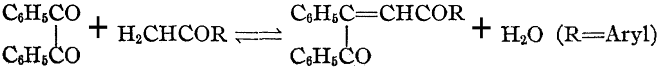
DIACYLSTYRENES. II

BY CHARLES F. H. ALLEN AND J. ROCKWELL HUBBARD

RECEIVED AUGUST 12, 1929 PUBLISHED JANUARY 8, 1930

In an earlier paper[1] it was shown that benzil easily condensed with acetophenones that did not have a substituent in the position ortho to the carbonyl group.

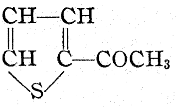


$$\begin{array}{l}C_6H_5CO\\ \quad|\\ C_6H_5CO\end{array} + H_2CHCOR \rightleftharpoons \begin{array}{l}C_6H_5C{=}CHCOR\\ \quad|\\ C_6H_5CO\end{array} + H_2O \quad (R{=}\text{Aryl})$$

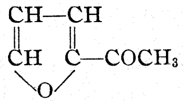
We have extended this investigation to include methyl ketones having different types of rings and found that diacylstyrenes are always formed under the conditions previously described. Methyl a-thienyl (I) and methyl a-furyl (II) ketones were selected as examples of heterocyclic compounds.

---

[1] Allen and Rosener, THIS JOURNAL, 49, 2110 (1927).



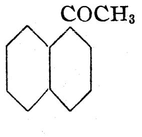
I



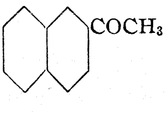
II

III

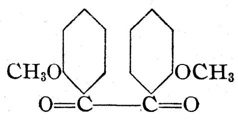
Since the acetophenones used in the earlier paper had only alkyl substituents, the p-phenyl compound (III) was taken, to show that an aryl group would not prevent the reaction.



IV



V



VI

We then examined the naphthyl methyl ketones for two reasons: (1) x-ray data indicate that one ring is bent over on the other, so that it might possibly exert a hindrance because of spatial relations; (2) in methyl a-naphthyl ketone (IV) there is an ortho substituent, that is, the second ring is fused on in an ortho position. It was found that while methyl P-naphthyl ketone (V) readily formed a diacylstyrene, the a-compound did not react. Thus rings in the ortho position offer the same kind of hindrance as other groups in the ortho position; elsewhere they have no effect.

The following acetophenones, which have become available since our earlier paper, were also investigated—p-ethyl, 3,4-dichloro, 3-nitro[2] and 2,4-dihydroxy. The first two formed diacylstyrenes, as expected. The last one, having an ortho substituent, did not react. With the third compound, the nitro group was attacked by alkali, and a mixture of high melting substances formed which it was not thought worth while to identify. Japp and Maitland[3] have previously examined pinacolone and found that it formed trimethacetylstyrene.

Finally, to see whether the effect of o-substituents was confined to the methyl ketone, *o,o'*-dimethoxybenzil (VI) in place of benzil was employed with acetophenone. As it was recovered quantitatively, unchanged, it may be concluded that groups in the ortho position of either component prevent the reaction from taking place. Since the effect is independent of the nature of the group, it is evidently due to spacial relations of some sort.

Experimental

Preparation **of β-Naphthyl** Methyl Ketone.—To the Grignard reagent prepared from 7 g. of magnesium and 40 g. of methyl iodide in 150 cc. of dry ether was added with stirring a warm solution of 14.5 g. of β-naphthonitrile in 50 cc. of the same solvent;

---

[2] For this substance we are indebted to Dr. B. B. Corson.

[3] Japp and Maitland, J. *Chem. Soc.*, 85, 1502 (1904).

the small amount of solid nitrile adhering to the dropping funnel was rinsed in with **30** cc. more ether. There was very little apparent action. After standing overnight, most of the ether was distilled by gradually immersing the flask in boiling water. The viscous residue was decomposed by ice and sulfuric acid in the usual way, the oily layer taken up in ether, dried and fractionally vacuum distilled; **6.5 g.** of a yellow oil that readily crystallized was separated. There was considerable gummy residue. We were unable to isolate any of this ketone by the Friedel–Crafts reaction from naphthalene and either acetyl chloride or acetic anhydride. The other ketones were prepared by methods already in the literature.

The condensation with benzil was carried out exactly the same as in the earlier paper, except that ethyl acetate was used as a solvent for recrystallization. The results are summarized in the table.

DERIVATIVES OF α,β-DIBENZOYLSTYRENE

No.	Ketone used	M. p., °C.	Formula	Analyses Calcd., % C	 H	 Found, % C	 H
I	Methyl a-thienyl[m]	152	$C_{20}H_{14}O_2S$	75.5	4.4	75.3	4.5
II	Methyl α-furyl[b]	168	$C_{20}H_{14}O_3$	79.5	4.6	79.7	4.6
V	Methyl β-naphthyl	152	$C_{26}H_{18}O_2$	86.2	4.9	86.2	5.0
III	p-Phenylacetophenone[c]	132	$C_{28}H_{20}O_2$	86.6	5.2	85.8	5.2
VII	p-Ethylacetophenone[e]	117	$C_{24}H_{20}O_2$	84.7	5.9	84.4	6.0
VIII	3,4-Dichloroacetophenone[d,e]	199	$C_{22}H_{14}O_2Cl_2$	69.2	3.7	69.1	3.9

[a] Prepared by excellent directions of Stadnikov and Goldfarb, *Ber.*, **61**, 2341 (1928). [b] Sandelin, *ibid.*, **33**, 493 (1900). [c] Adams and Noller's method, THIS JOURNAL, **46**, 1889 (1924). [d] Roberts and Turner, *J. Chem. Soc.*, **130**, 1855 (1927). [e] Recrystallized from anisole, insoluble in ethyl acetate and carbon tetrachloride.

o,o'-**Dimethoxybenzil**[2] (VI) **and** Acetophenone.—A methyl alcoholic solution of these two substances was treated in the same manner; as there was no apparent reaction after five minutes the whole was refluxed for eight hours. The dimethoxybenzil was recovered quantitatively.

We were unable to isolate any crystalline material from the reddish gums produced when either methyl @-pyridyketone or p-amino-acetophenone was used.

This work has been assisted by a grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences.

Summary

1. The investigation of the condensation of benzil with derivatives of acetophenone has been extended to include those in which the substituent group is a ring. It has been found that the reaction takes place readily unless the position ortho to the carbonyl group is a part of the ring.
2. Methyl ketones having heterocyclic ring systems can be used equally well in place of acetophenone.
3. The same kind of hindrance is observed whether the o-substituent is in the benzil or the ketone.

CATALYSIS IN ORGANIC CHEMISTRY. I. REACTIONS OF ETHERS WITH ACID CHLORIDES, ACIDS AND ANHYDRIDES[1]

BY H. W. UNDERWOOD, JR., AND R. L. WAKEMAN

RECEIVED AUGUST 15, 1929 PUBLISHED JANUARY 8, 1930

Ethers are usually described as inert compounds; the carbon-oxygen bond is firmly held, and drastic treatments, such as heating with hydriodic acid or anhydrous aluminum chloride, are generally employed to split ethers. Descudé[2] and Wedekind and Haeussermann[2] noted that esters and alkyl chlorides are formed by the reactions of ethyl and methyl *iso*-amyl ethers with acetyl chloride and with benzoyl chloride in the presence of anhydrous zinc or ferric chloride. More information about transformations of this type would be desirable on account of the frequent use of ethers as (presumably inert) solvents or diluents, and also as a contribution to our knowledge of factors which increase the reactivity of ethers. This paper deals with an investigation of the reactions of ethyl ether with a series of representative acid chlorides; experiments with *iso*propyl, *n*-butyl and iso-amyl ethers are also described. It was found that diphenyl ether and anisole behave like aromatic hydrocarbons in their reactions with acetyl and benzoyl chlorides, and yield ketones through the introduction of an acetyl or benzoyl group into the ring.

We have shown that a number of acids and anhydrides can be converted into esters by treatment with ethyl ether in the presence of hydrogen bromide.[3]

Discussion of Experiments and Interpretation of Results

All of the temperatures given are uncorrected.

Purification of Ethers.—The ethyl ether employed in our experiments was purified by Norris' procedure.[4] Pure isopropyl, n-butyl and *iso*-amyl ethers were dried for several days with anhydrous sodium sulfate and distilled before use.

Reactions of Ethers with Acid Chlorides

Preliminary Experiments and General Procedure.—In preliminary experiments the action of anhydrous aluminum, ferric and zinc chlorides in promoting the reactions

---

[1] Some of the experimental results described in this paper are taken from a thesis submitted to the Faculty of the Massachusetts Institute of Technology by R. L. Wakeman in partial fulfilment of the requirements for the degree of Master of Science.

[2] Descudé, *Compt. rend.*, 132, 1129 (1901); *Ann. chim. phys.*, [7] *29*, 497 (1903); Wedekind and Haeussermann, *Ber.*, 34, 2081 (1901).

[3] Fenton and Gostling [*J. Chem. Soc.*, *73*, 554 (1898)] stated that ethyl esters of dihydroxymaleic, oxalic, acetic, benzoic, boric and stearic acids are obtained by allowing the acids to stand for several days with anhydrous ethyl ether containing dry hydrogen bromide.

[4] Norris, "Experimental Organic Chemistry," McGraw-Hill Book Co., New York City, 1924, p. 73.

of ethyl ether with acetyl and benzoyl chlorides was investigated. Esters were obtained in each trial; since anhydrous zinc chloride gave the best yields and was most easily handled it was employed in all subsequent work.

The ether was added to a mixture of the acid chloride and finely powdered, anhydrous zinc chloride in a small, dry flask. A reflux water condenser, with a calcium chloride tube in the top, was attached immediately, and the mixture was heated at its boiling point until the reaction appeared to be complete; usually two to three hours of heating was required. The reaction mixture was then cooled in ice and shaken several times with two or three volumes of cold water until practically free from zinc chloride; in some cases a little pure ethyl ether was added to dilute the mixture. The ether layer was next dried with anhydrous sodium sulfate. After most of the ether had been removed by distillation, the residue was fractionated in case the expected reaction product was a liquid, or allowed to stand until crystallization occurred if the ester was a solid. Liquid esters were collected over a range of 5 to 6°; if necessary, solid esters were washed with cold, dilute sodium carbonate solution and crystallized from suitable solvents. A 10 to 15% excess of ether and approximately 0.25 mole of zinc chloride per mole of acid chloride were employed.

Ethyl Ether.—The acid chlorides investigated and the percentage yields of ethyl esters obtained are as follows: acetyl, 40; chloro-acetyl, 35; propionyl, 15; *n*-butyryl, 21; *iso*valeryl, 20; benzoyl, 60; phenylacetyl, 79; oxalyl, 4; diphenic acid chloride, 77. The amounts of the acid chlorides used were 31.4, 15, 20, 20, 16, 56, 9.7, 12.2 and 2.2 g., respectively.

No esters were obtained from benzenesulfonyl chloride (20 g.) or *p*-toluenesulfonyl chloride (15 g.). In order to determine whether compounds containing labile chlorine atoms would behave like acid chlorides, 50 g. of benzyl chloride and 15 g. each of *o*-nitrochlorobenzene, 2,4-dinitrochlorobenzene and picryl chloride were heated with ethyl ether in the presence of zinc chloride. Each halogen compound was recovered unchanged; benzyl chloride gave some high-boiling tar.

A mixture of 25.4 g. of *o*-phthalyl chloride, 10.3 g. of ethyl ether and 4.2 g. of anhydrous zinc chloride was refluxed for about two hours; white crystals were formed suddenly. After the contents of the flask had been cooled to room temperature, the solid was collected on a filter, washed with water and dried. The crystals, which weighed 15.5 g., were identified as phthalic anhydride. The liquid portion of the reaction mixture was washed twice with an equal volume of water, dried with anhydrous sodium sulfate and fractionated. Two grams of diethyl phthalate was isolated. The results of this experiment indicate that diethyl phthalate may be transformed into phthalic anhydride by zinc chloride; small scale experiments with some known diethyl phthalate proved that this splitting takes place.

Ethyl Ether and 3,5-Dinitrobenzoyl Chloride.—We prepared ethyl 3,5-dinitrobenzoate by treatment of a small quantity of the dinitrobenzoyl chloride with an excess of pure, dry ethyl ether in the presence of anhydrous zinc chloride. An investigation is now being carried out to determine whether this type of reaction can be employed in the identification of aliphatic (and possibly aromatic) ethers; the results will be discussed in a later paper. Mulliken[5] has described the use of 3,5-dinitrobenzoyl chloride for the identification of alcohols.

Higher Aliphatic Ethers.—The reactions of acetyl chloride with isopropyl (5 g.), *n*-butyl (20 g.) and iso-amyl (15 g.) ethers gave 30, 68 and 48% yields of the corresponding acetates. Benzoyl chloride was converted into isopropyl, *n*-butyl and *iso*-amyl benzoates; the yields were 10, 45 and 40%. Twenty-eight and 57% yields of

---

[5] Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York City, 1904, Vol. I, pp. 168–172.

n-butyl propionate and n-butyl n-butyrate were obtained by heating propionyl chloride (16 g.) and n-butyryl chloride (23 g.) with n-butyl ether.

Isolation of Alkyl Chlorides.--Small amounts of ethyl, *iso*propyl, n-butyl and *iso*-amyl chlorides were obtained from some of our reaction mixtures. More information about these alkyl chlorides is given in a later paper.[6]

Aromatic Ethers.--The behavior of the following pairs of compounds in the presence of anhydrous zinc chloride was studied: diphenyl ether and acetyl chloride, anisole and acetyl chloride, diphenyl ether and benzoyl chloride, anisole and benzoyl chloride. Each mixture was allowed to stand for half an hour at room temperature, and then heated under reflux in a water-bath for two hours. Hydrogen chloride was evolved and a dark viscous mass was formed in each case. The mixtures were cooled and diluted with several volumes of cold water and some ethyl ether. After being washed with water until practically free from zinc chloride, the ether solutions of the reaction products were dried with anhydrous sodium sulfate; then the solvent was removed by distillation. The products thus isolated were viscous oils which partly solidified upon long standing; in some cases it was necessary to fractionate the oils. The solids were pressed on a porous tile and crystallized from alcohol and water or from pure ethyl ether. The melting points as well as other physical properties and resistance to hydrolysis of our products indicate that they are 4-phenoxyacetophenone, *p*-acetylanisole, 4-phenoxybenzophenone and p-benzoylanisole; Kipper, and Gattermann, Ehrhardt and Maisch[7] prepared these compounds from diphenyl ether and anisole by treatment of the ethers with acetyl and benzoyl chlorides in the presence of anhydrous aluminum chloride. From two 17-g. lots of diphenyl ether we obtained 9 g. of 4-phenoxybenzophenone and 7 g. of 4-phenoxyacetophenone; two 10.8-g. lots of anisole gave 6 g. of p-benzoylanisole and 0.5 g. of *p*-acetylanisole. There was no evidence of the formation of esters in the reactions. One-gram samples of each (uncrystallized) reaction product were heated under reflux for an hour with 10 cc. of 10% sodium hydroxide solution; by extraction with pure ethyl ether practically all of the initial material was recovered in each case. Evidently the carbon-oxygen bonds in diphenyl ether and anisole are not readily broken by zinc chloride; the ketones which we obtained were previously prepared with better yields by the use of anhydrous aluminum chloride in place of zinc chloride. Consequently, no more aromatic ethers were investigated.

Reactions of Ethyl Ether with Acids and with Anhydrides

Preliminary Experiments and General Procedure.—The acids and most of the anhydrides employed in our experiments were pure Eastman products; succinic and diphenic anhydrides were synthesized. It was found that treatment of glacial acetic acid with a slight excess of pure, dry ethyl ether in the presence of anhydrous zinc chloride did not give a good yield of ethyl acetate.

Hydrogen bromide was prepared by dropping bromine on moist red phosphorus; moisture and bromine were removed by passing the gas through a drying train containing red phosphorus, calcium chloride and phosphorus pentoxide. The dry hydrogen bromide was passed into pure, anhydrous ethyl ether in a flask attached to a reflux water condenser, with a calcium chloride tube in the top, for about seven hours; the mixture was cooled from time to time but not continuously. This procedure did not completely saturate the ether, but it gave a fairly concentrated solution. It was found that treatment with hydrogen bromide for a longer time and continuous cooling were necessary for the complete saturation of the ether.

---

[6] Underwood and Toone, THIS JOURNAL, **52,** 391 (1930).

[7] Kipper, *Ber.,* **38,** 2490 (1905); Gattermann, *ibid.,* *22,* 1129 (1889); Gattermann, Ehrhardt and Maisch, *ibid.,* **23,** 1199 (1890).

About 75 cc. of the ether–hydrogen bromide mixture was added to each of the acids and anhydrides in an Erlenmeyer flask. The latter was closed by a tight-fitting stopper held in place by wire and covered with collodion. The reaction mixtures were allowed to stand for ten to twelve days. Each flask was then attached to a reflux water condenser provided with a calcium chloride tube, and the contents were boiled for three hours. After being cooled to room temperature, each reaction mixture was shaken two or three times with an equal volume of cold 10% sodium hydroxide solution until very slightly alkaline; then it was washed with an equal volume of cold water and dried with anhydrous sodium sulfate. Finally the excess ether was removed by distillation and the residue was fractionated if the expected ester was a liquid, or allowed to stand until crystallization occurred if the ester was a solid; if necessary, solid esters were washed with cold, dilute sodium carbonate solution and crystallized from suitable solvents.

Yields of Esters.—The acids investigated and the percentage yields of ethyl esters obtained are as follows: acetic, 8; chloro-acetic, 30; propionic, 34; n-butyric, 41; isovaleric, 42; oxalic, 8; malonic, 6; succinic, 16; benzoic, 28; phenylacetic, 56; hydrocinnamic, 80; p-toluic, 23; mandelic, 24; anisic, 5; p-chlorobenzoic, 10; o-nitrobenzoic, 5; m-nitrobenzoic, 42; p-nitrobenzoic, 10; 3,5-dinitrobenzoic, 27; *p*-aminobenzoic, 1; o-phthalic, 9; diphenic, 16. Three grams of hydrocinnamic acid, 4 g. of *p*-toluic acid and 10 g. each of the other acids were used. No esters were obtained from stearic, picric, *p*-toluenesulfonic and 2,4,6-trinitrobenzoic acids; Victor Meyer's esterification rule would lead one to expect that the trinitrobenzoic acid would not esterify.

The anhydrides investigated and the percentage yields of ethyl esters obtained are as follows: acetic, 13; propionic, 23; n-butyric, 38; isovaleric, 41; succinic, 13; benzoic, 49; o-phthalic, 13; diphenic, 25. Ten grams of each anhydride was used.

An investigation of the mechanism of the reactions of ethyl ether with acids and anhydrides in the presence of dry hydrogen bromide[6] has shown that the amount of the latter present influences the yields of esters. If two moles of hydrogen bromide per mole of ethyl ether is used, all of the ether is converted into ethyl bromide. In the experiments described above the same ether–hydrogen bromide mixture was used for each compound in a series and the results are comparable. Check runs with acetyl chloride, benzoyl chloride and acetic anhydride and different lots of ether–hydrogen bromide mixtures gave yields of esters which were nearly the same as those previously obtained.

Summary

In the presence of anhydrous zinc chloride, pure ethyl ether reacts with the chlorides of acetic, chloro-acetic, propionic, n-butyric, *iso*valeric, benzoic, phenylacetic, diphenic, o-phthalic, oxalic and 3,5-dinitrobenzoic acids to form ethyl esters. o-Phthalyl chloride gives phthalic anhydride as well as diethyl phthalate. Under the conditions tried, benzenesulfonyl and p-toluenesulfonyl chlorides do not form esters, and the chlorine atoms in benzyl chloride, o-nitrochlorobenzene, 2,4-dinitrochlorobenzene and picryl chloride are not replaced by ethoxy groups. Isopropyl, *n*-butyl and *iso*-amyl acetates and benzoates are obtained by the treatment of acetyl and benzoyl chlorides with isopropyl, n-butyl and *iso*-amyl ethers. Diphenyl ether and anisole behave like aromatic hydrocarbons when heated with acetyl and benzoyl chlorides in the presence of anhydrous zinc

chloride; ketones are formed by the introduction of an acetyl or benzoyl group into the aromatic nucleus.

Acetic, chloro-acetic, propionic, n-butyric, isovaleric, oxalic, malonic, succinic, benzoic, phenylacetic, hydrocinnamic, *p*-toluic, mandelic, anisic, p-chlorobenzoic, *o*-, *m*- and p-nitrobenzoic, 3,5-dinitrobenzoic, *p*-aminobenzoic, o-phthalic and diphenic acids and the anhydrides of acetic, propionic, n-butyric, isovaleric, succinic, benzoic, o-phthalic and diphenic acids are converted into ethyl esters by treatment with anhydrous ethyl ether containing dry hydrogen bromide. Stearic, picric, *p*-toluenesulfonic and 2,4,-6-trinitrobenzoic acids do not react with ethyl ether in the presence of hydrogen bromide.

CATALYSIS IN ORGANIC CHEMISTRY. II. MECHANISM OF THE REACTIONS OF ETHERS WITH ACID CHLORIDES, ACIDS AND ANHYDRIDES

BY H. W. UNDERWOOD, JR., AND G. C. TOONE

RECEIVED AUGUST 15, 1929 PUBLISHED JANUARY 8, 1930

In a previous paper[1] it was pointed out that a number of acid chlorides, acids and anhydrides are converted into esters by treatment with aliphatic ethers in the presence of anhydrous zinc chloride or hydrogen bromide. Zinc chloride might increase the reactivity of aliphatic ethers by loosening the alkyl groups so that a metathesis of the type $RCOCl + R'OR' = RCOOR' + R'Cl$ would occur. The possibility that aliphatic ethers may be split into two or more compounds capable of independent existence also deserves consideration. Experiments described in this paper show that ethyl, *iso*propyl, n-butyl and *iso*-amyl ethers yield small amounts of the corresponding alcohols and unsaturated hydrocarbons when heated with anhydrous zinc chloride. When an alcohol thus formed is esterified by an acid chloride, splitting of the ether continues, and the hydrogen chloride produced may convert some of the alcohol into an alkyl chloride. Equations for the transformations of acetyl chloride and ethyl ether might be written as follows

$$CH_3CH_2OCH_2CH_3 = CH_3CH_2OH + CH_2{=}CH_2$$
$$CH_3CH_2OH + CH_3COCl = CH_3COOCH_2CH_3 + HCl$$
$$CH_3CH_2OH + HCl = CH_3CH_2Cl + H_2O$$

The reaction of ethyl ether with acetyl chloride takes place in the presence of a very small amount of anhydrous zinc chloride, and the latter can be used several times; apparently zinc chloride acts as a true catalyst.

---

[1] Underwood and Wakeman, THIS JOURNAL, 52, 387 (1930).

We have also shown that ethyl, isopropyl, n-butyl and iso-amyl ethers are converted into alkyl bromides and alcohols when treated with dry hydrogen bromide.

Discussion of Experiments and Interpretation of Results

All the temperatures given are uncorrected.

Purification of Ethers.—Ethyl ether was purified by the method cited in a previous paper.' An explosion occurred during the distillation of isopropyl ether which had been purchased as pure; tests showed that this ether contained peroxides. The procedure described below was employed for the purification of isopropyl, n-butyl and iso-amyl ethers. In order to remove peroxides each compound was washed with one-fifth its volume of 10% potassium iodide solution as often as necessary (one to ten times); the iodine produced in this treatment was removed by shaking the ether with one-fifth its volume of 10% sodium thiosulfate solution. Next the compound was washed with one-fifth its volume of water, then cooled in ice, shaken with one-fourth its volume of a mixture of sulfuric acid and water (equal volumes of each) and finally washed with water. After being dried with anhydrous sodium sulfate the ether was distilled. The boiling points of the purified ethers were as follows: ethyl, 34–34.5°; isopropyl, 68–68.5°; n-butyl, 139.5–140.5°; iso-amyl, 169–170°.

Ethers **and** Anhydrous Zinc Chloride.—Ethyl, isopropyl, n-butyl and iso-amyl ethers were refluxed for two hours with anhydrous zinc chloride; one half mole of the latter per mole of ether was used. In each experiment the top of the reflux water condenser was connected with two flasks; one of these contained 10 g. of bromine to absorb unsaturated hydrocarbons, and the other flask was a trap. The quantities of ethers used are as follows: ethyl, 44.4 g.; isopropyl, 12.3 g.; n-butyl, 26 g.; *iso*-amyl, 31.6 g. n-Butyl ether yielded 0.5 cc. of a liquid boiling at 70–130°; a drop of this distillate gave the odor of n-butyl acetate when mixed with a drop of acetyl chloride. The remainder of the liquid boiling at 70–130° was added to 0.1 g. of 3,5-dinitrobenzoyl chloride; the mixture was allowed to stand for five minutes, placed in hot water for two minutes and filtered. The solid left on the filter was added to 5 cc. of 3 N sodium carbonate solution and well stirred in order to remove excess dinitrobenzoyl chloride. The insoluble residue was filtered and washed with 5 cc. of 3 N sodium carbonate solution and 5 cc. of water. After three crystallizations from alcohol the solid melted at 63–64"; this is the melting point of n-butyl 3,5-dinitrobenzoate.[2] A parallel experiment with some n-butyl ether which had not been treated with zinc chloride gave no ester. Iso-amyl ether yielded 0.6 cc. of a liquid boiling at 70–165°. By use of the procedure described above, 0.1 *g.* of iso-amyl 3,5-dinitrobenzoate (m. p. 60–61") was isolated. **A** parallel experiment with iso-amyl ether which had not been heated with zinc chloride gave no ester.

The bromine used to absorb unsaturated hydrocarbons which might be formed in the splitting of the ethers was treated with 10% sodium thiosulfate solution to remove unchanged bromine and the resulting mixture was extracted with 40 cc. of pure ethyl ether. The ether layer was dried with anhydrous sodium sulfate and distilled. No dibromides were isolated in any of our preliminary experiments; probably the amounts of unsaturated hydrocarbons formed were too small to be detected by this method. However, it was found that the ethers apparently contained traces of unsaturated compounds after heating with zinc chloride, since small portions of the ethers decolorized very dilute potassium permanganate solution.

---

[2] Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York City, 1904, Vol. I, p. 168.

In preliminary experiments with ethyl and isopropyl ethers we were unable to prepare dinitrobenzoates from the distillates. However, four drops of the distillate from isopropyl ether gave the iodoform reaction. Three and one-half moles of each ether was refluxed for three hours with zinc chloride and distilled. No portions of the distillates boiled as high as the corresponding alcohols, but dinitrobenzoates were obtained from the first 8 cc. of each distillate; these fractions also gave the iodoform test, and enough of the latter for a melting point was secured. Parallel experiments with ethers which had not been heated with zinc chloride gave negative results.

It was necessary to use 500 g. of the ethers in order to isolate the dibromides of the unsaturated hydrocarbons formed in the splittings by zinc chloride; very small amounts of these dibromides were obtained.

Anisole, phenetole and diphenyl ether (0.1 mole of each) were heated under reflux for two hours with anhydrous zinc chloride (0.05 mole). Upon distillation of each mixture the ether was recovered practically quantitatively; all of the liquid boiled within one degree. The distillates gave no color test for phenol when treated with ferric chloride solution; a violet color was readily obtained by adding one drop of dilute phenol solution and one of ferric chloride solution to a portion of each distillate. Evidently the carbon–oxygen bonds in these aromatic ethers are not broken by anhydrous zinc chloride under the conditions tried.

Ethers and Acid Chlorides.—The experiments described below were carried out to secure information about the products other than esters which are formed in the reactions of aliphatic ethers with acid chlorides. In each run 0.4 mole of zinc chloride per mole of acid chloride was used. Fifty-two and three-tenths grams of acetyl chloride and 54.2 g. of ethyl ether gave 37.8 and 30.2% yields of ethyl acetate and ethyl chloride and a trace of ethylene dibromide; 20.4 g. of isopropyl ether and 19.6 g. of acetyl chloride gave 66.5 and 30.6% yields of isopropyl acetate and isopropyl chloride and 1.8 g. of propylene dibromide. By distillation of the reaction mixture from 50 g. of n-butyl ether and 27.5 g. of acetyl chloride we obtained 65.7 and 29.9% yields of n-butyl acetate and n-butyl chloride and 10.6% of butylene dibromide. One-tenth mole of acetyl chloride and 0.11 mole of iso-amyl ether gave 12 and 6% yields of *iso*-amyl acetate and iso-amyl chloride, and 0.1 g. of isopropylethylene dibromide.

Catalytic Action of Anhydrous Zinc Chloride.—A mixture of 31.4 g. of acetyl chloride and 32.6 g. of pure anhydrous ethyl ether was heated under reflux for three hours with 5.44 g. of anhydrous zinc chloride, and then distilled from the latter through a long fractionating column. The yield of ethyl acetate was 77%. (This result shows that some ethyl acetate is lost in the isolation procedure, involving extractions with ether and washing the ether solution, described in a preceding paper[1] and followed in previous experiments.) The zinc chloride was used for three more runs; the yields of ethyl acetate were 78, 77 and 79%. Evidently zinc chloride acts as a true catalyst in this reaction.

Ethers and Hydrogen Bromide.—Hydrogen bromide was prepared and dried by the procedure described in a previous paper.[1] In experiments with n-butyl ether (22.1 g.), *n*-butyl ether (22.1 g.) + glacial acetic acid (10.2 g.), and n-butyl ether (22.1 g.) + acetic anhydride (17.3 g.) hydrogen bromide was passed into the liquids for six hours, with cooling during the last two hours; 0.36 mole of hydrogen bromide was absorbed in each case. Dry hydrogen bromide was passed into 20.4 g. of glacial acetic acid until 0.143 mole had been absorbed; this required two hours. The flasks containing these mixtures were closed with tight-fitting stoppers held in place by wire and covered with collodion. After standing for ten days at room temperature, the liquids were refluxed for three and one-half hours in a water-bath, and the layers which had formed were separated. In each case the non-aqueous layer was washed with dilute sodium carbonate solution and with water, dried with anhydrous sodium sulfate and distilled through a long fractionating column. The n-butyl ether yielded 29.2 g. of n-butyl bromide. The n-butyl etheracetic acid mixture gave 20.4 g. of n-butyl bromide, 1 g. of n-butyl acetate and 9.5 g. of acetic acid. From the acetic anhydride–ether mixture we obtained 16.3 g. of n-butyl bromide, 2 g. of n-butyl acetate and 8 g. of impure acetic acid. After standing for ten days, mixtures of 20.4 g. of acetic acid + 0.143 mole of hydrogen bromide, and 17.3 g. of acetic anhydride + 0.2 mole of hydrogen bromide were distilled through a long fractionating column; the former gave 17 g. of acetic acid and the latter yielded 2 g. of acetyl bromide and 9 g. of acetic acid. These experiments show that acetic anhydride is converted into acetyl bromide and acetic acid by reaction with hydrogen bromide.

In order to determine the behavior of n-butyl ether when treated with less hydrogen bromide than was used in previous experiments, hydrogen bromide was passed into 19.7 g. of the ether (0.15 mole) until 0.25 mole had been absorbed. After the mixture had stood for sixteen hours, it was heated under reflux for three hours. The two layers which formed were separated, washed with dilute sodium carbonate solution, dried with anhydrous sodium sulfate and distilled through a long fractionating column. Nineteen grams of n-butyl bromide and 1.5 g. of n-butyl alcohol were obtained; the latter was identified by preparation of the 3,5-dinitrobenzoate. Similar experiments with ethyl, isopropyl and iso-amyl ethers gave the alkyl bromide and a small amount of the corresponding alcohol in each case. By use of an excess of hydrogen bromide ethyl ether was entirely converted into ethyl bromide.

Summary

When heated with anhydrous zinc chloride ethyl, isopropyl, n-butyl and iso-amyl ethers yield small amounts of the corresponding alcohols and unsaturated hydrocarbons. When an alcohol thus formed is esterified by an acid chloride, splitting of the ether continues, and the hydrogen chloride produced in the esterification converts some of the alcohol into an alkyl chloride. Under the conditions tried the carbon-oxygen bonds in anisole, phenetole and diphenyl ether are not broken by zinc chloride. The reaction of ethyl ether with acetyl chloride takes place in the presence of a very small amount of anhydrous zinc chloride, and the latter can be used several times; apparently zinc chloride acts as a true catalyst.

Ethyl, isopropyl, n-butyl and iso-amyl ethers are converted into alcohols and alkyl bromides by treatment with dry hydrogen bromide. The reaction of acetic anhydride with anhydrous hydrogen bromide gives acetyl bromide and acetic acid.

CATALYSIS IN ORGANIC CHEMISTRY. III. DECOMPOSITIONS OF ESTERS BY ANHYDROUS ZINC CHLORIDE

BY H. W. UNDERWOOD, JR., AND O. L. BARIL

RECEIVED AUGUST 15, 1929 PUBLISHED JANUARY 8, 1930

During the course of investigations of the reactions of ethers with acid chlorides[1] it was noted that aliphatic ethers yield alcohols and unsaturated hydrocarbons when heated with anhydrous zinc chloride and that diethyl phthalate is converted into phthalic anhydride. These transformations involve the splitting of the bond between the oxygen atom and alkyl groups in the ethers and in the ester. In this paper we present evidence which shows that a number of esters undergo decompositions of this or similar types in the presence of anhydrous zinc chloride.

Discussion of Experiments and Interpretation of Results

All the temperatures given are uncorrected.

General Procedure.—Pure, freshly distilled esters were used in our experiments; 0.5 mole of anhydrous zinc chloride per mole of ester was employed. Unsaturated hydrocarbons formed by the decomposition of the esters were collected as dibromides by the procedure described in a previous paper.[1] Unless otherwise stated, each reaction mixture was distilled from the zinc chloride after refluxing; the distillate was then fractionated. In some experiments the residue in the reaction flask after distillation was dark colored and somewhat tarry; however, all the distillates were free from tar, and were easily separated into the components.

Ethyl Formate, Ethyl Acetate, Ethyl Propionate and Ethyl *n*-Butyrate.—No evidence of decomposition was found in experiments with these compounds. One-half mole of ethyl formate and acetate, one-third mole of the butyrate and one-fifth mole of ethyl propionate were used; in each case more than 95% of the ester was recovered; all the mixtures were heated under reflux for three hours before distillation.

Methyl and Ethyl Benzoates, Diethyl Phthalate.—From 30 *g*. of ethyl benzoate which had been refluxed with anhydrous zinc chloride for two hours we obtained 7.5 g. of benzoic acid,[2] 3 g. of benzene,[2] 2 g. of ethylene dibromide and carbon dioxide. Evidently zinc chloride converts some of the benzoic acid formed by the decomposition of the ester into benzene and carbon dioxide. We obtained benzene by heating some known benzoic acid with zinc chloride.

Thirty-four grams of methyl benzoate yielded 5 g of benzoic acid,[2] 4 g. of benzene[2] and 9 g. of the unchanged ester. No evidence of the formation of an unsaturated hydrocarbon was found. Three lots (34 g. each) of methyl benzoate were heated with zinc chloride for three hours, and the vapors from the top of the condenser were passed into 10 g. of bromine; treatment of the latter in the usual way[1] gave no ethylene dibromide. In these experiments a dark tarry residue was found in the reaction flask; possibly this was formed from the fragments of the methyl groups by the zinc chloride.

---

[1] Underwood and Wakeman, THIS JOURNAL, 52, 387 (1930); Underwood and Toone, *ibid.*, 52,391 (1930).

[2] The tests described by Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York City, 1904, Vol. I, were used for the identification of this compound.

A mixture of 44.4 g. of diethyl o-phthalate and 13.6 g. of anhydrous zinc chloride solidified after being heated for half an hour under reflux. Distillation of the product gave 22 g. of phthalic anhydride;[2] 2.5 g. of ethylene dibromide was also isolated.

Ethyl and Methyl Salicylates.—One-fourth mole of ethyl salicylate and one-fifth mole of the methyl ester were refluxed with anhydrous zinc chloride for one hour and one and one-half hours, respectively. The reaction mixtures were cooled and extracted several times with pure ethyl ether; the solutions thus formed were shaken with water to remove zinc chloride, dried with anhydrous sodium sulfate and fractionated. From the ethyl salicylate we obtained 4 g. of phenol,[2] 4 g. of *o*-ethylphenol,[3] 3.5 g. of the unchanged ester, I g. of ethylene dibromide and carbon dioxide. Apparently two types of decomposition occurred—one involved the removal of ethylene and the other the elimination of carbon dioxide from the ester group. Methyl salicylate gave 6 g. of *o*-cresol,[2] 7 g. of the unchanged ester and carbon dioxide.

Iso-amyl Acetate, Iso-amyl *n*-Butyrate, Iso-arnyl Benzoate.—A mixture containing 32.5 g. of iso-amyl acetate was refluxed for three hours and distilled. Twenty-seven grams of the ester was recovered and 1.4 g. of acetic acid[2] was isolated. The recovered iso-amyl acetate decolorized a small amount of dilute potassium permanganate solution and apparently contained a trace of an unsaturated compound. Decomposition of iso-amyl acetate takes place only to a slight extent.

After three hours' refluxing, 31.6 g. of iso-amyl n-butyrate yielded 6 g. of n-butyric acid,[2] 8 g. of unchanged ester, 7 g. of a liquid with the properties of the dimer of isopropylethylene, 0.2 g. of isopropylethylene dibromide and 4 g. of a high-boiling residue (possibly a high polymer of isopropylethylene). These products were difficult to fractionate. Evidently anhydrous zinc chloride splits iso-amyl n-butyrate into n-butyric acid and isopropylethylene, and polymerizes some of the latter.

From 38.4 g. of iso-amyl benzoate which had been heated under reflux with anhydrous zinc chloride for three hours, we obtained 11 g. of benzoic acid,[2] 0.9 g. of benzene,[2] 0.5 g. of a liquid with the properties of the dimer of isopropylethylene, 0.8 g. of isopropylethylene dibromide and carbon dioxide.

Ethyl Cinnamate.—Thirty-five and two-tenths grams of ethyl cinnamate was refluxed with anhydrous zinc chloride for three-fourths of an hour. The products are 3 g. of styrene, 6.5 g. of distyrene,[4] carbon dioxide and 5 g. of a dark brown material which had the properties of metastyrene. We also obtained 0.9 g. of ethylene dibromide. Apparently zinc chloride brings about the removal of ethylene and carbon dioxide from ethyl cinnamate, and polymerizes some of the styrene which is formed.

Diethyl Oxalate and Succinate.—When heated with anhydrous zinc chloride for an hour, one-fourth mole of diethyl oxalate was transformed into a white solid which weighed 33.5 g. This material was insoluble in hot and cold water and did not melt at 360". In order to determine whether the solid contained oxalic acid, a sample was heated for some time at 150°; no sublimation occurred. Ignition of the product caused the distillation of an organic liquid and gave a white residue which contained zinc. Another experiment with diethyl oxalate was carried out and the gases evolved during the heating were investigated. Carbon dioxide, ethyl chloride and a gas which behaved like a saturated aliphatic hydrocarbon were found; no ethylene was detected. The results of the experiments indicate that zinc chloride reacts with diethyl oxalate to give ethyl chloride and a zinc salt; some of the ester is split into carbon dioxide

---

[3] This compound was identified by the preparation of the tribromo derivative; the procedure described by Stoermer and Kahlert, Ber., 35, 1631 (1902), was used.

[4] The styrene and distyrene were identified by the preparation of the dibromides; the procedures described by Glaser, Ann., 154, 154 (1870), and by Fittig and Erdmann, *ibid.*, 216, 190 (1882), were used.

and a saturated aliphatic hydrocarbon, possibly butane. Diethyl succinate behaved like diethyl oxalate when heated with anhydrous zinc chloride.

Diethyl Malonate.—From one-fourth mole of diethyl malonate which had been refluxed with anhydrous zinc chloride for three hours we obtained 6 g. of ethyl acetate, 6 g. of unchanged ester and carbon dioxide; 0.2 g. of ethylene dibromide was secured. In a check run we isolated 8 cc. of a liquid which had the boiling point and other properties of n-pentane. Evidently two types of decomposition occurred—one involved the removal of both ethylene and carbon dioxide from one of the ester groups and the other involved the elimination of carbon dioxide from each ester group.

Summary

When ethyl formate, acetate, propionate and *n*-butyrate are heated with anhydrous zinc chloride each ester remains unchanged. Under similar conditions diethyl o-phthalate gives phthalic anhydride and ethylene, and ethyl benzoate yields benzoic acid, benzene and ethylene. Ethyl salicylate is transformed into phenol and o-ethylphenol through the loss of ethylene and carbon dioxide. From methyl benzoate we obtained benzoic acid and benzene, and from methyl salicylate we secured o-cresol and carbon dioxide. Anhydrous zinc chloride splits iso-amyl acetate, n-butyrate and benzoate into the corresponding acids and isopropylethylene, and polymerizes some of the latter. Ethyl cinnamate yields styrene, distyrene, metastyrene, carbon dioxide and ethylene. Diethyl malonate gives ethyl acetate, n-pentane, ethylene and carbon dioxide. Anhydrous zinc chloride reacts with diethyl oxalate forming ethyl chloride and a zinc salt; some of the ester is decomposed into carbon dioxide and a saturated aliphatic hydrocarbon. Diethyl succinate behaves like diethyl oxalate.

SKRAUP'S REACTION APPLIED TO THE PHENYLENEDIAMINES. PREPARATION OF THE PHENANTHROLINES AND RELATED DIPYRIDYLS

BY C. R. SMITH

RECEIVED AUGUST 16, 1929 PUBLISHED JANUARY 8, 1930

The Skraup reaction as applied to monoamines has proved to be a valuable synthetic method, but the double Skraup reaction, either in the original or in a modified form, applied to diamines, has generally given unsatisfactory results, especially with *p*- or m-phenylenediamine. It seems that either no attempts have been made to apply the reaction to o-phenylenediamine or, more probably, that no pure compounds were isolated from the resulting products and hence the results were not reported.

The writer has studied the production of phenanthrolines from the phenylenediamines and has found that results which compare favorably with the average monoamine as to yield and ease of purification can be obtained with the m- and *p*-diamine. o-Phenylenediamine, however, did not give o-phenanthroline but a compound, $C_{12}H_8N_2O$, crystallizing in deep, yellow colored needles. This compound was oxidized to a carboxylic acid which, on heating, loses carbon dioxide, forming a colorless base not identical with α,α-dipyridyl. o-Phenanthroline could not be separated from the Skraup reaction products, although it might have escaped detection, because of the large amount of amorphous products formed and the lack of information in regard to the properties of *o*-phenanthroline, which had not then been prepared.

According to Richter's "Organic Chemistry,"[1] o-phenanthroline is obtained from o-aminoquinoline, but no reference or description is given. a-Methyl-o-phenanthroline, however, has been prepared from 1-amidoquinaldine.

A. Kaufmann and Radoslav Radosevic[2] concluded that *p*-phenanthroline can be obtained only in small yield from *p*-phenylenediamine. They preferred to employ the corresponding aminoquinoline prepared from *p*-nitroaniline.

As the result of a study of the Skraup reaction, as applied to m- and *p*-phenylenediamines, with arsenic acid as the oxidizing agent, the conclusion has been reached that the important factors are water concentration and the method and time of heating. It is important to start the digestion with a high water concentration and to permit the gradual escape of water vapor as the reaction proceeds. There is a limited range of water concentration that is optimum; at a greater concentration the proper reaction will not take place at all and at a lower concentration the reaction is too vigorous for good results. This regulation of concentration is conveniently effected by using short air condensers; water condensers are used only toward the end of the reaction when the danger of tar formation is greatest.

A violent reaction is not permissible as with aniline and some other amines. The *m*- and *p*-diamines differ in behavior to such an extent that a method applicable to one is not suitable for the other. For example, in the case of *m*-phenylenediamine the reaction starts at a low water concentration and the temperature can be slowly elevated. Such treatment is not suitable for the $-diamine reaction. o-Phenylenediamine is a highly reactive substance, sensitive to oxidizing agents and subject to ring closure between the amino groups. Highly colored tarry products were always obtained from this compound, which yielded only a small amount of the yellow crystalline compound previously mentioned.

In following the directions of Skraup and Vortmann[3] in the preparation

---

[1] Vol. III, p. 207, English translation of 11th German edition.

[2] A. Kaufmann and Radoslav Radosevic, *Ber.*, 42, 2612 (1909).

[3] Skraup and Vortman. *Monatsh.*, 3, 571 (1882).

of *m*-phenanthroline and the corresponding dicarboxylic acid and dipyridyl the writer obtained results similar to those of Blau.[4] The methods given below improve the yields and ease of manipulation of this phenanthroline as well as the *p*-phenanthroline and the corresponding derivatives.

The only sources of the α,β- and β,β-dipyridyls have been the corresponding phenanthrolines. If the o-phenylenediamine could be made to produce o-phenanthroline in good yield, it might prove to be a convenient method of preparing α,α-dipyridyl. The negative results so far obtained from the o-diamine and the poor yield obtained from the *o*-aminoquinoline do not offer much promise. The writer has prepared α,α-dipyridyl conveniently from the sodium and pyridine reaction.[5] It can also be formed in less than 15% yield by heating copper picolinate[6] or by heating pyridine in sealed tubes under pressure with ferric chloride.[7]

It has usually been assumed that acrolein is produced in the Skraup reaction and that this first condenses with the amino group and is then oxidized with ring closure. No instance has been recorded in which an intermediate product of acrolein with the amine has been isolated which can be further changed to the end-product.

Mann[8] attempted to prepare quinoline from the acrolein–aniline condensation product, with a negative result. The author, using the *m*-phenylenediamine condensation product, did not succeed in obtaining any phenanthroline. While the experiments with acrolein were conducted in an attempt to improve yields, they are of interest in considering the mechanism of the Skraup reaction.

The *p*-phenylenediamine gave better yields by the recommended procedure than the m-diamine, which is commonly regarded as the easier to manipulate. By the addition of alkali previous to oxidation with permanganate, the yield of dicarboxylic acid from either phenanthroline is more than doubled. A nearly quantitative yield of β,β-dipyridyl results when the dicarboxylic acid is heated in glycerine suspension. This method does not work well with α,β-dicarboxylic acid. In this case the elimination of one carboxyl group is effected by heating in an oil-bath at 200°, while the remaining one is removed by heating to a higher temperature. The yield of α,β-dipyridyl is nearly quantitative.

The writer prepared o-phenanthroline from o-aminoquinoline with some difficulty and found it to be similar to the isomeric phenanthrolines. This reaction might be considerably improved. The yellow compound $C_{12}H_8N_2O$ from o-phenylenediamine was obtained with such difficulty

and in such small yield that the carboxylic acid and the base produced on heating it were barely examined. A further study of these compounds would prove interesting.

Experimental

***p*-Phenanthroline.**—Fifty grams of *p*-phenylenediamine is mixed with 200 cc. of glycerine in a 2-liter Erlenmeyer flask. A mixture of 100 cc. of concentrated sulfuric acid and 100 cc. of arsenic acid (specific gravity of 1.80 and containing about 55% of As_2O_5) is slowly added whiie the mixture in the flask is agitated. Heat is applied carefully to produce and maintain a gentle ebullition, the flask being loosely covered with a small glass funnel to permit the escape of steam. After about one-half hour the contents should begin to turn brown. The funnel is then replaced by a short tube used as an air condenser. After heating is continued for about two hours, a test to determine the approximate amount of unaltered diamine is made by removing 1 cc. of the reaction mixture, diluting to 5 cc. with water and adding an excess of alcohol. *p*-Phenylenediamine sulfate separates on cooling if an appreciable quantity of the material is still unchanged, indicating that the heating should be continued with the air condenser until the test is essentially negative. The heating may now be continued under a water condenser for two hours, making the total time of digestion about five hours. The reaction mixture is now cooled and diluted with several portions of water, strong ammonia is added in excess, and the phenanthroline is extracted with several portions of benzol before the mixture has had time to cool. These extractions should be made as hot as is possible with the use of benzol by digesting solvent and mixture on the steam-bath preliminary to separation in the separatory funnel. The combined benzol extractions contain little tar, but nearly all of the phenanthroline with a little unaltered diamine. After evaporation of the benzol the residual p-phenanthroline is distilled without a thermometer, leaving the tar in the flask. The *p*-phennathroline while still liquid is poured in a thin steam into a large volume of water with continuous stirring and allowed to crystallize as the hydrate, which is filtered off and dried. To further purify and free it from unaltered diamine, it is liquefied with boiling water and poured again into a large volume of water. The product is then very satisfactory but can be further purified by being dissolved in alcohol or acetic acid and poured into water. The purification is not difficult when the Skraup reaction has been properly conducted. The yield is 65 g. of phenanthroline hydrate, representing about 60% of the theoretical.

β,β-Dipyridyl-dicarboxylic Acid.—The p-phenanthroline oxidizes best when it is finely divided and the reaction is conducted in alkaline solution. Twenty-five grams of p-phenanthroline hydrate is melted in about 500 cc. of hot water and poured into approximately 3 liters of cold water; 10 g. of potassium hydroxide is added and the cooled mixture is oxidized with 50 g. of potassium permanganate. The manganese dioxide is coagulated by heating to boiling and filtered off. The filtrate is evaporated to small volume, cooled and any phenanthroline which may separate is filtered off. The solution is now made just acid with acetic acid and digested on the steam-bath to remove the carbon dioxide present; the dicarboxylic acid is precipitated by the addition of copper acetate. The copper salt is decomposed by hydrogen sulfide from a suspension in boiling water. The dicarboxylic acid is obtained from the filtrate by evaporation and crystallization in the usual way.

β,β-Dipyridyl.—The decomposition of the dicarboxylic acid is best effected by heating it with sufficient glycerine to completely wet it. Gentle heating removes the carbon dioxide. The mixture is diluted with water, made alkaline with caustic soda and the dipyridyl extracted with ether. The dipyridyl distils over at 300 to 301" (corr.).

***m*-Phenanthroline.**—Fifty grams of m-phenylenediamine is mixed with 200 cc. of glycerine in a 2-liter flask. A mixture of 100 cc. of concentrated sulfuric acid and 100 cc. of arsenic acid (specific gravity of 1.80) is slowly added while the mixture is agitated in the flask. Heating is conducted as with *p*-phenylenediamine, but the loss of steam is permitted to take place more rapidly. A thermometer should be suspended in the mixture to insure that the temperature at ebullition is below 140" for about three hours of heating. The reaction has begun when a small test sample on dilution and the addition of ammonium hydroxide shows a flocculent precipitate. A short air condenser is employed during the 3-hour period. The temperature is permitted to rise gradually by alternating the air and water condensers until it reaches 150°, when a two-hour digestion with the water condenser completes the reaction. Caution should be increased at the last stage to avoid the formation of an excessive amount of tar.

The hot benzol extraction is made and the phenanthroline residue is distilled as with the *p*-diamine. The further purification is also conducted in the same way.

An extended series of experiments was conducted to study the effect of varying empirically the proportions of sulfuric acid, arsenic acid and glycerine, the same quantity (50 g.) of the diamine being used. While the results were not always uniform, because the conditions cannot be rigidly controlled, the proportions reported gave the best results. The best yield of benzol extract was 55 g., and the yield of pure dihydrate was 40 to 45 g.

The attempt to pass acrolein into the reacting mixture to facilitate and increase phenanthroline production resulted instead in loss. Acrolein was also passed into the diamine dissolved in glycerine until a heavy buff-colored precipitate was no longer produced. The sulfuric acid and arsenic acid were then added and the reaction was allowed to proceed as usual. Very little phenanthroline was formed.

A quantity of the condensation product of acrolein with the diamine was prepared by passing the gas into its solution in water. The product was amorphous and insoluble in acetone, alcohol and all other solvents tried. An experiment to subject this material to the Skraup reaction yielded no phenanthroline that could be separated.

Variations in the method of adding the reagents did not improve matters. In one experiment glycerine, *m*-diamine and arsenic acid were added slowly in one part to the sulfuric acid mixed with glycerine. An insoluble compound was formed which did not appear to be phenanthroline, but might possibly be the acrolein condensation product.

α,β-Dipyridyl-dicarboxylic Acid.—The yield of dicarboxylic acid is more than doubled by getting the phenanthroline in a finely divided condition and by the addition of alkali. The theoretical quantity of permanganate is used.

Melt twenty-five grams of dihydrate in 500 to 700 cc. of hot water and pour into 3 liters of cold water, agitating while the crystallization takes place to form it in a finely divided condition. Add ten grams of caustic potash, followed by 50 to 55 g. of potassium permanganate dissolved in water and added in small portions. Heat to boiling, filter off the manganese dioxide and evaporate the filtrate to low volume. Cool, filter off any separated unaltered phenanthroline, make acid with acetic acid and digest on the steam-bath. Instead of the silver salt, the writer uses advantageously the lead salt, which is formed by adding lead acetate and digesting until it becomes crystalline.

Suspend the lead compound in a large volume of hot water and pass in hydrogen sulfide. It is important to keep the mixture hot and pass in a large excess of gas to insure the complete precipitation of the lead. Add charcoal, Nter off lead sulfide and charcoal and evaporate to dryness on the steam-bath. Take up with water, filter off the crystals, evaporate the filtrate for further crystals and combine all fractions. The yield of dicarboxylic acid is about 80 to 85% of the theoretical.

α,β-Dipyridyl-monocarboxylic Acids.—When the dicarboxylic acid is heated in an oil-bath to 190–200°, two different monocarboxylic acids are formed. The principal acid, described at length by Skraup, crystallizes in long woolly needles, but the second isocarboxylic acid crystallizes in prismatic needles, a small amount subliming up the sides of the vessel. A quantity of this was collected and analyzed.

Anal. Calcd.: C, **66.00;** H, 4.00. Pound: **C, 65.78;** H, **4.21.**

The α,β-isomonocarboxylic acid melts at 152–154°. When the acid is heated to about 290°, carbon dioxide is evolved and α,β-dipyridyl is formed.

α,β-Dipyridyl.—It has been found that the yield of dipyridyl produced by directly heating the dicarboxylic acid, instead of using the calcium salt, is very good if each carboxyl group is removed at the lowest possible temperature. The dicarboxylic acid is placed in a small distilling bulb, which is immersed in an oil-bath. The bath is carefully heated to and maintained at **200'** until all evolution of gas from the first carboxyl has ceased. The flask is removed and heated in a sand-bath until evolution of the second carboxyl is complete. The flask can now be heated over a direct flame until the α,β-dipyridyl is distilled off, and only a small amount of tarry residue is left. It distils completely at 298°.

Skraup Reaction with *o*-Phenylenediamine.—When the o-diamine is treated similarly to the *p*-diamine, the addition of ammonia brings down a dark colored precipitate. This is dissolved in acid and precipitated with ammonia several times to free it from coloring matter. The precipitate is finally washed with acetone and dried. A large volume of boiling benzol is used to extract a deep yellow compound crystallizing in silky needles. Final purification is effected by recrystallizing from benzol after filtering the hot solution previously digested with charcoal. The pure crystals melt at **253°** (corr.).

Anal. Calcd. for $C_{12}H_8N_2O$: C, **73.50;** H, **4.08;** N, **14.3.** Pound: C, **73.70, 73.45;** H, **3.96, 4.00;** N (by Dumas), **15.0.**

The substance is scarcely soluble in any of the usual solvents. It is slightly soluble in hot benzol or hot alcohol.

It is possible that some o-phenanthroline is formed, but the methods of separation were not adequate to separate it. The results were always variable, and sometimes even none of the yellow compound could be isolated.

Oxidation of $C_{12}H_8N_2O$.—When the compound was oxidized by means of alkaline permanganate, a carboxylic acid crystallizing in needles and melting at **167'** was formed. When this acid was heated above the melting point, carbon dioxide was evolved and a residue formed which finally distilled undecomposed. When recrystallized from water this compound formed needles which melted at 113°. This substance was very soluble in hot water or cold dilute acids. On cooling the water solution, or neutralizing the acid solution with ammonia, the needles were again formed.

***o*-Phenanthroline.**—Ten grams of o-aminoquinoline was mixed with **25** cc. of glycerine, **12** cc. of sulfuric acid and **12** cc. of arsenic acid. The digestion was carried out similarly to that of *p*-phenylenediamine. After the reaction was considered ended, a large volume of water was added, followed by ammonia in slight excess. **A** black tarry precipitate was produced which was filtered off. A large excess of soda lye was added to the filtrate to precipitate the o-phenanthroline, which slowly crystallized in prismatic needles. The crystals were filtered off, washed with a little water, dissolved in acid and reprecipitated with soda lye. The precipitate was filtered, washed and dried. The dried product, weighing two grams, was extracted with boiling benzol, decolorized with charcoal, filtered and evaporated. The residue was crystallized from water after treatment with charcoal. Drying over sulfuric acid for several days resulted in **8.97%** loss of water; calcd. for $1H_2O$, **9.09.** The hydrate began to melt at **91°** and finished at 95°. The anhydrous phenanthroliie melted at 97°.

Anal. Calcd. for $C_{12}H_8N_2$: C, **80.00;** H, **4.40.** Found: C, **80.29;** H, **4.73.**

o-Phenanthroline distils undecomposed above 300°. It is soluble in alcohol, benzol and acetone, but insoluble in petroleum ether. It gives a red color with ferrous salts similar to the color obtained from α,α-dipyridyl. It was shown to be *o*-phenanthroline by oxidation with alkaline permanganate, forming a dicarboxylic acid crystallizing in needles. On heating, the dicarboxylic acid lost carbon dioxide and gave α,α-dipyridyl, as shown by its melting point (68°) and agreement with the known substance in odor, crystalline form and reaction with ferrous sulfate. The dicarboxylic acid was isolated by filtering off the manganese dioxide, making just acid with sulfuric acid, then alkaline with ammonia and evaporating to dryness. The residue was extracted with hot absolute alcohol. The acid left after evaporation of the alcohol crystallized from water in needles.

Summary

1. The double Skraup reaction can be satisfactorily applied to the *m*- and *p*-phenylenediamines with proper observance of water concentration, temperature and time of heating. The separation and purification of the respective phenanthrolines are described.

2. Oxidation of the phenanthrolines to their dicarboxylic acids by permanganate is best conducted at low temperatures with the addition of alkali.

3. β,β-Dipyridyl is satisfactorily prepared by heating its dicarboxylic acid in glycerine. α,β-Dipyridyl is prepared from its dicarboxylic acid by first eliminating one carboxyl at 200–210° and the other at 280–290°.

4. The double Skraup reaction when applied to o-phenylenediamine could not be made to yield *o*-phenanthroline but resulted only in a variable and small yield of a yellow crystalline substance, $C_{12}H_8N_2O$.

5. o-Phenanthroline was prepared from o-aminoquinoline. Its identity was established by oxidation to the dicarboxylic acid, which gave α,α-dipyridyl on heating.

THE PREPARATION OF GAMMA-d-MANNONIC LACTONE

BY WILLIAM L. NELSON AND LEONARD H. CRETCHER

RECEIVED AUGUST 19, 1929 PUBLISHED JANUARY 8, 1930

Mannosaccharic lactone is a substance possessed of quite extraordinary properties.[1] The investigation of this lactone has been under way in this Laboratory for some time and has been especially time-consuming because of the difficulty of the preparation of the lactone in good yield. Fischer[2] reports only 2% on the basis of the weight of ivory nut meal hydrolyzed and oxidized and 7.5% from the oxidation of mannose.

The yield from the oxidation of pure mannonic lactone, however, is 30–35% according to Fischer[2] and even higher by the recently published method of Kiliani.[3]

---

[1] Cf. Butler and Cretcher, THIS JOURNAL, **51**, 2167 (1929), for literature references.

[2] Fischer, *Ber.*, **24**, 539 (1891).

[3] Kiliani, *ibid.*, **54**, 456 (1921).

It would thus appear that a simple method for the preparation of the latter substance is desirable.

Mannonic lactone was obtained in poor yield by Pischer and Hirschberger[4] by oxidation of mannose with bromine. The product of the oxidation was a sirup which would not crystallize even after standing for months. He states that for the preparation of the crystalline lactone it is necessary to convert to the phenylhydrazide, from which the desired product can be obtained on hydrolysis with aqueous barium hydroxide. The use of phenylhydrazine renders this method too expensive and inconvenient.

By application of the method of oxidation of sugars by bromine in the presence of buffering salts recently described by Hudson and Isbell,[5] we have been able to prepare y-mannonic lactone from mannose in good yield. The lactone crystallizes on evaporation of the aqueous solution obtained after removal of excess bromine and hydrobromic acid. The method has also been successfully applied to the mannose-containing solution obtained on hydrolysis of ivory nut meal. It was not necessary to isolate the sugar before oxidation.

Experimental Part

Preparation from Mannose.—Eighteen grams of d-mannose was oxidized in the manner described by Hudson and Isbell[5] for the oxidation of glucose to gluconic acid. Their directions were followed in every particular except that after removal of hydrobromic acid, the solution was not boiled with calcium carbonate to convert the sugar acid to a salt, but was evaporated under reduced pressure to a thick sirup. Mannonic lactone usually crystallized during the process of evaporation; if not, crystallization took place immediately on scratching the walls of the flask. Fifteen cc. of absolute alcohol was added to facilitate removal from the flask. After filtering and air drying the product weighed 15.5 g. and melted at 148–151°. On recrystallization from 95% alcohol 11.2 g. (63%) of γ-mannonic lactone melting at 151° was obtained.

Preparation from Ivory Nut Meal.—Six hundred grams of 20-mesh ivory nut meal was added to 6000 cc. of boiling 1% sodium hydroxide solution. The flame was removed before adding the meal. The mixture was allowed to stand with occasional stirring for thirty minutes and then filtered and washed with water until the washings were neutral and practically colorless.[6] The product was dried at 80°. The yield was 420 g.

One hundred grams of the purified meal was added in small portions and with constant stirring to 100 g. of cold 75% sulfuric acid and allowed to stand overnight. Eleven hundred cc. of water was added and the mixture boiled for three hours.[7] The hot solution was neutralized with barium carbonate, treated with decolorizing carbon and filtered. The filtrate was again treated with carbon and became practically colorless. Titration with iodine indicated the presence of about 90 g. (0.5 mole) of reducing hexose. The solution was diluted to 3750 cc. and cooled. Two hundred and eighty-

[7] Hudson and Sawyer, THIS JOURNAL, 39, 471 (1917).

five grams of barium benzoate was added and the mixture stirred until nearly all of the benzoate was dissolved. Thirty-one cc. of bromine was added and the flask shaken until all the bromine was in solution. The flask was set aside in a dark place for twenty-four hours. The precipitated benzoic acid was removed by filtration, the excess bromine by a stream of air and the barium by sulfuric acid. After filtration the solution was heated and treated with 140 g. of lead carbonate in aqueous suspension. After cooling and filtering the remaining bromide was removed with silver carbonate and the excess lead and silver precipitated with hydrogen sulfide. The insoluble sulfides were removed, the filtrate was heated with decolorizing carbon and evaporated under reduced pressure to 400 cc. The benzoic acid which had separated from solution was filtered off and that in solution was extracted with chloroform. Evaporation in *vacuo* was continued until the lactone suddenly precipitated in a solid crystalline mass. Enough 95% alcohol was added to dissolve all the lactone (hot). On cooling, the product crystallized. After filtering and drying it melted at 138–141°.

It was recrystallized from alcohol. Thirty-six grams of γ-mannonic lactone melting at 151° was obtained; $[\alpha]_D^{25}$ +51.3°. The physical constants of this substance as determined by Nef[s] are:' m. p. 151° and $[\alpha]_D^{20}$ +51.8°. On concentration of the combined mother liquors an additional 4 g. of pure lactone was recovered.

Summary

The method of oxidation of aldehyde sugars recently described by Hudson and Isbell applied to mannose has made possible the preparation of y-d-mannonic lactone in improved yield.

FURTHER OBSERVATIONS ON THE INTERFERENCE OF NITRO GROUPS ON THE ZEREWITINOFF METHOD FOR THE QUANTITATIVE ESTIMATION OF ACTIVE HYDROGEN

BY HENRY GILMAN, R. E. FOTHERGILL AND E. B. TOWNE

RECEIVED AUGUST 19, 1929 PUBLISHED JANUARY 8, 1930

Introduction

Where there is no hydrogen there can be no active hydrogen.

Recently, Gilman and Fothergill[1] showed that nitro, nitroso and azo groups interfered with the Zerewitinoff method for the quantitative estimation of active hydrogen. Long years ago attention was directed by Hibbert and Sudborough[2] to abnormal results given by some nitro substituted compounds. They obtained slightly more than the calculated volume of gas (based on the one hydroxyl group) when *o*-nitrophenol was treated at room temperature with an amyl ether solution of methylmagnesium iodide. The volume of gas increased when the mixture was allowed to stand for an additional eight hours at room temperature.

---

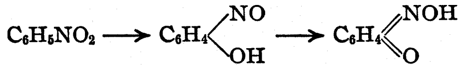
[8] Nef, Ann., 403, 316 (1914).

[1] Gilman and Fothergill, THIS JOURNAL, 49, 2815 (1927); 50, 867 (1928).

[2] Hibbert and Sudborough, J. *Chem. Soc.*, 85, 933 (1904).

Heating for twenty minutes at 115–120° caused the evolution of more gas, so that the total gas given off was almost twice that calculated for one active hydrogen.

They very correctly stated that "the high results obtained with *o*-nitrophenol appear to be due to the presence of the nitro group, as other nitro derivatives not containing hydroxyl groups, for example, *m*-dinitrobenzene, evolve a gas when mixed with methylmagnesium iodide, and the volume of gas is considerably increased when the mixture is heated." They suggested that this may be due to the nitro compound reacting as the tautomeric nitrosophenol or quinone-oxime, as follows



$$C_6H_5NO_2 \longrightarrow C_6H_4\left\langle\begin{matrix}NO\\OH\end{matrix}\right. \longrightarrow C_6H_4\left\langle\begin{matrix}NOH\\O\end{matrix}\right. \qquad (I)$$

This appears to be an altogether reasonable conjecture, and it has the merit of postulating two tautomeric forms each of which has an active hydrogen, namely, a hydrogen atom attached to oxygen. However, our studies on nitro[3] and nitroso[4] compounds have led us to the view that the interference of these groups is a property inherent in the nitro and nitroso groups, respectively. One way of finding a definite answer to this question is to determine the effect of a nitro group contained in a molecule free of hydrogen. This we have done. In the present study we have shown that tetranitromethane, $C(NO_2)_4$, and pentabromo-nitrobenzene, $C_6Br_5NO_2$, evolve considerable gas when treated with alkylmagnesium halides after the Zerewitinoff method for the quantitative estimation of active hydrogen. This proves that a phenolic or oximic or other active hydrogen grouping[5] is not necessary for the evolution of gas by a nitro compound. It does not prove, of course, that the tautomeric forms postulated in Reaction (I) are incorrect. However, our results do show that if the tautomeric phenolic and oximic forms of (I) are to have any claims to correctness they would rest on a more secure foundation on evidence other than that given by the reaction with alkylmagnesium halides.

Experimental Part

The several determinations were carried out in accordance with the procedure used by Gilman and Fothergill[1] in their earlier studies on nitro compounds. Methylmagnesium iodide was used with all compounds. The solvent, both for the Grignard reagent and the nitro compound, was *n*-butyl ether, excepting that the Grignard reagent for the tetranitromethane experiment was prepared in iso-amyl ether.

In a typical determination, 0.2497 g. of tetranitromethane when heated at 70°

---

[3] Gilman and McCracken, THIS JOURNAL, 51, 821 (1929).

[4] Gilman and McCracken, *ibid.*, 49, 1052 (1927).

[5] By active hydrogen we mean here, in general, hydrogen attached to any element other than carbon, and in certain compounds of the latter class where, for example, the hydrogen is attached to a trebly bonded carbon of the acetylenic series.

for fifteen minutes gave 40.7 cc. of gas (measured under standard conditions). This is equivalent to 1.43 so-called "active hydrogens."

With pentabromo-nitrobenzene, 0.2552 g. of the compound when heated with methylmagnesium iodide at 70° for one and one-half hours gave 10.95 cc. of gas[6] (measured under standard conditions). This is equivalent to 0.99 so-called "active hydrogens." By way of reference, mention should be made of an experiment with pentabromobenzene, C_6HBr_5. When 0.2763 g. of this compound was heated at 70° for one-half hour, 0.35 cc. of gas was evolved. This is equivalent to 0.027 so-called "active hydrogens," and is within experimental error.

The pentabromo-nitrobenzene was prepared by the following reactions. First, *p*-nitro-aniline was brominated to 2,6-dibromo-4-nitro-aniline.[7] This was then diazotized and the amino group replaced by hydrogen to give 3,5-dibromonitrobenzene,[7] which was then reduced to 3,5-dibromo-aniline.[8] Bromination of the 3,5-dibromo-aniline gave the pentabromo-aniline,[9] from which the amino group was replaced by hydrogen by means of the diazo reaction to give pentabromobenzene.[10] The pentabromobenzene when nitrated gave the desired pentabromo-nitrobenzene, which melted at 230°. The melting point of our pentabromobenzene was 158–159°.

Summary

The interference of the nitro group in the Zerewitinoff method for the quantitative estimation of active hydrogen is an inherent property of the nitro group because gas is evolved from compounds such as tetranitromethane and pentabromo-nitrobenzene which contain no hydrogen.

THE IRREVERSIBLE OXIDATION OF ORGANIC COMPOUNDS. IV.[1] THE OXIDATION OF ALDEHYDES

BY J. B. CONANT, J. G. ASTON AND C. O. TONGBERG

RECEIVED AUGUST 22, 1929 PUBLISHED JANUARY 8, 1930

The first two papers of this series[2] were concerned with the rate of oxidation of phenols and enols by strictly reversible oxidizing agents such as potassium ferricyanide. It was found that the speed of these irreversible oxidations was a function of the oxidation potential of the reagent and that the results could be formulated in terms of "apparent oxidation potentials."

In attempting to extend our methods to the study of the oxidation of aldehydes, we encountered surprising complications. A qualitative study[1]

---

[6] Some halogen-nitro compounds like bromopicrin, when treated with methylmagnesium iodide evolve a mixture of gases, a part of which is methyl bromide.

of the action of a number of reversible oxidizing agents on aldehydes showed that the oxidation products were rarely the expected acids. Instead, the products were usually the result of a process of alpha oxidation, particularly if the reaction was carried out in a very dilute solution. For example, if ceric sulfate in sulfuric acid is employed, isobutyraldehyde is oxidized to the a-hydroxy-aldehyde; the same aldehyde with potassium ferricyanide in alkaline solutions yields a dihydropyrazine, presumably through the intermediate formation of an a-amino aldehyde, some of the nitrogen of the complex cyanide being transferred to the organic molecule. In the concluding portion of this present paper we are able to present conclusive evidence that a-amino compounds are formed by the oxidizing action of alkaline ferricyanide at elevated temperatures.

In spite of the complexity of the situation as revealed by the qualitative results, a quantitative study of the rates of oxidation has yielded quite definite results of considerable interest. Our electrochemical method of studying the rate of oxidation has been applied to the oxidation at 80° of a variety of aldehydes in acid solution using ceric sulfate and in alkaline or neutral solution using molybdicyanide, tungsticyanide and ferricyanide. On the whole, the results obtained with acid solutions and with alkaline solutions are consistent with the qualitative information, which showed that the primary reaction was the same under both sets of conditions and involved two equivalents of oxidizing reagent. In the following presentation of the quantitative results which we have obtained in the course of the last three years, we shall purposely avoid a detailed mathematical treatment of the data. Considering the complexity of the reaction which we are measuring, we can only hope to outline a first approximation to the final quantitative formulation.

The Rate of Oxidation in Acid Solution.—Since the object of this entire investigation was to examine the relationship between the rate of oxidation and the oxidation–reduction potential of the reagent employed, only those reagents could be used which are strictly reversible[3] and whose oxidation–reduction potential can be measured. Furthermore, since our experimental method of determining the rate of the reaction consists in noting the change of potential of the oxidizing mixture, only those reversible systems could be employed with which electrode equilibrium is established rapidly.

The ceric ion appears to be the only oxidizing agent which meets these specifications and which attacks aldehydes in acid solution at 80° at a measurable rate. The ferric ion and reagents of lower oxidizing potential are without effect; the action of the chromate ion is very slow and the system CrO_4^{--}–Cr^{+++} is not rapidly reversible. The action of potassium permanganate is too rapid and, as will be shown elsewhere, this reagent has

---

[3] Conant, *Chem. Reviews*, 3, 1 (1926).

peculiarities of its own. The thallic–thallous system has a potential of 1.20 volts at 80° in 1 N sulfuric acid as compared with 1.42 for the ceric–cerous system and 0.71 for the ferrous–ferric. It would thus seem at first sight that the thallic ion would be a reversible oxidizing agent suitable for our study, particularly as acetaldehyde reduces it at 80° in 1 N sulfuric acid. Investigation, however, proved that the system was not rapidly reversible. Thus, although the ferric–ferrous system is 500 millivolts lower in potential, it takes more than a minute for an excess of thallic sulfate to oxidize ferrous sulfate in dilute solution to a point where ferrous ions can no longer be detected with ferricyanide. Similarly the characteristic yellow color of ceric sulfate is not discharged by an excess of thallous sulfate even on long standing, although there is a difference of about 200 millivolts representing the driving force of the reaction. The thallous–thallic system is clearly not sufficiently mobile to be of service. We were, therefore, confined to the use of one reagent, ceric sulfate.

The results obtained with ceric sulfate are summarized in Tables I and II. The apparatus and procedure were identical with those used in our previous work. The essential experimental facts are given in the footnote to Table I. The fraction of ceric sulfate (S) reduced at a given time was calculated from the change in potential (ΔE) of the electrode immersed in the reaction mixture, an equimolecular mixture of cerous and ceric sulfate being used in every experiment. The validity of this

$$\Delta E = 0.000198\ T \log \frac{1 + S}{1 - S} \qquad (1)$$

calculation was tested by adding definite amounts of ferrous sulfate solution to an equimolecular mixture of cerous and ceric sulfates. Each increment of ferrous ion produced a practically instantaneous drop in potential which corresponded within the experimental error of 1 millivolt to the change of potential calculated from Equation 1.

TABLE I

RATE OF OXIDATION OF ALDEHYDES AND GLUCOSE AT 80° IN 1 N SULFURIC ACID WITH CERIC SULFATE ($E_0' = 1.424$, PH, 0.37)

Concn. of reagent, moles, /liter × 10^3	Subs. oxidized	Concn. moles /liter × 10^3	Fraction (S) of reagent reduced in, minutes				$k \times 10^2$ Calcd. from S at, minutes				Average
			3	5	8	15	3	5	8	15

0.2	Glucose	0.2	..	..	.09	.18	..	..	1.2	1.3	1.25

NOTE.—In each experiment 100 cc. of 1 N sulfuric acid was placed in the cell and such amounts of ceric and cerous sulfate added (as 0.2 M solutions) as necessary to make an equimolecular mixture with the concentration of ceric ion given in Col. 1. The ceric sulfate was prepared by electrolytic oxidation of cerous sulfate and the concentration was determined by electrometric titration with ferrous ammonium sulfate. The temperature was 80 ± 0.5°. The aldehyde was added in a 0.2 M water solution in such amounts as to give the concentration noted in Col. 3; the time was recorded with a stop-watch. The potentials of the bright platinum electrodes (two were employed) were measured against a saturated calomel electrode at the same temperature. The potential of this calomel at 80° against a hydrogen electrode in 0.2 N hydrochloric acid at the same temperature was 0.253 which, corrected for vapor pressure, gives a value of 0.263 for 1 atm. of hydrogen. We have arbitrarily assumed the hydrogen-ion activity of hydrochloric acid to be independent of the temperature; therefore, the activity in 0.2 N hydrochloric acid is 0.76. Using this value and the measurement just mentioned, we assign the value of 3-0.210 volt to the calomel saturated electrode at 80° on the hydrogen scale. Using this value and measuring the hydrogen electrode in 1 N sulfuric acid at 80°, we find a PH value of 0.37. The ceric–cerous electrode against the saturated calomel was found to be 1.214 at 80°, thus giving a value of 1.424 for E_0' at 80°. This was the initial potential (±3 millivolts) in all the experiments listed above.

The values of the velocity constant given in Table I were calculated from the usual monomolecular Equation 2, the time being in minutes.

$$k = \frac{2.3}{t} \log \frac{1}{1 - S} \tag{2}$$

It is evident from an inspection of Table I that, in the case of the aldehydes, changing the concentration of the reactants affects the rate only slightly, which fact points to a rate-controlling step which is monomolecular. In the case of glucose the effect of dilution, however, is almost as much as would be predicted if a bimolecular process were involved. Since this work has been primarily concerned with aldehydes, we will leave to another paper a further consideration of the peculiarities of the glucose reaction. The data given in Table II show that lowering the temperature 20° decreases the rate of the reaction 3- to 4-fold.

TABLE II

RATE OF OXIDATION OF ALDEHYDES AND GLUCOSE AT 60° IN 1 *N* SULFURIC ACID WITH CERIC SULFATE

Concn. of reagents × 10^3	Sups. oxidized	Concn. moles /liter × 10^3	Fraction (*S*) of reagent reduced in, minutes				k × 10^2 Calcd. from *S* at, minutes				
			3	5	8	15	3	5	8	15	Average
2	Acetaldehyde	2	0.07	0.11	0.19	0.33	2.4	2.3	2.6	2.7	2.5
2	Propionaldehyde	2	.28	.45	.59	.83	11.0	12.0	11.1	11.8	11.5
2	n-Butyraldehyde	2	.16	.28	.43	.67	5.8	6.6	7.0	7.6	6.9
2	Isobutyraldehyde	2	.28	.44	.63	..	10.9	11.6	12.4	..	11.6
2	Glucose	2	..	..	..	.22	..	..	..	2.6	2.6

The potential of the ceric–cerous electrode at 60° was 1.200 against the saturated calomel at the same temperature.

The Rate of Oxidation in **Alkaline** Solution.—The only oxidizing agents which we have been able to employ in neutral or alkaline solution are the complex cyanides of iron, tungsten and molybdenum which were used in our previous papers. Such reagents as Tollens' solution and Fehling's solution are not reversible oxidizing agents and none of the quinones or dyes which have been investigated are sufficiently powerful oxidizing agents to attack aldehydes in dilute solution even at 80°.

The data in Table 111 show the effect of dilution on the rate of the reaction. In the case of the aldehydes (Section A), the reaction is clearly of the second order and the values of k_2 have been calculated from Equation **3.** With glucose and the naphthols (which are included for purposes

$$k_2 = \frac{1}{tC} \times \frac{S}{1 - S} \qquad (3)$$

of comparison) the rate of the reaction is more nearly independent of the dilution and the values of k given are those calculated by means of the first-order equation.

TABLE III

EFFECT OF DILUTION ON THE RATE OF OXIDATION OF CERTAIN SUBSTANCES AT 80°. REAGENT, POTASSIUM FERRICYANIDE

PH	Concn. of reagent, moles per liter X 10^3	Subs. oxidized	Concn., moles per liter X 10^3	Fraction (S) of reagent reduced in, minutes 5	15	30	k_2 calcd. from S at minutes 5	15	30

7.5	1.93	β-Naphthol	1.93	.06	.13	.25	1.2	.92	.96
7.5	9.6	β-Naphthol	9.6	.14	.35	.49	3.0	2.9	2.2

In each experiment 100 cc. of buffer solution was placed in the cell and **after it** had come to temperature equilibrium in the thermostat, 2 cc. each of a solution of oxidized and reduced forms of reagent were added; the resulting concentrations were those in Col. 2. After waiting for ten minutes (to allow for temperature readjustment), a 0.2 molar solution of tho aldehyde was added in such amount that the concentration of the cell was that given in Col. 4. The naphthols were added as solids.

As in the case of the oxidation of phenols and enols, the rate of oxidation of aldehydes by the complex cyanides is a function of the alkalinity of the solution. The more alkaline the solution the more rapid the reaction. In this connection it must be remembered that the potential of the complex cyanides (unlike the quinones) is practically constant from PH values 3–12. We have determined the PH at which each aldehyde is just appreciably oxidized by (a) ferricyanide, (b) tungsticyanide, (c) molybdicyanide. The data are summarized in Table IV.

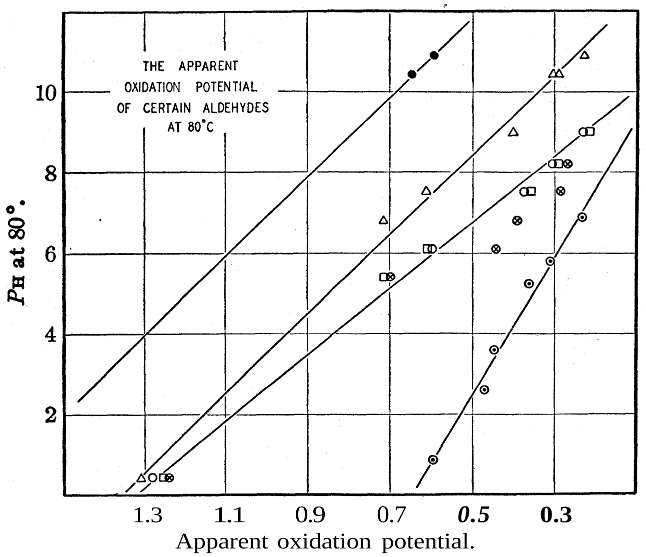
NOTE.—The experiments recorded in the above table were all performed in duplicate. The results agreed within 20% (expressed as fraction reacted in a given time). To save space only one determination has been recorded and the 15-minute values of *S* and ks have been omitted, but were included in the average value of ks used in calculating the apparent oxidation potential. With most of the compounds many experiments in other buffer solutions were carried out, in which the rates were too fast or too slow to give significant values for ks. All these results were consistent with our electrochemical formulation. The following experimental details are to be noted in connection with the above data. The hydrogen electrode (corrected for vapor pressure) in 0.2 *N* hydrochloric acid was taken as the standard of potential at 80°. It was arbitrarily assumed that the activity of the hydrogen ion at this temperature in this solution was 0.76 (the value at 25°). On this basis the hydrogen electrode in 0.2 N hydrochloric acid was given the value of —0.053 at 80°. The particular saturated calomel electrode used as a working standard at 80° had a value of +0.225 on this basis; this value was repeatedly checked. The normal potentials of the reagents were determined at 80° against this calomel electrode. The PH of the buffer solutions at 80° was determined directly with the hydrogen electrode. All the buffer solutions were 0.2 molar with respect to the buffering ion and were made up to an ionic strength of 0.6 with appropriate amounts of sodium chloride. The materials used in preparing the various solutions were as follows: *PH* 5.3, sodium acetate and acetic acid (molybdicyanide potentials showed an abnormally large "drift" in acetate buffers and they were not employed with this reagent); *PH* 5.4, 6.1, 6.8, potassium dihydrogen phosphate and sodium hydroxide; *PH* 8.2, 8.6, 9.0; *PH* 10.4, 10.75, 10.9, secondary and tertiary sodium phosphates.

The most convenient method of summarizing the behavior of aldehydes toward reversible oxidizing agents is by formulating the results in terms of "apparent oxidation potentials." This method has been developed and used in previous papers. In this instance it is more difficult to apply because the rate of oxidation in alkaline solution is so dependent on the dilution. In spite of this complication a fairly satisfactory picture of the process may be developed by confining the attention to one concentration (0.002 M) and in the case of the results with both ceric sulfate and the complex cyanides calculating the rate constant from the monomolecular formula. The apparent oxidation potential is then defined as the potential of the reagent which will just bring about the oxidation at the rate $k = 0.01$ at 80° and the *PH* specified. The rate constants given in Table IV are the *first* order *constants.* Since it rarely happens that $k = 0.01$ in any actual experiment, an interpolation between two values is necessary (or sometimes an extrapolation). In a few cases it was possible to measure the rate of oxidation of a given aldehyde with two reagents in the same buffer. The results of these experiments show that consistent values of the apparent oxidation potential are obtained by using Equation 4, which is of the usual form but contains the quite empirical factor 0.003 T (instead of the usual 0.002 T or 0.001 T).

$$\text{Apparent oxidation potential} = E_0' \text{ (of reagent)} + 0.003\ T \log \frac{0.01}{k} \qquad (4)$$

The values of the apparent oxidation potential given in Table IV and plotted in Pig. 1 were thus calculated using the average value of k. The success of the empirical equation in representing the data is shown by the calculation of apparent oxidation potential of acetaldehyde at PH = 10.4, propionaldehyde PH = 8.2, and n-butyraldehyde at *P*H = 8.2. The two values in each case calculated from the results with two reagents agree within a few millivolts.

The general consistency of the results is also shown by Pig. 1. The results at *P*H 0.37 were calculated from the data in Table I using Equation 4; they are as follows: acetaldehyde, apparent oxidation potential = 1.307; propionaldehyde, 1.252; n-butyraldehyde, 1.278; *iso*butyraldehyde, 1.236. It should be noted that formaldehyde is not appreciably attacked by ceric sulfate, a fact which fits perfectly with the results at PH 11. For the purposes of comparison the results with a-naphthol and 8-naphthol are included. Some of these are new measurements (Table VI) and some from a previous paper. The best straight line has been drawn through the formaldehyde, acetaldehyde and the *n*-butyraldehyde points; n-propionaldehyde is indistinguishable from *n*-butyraldehyde. The isobutyraldehyde values are the most irregular. It is quite clear that the data obtained in acid solution with ceric sulfate are part of the general picture. The position of the points in alkaline and



●, Formaldehyde; □, propionaldehyde; ⊗, isobutyraldehyde; A, acetaldehyde; O, n-butyraldehyde; ⊙, 8-naphthol at 60° (from previous work).

Fig. 1.—The apparent oxidation potential of certain aldehydes at 80°.

neutral solution would have led to the prediction of the apparent osidation potential at PH = 0.37 within at least 100 millivolts.

TABLE V

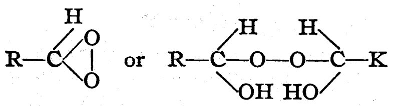
Discussion of Results

While Equation **4** and Fig. **1** are a satisfactory empirical formulation of the results, interpretation of them in terms of a simple mechanism does not seem possible. The slope of the PH–apparent oxidation potential line corresponds approximately to 0.003 T. This is in marked contrast to the oxidations of enols and phenols, where in almost every case the slope is 0.0002 T, the apparent oxidation potential curve paralleling the line for the hydrogen electrode. The contrast between the behavior of aldehydes and the naphthols is clear from Fig. 1. Since the rate of the oxidation of aldehydes by reversible reagents (at 80° in dilute solutions) seems to be a regular function of the potential of the reagent and the *P*H of the solution, this reaction must be classified with those oxidations which may be formulated on an electrochemical basis. For the reasons given elsewhere[3] it seems that in all such processes there is a reversible step followed by a slow irreversible rate-controlling reaction. We are inclined to believe that the reversible step in the case at hand involves the formation of a peroxide of the types



or a free radical from the hydrated form of the aldehyde. The abnormal slope of the apparent oxidation potential–PH curve might be due to hydroxyl-ion catalysis of the irreversible step. The apparent second order reaction with the complex cyanides may be due to the interaction of the first product and the cyanide with the formation of the dihydropyrazine. We have not been able, however, to devise a combination of any such mechanisms which will lead to the quantitative relationships actually found. Considering the complexities revealed by the qualitative study of the reactions, it is perhaps not surprising that the quantitative results defy analysis.

In considering Fig. 1 as a description of the oxidation of aldehydes at 80° in dilute solution, several points must be kept in mind. The curves refer to one concentration (0.002 M); in more concentrated solution the apparent oxidation potential would be lowered, in more dilute solutions raised, at least in the alkaline solutions. Judging from the results of Table III, the effect would be about 100 millivolts for each 10-fold change. The acid points would also be changed by change in concentration, since it is clear from Table I that there is a change of rate with change of concentration, though it is less than when ferricyanide is used. The effect of change in temperature is complicated because of the change of the PH value, the potential of the reagent and the rate of the oxidation. At temperatures near 80° the increase in the apparent oxidation potential of 80 to 100 millivolts for a 20° lowering of temperature would be expected from the data in Tables II and V. At 25° the aldehydes are only attacked by molybdicyanide in extremely alkaline solution.

The process or processes which are involved in the reaction which we have attempted to formulate in Fig. 1 involve the oxidation of the aldehyde in the a-position. The so-called "normal" oxidation of aldehydes to acids is another story. In this connection the action of two common reagents—Fehling's solution and Tollens' solution—is of interest. In neither of these reagents is there a mobile equilibrium between the oxidized and reduced form. According to our views, their action would therefore not be expected to fit into the electrochemical picture. That this is the case is shown by the fact that rough estimations of the rate of reduction of Fehling's solution at 80° gives the order: acetaldehyde > a- and 8-naphthol > formaldehyde. Tollens' reagent at room temperature gives the order, formaldehyde > acetaldehyde > α-naphthol > @-

naphthol. Ammoniacal silver nitrate at 80° shows the following: formaldehyde and the naphthols instantaneous action, acetaldehyde much slower. The predicted speed of oxidation by reversible reagents from Fig. 1 is a-naphthol > β-naphthol > acetaldehyde > formaldehyde; this does not correspond with that found with any of the reagents just mentioned. It seems probable that in the case of the oxidation of aldehydes with the complex metal positive ions, an addition compound is first formed. The formation of such a compound and its rate of decomposition would not be expected to be a function of the oxidation–reduction potential of the reagent. It might further be noted that it is extremely probable that the chief product of the oxidation of aldehydes by cupric and silver hydroxide and their complexes is in every case the corresponding acid.

Further Evidence Concerning the Nature of the Product.—Except in a few cases, the process of a-oxidation does not stop with the formation of the hydroxy-aldehyde but proceeds further. This was made evident by the results published in the last paper. We have obtained further evidence on this point by determining the number of equivalents of ferricyanide or of ceric sulfate which are required for complete oxidation of a few aldehydes and sugars. The general procedure was to add an excess of reagent together with its reduced form and follow the change of potential with time. The rate of change of potential, which was at first rapid, gradually decreased until after two or three hours there was no appreciable change; this was taken as the end of the reaction. The total change of potential is a measure of the amount of oxidizing agent which has been reduced. A few typical results obtained using ceric sulfate are given in Table VII. A test of the method is given by the results with oxalic acid in which two equivalents must almost necessarily be involved.

TABLE VII

DETERMINATION OF THE NUMBER OF EQUIVALENTS INVOLVED IN THE OXIDATION OF CERTAIN COMPOUNDS BY CERIC SULFATE IN 1 N SULFURIC ACID AT 80°.

TYPICAL RESULTS

Substance	Time, min.	*AB*, mv.	*S*	Equivalents
Oxalic acid,	0	0	0	
concn., 0.008	1	74	0.84	
mole per liter	14	74	.84	2.1
Isobutyraldehyde,	0	0	0	
concn., 0.001	65	56	.72	
mole per liter	88	60	.76	
	100	61	.77	
	126	64	.78	1.6

Where the number of equivalents is large the results are less certain and may be in error in the case of glucose, for example, by one or two equivalents. The following results have been obtained, all at 80°.

Substance and reagent	No. of equivalents
Acetaldehyde with ferricyanide (P_H 10.8)	1.9
Acetaldehyde with ceric sulfate (P_H 0.37)	2.5
Propionaldehyde with ferricyanide (P_H 10.8)	2.6
n-Butyraldehyde with ferricyanide (P_H 10.9)	at least 5
n-Butyraldehyde with ceric sulfate (P_H 0.37)	4
Isobutyraldehyde with ferricyanide (P_H 10.9)	2
Isobutyraldehyde with ceric sulfate (P_H 0.37)	1.6–3.0
d-Glucose with ferricyanide (P_H 10.4)	12.2
d-Glucose with ceric sulfate (P_H 0.37)	8.8
d-Fructose with ferricyanide (P_H 10.4)	11.2
d-Arabinose with ferricyanide (P_H 10.4)	7.5

The oxidation of d-glucose by both ferricyanide and ceric sulfate is probably complete, since a determination of the amount of carbon dioxide evolved using ceric sulfate showed 6 moles per mole of sugar; the value of the number of equivalents obtained with this reagent is therefore probably below the true value.

In the previous paper the formation of dihydropyrazine derivatives by the action of potassium ferricyanide on aldehydes and ketones was explained by the assumption that the a-amino compound was first formed and then underwent condensation. We have been able now to demonstrate the correctness of this mechanism, at least in the case of ketones. Gabriel[4] has shown that a-aminophenyl isopropyl ketone, unlike most a-amino ketones, does not condense to a dihydropyrazine. We therefore oxidized phenyl *iso*propyl ketone with ferricyanide according to our usual procedure and obtained the a-amino compound. The yield was small and all attempts to change the conditions to obtain a better yield failed. The method therefore does not appear very suitable for the preparation of this compound. The experimental details are given below.

A solution of 58 g. of potassium ferricyanide in 500 cc. of water was heated to 85–95' and 10.4 g. of phenyl isopropyl ketone and 200 cc. of 2 N sodium hydroxide was added. The hydroxide was added gradually and finally 25 cc. of 5 *N* sodium hydroxide was introduced. The characteristic red precipitate of ferric hydroxide formed rapidly. After thirty minutes the solution was cooled, filtered and extracted with chloroform. The basic material was extracted from the chloroform with dilute hydrochloric acid, then liberated by the addition of alkali and extracted with chloroform. On distillation 0.5 g. of α-aminophenyl isopropyl ketone was obtained (b. p. 247–257°, hydrochloride m. p. 187–188° after recrystallization from acetoacetic ester).

Evidence of the formation of a-aminomethyl isopropyl ketone was also obtained in some experiments conducted with methyl isopropyl ketone. The reaction mixture, obtained in the usual way, was filtered from the iron oxide, acidified with acetic acid and evaporated at 40° under diminished pressure to a small volume. The solution was then made strongly alkaline and stirred with benzene sulfone chloride for four hours. On working up the reaction mixture in the usual way, 1 g. of a white crystalline solid was obtained which was evidently the benzenesulfone derivative of the α-amino

---

[4] Gabriel, *Ber.*, 44, 60 (1911).

ketone. It melted at 93.5–94.5° after recrystallization from hot water. It was soluble in alkali but insoluble in acid; it contained nitrogen and sulfur.

Anal. Calcd. for $C_{11}H_{15}NSO_3$: C, 54.7; H, 6.3. Found: C, 53.9; H, 6.6. Mol. wt. in camphor (micro method): 255. Calcd.: 241.

In connection with the quantitative results reported in the first portion of this paper, it should be mentioned that a study was made of the action of molybdicyanide on *iso*butyraldehyde at 80° in a phosphate buffer. No evidence of the formation of acetone could be obtained. The distillate gave the test for the α-hydroxy*iso*butyraldehyde (see experimental portion of previous paper) but only in the first 30 cc. The amount of this found is therefore slight. The reaction mixture, also, did not give the characteristic precipitate of the dihydropyrazine perbromide when treated with bromine. However, after making alkaline, heating and reacidifying, the addition of bromine yielded a precipitate of what appeared to be the perbromide of the dihydropyrazine. It thus appears that with molybdicyanide as with ferricyanide the oxidation product is the a-amino aldehyde.

Summary

1. The rate of oxidation of a number of aldehydes at 80° in 1 *N* sulfuric acid by ceric sulfate has been measured.

2. The rate of oxidation of certain aldehydes at 80° in alkaline and neutral buffer solutions by ferricyanide, tungsticyanide and molybdicyanide has been determined.

3. A comparison of the results obtained at the different acidities shows that the reaction between aldehydes and reversible oxidizing agents can be formulated in electrochemical terms. The equations necessary to describe the change of rate with change in acidity (P_H) and change of potential of the reagent, however, contain factors which do not correspond to any simple mechanism.

4. The action of Fehling's solution, ammoaiacal silver nitrate and Tollens' reagent are quantitatively different from the action of the reversible reagents.

5. a-Aminophenyl *iso*propyl ketone has been isolated from the products obtained by the oxidation of phenyl *iso*propyl ketone by ferricyanide.

A STUDY OF THE PREPARATION AND PROPERTIES OF VITAMIN C FRACTIONS FROM LEMON JUICE[1]

BY H. L. SIPPLE AND C. G. KING

RECEIVED AUGUST 26, 1929 PUBLISHED JANUARY 8, 1930

Vitamin C fractions from lemon juice have been studied by Zilva and co-workers,[2] and Bezssonov has investigated the antiscorbutic vitamin as obtained from such sources as cabbage juice and potatoes.[3] However, very little is known as yet regarding the constitution of Vitamin C. It is probably the least stable of the vitamins and accordingly has been studied very little from a chemical point of view. This investigation of the preparation and properties of antiscorbutic fractions from lemon juice has been carried out in cognizance of the fact that such a study might furnish further information leading toward the isolation of Vitamin C.

Experimental

The general procedure used in testing the various fractions was the method which has been described by Sherman and co-workers.[4]

The guinea pigs used for testing the preparations were fed daily doses which were known to be equivalent to a certain volume of original lemon juice. The test period used was generally fifty-six days.

In order to avoid inactivation of the vitamin, all laboratory operations were carried out rapidly, under nitrogen gas, at relatively low temperatures, and in acid solution if possible. Fresh preparations were made each week. All fractions were stored under nitrogen in tightly stoppered bottles kept in a refrigerator. The liquids fed were always water solutions, free from toxic substances such as alcohols, ethers, heavy metals or appreciable amounts of acids.

Preparation of Vitamin C Fractions

Preparation I.—Lemon juice was decitrated with an excess of neutral lead acetate solution, the lead being removed from the remaining solution

---

by precipitation with 10% phosphoric acid solution. After concentration in *vacuo* below 50°, the liquid was treated with two volumes of alcohol and filtered. The alcohol was removed from the filtrate by vacuum evaporation, the residual concentrate diluted with distilled water to one-half the equivalent volume of lemon juice, and fed to guinea pigs. Table **I** clearly indicates that no appreciable loss in Vitamin C content occurred in this treatment.

TABLE I

TEST DATA ON PREPARATION I

Lemon juice equivalent fed daily, cc.	Number of animals	Average survival (56-day test)	Average scurvy score	Average gain in weight, g.
Lemon juice, **1.5**	2	56	0	151
Decitrated lemon juice, **1.5**	2	56	0	169
Decitrated lemon juice, **3.0**	2	56	0	155
0	2	26	15	−68

Preparation II.—Decitrated lemon juice containing an excess of lead acetate was treated with dilute ammonium hydroxide until the *P*H was brought to 7.4–7.6 (phenol red). The yellow precipitate which formed was quickly centrifuged and the supernatant liquid decanted. The precipitate was dissolved in dilute acetic acid and dilute ammonium hydroxide added until the solution was brought to **a** PH of 7.4–7.6. The yellow precipitate was again centrifuged and dissolved in dilute acetic acid. The lead was removed from all fractions by precipitation with 10% phosphoric acid solution.

The results of feeding the various fractions of Preparation II appear in Table II. Both the first and second precipitates retain the vitamin with but slight loss in potency. Reprecipitation can evidently be employed as a further step in the purification since the first precipitate, as fed, contained 6.72 mg. of total solids per cc. of lemon juice equivalent while the second precipitate fraction contained 4.45 mg. of solids per cc. of lemon juice equivalent.

TABLE II

TEST DATA ON PREPARATION II

Lemon juice equivalent fed daily, cc.	Number of animals	Average survival (56-day test)	Average scurvy score	Average gain in weight, *g*.
Filtrate from first active ppt., **1.5**	3	26	21	−83
Filtrate from second active ppt., **1.5**	3	23	18	−87
First act. ppt., **1.5**	2	56	tr.	10
First act. ppt., **3.0**	2	56	0	113
Second act. ppt., **1.5**	3	56	8	12
Second act. **ppt., 3.0**	2	56	tr.	50
Lemon juice, **1.5**	2	56	0	189
0	2	22	19	−72

Preparation 111.—Continuing the purification of Preparation II, an aqueous solution of the material from the second active precipitate (lead free) was treated with two successive portions of n-butyl alcohol, the alcohol being drawn off each time. The butyl alcohol removed practically all of the yellow coloring matter from the aqueous solution, leaving the vitamin in the water phase (Table 111), showing that Vitamin C is not closely associated with the bulk of the yellow coloring matter, and that the vitamin is much more soluble in water than in n-butyl alcohol. This does not necessarily indicate that Vitamin C is insoluble in n-butyl alcohol.

TABLE III

TEST DATA ON PREPARATION III

Lemon juice equivalent fed daily, cc.	Number of animals	Average survival (56-day test)	Average scurvy score	Average gain in weight, g.
Lemon juice, 1.0	2	56	0	178
Aqueous fraction, 1.0	3	56	7	41
Aqueous fraction, 2.0	3	56	tr.	70
Butyl alc. fraction, 1	5	30	19	−127
Butyl alc. fraction, 2	5	29	18	−112
0	2	27	17	−97

Preparation IV.—The solid material obtained from an active aqueous fraction prepared as in Preparation III was dissolved in 98% alcohol and the solution treated with one volume of peroxide-free absolute ethyl ether. The white crystalline precipitate (principally ammonium salts) which formed was centrifuged and the supernatant yellow liquid decanted. Table IV shows that in this preparation the vitamin remained in the liquid phase.

TABLE IV

TEST DATA ON PREPARATION IV

Lemon juice equivalent fed daily, cc.	Number of animals	Average survival (49-day test)	Average scurvy score	Average gain in weight, g.
Positive controls, second act. ppt., 1	2	49	tr.	83
Solid phase, 2	5	25	18	−75
Liquid phase, 2	6	49	0	90
Both phases, 2 **cc. each**	5	49	0	100
0	3	20	15	−69

Upon analysis the ether–alcohol liquid was found to contain 0.56 mg. of total solids per cc. of equivalent lemon juice. The ash was inappreciable. Reducing substances (Munson–Walker method) calculated as glucose gave a value of 0.45 mg. per cc. The ammonium salts present were found, by steam distillation from alkaline solution, to be 0.045 mg. per cc. expressed as nitrogen. The total nitrogen as determined by the micro-Kjeldahl method was 0.145 mg. of N per cc. The acidity of the total solids was equivalent to 0.39 cc. of 0.01 N NaOH per cc. The ferric chloride test for phenolic bodies was negative. Ammoniacal silver nitrate was reduced slightly in the cold. An osazone reaction indicated glucosazone by its crystal form. A mildly positive carbylamine reaction was obtained, which might have been due to the interaction of sugars and ammonium salts present.

Barium Acetate and Sodium Hydroxide as Precipitating Reagents.—The precipitation of the vitamin by lead at a P_H of 7.4–7.6 seems to be a more or less specific adsorption phenomenon and not dependent upon the hydrogen-ion concentration alone. This was indicated by the results of substituting barium acetate for lead acetate or sodium hydroxide for ammonium hydroxide in making vitamin precipitations.

When barium acetate was substituted for neutral lead acetate in the precipitation procedure, the procedure being unchanged otherwise, a yellow precipitate formed at the usual P_H (7.4–7.6) but it did not remove the antiscorbutic factor from solution. The filtrate proved to be nearly as active as the original lemon juice.

In another experiment dilute sodium hydroxide solution was substituted for ammonium hydroxide in making the basic lead acetate precipitation, care being taken to make the precipitation in the customary P_H range of 7.4–7.6. It was found that the antiscorbutic material was not precipitated and that the treatment caused some inactivation of the vitamin.

Extraction with Absolute Ether.—The highly purified active alcohol–ether preparation of Vitamin C described above was evaporated to dryness in *vacuo,* and the residue extracted with absolute ether. The vitamin was not extracted from the solid material by the absolute ether, but a significant amount of amorphous material was removed by the ether, which would not redissolve in water. This left the total solids of the active fraction equivalent to 0.28 mg. per cc. of lemon juice.

Conclusions and Summary

Lemon juice has been decitrated by the addition of an excess of neutral lead acetate, and a lead complex containing practically all of the Vitamin C has been precipitated from the resulting liquid at a P_H of 7.4–7.6 by the addition of dilute ammonium hydroxide. This active complex has been reprecipitated, effecting a decrease in the total solids without appreciable loss of the vitamin. Barium acetate or sodium hydroxide could not be substituted for lead acetate or ammonium hydroxide in the precipitation of the vitamin. Absolute ethyl ether precipitated white crystalline inactive material, principally ammonium salts, from alcoholic solution of a highly purified vitamin preparation without precipitating the vitamin. Absolute ethyl ether did not extract Vitamin C from the solid material obtained by evaporation of the active alcohol–ether fraction. The total solids per cc. of lemon juice has been reduced from approximately 100 mg. in the original juice to 0.28 mg. for the final active preparations. The solid material in the final active fraction was chiefly carbohydrate in nature. The removal of inactive material has been accomplished without a great loss of the original Vitamin C content.

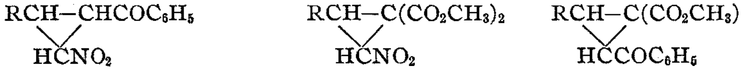
STUDIES IN THE CYCLOPROPANE SERIES.
XII. NITROCYCLOPROPANES

BY E. P. KOHLER AND S. F. DARLING

RECEIVED OCTOBER 14, 1929 PUBLISHED JANUARY 8, 1930

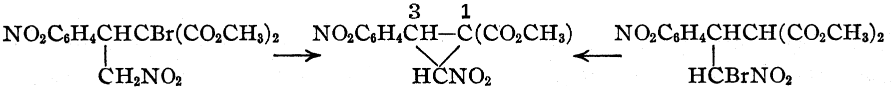
The manner in which bases convert derivatives of nitrocyclopropane into open-chained compounds is still obscure because each type of derivative that has been studied has ended in a different type of open chained compound, and it has not been possible to isolate intermediates in the process. In the hope of discovering such intermediates we have prepared still another type of derivative which is closely related to two that have been studied heretofore



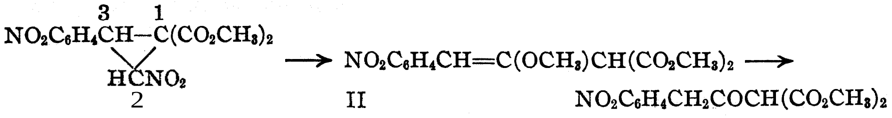
A B C

In order to keep as close as possible to known substances, we planned to prepare a nitrocyclopropane derivative of the type represented by B in which the hydrocarbon residue was to be a phenyl group; but owing to experimental difficulties, it became necessary to secure greater crystallizing power by resorting to substances in which the phenyl groups were substituted. Most of our experiments were carried out, therefore, with the m-nitrophenyl derivative.

The fact that our parent substance was obtained both from an α-bromo and from a γ-bromo compound is adequate proof that it is a cyclopropane derivative

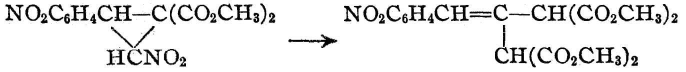


When this cyclopropane derivative is heated with methyl alcoholic potassium acetate—a very feeble base—it is slowly converted into a yellow methoxy compound. The structure of this yellow product was easily established. Its composition and molecular weight are represented by the formula $C_{14}H_{15}O_7N$. It is actively unsaturated, contains three methoxyl groups, is hydrolyzed to a @-ketonic ester, and yields *m*-nitrobenzaldehyde when ozonized. It is, therefore, an open-chained compound that has a methoxyl group in the @-position.



I II III

When the same cyclopropane derivative is allowed to react in the cold with a methyl alcoholic solution of sodium dimethyl malonate—a relatively strong base—it is rapidly and quantitatively converted into the sodium salt of an unsaturated compound which contains two malonic ester residues and likewise gives m-nitrobenzaldehyde when ozonized

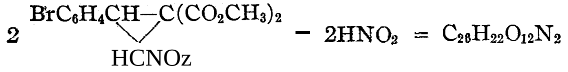


$$\underset{\displaystyle \text{HCNO}_2}{\text{NO}_2\text{C}_6\text{H}_4\text{CH—C(CO}_2\text{CH}_3)_2} \longrightarrow \text{NO}_2\text{C}_6\text{H}_4\text{CH=}\underset{\displaystyle \text{CH(CO}_2\text{CH}_3)_2}{\text{C}}\text{—CH(CO}_2\text{CH}_3)_2 \qquad \text{IV}$$

From these two reactions it is clear that bases open the new cyclopropane derivative between the carbon atoms numbered 1 and **3.** Since this is the same point at which they open the chain in the nitrocyclopropane derivative represented by **A** while that in C is opened between the atoms numbered 2 and **3,** it is evident also that the presence or absence of hydrogen in the 1-position does not affect the process.

By using cold concentrated sodium methylate it was possible to secure a substance which appears to be an intermediate in the process by which the ring is opened. The cyclopropane derivative dissolved readily in the cold methylate, forming a dark red solution which by suitable manipulation could be made to yield a red crystalline sodium compound that still contained nitrogen and also had additional methoxyl. While this sodium compound appeared to be an addition product, it was not possible to establish this with certainty because the substance is extremely unstable and we found no way to purify it. Its remarkable red color is not due to the m-nitro group because unsubstituted nitrocyclopropanes of the same type likewise develop this color,

When this red sodium compound was added to a cold solution of hydrogen chloride in dry methyl alcohol it formed nitrous acid, sodium chloride, a yellow, and a colorless organic compound. The yellow product is the same unsaturated methoxyl compound (II) that is formed by the action of methyl alcoholic potassium acetate on the cyclopropane derivative. The colorless product is more interesting, because its composition and molecular weight show that it is formed from two molecules of the cyclopropane in accordance with the equation



$$2\ \underset{\displaystyle \text{HCNO}_2}{\text{BrC}_6\text{H}_4\text{CH—C(CO}_2\text{CH}_3)_2} - 2\text{HNO}_2 = \text{C}_{26}\text{H}_{22}\text{O}_{12}\text{N}_2$$

The behavior of this colorless substance is peculiar. It is extremely sensitive to basic reagents. In the presence of sodium methylate it combines with two molecules of methyl alcohol and forms, quantitatively, two molecules of the yellow unsaturated methoxyl compound II. It likewise combines with sodium dimethyl malonate in the cold and forms—again quantitatively—the same unsaturated compound (III) that is obtained by the interaction of the malonate and the cyclopropane derivative. Even potassium permanganate, which does not attack the cyclopropane derivative, readily oxidizes this colorless product in the cold. All these basic reagents cleave the molecule symmetrically.

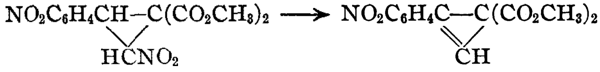
Toward acidic reagents the colorless substance is comparatively indifferent. Acids inhibit its reaction with permanganate. It does not combine with bromine. By prolonged heating with excess of bromine the two hydrogen atoms that are not located either in the phenyl or in the ester groups are replaced step by step but the carbon skeleton of the molecule remains intact. The skeleton even survives the action of concentrated sulfuric acid, which deprives the substance of two ester groups without causing cleavage. Acidic reagents in no circumstances bring about the symmetrical cleavage that invariably accompanies the action of bases.

The peculiar properties of this colorless product may be summed up in the statement that it behaves toward acidic reagents as if it were saturated and toward basic reagents as if it were an extremely sensitive unsaturated compound. Such peculiar properties must be due to an equally peculiar structure. Since the substance is cleaved symmetrically, it may be assumed that it is composed of two halves each of which has the skeleton that is present in all of its cleavage products, namely

$$NO_2C_6H_4\text{—}C\text{—}C\text{—}C(CO_2CH_3)_2$$

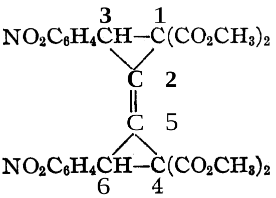
For each of these skeletons but one hydrogen atom is available, and neither of these two hydrogen atoms is sufficiently active to be detected by the Zerewitinoff method; neither is, therefore, in the a-position to the ester groups. The substance is slowly attacked by ozone but it gives neither nitrobenzaldehyde nor nitrobenzoic acid when ozonized—therefore does not, like its cleavage products, have an outlying $NO_2C_6H_4CH{=}$group.

The formation of the substance is associated with the elimination of nitrous acid from the cyclopropane derivative. As far as is known the only way in which this can occur is that represented by the equation



$$\underset{HCNO_2}{NO_2C_6H_4CH\text{—}C(CO_2CH_3)_2} \longrightarrow \underset{CH}{NO_2C_6H_4C\text{—}C(CO_2CH_3)_2}$$

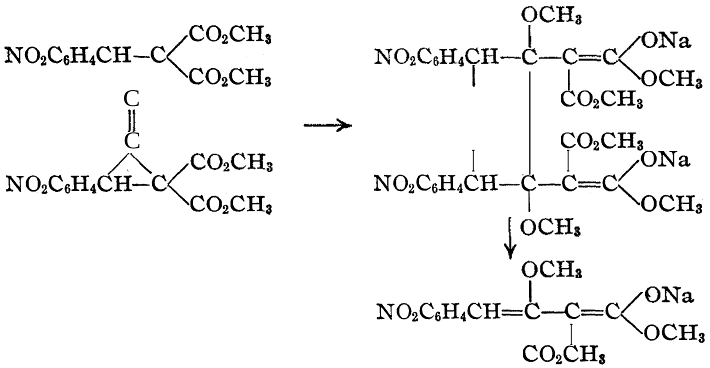
Polymerization of the resulting cyclopropene derivative in a manner that is common in ethylenic compounds would involve the usual shift of the hydrogen and of double linkages, and would lead to the formula indicated.



V

This peculiar formula, in our opinion, best expresses our present knowledge of the substance. It doubtless represents a structure with considerable internal strain, but it is not possible to construct a cyclic model that meets the requirements and has less. It manifestly accounts for the lack of active hydrogen atoms, the inability to add bromine, the sluggishness toward ozone, and the fact that ozonization does not result in nitrobenzaldehyde.

The formula also is consistent with and to a degree accounts for the cleavage of the dimer by bases. Addition of sodium methylate to a substance so constituted would, as is usual in the case of cyclopropane derivatives, lead to a 1,4-addition product, the sodium going to carbonyl, the methoxyl either to the 2- or 3-positions in the upper ring and to the corresponding positions in the lower ring. In the case of so novel a structure it would be reckless to choose between these alternatives; but if we assume that for adequate reasons the methoxyl groups seek the positions 2 and 5, then the necessary readjustments within the molecule will inevitably result in rupture of the rings between atoms 1 and 3 and between atoms 4 and 6, in cleavage between atoms 2 and 5, and in the formation of the cleavage product that is actually obtained



Experimental Part

The general scheme for securing our parent substance was the same that has been used for obtaining a number of cyclopropane derivatives—the preparation of the proper unsaturated compound, addition of nitromethane, bromination of the addition product, and elimination of hydrogen bromide from the bromo compound. In order to be able to select the most advantageous materials, we carried out these preliminary operations with a number of closely related substances.

Thus we prepared not only the methyl ester of benzalmalonic acid but also the methyl and ethyl esters of *p*-nitrobenzalmalonic and *m*-nitrobenzalmalonic acid. Except in solubility and melting point the nitrated members are, naturally, very similar to benzalmalonic esters, but we found that they combine much more readily with methyl alcohol and that the resulting addition products are sufficiently stable to survive bromination.

The unsaturated esters were prepared by the method of Knoevenagel.[1] The methyl alcohol addition products were formed by adding one equivalent of sodium methylate to methyl alcoholic solutions of the esters and, within a minute, acidifying with glacial acetic acid; the brominations

---

[1] Knoevenagel, *Ber.*, 31, 2593 (1898).

were carried out in dry chloroform at the ordinary temperature. All yields were good. The properties of the new substances are given in the following table.

No.	Formula	M. p., °C.	Appearance	Analyses Calcd. C	H	OCH₃	Found C	H	OCH₃

The Nitromethane Addition Products.—The method used for adding nitromethane to the unsaturated esters was essentially that given by Kohler and Engelbrecht.[2] For preparing the a-bromo compounds the addition products were treated with bromine in dry chloroform with the help of sunlight to start the reaction when this was necessary, and the bromo compounds were isolated by removing excess bromine and solvent under diminished pressure at the ordinary temperature. For bromination in the y-position a solution of the addition product in sodium methylate was added to a solution of bromine in dry methyl alcohol. The mixture was evaporated to crystallization under diminished pressure, then diluted with water.

The Cyclopropane Derivative.—Of all the bromine compounds tabulated, the last (XVII) alone gave a satisfactory yield of a cyclopropane.

---

[2] Kohler and Engelbrecht, THIS JOURNAL, 41, 764 (1919).

Fortunately this gave a single substance in almost calculated quantity. The procedure was as follows.

Dimethyl 2-(3-Nitrophenyl)-3-nitrocyclopropane Dicarboxylate, I.—Equal weights of the γ-bromo compound XII and potassium acetate were added to sufficient dry methyl alcohol to dissolve all of the acetate at the boiling point. The suspension was boiled until all of the bromo compound had dissolved, then diluted with enough water to dissolve the precipitated potassium bromide. From the resulting clear light yellow solution, the cyclopropane crystallized in almost the theoretical quantity. It was purified by recrystallization from methyl alcohol.

Anal. Calcd. for $C_{13}H_{12}O_8N_2$: M, 324; C, 48.1; H, 3.7. Found: M, 322; C, 48.1; H, 3.8.

The substance is moderately soluble in most organic solvents. It crystallizes in small hexagonal plates and melts at 122–123.5°. It does not reduce a solution of potassium pennanganate in acetone.

The same substance was obtained in a similar manner from the α-bromo compound IX. Since it is much easier to prepare this bromo compound than its isomer XVI, many efforts were made to find a satisfactory method for converting it into the cyclopropane derivative, but the yield was in all cases very small.

Reaction between the Cyclopropane Derivatives and Basic Reagents.—The cyclopropane derivative, like all the other nitrocyclopropanes, is very sensitive to bases. We studied the action of methyl alcoholic potassium acetate, aqueous alkalies, dilute and concentrated sodium methylate and the sodium derivative of dimethyl malonate. All of these reagents dissolve the substance and form brilliant red solutions, but the last alone forms a single product which is formed quantitatively and is readily isolated.

Reaction with Sodium **Dimethylmalonate,** Methyl **Benzalpropanetetracarboxylate.**—A solution of 0.8 g. of sodium in 35 cc. of dry methyl alcohol containing 7 g. of dimethyl malonate was cooled in ice water. To this solution was added 5 g. of the cyclopropane derivative. It dissolved promptly, forming a deep red solution which was boiled for a few minutes, then cooled again to 0° and poured into cold dilute hydrochloric acid. The pale yellow oil that precipitated soon solidified. By recrystallization from methyl alcohol the solid was obtained as small colorless prisms melting at 92–94°.

Anal. Calcd. for $C_{18}H_{19}O_{10}N$: C, 52.8; H, 4.6. Found: C, 52.9; H, 4.8.

The substance is very soluble in ether and boiling methyl alcohol. It neither combines with bromine nor reduces permanganate in acetone.

Ozonization.—A current of ozonized oxygen was passed through a solution of 1 g. of the substance in ethyl bromide. At the outset the absorption of the ozone was complete. After an hour, the solution was shaken with ice water and then freed from solvent in a current of air. It left an oil. This was dissolved in methyl alcohol and treated with semicarbazide. The methyl alcoholic solution soon began to deposit a crystalline semicarbazone which melted at 233–236°. The melting point remained the same when the substance was mixed with the semicarbazone of m-nitrobenzaldehyde.

Methyl Alcoholic Potassium Acetate.—A solution of 1 g. of the cyclopropane derivative and 3 g. of potassium acetate in 25 cc. of methyl alcohol was boiled for fifteen minutes, during which it turned to a bright red color. On concentrating and cooling, it deposited **0.4** g. of unchanged cyclopropane derivative. The mother liquors yielded. in addition to a small quantity of discolored oil, **0.3** g. of a substance that crystallized in yellow needles and melted at 104–105°. The same substance was obtained in larger amounts by the action of sodium methylate.

Aqueous Alkalies **and** Sodium Methylate.—The cyclopropane derivative is soluble in aqueous alkalies and in dilute sodium methylate but it is not possible to get solid products by acidifying the resulting red solutions. Solid products were finally obtained in the following manner. A solution of **10** g. of sodium in the smallest possible quantity of methyl alcohol was cooled in a freezing mixture to −5°. To this cooled solution was added, with constant shaking, **10** g. of the substance in the form of minute crystals or a fine powder. The solution at once became yellow and soon turned red. In order to hasten solution, the flask was removed from the freezing mixture and shaken until solution was complete and crystallization started. It was then returned to the freezing mixture to complete the crystallization.

The red crystalline product was collected on a suction filter, drained as completely as possible and finally washed thoroughly with anhydrous ether. Various preparations were analyzed but the results have no significance because no two preparations gave the same values. It is variable in composition, too sensitive for recrystallization, and it deteriorates at the ordinary temperature. It dissolves in water to a strongly alkaline red solution containing sodium nitrite. The yield was, uniformly, **7–7.5** g. from **10** g. of the cyclopropane derivative.

Action of Acids on the Red Sodium Compound.—When the sodium compound is **acidified** in the usual manner it yields only oily products. To get solids it is necessary to add the sodium compound to the acid. The best procedure was found to be as follows. The freshly prepared red material was ground and added gradually to an ice cold solution of hydrogen chloride gas in **dry** methyl **alcohol**. The red color disappeared and salt was precipitated. After dilution with water the solution was extracted with ether. The ethereal extract on evaporation deposited two products—one yellow and the other colorless. The mixture was separated by crystallization from a mixture of ether and petroleum ether. The relative amounts of these products varied with different samples of the red product, but the total yield was usually **4.5** g. from **7.5** g. of the red compound.

Dimethyl β-Methoxy-γ,β-nitrophenyl Vinyl Malonate, **(II)**.—The yellow product, obtained as described in the preceding paragraph, is identical with the substance that was obtained by the action of methyl alcoholic potassium acetate on the cyclopropane derivative. It crystallizes from methyl alcohol in plates and from ether–petroleum ether in thin needles which melt at 104–105°.

Anal. Calcd. for $C_{14}H_{15}O_7N$: C, **54.4;** H, **4.9;** OCH_3, **30.1; M, 309.** Found: C, **54.2;** H, **5.0;** OCH_3, 30.1; M, 301.

Ozonization.—A current of ozonized oxygen was passed through a solution of **0.45** g. of the yellow unsaturated compound in ethyl bromide for fifty minutes, after which the solvent was removed under diminished pressure and the residue shaken with ice water. The resulting colorless oil, when boiled with methyl alcoholic semicarbazide hydrochloride, formed the semicarbazone of m-nitrobenzaldehyde.

Hydrolysis to m-Nitrophenacyl **Dimethyl Malonate.—A** solution of **2** g. of the yellow unsaturated compound in aqueous methyl alcohol containing a little hydrochloric acid was boiled for an hour and a half, during which the color disappeared. The solution was then diluted with water and extracted with ether. After washing with sodium bicarbonate, the ethereal solution was shaken with saturated aqueous copper acetate, which precipitated a gray-green crystalline solid. The solid was recrystallized from benzene, from which it separated in fine needles melting, with decomposition, at 195–200°.

Anal. Calcd. for $(C_{13}H_{12}O_7N_2)Cu$: C, 48.0; H, 3.7; Cu, 9.8. Found: C, 47.8; H, 3.7; Cu, 9.6.

The free ketonic ester was obtained by shaking a suspension of the copper derivative in ether and methyl alcohol and with a little dilute aqueous hydrochloric acid. After several recrystallizations from ether–petroleum ether it was obtained in the form of fine needles melting at 64–66°.

Anal. Calcd. for $C_{13}H_{13}O_7N$: C, 52.9; H, 4.4. Found: C, 53.5; H, 4.8.

Reaction with **Semicarbazide.**—When the ketonic ester is allowed to react with semicarbazide in the usual manner, it gradually deposits a crystalline solid which melts at 177–179°. This is, doubtless, a cyclic compound because its composition corresponds to that of a substance formed from the semicarbazone by loss of water.

Anal. Calcd. for $C_{14}H_{14}O_6N_4$: C, 50.9; H, 4.2. Found: C, 50.8; H, 4.5.

The **Dimeric** Product, **VI.**—This colorless substance always constitutes the major portion of the mixture obtained by treating the cyclopropane derivative with bases and acidifying. It crystallizes in needles and melts at 115–116°.

Anal. Calcd. for $C_{26}H_{11}O_{12}N_2$: M, 555; C, 56.3; H, 4.0; OCH_3, 22.4. Found: M, 566; C, 56.1; H, 4.2; OCH_3, 22.9.

Oxidation.—A solution of the substance in acetone reduced a solution of permanganate in the same solvent as rapidly as it was added. The principal oxidation product was m-nitrobenzoic acid, which was identified by comparison with a sample on hand. In addition to this there was formed a minute quantity of a neutral oil which could not be identified. A current of ozonized oxygen containing about 6% ozone was passed through a solution of the substance in pure dry ethyl bromide. Ozone appeared in the effluent gas from the outset, and no ozonide appeared in the liquid. After one and one-half hours the solvent was removed and the residue decomposed in the usual manner; it yielded only oily neutral products. When these oils were collected in methyl alcohol and treated with semicarbazide they formed a minute quantity of the semicarbazone of m-nitrobenzaldehyde. Repeated ozonizations in chloroform and in glacial acetic acid likewise gave only oily products.

Bromination.—The colorless substance does not combine with bromine. A chloroform solution containing one equivalent of bromine was boiled for two hours, then allowed to stand overnight. After removing solvent and excess of bromine there remained a colorless oil that soon solidified. The solid crystallized from a mixture of methyl alcohol and benzene in fine silky needles melting at 154–155°.

Anal. Calcd. for $C_{26}H_{21}O_{11}N_2Br$: C, 49.6; H, 3.5. Found: C, 49.6; H, 3.6.

This substance is evidently a monobromo derivative of the cyclic compound. When it was boiled with excess of bromine in chloroform it very slowly lost hydrogen bromide but even after twenty hours some unchanged substance was recovered along with oily bromine compounds.

Action of Concentrated Sulfuric Acid.—Five grams of the finely powdered substance was added to 50 cc. of pure concentrated sulfuric acid. The substance dissolved to a clear colorless solution which gradually became yellow, acquired the odor of sulfur dioxide and evolved a small quantity of gas. After fifteen minutes the solution was stirred into chipped ice. A light yellow solid separated. It was collected on a filter, thoroughly washed with water and dissolved in ether. The dried ethereal solution on evaporation deposited a mixture of two substances, which was separated by laborious fractional crystallization from mixtures of chloroform, benzene and petroleum ether.

One of the substances crystallized from benzene and petroleum ether or chloroform and petroleum ether in colorless plates that melt with effervescence at 122°. The effervescence is due to water of crystallization. The same substance crystallizes from methyl alcohol in colorless needles which melt at 156–157°, which is also the melting point of the dehydrated form.

One of the substances has a tendency to extract amorphous coloring matter from the solution and separate in orange colored crystals, but if its solution in benzene is shaken with fuller's earth and then diluted with petroleum ether, it separates in stout canary-yellow needles that soften at 135° and melt at 140'.

Anal. Calcd. for $C_{22}H_{18}O_8N_2$: M, 438; C, 60.3; H, 4.1; OCH_3, 14.0. Found: M, 458; C, 60.0; H, 4.0; OCH_3, 12.7.

The substance is readily soluble in benzene and in chloroform, sparingly soluble in ether and in methyl alcohol. It reduces permanganate rapidly but m-nitrobenzoic acid was the only product that could be isolated.

The second substance that was formed by the action of concentrated sulfuric acid separated from benzene and petroleum ether in colorless plates which melted with effervescence at 122". The effervescence is due to loss of water, which can be removed by heating it at 100° in a Fischer pistol. Since the molecular weight of the hydrated form in freezing benzene is only about half that of the anhydrous form, the loss is evidently due to water of crystallization. The anhydrous form crystallizes from methyl alcohol in colorless needles and melts at 157°.

Anal. Calcd. for $C_{24}H_{20}O_{11}N_2.H_2O$: H_2O, 3.4. Found: H_2O, 3.0.

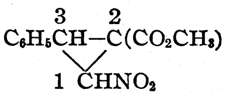
Anal. Calcd. for $C_{24}H_{20}O_{11}N_2$: M, 512; C, 56.2; H, 3.9; OCH_3, 12.1. Found: M, 528; C, 55.5; H, 4.1; OCH_3, 14.3.

This substance seems to be some sort of an anhydride of a dibasic acid formed by hydrolysis and reduction of the dimer. It is not an acid and it differs from all the other complex products in that it does not reduce permanganate in acetone.

Reaction with Basic Reagents, Sodium Methylate and Sodium Diethyl Malonate.—A quarter of a gram of the "dimer" was dissolved in an excess of dilute sodium methylate at the ordinary temperature and the resulting red solution acidified with dilute acid. It deposited the unsaturated yellow methoxyl compound in the calculated quantity. The reaction with sodium dimethyl malonate was carried out in the same manner. The dimer behaved exactly like the cyclopropane derivative and gave an excellent yield of the same m-nitrobenzal derivative.

Summary

1. The action of bases on the cyclopropane derivative



$$\overset{3}{C_6H_5CH}-\overset{2}{C}(CO_2CH_3) \quad \underset{1}{CHNO_2}$$

results in ring cleavage between the carbon atoms in Positions 2 and 3.

2. By operating in a very particular manner it is possible to isolate a dimeric product which has a peculiar structure and which appears to be an intermediate between the cyclopropane derivativd and the open-chained ethylenic cleavage products.

Cambridge, Massachusetts

NEW BOOKS

August **Kekulé.** By Richard Anschütz. Vol. I. Leben und Wirken. (Life and Work.) Vol. II. **Abhandlungen,** Berichte, **Kritiken, Artikel, Reden.** (Communications, Reports, Criticisms, Articles, Addresses.) Verlag Chemie, G. m. b. H., Berlin W 10, Germany, 1929. Vol. I. xxiv + 708 pp. 120 illustrations. Vol. II. xvi + 960 pp. Illustrated. 17.5 × 25 cm. Price, M. 120.

Thirty-three years ago, Richard Anschutz at the request of Emil Fischer began the preparation of what was at first intended to be a "Nachruf" of KekulC for the Berichte of the German Chemical Society. Through the years, this has become the masterly biography which is now before us.

No one could have been better qualified for this task than was Anschütz. He came to Bonn in 1875, at the height of KekulC's intellectual and scientific activities, to be Kekulk's lecture assistant. He came from Darmstadt, KekulC's home city, and this biography was completed in that city. He remained with Kekulé as assistant, pupil, associate and friend until KekulC's death in 1896.

The biography is divided into two volumes. The first is devoted to the life and work of Kekulk, while the second contains a complete compilation of his publications, some one hundred and twenty-five in number, and of his addresses. The author has not made the mistake of writing one account of KekulC's life and another separate discussion of his scientific contributions. KekulC's scientific activities, like those of every great scientist, were the dominating events of his life, and Anschütz has wisely and skilfully woven them into the fabric of his biography.

And Kekulé's life offers a splendid opportunity for a biographer! Kekulk was a student of Liebig at Giessen, of Dumas, Wurtz and Gerhardt in Paris, an assistant of von Planta in Switzerland and of Stenhouse in London. He was Privatdocent at Heidelberg in Bunsen's time, Professor at Ghent at Stas' solicitation and finally Professor at Bonn. This wide experience in the leading countries of Europe brought KekulC into contact with practically all the great figures in the chemical science of the second half of the nineteenth century. Again, KekulC was a protagonist both experimentally and theoretically in the most important developments of chemistry during his period. Anschütz has taken full advantage of these exceptional opportunities, and the biography is not only an excellent account of Kekulé's life and achievements but an illuminating study of the development of chemistry during these important years.

"The biographer's task was further lightened by the fact that KekulC was an inveterate collector; he collected butterflies, plants, minerals, chemical preparations and photographs of his teachers, friends, fellow-workers and pupils. He preserved letters written to him by his colleagues, to the number of several thousand. These have added greatly to the interest of the biography. Many of the photographs are of particular interest because they represent the contemporaneous youthful appearance of their subjects, as contrasted with the more usual photographs taken in maturer years.

In addition to KekulC's already published contributions, this biography contains new material of much historical interest, for instance, the "Cassirte Kapitel zur Geschichte der Benzol Theorie und der Valenz Theorie," which Kekulé prepared in reply to the violent attacks of Kolbe but which his friend Volhard dissuaded him from publishing; also an account, previously unpublished, of KekulC's lecture on the structure of pyridine, given before the German Chemical Society at the celebration of the twenty-first anniversary of the Benzol Theory.

All told, this biography is indeed an outstanding achievement. It is not merely the labor of a lifetime by a devoted friend, but it is also a critical presentation of KekulC's contributions toward the solution of the great chemical problems of his time, written by an eminently qualified scholar. Anyone interested either in the development of the theories of valence and of the structure of organic substances, or in the great figures of our science during this period, should not fail to read this excellent biography.

ARTHUR B. LAMB

Smith's College Chemistry. BY JAMES KENDALL, F.R.S., **Professor of Chemistry in the University of Edinburgh. Revised edition. The Century Co., 353 Fourth Ave., New York, 1929. xii + 759 pp. 179 figs. Illustrated. 14.5 × 22 cm. Price, $3.75.**

In this revision of what is probably the most commonly used of the Smith texts, Dr. Kendall has made many improvements. The most noticeable of these is the rearrangement of topics so as to introduce the atomic theory early in the book. At the same time, the chapter on atomic weights and crystal structure has been expanded and improved. This has enabled him to give explanations of chemical action in modern terms practically from the beginning. Early mention is also made of the ion and a simple explanation of electrolysis is given at its first mention.

While Dr. Kendall has not yet given up the old system of ionization, he has explained much more clearly the reasons for the newer view. We still suggest as in a previous review that if the subject be taken up according to the modern standpoint from the beginning, the idea of complete dissociation will be as easily grasped as the older one. It is not necessary to give to a beginner the mathematics of Debye and Hiickel any more than it is necessary to accompany a statement of the old theory with its mathematical treatment in order to make it intelligible.

The distinction between primary and secondary products of ionization is still not sharply drawn, although the inaccurate statement of the original texts has been avoided.

The book is printed on larger pages and through the introduction of new matter has been considerably expanded.

There are many new illustrations which add to the attractiveness of the book. The line drawings, however, for some reason do not appear to print as well as formerly, possibly because they have been complicated by shading.

Taken altogether the book is the best we have seen since the edition of 1916 and a decided improvement on Dr. Kendall's first revision of the Chemistry for Colleges.

P. A. BOND

A Laboratory Outline of Smith's College Chemistry. BY JAMES KENDALL, F.R.S., Professor of Chemistry in the University of Edinburgh. Revised edition. The Century Co., 353 Fourth Ave., New York, 1929. vii + 198 pp. 32 figs. 14.5 X 22 cm. Price, $1.50.

This laboratory manual, which is designed to accompany the College Chemistry and the Inorganic Chemistry by the same author, is much like its predecessors. Some additional experiments have been inserted and new questions have been added in places where closer reasoning regarding the experiment has seemed desirable. The size of the pages has been increased slightly in order that the student may be able to use the blank interleaves to a better advantage. References are to both the College and Inorganic Chemistry.

P. A. BOND

Anorganische Chemie. Ein Lehrbuch zum Weiterstudium und zum Handgebrauch. (Inorganic Chemistry; a Textbook for Advanced Study and for Reference.) BY DR. FRITZ EPHRAIM, Professor at the University of Berne. Fourth revised and enlarged edition. Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1929. xii + 809 pp. 81 figs. 16.5 X 24.5 cm. Price, unbound, RM. 28; bound, RM. 30.

In spite of the relatively short time that has elapsed since the appearance of the last edition (1923) of this book, there have been noteworthy advances in our knowledge both of descriptive and of theoretical inorganic chemistry. Thus no fewer than five new elements have been discovered— Hafnium, the higher homolog of manganese, Masurium and Rhenium, Illinium the last missing rare earth metal and Protactinium. Even more striking advances have been made in our knowledge of the structure of the atom and of the relationships of the elements.

To give adequate consideration to this new material the present edition is about 10% larger than the preceding one; it has also been extensively revised, particularly in the introductory sections dealing with the structure of the atom and the periodic system of the elements, and in the later sections dealing with halogeno salts, the compounds of the metals with one another, the fourth group of the periodic system and the rare earths.

The book maintains its emphasis on the descriptive rather than the theoretical aspect of the subject. It succeeds, better than any other text of its size with which I am familiar, in presenting the innumerable discrete facts of descriptive inorganic chemistry in a correlated and easily comprehensible form. The appearance of translations of this book into English, Spanish and Italian is an evidence of the well-deserved appreciation which it enjoys.

ARTHUR B. LAMB

A Text-book of **Inorganic** Chemistry. Edited by J. NEWTON FRIEND, D.Sc., Ph.D., F.I.C. Vol. X. The Metal-ammines. By MISS M. M. J. SUTHERLAND, D.Sc., F.I.C., Royal Technical College, Glasgow. J. B. Lippincott Company, Philadelphia, 1928. **xxvi** + 260 pp. 15.5 X *23* cm.

The ammines of cobalt and of chromium are widely known and have been described systematically, for instance in the Seventh Edition of the Gmelin-Kraut Handbook. The ammines of the other metals have not been so adequately considered.

The present volume describes the ammines of all the metals and in the order in which the metals occur in the Periodic System, thus keeping this volume in line with the others of the Series. There are also brief introductory chapters on the history and general characteristics of the metal ammines.

This volume should be useful to those concerned with these interesting substances.

[CONTRIBUTION FROM FERTILIZER AND FIXED NITROGEN INVESTIGATIONS, BUREAU OF CHEMISTRY AND SOILS]

THE PREFERENTIAL CATALYTIC OXIDATION OF CARBON MONOXIDE IN THE PRESENCE OF HYDROGEN. I THE ACTIVITY OF TWO WATER GAS CONVERSION CATALYSTS, OF COPPER OXIDE, OF MANGANESE DIOXIDE AND OF A MIXTURE OF THESE OXIDES

BY WARD E. KUENTZEL

RECEIVED MAY 16, 1929 PUBLISHED FEBRUARY 6, 1930

Present practice in the Haber–Bosch process utilizes water gas containing nitrogen, which is mixed with three to four volumes of steam and passed in contact with promoted iron oxide catalysts to yield a 3:1 hydrogen–nitrogen mixture suitable for the synthesis of ammonia after removal of the 1–2% of residual carbon monoxide and the 29–30% of carbon dioxide by scrubbing with cuprous ammonium carbonate or formate solution and water, respectively.

The practicability of a catalytic preferential oxidation process for the removal of carbon monoxide from hydrogen has long been recognized provided the concentration of the carbon monoxide does not exceed 0.5%.[1] Higher concentrations invariably led to reduction of the oxide catalysts by the hydrogen, due to difficulties in heat dissipation.

The necessity of rapid dissipation of the heat of reaction was stressed by Lamb, Scalione and Edgar,[1d] who pointed out the possibility of utilizing hopcalite[2] to oxidize preferentially 0.5% of carbon monoxide in hydrogen by adding air sufficient to give a slight excess of oxygen over that required for complete combustion of the carbon monoxide, saturating the mixture with water vapor at 40° and passing it over hopcalite contained in a small

Patent 1,418,246, May 30, 1922.

[2] Mixtures of finely divided manganese dioxide with various metallic oxides, such as copper, cobalt, silver, etc., have been termed hopcalite. (a) Lamb, Bray and Frazer, J. *Ind. Eng. Chem.*, 12, 213 (1920); (b) Frazer and Scalione, U. S. Patent 1,345,323, June 29, 1920.

bore copper tube immersed in a liquid-bath. These investigators, as well as others,[3] also showed the importance of water vapor, which seemingly "poisons" the hopcalite toward the oxidation of both hydrogen and carbon monoxide, but more especially toward that of the former. Furthermore, in accord with the results of Lamb and Vail, the water vapor concentration of the gas phase may be greatly increased since their results indicated that the activity of hopcalite was dependent, not upon the water vapor concentration of the gas phase, but upon the actual water content of the catalyzer material and at the same time practically independent of the temperature. It should be possible, therefore, to utilize a large excess of steam in the gas phase at somewhat elevated temperatures in the preferential oxidation process over hopcalite. The use of three or four volumes of steam per volume of gas would then furnish a means of preventing local overheating of the catalyst granules by diluting the reaction mixture and of dissipating the heat of reaction by virtue of the heat capacity of the large volume of steam. The object of the present investigation was to determine experimentally whether under these conditions the higher concentrations of 1–2% or more of carbon monoxide could be efficiently oxidized.

Part I of this paper will refer to preliminary trials of a number of possible catalysts including two catalysts of the water gas conversion type, doubly promoted iron oxide and singly promoted cobalt oxide; two single oxides, copper oxide and manganese dioxide; and two hopcalite mixtures, a 2-component and a 5-component catalyst. Part II will include the more exhaustive tests with a commercially prepared hopcalite of the 2-component type.

Apparatus, Materials and Procedure

The essential features of the apparatus are shown in Fig. 1. By means of the three flowmeters, Q, R and S, mixtures of carbon dioxide and air with a carbon monoxide–hydrogen–nitrogen mixture could be continuously prepared. The gases passed through the indented tube U, which served as a mixing chamber. A continuous flow of steam, generated electrically in the boiler X, met the gas stream at the point G. The mixture of steam and gas could then be passed either through the catalyst tube Y, or through a by-pass depending upon the position of the two stopcocks H and I. The top of the steam generator and the tubes connecting this apparatus with the catalyst tube were heated to above 100° to prevent the condensation of steam. After passage through the condenser J, where the excess steam was condensed and removed through the trap K, the gases could be passed out either (1) to waste through the downward outlet cock L, or *(2)* partly through the capillary tube M to waste, and partly through the caustic potash scrubber N and soda-lime tube O, for complete removal of carbon dioxide, to the flowmeter P and thence to the carbon monoxide analyzer. The capillary tube M was so proportioned as to cause the proper flow of gas through the analyzer.

Catalysts.—The copper oxide, manganese dioxide and 5-component hopcalite were well preserved samples which had been prepared by the

Chemical Warfare Service investigators in 1918 during the development of hopcalite. The two water gas catalysts were prepared several years before this investigation by Mr. M. C. Molstad, at this Laboratory. The method of preparation, source and approximate composition of the catalysts are shown in Table I.

TABLE I

CATALYSTS

Catalyst	Method of preparation	Source	Approximate composition
No. 50	Pptn.	FNRL	94 parts Fe as Fe_2O_3, 5 parts Al as Al_2O_3, 1 part K as KOH
No. R-5	Pptn.	FNRL	95 parts Co as Co_2O_3, 5 part.: Al as Al_2O_3
Copper oxide	Pptn.	CWS	100% CuO
Manganese dioxide	Electrolytic	CWS	100% MnO_2
2-Component hopcalite	Mixture of the CuO and MnO_2	...	60% MnO_2, 40% CuO
5-Component hopcalite	Pptn.	CWS	39% MnO_2, 30% CuO, 17% Co_2O_3, 8% Fe_2O_3, 6% Ag_2O

Temperature of the Catalyst.—In some of the tests the catalyst was maintained at a constant temperature by immersion of the catalyst tube in a well-stirred, manually controlled glycerine bath. The catalyst temperature as recorded in the data was taken as that of a mercury thermometer immersed in the bath liquid near the catalyst chamber. The temperature was constant to within 1 or 2°. In other tests a vapor-bath boiling at the prevailing atmospheric pressure was used. The temperature here was constant to within 0.5°. The temperature bath and control device shown in Fig. 1 were used in the work presented in Part II and have been described elsewhere.[4]

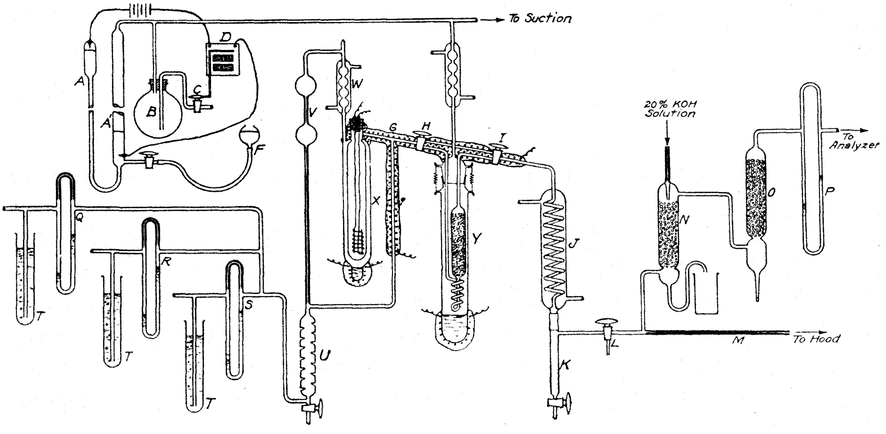

Fig. 1.—Apparatus.

[4] Kuentzel, THIS JOURNAL, 51, 3847 (1929).

Preparation of the Gases.—The carbon monoxide was made by the interaction of formic and sulfuric acids and freed from acid and carbon dioxide by bubbling through potassium hydroxide solution. A supply of gas mixture containing 1.6% of carbon monoxide was made by compressing a 3:1 hydrogen–nitrogen mixture[5] to 135 atmospheres' pressure in a cylinder previously filled with the required amount of carbon monoxide. Oxygen or air and carbon dioxide were added to this gas mixture before it entered the catalyst chamber. The air was taken from the laboratory service lines with no purification other than a cotton–wool dust trap. The carbon dioxide was the unpurified commercial product. Tests in which continued high carbon monoxide oxidation efficiencies were obtained proved the absence of catalyst poisons from these materials.

Procedure.—Each experiment consisted in passing a 3:1 by volume steam–gas mixture at 720 dry gas space velocity over one of the catalysts at a fixed temperature and analyzing the effluent gases. Samples were taken, after condensation of the excess steam at the downward outlet stopcock I, (Fig. 1), directly into an improved Orsat type of gas analysis apparatus equipped with a long 100-cc. compensated buret and analyzed in the usual way.

In order to obtain more accurate data, the continuous carbon monoxide analyzer described by White[6] was used in the final experiments. When the continuous analyzer was operating, a constant flow of gas through this instrument provided analytical data as often as desired.

Experimental Results

Experiments with Water Gas Conversion Catalysts.—The results of experiments in which two precipitated water gas conversion catalysts, No. 50 and No. B-5, were tested as preferential oxidation catalysts indicated that these catalysts were of little or no value as selective oxidation agents. Practically identical results were obtained with gas containing no oxygen and with gas containing oxygen 100% in excess of that required for complete oxidation of the carbon monoxide present. In the case of the iron oxide catalyst, No. 50, a separate test in which the steam–gas ratio was varied from 0 to 8 resulted in the establishment of the water gas equilibrium regardless of oxygen content up to 100% in excess. When the steam content was decreased or cut off entirely in the case of the cobalt oxide catalyst, No. B-5, however, the carbon monoxide was converted to methane. These catalysts, therefore, are in the presence of an excess of steam predominantly water gas conversion catalysts. The addition of air to the final stages of a water gas converter operating at a lower temperature would have little or no effect upon the carbon monoxide content of the effluent gases.

Experiments with Copper Oxide.—The results of a few typical tests with a copper oxide catalyst are shown in Table II.

A preliminary test indicated that only about 50% of the influent carbon monoxide could be oxidized at temperatures up to 174°. From 185 to 225° the results were characterized by excessive reduction of the oxide

catalyst, as shown by the last column of Table II, in which the mg. of oxygen removed from the catalyst have been tabulated. This was true especially during the first few minutes of the test at each succeeding higher temperature. High carbon monoxide and hydrogen oxidation efficiencies were usually obtained during this initial period of excessive reduction. When the amount of reduction decreased, the efficiency of carbon monoxide and hydrogen oxidation also diminished. This behavior indicated that during the first part of the test at a given temperature the catalyst was so active that both carbon monoxide and hydrogen were oxidized, not only catalytically by means of the free oxygen but also chemically at the expense of the oxygen content of the catalyzer itself. This loss of oxygen on the part of the catalyst resulted in lower activity toward both carbon monoxide and hydrogen oxidation, but more especially toward the oxidation of the latter.

Operation at the lower temperature of 185° after high temperature treatment at 225' resulted in decreased efficiencies. This was probably due to the excessive reduction occurring at the higher temperatures. Copper oxide, therefore, although catalytically active in the oxidation of carbon monoxide is partially reduced by carbon monoxide and hydrogen to such an extent that its activity is markedly impaired. Its use as a preferential oxidation catalyst for the removal of over 1% of carbon monoxide from hydrogen in the presence of carbon dioxide and a large excess of steam is not recommended.

Experiments with Manganese Dioxide.—The results obtained with a sample of electrolytic manganese dioxide are shown in Table III.

With this particular sample the carbon monoxide oxidation efficiency was markedly low at 167° and reached a value of only 91% at the high temperature of 250°. Even then it fell off to 77% after only a short time of testing. At these temperatures the catalyst was appreciably reduced, as shown by the loss of oxygen in the last column of Table III. This particular catalyst is therefore of little value as a selective oxidation agent under the conditions of steam and gas compositions here encountered.

Experiments with a 2-Component Hopcalite.—A 2-component hopcalite catalyst was prepared by weighing out unused portions of the two previously tested oxides in the proportions of 60% of manganese dioxide to 40% of copper oxide and mixing them in a finely ground wet paste. Most of the water was then filtered off, the mixture kneaded and finally pressed under hydraulic pressure of about 2000 pounds per square inch. The resulting product was dried at 50°, crushed and screened to 6–10 mesh and then finally dried at 190°. The results of tests on this material are shown in Table IV.

[a] The accumulated time of testing at each temperature is indicated in this column.

The effect of simply mixing the two constituent catalysts was very marked. Over 90% of the influent carbon monoxide was oxidized at a temperature of only 150" during the first hour of operation, and after nine and one-half hours over 81% efficiency was still obtained. At 163° an efficiency of 95% was obtained for two and one-half hours. Operation at 150° after this gave over 81% oxidation. Such efficiencies were obtained only when the temperature ranged around 185° in the case of copper oxide alone, and over 200° in the case of manganese dioxide alone. This behavior of oxide mixtures is in accord with the observations of Almquist and Bray[7] and Bray and Doss[8] who studied the so-called "mixture effect" with these oxides. The reduction of the catalyst was quite appreciable during the initial stages of the test at 150°, but became negligible with continued operation.

Effect of High Temperature and Continued Usage upon the Activity of 2-Component Hopcalite.—The same charge of hopcalite already tested at 150 and 163° was used in determining the effect of higher temperatures. The results are given in Table V.

165	0.5	.17	89.2				

[a] The accumulated time of testing at each temperature is indicated in this column.

A study of these results, obtained with the continuous analyzer, shows that in the range 165 to 190° efficiencies of over 95% may readily be attained, but the high temperature of 220" had a marked deteriorating effect upon the activity of the catalyst. The oxides composing the catalyst were no doubt considerably reduced by this high temperature treatment.

A test was next made in which a fresh charge was maintained constantly at 175° during the passage of gas–steam mixture over it. The test was intermittent in that the catalyst was allowed to cool down to room tem-

---

[7] Almquist and Bray, THIS JOURNAL, 45, 2305 (1923).

[8] Bray and Doss, *ibid.*, 48,2060 (1926).

perature overnight, but otherwise conditions were constant throughout the entire run of thirty-seven hours. An initial efficiency of nearly 99% decreased during the first fourteen hours to 96% and remained constant at this value thereafter.

Experiments with a 5-Component Hopcalite.—A few preliminary experiments were made at the beginning of this investigation with a 5-component hopcalite. At the temperature of 218° the catalyst charge was completely reduced with incandescence when the steam–gas mixture containing 1.6% carbon monoxide in 3:1 hydrogen–nitrogen mixture to which 1.6% oxygen had been added was passed over it at the high space velocity of 6000. Further tests at 720 space velocity upon fresh charges of this catalyst with 28% carbon dioxide added to the influent gases yielded practically complete oxidation of carbon monoxide initially at temperatures ranging from 162 to 200°, but only about 50% efficiency upon continued testing. No attempt was made to determine the cause or causes of its failure. It is of interest, however, to indicate that under conditions at which the 2-component catalyst gave excellent results, the 5-component catalyst was decidedly inferior.

The author wishes to express his deep appreciation to Dr. J. A. Almquist, at whose suggestion this problem was undertaken, for his kind advice and encouragement.

Summary

A study has been made of the preferential oxidation of carbon monoxide by oxygen in the presence of hydrogen and carbon dioxide and a large excess of steam in contact with the catalysts (a) promoted iron oxide, (b) promoted cobalt oxide, (c) copper oxide, (d) manganese dioxide, (e) a 5-component hopcalite and (f) a 2-component hopcalite.

Only the last named catalyst showed any promise as a preferential oxidation agent under these conditions. An efficiency of over 96% was obtained with it for a period of thirty-seven hours. The promoted iron oxide and cobalt oxide catalysts were predominantly water gas conversion catalysts and the presence of oxygen in the gas mixture apparently had no effect upon the final result, which was governed entirely by the water gas reaction, $CO + H_2O \rightleftharpoons CO_2 + H_2$. The copper oxide, the manganese dioxide and the 5-component hopcalite, although catalytically active in the preferential oxidation of carbon monoxide, suffered serious reduction with consequent loss in activity.

THE PREFERENTIAL CATALYTIC OXIDATION OF CARBON MONOXIDE IN THE PRESENCE OF HYDROGEN. II. THE ACTIVITY OF 2-COMPONENT HOPCALITES

BY WARD E. KUENTZEL

RECEIVED MAY 16, 1929 PUBLISHED FEBRUARY 6, 1930

Introduction

Preliminary experiments[1] have shown the possibility of effectively removing the 1–2% of carbon monoxide present in converted water gas of the Haber–Bosch process by preferential catalytic oxidation over hopcalite consisting of 60% MnO_2 and 40% CuO. The present paper presents the results of an extended investigation of various factors influencing the activities of an essentially 2-component commercial hopcalite and of a 2-component laboratory scale preparation for the catalytic oxidation of carbon monoxide.

Apparatus, Materials and Procedure

The apparatus and methods, in general, were those described in Part I.[1] The catalyst was maintained at a constant temperature by means of a vapor-bath with a liquid boiling either at the prevailing atmospheric pressure or under automatically controlled reduced pressure as described elsewhere.[2] The flow of gas through the friction tube flowmeters was automatically controlled to give a constant ratio of air to gas by means of an improved modification of the device described by Oberfell and Mase.[3]

Preparation of the Gases.—Practically all of the experiments were made with actual converted water gas prepared in a moderate scale Haber–Bosch plant at this Laboratory. This consisted in the preparation of water gas from coke and steam, the "conversion" by means of steam of most of the 30% or more of carbon monoxide to carbon dioxide in contact with promoted iron oxide catalyst, the condensation of the excess steam and compression of the resulting "converted water gas" into high pressure cylinders. Air was added in the selective oxidation experiments by means of a flowmeter after expansion of the gas to atmospheric pressure.

In a few experiments pure gases rather than "converted water gas" were used. These gases were prepared as described in Part I.

Catalysts.—Two catalysts were used in the present experiments, a 6–14 mesh essentially 2-component commercial hopcalite (designated "MSA hopcalite" throughout this paper) and a 10–16 mesh 2-component hopcalite prepared at the American University Experiment Station in

1918 by the Chemical Warfare Service (designated "CWS hopcalite") and preserved in a sealed jar since that time. It is highly probable that this latter catalyst and that used in preferential combustion experiments by Lamb, Scalione and Edgar[4] are identical. The compositions of these catalysts are tabulated in Table I.[5]

TABLE I

COMPOSITION OF MSA AND CWS HOPCALITES ON BASIS OF COMPLETELY DRIED MATERIAL

	Percentages												
	CuO	MnO_2	MnO	MgO	Fe_2O_3	K_2O	Na_2O	H_2O	CO_2	SO_3	SiO_2	Avail. O_2, %	Total %
MSA	12.9	77.5	5.4	1.5	1.0	1.6	...	17.8	0.1	2.0	...	15.7	102.0
CWS	45.0	42.1	3.0	1.0	2.3	0.3	0.8	10.6	4.0	0.1	0.6	12.5	99.2

Methods of Analysis.—The efficiency of carbon monoxide oxidation was determined by following the effluent carbon monoxide content with a continuous conductivity analyzer.[6] In the later experiments a shunted Leeds and Northrup recording potentiometer recorded the conductivity continuously. With these devices the carbon monoxide content of the gases could be determined accurately to 0.002%.

When a complete analysis of the gaseous mixture was required an improved exact gas analysis apparatus was used.[7]

The loss of oxygen from the oxide catalysts was obtained by determining the "available oxygen" before and after the run. The "available oxygen" was determined in the manner described by Almquist and Bray[8] except that nitrogen was used as a flushing gas instead of carbon dioxide.

Conditions of Operation.—Certain conditions of operation were chosen as standard, such as a dry gas space velocity of 1000 with 10 cc. apparent volume of catalyst; a 3:1 volume mixture of steam and gas; and an oxygen concentration approximately equal to that of the carbon monoxide. Preliminary tests with MSA hopcalite in which the effect of slight variations in these operating conditions were determined indicated that variations in space velocity of 760 to 1500 resulted only in slightly lower efficiencies at the higher space velocity with no appreciable effect on the subsequent activity at the lower space velocities. Variations in oxygen content ranging from 100 to 145% in excess of that required for complete combustion of the carbon monoxide had only a slight effect, the higher concentration always yielding only a slightly higher efficiency. Although a change in the quantity of admixed steam from 3:1 to 4:1 by volume resulted in efficiencies lower than those obtained with the standard

mixture of 3:1, no permanent injury followed the use of the higher steam concentrations, but a definite decrease in efficiency usually resulted from treatment with steam in the volume ratio of 2:1. The flow of steam could be controlled accurately to within ±1%, which precluded the possibility of any appreciable influence of the latter condition.

Experimental Results

Influence of Temperature and Continued Usage on the Activity of MSA Hopcalite.—The results of a study of the effect of temperature and continued usage upon the activity of MSA hopcalite are shown in Fig. 1.

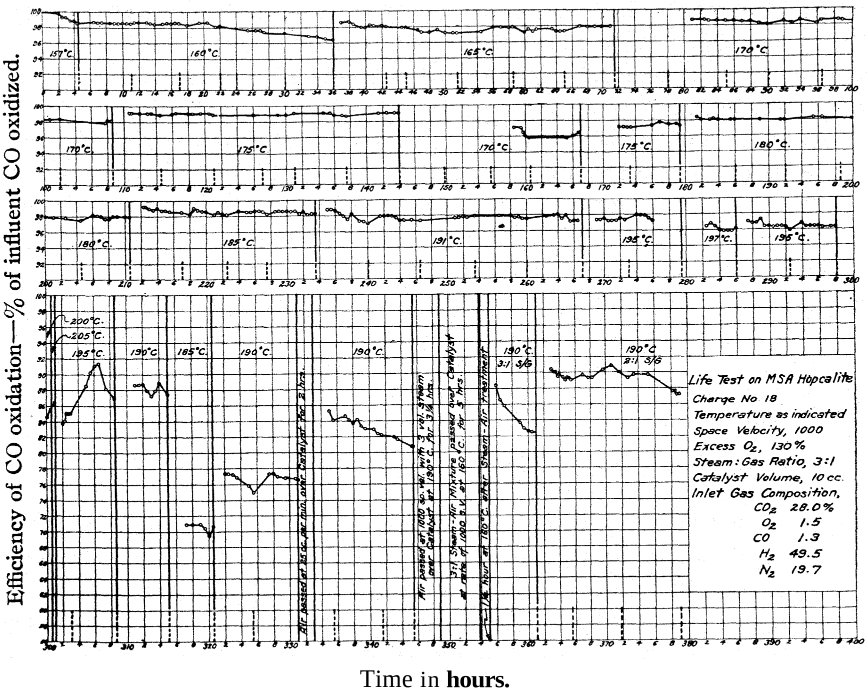

Fig. 1.

The activity was studied at progressively higher temperatures, starting at the lowest feasible temperature. These data were all obtained with a single charge of catalyst during 379 hours of actual testing. (The short vertical broken lines either along the curve or axis of abscissas indicate that the test was discontinued overnight at these points.)

A study of these data indicates that from 97 to 99% of the carbon monoxide may be oxidized in the presence of three volumes of steam to one of gas containing approximately 1.3% carbon monoxide, 1.5% oxygen, 49.5% hydrogen, 28.0% carbon dioxide and 19.7% nitrogen in the temperature range of 160 to 195°.

Attempts to restore the activity after it had been greatly decreased by high-temperature operation through the agency of re-oxidation by means of both dry air and air mixed with steam at 190 and at 160° were only partly successful. The activity at 190° was improved, but the activity at 160° was still very low after these air treatments, as shown by the single point at 56% efficiency at the 355th hour. Decreasing the quantity of steam to a 2:1 volume ratio also only slightly improved the efficiencies.

Factors Contributing to a Decrease in Efficiency of the Catalyst.—Although a high efficiency of carbon monoxide oxidation was maintained in the above tests for a considerable period of time, there is evidence that the catalyst continually decreased in activity, as indicated by the necessity of increasing the temperature in order to maintain the high efficiency, as well as by the rather rapid decrease in efficiency after high temperature operation.

Several factors which might contribute to a decrease in the efficiency of the catalyst readily suggest themselves, such as (1) reduction of the catalyst by carbon monoxide, (2) reduction of the catalyst by hydrogen, (3) loss of available oxygen through thermal dissociation of the oxides composing the catalyst, (4) insufficient dissipation of heat of reaction and (5) the possible presence of catalyst poisons. Experiments to test the part played by these various factors were accordingly carried out.

Influence of Carbon Monoxide and Hydrogen Concentration on Catalyst Reduction.—Three experiments were made at 156° in which carbon monoxide concentrations of 1.3, 0.5 and 0% were used. The results of the first two are plotted in Fig. 2, Curves 17 and 28, respectively. In the former the gas concentrations were the same as those used in the long-time test (Fig. 1), while in the latter the converted water gas entering the catalyst chamber consisted of 0.5% carbon monoxide, 0.5% oxygen, 31.2% carbon dioxide, 50.8% hydrogen and 17.0% nitrogen.

Analysis of the catalyst charges used in these two tests showed that No. 17 had lost 33.5% of the total available oxygen content of the original material during thirty-six hours of testing, whereas No. 28 lost 27.8% of its total available oxygen in twenty-five hours of testing. When due corrections are applied for the relative lengths of the runs and cognizance is taken of the fact that most of the reduction occurred in the early part of each run, it will be seen that a slightly greater loss of available oxygen occurred with the higher concentration of carbon monoxide.

The slightly greater efficiency with 1.3% carbon monoxide as compared to 0.5% may be explained by the plausible assumption that the greater heat of reaction in the former served to heat the catalyst granules to a slightly higher temperature than that existing in the latter.

The third experiment, in which the concentration of carbon monoxide was zero, was also carried out at 156°. The gas mixture prepared from pure hydrogen–nitrogen mixture, carbon dioxide and air which together with three volumes of steam entered the catalyst chamber, contained 32.0% carbon dioxide, 1.0% oxygen, 50.2% hydrogen and 16.8% nitrogen.

The activity of the catalyst was followed by determining the oxygen consumed rather than the actual decrease in hydrogen content. Samples of both influent and effluent gases were taken from time to time and analyzed for oxygen in the bulbed exact gas analysis apparatus. These analyses were then plotted against time and the quantities of oxygen entering and leaving the catalyst chamber determined by taking the areas under the smoothed curves. Upon completion of the test the loss in available oxygen was determined by analysis of the catalyst. The total hydrogen oxidized was then the sum of the hydrogen equivalents of the free and combined oxygen consumed.

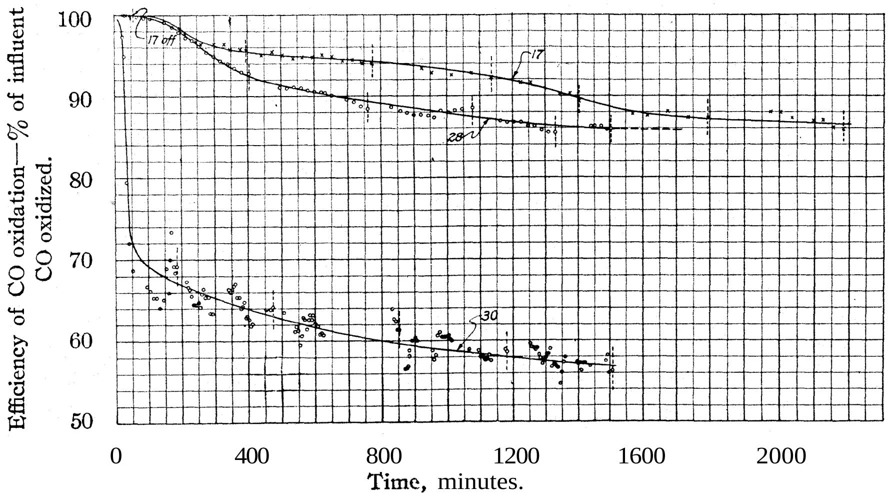

Fig. 2.—Comparison of oxidation of 0.5 and 1.3% carbon monoxide in converted water gas and effect of substituting nitrogen for steam. Curve 17—oxidation of 1.3% CO at 156°, 3:1 steam–gas mixture in glass catalyst chamber; Curve 28—oxidation of 0.5% CO at 156°, 3:1 steam–gas mixture in glass catalyst chamber; Curve 30—oxidation of 0.5% CO at 156°, 3:1 nitrogen–gas mixture in glass catalyst chamber.

A loss of 24% of the total available oxygen content of the catalyst resulted from twenty-five hours of operation, as compared to losses of 27.8 and 33.5% with hydrogen plus 0.5 and 1.3% carbon monoxide, respectively. The efficiency of hydrogen oxidation was calculated to be 1.1%.

Further evidence that the presence of hydrogen contributed to the reduction of the catalyst is shown by a comparison of the above tests utilizing carbon monoxide-free gas with tests carried out with hydrogen-free gas containing 0.5% carbon monoxide. Two tests, the results of which are plotted in Fig. 3 (Curves 31 and 32), were made at 156° with a gas mixture prepared from carbon monoxide, carbon dioxide, nitrogen and air. The mixture entering the catalyst chamber, together with three volumes of steam, contained 0.5% carbon monoxide, 0.7% oxygen, 29.1% carbon dioxide and 69.7% nitrogen. In Run 31 an accidental lowering of the temperature to 140° produced a temporary lowering of efficiency. In the duplicate test (No. 32) a very gradual decline in efficiency from 100 to 98% resulted in twenty-five hours of testing. Analysis of the catalyst charges showed losses of 18.4 and 20.3% of the total available oxygen content of the original material, respectively, compared to a loss of 24.0% with gas containing 50% hydrogen but no carbon monoxide.

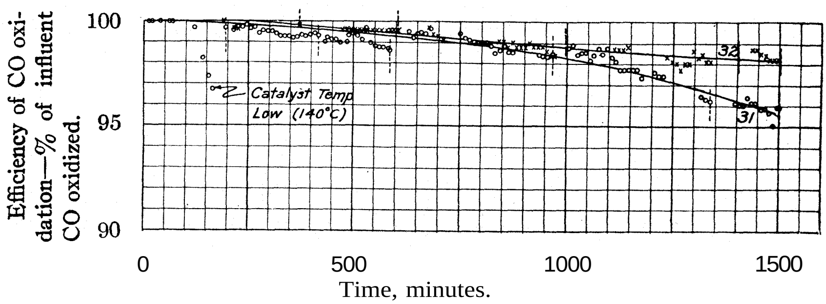

Fig. 3.—Oxidation of carbon monoxide alone. Curves 31 and 32—MSA hopcalite at 156°, 3:1 steam-gas mixture in glass catalyst chamber.

Loss of Available Oxygen by Thermal Dissociation.—In order to ascertain what fraction of the above-mentioned oxygen losses might be caused by thermal decomposition, a separate test was made. This test consisted in determining the loss in weight, other than water, of a fresh sample of the material after having been swept with dry nitrogen at 156° for 20.25 hours. This value when extrapolated to twenty-five hours, showed that the maximum loss in available oxygen would have been 8.2% due to thermal dissociation alone. The greater part of the oxygen loss in the presence of reducing gases was therefore probably due to reduction of the catalyst.

Influence of the Heat Conductivity of the Catalyst Tube on the Efficiency of the Catalyst.—Lamb, Scalione and Edgar[4] successfully oxidized 0.5% of carbon monoxide in slightly moist gas containing hydrogen over hopcalite by utilizing a copper catalyst tube to dissipate the heat of reaction. It was considered of interest to duplicate their experiments in both glass and copper catalyst chambers.

A gas mixture containing 0.5% carbon monoxide, 0.5% oxygen, 74.8% hydrogen and 24.2% nitrogen was saturated with water vapor at 40 ± 0.1° and passed over catalyst samples at a space velocity of 6000 and a temperature of 102°. The results of tests with CWS and MSA hopcalites in glass catalyst tubes are plotted in Fig. 4, Curves 35 and 36, respectively. In both instances high initial efficiencies of about 94% which rapidly decreased with time to 70 and 48%, respectively, were obtained.

An exact duplication of the conditions of Lamb, Scalione and Edgar with a copper catalyst chamber of the same general dimensions except that the copper tube preheater was somewhat shorter, gave, with new charges of the same catalysts, the results shown in Curves **37** and **38** of Fig. **4.** The CWS catalyst now gave 100% oxidation for several hours and as high as **98%** after twenty-five hours. The test was continued without interruption for sixty hours with a final efficiency of over 96%. The MSA hopcalite likewise gave a high initial oxidation efficiency, but its activity declined, rapidly at first and then more gradually to a final value of 75%. The superior activity of the CWS catalyst is quite apparent.

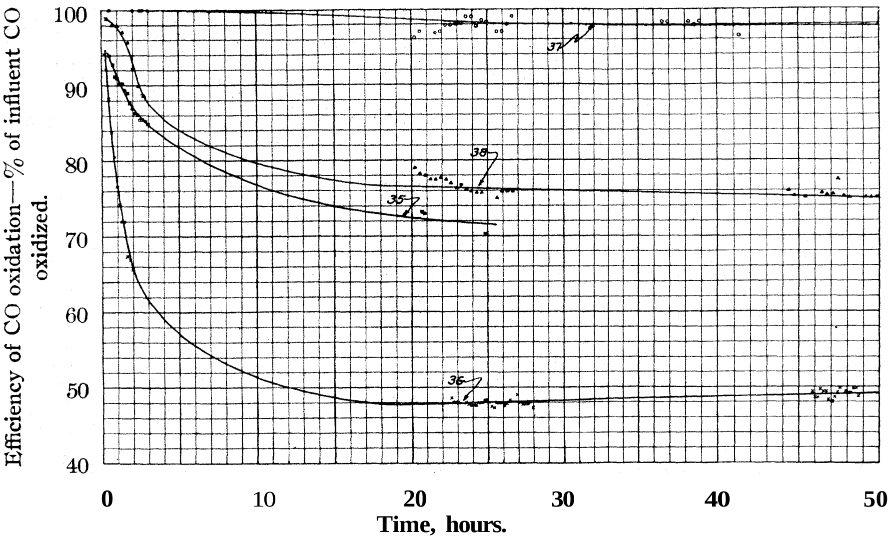

Fig. 4.—The effect of using a copper catalyst chamber. Curves 35 and 36—CWS and MSA catalysts at 102°, gas saturated with H_2O vapor at 40° in glass catalyst chamber, respectively; Curves 37 and 38—CWS and MSA catalysts at 102°, gas saturated with H_2O vapor at 40° in copper catalyst chamber, respectively.

These tests indicate, as Lamb, Scalione and Edgar have pointed out, the extreme importance of rapid and efficient dissipation of the heat of reaction. The inefficiency of the catalysts in glass as compared with copper catalyst chambers can be considered as due to the inability of the glass to conduct away rapidly the heat of reaction.

Influence of an Excess of Steam on the Efficiency of the Catalyst.—The large excess of steam used in previous tests in glass catalyst chambers probably served (1) to dissipate the reaction heat and (2) to exert a specific inhibition to oxidation of hydrogen and to reduction of the catalyst by hydrogen.[10] The necessity of using a copper catalyst chamber with slightly moist gases for dissipation of the heat of reaction and the excellent results obtained in glass with an excess of steam indicate that the steam actually served as a dissipator of heat. This was further proved by an experiment in which both steam and a copper catalyst chamber were used.

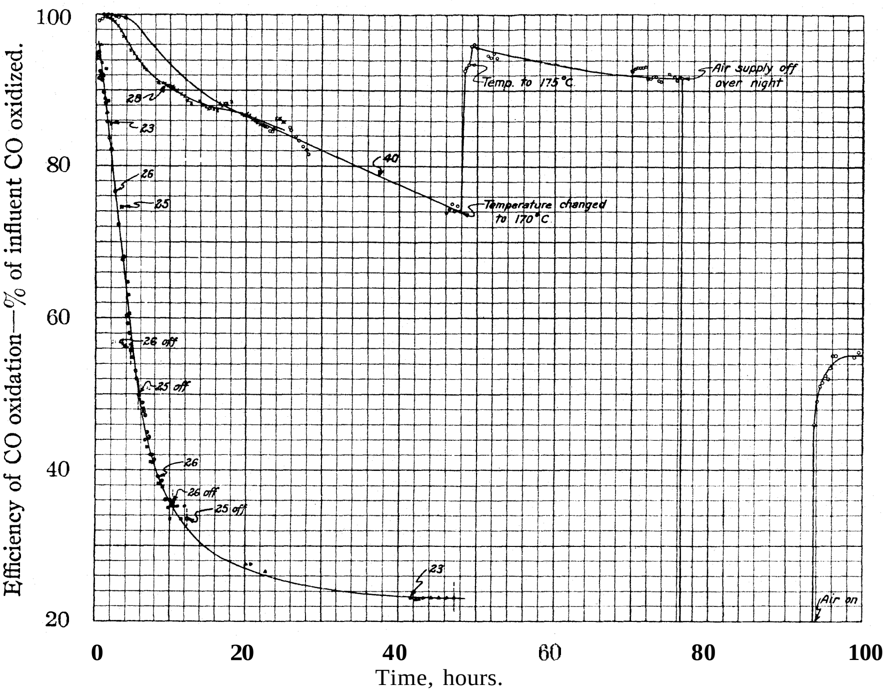

Fig. 5.—affect of steam in copper catalyst chamber and tests with purified and unpurified gases. Curve **28—MSA** hopcalite at 156°, 3:1 steam–gas mixture in glass catalyst chamber; Curves **23** and 25—tests at 130° with unpurified converted water gas; Curve 26—test at 130° with converted water gas purified by hot copper and chromic–sulfuric acid; Curve **40—MSA** hopcalite at 156°, 3:1 steam–gas mixture in copper catalyst chamber.

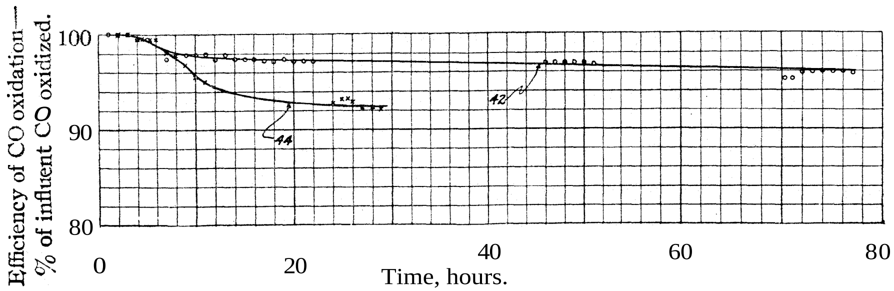
The results of a "steam-in-copper" test are plotted together with a "steam-in-glass" experiment in Curves 40 and 28, Fig. 5. Both curves show decreasing efficiencies with time; those in the glass tube fell only slightly more rapidly during the initial stages than those in the copper, but both were practically coincident after about twenty hours. It may therefore be concluded that the excess of steam eliminated overheating of the catalyst sufficiently well to make a copper catalyst tube of no added benefit.

[9] **A, B.** Lamb and W. E. **Vail, This** JOURNAL, 47,123 (1925).

[10] R. N. Pease and H. **S.** Taylor, *ibid.*, **43,2179** (1921).

Experiment No. 40 was continued for 100 hours' duration in all at temperatures up to 175°. While the catalyst was operating at an efficiency of 92% after seventy-six hours, the air supply to the catalyst was accidentally cut off overnight while gas and steam containing no oxygen passed over the catalyst for a period of about fifteen hours. When the air supply was again admitted, the efficiency was only 55%. Reduction of the catalyst occurred in the absence of oxygen. Thus it would appear that not only steam, but free oxygen as well, is essential to the prevention of the reduction of the catalyst.

The specificity of water vapor in inhibiting reduction of the catalyst was confirmed by an experiment in which nitrogen was substituted for steam. The heat capacity and consequently the heat dissipating ability of nitrogen at 156° is roughly of the same order of magnitude as that of steam, the latter being only about one-fifth greater. Nevertheless, as can be seen by comparing Curve 30, Fig. 2, obtained with nitrogen, and Curve 28, Fig. 2, obtained with steam, the steam acts specifically to maintain the catalytic activity. Subsequent analysis revealed that the catalyst charge had lost 64.5% of its total available oxygen in the nitrogen experiment whereas only 27.8% loss was incurred in the steam experiment. The inhibition of reduction by the excess steam is thus quite apparent.



Pig. 6.—Comparison of activities of MSA and CWS hopcalite in presence of steam in glass catalyst chambers. Curve 42—CWS hopcalite at 156°, 3:1 steam–gas mixture; Curve 44—MSA hopcalite at 175°, 3:1 steam–gas mixture.

Catalyst Poisons.—The absence of catalyst poisons in the converted water gas used in these tests was definitely proved by a series of tests with MSA hopcalite at the low temperature of 130° in which both purified and unpurified gases gave identical results. Purification was by means of hot reduced copper and chromic–sulfuric acid scrubbing. Comparison of the data for Tests 23 and 25, Fig. 5, obtained with unpurified gases and those shown in Test 26 with purified gases reveals no evidence of poisoning by the unpurified gases. The duplicability of results with different charges of the same catalyst is also illustrated by the results of these tests.

Activity of CWS Hopcalite in the Presence of Steam.—The effect of using the very active CWS catalyst in the presence of steam remained to be determined. A glass catalyst chamber was used. The conditions of the test were 156°, 3:1 steam–gas mixture, 1000-space velocity, composition of influent gas: 0.57% carbon monoxide, 0.6% oxygen, 74.1% hydrogen and 24.7% nitrogen. The data are plotted in Fig. 6, Curve 42. The efficiency remained over 96% during the entire test of seventy-seven hours.

A test with MSA hopcalite utilizing the same gas and other conditions as in the above experiment with CWS catalyst with the exception of a higher temperature of 175° is also plotted in Fig. 6, Curve 44. The efficiency after twenty-nine hours was 92%. The superiority of the CWS catalyst is here again quite evident.

Discussion

The Function of Steam.—Although previous investigators found that it was impossible to oxidize carbon monoxide in excess of 0.5% in the presence of hydrogen with moderate amounts of water vapor, it has here been demonstrated that in the presence of a large excess of steam it is possible to burn as high as 1.6%. With proper steam concentrations and temperature adjustment higher concentrations of 2–4% of carbon monoxide undoubtedly can also be handled. The functions of the steam are two-fold: (1) to dissipate rapidly the heat of reaction, thus preventing local overheating of the catalyst granules and (2) to specifically inhibit reduction of the catalyst and oxidation of hydrogen. The use of steam should permit the use of large catalyst beds and catalyst chambers built of poor heat-conducting materials.

The Decline in Activity.—The gradual decline in activity at the low temperature of 156° in the presence of three volumes of steam per volume of gas with 0.5–1.3% of carbon monoxide (Curves 28 and 17, Fig. 2) in converted water gas may have been due either (1) to the presence of catalyst poisons or (2) to a change in structure of the catalyst with decrease of active catalytic surface, most probably incurred through loss of oxygen.

The first of these possibilities is rendered improbable by the poisoning experiments cited above. The probable correctness of the second hypothesis is shown by the fact that, as can be seen in Table II, the activities decrease with increased loss of oxygen.

TABLE II

VARIATION OF ACTIVITY WITH OXYGEN LOST FROM CATALYST

Run number	32	28	17	30
% of total avail. oxygen lost	20.3	27.8	33.5	64.5
Efficiency of CO oxidation, %	98	89	86	57

It should be noted that no appreciable portion of the total carbon monoxide consumed in the 379-hour test run could have been furnished by the available oxygen in the catalyst. Calculation shows that the total available oxygen of the catalyst is equivalent to only 4% of the total carbon monoxide consumed.

In conclusion the author wishes to express his deep appreciation to Doctors E. C. White and P. H. Emmett for their kindly suggestions in the course of this work.

Summary

1. A study of the activity of a commercial hopcalite as a preferential carbon monoxide oxidation catalyst has shown that from 97 to 99% of the influent carbon monoxide may be oxidized catalytically by free oxygen in the temperature range of 160–195° from converted water gas of the composition: 1.3% carbon monoxide, 1.5% oxygen, 28.0% carbon dioxide, 49.0% hydrogen and 20.2% nitrogen, in the presence of three volumes of steam per volume of gas at 1000 dry gas space velocity.

2. A further study indicated that the catalyst always suffered a loss in available oxygen both through thermal dissociation and reduction by hydrogen and carbon monoxide. A decrease in the catalytic activity resulted from this loss of available oxygen.

3. The importance of rapid and efficient dissipation of the heat of reaction has been shown by tests with slightly moist gases in which very inefficient oxidations were obtained with hopcalite in poorly conducting glass catalyst containers while continued high efficiencies were obtained with a copper catalyst chamber.

4. The steam has the two-fold function of dissipator of reaction heat and inhibitor of reduction of the catalyst by hydrogen. The use of catalyst chambers constructed of good heat-conducting material would be of no added benefit in the presence of an excess of steam.

5. A comparison of the activities of commercial hopcalite and a laboratory scale preparation by the Chemical Warfare Service showed the former to be the less active.

FERRIC OXYBROMIDE HYDROSOLS

BY ARTHUR W. THOMAS AND EDNA R. HAMBURGER

RECEIVED MAY 17, 1929 PUBLISHED FEBRUARY 6, 1930

In a study of the behavior of ferric oxychloride hydrosols[1] previously reported[2] from this Laboratory, it was suggested that the nature of the anion was dominant in the behavior of hydrosols of this type. For example, while a ferric oxychloride hydrosol can be diluted with alcohol without precipitation of the dispersed phase, the addition of alcohol to a ferric oxysulfate hydrosol provokes instant precipitation. This is in accordance with the fact that chlorides in general are soluble in alcohol while sulfates are not. The above mentioned difference between ferric oxychloride and ferric oxysulfate hydrosols together with quantitatively measured behavior of ferric oxychloride sols on dialysis led to the contention that the stability of "ferric oxide" hydrosols resides in the solution forces of the ferric salts or of the basic ferric salts which are part of the colloidal aggregate.[2]

A chemical mechanism accounting for the precipitation of ferric oxychloride hydrosols by silicic acid–sodium silicate and arsenious sulfide–hydrogen sulfide hydrosols was also offered[3] showing that the chemical nature of all ions of a hydrosol must be reckoned with rather than merely considering the charge of the colloidal micelle. This idea is not new; Linder and Picton[4] in 1892 suggested that "the aggregates of ferric hydrate are held in solution almost entirely by their loose union with surrounding molecules of ferric chloride, themselves in a state of more perfect solution." In 1905 they concluded that the colloid was an hydroxychloride and not a hydrate associated with ferric chloride or free hydrochloric acid.

In this connection it is interesting to note that Freundlich and Wosnessensky[5] prepared a ferric oxide hydrosol by oxidizing a solution of iron carbonyl with hydrogen peroxide. Boiling the sol for a few minutes precipitated it; bubbling carbon dioxide through the coagulum repeptized it—this sol possesses the properties of a bicarbonate.

The present investigation was undertaken with the aim of extending

---

[1] While sols of this type are generally described as hydrous ferric oxide peptized by certain cations, it is necessary in this paper as a result of certain differences in properties caused by the anion of the peptizing electrolyte, to include the name of the anion. The name hydrous ferric oxide sol may be applied accurately only in one case described in the literature, *i. e.*, the dispersion prepared and described by C. H. Sorum, THIS JOURNAL, 50, 1263 (1928).

the knowledge of the nature of "iron oxide" sols particularly from the angle of the "peptizing agent" which is responsible for and governs the stability and reaction of sols of the hydrous ferric oxide type. Ferric oxybromide sols were selected for this purpose.

Ferric oxybromide hydrosols have been known since **1859.** In that year Ordway[6] reported that "bromohydric acid takes up at least five equivalents of ferric oxyd" and Béchamp[7] that ferric bromide dissolves gelatinous ferric hydroxide as readily as ferric chloride. The work of these two investigators seems to constitute the only account of ferric oxybromide hydrosols in the literature.

Preparation

Since ferric bromide is not readily available, Béchamp's method could not be used. At first an attempt was made to prepare the sols by peptizing the freshly precipitated ferric oxide obtained from a Graham ferric oxychloride sol (by addition of ammonium hydroxide) with hydrobromic acid, reprecipitating with ammonium hydroxide and repeptizing with hydrobromic acid until chloride ion was absent. This method proved unsatisfactory due to the difficulty of removing all traces of chloride and the following procedure, the oxidation of ferrous bromide by hydrogen peroxide, was adopted. This is the same as Neidle's[8] method of preparing ferric oxychloride sols.

The details of the method are as follows: to each 100-g. portion of pulverized iron is added 500 cc. of 40% hydrobromic acid and one liter of distilled water. The mixture is heated gently and stirred constantly. As the rapid evolution of gas slows dawn somewhat the temperature may be raised. The reaction is assumed to be complete when the evolution of hydrogen ceases and oxidation to the ferric condition is just starting (as evidenced by traces of red, precipitated ferric oxide). The greenish-blue ferrous bromide solution is then filtered from the residual iron, carbon, etc., and oxidized by slowly adding hydrogen peroxide,[10] stirring constantly until ferrous ion test is negative. When approaching the end-point, the odor of free bromine is also observed. This free bromine is removed in the first twenty-four hours of dialysis.

Immediately after preparation, the sol is dialyzed against running water for twelve to twenty-four hours and then dialyzed against distilled water until the desired "purity" is obtained.

All sols dialyzing against distilled water, unless otherwise mentioned, were stirred by means of a current of compressed air washed with dilute sulfuric acid, dilute sodium hydroxide, passed through a column of glass beads and of absorbent cotton.

[8] Neidle, THIS JOURNAL, 39, 2334 (1917).

[9] Pulverized iron (of 99.7 to 99.9% purity) kindly furnished by the Hawthorne Works of the Western Electric Company was used. According to analysis supplied by the donor, the following impurities were present: carbon, 0.022–0.058%; sulfur, 0.003–0.013%; silicon, 0.034–0.117%; manganese, 0.023–0 048%; phosphorus, 0.004–0.028%.

[10] The proprietary "Dioxygen" was used.

Tests with Laar's[11] reagent (sulfuric acid solution of diphenylamine) for the presence of bromate, peroxide, etc., gave negative results with sols prepared in this fashion.

Ferric oxychloride hydrosols were prepared in the same manner, using 100 g. of pulverized iron, 200 cc. of concd. C. P. hydrochloric acid and 1200 cc. of distilled water.

Analytical Procedure

The analytical results herein reported are expressed in terms of milli-equivalents per liter. In all cases analyses were made for total iron and total halide content.

Iron.—A portion of the sol evaporated to fuming with sulfuric acid to remove all bromine was then diluted, reduced in a Jones reductor in the customary manner and titrated with standardized potassium permanganate solution.

Halide.—To a portion of the sol 10 cc. of 16 M nitric acid, 10 cc. of 0.1 M silver nitrate and water were added to a volume of 125 cc. This mixture was heated overnight at about 60° in a dark place.[12] Check analyses made on potassium bromide solutions proved that no bromine was lost by this method.

Comparative Behavior of Ferric Oxybromide and **Ferric** Oxychloride Hydrosols.—A series of sols of varying Fe/halide ratios was prepared and the following properties measured: sodium sulfate liminal value, viscosity and electrical conductivity. While attention was concentrated upon the ferric oxybromide sols, a sufficient number of ferric oxychloride hydrosols were studied, however, to enable comparisons to be drawn between the two. All sols were "pressure" dialyzed in nitrocellulose bags against distilled water at room temperature until the desired ratio of iron to halide was obtained. They were then diluted to a concentration of about 400 milli-equivalents of iron per liter.

Since it was found that ferric oxybromide sols hydrolyze readily, they were used as soon as feasible after being prepared.

By liminal value is meant the average in millimoles of the amount of a salt which just fails to precipitate and the amount which just does precipitate the sol under given conditions. The technique adopted was as follows: into one series of test-tubes were pipetted 5-cc. portions of the sol, and in another series of tubes were placed 5-cc. volumes of salt solutions of varying concentration. The electrolyte solution was added to the sol by pouring slowly down the side of the tube and the contents were mixed by inverting twice. The tubes were then centrifuged for two minutes at 1300 revolutions per minute (radius, 28 cm.). The end-point was judged to be the tube in which the supernatant solution above the precipitate was clear and colorless, the supernatant solution of the tube just preceding being a pale yellow, and that of the tube following also being clear and colorless. The values in the tables are the averages of the readings of two series of measurements.

---

[11] Laar, *Ber.*, 15, 2086 (1882).

[12] It is interesting to note that freshly prepared sols are thus decomposed much more readily than aged ones. The former are decomposed in the cold, whereas the latter require the elevated temperature for decomposition in the time mentioned.

Viscosity measurements were made at 25 ± 0.1° in an Ostwald viscometer. Readings are recorded as time of outflow, since the only significance which they have is a comparative one. The outflow time for water was 80.0 seconds.

The conductivity measurements were made at 25 ± 0.01° using a Freas cell with polished platinum electrodes, a circulary slide wire bridge and variable air condensers. The source of the alternating current was a Leeds and Northrup Vreeland oscillator. When not in use the cells were kept short-circuited as advised by Morgan and Lammert.[13] Parker and Parker's[M] revised value for the specific conductivity of 0.01 *N* potassium chloride was employed in determining the cell constant. Certain difficulties were encountered, rendering the experimental error about ±2.5%.

The results obtained for ferric oxybromide hydrosols are recorded in

[13] Morgan and Lammert, THIS JOURNAL,, **45**, 1672 (1923); **46**, 1117 (1924).

[14] Parker and Parker, *ibid.*, 46, 312 (1924).

Table I and plotted in Fig. 1. Similar results for ferric oxychloride hydrosols are given in Table II and in Fig. 1.

The measurements charted in Fig. 1 were not carried beyond the ratio Fe/Cl = 30 due to irregularities caused by incipience of precipitation in the ferric oxychloride sols. Incipience of precipitation is not observed in ferric oxybromide hydrosols until the Fe/Br ratio is much greater.

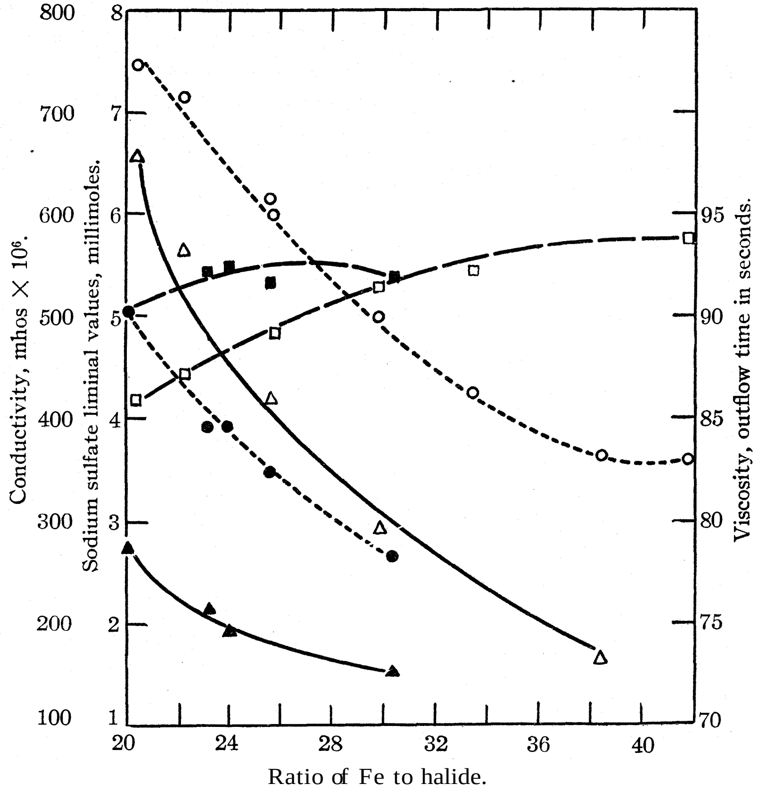

Fig. 1.—Variation of certain properties with variation of Fe : halide ratio. ●, **Liminal** values, ferric oxychloride sols; O, liminal values, ferric oxybromide sols; ■, viscosities, ferric oxychloride sols; O, viscosities, ferric oxybromide sols; ▲, conductivities, ferric oxychloride sols; A, conductivities, ferric oxybromide sols.

It is seen that as the Fe/halide ratio increases, the conductivity and sodium sulfate liminal value decrease, while the viscosity increases in each case. In every case, however, at a given Fe/halide ratio the conductivity of a ferric oxychloride hydrosol is less than that of a ferric oxybromide sol, and the dispersed phase of a "chloride" sol is more easily salted out by sodium sulfate than the dispersed phase of a "bromide" sol.

Pairs of ferric oxybromide and oxychloride hydrosols were dialyzed simultaneously as nearly as possible to the same Fe/halide ratio and the concentrations then adjusted so that they were identical in each pair. Liminal values were then determined for sodium chloride, sodium bromide and sodium hydroxide, using the technique previously described. In order to obtain a sharply defined precipitate it was necessary to centrifuge the coagula caused by sodium chloride and sodium bromide for three minutes. For purposes of comparison, the liminal values for sodium sulfate are repeated from the previous tables. The results obtained are reported in Tables IIIA and IIIB.

TABLE III

LIMINAL VALUES FOR ELECTROLYTES ON FERRIC OXYCHLORIDE AND FERRIC OXYBROMIDE HYDROSOLS OF CORRESPONDING FE/HALIDE RATIO

A. SOLS PREPARED BY ROOM TEMPERATURE DIALYSIS

Sol	Fe/halide equiv.	Millimoles/liter NaCl	NaBr	Na_2SO_4	NaOH	$K_4Fe(CN)_6$
Cl-10	25.7	162	395	3.49	6.76	..
Br-42A	25.5	320	644	5.96	11.7	..

Fe/liter = 415 milli-equiv.

B. SOLS PREPARED BY HOT DIALYSIS

Sol	Fe/halide equiv.	Millimoles/liter NaCl	NaBr	Na_2SO_4	NaOH	$K_4Fe(CN)$
Cl-4P2	23.7	202	324	4.45	...	3.13
Br-37	24.4	381	787	6.37	...	3.25

Fe/liter = 440 milli-equiv.

The data in Table III show in general that ferric oxybromide sols are less easily salted out than corresponding[15] ferric oxychloride sols.

Aging Experiment.—Ferric oxybromide hydrosols when freshly prepared are clear brownish-red when viewed by either reflected or transmitted light. It was noticed that after such sols stand at room temperature for about six months they assume a turbid appearance to reflected light while still clear brownish-red to transmitted light. From past experience with ferric oxychloride sols in this Laboratory, it is known that the latter undergo such a change only after several years' standing.

Repeatedly in the preparation of these sols it has been noticed that ferric oxychloride hydrosols require at least twice the time to reach a given Fe/halide ratio by dialysis that ferric oxybromide sols do, thus indicating a greater rate of hydrolysis of the latter. Evidence for greater degree of hydrolysis is suggested by the fact that while ferric oxychloride sols of the concentration and Fe/Cl ratio studied here show a P_H value of 4.9,[2] the P_H value of similar freshly prepared ferric oxybromide hydrosols is indicated to be about 3, by means of the quinhydrone electrode, taking initial potentials.

[15] The word *corresponding* is used *here* and subsequently to mean hydrosols of the same total iron content and like ratio of total iron to total halide.

Several hydrosols were submitted to accelerated aging by enclosing in securely stoppered pyrex glass containers which were placed in an oven at 90 ± 2°. The results for two hydrosols are recorded in Tables IV and V and in Fig. 2.

The increase in conductivity and the decrease in viscosity upon heating indicate that the micelles undergo hydrolysis and dehydration. Comparing the curves for the two sols, it is seen that ferric oxybromide hydrosol micelles hydrolyze much more rapidly than ferric oxychloride micelles.

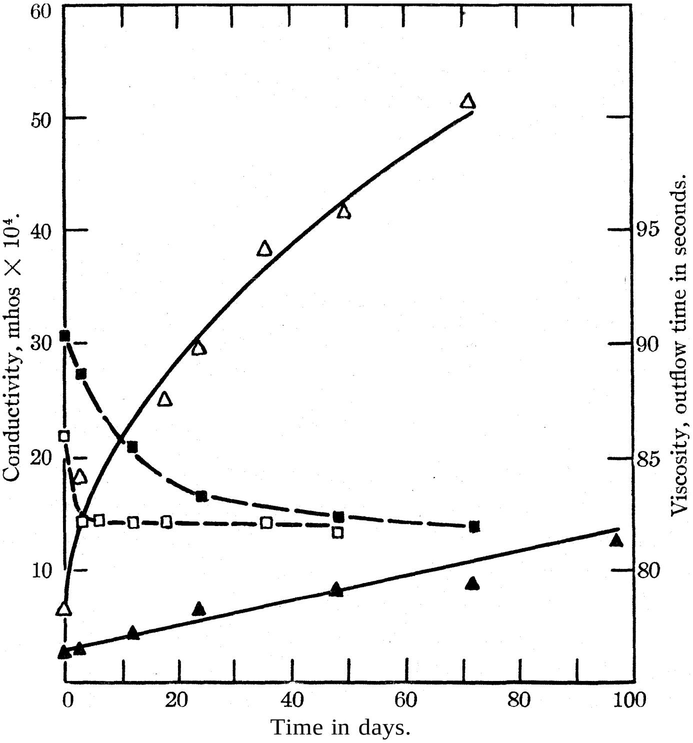

Fig. 2.—Change in certain properties as *a* function of time at 90°.
■, Viscosity, ferric oxychloride sol; □, viscosity, ferric oxybromide sol; ▲, conductivity, ferric oxychloride sol; A, conductivity, ferric oxybromide sol.

It will be recalled that the data in Tables I and II indicate that ferric oxybromide sols are hydrolyzed to a greater extent than corresponding ferric oxychloride sols.

Since the viscosity of a given ferric oxyhalide sol varies with degree of hydrolysis, it is evident that the ratio of iron to halide is insufficient for exact definition of a hydrosol of this type.

Greater hydrolysis of the dispersed phage results in micelles richer in

TABLE IV

AGING OF FERRIC OXYBROMIDE HYDROSOL NO. 44[a]

Heated, hours	Appearance[c]	Visc., sec. outflow	Cond., mhos × 10^5
0	A	86.0	66
3	B	82.1	183
12	B	82.1

90	H		. .

[a] The concentration was 416 milliequivalents of Fe per liter; ratio Fe/Br = 20.4.

TABLE V

AGING OF FERRIC OXYCHLORIDE HYDROSOL NO. 11[b]

Heated, hours	Appearance[c]	Visc., sec. outflow	Cond. mhos × 10^5
0	A	90.4	28
3	B	87.6	29
12	B	85.0	45
24	B	83.3	63
48	C	52.4	83
72	F	. .	89
97	G	. .	125
120	G	. .	131
1 month	H	. .	

[b] Same concentration as Sol 44; ratio Fe/Cl = 20.0.

[c] The key letters under "appearance" have the following significance: A, characteristic color; B, redness of characteristic color intensified; C, B plus slight yellow precipitate; D, brownish turbidity to reflected light just starting; E, chocolate brown to reflected light, clear red brown to transmitted light; F, chocolate or orange brown somewhat turbid to transmitted light, yellow sediment; G, orange, absolutely opaque, usually a layer of clear red sol above and a layer of yellow sediment; H, complete precipitation, orange, finely divided solid covered with clear supernatant liquor which gives a positive test for halide ion.

ferric oxide and poorer in halide, and consequently less stable, yet more sodium sulfate is required for the salting out of ferric oxybromide sols than for corresponding ferric oxychloride sols despite the greater hydrolysis of the former, thus showing the significance of the anion or anionogen upon the properties of sols of the ferric oxide type.

Summary

1. As the ratio of iron to halide in ferric oxybromide and ferric oxychloride hydrosols diminishes, the viscosity increases while the liminal value and electrical conductivity decrease.
2. Ferric oxybromide sols have higher electrical conductivities than corresponding ferric oxychloride sols.
3. The micelles of ferric oxybromide sols appear to hydrolyze more readily and to a greater extent than those of corresponding ferric oxychloride sols.
4. The dispersed phase of ferric oxychloride sols is more easily salted out than that of the corresponding ferric oxybromide sols.

A NOTE ON THE DETECTION AND ESTIMATION OF COBALT IN PRESENCE OF NICKEL

BY ABRAHAM LIEBERSON

RECEIVED JUNE 11, 1929 PUBLISHED FEBRUARY 6, 1930

The methods to be described provide for the colorimetric detection of cobalt in the presence of 300 to 400 times its weight of nickel, and for the rapid and accurate colorimetric determination of 0.5 mg. (or 0.25 mg.) of cobalt in the presence of as much as 10 times its weight of nickel. Since nickel and cobalt are readily separated from other metallic ions, the method should prove useful, although, as will be detailed later, certain other cations give a reaction similar to that of cobalt.

The colorimetric reaction employed is the reduction by cobalt of arsenophosphotungstic acid in presence of cyanide whereby intensely blue tungstous acid is formed and the cobalt is oxidized to cobalticyanide. Under identical conditions nickel fails to reduce the complex tungstic acid reagent.

Solutions Required

1. Reagent.—The arsenophosphotungstic acid[1] is prepared by placing 100 g. of pure sodium tungstate in a liter pyrex flask and dissolving in about 600 cc. of water; **50** g. of pure arsenic acid (As_2O_5) is now added, followed by **25** cc. of 85% phosphoric acid and **20** cc. of concentrated hydrochloric acid, as condensing agent. The mixture is boiled for twenty minutes, cooled and diluted to one liter. The reagent appears to keep indefinitely.

2. Sodium Cyanide.—A 5% solution of sodium cyanide, to which 2 cc. of concentrated ammonia have been added per liter. This solution should be prepared fresh about every two months.

3. The standard cobalt solution, containing **0.5** mg. of cobalt in 10 cc. of solution, is prepared by dissolving in a liter of distilled water **1.25** g. of pure $CoCl_2 \cdot H_2O$, or **2.02** g. of $CoCl_2 \cdot 6H_2O$ or **2.47** g. of $Co(NO_3)_2 \cdot 6H_2O$. To obtain the standard, the solutions are diluted **1:10** before using.

For the qualitative detection of cobalt the following procedure is best. To 5 cc. of unknown solution in a test-tube add **2** cc. of the arsenophosphotungstic acid reagent, followed by 2 cc. of the 5% sodium cyanide; **0.01** mg. of cobalt gives immediately a recognizable blue color. Nickel, unless present in such concentration as to obscure a faint blue color by its dark green shade, does not interfere with this color test. Thus **0.01** mg. of cobalt can be detected in the presence of **2** or **3** mg. of nickel. Stannous tin, manganese, ferrous iron, mercurous mercury, copper and sulfide are interfering ions and must not be present. The fact that nickel does not react with the reagent permits the testing of nickel salts by this method for the presence of cobalt and iron as impurities. This qualitative test is made as follows. Add to **5** cc. of approximately 1% nickel salt, **3** cc. of reagent and enough 5% sodium cyanide just to redissolve the nickel cyanide that is first formed on the addition of the cyanide. An immediate blue or greenish-blue solution is formed if iron or cobalt is present.

The method for the estimation of cobalt in the presence of nickel is as follows.

---

[1] S. R. Benedict, *J. Biol. Chem.* **51, 187 (1922).**

To 10 cc. of approximately neutral cobalt solution containing about 0.5 mg. of cobalt, and also to 10 cc. of standard cobalt solution containing exactly 0.5 mg. of cobalt,[2] add 3 cc. of arsenophosphotungstic acid reagent. Invert once. Add 4 cc. of the cyanide solution from a buret. Invert both tubes once simultaneously. Compare the standard and unknown blue solutions in a colorimeter. For best results the colorimetric reading should be made from two to ten minutes after inversion of the tubes. The ratio of the reading of the standard to the reading of the unknown, multiplied by 0.5 gives the mg. of cobalt in 10 cc. of unknown solution. The colors obtained match exactly. No turbidity develops even after twenty-four hours of standing. Nickel does not interfere with this test except that if the 10 cc. of solution contains more than 5 mg. of nickel, nickel cyanide tends to be precipitated when the cyanide is added. If more cyanide is used (*i. e.*, 6–8 cc.), more nickel can be kept in solution, but the tendency to turbidity is increased. In the presence of up to 5 mg. of nickel, the readings are accurate to within about 1% (0.005 mg. of cobalt). The ions mentioned above which interfere with the qualitative reaction must be absent. There is another group of metallic ions which, although not giving the test directly, may interfere if present in appreciable amounts (*i.e.*, more than 4 or 5 times the concentration of cobalt) by yielding a turbid solution. This group includes NH_4, Mg, Ca, Sr, Ba, Sn, Sb, As, Cd, Bi, Pb, Ag. Finally, it should be noted that colored solutions of manganese and chromium obviously interfere with the proper color readings between standard and unknown.

The essential accuracy of this method was demonstrated by the determination of the cobalt present in pure cobalt solutions and in potassium cobaltinitrite precipitates (after converting the cobaltinitrite to a cobaltous salt by heating with *N* hydrochloric acid. The results obtained in a long series of determinations in the latter case showed a maximum deviation from the theoretical of 1.5%, with an average deviation of about 0.5%.

In conclusion the writer wishes to express his indebtedness to Professor S. R. Benedict, whose help has been essential to the completion of this work.

SOME NEW EXPERIMENTS ON THE CHEMICAL EFFECTS OF X-RAYS AND THE ENERGY RELATIONS INVOLVED

BY GEORGE L. CLARK AND LUCY W. PICKETT

RECEIVED JULY 1, 1929 PUBLISHED FEBRUARY 6, 1930

Although the photochemical action of x-radiation is of interest because of its possible significance in interpreting the physiological effects, very few studies in this field have been made until recently. Within the last two years, however, the oxidation of ferrous to ferric sulfate has been studied by Fricke and Morse,' oxyhemoglobin to niethemoglobin by Fricke and Petersen,[2] the inversion of sugar by Reinhardt and Tucker,[3] and the

---

[2] If less than 0.5 mg. of cobalt is available, the volume of solution and of reagents used can be reduced correspondingly.

decomposition of iodoform,[4] hydrogen peroxide and potassium persulfate[5] by Glocker. These researches have established the facts that the photochemical action is very small and is independent of the wave length of the radiation within limits of about 0.2 to 0.8 Å. Studies of the coagulatory action of x-rays on colloids have been carried on recently by Fairbrother and co-workers.[6]

TABLE I

RESULTS OF EXPERIMENTS ON CHEMICAL EFFECTS OF X-RADIATION OF EFFECTIVE WAVE LENGTH 0.24 Å.

Initial substance	Change	Remarks
Anthracene	No change in 200 hours	
Dianthracene	No change in 200 hours	
Maleic acid	No change in 200 hours	
Fumaric acid	No change in 200 hours	
Iodine and benzene	Absorption of iodine 6.5%	
Ferrous sulfate	40% oxidation to ferric	Agreement with Fricke's result
Ferric sulfate	No change	Kailan reported slight reduction by radium rays
Potassium iodide	Iodine freed	Quantitative results below
Potassium nitrate	O_2 and KNO_2	
Potassium iodate	I_2 and KI	Reported by Chamberlain
Potassium permanganate	MnO_2	Reduction to Mn^{++} noted by Chamberlain
Methylene blue in acetone	No change	
Sucrose	Slight inversion	Effects of presence of colloidal lead and lead nitrate, and of simultaneous irradiation with ultraviolet and x-rays presented below
Dyes	No change	
Triphenylmethane		
Diphenylmethane		
Azoindigo		
Condensation		
Benzaldehyde + benzaldehyde		5% in 5 hours of raying
Benzaldehyde + acetophenone		35%
4-Hydroxy-benzaldehyde + acetophenone		75%
4-Hydroxy-benzaldehyde + benzaldehyde		19%
Acetone + acetaldehyde		Very small
Piperonal + acetophenone		14%
Colloid coagulation		
Pb	Stabilized	
Albumin	Coagulated	
Clay	Coagulated	Pure kaolin unaffected

The present researches were undertaken in order to determine what types of reactions are sensitive to radiation and, secondly, to study the energy relations involved. In order to satisfy the first point, a number of reactions were investigated. The procedure followed in general was to expose the specimen in a thin-walled pyrex bulb to polychromatic radiation from a tungsten target of effective wave length 0.24 Å. at a distance of eight inches from the focal spot. In each case a control of a similar bulb treated in the same manner but protected from radiation by a lead shield was used. The qualitative results obtained are shown in Table I.

Details of Experiments on Chemical Changes by X-Rays

Ferrous Sulfate ⟶ Ferric Sulfate.—A 10-cc. solution of ferrous ammonium sulfate in 0.04 N H_2SO_4 was exposed to x-rays from a molybdenum tube for twenty hours and then titrated with 0.01010 $KMnO_4$: exposed, 8.18 cc. required; blank, 5.85 cc. required. Experiments in which sealed bulbs of ferric sulfate were given exposures of several months gave negative results.

Anthracene ⟶ Dianthracene.—A saturated solution of anthracene in phenetole was exposed to radiation for forty-six hours with no effect.

A saturated solution of anthracene in xylene was exposed for several hours to ultraviolet light from a mercury arc in quartz and a considerable precipitate of dianthracene was formed. A portion of the original solution of anthracene sealed in a bulb, and a second bulb containing a suspension of the dianthracene formed in xylene, were exposed to over 150 hours of raying and no apparent change in either took place.

Iodine and Benzene.—A solution of iodine in benzene sealed in a bulb was exposed to x-rays. One-cc. samples of this and of a similar sample unexposed were titrated with sodium thiosulfate. Results—cc of 0.10 N $Na_2S_2O_3$ used: unexposed, 35.70, 35.70; exposed, 32.37, 32.27.

Acetone, Iodine and Water.—Apparently unaffected by x-rays. The high temperature coefficient makes this reaction impracticable for study.

Inversion of Sugar in the Presence of Lead Nitrate.—The presence of lead nitrate apparently aids the inversion of sugar under the action of x-rays but the effect is probably secondary due to a change in P_H. Results obtained after twenty-three hours of exposure to radiation from a tungsten target tube at 75,000 volts and 4 to 5 milliamperes lasting over an interval of one week were as follows.

Solution	Saccharimeter reading at 20°	P_H
Sugar solution unexposed	38.8	5.8
Sugar solution exposed to x-rays	38.4	5.8
100 cc. of sugar solution +1 cc. of 10% $Pb(NO_3)_2$	38.2	5.8
100 cc. of sugar soln. +1 cc. of 10% $Pb(NO_3)_2$ exposed to x-rays	36.4	$4.4 < P_H < 5.2$

Condensations of Aldehydes and Ketones

Reactions in the field of organic chemistry offer many opportunities for the study of the effects of x-radiation with the possibility that much larger changes may be observed than in the examples of inorganic compounds thus far considered. As one promising type was chosen the condensation reaction of aldehydes and ketones, particularly on account of the known photochemical reactions of formaldehydes to form sugars. Claisen and Claparède[7] prepared phenylstyryl ketone by mixing benzaldehyde and acetophenone in equal proportions, saturating with hydrogen chloride gas and allowing to stand in the cold for twelve hours. The hydrogen chloride was then removed from the product by heating the mixture on the water-bath for several hours. The ketone so produced was crystallized from petroleum ether with a yield of **32%.** While this reaction has the disadvantage that it will proceed without radiation, it was thought that there might be a distinct catalytic effect in irradiation. Accordingly two samples of each of the several mixtures were placed in exactly the same place, at 50°, one being entirely protected by lead as a control and the other exposed to x-rays from a tungsten target tube with an effective wave length of 0.24 Å. for a period of five hours.

RESULTS OF SERIES OF EXPERIMENTS

No.	Aldehyde	G.		G.	HCl	Product			
						Exposed to x-rays		Control	
						G.	%	G.	%
1[a]	Benz-	15	Acetophenone	15	2 g.	10.5	35	7.0	23
2	4-OH-Benz-	1	Acetophenone	1	5 drops	1.5	75	1.2	60
3	4-OH-Benz-	1	Benzaldehyde	1	5 drops	0.38	19	0.27	13.5
4[b]	Benz-	30	......	..	1 cc. (concd.)	1.5	5	1.4	4.7
5"	Piperonal	5	Acetophenone	Excess	10 drops	1.4	14	0.6	6
6	Acetal-	..	Acetone.—Two samples were treated in similar manner but only a small amount of dark red oil was formed, probably due to the formation of para-acetaldehyde.						
7	Salicyl-	..	Acetophenone.—The product formed only with exposure to x-rays is a dark red oil, and not chalcone, which the usual condensation gives. The oil could not be crystallized from alcoholic solution.						

[a] Benzaldehyde + acetophenone ⟶ phenyl styryl ketone ($C_6H_5CH{=}CHCOC_6H_5$).

[b] Melting point of product 125°, probably stilbene, $C_6H_5CH{=}CHC_6H_5$.

[c] Melting point of product (both) 119–120°, colorless needles.

Summarizing the results of these reactions, it may be concluded that the condensation of aldehydes with ketones is markedly catalyzed by x-radiation, while the condensation of aldehyde with aldehyde is affected not at all or to only a small extent by the rays.

It is evident from many of these results that sensitivity to ultraviolet light is no criterion for prophesying a sensitivity to radiation in the region of 0.2–0.3 Å. The second conclusion to be noted is that the reactions most affected are those which involve oxidation in aqueous solution.

The above results shed no light on the question of the physiological action of x-rays. No chemical action yet studied, with the exception of the reduction of the silver bromide on a photographic plate, the oxidation of ferrous sulfate and possibly of the new aldehyde and ketone conden-

---

[7] Claisen and Claparède, *Ber.*, 14, 2463 (1881).

sation reactions presented in this paper, is of the same order of magnitude as that change which occurs in body tissue. It is possible that some chemical reaction sensitive to radiation, whose counterpart has not yet been discovered, may underlie physiological action, or that the latter depends on such an effect as the coagulation of a colloid. Several examples of the latter were investigated such as the coagulation of egg albumin and of colloidal clays, which give changes of larger magnitude than those observed in the case of chemical reactions. Further studies were discontinued inasmuch as several recent papers by Fairbrother have appeared on the subject.

A Test of the Theory of Hydrogen Peroxide Formation in the Photochemical Oxidation of Potassium Iodide and the Reduction of Potassium Nitrate

Inasmuch as experiments by Glocker have shown that x-radiation influences the decomposition and also the formation of hydrogen peroxide, it seemed possible that the oxidations noted in aqueous solution were merely secondary reactions following the production and subsequent decomposition of hydrogen peroxide from water and oxygen, The following set of experiments was designed to test this hypothesis.

1. Two thin-walled pyrex tubes were filled with a 2% potassium iodide or 0.1 *M* potassium nitrate solution. Through the following devices one was kept saturated with oxygen while the other was freed of the gas, and both were exposed to the same dose of radiation.

(a) One was boiled to expel oxygen, cooled in a nitrogen atmosphere and sealed. The other was provided with an outlet into an absorption bulb of potassium iodide not exposed to the radiation, and a slow stream of oxygen or air bubbled through during the exposure.

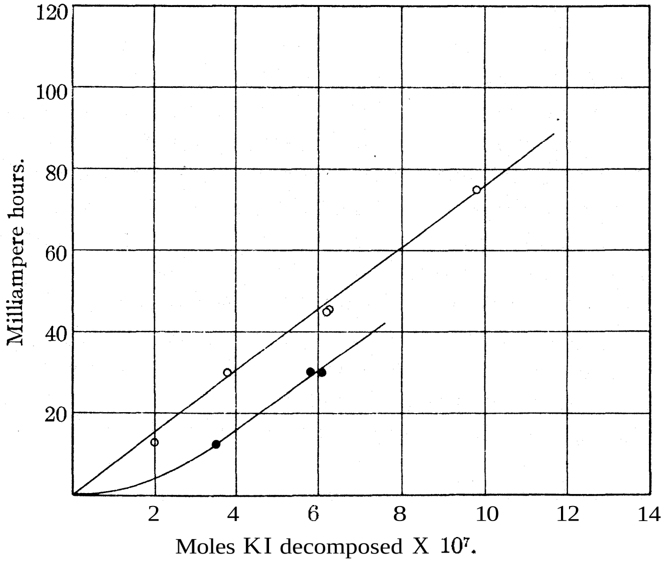
(b) One was heated at 100° to expel oxygen and sealed at that temperature; the other was saturated with oxygen at 0° and sealed.

The experimental data, which are illustrated by the accompanying graph, Pig. 1, revealed the following facts. (1) The decomposition of potassium iodide in the absence of oxygen is a straight line function of the dosage of radiation. (2) The decomposition of potassium iodide in the *presence* of an excess of oxygen takes place to a larger extent, and is not in direct proportion to the amount of radiation. (3) The decomposition of potassium nitrate is a straight line function of the dosage of radiation, and is independent of the presence of oxygen. (4) The ratio of molecules of potassium nitrate to molecules of potassium iodide decomposed by the same amount of radiation is 2.90.

The following conclusion might, therefore, be drawn from the data: the decomposition of potassium iodide in the first case (absence of oxygen) is independent of any hydrogen peroxide mechanism which requires the presence of oxygen. Even if the objection should be raised that a very slight amount of oxygen might have been retained by the water under experimental conditions, the direct proportionality between dosage of radiation and amount of change would indicate that the concentrations of the initial reactants do not change appreciably, a condition which is true for the water and potassium iodide but not for the oxygen. The reaction occurring would seem to be

$$KI + H_2O = KOH + I + {}^1/_2H_2$$

Though this reaction would involve a large increase in free energy, the amount of energy absorbed in the radiation is much greater. The production of hydrogen from water under the radiation by x-rays has been noted by Fricke.



○, In absence of oxygen; ●, in presence of oxygen.

Fig. 1.

In the presence of excess oxygen, however, there is a possibility of the formation and subsequent decomposition of hydrogen peroxide suggested by Glocker, and consequent freeing of iodine. This effect might either supplant or merely add to the reaction discussed above; in either case more iodine would be freed, and the relation between dosage and chemical change might not be linear. This conclusion is consistent with the experimental data.

The same reasoning shows that the decomposition of potassium nitrate is independent in any case of the hydrogen peroxide formation. The reaction occurring is $KNO_3 = KNO_2 + {}^1/_2O_2$. This is consistent with the tact that hydrogen peroxide does not affect a solution of potassium nitrate but oxidizes a solution of potassium iodide.

Thus it is concluded that the mechanism of the formation and subsequent decomposition of hydrogen peroxide is not essential for oxidation in aqueous solutions. In certain special cases, however, it may play a contributory part in the total effect.

In connection with the above results, tests were made for the presence of ozone and hydrogen peroxide. A stream of oxygen saturated with water vapor was allowed to flow past a thin glass window which was exposed to radiation. The gas was then passed into an absorption tube containing potassium iodide solution. No trace of free iodine was found after an exposure of fifteen hours, during which time 12 liters of oxygen passed the window, thus indicating that the formation of ozone, unless immediately decomposed, occurred to a negligible extent.

In order to test for hydrogen peroxide, a tube of distilled water was exposed to radiation for nine hours and opened into a solution of potassium iodide. No free iodine was detected. Glocker reports the detection of a small amount of hydrogen peroxide under similar circumstances. Inasmuch as radiation has been conclusively shown to cause the decomposition of hydrogen peroxide, it is probable that a small amount may have formed and decomposed before detection.

Experiments with Simultaneous Irradiation by Ultraviolet Light and X-Rays

Some recent evidence has been obtained in this Laboratory that the physiological effects of x-rays, for example, on fungi are accentuated by previous or simultaneous ultraviolet irradiation; in other words, the effects of the two kinds of rays are not additive. It was then thought advisable to test this observation with inorganic substances.

Two similar quartz weighing bottles containing 12 cc., each filled with 0.01 M potassium iodate are arranged so that the light from a mercury arc lamp is evenly distributed between them. One is in the path of x-rays, from which the other is shielded by a lead screen. The temperature coefficient of the reaction is low, but the temperatures are maintained as nearly equal as possible by cooling with a stream of water or of air from two equal openings in the same nozzle. Inasmuch as there is no procedure suitable for directly determining such small amounts of iodine and potassium iodide in the presence of potassium iodate, the following method was adopted: 10 cc. of the reaction mixture was shaken in a separatory funnel with chloroform. The chloroform layer was drawn off and the residue weakly acidified with 0.4 cc, of N sulfuric acid. Under these conditions the potassium iodide and potassium iodate react to give iodine, which is extracted with chloroform. The extracts are titrated with 0.001

N sodium thiosulfate. In a run of three and one-half hours at 70 k. v. and 5 m. a., the following results were obtained

		U. v.	U. v. + x-rays	x-rays
Cc. of 0.001 *N* thiosulfate used	I	0.20 cc.	0.13 cc.	....
	KI	0.10 cc.	0.20 cc.	....
	Total	0.30 cc.	0.33 cc.	0.03 cc.

In two other experiments, where the difference was measured qualitatively by the depth of color in the chloroform layer, the potassium iodide was found to be appreciably greater in the tube subjected to x-rays, while the iodine formed in the two cases seemed to be about the same with a little more perhaps in the ultraviolet alone. Apparently the effects of ultraviolet light and x-rays in this case are, within experimental error, additive. The mechanism of this complicated decomposition as shown by the distribution between iodine and potassium iodide is evidently affected. The additive effect has been further verified more directly in the photolysis of potassium nitrate.

Energy Relations in the Photolysis of Potassium Nitrate by X-Rays

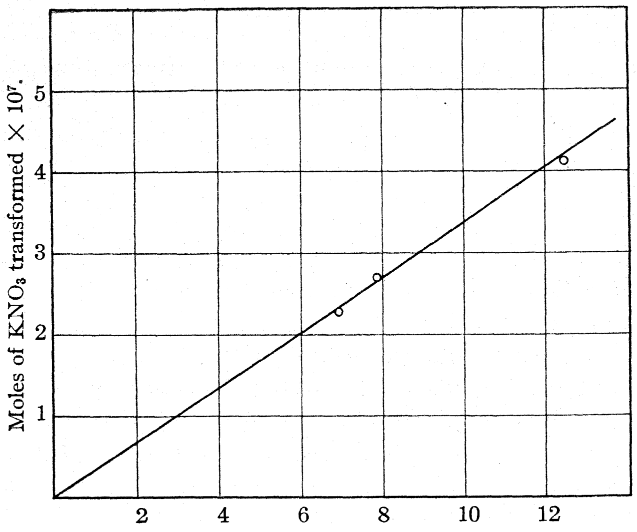
A study has been made of the energy relationships involved in the photolysis of potassium nitrate by x-rays. This reaction has been the subject of much study in connection with the photochemical action of ultraviolet light. The unfiltered radiation from a tungsten target Coolidge tube, operating at 105 k. v. as measured by a sphere gap and 3 m. a., was used in this work. The effective wave length, measured by the Duane method, which involves the determination of the thickness of aluminum which has the same absorbing power as 1 mm. of copper, was found to be 0.236 . The intensity and dosage in "*r*" units[9] of the radiation were measured by a small air wall ionization chamber constructed of Acheson graphite which analyzed as containing 0.2% impurity, and an electrode of aluminum which contained 0.3% iron. The walls of the chamber were 1 mm. thick and the volume 0.999 cc. The saturation current was measured by a Lindemann electrometer calibrated with a standard cell. The solutions used were of 0.01 M potassium nitrate contained in pyrex glass bulbs which were blown with thin-walled flat sides. Intensity measurements were made of the incident radiation and of the radiation which had passed through the solution. From measurements of the total area exposed the total amount of energy absorbed could be computed. The solutions

---

[8] Clark, "Applied X-Rays," McGraw-Hill Book Co., New York, 1927, p. 25.

[9] The international "*r*" unit adopted by the International Congress of Radiology at Stockholm in 1928 is the quantity of x-radiation which, when the secondary electrons are fully utilized and the wall effect of the chamber is avoided, produces in 1 cc. of atmospheric air at 0° and 76 cm. of mercury pressure, such a degree of conductivity that one electrostatic unit of charge is measured at saturation current.

were analyzed for nitrite by the Warburg method as modified by Villars,[10] using weight burets and 0.001 N thiosulfate.



Total energy absorbed in *r* units ÷ 36,000.
Fig. 2.

The results of three entirely independent experiments illustrated in Fig. 2 are as follows:

Expt.	Exposed area, cm.^{2}	Thickness of layer, cm.	Weight of 0.001 *N* thio, g.	Incident energy per cm.^{2} per sec., *r*	Energy absorbed per cm.^{2} per sec., *r*
1	15.48	1.62	0.4117	2.56	0.80
2	15.90	1.04	.2702	2.32	.490
3	12.91	1.12	.2291	2.40	.535

Total energy absorbed (10 hrs.)	Molecules reacting per *r* unit	Molecules per ion pair (*M/N*)	Energy cal./mole
445,680 *r*	5.58×10^{11}	0.2–0.3	1.31×10^7
280,476 *r*	5.83×10^{11}	0.2–0.3	1.25×10^7
248,400 *r*	5.58×10^{11}	0.2–0.3	1.31×10^7

Fairbrother makes the assumption that a given amount of radiation will produce approximately the same number of ion pairs in a dilute aqueous solution as are produced in the same weight of air, inasmuch as the atomic numbers of air and water are not very different. To allow for relative densities of air and dilute solution, a factor of about 1000 is involved. If this assumption is adopted, the number of molecules of potassium nitrate which react for each ion pair may be calculated

[10] Villars, THIS JOURNAL, **49**, 326–337 (1927).

$\frac{\text{total energy}}{\text{charge on electron}}$ = no. ion pairs per cc. in air $= \frac{10^{10}}{4.774} = 2.1 \times 10^9$ ion pairs per cc. in air, or approximately 2×10^{12} ion pairs per cc. in the solution;

$\frac{\text{no. molecules reacting}}{\text{no. ion pairs}}$ = molecules per ion pair

Using the data given above, the values for the latter are between 0.2 and 0.3 for this endothermic decomposition of potassium nitrate. The number of molecules per ion pair may be calculated independently from the energy in calories per mole and the work required to form one ion pair (35 volts): $(1.313 \times 10^7$ cal./mole $KNO_3)/(23{,}000 \times 35$ cal./mole ion pairs), or approximately 0.1 molecule of potassium nitrate per ion pair. This is in satisfactory agreement with the value calculated above, considering experimental difficulty, and with the order of magnitude to be expected thermodynamically.

In order to express results in terms of absolute energy, the absorption coefficients and the fraction of the absorbed energy which is converted into the kinetic energy of electrons and thence into the work of formation of ions must be known. The absorption coefficient, 0.228, as calculated from the above data agrees very closely with the value for absorption of the same wave length in water interpolated from a series of values given by Glocker.[5] The fraction of the total absorbed energy converted into work of formation of ions is the ratio of the values of the absorption coefficients for the energy given to recoil and photoelectrons to that of the total absorption coefficient. Using values recorded by Glocker, this fraction for the effective wave length used is 0.263.

The absorbed energy as measured in *r* units may be converted into ergs by the use of the formula proposed by Rump[11] and Kulenkampff's[12] experimental value of 35 volts as the work required to form one ion pair in air

$$\frac{E}{i} = \frac{\epsilon}{0.36}\left(\frac{\rho}{\tau + \sigma_v}\right)$$

where $E/i = 1944$ ergs/r unit, ρ = density, $\epsilon = 35$ volts and $\tau + \sigma_v$ = absorption coefficient attributed to recoil and photoelectrons.

Thus the total energy absorbed in Expt. 1 is $445{,}680 \times 1944$ ergs, the fraction 0.263 of which is transformed into work of ionization. At the same time 4.117×10^{-7} moles of potassium nitrate are transformed. Thus the energy rate is 1.313×10^7 cal./mole of reactant.

The heat of decomposition of potassium nitrate calculated from band spectra of oxygen and thermochemical data[13] is 1.03×10^5 cal./mole. Thus it seems evident that not more than 0.8% of the energy absorbed and utilized in formation of ions in the solution appears as chemical dissociation of the molecule of potassium nitrate.

X-Rays and Colloidal Lead

Since the discovery by Blair–Bell in England that in the treatment of cancer injection of colloidal lead followed by irradiation with x-rays materially increases the therapeutic benefits beyond those from radiation alone, there has been a great interest in the mechanism involved. There are two possibilities: that the finely divided lead produces secondary x-rays *in situ* in the tissues, or that the lead has a specific chemical effect in the tissues entirely apart from any interaction between the colloid and x-rays. In an effort to throw some light upon the mechanism, several experiments have been undertaken with colloidal lead and simple inorganic systems instead of the complex biological tissues.

Preparation of Colloidal Lead.—Solutions of colloidal lead were prepared in various dispersion media by the Bredig arc method, using pure lead electrodes of 6 mm. diameter held in an adjustable spark gap device. The beaker in which the colloid was prepared was surrounded by an ice-bath at all times. Some preparations were carried out in a nitrogen atmosphere. Much of the lead used was prepared by the following procedure. An arc was maintained for 30 minutes in 300 cc. of water redistilled from alkaline permanganate, and having a PH of 6.6 as measured by Pierre and Fudge's method. The product was centrifuged at 1200 r.p.m. for twenty-five minutes and 1600 r.p.m. for five minutes, siphoned off into containers and covered with a layer of paraffin. In some cases 0.1 cc. of 1% acetic acid was added to 30 cc. of colloidal lead before sealing.

The colloidal lead is black in thick layers and brown in thin layers or at high concentrations. It is stable for months when protected from the air but decomposes rapidly when exposed to air to form a white suspension determined by Telkes[14] as lead carbonate. It is much more stable in a nitrogen atmosphere but decomposition is not entirely prevented. Boiling does not affect the stability. Colloidal lead is coagulated by electrolytes and is a rather vigorous reducing agent. When it is placed in a U-tube fitted with electrodes the boundaries may be seen to move toward the cathode, indicating that the particles are positively charged.

TABLE II

PREPARATION OF COLLOIDAL LEAD

	Dispersion medium	Time, min.	Arc amps.	Volts	Centrifuge		Pb per 100 g. of soln.	Remarks
					Min.	R.p.m.		
1	Redist. H_2O[a]	10	2.5	40	5	840	0.04451	. .
2	Redist. H_2O	10	2.6	40	5	1200	.04451

[a] Plus one drop of 0.1 N sodium hydroxide (PH 7). [b] Some further settling out at higher rate of centrifuging. [c] 0.1–0.2 cc. of 1% acetic acid added to tubes before sealing. [d] Coagulated. Partially settled. Some remained as colloid for over a week. [e] Less stable on standing than water solution.

---

[14] Telkes, THIS JOURNAL, 49, 1382 (1927).

Table II lists the results obtained in several preparations.

The method used by Telkes for analysis was followed with slight modifications. A 25-cc. sample of colloidal lead was dissolved in 0.8 cc. of 10% acetic acid. Standard potassium dichromate was added in excess and the precipitate allowed to settle. The precipitate was then filtered off, and to the filtrate and washings were added 5 cc. of concd. hydrochloric acid and 5 cc. of 10% potassium iodide. The iodine freed was titrated after three minutes with standard thiosulfate using starch indicator.

Effect of X-Rays on the Coagulation of Colloidal Lead.—According to Crowther and Fairbrother, positive colloids are coagulated by exposure to x-rays and consequently this effect should be noted in the case of colloidal lead. A series of experiments seemed to show that the lead was not coagulated but even stabilized to a slight extent.

1. Ten cc. of colloidal lead was placed in each of two thin pyrex test-tubes and covered with a paraffin seal. One was exposed for thirty minutes at a distance of ten inches from the target of a tungsten target tube running at a voltage of 60,000 and a current of 4 to 5 amperes while the other (unexposed) was maintained at nearly the same temperature; 0.6 cc. of 2.7% calcium chloride was added to each and the tubes were viewed against a brightly illuminated background. Eight minutes elapsed before coagulation was visible in the unexposed, eleven minutes for the exposed.

2. The experiment was repeated using a 145-minute exposure at a voltage of 70,000; 0.4 cc. of 0.5% sodium chloride was added to coagulate and forty-four minutes were necessary to obtain visible coagulation of the unexposed, while fifty-three minutes were required for the exposed. This result was duplicated.

3. Two tubes of lead which had been prepared for over a month were placed in the x-ray housing, five inches from the target, one protected by a lead shield, and exposed for ten and one-half hours. A slight amount of decomposition was evident in both; 0.5 cc. of sodium chloride was added to each. In two minutes both had coagulated but the liquid in the case of the unexposed was clear, showing complete coagulation, while the other had the brown color of dilute colloidal lead, evidencing incomplete coagulation lasting for over an hour.

4. The action of rays from a molybdenum target tube operating at 30,000 volts had no apparent coagulatory effect on colloidal lead in a pyrex glass bulb 0.0035 mm. in thickness.

Secondary Radiation from Colloidal Lead.—A very thin walled pyrex tube 7 mm. in diameter and 10 mm. in length was adjusted so that a beam of x-rays from a pinhole would pass down the length without hitting the walls of the tube. Around this a piece of film was placed in a cylindrical holder of radius 2 cm. A blank taken with a ten-minute exposure of the empty tube showed no effect upon the film. The film was completely blackened in a ten-minute exposure when the tube was filled with water. With the tube filled with colloidal lead, the blackening decreased with increase in distance from the point where the beam entered the column of lead and increased with time of exposure. It is evident that the intensity of secondary rays produced from the lead when measured at a given distance from the primary beam is very much less than that for secondary rays from water under identical conditions.

Effect of Colloidal Lead upon a Chemical Reaction.—The inversion of sugar was chosen for investigation because the reaction in neutral or alkaline solution has been found to be very slightly accelerated by x-rays.

A series of experiments shows that the reaction is not appreciably affected by the presence of colloidal lead during the exposure to x-rays.

1. A 5% solution of sugar with specific rotation at 20° of 66.5 was prepared. Tests showed that the rotation was not affected by several days' standing or prolonged heating at 30°. Then 25 cc. of this solution with 2 cc. of a 0.05% solution of colloidal lead was sealed in a bulb and exposed to x-rays. A similar bulb was protected from the rays. At the end of a six-hour exposure at 60,000 volts and 2 to 5 m. a. the lead was dissolved by 0.1 cc. of *N* acetic acid and the rotation measured. The two readings checked exactly.

2. A solution of colloidal lead in sugar solution was made by arcing for five minutes in a 5% sugar solution and centrifuging for twenty minutes at 1200 r.p.m. After a four-hour exposure at 70,000 v. and 4 m. a. the saccharimeter reading of 38.3 was found to be identical for the solution containing colloidal lead and the original solution similarly exposed to x-rays.

3. Colloidal lead was prepared in a 5% sugar solution and a similar experiment carried out using an irradiation of seventeen and one-half hours. The following data were obtained.

Solution	Sacch. reading, 20°	PH
Original sugar solution	19.1	6.8
Sugar solution exposed to x-rays	19.07	6.8
Sugar soln. contg. coll. lead, 0.05 g. per 100 g. of soln.	19.15	
Sugar soln. contg. coll. lead exposed to x-rays	19.13	7.8
Sugar soln. contg. $Pb(NO_3)_2$ exposed to x-rays	18.85	5.6

Inasmuch as acetic acid had to be added to the lead in order to dissolve it, *PH* measurements could not be made. The value given was for an undissolved portion which had been exposed to the air and had formed the white cloudy lead carbonate, which did not interfere with the colorimetric measurement but showed nothing about PH of colloidal lead except that it was not acid.

It may be concluded that colloidal lead has no effect upon the inversion of sucrose by x-rays; a considerable effect is observed in the presence of lead nitrate, but the change in *PH* alone may account for this. Hence upon the basis of these experiments the mechanism of the action of colloidal lead in the tissues seems to be the specific chemical effect, rather than the production of secondary rays. This agrees with the recent observation that colloidal gold which should produce secondary rays as easily as lead, has no beneficial effects whatever in the Blair–Bell technique.

The Flocculation of Colloidal Clays

The action of x-rays in flocculating colloids is an established fact. Clay solutions are usually highly colloidal. It was the purpose of this experiment to find out the action of x-rays on the clay slips. It was taken for granted that flocculation bears a direct relationship with the viscosity of the slip, that is, flocculation increases with viscosity, other things being equal.

Advantage was taken of this relationship, therefore, by first taking a measurement of the viscosity of the slip before raying, and then after raying for a certain time. The change of viscosity is a direct measure of amount of flocculation.

The viscosity was measured by means of a viscosimeter. A certain volume of the solution was allowed to drain off continuously from a large capillary, and the time recorded accurately by means of a stop watch. The following formula expresses the relative viscosity of a slip

$$V = \frac{t_s \cdot S_s}{t_w \,.\, s_w} \,.$$

where V is relative viscosity of the slip, t_s is the time required for 100 cc. of the clay slip to flow through the viscosimeter (in seconds), S_s is the specific gravity of the clay slip, t_w is the time required for 100 cc. of distilled water at the same temperature of the slip to flow through the viscosimeter (in seconds) and s_w is the specific gravity of water at that temperature.

The clay slips were enclosed in 1-liter glass vessels tightly closed and exposed to radiation from a molybdenum target x-ray tube at 30,000 volts for 1200 milliampere hours.

The data and calculations are as follows

1. Florida Kaolin

t_s = time for 100 cc. of slip before raying to flow through the viscosimeter = 21 sec.
t_w = time for 100 cc. of water to flow through the viscosimeter = 12.0 sec.
t'_s = time for 100 cc. of slip after raying to flow through the viscosimeter = 21 sec.
$S_s = 1.210$ = specific gravity of the slip.
$s_w = 1.0$ = density of water.

Relative viscosity before raying $= \dfrac{21 \times 1.210}{12 \times 1.00} = 2.12$, the same as that after raying.

Hence x-rays have no effect of flocculation on Florida kaolin, which is a very pure kaolin.

2. Anna, Illinois, Kaolin.

t_s = 25 sec. before raying.
t'_s = 29 sec. after raying.
$S_s = 1.197$
t_w = 12 sec. $s_w = 1.0$
V before raying $= (25 \times 1.197)/(12 \times 1) = 2.49$
V after raying $= (29 \times 1.197)/(12 \times 1) = 2.90$
Increase in relative viscosity due to raying, 16.5%.

3 Tennessee Ball Clay No. 5

t_s = 22.5 sec. before raying
t'_s = 25.5 sec. after raying
$S_s = 1.200$
V before raying $= (22.5 \times 1.20)/(12 \times 1) = 2.25$
V after raying $= (25.5 \times 1.20)/(12 \times 1) = 2.55$
Increase in relative viscosity due to raying, 11.8%.

An analysis of the latter two clays shows that they are impure kaolins containing some proteins and other organic substances; the increase in relative viscosity due to raying is a relative measure of the amount of protein substance present, since the pure Florida kaolin is entirely unaffected. Therefore, the protein is most sensitive to coagulation and affects the slips markedly even though present in very small amounts.

The authors are indebted to Mr. T. Kurosawa and to Mr. D. T. Shaw for assistance in making observations, respectively on the condensation reactions and on the coagulation of colloidal clays.

Summary

1. Several chemical systems which are known to undergo photochemical change in ultraviolet light are investigated with x-rays, in most cases of an effective wave length of 0.24 Å. Most of the changes, if any, are very small.

2. The most sensitive reactions found besides oxidation of solutions of ferrous to ferric salts are a series of aldehyde-ketone condensations, investigated photochemically for the first time. Aldehyde–aldehyde condensations are much less affected by x-radiation.

3. The energy relations involved in the photolysis of potassium nitrate by x-rays are quantitatively determined, including an accurate measurement of intensity and dosage in "*r*" units with a 1 cc. air-wall ionization chamber. There are 5.58×10^{11} molecules reacting per *r* unit or approximately 0.2 molecule per ion pair. The energy in calories per mole is 1.31×10^7. Thus less than 0.8% of the energy absorbed and utilized in the formation of ions in solution appears as chemical dissociation of the potassium nitrate molecule.

4. Simultaneous irradiation of potassium iodate and potassium nitrate solutions with x-rays and ultraviolet light produces additive chemical effects in contrast with non-additive biological effects on fungi, etc.

5. A thorough test is made in potassium iodide and potassium nitrate solutions of the theory that chemical effects are secondary and due to the formation of hydrogen peroxide.

6. Colloidal lead used in the Blair–Bell technique for cancer therapy is studied from the standpoints of preparation, stability, coagulation by x-rays, production of secondary x-rays and catalytic effect in reactions subjected to irradiation. The specific chemical effect rather than the action of producing secondary x-rays in *situ* in the tissues is indicated.

7. The coagulation by x-rays as determined by viscosity changes of colloidal clay slips is found to be a function of the amount of organic protein materials present.

THE REACTION OF IODATE AND TETRAVALENT VANADIUM IN ALKALINE SOLUTIONS

BY J. B. RAMSEY AND A. ROBINSON

RECEIVED JULY 22, 1929 PUBLISHED FEBRUARY 6, 1930

Whether or not a reaction occurs between iodate and tetravalent vanadium in alkaline solutions has apparently not been determined. That no reaction takes place in hydrochloric acid solutions of moderate concentrations (6 N or above) is evident from the results recently obtained by Swift and Hoeppel.[1] The accepted molal electrode potentials of the half-reactions involved, as given by Latimer and Hildebrand,[2] indicate that a measurable equilibrium may exist in dilute acid solutions.

The present work was initiated with the hope of making use of the reaction in alkaline solution, if such occurs, in the determination of tetravalent vanadium. The results obtained show that a reaction does take place in a conveniently short time in hot alkaline solutions, the equation of which may be written

$$6VOSO_4 + KIO_3 + 18KOH = 6KVO_3 + 6K_2SO_4 + KI + 9H_2O$$

A method of determining tetravalent vanadium by means of this reaction has been developed.

Reagents Used.—The solutions of potassium permanganate and sodium thiosulfate were prepared and standardized by the methods previously used.[3] The tetravalent vanadium solutions were prepared from ammonium metavanadate, by converting to sodium vanadate, acidifying with sulfuric acid and reducing with sulfur dioxide. After the excess sulfur dioxide had been removed by sufficient boiling in a rapid stream of air, the concentration of vanadium was determined by oxidation with a known permanganate solution.[3,4] The potassium iodate solutions were prepared from pure potassium iodate and standardized against known thiosulfate solutions. The potassium iodide was tested for iodate with negative results. All other reagents were of standard C. P. quality.

Preliminary Experiments and Results

1. Evidence of Reaction and Probable Use in Analysis.—In solutions from 0.02 to 0.2 N in alkali, nearly 0.025 *N* in tetravalent vanadium and from 0.03 to 0.05 *N* in iodate, the brown color due to tetravalent vanadium is not changed appreciably after standing for several hours at room tem-

[4] Lundell and Knowles, *ibid.*, 43, 1560 (1921).

perature. (Pentavalent vanadium is colorless in alkaline solutions.) If these brown solutions are heated, they become colorless after boiling for a short time (not longer than twenty minutes in the case of any solution used). The time required is appreciably decreased by a relatively small increase in the concentration of the iodate but is not noticeably changed by a considerable change in the alkali concentration. These results indicate the possibility of determining tetravalent vanadium by oxidation with an excess of iodate in boiling alkaline solutions provided the excess iodate may be determined in the resulting solution. An obvious method of finding the quantity of excess iodate consists of adding potassium iodide, acidifying and determining the iodine formed with known thiosulfate solution.

2. Acidity Tests in Determination of Excess Iodate.—Since vanadic acid and oxygen will be present during the determinations of the excess iodate by the method proposed, it is necessary to have a concentration of acid sufficient to cause rapid reduction of iodate but not so great as to cause formation of iodine due to either the vanadic acid or oxygen during the titration with thiosulfate solution. Experiments show that if the acid concentration is 0.02 N or less in solutions containing vanadic acid, oxygen and iodide at concentrations used in obtaining the results given in the table, the quantity of iodine formed in the time required for titration is not measurable. In acidifying the alkaline iodate solution it is found that sulfuric acid having a concentration as high as 1.2 N may be used without causing the liberation of iodine by vanadic acid or oxygen due to the momentary production of high acidity. Since the volume (10 to 20 ml.) of this acid required is conveniently small, no experiments were conducted with greater acid concentration. The acid is introduced as rapidly as it will flow from a buret against the side of the reaction flask, which is kept moving in such a way as to give the solution a swirling motion.

3. Effect of Oxygen during Iodate–Vanadium Reaction.—It is well known that tetravalent vanadium is slowly oxidized by oxygen in alkaline solutions. That a large effect is produced by oxygen during the iodate–vanadium reaction is shown by the fact that if solutions of the reactants are prepared without previously excluding oxygen, as much as 20% of the tetravalent vanadium may be oxidized by the oxygen present. Results given in the table show the effect of oxygen present in the vanadium solution alone.

4. Catalysis of the Iodate–Vanadium Reaction.—Failure to remove the dissolved oxygen completely in the earlier attempts gave results which were then assumed to be due to the incompleteness of the reaction. Various substances were introduced which might remove the vanadate more completely from the assumed equilibrium. None of the substances tried eliminated the error. However, disodium acid phosphate, one of those used, was found to catalyze the reaction appreciably. With phosphate present, the solution became colorless after boiling four or five minutes while without it, ten to twelve minutes were required in solutions otherwise the same. At present we are unable to give a probable explanation of this catalytic effect.

General Analytical Procedure

On the basis of these experiments, the following procedure is the one finally adopted. Measured volumes of known solutions of alkali, iodate and phosphate are mixed in a 400-ml. Florence flask. The resulting solution is boiled for about four minutes to remove oxygen. During this time a measured volume of acid vanadyl sulfate solution is treated for removal of oxygen in one of two ways, either by boiling or by addition, in the cold, of a small volume of saturated sodium bicarbonate solution. About five minutes after adding the bicarbonate, the vanadium solution is added dropwise from a dropping funnel to the boiling iodate solution. When the vanadium solution is boiled to remove the oxygen, it is added while still hot to the boiling iodate solution. After the reaction is completed, as shown by the disappearance of the brown color, the solution is cooled in tap water and diluted to approximately 250 ml. About two grams of potassium iodide is then added and the solution is acidified. To determine the quantity of acid needed, one run is made in which the acid is added slowly until iodine is formed. Starch solution is added and the iodine reduced carefully with thiosulfate. With addition of more acid, iodine is liberated and again reduced. This is continued until no iodine is formed on addition of more acid. The last portion of acid is added dropwise. The quantity of acid found necessary is introduced in all other runs in the manner previously described. The titration with thiosulfate solution is made immediately after acidification. The starch solution is added after almost all of the iodine has been reduced.

Results

In obtaining the results given in the following table, the volumes and approximate concentrations of the solutions used were as follows: 50 ml.

TABLE I

OXIDATION OF TETRAVALENT VANADIUM BY IODATE IN ALKALINE SOLUTION

Expt.	Vanadium taken, millieq.	Iodate reduced, millieq.	Diff., millieq.	Treatment of vanadium solution
1	2.027	2.033	+0.006	Boiled for three to five minutes
2	2.027	2.027	.000	
3	2.027	2.031	+ .004	
4	2.027	2.026	− .001	
5	2.027	2.028	+ .001	
6	2.027	2.028	+ .001	
7	2.027	2.025	− .002	
8	2.027	2.009	− .018	Oxygen not removed
9	2.027	2.001	− .026	
10	2.990	2.989	− .001	Treated with sodium bicarbonate solution
11	2.990	2.986	− .004	
12	2.990	2.988	− .002	
13	2.990	2.991	+ .001	
14	2.990	2.986	− .004	
15	2.990	2.986	− .004	
16	2.990	2.987	− .003	

of standard potassium iodate solution (approximately 0.1 *N*); such a volume (between 10 and 20 ml.) of approximately 4.0 *N* potassium hydroxide that the solution remains alkaline after completion of the reaction; 10 ml. of approximately 0.25 F disodium hydrogen phosphate; 25 ml. of standard vanadyl sulfate solution, approximately 0.1 *N* in vanadium and 1.5 *N* in sulfuric acid; the required volume of approximately 1.2 N sulfuric acid, which is usually between 10 and 20 ml. The volume of standard thiosulfate solution (approximately 0.1 *N*) is in every case between 20 and 30 ml.

From the results of Expts. 8 and 9 it is seen that, on the average, approximately 1% of the tetravalent vanadium used is oxidized by the oxygen present in the vanadium solution alone. If oxygen is excluded from all solutions, the results obtained are, on the average, within 0.1% of those calculated.

Summary

It has been shown that iodate and tetravalent vanadium react completely in hot alkaline solutions. Phosphate has been found to catalyze this reaction.

A method of determining vanadium by means of this reaction has been described. The results check on the average within 0.1% of the calculated if oxygen is excluded during the reaction.

THE DIELECTRIC CONSTANTS OF WATER AT VARIOUS TEMPERATURES

BY A. C. CUTHBERTSON AND O. MAASS

RECEIVED AUGUST 2, 1929 PUBLISHED FEBRUARY 6, 1930

As a step in the measurement of the dielectric constant of hydrogen peroxide it was found necessary to use water for purposes of comparison. A large divergence exists in the values of the dielectric constant given for water and little attention has been paid to the measurement of the temperature coefficient over a wide range. This led to the development of the method described below in which measurements were carried out between 0 and 75°. This method offers no originality in its main principles but in the details of procedure improvements have been made which lead to consistent results.

Experimental

General Outline.—The method employed involves the resonance principle for the measurement of capacity in the ingenious set-up described by Williams and Krchma.[1] The distinguishing feature from that used

---

[1] Williams and Krchma, THIS JOURNAL, 48,1892 (1926).

by them lies principally in the design of the dielectric cell and the insertion of an invariable capacity in series with the dielectric cell and tuning condenser.

A diagram of the apparatus is shown in Fig. 1. As the source of oscillations two Hartley oscillators were employed designated as A and B in the figure. The inductances in both cases consisted of 75-turn honeycomb coils. A tap taken off at 50 turns was connected to the filament lead of the vacuum tube. In the case of A the inductance was shunted by a General Radio Condenser of the type used in wavemeters. In order to increase the accuracy of the readings a mirror was mounted vertically at the center of the dial so that the scale readings could be read by reflected light on a circular millimeter scale 4 feet in diameter. This type of condenser was supplied with a vernier control. The small composition knob was removed and a 1-inch brass pulley substituted. By means of a cord belt and another pulley 5 feet distant it was possible to tune the condenser without being sufficiently close to introduce body capacity effects. In the plate circuit a choke coil F was inserted to act as an impedance, which prevented radio frequency currents from passing through the plate circuit.

The fixed oscillator B was shunted with a variable condenser whose capacity could be varied to suit the measurement, but it was of course fixed at a definite value for any one. The telephones G used to indicate the point of resonance between the two circuits occupy the same position in B that the impedance F does in A.

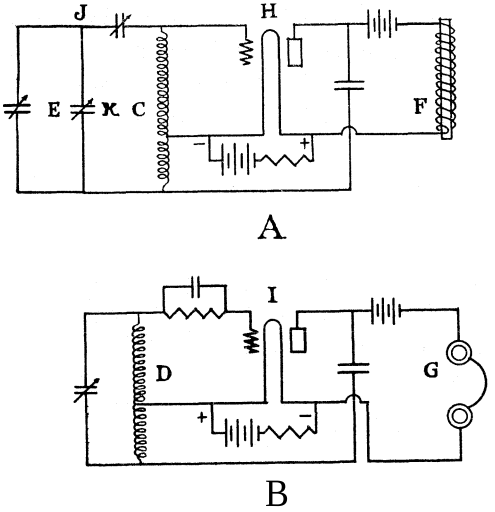

Fig. 1.—A, Variable oscillator; H, 171A. radiotron; F, impedance coil; C, inductance; J, series condenser; K, tuning condenser; E, dielectric cell; B, fixed oscillator; I, U. v. 199 Radiotron; G, phones; D, inductance.

A 171A Radiotron tube was found satisfactory for the circuit in which the dielectric cell was connected, *i. e.*, A. In this circuit the oscillations have to be forced through substances which have a measurable conductivity and which show a tendency to absorb, and therefore it was necessary to place a capacity J in series with the variable tuning condenser and dielectric cell. Measurements could be made up to a conductivity of 10^{-5}. In the fixed oscillator B a U. v. 199 Radiotron was used.

Dielectric Cell.—The success of the method was found to depend very largely on the construction of the dielectric cell. The ordinary type of two fixed plates has disadvantages, one of the most important being "capacity lead effects." The one to be described was constructed on the principle of a variable condenser the plates of which could be immersed in the liquid. The container of the liquid acted as a support for the cell. It consisted of two sets of semicircular plates. One set was fixed and may be designated as the stator plates. These were bolted by means of brass rods to an insulating frame of hard rubber. The other set, known as the rotor, was fitted to a brass axle. The vertical position of the axle was so adjusted that the rotor plates would mesh with the stator plates. In order to fix rigidly the position of the two sets, the axle supporting the rotor one passed through two bearings, one through the insulating Frame, the other a short distance above the plates. The latter was attached to but insulated from the brass rods supporting the stator plates, A vernier dial was fixed by means of a set screw to the brass axle and bolted by two screws to the same frame which supported the stator plates. This dial served to hold the rotor plates in position and also provided a means of setting the plates to a given capacity value. The liquid to be measured was placed in the container and the plates of the cell were immersed in it. A lid fastened to the insulating frame held it in position.

This type of cell removed any capacity lead effects. In actual use it was permanently connected in the circuit and set at a definite capacity value as given by the dial reading. Tuning of the variable condenser to which it was connected in parallel brought the oscillator A to resonance with B and the scale reading was noted. Readings were taken at two resonance positions of the variable condenser, first when the cell was filled with air, or a substance of known dielectric constant, second with the substance whose value was to be determined. The ratio of the differences in readings on the tuning condenser gives the ratio of the dielectric constants. This eliminates the end effects in the condenser, provided that the capacity setting is neither too small nor too large. Under these conditions the capacity varies in a linear way.

The dielectric constants of various substances vary from about unity to one hundred. It is not always practical to compare the liquid in question to air. The reason for this is that either the accuracy in the determination of air or the substance possessing a large dielectric would have to be sacrificed. With water as the dielectric the capacity of the cell is approximately 80 times that when air is present. If a large enough capacity were used to give a large scale reading for air then, using the same tuning condenser, the capacity of the same cell with water would be too large to measure.

In order to avoid sacrificing the accuracy of the air or water measurement, a "step-by-step" method was adopted. The flexibility in design of the cell permitted this to be accomplished easily. The stator plates were held in position by means of nuts threaded to the supporting brass rods. Separation was accomplished with machined brass washers. The capacity of such a condenser could be altered in one or both of two ways. In the first place the stator plate separation could be increased or decreased by a thickness of one or more washers. A corresponding alteration was of course made in the rotor plates. En the second place the number of stator and rotor plates could be increased or decreased, *i. e.*, a 3, 5, 7, 9, etc., plate condenser was readily constructed, depending on the magnitude of the constant to be measured.

The scheme is exemplified in the following way. A 9-plate condenser made possible an accurate determination of chlorobenzene relative to air. A 5-plate condenser allowed a comparison to be made between chlorobenzene and nitrobenzene, while 3 plates served to establish the relationship between nitrobenzene and water. The vernier dial was divided into 100 divisions corresponding to 180°. Instead of merely taking a reading at 20 and re-setting the dial at 80, resonance points were obtained at 20, 30, 40, 50, 60, 70 and 80—or whatever range was most convenient. In order to illustrate the experimental procedure, results are given for this particular series and are tabulated in Table I and plotted in Fig. 2.

Results

Curves 1 and 2 represent the relative capacity of air and chlorobenzene using a 9-plate condenser; 3 and 4 that of chlorobenzene and nitrobenzene with a 5-plate condenser, while 5 and 6 represent the relationship between nitrobenzene and water, the comparison being made in a 3-plate condenser.

The values of the dielectric constants can be computed easily from the

				55	46.90

above data as in every case they are inversely proportional to the slope of the line which is obtained by plotting the setting of the condenser against the capacity. As a result the dielectric constants for chlorobenzene, nitrobenzene and water based on air as unity are found to be 5.61, 35.20 and 75.40, respectively.

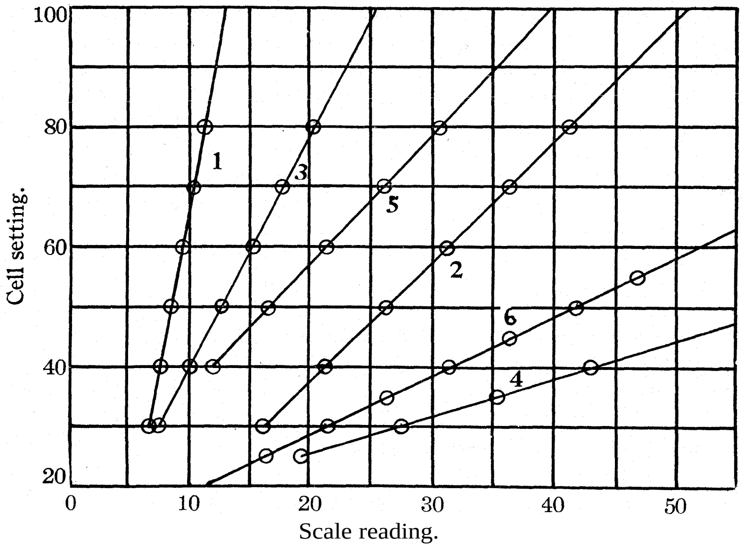

Fig. 2.

In order to check the value for water a 5-plate condenser made possible a comparison between air and ether, a 3-plate between ether and water. The results gave 4.02 and 75.5 as the dielectric constants of ether and of water at 25°.

A direct comparison was made for benzene. The value obtained was 2.28. All substances mentioned above had been carefully purified by standard methods. It may be pointed out that the value obtained for water will be independent of the purity of the substances used in the intermediate steps.

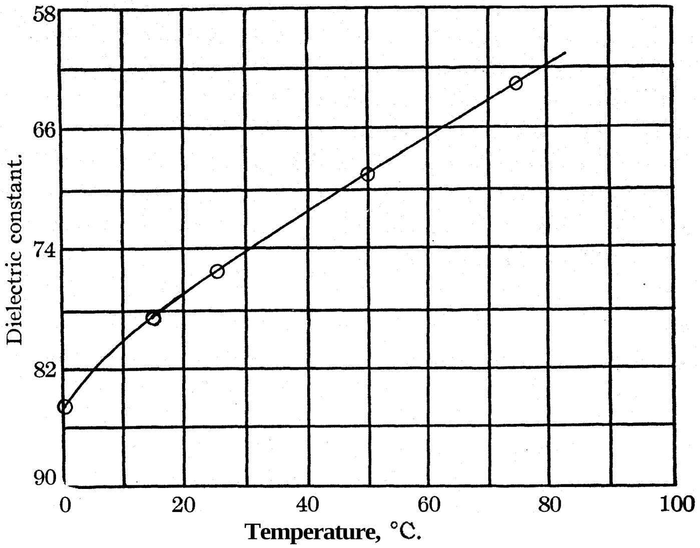

Fig. 3.

The Temperature Coefficient of Water.—From the above results the dielectric constant of water at 25° is 75.4. The effect of temperature was then investigated over the range 0 to 75°. Using the same 3-plate condenser which gave the value for water at 25°, the others were obtained at 0, 15, 50 and 75°. The values obtained at 0, 15, 50 and 75° were 84.4, 78.5, 69 and 62.9, respectively, all based on the value 75.4 at 25°. The above values were obtained repeatedly; especially the one at 0° was measured often. The values checked with one another within 1%, of which the above values are the mean.

The relationship between the dielectric constant and temperature is shown in Fig. **3.**

Discussion of Results

From 25 to 75° the relationship between the dielectric constant of water and temperature is approximately linear, the temperature coefficient being -0.258. From 0 to 15° the average value is -0.390, while the intermediate value between 15 and 25° is −0.310. The temperature coefficients[2] over a narrow range found by various observers vary from −0.28 per °C. to −0.495; the lowest value, −0.28, obtained by Nernst[3] is in best agreement with the value obtained by the authors

The most thorough investigation of the temperature coefficient of the dielectric constant is that carried out after the above compilation was made by Lattey. L. Kockel[4] made measurements over the range 0 to 100°. The resonance method with the particular set-up used did not give results on account of the conductivity of the water. The Nernst bridge method was then resorted to and the results were based on the absolute value of the dielectric constant of toluene. At 50° the value obtained by L. Kockel agrees with that of the authors, below the values are greater and above less. At 0° the difference amounts to 4%. The average temperature coefficient over the range 0 to 15° is 0.30 as compared to 0.35 above.

As to the value of the dielectric constant at 18°, the mean of the values obtained by various observers is S1.05, while that of the authors is 77.0 (the wave length used was 200 meters).[2]

The dielectric constants of benzene, chlorobenzene and nitrobenzene check well, however, with the accepted values. That of Isnardi,[5] 2.273, is usually taken as standard, so that the value 2.28 is probably accurate to 0.5 of 1%. In the case of chlorobenzene the constant 10.95 of Veley in Landolt-Börnstein's Tables is in error, as pointed out by Williams and Krchma[1] and Smyth, Morgan and Boyce.[6] The value 5.61 is in good agreement with their values. For nitrobenzene the values in Landolt-Börnstein's Tables are reasonably close to 35.2.

The Polarizability of Water at Various Temperatures.—The molecular polarizability P of a substance is given by

$$P = \frac{E-1}{E+2}\cdot\frac{M}{d}$$

E = dielectric constant
M = molecular weight
d = density

The values of P at various temperatures were calculated and the results tabulated in Table II.

TABLE II

POLARIZABILITY OF WATER

Temperature, °C.	0	15	25	50	75
Polariz., $(E-1)/(E-2)\cdot M/d$	17.38	17.35	17.36	17.45	17.62

For a substance having a large dielectric constant, the polarizability will vary less with the temperature than for a substance having a small one. Consequently, when the dielectric constant reaches a large value,

m

as is the case in water, variation in density will largely govern the variation in the polarizability. Furthermore, water in the liquid state is a substance in which the molecules show a great tendency toward association, which doubtless varies with the temperature. The Debye equation which would apply when the molecules are free to assume a random orientation, has no significance for a substance of this kind. An attempted calculation of the electric moment only serves to make this evident.

Any significance which may be attached to the above values is best left until more data are obtained.

Acknowledgment is made to the National Research Council of Canada for a bursary and studentship held by one of us, during the tenure of which the above work was carried out.

Summary

A resonance method for the measurements of the dielectric constant of pure liquids is described, involving the use of a variable dielectric cell in which lead and end effects are eliminated and the dimensions of which can be altered over wide limits.

The dielectric constants of ether, benzene, chlorobenzene and nitrobenzene were measured at 25°. The dielectric constant of water was determined between 0 and 75°. The step-by-step method used made it possible to make absolute determinations based on air as unity.

The polarizability of water was calculated from the dielectric constant data. The futility of applying the Debye equation for this substance was pointed out.

HYDROGEN PEROXIDE. VII. THE DIELECTRIC CONSTANTS, REFRACTIVE INDICES AND IONIZING POWER OF HYDROGEN PEROXIDE AND ITS AQUEOUS SOLUTIONS

BY A. C. CUTHBERTSON AND O. MAASS

RECEIVED AUGUST 2, 1929 PUBLISHED FEBRUARY 6, 1930

Dielectric Constants.—The measurements referred to in the title may most conveniently be taken up in separate sections.

The determination of the dielectric constants of hydrogen peroxide and its aqueous solutions presents two difficulties: the tendency of the peroxide to decompose and conduction of the solutions due to impurities. The first of these was very largely overcome by constructing a cell similar to the one described elsewhere[1] but made of tin. The second difficulty was eliminated by paying particular attention to the purification of the peroxide. It was found that of all metals very pure tin showed the least

---

[1] Cuthbertson and Maass, THIS JOURNAL, 52,483 (1930).

catalytic effect in causing decomposition. Every part of the condenser which had contact with the peroxide was therefore made from tin. The stator plates of the three-plate condenser were tin soldered to two tin tubes which were reinforced by inner brass rods, the upper ends of which were tightly clamped to a plate of bakelite. The center of the rotor plate was similarly fastened to a rod which passed through a bushing and then fastened to a vernier dial. This ensured the necessary rigidity and reproducibility in the setting of the cell. All the measurements were carried out at zero in order to minimize decomposition, which after a long immersion made itself evident by the formation of small bubbles of oxygen on the plates of the condenser.

The peroxide used was distilled from alkaline solution and subsequently recrystallized after concentration. The aqueous solutions were obtained by diluting with distilled water. It might be mentioned in this connection that conductivities higher than 10^{-5} made measurements difficult. In order to indicate the reproducibility and accuracy of the results the experimental data are given in Table I. The calculations of the dielectric constants are based on 84.4 for water at 0°. The relationship between percentage of hydrogen peroxide and dielectric constant is shown in Fig. 1.

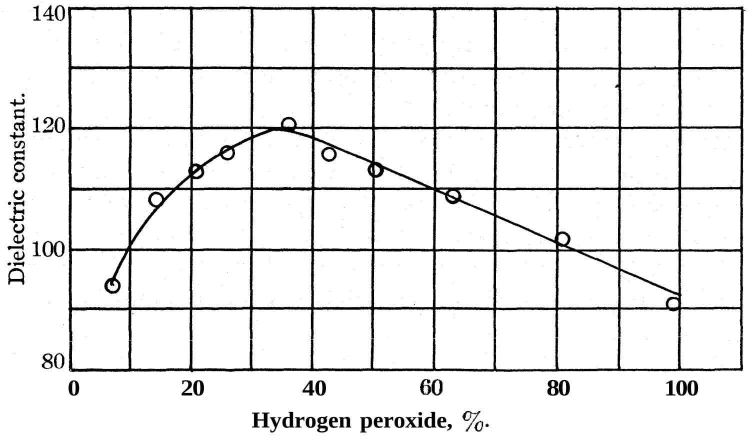

Fig. 1.

It will be noticed that the calibration value for water remains constant in a series of readings but varies a little from one series to another for the same cell setting. This was due to permanent changes on the handling of the cell between runs and does not enter into the results as calculated for any one series. After each peroxide measurement a water determination was made.

Observation showed that only very slight decomposition occurred, so that after a five-minute interval no appreciable change could be detected. After standing for a period of two hours, however, the relative

capacity was measurably lowered due to the formation of bubbles, although the extent of the decomposition could not be detected analytically. All the measurements tabulated above were made before the capacity was altered by bubble formation.

The occurrence of a maximum in the curve relating the dielectric constant and percentage hydrogen peroxide was not anticipated. The phenomenon has, however, been observed before. Partington[2] showed that a maximum exists in the binary mixture benzoic acid and benzene. It is known that peroxide and water form a complex but whether this exists at so high a temperature as 0° and at the same time is responsible for the maximum is problematical. The maximum occurs at **35%** hydrogen peroxide and this does not correspond with the composition of the molecular compound.[3] This fact however does not prove that the latter has no influence on the constant. The fact that the complex is bound to be dissociated and the hydrogen peroxide with its higher dielectric constant might have less influence on the slope of the curve.

The dielectric constant of pure hydrogen peroxide is 89.2 at 0°, based on a value of 84.4 for water. There is a reference in the literature to a value obtained by Calvert[4] of 84.7 for a 45.9% solution at 18°. This value has been extrapolated for the 100% solution. Measurements at temperatures other than 0° will be attempted in the near future.

Refractive Indices.—The measurements were carried out with a goniometer using the method described previously.[5] A hydrogen tube was used and the refractive indices were measured by means of the three lines 6563, 4861 and 4340. The values are given in Table II.

TABLE II

REFRACTIVE INDICES 24.5°

H_2O_2, %	H lines 6563	4861	4340
13.85	1.3409	1.3476	1.3515
35.48	1.3557	1.3623	1.3657
55.60	1.3701	1.3768	1.3814
74.79	1.3851	1.3914	1.3984
89.36	13.957	1.4032	1.4091

The above values were plotted against concentration of hydrogen peroxide and the refractive indices of 20, **35,** 40, 60, 80 and 100% hydrogen peroxide were taken. n_∞ was obtained for the above concentrations by extrapolation by means of the Cauchy Formula and MR_∞ was calculated.

The curves relating refractive index to concentration show no abnormalities as observed in the dielectric constant determination. The same

80	1.3756	4.964	20.71
100	1.3910	5.643	22.52

holds true for n_α plotted against concentration. All the values fall approximately on continuous gentle sloping lines and the largest deviation occurs in the case of the blue line for H_2, viz., 4340. This is undoubtedly due to the experimental error because the blue image was not as well defined as the other two and therefore increased somewhat the difficulty of focusing the cross hairs of the telescope on it.

Maass and Hatcher[6] obtained 1.4140 for the refractive index of pure peroxide for the sodium D line and 1.4043 at 96.81%. From the values given the latter is in good agreement but the first is too high. On recalculating the value for pure peroxide from the prism and angle of minimum deviation in their paper an arithmetical error was found. Recalculation gave 1.4063, in agreement with the above results.

The change in the value as originally published is too slight to affect the argument relating MR_D and constitution. The value of the molecular refractive power 5.805 is too large for two hydroxyl oxygens and too small for a quadrivalent oxygen if the value found by Miss Homfray[7] in pyrone salts be accepted. The dispersive power also gives values for hydrogen peroxide not truly additive on the basis of hydroxyl oxygens. The dispersive power between the H lines—6563 and 4340—equals 0.410. The atomic dispersions for the same lines amount to 0.036 and 0.019 for hydrogen and hydroxyl oxygen, respectively. This gives a calculated value of 0.110 compared to an observed of 0.410.

Neither the refractive power nor dispersive power of hydrogen peroxide appears to offer decisive proof as to the correct formula for this substance. Some evidence of value may, however, be obtained by a consideration of Sugden's[8] parachor. On the basis of the following formulas the calculated values of the parachor are given.

Formula	HO—OH	H—O—H O	H—O ⟶ O H
Parachor calcd.	74.1	97.7	72.5
Parachor obs.	69.6	..	..

---

[6] Maass and Hatcher, THIS JOURNAL, 42, 2548 (1920).

[7] Homfray, J. Chem. *Soc.*, 87, 1443 (1905).

[8] Sugden, *ibid*., 125, 1185 (1924); *ibid*., 127, 1525 (1925).

The calculated value for the parachor corresponding to (3) most nearly approaches the observed value of 69.6. This formula represents what is termed a coordinate link, *i. e.*, the electrons shared by the two oxygen atoms come from the oxygen atom attached to the two hydrogen atoms.

It appears reasonable then to suppose that the calculated values of the molecular refractive and dispersive power of hydrogen peroxide would agree, were the atomic refractive power of a coordinate linked oxygen atom known. On the basis then of the deviation shown in all three cases for Formulas 1 and 2, 3 is to be taken as correct, and the atomic refractive power of a coordinate oxygen linked to another is 2.1.

The electric moments calculated by the Debye equation for aqueous solutions of hydrogen peroxide of various strengths were all found to have approximately the same value. This value has no significance in view of the fact that one is dealing with a binary mixture both the components of which are highly associated. The interest of such a calculation lies in that it makes evident that even if a maximum occurs in the dielectric constant no such maximum need be expected in n_∞. The polarizability is given by $\frac{E-1}{E+2}\cdot\frac{M}{d}$, where M is calculated on the basis of molar fractions and, although E passes through a maximum on varying the concentration of peroxide, the polarizability increases continuously when E is large.

Ionizing Power.—In measuring the conductivity of solutions in which peroxide is the solvent, care must be taken to avoid decomposition at the electrodes. Tin has proved to be the most suitable metal and to avoid polarization a method was employed the principle of which is described by Bouty[9] and Sheldon.[10] In outline the apparatus used in this investigation consisted of a glass cell into which four tin electrodes could be inserted. A current of less than 0.001 ampere was passed through the solution, the circuit being made through the two outer electrodes, which may be termed the primary ones. A quadrant electrometer connected to the other two (secondary electrodes) made possible the measurement of the potential difference between two fixed points in the solution. By means of a double throw switch connected to the electrometer and across a resistance box which is in series in the primary circuit, it was possible to measure the drop of potential across both the fixed electrodes and the known resistance. The ratio of the quadrant electrometer readings in the two cases made possible the calculation of the resistance of the solution in question since the same current is flowing through both.

Figure 2 gives a diagrammatic sketch of the cell in the form of a U-tube with two other glass tubes sealed into the horizontal portion and in

---

[9] Bouty, *J. de phys.*, 3, 325 (1884).

[10] Sheldon, *Ann. Physik*, 34, 122 (1888).

the same plane as the two outer arms. In the outer arms the primary electrodes were inserted while the drop of potential was measured across the two inner ones by means of the electrometer. The current was supplied by a number of dry cells and passed through the resistance box R and solution on closing the switch S. The double switch K made possible the quick comparison of the potential drop across E, E or R.

Owing to the irregularities in the semi-circular scale and the position of the electrometer relative to it, the scale deflections were not exactly proportional to the potential differences measured. The following method of correction was applied. Three dry cells were used. Each in turn was connected across the quadrants of the electrometer and the deflection determined in all three cases. Two were then connected in series and finally the deflection was noted for all three in series. A graph of the necessary correction for any deflection was then used.

The method used in the determination of the cell constant will illustrate the general method employed in the conductivity measurements. A solution of $N/10$ potassium chloride was poured into the cell and the four tin electrodes were placed in position. The two outer electrodes were connected in the circuit of the cell C and the resistance R. R had in this case a value of 22,000 ohms. The secondary electrodes were connected to one pair of end terminals of the double throw switch K while the other two shunted the resistance R. One of the center terminals was connected to ground, the other to one pair of quadrants. The other pair of quadrants was grounded. The switch K was thrown in turn across the secondary electrodes E, E and the resistance R and the corrected scale readings 4.02 and 13.65 were obtained. Hence the resistance of the cell was $(4.02/13.65) \times 22{,}000 = 6471$ ohms, and the cell constant k becomes $= 6471 \times 1.17 \times 10^{-2} = 75.82$, where 1.17×10^{-2} is the specific conductivity of a $N/10$ potassium chloride solution at 20°. The solution in the cell was then replaced by a $N/100$ potassium chloride solution and deflections of 15.42 and 5.72 were obtained for the secondary electrodes and resistance. Hence the specific conductivity of this solution is

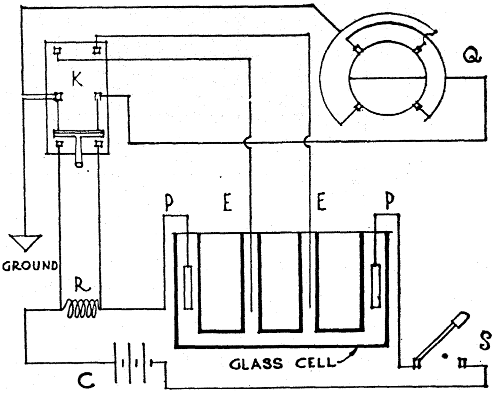

Fig. 2.

$$(75.82) \div \left(\frac{15.42}{5.72} \times 22{,}000\right) = 1.278 \times 10^{-3}$$

which is in agreement with the established value.

It might be mentioned here that in a series of measurements involving the same cell and electrodes, any change in the position of the secondary electrodes was obviated by having the electrodes of such a length that they did not reach the main body of the liquid in the horizontal portion of the cell,

Varying the position of the primary electrodes between measurements makes no difference in the ratio of the deflections.

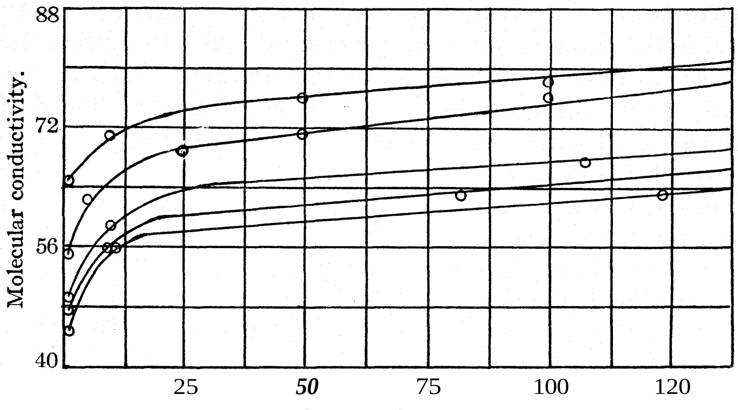

Fig. 3.

By varying the cross section of glass connection several cells were made having widely different constants and these cells were used according to the resistance of the solution. As a source of current dry cells up to **30** volts were employed and their number and the resistance up to 100,000 ohms chosen in such a way that deflections of proper magnitude were obtained. With the small currents used, no variation in the current could be detected during long periods. In any case the measurements as carried out are quite independent of the current, provided it does not change during the short interval required to measure the two deflections.

Excellent results were obtained by means of the above method. Especially noticeable was the accuracy with which solutions having a very low conductivity could be measured.

The specific conductivity of freshly crystallized peroxide was found to be of the order 2×10^{-6}. This must be taken as the upper limit since the crystallization and measurements were carried out in glass vessels. This conductivity would correspond to a hydrogen-ion concentration of 4×10^{-6} or less than one-tenth of that given by boric or carbonic acids but fifty times as great as pure water. If therefore hydrogen peroxide is an acid it is an exceedingly weak one. On diluting the peroxide the concentration of some of the solutions was found to increase if they were allowed to stand in glass vessels.

In the case of solutions of low conductivity, for which the results are given below, the conduction of the solvent was determined so that proper corrections could be applied. This was only necessary in the case of the acetic acid solutions and very dilute potassium chloride solutions.

Table IV

Conductivity of Potassium Chloride in Hydrogen Peroxide and its Aqueous Solutions at 0°

	60.00	7.34×10^{-5}	4.40
	120.0	5.12×10^{-5}	6.14
	600.0	2.09×10^{-5}	12.5
	1200.0	1.69×10^{-5}	20.3
90.2	0.901	2.22×10^{-5}	0.020
	5.64	1.01×10^{-5}	.057
	273.0	6.1×10^{-6}	1.66

Probably the most satisfactory method of discussing the conductivities of potassium chloride and acetic acid in aqueous solutions of hydrogen peroxide is to compare them with those of water. For this purpose a series of curves is included to show the relation between the molecular conductivity and dilution for potassium chloride. The curves for water and 22.26, 35.48, 90.2 and 100% H_2O_2 are all of the same type as water. Further, as the percentage of H_2O_2 increases, the molecular conductivity for any one dilution decreases regularly. It might have been expected that the 35.47% H_2O_2 solution would show abnormalities comparable with the dielectric constant. Such, however, does not appear to be the case. From the fact also that the dielectric constant of all the solutions is higher than in the case of water, it would be anticipated that all of the solutions would show a higher value than water with respect to specific or molecular conductivity.

The ionizing power, however, with which the value of the dielectric constant is presumably most directly connected, is best investigated by determining the ratio of the molecular conductivity at any dilution with that at infinite dilution. To calculate accurately by extrapolation methods the molecular conductivity at infinite dilution necessitates the specific conductivities of solutions of from $N/1000$ to $N/10{,}000$. Such data are not available from the present measurements. In order to approximate this value for the various solutions, the following method was resorted to. The molecular conductivities were plotted against percentage of peroxide for dilutions of 10, 20, 40 and 100.

The value of the molecular conductivity of potassium chloride in water was taken as 81.5 at infinite dilution and 0° and the curve was drawn, by proportionality considerations, to those obtained at dilutions of 10, 20, 40 and 100. In this way then an approximation to the conductivities at infinite dilution was made, and was for 100% H_2O_2, 65.5; 90% H_2O_2, 66.0; 35.5% H_2O_2, 71.5; 22.2% H_2O_2, 75.8. A comparison can now be made for the apparent dissociation of potassium chloride in water and in the peroxide solutions.

TABLE VI

COMPARISON OF POTASSIUM CHLORIDE DISSOCIATION IN WATER AND IN HYDROGEN PEROXIDE SOLUTIONS AT VARIOUS DILUTIONS

H_2O_2, %	Dissociation	H_2O_2, %	Dissociation	H_2O_2, %	Dissociation
Dilution 10		Dilution 50		Dilution 100	
100	0 848	100	0.945	100	0 957
90	.856	90	.952	90	.962
35.5	.830	35.5	.928	35.5	.942
22 2	.868	22.2	.941	22 2	.971
Water	.877	Water	.932	Water	.955

The approximate ionizing power so calculated leads one to the conclusion that the degree of dissociation of strong electrolytes is about the same as in water. This point of view is fully substantiated by the lowering of the freezing point of salts dissolved in pure hydrogen peroxide.

Certainly there is no evidence to show that the higher dielectric constant of the peroxide solutions markedly increases the ionizing power. In point of fact it is to be noted that in all three cases, *i. e.*, for dilutions 10, 50 and 100, if anything a minimum value for the ionizing power is obtained for the 35% solution whose dielectric constant is higher. Due however to the approximate character of the data definite statements cannot be made until more accurate values are obtainable. The only conclusion which appears justifiable, until more data are available, is that, due to the abnormally high values of the dielectric constant of water, hydrogen peroxide and its aqueous solutions, the ionizing power of these solvents is high and of a comparable magnitude.

The conductivity of the acetic acid in peroxide solutions is astonishingly small in the higher concentrations of peroxide and will be investigated more thoroughly before any comments are made.

Hydrogen peroxide shows a great similarity to water in many of its physical properties. Hence it will be of interest to make a thorough investigation of the conductivities of electrolytes in hydrogen peroxide as a medium.

Acknowledgment is made to the National Research Council of Canada for a bursary and studentship awarded to one of us, during the tenure of which the work was carried out.

Summary

The dielectric constants of hydrogen peroxide and its aqueous solutions were measured. It was shown that a maximum occurs at a concentration of 35% of H_2O_2.

The refractive indices of hydrogen peroxide solutions were measured over the whole range of concentration and at three wave lengths. The molecular refractive power and dispersive power indicate that the structure cannot be represented by two hydroxyl oxygens. It is suggested that the coordinate oxygen linkage which is given by Sugden's parachor has a definite atomic refractive power.

The polarizability as calculated from the refractive indices was shown to increase continuously with increased concentration of peroxide.

A method was described for measuring electric conductivities in hydrogen peroxide and its solutions.

Potassium chloride solutions were measured and the amount of dissociation was shown to be nearly the same as in water.

Acetic acid solutions were found to have far smaller conductivities than the corresponding solutions in water.

The specific conductivity of pure hydrogen peroxide was shown to be less than 2×10^{-6} and consequently it can be only very slightly dissociated.

THE PHOTOCHEMICAL FORMATION OF PHOSGENE

BY S. LENHER[1] AND G. K. ROLLEFSON

RECEIVED AUGUST 12, 1929 PUBLISHED FEBRUARY 6, 1930

A photochemical reaction which has been the subject of considerable interest during the last few years is the formation of phosgene from carbon monoxide and chlorine. The principal investigations on this reaction have been carried out by Bodenstein and his co-workers? They have shown that at room temperature the reaction rate is given by the expression

$$\frac{d(COCl_2)}{dt} = kI^{1/2}_{abs.}(Cl_2)\,(CO)^{1/2}$$

The quantum yield was found to be from 1000 to 3000 molecules of phosgene for every quantum of light absorbed by the chlorine. In the most recent paper cited above this is explained by a mechanism in which phosgene is formed by direct union of carbon monoxide and chlorine with chlorine atoms as a catalyst. It is the purpose of this paper to show that the observed rate law can be derived from a chain mechanism with fewer assumptions than were necessary in the previous case.

In the paper by Bodenstein, Lenher and Wagner the following set of reactions has been used in deriving the rate law

$$Cl_2 + h\nu = 2Cl \tag{1}$$
$$CO + Cl = COCl \tag{2}$$
$$COCl = Cl + CO \tag{3}$$
$$CO + Cl_2 + Cl = COCl_2 + Cl \tag{4}$$
$$COCl + Cl = CO + Cl_2 \tag{5}$$

Reaction 3 is obviously the reverse of (2) and it is assumed that the rates are such that the three substances, CO, Cl and COCl, can be considered to be present in their equilibrium concentrations. In order to account. for the inhibiting action of oxygen and the sensitized formation of carbon dioxide, the following reactions were used

$$COCl + O_2 = CO_2 + ClO \tag{6}$$
$$ClO + CO = CO_2 + Cl \tag{7}$$

The principal weakness in the above scheme is that it disregards the formation of phosgene by the action of chlorine on COCl. If the COCl reacts with oxygen as is indicated by (6), then it is certain to react with chlorine, which is a much more reactive substance than oxygen. The mechanism which we wish to present has the phosgene formed from COCl and chlorine at room temperature and retains the idea that the action of

[2] (a) Bodenstein, *Z. physik. Chem.*, **130**, 422 (1927); (b) Schumacher, *ibid.*, 129, 241 (1927); (c) Bodenstein and Onoda, *ibid.*, 131, **153** (1927); (d) Bodenstein, Lenher and Wagner, *ibid.*, **3B**, 459 (1929).

the oxygen is on the COCl but does not consider that the COCl is present in its equilibrium concentration at room temperature.

For the first step in our mechanism we must consider that the chlorine molecule is dissociated by light.[3] The second step is the formation of COCl, which occurs by a triple collision as indicated by the equation

$$CO + Cl + M = COCl + M^1$$

where M is a molecule which takes up energy in the form of vibrational, rotational or kinetic energy sufficient in amount to stabilize the COCl molecule. The latter molecule reacts with chlorine to form a phosgene molecule and a chlorine atom. The rate of formation of phosgene in this way is considered to be so fast compared to the rate of decomposition of COCl that it may be considered the determining factor in fixing the concentration of COCl. For a chain terminating reaction we shall use Reaction 5 of the mechanism proposed by Bodenstein, Lenher and Wagner. The complete mechanism is therefore

$$Cl_2 + h\nu = 2Cl \qquad (I)$$
$$CO + Cl + M = COCl + M^1 \qquad (II)$$
$$COCl + Cl_2 = COCl_2 + Cl \qquad (III)$$
$$COCl + Cl = CO + Cl_2 \qquad (IV)$$

From an inspection of the proposed scheme it is not obvious what rate law can be derived, hence we shall make a rather detailed calculation of the rate law. The assumption back of this derivation is that the intermediate compounds, COCl and Cl, are present in steady state concentrations which are controlling factors in determining the rate. In the usual way we can calculate the steady state concentrations as follows

$$\frac{d(Cl)}{dt} = k_1 I_{abs.} + k_3(COCl)(Cl_2)$$

$$\frac{d(Cl)}{dt} - k_2(CO)(Cl)(M) + k_4(COCl)(Cl)$$

$$\frac{d(COCl)}{dt} = k_2(CO)(Cl)(M)$$

$$-\frac{d(COCl)}{dt} = k_3(COCl)(Cl_2) + k_4(COCl)(Cl)$$

$$(COCl) = \frac{k_2(CO)(Cl)(M)}{k_3(Cl_2) + k_4(Cl)}$$

In this case and in all others following where a term due to Reaction IV occurs in a sum with a term due to Reaction III, the principal chain reaction, we shall neglect the former. This is justified by the quantum yield, which shows that Reaction III occurs about one thousand times more frequently than Reaction IV. With this simplification, we obtain for the concentration of COCl

$$(COCl) = \frac{k_2(CO)(Cl)(M)}{k_3(Cl_2)}$$

---

[3] The dissociation of molecules by light has been discussed by Franck, *Trans. Faraday Soc.*, 21, **536** (1925), and Franck, Kuhn and Rollefson, *Z. Physik*, 43, 155 (1927).

The concentration of chlorine atoms is obtained by equating d(Cl)/d*t* and $-$d(Cl)/d*t*, substituting for COCl where it occurs.

$$k_1I_{abs} + k_2(CO)\,(Cl)\,(M) = k_2(CO)\,(Cl)\,(M) + k_4\,\frac{k_2(CO)\,(Cl)^2\,(M)}{k_3(Cl_2)}$$

$$k_1I_{abs.} = k_4\,\frac{k_2(CO)\,(Cl)^2\,(M)}{k_3(Cl_2)}$$

$$(Cl)^2 = \frac{k_1k_3I_{abs.}(Cl_2)}{k_2k_4(CO)\,(M)}$$

$$(Cl) = \sqrt{\frac{k_1k_3I_{abs.}(Cl_2)}{k_2k_4(CO)\,(M)}}$$

Substituting the expression for (Cl) in the expression for COCl, we obtain

$$(COCl) = \frac{k_2}{k_3}\sqrt{\frac{k_1k_3I_{abs.}(CO)\,(MI}{k_2k_4(Cl_2)}}$$

The rate of formation of phosgene is

$$\frac{d(COCl_2)}{dt} = k_3(COCl)\,(Cl_2) = k_2\sqrt{\frac{k_1k_3I_{abs}\,(CO)\,(M)\,(Cl_2)}{k_2k_4}}$$

$$\frac{d(COCl_2)}{dt} = k^1I^{1/2}{}_{abs}\,(Cl_2)^{1/2}\,(CO)^{1/2}\,(M)^{1/2}$$

where $k^1 = k_2\sqrt{k_1k_3/k_2k_4}$. Comparing this equation with the experimental one given by Bodenstein,[2] we see that if we set (M) = (Cl_2) the two expressions are identical. Since M comes into the scheme in II as the substance which takes up the energy which the COCl must lose to become stable, the only condition which must be fulfilled for M to equal (Cl_2) is that chlorine should have a greater efficiency for such a process than carbon monoxide or phosgene. Such differences in efficiency in taking up energy are well known in the study of the extinction of fluorescence.[4]

Now that we write Equation II in our scheme as[5]

$$CO + Cl + Cl_2 = COCl + Cl_2^1$$

two questions arise, (a) why cannot Cl + Cl_2 in this reaction be written as Cl_3, and (b) why do we have COCl formed instead of phosgene as is the case in the mechanism proposed by Bodenstein, Lenher and Wagner? In regard to the first question, we can say that the experimental data available does not enable one to settle this question. If the Cl_3 can be considered to be present in its equilibrium concentration, then the two mechanisms are kinetically identical. Such an assumption must be considered improbable since the formation of the Cl_3 molecule must be through a triple collision and, therefore, the rate of formation probably is not very fast compared to the second order reactions which make up the following stages, hence the Cl_3 concentration would be below the equilibrium value. In such a case, the rate law would have to contain a factor corresponding to the

---

[4] Geiger and Scheel, "Handbuch der Physik," Quanten XXIII, Julius Springer, Berlin, 1926.

[5] Cl_2^1 is an energy-rich chlorine molecule which dissipates its excess energy thermally.

third body involved in the triple collision. No evidence for such a factor has been obtained. Another possibility is that Cl_3 is formed as a quasimolecule[6] which reacts with the carbon monoxide, thus greatly increasing the number of collisions in which COCl is formed over the number which would be calculated on a simple kinetic theory basis. Such a mechanism would account for an extremely specific action on the part of chlorine. We feel, however, that the latter case is adequately covered by writing the equation as a triple collision which involves chlorine specifically rather than to write equations involving such indefinite substances as quasimolecules. At present, experiments are being carried out in the hope that the chlorine molecule may be replaced by some other molecule in this step.

Turning to the second question, we must consider the relative probabilities for the formation of COCl and phosgene in the triple collision. The formation of phosgene requires that the energy which must be removed from the phosgene molecule to stabilize the molecule must be converted into kinetic energy. The probability for the loss of energy of activation as kinetic energy is given by Frenkel and Semenoff as 10^{-4}.[7,8] If this figure is taken as applicable to energies of the magnitude we are concerned with, it means that the formation of phosgene would occur only once in ten thousand triple collisions of the kind we have. On the other hand, if we have COCl formed, the energy goes into both kinetic energy and energy of vibration and rotation of the chlorine molecule. Examining the data on the quenching of fluorescence by various gases we find that the diatomic gases are generally much more efficient than the monatomic gases.[9] A general quantitative comparison cannot be made because of various specific effects which are always present, but we can say that in a triple collision such as the one under consideration the most probable reaction is the one requiring a minimum amount of energy to be dissipated as kinetic energy, and in this case that is the formation of COCl. By this we do not mean to imply that no phosgene can be formed directly by such a triple collision but merely that at room temperature the amount of phosgene so formed is not sufficient to affect the rate law.

Bodenstcin, Lenher and Wagner avoid any consideration of the mode of formation of COCl by assuming that it is present at its equilibrium concentration. In view of the fact that the formation process must be considered a triple collision, we can apply the same argument against COCl existing in its equilibrium concentration that we have already applied to the assumption of Cl_3.

[9] Pringsheim, "Fluorescenz und Phosphorescenz," Springer, Berlin, **1928,** 3d ed., p. 126.

For the chain terminating reaction we have retained the one used by Bodenstein, Lenher and Wagner, *i.* e.

$$COCl + Cl = CO + Cl_2$$

Since this is a bimolecular reaction, it must be considered as more probable than any reaction involving a triple collision or diffusion to the walls of the reaction vessel. We also wish to carry over Reactions 6 and 7 for the action of oxygen on the system, so our complete scheme for the photochemical reaction at room temperature becomes as follows

$$Cl_2 + h\nu = 2Cl \qquad \text{(I)}$$
$$CO + Cl + Cl_2 = COCl + Cl_2{}^{1} \qquad \text{(II)}$$
$$COCl + Cl_2 = COCl_2 + Cl \qquad \text{(III)}$$
$$COCl + Cl = CO + Cl_2 \qquad \text{(IV)}$$
$$COCl + O_2 = CO_2 + ClO \qquad \text{(V)}$$
$$ClO + CO = CO_2 + Cl \qquad \text{(VI)}$$

Let us now summarize the advantages of this scheme over the one previously presented. We have eliminated the necessity for the following assumptions: (a) that COCl reacts with oxygen but not with chlorine; (b) that COCl or any other substance is present in its equilibrium concentration; (c) that the formation of phosgene depends on a triple collision of a type known to have a low probability. In order to accomplish this, the sole assumption needed is that chlorine molecules shall have a relatively high efficiency in causing the formation of COCl. We feel, therefore, that our scheme is preferable since it rests on fewer assumptions.

At temperatures around 300° or higher it has been found[2b] that the rate law becomes

$$\frac{d(COCl_2)}{dt} = kI_{\text{abs.}}(Cl_2)\ (CO)$$

In order to account for this change it is considered that at high temperatures the rate of decomposition of COCl into carbon monoxide and atomic chlorine increases until it becomes fast compared with the other reactions involving COCl and, therefore, we can assume that under such conditions the COCl is present in its equilibrium concentration. We shall also assume that this equilibrium concentration is very small, thus accounting for the absence of CO_2 formation at the higher temperature, since reducing the COCl concentration to a low value reduces the rates of V and VI to very low values. Such a reduction in the COCl concentration must necessarily also reduce the rates of III and IV and, therefore, we must seek some reaction other than III as the source of phosgene. The only one permitted by our mechanism is that phosgene is formed by the triple collision of chlorine atom, chlorine molecule and carbon monoxide. At room temperature this source of phosgene has been considered subordinate to the formation by way of COCl. With the latter reaction eliminated this triple collision becomes the sole source of phosgene. Now in order for the rate of formation of phosgene at the higher temperature to be of the same order of magnitude as the room temperature rate, it is necessary for the concentration of chlorine atoms to increase. That this must occur is seen from the elimination of IV, which is the principal cause of the destruction of chlorine atoms in the room temperature reaction. With IV eliminated, the rate of disappearance of chlorine atoms will be determined by such factors as the rate of recombination at the wall or by collisions in the gas phase. These processes are subordinate to IV in the room temperature reaction but at the higher concentrations of chlorine atoms such as we have with IV out, the rates may become quite large. The work of Bodenstein, Lenher and Wagner at low pressures indicates that recombination at the wall is not much slower than IV, even under the conditions prevailing at room temperature. It is possible, however, that these rates are slow enough so that the concentration of chlorine atoms at high temperature is ten or a hundred times as great as it is in the presence of COCl. Such being the case, the amount of phosgene formed by the triple collision would be ten to a hundred times as great as before. For example, suppose that at room temperature one out of a hundred of the triple collisions yields phosgene, the other ninety-nine giving COCl; on raising the temperature this ratio between the amounts of COCl and phosgene formed remains the same but the COCl immediately decomposes without entering into any other reaction, leaving the phosgene, which appears at a measurable rate due to the increased number of collisions of the kind mentioned.

According to what has just been said, we attribute the high temperature formation of phosgene to the reaction

$$\mathrm{CO + Cl + Cl_2 = COCl_2 + Cl}$$

The rate of this reaction is given by

$$\frac{d(\mathrm{COCl_2})}{dt} = k_1(\mathrm{Cl})\ (\mathrm{Cl_2})\ (\mathrm{CO})$$

A comparison of this equation with the empirically determined rate equation shows that the two are identical if we can show that the concentration of the chlorine atoms is proportional to the amount of light absorbed. To prove such a proportionality rigorously requires more knowledge concerning factors controlling the rate of recombination of chlorine atoms than we possess. It is possible, however, to prove the relation for a special case. Suppose that the rate of disappearance of chlorine atoms is proportional to the number of collisions between the atoms and the wall. According to the kinetic theory this will be proportional to the partial pressure of the chlorine atoms. Thus we may write

$$\frac{-d(\mathrm{Cl})}{dt} = k_2(\mathrm{Cl})$$

For the formation of the atoms we may write

$$\frac{d(Cl)}{dt} = k_3 I_{abs.}$$

where k_3 is 2 if we give $I_{abs.}$ in quanta and consider that one quantum of light breaks a molecule into two atoms. Equating, we have

$$k_3 I_{abs.} = k_2(Cl)$$

or

$$(Cl) = \frac{k_3}{k_2} I_{abs.}$$

which is all we need to be able to write

$$\frac{d(COCl_2)}{dt} = kI_{abs.}(CO)\ (Cl_2)$$

where

$$k = \frac{k_1 k_3}{k_2}$$

It is quite possible that other methods of destroying the chlorine atoms will lead to the same result but, since we have no information concerning the details of such mechanisms, it is useless to attempt to make quantitative calculations.

Summary

A mechanism has been proposed for the photochemical formation of phosgene at room temperature involving COCl as an intermediate step. This mechanism has been compared with one proposed by Bodenstein, Lenher and Wagner involving COCl in a side reaction, and the assumptions involved in the two mechanisms have been discussed. **A** possible mechanism for the reaction above 300° has been suggested and discussed briefly.

SOLUTIONS OF SALTS IN PURE ACETIC ACID. II. SOLUBILITIES OF ACETATES[1]

BY ARTHUR W. DAVIDSON AND WALTER H. MCALLISTER

RECEIVED AUGUST 13, 1929 PUBLISHED FEBRUARY 6, 1930

Introduction

In the first paper of this series,[2] it was pointed out that anhydrous acetic acid is a far better solvent for salts than had been previously supposed, and existing data concerning solubilities and reactions of salts in this solvent were summarized. In the present investigation the solubilities of a number of typical acetates in acetic acid were measured over a wide range of temperature, and the compositions of all the compounds appearing as solid phases in these systems were determined. Although a number of addition compounds of acetates with acetic acid have been reported in the literature,[3] only two such systems, namely, those consisting of sodium and silver acetates in acetic acid, have been accurately investigated at more than one temperature.[4] In the present paper data are given for the acetates of potassium, ammonium, lithium, lead, barium and calcium. Other systems will be reported on in subsequent papers.

It has been shown by Kendall and co-workers[5] that, in polar solutions, compound formation between solute and solvent, or solvation, is a major factor in determining solubility, and further that in several series of systems of the type HX:RX, where the solute and solvent have a common anion, both solvation and solubility increase with increasing diversity in electropositive character between the metal R and hydrogen. It is to be expected, therefore, that in such a series solvation and solubility will be found to be greatest in the case of the salts of the alkali metals, less for those of the alkaline earth metals, while the salts of other metals, with few exceptions, are likely to be little solvated and not very soluble. The data here presented afford further opportunity for testing the validity of this view-point.

It has been repeatedly pointed out that any salt RX in solution in its own acid HX may be considered, formally at least, as a base.[6] That this

---

[5] Kendall, Davidson and Adler, *ibid.*, 43, 1481 (1921). Cf. Hildebrand, "Solubility," Chemical Catalog Co., Inc., New York, 1924, pp. 118–120, 169–170.

[6] See, for instance, Schlesinger and Calvert, THIS JOURNAL, 33, 1924 (1911); also Ref. 5, p. 1494.

conception is of real significance, and not merely a matter of nomenclature, has recently been brought out very strikingly by the work of Hall and Werner,[7] who showed that sodium acetate could be titrated electrometrically with perchloric acid in acetic acid solution to a perfectly definite point of complete neutralization. According to Bronsted's conception of acids and bases,[8] the basicity of acetates is due to the strong tendency for the acetate ion to unite with a proton. Further evidence of the actual basicity of acetates in acetic acid will be presented in the latter part of this article.

Method

The freezing-point method was employed in this work for the determination of compound formation and solubility relationships. Solutions of known composition were prepared, cooled until crystallization occurred and then heated slowly, the temperature at which the last trace of crystals disappeared being recorded as the freezing point of the solution.[9] Freezing points below 100° were determined in large test-tubes provided with a thermometer and stirrer, suitable precautions being taken to exclude moisture. For solutions in which the equilibrium temperature was above 100°, small sealed bulbs were employed. Eight mercury thermometers were used, each of them having been calibrated either at fixed points or by comparison with certified thermometers. All temperatures were corrected for exposed stem. Each freezing point was determined at least twice.

Pure anhydrous acetic acid was prepared by the addition of the required amount of acetic anhydride to a special grade of C. P. glacial acetic acid, as described by Kendall and Gross.[10] The acid used in the determinations had a freezing point of 16.5 to 16.6°, which agrees with that given by Kendall and Gross for acetic acid of minimum conductivity.

Analysis of solvated compounds was unnecessary in those cases where the congruent melting point could be determined. In other cases, the compound was obtained in crystalline form by cooling a solution of appropriate composition, filtered off with the aid of suction and dried as rapidly as possible between porous tiles. The dried sample was then weighed and the acetic acid of solvation determined, except in the case of ammonium acetate, by titration with standard sodium hydroxide solution, using phenolphthalein as indicator. Neutral and solvated ammonium acetates were analyzed by adding concentrated sodium hydroxide solution to a weighed sample in a Kjeldahl flask, distilling the liberated ammonia into a measured amount of standard hydrochloric acid and titrating the excess acid with sodium hydroxide.

The results for the various systems are given below, and are represented also in the accompanying diagrams. Compositions are expressed in molecular percentages throughout; T denotes the equilibrium temperature.

Results

System Potassium Acetate–Acetic Acid.—Although no thorough study has been made of this system previously, two addition compounds

T	170	191	206	207	230	249	292

The curve for this system is given in Fig. 1. Analyses of the solid phase (b) gave a mean value for the acid content of 66.9 mole %, corresponding to the compound $KC_2H_3O_2{\cdot}2HC_2H_3O_2$.

The existence of the two acid salts previously reported has been confirmed. The melting point of 112° reported for the compound $KC_2H_3O_2{\cdot}2HC_2H_3O_2$ is erroneous, however, as this compound undergoes transition below its melting point, which, as indicated by extrapolation, would be about 100°. The compound $KC_2H_3O_2{\cdot}HC_2H_3O_2$ is stable up to its melting point, which is 148°, as reported by Melsens.

System Ammonium Acetate–Acetic Acid.—This system has not been studied previously, although isotherms for the ternary system ammonium

acetate–acetic acid–water have been determined at 16 and 25°.[15] The compound $NH_4C_2H_3O_2 \cdot HC_2H_3O_2$, melting at 66.5°, has been reported.[16] Two different melting points have been reported for unsolvated $NH_4C_2H_3O_2$, 89° (which still is found in a number of standard reference books) and 112.5–114°.[16] The results of this work show the former to be entirely erroneous.

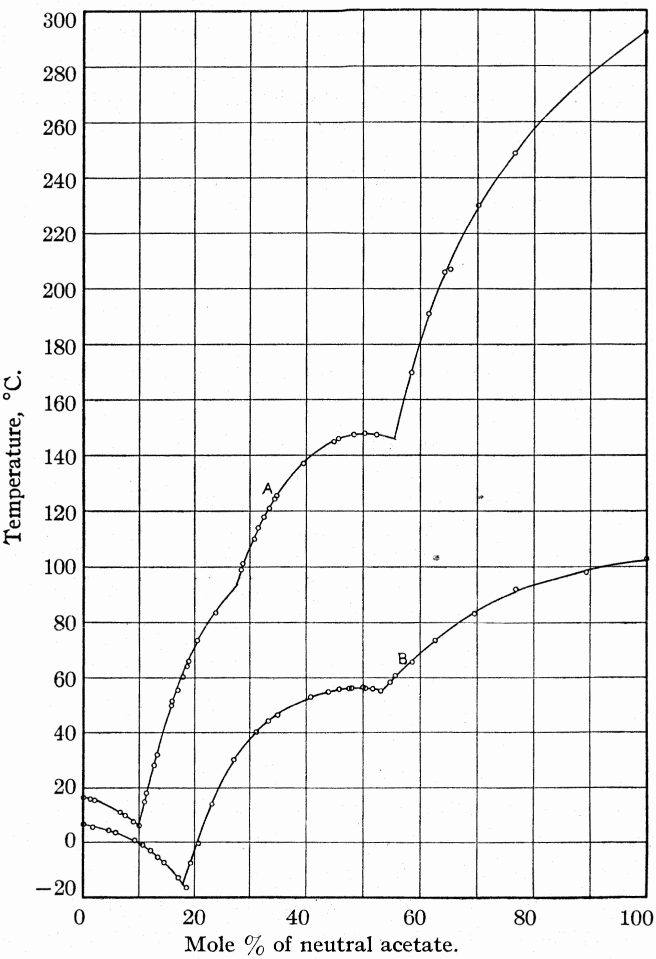

Fig. 1.—A, system $KC_2H_3O_2$–$HC_2H_3O_2$; B, system $NH_4C_2H_3O_2$–$HC_2H_3O_2$, add 10° to temperature scale.

No satisfactory method for the preparation of pure anhydrous ammonium acetate was found in the literature. The salt used was prepared

---

The curve for this system is given in Fig. 1. The existence of the acid salt $NH_4C_2H_3O_2 \cdot HC_2H_3O_2$, which has been previously reported, is confirmed. This compound has a congruent melting point at 66.5°. The melting point of unsolvated $NH_4C_2H_3O_2$ is 113°.

System Lithium Acetate–Acetic Acid.—The compound $LiC_2H_3O_2 \cdot HC_2H_3O_2$, said to melt at 99°, has been reported.[17] The present work has shown this melting point to be erroneous. The location of the eutectic point in this system has been determined also.[13]

The salt used was prepared from a c. p. hydrate, which was recrystallized and then kept at 150° for three days. Its melting point, not previously reported, was found to be 272°.

$LiC_2H_3O_2$, %	52.41	55.89	56.90	70.87	100.0	
T	178.5	188.0	192.0	221	272	

The curve for this system is given in Fig. 2. Analysis of the solid phase (b) gave a value for the acid content of 50.06 mole %, corresponding to the compound $LiC_2H_3O_2 \cdot HC_2H_3O_2$. The existence of the acid salt previously reported is thus confirmed. This compound undergoes transition before its melting point is reached, but its metastable melting point can readily be determined; it is 112.5°. The melting point of unsolvated lithium acetate is 272°.

System Lead Acetate–Acetic Acid.—This system has not been thoroughly studied previously, although a large part of the isotherm for the ternary system lead acetate–acetic acid–water at 25° has been determined.[19] Sandved states that it is impossible to bring about crystallization in very concentrated solutions of lead acetate in acetic acid. This was not found to be the case in the present work, although such solutions were exceedingly viscous and exhibited an enormous degree of supercooling, so that a great deal of patience was required in order to obtain satisfactory results with them.

The salt used was prepared from a c. p. hydrate by recrystallizing from dilute acetic acid and then drying over phosphorus pentoxide in a vacuum desiccator to constant weight, which required about six weeks. The product melted at 204°, agreeing with the figure previously reported.[20]

[18] Although the temperatures given here for systems containing from 40 to 50% $LiC_2H_3O_2$ correspond *to* a metastable equilibrium, these temperatures were invariably far easier to determine than those corresponding to the stable equilibrium between unsolvated $LiC_2H_3O_2$ and solution in this region. In fact, $LiC_2H_3O_2$ could be obtained from these solutions as solid phase only by seeding them with a crystal of this compound

$Ba(C_2H_3O_2)_2$, %	6.82	7.53	8.11	8.53	8.62	8.74	9.84
T	32.0	40.8	48.0	51.5	54.0	55.0	64.0
$Ba(C_2H_3O_2)_2$, %	11.37	11.70	12.46	14.06	15.08	15.58	
T	72.3	74.1	77.9	84.0	88.0	90.3	

(d) Solid Phase $Ba(C_2H_3O_2)_2 \cdot 2HC_2H_3O_2$ (Unstable Modification)

$Ba(C_2H_3O_2)_2$, %	8.11	9.70	10.78	11.37	11.88	12.38
T	13.8	19.9	24.3	27.1	29.8	32.0

The curve for this system is shown in Fig. 3. Analyses of the solid phase (b) gave a mean value for the acid content of 75.46 mole %, corresponding to the compound $Ba(C_2H_3O_2)_2 \cdot 3HC_2H_3O_2$. This compound has not been reported previously. Analyses of the solid phase (c) gave a mean value of 66.57 mole %, and of the solid phase (d), 65.69 mole % of $HC_2H_3O_2$, showing both these phases to consist of the compound $Ba(C_2H_3O_2)_2 \cdot 2HC_2H_3O_2$. The latter compound thus exists in two different crystalline modifications, one of them being metastable throughout the temperature range studied.

It was considered inadvisable to attempt to continue this curve beyond 16% $Ba(C_2H_3O_2)_2$ because of the high vapor pressure of acetic acid at the elevated temperatures required to bring about complete solution, in any reasonable time, at this concentration.

System Calcium Acetate–Acetic Acid.—Calcium acetate was reported to be little soluble in glacial acetic acid by Lescoeur.[22] Kendall and Adler[23] found its solubility to be less than 0.35 mole % of $Ca(C_2H_3O_2)_2$ at 30°. A compound $Ca(C_2H_3O_2)_2 \cdot HC_2H_3O_2$ has been reported by Colson.[24]

T	88.0	89.0	91.0	97.8	111.0

The curve for this system is shown in Fig. 3. Analyses of the solid phase (a) gave a mean value for the acid content of 50.66 mole %, corresponding to the compound $Ca(C_2H_3O_2)_2 \cdot HC_2H_3O_2$, which has been reported

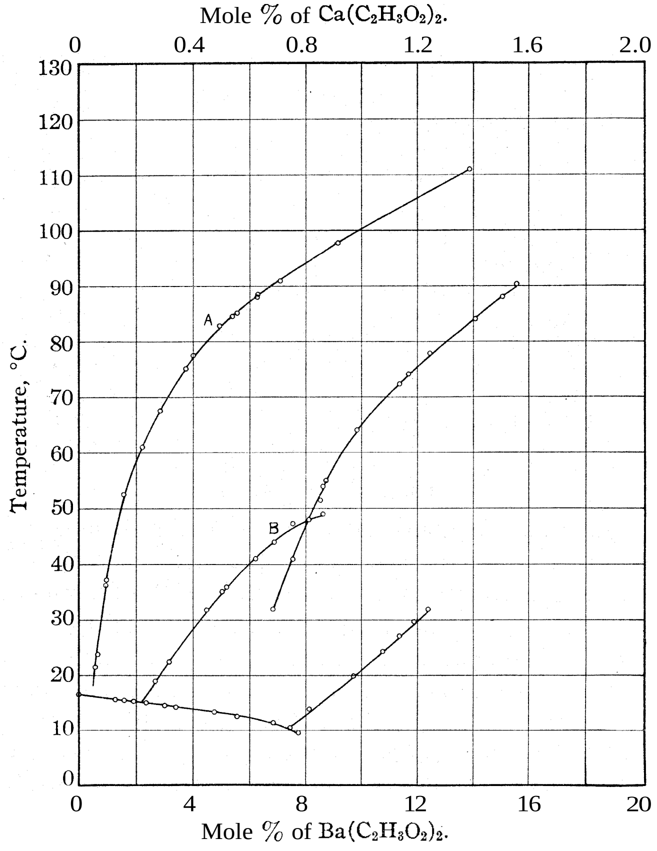

Fig. 3.—A, system $Ca(C_2H_3O_2)_2$–$HC_2H_3O_2$ (use upper concentration scale); B, system $Ba(C_2H_3O_2)_2$–$HC_2H_3O_2$ (use lower concentration scale).

previously. The curve was not continued beyond 1.4% of $Ca(C_2H_3O_2)_2$, for the same reason as in the case of the barium salt.

System Thallous Acetate–Acetic Acid.—The compound $TlC_2H_3O_2 \cdot HC_2H_3O_2$ has been reported.[25] Thallous acetate was prepared by the reaction between barium acetate and thallous sulfate in aqueous solution. After it had been dried for several days in a desiccator, the compound was found to melt at 127° (not 110°, as previously reported). The solubility was not accurately determined because of the limited quantity of salt available and its ready decomposition in sunlight. However, a rough determination showed the solubility to be approximately 2 mole % at 25°. The composition of the solid phase was not determined.

Summary of Data on Solvation and Solubility in Acetate–Acetic Acid **Systems.**—For ready comparison, the solvates which have been isolated in these systems, and the solubilities of acetates in pure acetic acid at 25°, are tabulated herewith.

Metal	Solvates isolated	Soly., mole per cent at 25°	Moles of $HC_2H_3O_2$ per mole of acetate in solid phase

Cu[26]	$Cu(C_2H_3O_2)_2 \cdot HC_2H_3O_2$	0.166	1
Ag[2]	None	0.094 (76°)	0

Discussion of Results

It is evident from the above table that solvation is most marked, and solubility is greatest, for the acetates of the most electropositive metals Only two of the acid salts isolated have been found to be sufficiently stable to reach their melting points before undergoing transition, namely, the 1:1 compounds of potassium and ammonium. The 1:2 compound of potassium, and the 1:1 compound of lithium (like the corresponding sodium compounds) undergo transition just before the melting point is reached. The high solubility of ammonium acetate is, of course, related to its low melting point. The solubility of lead acetate, even when its low melting point is taken into consideration, is surprisingly great.[27] This fact is

[25] Ref. 12, p. 249.

[26] From unpublished work in this Laboratory.

[27] Cf. Sandved, **Ref.** 19, p. 2974.

in line with the comparatively high solubility of the lead salts in other similar series, which was pointed out previously.[28]

Basic Properties of Acetates and of Water in Acetic Acid Solution.—Hall and Conant[29,30] studied the hydrogen-ion activity of glacial acetic acid solutions by means of the chloranil electrode and by their action upon indicators, and reached the tentative conclusion that the hydrogen-ion activity of pure glacial acetic acid can be represented by a P_H value in the neighborhood of zero[31] on a scale which is as yet an arbitrary one for this solvent, but which, it is hoped, may be found ultimately to coincide very nearly with the P_H scale in water. In the present investigation, qualitative experiments were made with a number of indicators which, according to Clark,[32] show color changes in water solution at a P_H value of about zero. We shall not take space here to report in detail the results of these experiments, especially since the names of the indicators are inadequate for complete identification, but shall merely summarize briefly the observations which we believe to be of interest. Acetic acid solutions of most of the indicators tried[33] showed definite color changes, in the direction of greater acidity (lower P_H), upon the addition of a small amount of a solution of dry hydrogen chloride in the same solvent. The original color of the indicator solution could then be restored, in every case, by the addition to the acid solution of a small amount of a solution of sodium or ammonium acetate. Other indicators[34] showed distinct color changes in the direction of greater basicity upon the addition of sodium or ammonium acetate, the original color being restored upon addition of hydrogen chloride solution. The acetates evidently act as bases in neutralizing acids in this solvent, the acetate ion of the base reacting with hydrogen ion of the acid to form undissociated acetic acid.

In this connection, it also seems worthy of mention that the behavior of water toward indicators was found to be similar to that of acetates, though less marked. Indicators in dilute solutions of dry hydrogen chloride or of anhydrous sulfuric acid in acetic acid could be restored to their "neutral" colors by the addition of a few drops of water. In other words, water, in acetic acid solution, behaves as a weak base. Such behavior is not surprising, since it has been pointed out repeatedly, in the work of Hantzsch and others, that water possesses basic properties be-

[34] Including methylene blue, benzopurpurin 4B and picric acid.

cause of its tendency to combine with hydrogen ion to form oxonium ion, OH_3^+.[35] In this respect water is quite analogous to ammonia, although the former is a somewhat weaker base because the OH_3^+ ion gives up its extra hydrogen ion, or proton, more readily than does the NH_4^+ ion. The behavior of ammonia and of water in acetic acid solution may be represented by the parallel equations

$$NH_3 + HC_2H_3O_2 \rightleftharpoons NH_4C_2H_3O_2 \rightleftharpoons NH_4^+ + C_2H_3O_2^-$$
$$H_2O + HC_2H_3O_2 \rightleftharpoons OH_3C_2H_3O_2 \rightleftharpoons OH_3^+ + C_2H_3O_2^-$$

In the latter case, the addition compound, which might be called oxonium acetate, must, indeed, be regarded as hypothetical, since it cannot be isolated in the solid state, even at low temperatures.[36] However, the existence of such a compound *in solution* appears quite probable from the fact that the cryoscopic effect of water in moderately dilute solution in acetic acid is practically identical with that of ammonia.[37] Thus, the curve obtained by plotting the freezing-point data of Rüdorff[38] for solutions of water in acetic acid, after recalculating the concentrations in terms of mole per cent. of $OH_3C_2H_3O_2$, coincides within the limit of experimental error, up to 5 mole per cent. of solute, with the curve found in the present investigation for $NH_4C_2H_3O_2$.[39] Although this method of comparison is admittedly imperfect,[40] and it is impossible to determine the degree of solvation of either ammonia or water in acetic acid solution from freezing-point depression data, nevertheless the exact coincidence of the two curves may be taken as a strong confirmation of the hypothesis that in this instance again, as in so many others, the parts played by water and by ammonia are essentially the same.

Summary

1. Freezing-point curves have been determined for binary systems consisting of acetic acid with the acetates of potassium, ammonium, lithium, lead, barium and calcium, and a number of addition compounds have been isolated and analyzed. Incidentally, a method has been given

[35] For an outline of Hantzsch's results and other evidence for the existence of oxonium ion, see Hammett, THIS JOURNAL, 50, 2666 (1928). *Cf.* also Conant and Hall, Ref. 30, p. 3068.

[36] The complete freezing-point curve for the system H_2O–$HC_2H_3O_2$ is given by' Faucon, Ann. *chim. phys.*, [8] 19, 70 (1910). No compound appears as solid phase. *Cf.* Kremann, *Monatsh.*, 28, 893 (1907).

[37] The data of Hantzsch, *Z. physik. Chem.*, 61, 257 (1907), show the same thing to be true for solutions in sulfuric acid.

[38] Riidorff, ***Ber.*, 3,** 390 (1870).

[39] Obviously, the system $NH_4C_2H_3O_2$–$HC_2H_3O_2$ might have been regarded as a portion of the system NH_3–$HC_2H_3O_2$, in which case $NH_4C_2H_3O_2$ would have appeared as a 1:1 compound. The study of the latter system in its entirety is, however, beyond the scope of this work; it seemed preferable to choose $NH_4C_2H_3O_2$ and $HC_2H_3O_2$ as components in order to emphasize the analogy between ammonium and the alkali metals.

[40] *Cf.* Kendall, Booge arid Andrews, THIS JOURNAL, 39, 2308 (1917).

for the preparation of pure ammonium acetate, and the uncertainty as to the melting point of this salt has been cleared up.

2. Solvation and solubility in these systems, and in others of the same type for which data are available, have been found to be closely related, in accordance with the theories of Kendall.

3. Attention has been called to the basic properties of acetates in acetic acid solution, and to the similarity in function between ammonia and water in this solvent.

SOLUTIONS OF SALTS IN PURE ACETIC ACID. III. ZINC ACETATE AND SODIUM ZINC ACETATE[1]

BY ARTHUR W. DAVIDSON AND WALTER H. MCALLISTER

RECEIVED AUGUST 13, 1929 PUBLISHED FEBRUARY 6, 1930

Introduction

The solubility of zinc acetate in acetic acid was found by Kendall and Adler[2] to be very small, the saturated solution at 130° containing only about **0.1** mole per cent. of zinc acetate; no further data are given by these authors. In the first article of this series,[3] mention was made of the fact that the solubility of zinc acetate is greatly increased by the presence of sodium acetate, and it was pointed out that this was analogous to the behavior of zinc hydroxide, in aqueous solutions, upon the addition of sodium hydroxide; no quantitative work, however, has been done previously upon the ternary system sodium acetate–zinc acetate–acetic acid. In the present investigation the solubility of zinc acetate in acetic acid over a range of temperatures has been measured, both in the absence of sodium acetate and in the presence of increasing concentrations of the latter solute. Comparison of the results of these measurements with data given in the literature for the corresponding aqueous system has established the analogy between the two cases upon a firmer basis, and has made possible its further development, as will be shown below.

Method

Preparation of Materials.—The acetic acid employed was prepared as described in the preceding paper of this series. The sodium acetate was prepared by recrystallizing a C. P. hydrate from water and dehydrating it at 150° for about a week. Zinc acetate, it was found, could not be dehydrated even at temperatures as low as 90° without slow partial decomposition to a basic salt. The pure salt was made by re-

---

[1] The material presented in this paper is from part of a thesis submitted by Walter H. McAllister to the Graduate School of the University of Kansas in partial fulfilment of the requirements for the degree of Doctor of Philosophy, **1929.**

[2] Kendall and Adler, THIS JOURNAL, 43, **1470** (1921).

[3] Davidson, **ibid.,** 50, 1890 (1928).

crystallizing the hydrate from dilute acetic acid, heating to 85–90° for several days, and then moistening the slightly basic product with pure acetic acid and heating again to 85° for six hours. A sample of this product showed, upon analysis carried out as described below, 35.64% of zinc (calcd. for $Zn(C_2H_3O_2)_2$, 35.65%).

Binary System.—The method used for determining the solubility of zinc acetate in pure acetic acid was the same as that described for other acetates in the preceding paper. Because of the very small solubility, in this case, and the very minute amount of solid which separated on cooling, the determination of the equilibrium temperature was somewhat troublesome. Nevertheless, with a reasonable amount of care, the temperatures were found to be reproducible, and those given are believed to be correct to within 0.5°.

Ternary System.—In the study of the ternary system, acetic acid solutions were prepared containing exactly 1, 2.5, 5 and 7 mole per cent., respectively, of sodium acetate. To these solutions increasing amounts of zinc acetate were added, and the equilibrium temperatures were determined just as in the binary systems. These temperatures were then plotted as ordinates against the mole percentages of zinc acetate as abscissas to give a series of curves, each individual one of which should represent the solubility of zinc acetate in a solution having a fixed value of the ratio, number of moles of sodium acetate/number of moles of (sodium acetate + acetic acid). To save space this mole ratio will subsequently be referred to simply as R.

Methods of Analysis.—Samples of the solid phases present at equilibrium were obtained by crystallization from the solutions under suitable conditions, followed by filtration and drying on porous tile as in previous work. In these cases, however, it was found to be impracticable to determine the acetic acid by direct titration, no accurate end-point being obtainable in the presence of zinc ion.[4] Analysis of these compounds was therefore carried out by the following means. In the case of the binary system the weighed sample was dissolved in water and the zinc determined by potentiometric titration at 65° with fortieth molar potassium ferrocyanide solution containing 0.1% potassium ferricyanide; this determination was sufficient to fix the composition of the compound. In the ternary system, however, it was necessary to determine a second constituent also. The acetates in the weighed sample were changed to sulfates by treatment with concentrated sulfuric acid, followed by heating to drive off acetic acid and excess sulfuric acid. The residue of sulfates was weighed, dissolved in water and zinc determined by potentiometric titration as above. The weight of zinc acetate in the original sample could be calculated directly from this titration, that of sodium acetate from the amount of sodium sulfate found by difference in the mixed sulfates, and acetic acid by difference between the total weight of the sample and the combined weights of zinc and sodium acetates.

The data obtained are tabulated below, and are represented also in the accompanying diagrams. The concentration of zinc acetate in the solution is expressed throughout in mole percentage; T is the equilibrium temperature.

A, BINARY SYSTEM $Zn(C_2H_3O_2)_2$–$HC_2H_3O_2$

(a) Solid phase $Zn(C_2H_3O_2)_2$

$Zn(C_2H_3O_2)_2$, %	0.0050	0.0054	0.0085	0.0109
T	40.5	43	48	52
$Zn(C_2H_3O_2)_2$, %	0.0150	0.0231	0.0382	
T	56	62	72	

---

[4] An approximate determination could be made by potentiometric titration with sodium hydroxide solution, using a saturated quinhydrone electrode, but preliminary experiments showed the end-point obtained to be unreliable.

The curve for this system is given in Fig. 1. Due to the extremely small solubility of zinc acetate at low temperatures, it was found to be practically impossible to determine equilibrium temperatures below 40°. Enough points were obtained at higher temperatures, however, to make it possible to continue the curve to the eutectic point, with some degree of confidence, by extrapolation. The solubility at 25° appears to be 0.0018 mole per cent.

For the same reason, the solid phase (a) could not be obtained in sufficient quantity to afford as accurate an analysis as might be desired. However, analysis of a sample weighing 0.0720 g. showed **36.53%** of zinc (calcd. for $Zn(C_2H_3O_2)_2$, 35.65%). The compound, therefore, is evidently unsolvated $Zn(C_2H_3O_2)_2$.

B. TERNARY SYSTEM $NaC_2H_3O_2$–$Zn(C_2H_3O_2)_2$–$HC_2H_3O_2$

1. Mole Ratio R = 0.01. (a) Solid Phase $Zn(C_2H_3O_2)_2$

T	35.5	65	73	78	82

2. Mole Ratio *R* = 0.025. (a) Solid Phase $Zn(C_2H_3O_2)_2 \cdot 2NaC_2H_3O_2 \cdot 4HC_2H_3O_2$

$Zn(C_2H_3O_2)_2$, %	0.445	0.495	0.588	0.646	0.764
T	26.1	26.3	26.1	27.0	28.0
$Zn(C_2H_3O_2)_2$, %	0.862		0.865		
T	27.8		28.0		

(b) Solid Phase $Zn(C_2H_3O_2)_2$

$Zn(C_2H_3O_2)_2$, %	0.895	0.919	1.028	1.123
T	30	36	72	82

3. Mole Ratio R = 0.05. (a) Solid Phase $Zn(C_2H_3O_2)_2 \cdot 2NaC_2H_3O_2 \cdot 4HC_2H_3O_2$

$Zn(C_2H_3O_2)_2$, %	0.251	0.442	0.487	0.594	0.625	0.666
T	25.0	29.2	29.1	31.7	32.5	33.5
$Zn(C_2H_3O_2)_2$, %	0.701	0.763	0.809	0.852	1.106	2.162
T	33.5	35.0	35.5	36.7	39.8	42.0

4. Mole Ratio *R* = 0.07. (a) Solid Phase $Zn(C_2H_3O_2)_2 \cdot 2NaC_2H_3O_2 \cdot 4HC_2H_3O_2$

$Zn(C_2H_3O_2)_2$, %	0.247	0.294	0.464	0.469	0.662
T	26.7	28.5	33.9	33.2	36.1
$Zn(C_2H_3O_2)_2$, %	0.903	1.030	1.318	1.927	
T	41.2	42.7	46.0	48.6	

The curves for this system are given in Fig. 1. It is immediately evident that these curves exhibit a marked change in slope with change in the solid phase in equilibrium with the solution. The solid phase 1 (a) could not be obtained in sufficient amount for analysis, but it seemed certain, from their similarity in appearance and behavior, that it was the same as solid phase 2 (b). Analyses of the latter gave a mean value of 35.45% of zinc, which showed that the compound was unsolvated $Zn(C_2H_3O_2)_2$. Again, it seemed probable from the similarity in their appearance and in the slope of the corresponding curves that solid phases 2 (a), **3** (a) and 4 (a) were identical. Analyses gave the following figures:

Solid **phase**	Mole % of $Zn(C_2H_3O_2)_2$	Mole % of $NaC_2H_3O_2$	Mole % of $HC_2H_3O_2$
2(a)	14.38	29.45	56.17
3(a)	14.37	29.84	55.79
4(a)	13.33	27.80	58.88
Calcd. for $Zn(C_2H_3O_2)_2\cdot$-$2NaC_2H_3O_2\cdot 4HC_2H_3O_2$	14.29	28.57	57.14

Considering the difficulties involved in freeing these solid phases completely from the mother liquor, their instability in moist air and the necessity of determining one of the constituents by difference, these figures, it is believed, establish satisfactorily that the substances are all identical

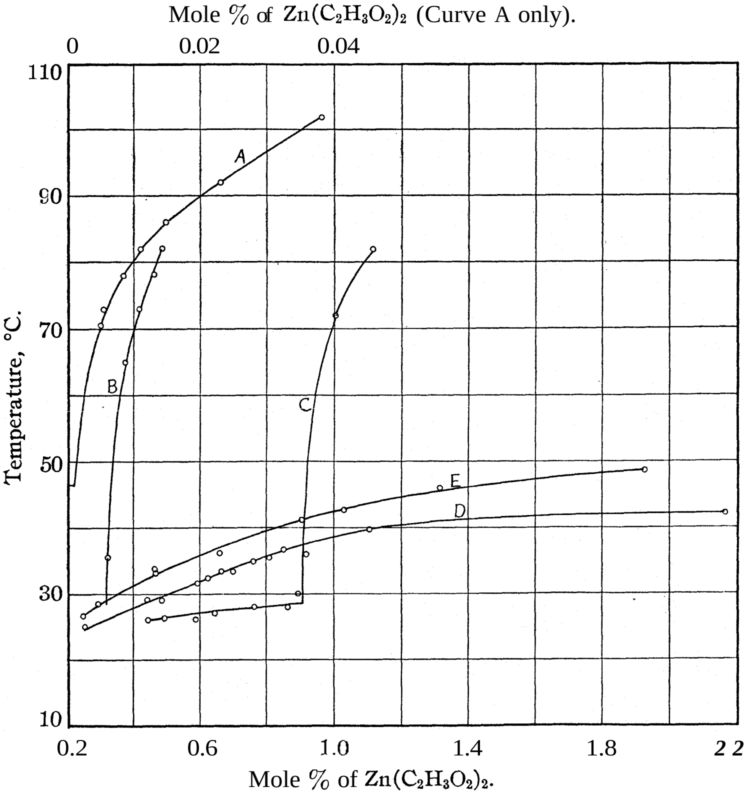

Fig. 1.—Solubility curves of $Zn(C_2H_3O_2)_2$ in pure $HC_2H_3O_2$ and in the presence of various concentrations of $NaC_2H_3O_2$. **A,** R = 0.00 (pure acetic acid); subtract 30° from temperature scale. B, R = 0.01; C, R = 0.025; D, R = 0.05; E, R = *0.07.*

and consist of a ternary compound, or solvated sodium zinc acetate, of the composition given.

It now becomes apparent that the solubility of zinc acetate in acetic acid at a fixed temperature increases with increasing concentration of sodium acetate, so long as zinc acetate itself is the stable solid phase. Upon the appearance of the ternary compound, however, the mole percentage of zinc acetate in the saturated solution begins to decrease with increase in concentration of sodium acetate. This is brought out more clearly in Fig. 2, which shows an isotherm for 28.5°, plotted from data obtained from the curves in Fig. 1. Here the solubility of zinc acetate, which is only 0.0022 mole per cent. in pure acetic acid, increases upon the addition of sodium acetate until R is 0.025, where the solubility reaches a maximum of 0.91 mole per cent. At this point the solution can exist in equilibrium with both solid phases. Then with further addition of sodium acetate the mole percentage of zinc acetate in the saturated solution falls off, becoming 0.30 for R = 0.07. At slightly higher values of R, the compound $NaC_2H_3O_2{\cdot}2HC_2H_3O_2$ appears as solid phase. The investigation was not continued into this region.

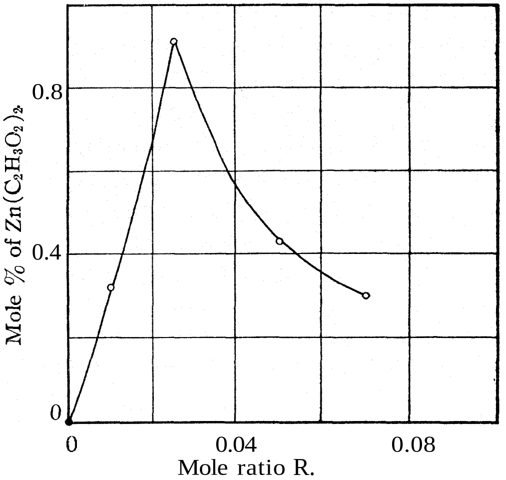

Fig. 2.—Effect of increasing concentrations of $NaC_2H_3O_2$ upon the solubility of $Zn(C_2H_3O_2)_2$ in $HC_2H_3O_2$ at a fixed temperature; isotherm at 28.5°.

Comparison of Results with Data for the Corresponding Aqueous System.—The system $Zn(OH)_2$–NaOH–H_2O has been studied quantitatively by a number of investigators.[5] Although the data of the various workers show rather poor agreement,[6] it has been observed in every case that the solubility of zinc hydroxide at a fixed temperature at first increases with increasing concentration of sodium hydroxide. Whenever the investigation has been continued up to very high concentrations of sodium hydroxide, however, a new solid phase, referred to in every case

---

[5] The most recent and apparently the most reliable of these studies are the following: (a) Goudriaan, *Rec. trav. chim.*, **39, 505** (1920); (b) Muller, Z. *Elektrochem.*, **33, 135** (1927); (c) Dietrich and Johnston, THIS JOURNAL, **49,** 1419 (1927); **(d)** Fricke, *Z. anorg. allgem. Chem.*, *172, 234 (1928).*

[6] Due, according to Dietrich and Johnston (Ref. 5c, p. 1423), to the fact that in most cases the exact nature of the solid phase is open to question.

as sodium zincate, has been found to appear,[7] and from this point on the concentration of zinc hydroxide in the saturated solution decreases with further addition of sodium hydroxide. Obviously, from the data obtained in the present investigation, the relationships in the corresponding ternary system in acetic acid are quite analogous to those just discussed, with the ternary addition compound which occurs in the acetic acid system playing the same part as the sodium zincate in the aqueous system.[8]

This analogy now naturally brings up the question of the composition of the solid phase referred to as sodium zincate. Here again there is no agreement between the results of different investigators. Selecting those which appear to be the most reliable, we find the following formulas reported for compounds of this type: (1) $NaHZnO_2 \cdot 3H_2O$,[9] (2) $Na_2ZnO_2 \cdot 4H_2O$,[10] (3) $NaHZnO_2 \cdot 4H_2O$.[11] Still other compounds of this nature have been reported by other investigators.[12] All of these so-called sodium zincates, however, have this property in common, namely, that they may be formulated as addition compounds, generally hydrated, of the two hydroxides. Thus the formulas of the three listed above may be rewritten as follows: (1) $Zn(OH)_2 \cdot NaOH \cdot 2H_2O$, (2) $Zn(OH)_2 \cdot 2NaOH \cdot 2H_2O$, (3) $Zn(OH)_2 \cdot NaOH \cdot 3H_2O$. The similarity between such formulas and that of the solvated sodium zinc acetate isolated from the acetic acid system in this investigation is plainly evident. The resemblance between the latter compound and the hydrated disodium zincate of Goudriaan[10] is particularly close, as appears in the following comparison:

$$Zn(OH)_2 \cdot 2NaOH \cdot 2H_2O \text{ or } Na_2ZnO_2 \cdot 4H_2O$$
$$Zn(C_2H_3O_2)_2 \cdot 2NaC_2H_3O_2 \cdot 4HC_2H_3O_2 \text{ or } Na_2Zn(C_2H_3O_2)_4 \cdot 4HC_2H_3O_2$$

Discussion

It has been customary to attribute the reaction between zinc hydroxide and sodium hydroxide in aqueous solution to the so-called amphoteric nature of zinc hydroxide. This compound is thought of as possessing weakly acidic as well as weakly basic properties and as being capable, by virtue of the former, of reacting with bases to form zincates. The same point of view and system of nomenclature have been carried over

---

[7] At 30°, according to Müller (Ref. 5 b, p. 140), this occurs when the concentration of sodium hydroxide reaches about 12 moles per liter. Dietrich and Johnston found only zinc hydroxide as solid phase, their investigation not having extended to concentrations of alkali sufficiently high for the appearance of sodium zincate.

[8] It should be noted that, just as the sodium zincate is unstable in the presence of water, changing to zinc hydroxide, so the ternary compound is unstable in pure acetic acid, changing to zinc acetate.

to the ammonia system of compounds.[13] Thus, when it was found by Fitzgerald that zinc amide reacted with a liquid ammonia solution of potassium amide to give a crystalline product whose formula could be written $Zn(NH_2)_2 \cdot 2KNH_2$, or $Zn(NHK)_2 \cdot 2NH_3$,[14] this new compound was immediately named potassium ammonozincate, and its formation was cited as evidence of the amphoteric nature of zinc amide.[15] With these precedents in mind, and in view of the composition and mode of formation of the new compound, $Zn(C_2H_3O_2)_2 \cdot 2NaC_2H_3O_2 \cdot 4HC_2H_3O_2$, obtained in the present investigation, it would appear to be entirely logical to call this compound, provisionally at least, sodium acetozincate, and to regard its existence as supplying further confirmation of the amphoteric nature of zinc. It must be borne in mind, however, that no evidence has as yet been obtained for the presence, in acetic acid solution, of analogs of the zincate ions, ZnO_2^{--} and $HZnO_2^{-}$, which are supposed to exist in aqueous solution. Preliminary experiments have indicated that the solubility of a number of other acetates in acetic acid is also increased by the presence of sodium acetate. Further investigation of these systems will be necessary, therefore, before it can be decided whether or not the concept of amphoterism[15b] affords the most satisfactory interpretation of their behavior.

Reactions of Zinc Salts in Acetic Acid Solution.—The quantitative study of solubilities reported above was supplemented by a few further experiments of a qualitative nature, the results of which appear to the writers to be of sufficient interest to warrant brief description here.

Metallic zinc did not react noticeably with pure acetic acid at room temperature; on heating, a slight reaction occurred, with the evolution of hydrogen and the appearance of insoluble zinc acetate. With a solution of dry hydrogen chloride, zinc reacted fairly readily, giving a clear solution; after a time a precipitate appeared, doubtless consisting of zinc chloride. With a solution of sodium acetate zinc gave no noticeable reaction until the mixture was heated, when the evolution of hydrogen took place more rapidly than with pure acetic acid; in this case no insoluble product was formed. This last reaction appears to be analogous to the action upon zinc of aqueous sodium hydroxide solution.

Zinc acetate dissolved readily in the calculated amount of hydrogen chloride solution to give a clear solution of zinc chloride, which was used in the following tests. When a small amount of ammonium acetate solu-

---

[14] Fitzgerald, *ibid.*, 29, 656 (1907); see also Franklin, *ibid.*, 29, 1274 (1907). It should be mentioned that this compound is stable in the presence of liquid ammonia, in which it is but slightly soluble.

[15] (a) Franklin, *ibid.*, 35, 1455 (1913). See also (b) Kraus, Trans. Am. *Electrochem. Soc.*, *45*, 175 (1924), where the concepts of amphoterism and amphoteric properties of elements are discussed at some length.

tion was added to zinc chloride, a heavy precipitate of zinc acetate was formed after a few minutes. This precipitate dissolved readily in excess ammonium acetate. Similarly, a small amount of sodium acetate solution, added to zinc chloride, produced a precipitate[16] which dissolved readily in excess sodium acetate. Thus, just as zinc hydroxide, insoluble in water, dissolves in hydrochloric acid or in aqueous sodium or ammonium hydroxide, so zinc acetate, insoluble in acetic acid, dissolves in a solution of hydrogen chloride or of sodium or ammonium acetate in this solvent.

The precipitation of zinc sulfate upon the addition of sulfuric acid solution to zinc chloride, and of zinc sulfide upon the introduction of gaseous hydrogen sulfide, have been mentioned previously.[17] The latter precipitate was found to occur even in the presence of a small concentration of hydrogen chloride, but took place more readily in the absence of the latter, that is, in what might be spoken of as a "neutral" solution.[18] The precipitate dissolved when excess of hydrogen chloride solution was added.

Solutions of sodium oxalate and of orthophosphoric acid gave with zinc chloride white precipitates of the oxalate and phosphate, respectively, both of which dissolved readily in hydrogen chloride solution.

It may be noted that all of these qualitative observations, as well as those reported previously, point toward the generalization that if a salt is insoluble in water, it will be found to be insoluble in acetic acid also; if it is readily soluble in water, however, it may or may not be soluble in acetic acid.

Summary

1. The solubility of zinc acetate in pure acetic acid and in the presence of concentrations of sodium acetate up to about 7 mole per cent. has been determined at various temperatures.

2. The concentration of zinc acetate in the saturated solutions has been found to increase with increasing concentration of sodium acetate as long as zinc acetate itself is the stable solid phase, but to decrease with further addition of sodium acetate after the appearance of an addition compound as solid phase.

3. A solvated sodium zinc acetate of the formula $Zn(C_2H_3O_2)_2 \cdot 2NaC_2H_3O_2 \cdot 4HC_2H_3O_2$ has been isolated and analyzed.

4. Attention has been called to the marked analogy between the ternary system here studied and the corresponding aqueous system.

---

[16] In this case the precipitate was obtained more readily from a zinc chloride solution prepared by heating hydrogen chloride solution with excess zinc acetate and filtering.

[17] Ref. 3, p. 1893.

[18] In this connection, it is worthy of note that cobalt and nickel sulfides could be precipitated from dilute solutions of their chlorides only in "basic" solution, that is, in the presence of sodium acetate, for example.

5. Some further reactions of zinc salts in acetic acid solution have been described.

PHOTOCHEMICAL STUDIES. X. THE ELECTRONIC AND PHOTOCHEMICAL DECOMPOSITIONS OF POTASSIUM CHLORATE

BY JOHN G. MEILER AND W. ALBERT NOYES, JR.

RECEIVED AUGUST 15, 1929 PUBLISHED FEBRUARY 6, 1930

The chemical effects of alpha and beta particles have been studied in some detail during the past few years.[1] These studies have served to demonstrate an equivalence between the extent of ionization and the amount of chemical reaction produced. It has also been shown[2] that reactions initiated by electron bombardment obey laws very similar to those applicable to a-particles. Other reactions have been studied in an effort to determine the minimum kinetic energy of electron which will produce an effect. Thus ammonia is formed in a mixture of nitrogen and hydrogen when these gases are under the influence of electrons of speed greater than those corresponding to the ionization potentials of both reacting gases.[3]

The present work was undertaken with the object of ascertaining whether solid potassium chlorate could be decomposed by slow speed electrons and to ascertain whether any relationship could be found between the kinetic energy of the electrons and the wave length of radiation necessary to bring about photochemical decomposition. The conditions for photochemical decomposition have been obtained, but the results on the electronic decomposition are somewhat less conclusive. They indicate, however, that solid potassium chlorate may be decomposed by fairly high speed electrons.

I. Experimental Procedure'

(a) The Electronic Decomposition.—Preliminary studies[4] indicated that solid oxalic acid could be decomposed by electron bombardment

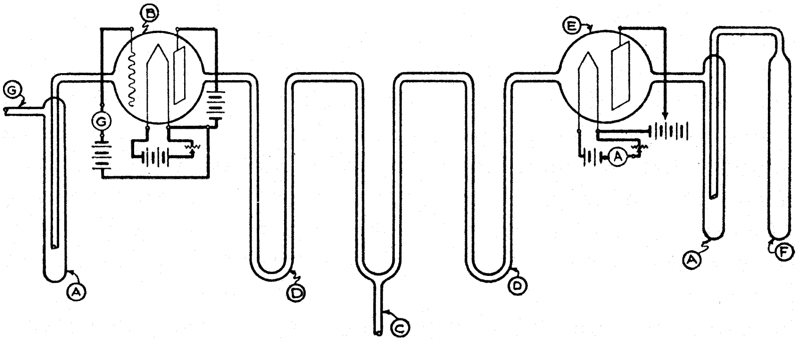
when the kinetic energy of the electrons exceeded a value corresponding to between 4.5 and 5.5 volts. In this study a filament was used as a source of electrons and their speeds were limited by grids in the ordinary way. The results obtained were open to question for the following reasons: (1) the charge on the solid may have rendered the velocity of the electrons uncertain; (2) oxalic acid does not have a negligible vapor pressure at room temperature;[5] (3) thermal radiation from the filament may have caused a slight amount of decomposition. This error was probably small.

To meet these objections partially it was decided to undertake a similar study of solid potassium chlorate, since it has a negligible vapor pressure at ordinary temperatures. Moreover, it undergoes a decidedly exothermic decomposition, which should cause any decomposition initiated by an electron to be magnified by an expected chain reaction.



A, Liquid-air trap; B, ionization gage; C, mercury shut-off; D, liquid-air trap; E, reaction vessei immersed in liquid air; F, mercury reservoir; G, to McLeod gage and pumps.

Fig. 1.—Schematic diagram of apparatus.

The method used in the electronic decomposition of solid potassium chlorate is similar to that used in work on critical potentials. It was necessary to simplify the apparatus by omitting the grids in order to increase the electron current.

Figure 1 shows a schematic diagram of the apparatus used. It was attached to the usual high vacuum line. The vacuum attainable was limited only by the vapor pressure of mercury at liquid-air temperatures (below 10^{-9} cm.).[6] The ionization gage (B) was the Poindexter modifications of the Buckley type,[7] depending on the ionization of the gas by electrons. The volume was only 250 cc., due to the necessity of developing an apparatus which could be thoroughly outgassed by baking in a furnace. The ionization gage was capable of measuring changes in pressure of 10^{-8} cm.

The reaction vessel was a two-electrode vacuum tube (E). The source of electrons was a hot filament in the shape of a spiral one centimeter in length containing three

centimeters of tungsten wire. The first tubes had a metallic plate. It was found, however, that the potassium chlorate decomposed slightly before it was subjected to bombardment with electrons. Figure 2 shows the type of reaction vessel used in the final experiments. It was designed to meet the following requirements: (1) to fit in a quart Dewar vessel; (2) to facilitate the conduction of heat away from the potassium chlorate; (3) to have the major portion immersed in liquid air with only the seals above the liquid air level. In order to meet the second of these requirements a mercury plate was substituted for the solid metallic plate.

Fig. 2.—Diagram of reaction vessel.

The entire apparatus, including the ionization gage, was first outgassed in a furnace heated to about 500° for eight hours. The part of the line not included in the furnace was kept hot by a hand torch. The liquid-air traps were then surrounded by liquid air and the filaments lighted. The plate and grid of the ionization gage were outgassed by bombardment with electrons accelerated through a potential of **10,000** volts. This treatment lasted for three hours. This prolonged outgassing not only removed adsorbed gases and vapor, but also the tungsten oxide coating sometimes formed on the inside of the ionization gage during the early stages of the outgassing.

After the outgassing the reaction vessel was cooled in a salt–ice bath and the mercury distilled into it. The reaction vessel was then immersed in liquid air and the solid mercury plate subjected to electron bombardment. No change in pressure was recorded by the ionization gage after a long interval. The entire process was repeated until no change in pressure was observed on standing for a twenty-four hour period.

The potassium chlorate (which had been kept in a vacuum desiccator over phosphorus pentoxide for six months) was now introduced into Tube B (Fig. 2) and sealed off. The weight A was raised by an electromagnet and allowed to drop. The weight was prevented from falling into the reaction vessel by the catch D. In this manner the potassium chlorate and a small amount of air were admitted to the reactionvessel while the vacuum pumps were running. The line was evacuated with the liquid air removed from around the reaction vessel and allowed to stand for twelve hours. A final evacuation was made before an experiment was started.

The mercury, H, was then given a negative potential with respect to the filament G and the filament lighted until an equilibrium condition was obtained, i. e., until there was no further diffusion of traces of air from the ionization gage to the reaction vessel or vice versa. During this time the reaction vessel was surrounded by liquid air. The mercury was now raised in the cut-off, C (Fig. 1), and the electrons were accelerated toward the potassium chlorate in the reaction vessel with a definite voltage. The two traps, D, were, of course, immersed in liquid air. The liquid air was continually replenished around the reaction vessel and the traps to keep conditions as nearly constant as possible.

Due to the gradual change of the storage batteries and to vibration in the building, there was a continual drift in the current through the ionization gage which could not be ascribed to a change in pressure. Accordingly, after one and three-fourth hours, the positive-ion current through the ionization gage was determined at two-minute intervals for fifteen minutes and then the mercury in the cut-off, C, was lowered and readings again taken at two-minute intervals. Any gas admitted to the ionization gage from the reaction vessel at this time would cause a change in the slope of the current–time curve. By this method a change in pressure of 10^{-8} cm. should be detectable.

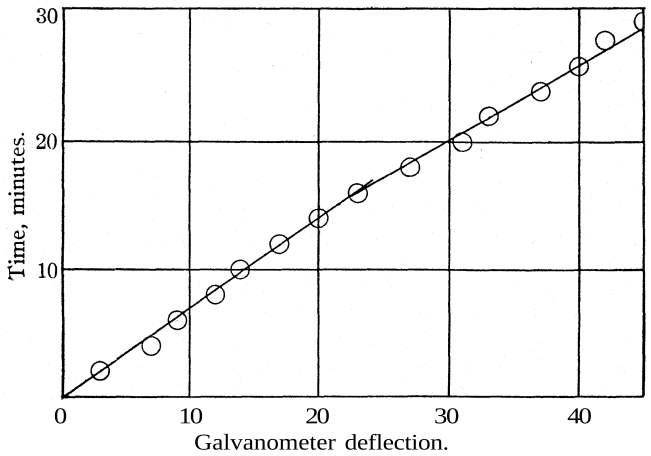

Fig. 3.

Figure 3 shows one typical curve when the accelerating voltage in the reaction vessel was 22 volts. There is a change in slope in the middle of the curve which indicates quite definitely that there was a real decomposition of the potassium chlorate brought about at this voltage. Curves at lower potentials showed no breaks which could be ascribed definitely to an increase in pressure. The experimental error in the determination of the minimum voltage is quite large.

There are two complicating factors which might make the detection of any reaction by this method difficult. The first of these is the adsorption of oxygen by the walls of the apparatus at liquid-air temperatures. This problem has been investigated by Langmuir.[8] He developed the equation $Q = abp/(1 + ap)$, where Q is the quantity of gas adsorbed in $mm.^3$ (measured at standard conditions) per $cm.^2$ of surface, a is a constant, 0.079, b is a constant, 8.46 and p is the pressure in dynes per $cm.^2$ This equation is not valid at very low pressures, but may be used to determine the order of magnitude of the adsorption. It can be shown that

---

[8] Langmuir, THIS JOURNAL, 40, 1361 (1918).

if the surface at liquid-air temperatures is 200 cm.^{2}, the volume 1 liter and the bombarding current 10^{-8} amp., the decomposition should be detectable on the ionization gage without any difficulty if one electron causes the formation of one gas molecule. The second factor is the chemical clean-up. This matter has been discussed by Dushman.[9] Since the maximum pressure to be expected if one molecule of oxygen is liberated per electron passing through the reaction vessel is 10^{-5} cm., the chemical clean-up would undoubtedly reduce the pressure just about to the limit detectable by the ionization gage.

In view of these considerations it seems probable that detection of the decomposition would be difficult and would not be decisive unless a short chain reaction (say 10 to 100 molecules in length) were initiated by the electron bombardment. The only curves which showed any definite break were at accelerating potentials of 22 volts. This may possibly be ascribable to the slightly greater current at this potential.

(b) The Photochemical Decomposition.—Preliminary work on the photochemical decomposition of solid potassium chlorate was carried out with various glasses as color filters. It was found at first that there was an apparent photochemical decomposition brought about by radiation transmitted by soft glass unless the potassium chlorate was separated from the evacuating pumps and McLeod gage by a trap immersed in carbon dioxide snow and ether. Whether this means that there is some secondary reaction between potassium chlorate and mercury vapor was not investigated. When mercury vapor was removed, it was found that no decomposition could be produced by radiation from either a carbon or an iron arc except through quartz itself. All of the color filters excluded the active radiation. The solid was prevented from warming up by immersion of the reaction vessel in water. The pressure changes were measured by a quartz fiber manometer.[10]

The final measurements were made with a constricted arc[11] and a monochromatic illuminator with quartz prisms and lenses. The potassium chlorate was dried at a temperature of 105° for several days under a high vacuum and during illumination mercury vapor was excluded by a trap immersed in liquid air. The liquid air was removed from the trap in making the pressure reading.

With the monochromatic illuminator set at 313mμ no decomposition was observed, whereas decomposition was observed with the setting at 253mμ. The purity of the radiation was tested by photographing the spectrum with a quartz spectrograph. With the setting at 313mμ, lines down to 280mμ were faintly visible and with the setting at 253mμ lines

[11] Forbes and Harrison, THIS JOURNAL, 47,2449 (1925).

up to 290mμ were detectable. No setting of the illuminator which completely excluded the 253.7mμ line of mercury caused any observable decomposition.

As a result of these experiments, it would seem that photochemical decomposition of potassium chlorate to give oxygen may be brought about by radiation of wave length below 280mμ. It would not seem possible to make any more accurate determination of the photochemical threshhold than this. The line at 313mμ is much more intense than the line at 253.7mμ. The lines in between are relatively weak in intensity.[11]

The quantum efficiency is of the order of 1/100 at 253.7mμ, neglecting radiation scattered by the solid.

II. Discussion of Results and Conclusions

The wave length required to produce photochemical decomposition of solid potassium chlorate is found to correspond to about 4.5 to 5.0 volts. The experiments on the electronic decomposition indicate that electrons of this kinetic energy do not cause a rapid decomposition of the potassium chlorate. The fact that from 10 to 100 molecules would have to decompose per electron to be conclusive would make any definite decision on this point impossible. There is the further difficulty in dealing with an insulating solid that the surface might well acquire a charge which would reduce the kinetic energy of the electrons below the threshold value. However, any decomposition at 20 volts would lead to the production of ionization in the gas phase, a fact which would lead to a partial dissipation of the surface charge as well as superimposing a photochemical on the electronic decomposition. It would seem entirely probable, therefore, that even with a decomposition of one molecule per electron at this high voltage, the resulting amplification would have made the effect detectable.

The possibility of increasing the rotation of a diatomic molecule to such a point that dissociation results is negligible, for the selection principle makes changes in rotational quantum number by ±1 only possible. Molecules may be dissociated, however, by increasing the vibrational quantum number beyond the convergence limit. For certain types of molecule this may be accomplished directly by the absorption of radiation. Dissociation may be produced by increasing the vibrational quantum number to such a point that change in electron level becomes possible. Dissociation of the excited molecule results if it possesses the requisite amount of energy. Thus hydrogen should be dissociated by energy corresponding to 4.46 volts[12] but radiation of this wave length is not absorbed by H_2 molecules and inelastic collisions of electrons in hydrogen are not observed at this voltage. However, it is possible to dissociate hydrogen

---

[12] Richardson and Davidson, *Proc.* Roy. *Soc. London,* **123A, 466** (1929).

by wave lengths below 90mμ with the production of one normal atom and one atom in a two quantum state.

If a molecule is to be dissociated by electron impact, it may happen that an energy greater than that theoretically necessary for dissociation would be required. That is, to change the electron level without change in vibrational quantum number it may be necessary to add energy greater that that necessary to bring the molecule in the new electron state to dissociation. Hence the voltage required for dissociation may not agree with that calculated from spectroscopy, for there seem to be few if any cases on record where vibrational quantum number is changed by electron impact without accompanying change in electron level. In most cases the difference is not very great. For these reasons we see that it may not necessarily be possible to calculate the wave length required for photochemical decomposition from the kinetic energy of the electron which will produce the change and *vice versa*. Thus the simple relationship $eV = hc/\lambda$ (e is the charge on the electron, V is the accelerating voltage, h is Planck's constant, c is the speed of light and λ is the wave length) may not hold for the types of process referred to. In so far as conclusions are justified from these experiments, it would seem that there is lack of agreement between the two phenomena for solid potassium chlorate and that the activating processes are probably different.

The phenomenon of pre-dissociation[13] may be of importance in the photochemical decomposition of solids. That is, when the electron level is changed, the molecule may be in such a vibration state that change to another electron level becomes possible with resultant dissociation. For complicated molecules this type of process may easily occur. A diffuseness of the absorption bands is an indication of this phenomenon. Little quantitative work on the absorption spectra of solids has been done which would permit conclusions to be drawn on this point, although it is true that sharp absorption lines are not usually observed.

Summary

1. An attempt has been made to study the decomposition of solid potassium chlorate by bombardment with slow electrons. The results indicate that decomposition may be brought about by 22-volt electrons. Results with lower voltages are somewhat inconclusive but are, on the whole, negative.

2. Oxygen is evolved from solid potassium chlorate by the action of radiation of wave length shorter than about 280mμ.

3. A brief theoretical discussion is given.

ABSOLUTE COHESION IN METALS. DISRUPTIVE NEGATIVE PRESSURES AND CRITICAL DISRUPTIVE VOLUMES[1]

BY ROBERT FRANKLIN MEHL

RECEIVED AUGUST 16, 1929 PUBLISHED FEBRUARY 6, 1930

The work of A. F. Joffe[2] has served to demonstrate that the tensile strength of crystals of sodium chloride as measured in air may be very greatly increased by the solvent action of water operating on the crystals during the tensile test (from 0.44 kg./mm.^{2} to 160 kg./mm.^{2}) and that this higher tensile strength indeed approaches the theoretical tensile strength (200 kg./mm.^{2}) as calculated by Zwicky[3] by an extension of the Born lattice dynamics.

Zwicky's calculation was based on the "theory of heteropolar crystals as developed by Madelung, Kossel, Born and others." It gives a negative pressure exerted in one dimension only, that is, as in the case of two separating plane surfaces, and is in qualitative agreement for sodium chloride with the calculation performed by Polanyi[4] making use of values for surface energy computed by the use of the lattice theory of Born. Joffe[5] has carried out a somewhat similar calculation which yields a negative pressure exerted in three dimensions, a quantity which likewise may be taken as a measure of absolute cohesion. The calculation of this maximum negative pressure is carried out in the following way. Born's well-known lattice energy equation is

$$U = -\frac{A}{r^m} + \frac{B}{r^n} \tag{1}$$

where U is the energy, A and B are constants, r is the interatomic distance defined as the cube root of the atomic volume divided by Avogadro's number. The first term represents the attractive potential and the second term the repulsive, with the condition that $n \gg m$. At the normal (zero external pressure) distance r_0, $\partial U/\partial r = 0$, that is, the force is zero. At any other distance we have

$$\frac{\partial U}{\partial r} = f = \frac{mA}{r^{m+1}} - \frac{nB}{r^{n+1}} \tag{2}$$

The terms for attraction and repulsion, mA/r^{m+1}, and $-nB/r^{n+1}$, respectively, may be plotted against r, as Joffe has done.[6] This gives a

[5] Ref. *2*, p. 21.

[6] Ref. *2*, p. 16. The terms of potential in Equation 1 can be plotted in a similar way. It is to be noted, however, that Joffe's diagram for potentials is incorrect, since it shows the energy curve passing through zero at $r = r_0$, whereas at equilibrium the potential is not zero but a minimum.

set of curves similar to those given in Fig. 1, where $\pi/V^{n'}$ is to be compared with mA/r^{m+1} and $-\pi/V^{m}$ with $-nB/r^{n+1}$, and where V replaces r. Since we have the condition n $\gg$ m, upon expansion (increasing r) the force reaches a maximum negative value and thereafter approaches the r-axis asymptotically. This maximum negative value of the force corresponds to a maximum possible expansion of the crystal, beyond which it will disrupt. Transferring into terms of pressures ($p = -\partial U/\partial V$; $\partial p/\partial V = -\partial^2 U/\partial V^2$) and making use of Equation 2 we may

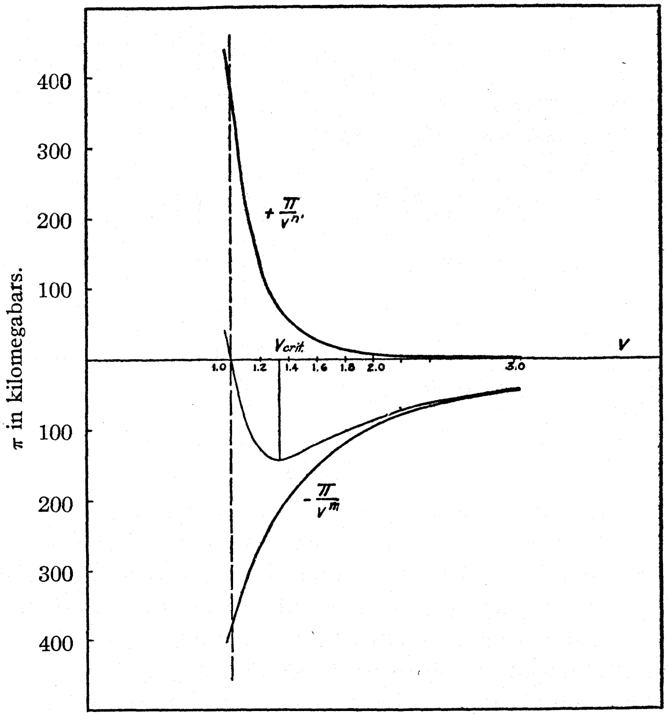

Fig. 1.—Internal **pressure–volume curves** for **copper.**

calculate the value of r at which the crystal will disrupt. Using this value the maximum negative pressure may be computed.[5] For sodium chloride this value is 350 kg./mm.[2]

This method has not been applied with success to metals, largely because of difficulty with the exponents m and n, and also because of the uncertainty in the application to metals of the conceptions underlying Equation 1, which is intended to treat of point charges in definite and known positions. It is the purpose of this paper to point out that the negative pressures necessary for disruption—disruptive negative pressures—may be calculated from the equation of state for solids developed by the late T. W. Richards.[7]

$$p + \pi_0 \left(\frac{V_0}{V_1}\right)^m = \pi_{\rho_0} \left(\frac{V_0}{V_1}\right)^n + P_\theta \tag{3}$$

in which p represent the external (atmospheric) pressure, $\pi_0(V_0/V_1)^m$ the internal cohesive pressure, $\pi_{\rho_0}(V_0/V_1)^n$ the internal expansive pressure, P_θ the internal expansive pressure caused by thermal agitation, V_0 the volume at p_0, and V_1 the volume at p_1. In this case also $n \gg m$.

For convenience in mathematical treatment this equation may be condensed[8] to

$$p + \pi_0 \left(\frac{V_0}{V_1}\right)^m = (\pi_{\rho_0} + P_\theta) \left(\frac{V_0}{V_1}\right)^{n'} \tag{4}$$

With zero external pressure $\pi_0 = \pi_{\rho_0} + P_\theta$, since $V_0 = V_1$. π_0 and $\pi_{\rho_0} + P_\theta$ are thus constant and equal.

Rewriting (4) we have

$$p = -\pi_0 \left(\frac{V_0}{V_1}\right)^m + (\pi_{\rho_0} + P_\theta) \left(\frac{V_0}{V_1}\right)^{n'} \tag{5}$$

Setting $V_0 = 1$ and $\pi_0 = (\pi_\rho + P_\theta) = \pi$, we have

$$p = -\frac{\pi}{V^m} + \frac{\pi}{V^{n'}} \tag{6}$$

The condition that p passes through a maximum (negative) pressure, which Equation 6 demands, is $\partial p/\partial V = 0$. Differentiating (6) with respect to volume we may solve for V

$$V = V_{\text{critical}} = \left(\frac{n'}{m}\right)^{1/(n' - m)} \tag{7}$$

This gives, then, the value for V at which the pressure passes through a maximum, in terms of the coefficients m and n, and is, therefore, the critical disruptive volume. In order to obtain the corresponding value for the disruptive negative pressure we may substitute this value in Equation 6 with the introduction of known values for m, n', π_0 and $\pi_{\rho_0} + P_\theta$, and solve for p, which may then be designated $p_{\text{max.}}$.

This formal treatment of Richards' equation of state, then, gives values for $p_{\text{max.}}$ and V_{critical} in a manner wholly analogous to the treatment of Born's equation as performed by Joffe. With the values of the coefficients m and n' and of the internal pressures calculated for the pure metals by Richards, it is, therefore, possible to obtain approximate values for the disruptive negative pressures and the critical disruptive volumes in metals.

It should be immediately remarked that both the method given here and that of Joffe can be regarded as only approximate because of the fact

---

[7] Richards' paper in *Chem. Rev.*, 2, 315 (1925), is a good summary of his work and contains a complete bibliography, and together with his most recent paper on the subject, THIS JOURNAL, 48, 3063 (1926), may be regarded as sufficient reference to the many papers he published in this field.

[8] Richards, *ibid.*, 48, 3065 (1926).

that the constants in both cases are calculated from quantities measured at one atmosphere pressure or over a small range of pressures (up to only 10,000 kg./cm.^{2} in favorable cases). In addition, in the present case Equation 3 has been condensed into Equation 4, which may cause inaccuracies in higher ranges of pressures.[9] But admitting no great exactness in the final values, it is thought sufficiently interesting to make such calculations for the pure metals. At worst the present method suffers only those defects inherent in Joffe's method.

A comparison between the method proposed here and that given by Joffe may be carried out in the following way. π can be calculated for sodium chloride by the use of Richards' later and more accurate expression[10]

$$\pi = \frac{n'}{n' - m}\,\frac{R}{V_A\alpha_S} \qquad (8)$$

where R is the gas constant, V_A the atomic volume, and α_S the volume coefficient of thermal expansion. Richards has not calculated the exponents m and n' for sodium chloride, but these may be borrowed from Born after suitable transformation.[11]

Taking $\mathbf{m} = 1$ and $\mathbf{n} = 9$, we find m to be 4/3 and n' 4. Using these calculated values for m and n' we can calculate the internal pressure π (which Richards designated π_0), as in Equation 3

$$\pi = \frac{n'}{n' - m}\,\frac{R}{V_A\alpha_S} = \frac{4}{4 - \frac{4}{3}} \times \frac{(83.16 \times 10^6)}{13.53 \times 115 \times 10^{-6}} \times 10^{-6} = 80{,}000 \text{ megabars}$$

---

[9] It should be noted in passing, however, that T. W. Richards (*J. Franklin Inst.*, *July*, 1924, *p*. 23) has shown that the heat of vaporization of mercury can be calculated by integrating the surface enclosed by internal pressure curves calculated from $m = 1.7$ and $n = 9.8$ with remarkable accuracy, the calculated and observed values being 55 kilojoules and 56 kilojoules, respectively. This calculation depends upon the extension of the range of applicability of the exponents to volumes (V_1) of five to ten times the original volume (V_0).

[10] Richards, THIS JOURNAL, 48,3067 (1926).

[11] I am indebted to Dr. R. H. Canfield of the staff of the Laboratory for the following transformation of exponents

$$p = \frac{\partial U}{\partial V} = \frac{\partial U}{3r^2\partial r} = -\pi\left(\frac{V_0}{r^3}\right)^m + (\pi_{\rho_0} + P_\theta)\left(\frac{V_0}{r^3}\right)^{n'}$$

$$\frac{\partial U}{\partial r} = -\frac{3\pi_0 V_0^m}{r^{3m-2}} + \frac{3(\pi_{\rho_0} + P_\theta)V_0^{n'}}{r^{3n'-2}}$$

$$U = -\frac{1}{1-m}\,\frac{\pi_0 V_0^m}{r^{3m-3}} + \frac{1}{1-n}\,\frac{(\pi_{\rho_0} + P_\theta)V_0^{n'}}{r^{3n'-3}}$$

$$= -\frac{A}{r^{\mathbf{m}}} + \frac{B}{r^{\mathbf{n}}}$$

$$\mathbf{m} = 3m - 3 \qquad m = \frac{\mathbf{m}}{3} + 1$$

Therefore

$$\mathbf{n} = 3n' - 3 \qquad n' = \frac{\mathbf{n}}{3} + 1$$

and also the critical disruptive volume, through Equation 7. The value obtained for the critical disruptive volume $V_{\text{critical}} = 1.52$, is, of course, identical with Joffe's value of $r_{\text{max.}} = 1.15$ ($r^3_{\text{max.}} = 1.52$), since the calculations of V_{critical} and $r_{\text{max.}}$ depend only upon the exponents which with the necessary transformation are identical in the two cases.

Introducing values for m, n', a and V_{critical} into Equation 6, $p_{\text{max.}}$ may be calculated and found to be 31,000 megabars. Converting this to kilograms per sq. mm. we obtain

$$p_{\text{max.}} = 316 \text{ kg./mm.}^2$$

which checks fairly closely with Joffe's value of 350 kg./mm.^{2}

This calculation, it is obvious, merely indicates that Richards' calculation of internal pressure gives a quantity which, after suitable transformation, is in definite agreement for sodium chloride with the constants in Born's equation. It must be taken as additional confirming evidence for the validity of Richards' equation.

It seems permissible, therefore, to carry out the calculation of disruptive negative pressures and critical disruptive volumes as outlined above for the metals, using the values for m, n' and π as given by Richards in one of his last papers.[12] From these values V_{critical} can be calculated by Equation 7, and with this $p_{\text{max.}}$ from Equation 6. The values thus obtained are listed in Table I.

These disruptive negative pressures may be taken as a measure of absolute cohesion. The conversion of this three-dimensional loading for metals to a one-dimensional loading seems impossible. Obviously it would be interesting to compare such a calculated tensile strength with the values for actual tensile strength. It is, however, by no means certain that a conversion of this sort would give a value strictly comparable to tensile strength values. It seems certain that the stress distribution in a breaking metal can by no means be represented as that occurring in two plane surfaces simply separated, but that there is a condition obtaining closely similar to the three-dimensional loading considered in the calculation above.[13]

Whatever might be the outcome of a calculation converting these disruptive negative pressures into true or absolute tensile strengths, it seems probable that the true or absolute tensile strengths would not be far from the calculated disruptive negative pressures, certainly of the same order of magnitude. Nothing further or more definite, however, can be said on this point.

Table I lists the tensile strengths of the pure metals corrected for reduction in area. It should be noted, however, that the reduction in area is always calculated from the area after fracture, which is usually less

---

[12] Richards, THIS JOURNAL, 48, 3063 (1926).

[13] B. P. Haigh, *Proc. Int. Cong. App. Mech.*, Delft, 1924, p. 328.

than the area which bears the maximum load. In other words, the values for the reduction in area are rather too large, making the corrected tensile strength somewhat too great. The literature is surprisingly deficient in trustworthy data on the tensile strength of pure metals and even more so in data on reduction in area, so that the figures given must be regarded as approximate except for the common metals such as copper, iron and aluminum.

[a] The numbers in parentheses in the last two columns are uncorrected for reduction in area, no data being available. Those with the single star are from "International Critical Tables," Vol. II; those with a double star are from the Bureau of Standards Circular No. 101, "Physical Properties of Material," 1924. The tensile strength values chosen were always the highest found for metals of high purity.

It may be seen immediately that the corrected tensile strength data are very much lower than the calculated disruptive negative pressures, even allowing for a factor of conversion. The explanation which Joffe[14] gives for the low tensile strength of sodium chloride crystals in air, namely, the presence of cracks inducing stress concentrations and a resultant low tensile strength, is directly applicable to the case of metals. In fact, the importance of very fine cracks in the behavior of metals is now becoming generally appreciated throughout metallurgical literature. It is not impossible that the surface of most metals should be cracked in an ultra-microscopic fashion, as indeed Kapitza[15] has demonstrated for bismuth. In addition, the phenomenon of slip which generally attends

---

[14] Ref. 2, pp. 56-66.

[15] Kapitza, *Proc. Roy. Soc. London*, *119*, 358 (1928); *cf.* Zwicky, *Proc. Nat. Acad. Sci.*, *15*, 253 (1929).

the failure of metals and alloys in the tensile test is conducive to the formation of a roughened surface (easily visible to the naked eye) through the sliding of crystalline blocks, producing reentrant angles on the surface of the test piece with accompanying concentration of stress. Such a stress concentration should lead to the formation of cracks, with a resulting observed tensile strength much lower than that possible through the complete elimination of cracks. Any condition imposed upon the metal to make slip more difficult should, therefore, increase the tensile strength. In a completely isomorphous series of solid solutions the tensile strength is much greater than the calculated rule of mixtures value, as is the hardness. It does not seem likely that the forces of cohesion are much affected by the solid solution formation,[16] so that it is possible that the recognized increased resistance to slip originating in lattice distortion should restrain the tendency for the formation of cracks through slip. The improvement in tensile strength of alloy steels and of the "age-hardening" alloys by heat treatment may then be regarded as caused partly or perhaps wholly by improved resistance to slip.[17] The high absolute cohesion as indicated by $p_{\text{max.}}$ therefore, suggests that alloys have by no means reached their maximum possible values of tensile strength, and that a complete knowledge of the ultramicroscopic cracks and of the phenomenon of slip might lead to the development of extremeiy strong alloys.

Summary

1. It is pointed out that Richards' equation of state for solids can be used in the calculation of the negative pressures necessary for the disruption of metallic lattices and of the critical volumes at which the disruption should take place, a calculation not hitherto performed.

2. With exponents borrowed from Born after suitable transformation the method yields a disruptive negative pressure for sodium chloride in agreement with that which Joffe calculated from Born's potential energy equation.

3. Disruptive negative pressures and critical disruptive volumes are calculated for the twelve cubic metals for which Richards has given the constants in his equation of state.

4. The values of the disruptive negative pressures obtained suggest that the tensile strengths of metals and alloys have by no means reached their maximum possible values.

WASHINGTON, D. C.

THE DETERMINATION OF TRACES OF IODINE. III. IODINE IN MILK, BUTTER, OIL AND URINE[1]

BY J. F. McCLENDON, ROE E. REMINGTON, HARRY VON KOLNITZ AND REDDING RUFE

RECEIVED AUGUST 21, 1929 PUBLISHED FEBRUARY 6, 1930

In the first paper of this series[2] was described a combustion tube method for the destruction of organic matter in foodstuffs for the purpose of determining traces of iodine. This method has since been used by Reith,[3] Schwaibold,[4] and others, and is the only workable method which we have found for iodine estimation in some classes of organic material. The second paper[5] describes a method of introducing dried vegetables into the tube, and some improvements which experience has suggested in the manipulation. It also describes a method of low temperature ignition in a muffle which has been found reliable for root and leafy vegetables (with a loss of about 15%) and which materially simplifies and shortens the technique. This alternative method was checked on known quantities of iodine added to potatoes, and on dried thyroid added to potatoes, with very satisfactory results.[6] When applied to skim milk powder this method sometimes failed. The loss was evidently sometimes due to too high a temperature in the first heating or smoldering of the sample. Duplicate samples done by the same chemist would check very accurately. Sometimes another pair of duplicates of the same sample done by another chemist would check but not check with the first pair. The smoldering must be carefully watched so that no live coals appear at the surface, in order to prevent loss. This is especially true of evaporated urine residues, particularly if only calcium oxide is added as an alkali. In this case only about 80% of added iodide was recovered. The low temperature method depends on the presence of a great excess of alkali and is, therefore, best adapted to vegetables other than cereal grains. Loss of iodine in ashing other samples can be prevented only by large additions of alkali and, therefore, to a certain extent defeats the purpose of the method, which is the freeing of the iodide from any large amount of other substances. The

low temperature ashing method is not applicable to whole milk, fatty seeds, nuts or fats and oils. The present contribution will, therefore, describe methods which have been found suitable for these products, and some additional improvements in the original procedure.

Method for Fat (Including Butterfat).—The fat is melted and, if necessary, filtered free from water and suspended impurities. It is then introduced into the bottle of a large atomizer or lacquer spray apparatus (New Way Spray Gun Co., Cleveland), and sprayed into a silica tube (1 inch bore, 2 feet long with elbow 1 foot long) by means of a current of oxygen. The general set-up (Fig. 1) is the same as described in the preceding paper with some exceptions. It is necessary that the silica tube be very hot during the combustion or that a point in front of the atomizer be kept hot by means of a minute blast-flame or electrically heated platinum spiral. If electric heat is used outside the tube some provision for visibility should be made. A piece of platinum foil[7] or a platinum spiral of heavy wire in the tube acts as a catalyst. To close the end of the tube and prevent carbonization at the nozzle, it is surrounded with a pad of moist asbestos, which can be cooled by dropping water on it. The sodium hydroxide in the first wash bottle or absorption flask has been replaced by 0.25 g. of sodium sulfite, which insures that the iodine is reduced to the iodide form. In order to hasten the combustion, a rotary air pump drawing 2 cu. ft. of air per minute is used to suck the exhaust gases through the apparatus and ten Milligan wash bottles are used in parallel. It is necessary to cut the gas stream velocity down to a point where absorption is complete. All wash bottles are immersed in ice water. Following the wash bottles one or more towers packed with glass wool or an alundum extraction thimble to filter particles from the exhaust gases is inserted.

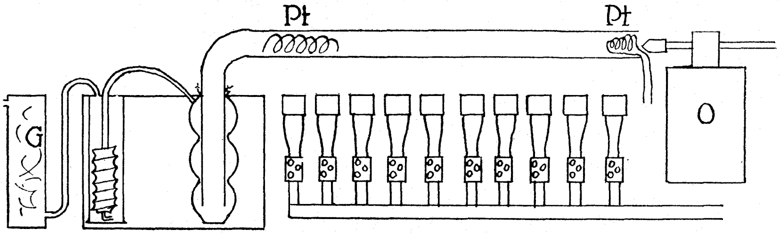

Fig. 1.—Combustion apparatus for burning fat and oil. The oil is placed in the container (O) of the atomizer and sprayed with oxygen into the silica tube, 2 feet long, 1 inch bore, with elbow 1 foot long. A platinum spiral (Pt) right in front of the atomizer tip is kept at white heat by means of an electric current. Another platinum spiral (Pt) further in the tube is heated by means of Meker burners under the tube. The elbow in the silica tube dips into an absorption flask of three compartments and the joint is packed with asbestos fiber. This is connected with ten Milligan wash-bottles in parallel, all immersed in ice water, which are connected with a tower packed with glass wool (G) and finally with an exhaust pump.

The adjustment of the atomizer is very important, for if the ratio of oxygen to fat is too high, the fatty acids will not burn, but will distil over. If, on the other hand, too little oxygen is used, soot will form. The atomizer is best adjusted in a preliminary

---

[7] A tube lined with a platinum film soon cracked. A manganous salt added to the fat as a catalyst did not improve the combustion. Probably a rare earth salt would be useful.

trial and kept set during the combustion. The amount of fat burned is determined by weighing the atomizer bottle before and after the combustion. If the iodine content is low, it may be necessary to burn as much as 500 g. of fat. It is possible to so conduct the burning that no soot and tarry products are formed. The liquid in the wash bottles is placed in a beaker, the rinsings of the apparatus added, evaporated to small volume, transferred to a nickel boat, evaporated to dryness and ignited in a pyrex tube (Fig. 2), using about 5 cc. of water and a few milligrams of sodium sulfite in a side-necked test-tube to absorb volatilized iodine. If an alundum capsule is used it is ignited in the same tube. The boat is placed in the smallest test-tube into which it may be introduced, the sulfite solution added, together with rinsings of the tube, and left until the ash has dissolved. The solution is centrifuged free from insoluble residue, decanted into a 30-cc. beaker, a few drops of sulfurous acid (to reduce iodate) and a few milligrams of sodium azide added (to decompose nitrites) and neutralized with sirupy phosphoric acid, using bromphenol blue paper as indicator. Four drops of phosphoric acid are added in excess and the solution boiled to remove sulfur dioxide (as well as excess hydrazoic acid).

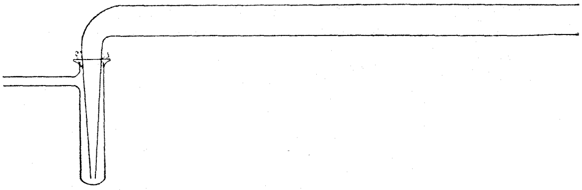

Fig. 2.—Small pyrex combustion tube and side-necked test-tube for absorbing iodine from the combustion.

If the odor of hydrazoic acid is not perceived, more sodium azide is added. It was shown by Reith that there might be considerable nitrite formed in the combustion of foodstuffs containing nitrogen, and that the nitrite might be decomposed by hydrazoic acid.

The solution is now transferred to a small separatory funnel with an etched mark at **10** cc., made up to the mark with distilled water and about 1 mg. of sodium nitrite added, followed by **1** cc. of purified carbon tetrachloride. The separatory funnel is shaken for at least two minutes, during which time the iodide is oxidized to iodine and 85/95 of the iodine passes into the carbon tetrachloride solution and is compared with a standard containing 0.1 mg. of iodine per cc. in a Bausch and Lomb micro-colorimeter. This is multiplied by 1.118 to correct for the partition coefficient of iodine between carbon tetrachloride and the dilute salt solution. Or, since this partition coefficient varies

TABLE I

slightly with variation of salt content, the solution may be repeatedly extracted with carbon tetrachloride and the yields of the different extractions added together.

By this method the iodine content of a sample of Norwegian cod-liver oil was found to be 5800 parts per billion.

Method for Oily Seeds and Nuts and Milk.—On account of the large amount of fat or protein present, low-temperature ignition is not successful on this class of products, even though one is content with 85% recovery, and since the material cannot be sprayed, the tube furnace with the screw feed is used. Visking sausage casing has been found very satisfactory as a lining in which to pack the dry material before introduction into the screw feed device. The mouth of the feed tube ($^7/_8$-inch bore) is brought into juxtaposition with the end of the silica tube furnace (1-inch bore) and oxygen delivered to the crack by a nozzle made from an ordinary flame spreader ("fish-tail" or "wing-top" for Bunsen burner) which has been bent into a curve to fit the outside of the feed tube (Fig. 3, the detail above the diagram shows the flame spreader from another angle).

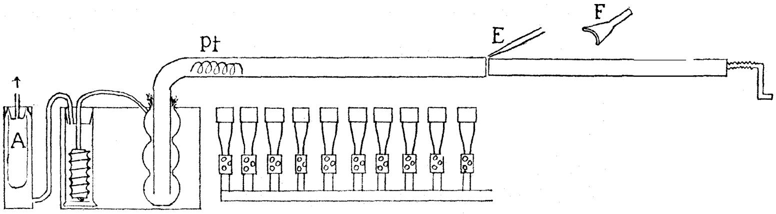

Fig. 3.—Combustion apparatus for burning solid food materials. The arrangement is the same as in Fig. 1, except that the atomizer is replaced by a steel tube of $^7/_8$-inch bore with a micrometer screw for forcing the foodstuff into the silica tube. The foodstuff is packed in a Visking sausage casing which is inserted in the steel tube. Oxygen is emitted through the adapter (E) which is shown at perspective at (F). The tower of glass wool shown in Fig. 1 is replaced by an alundum capsule (A) for straining out the particles of smoke that might escape the absorption flask.

About 6 inches of the silica tube is lined with sheet iron or nickel for protection from the ash. After igniting the material by means of a flame, the joint is covered with a lump of wet asbestos fiber and kept moist. The combustion is then carried on as previously described. The ash is ground for one hour with 100 cc. of 95% alcohol in a 250-cc. ball mill and then for one hour with 100 cc. of 80% alcohol; the combined extracts are centrifuged and the combined alcohol extracts decanted, evaporated and added to the evaporated washings of the apparatus. If a yellow or dark color appears, the residue must be transferred to a nickel boat and ignited in the small tube, Fig. 2.

Milk is best neutralized with sodium hydroxide, using phenol red paper as indicator, evaporated to small volume on a water-bath, some rare earth (ceria or thoria) and sulfur added, heated in an oven at 100° until dry, then ground in a burr mill or broken into pieces and packed in Visking sausage casing. The evaporation of milk in open dishes is tedious and wherever possible milk powder is obtained. The rare earth seems to act as a catalyst in combustion,[8] and the sulfur aids in the reduction of iodine.

Geographical surveys on the iodine content of milk are meaningless unless considerable data are collected, since it has been shown that the feeding of iodine compounds increases the iodine content of the milk, and there are now on the market many dairy feeds which contain fish

---

[8] Personal communication of O S Rask.

meal, ground kelp and mineral iodides. The iodine content of whole milk may be calculated from the iodine content of butterfat and skim milk. We were able to determine the iodine content of the "hulls" of the fat droplets after feeding a cow iodide, but ordinarily we think this fraction is negligible.

Since butterfat is used for human consumption to a greater extent than are the other constituents of milk, it is of interest to know the ratio of the iodine in the butterfat to that in the skim milk of the same sample of milk. For this purpose about five gallons of milk are separated, the cream is churned and the total iodine content of the skim milk plus buttermilk determined separately from that of the butter.

TABLE II

[b] Made by adding 20 *g.* of ICl_3 to a gallon of linseed oil.

[c] Iodine in hulls, 26,000.

The above results of feeding a cow iodized salts equivalent to 10 g. of iodine a day for five days and another cow iodized oil are not in agreement with those of Scharrer and Schwaibold[9] or of Rasche.[10] It seems probable that these discrepancies are due to losses of iodine in analysis and we doubt whether accurate analyses can be made on samples much smaller than ours by any method.

Method for Urine.—If the urea is not destroyed it becomes troublesome to burn the urine residue because the decomposing urea forms gases which foam and sputter, causing loss and putting out the flame. The twenty-four hour urine specimen is colored with phenol red, neutralized

with lime water and subjected to hydrolysis with urease (about 5 cc. of the extract of 5 g. of jack bean meal). An hour suffices for the hydrolysis of the urea, after which 5 g. of lime is added and the urine evaporated to a small volume. (The use of a hot-plate regulated at 100°, Fig. 4, avoids the danger of overheating.) When evaporated to small volume the urine is transferred to a nickel boat, some rare earth and sulfur added, evaporated to dryness and ignited in an excess of oxygen in a pyrex tube furnace (Fig. 5) by first heating the material nearest the absorption flask by means of an oxy-gas torch or electrically heated platinum loop and working back to the open end of the tube.

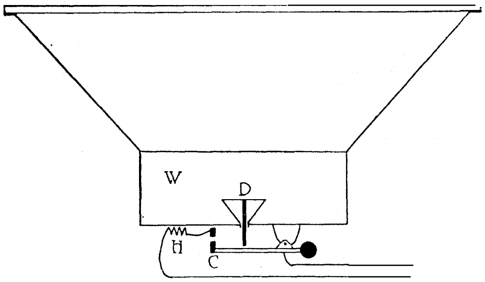

Fig. 4.—Constant temperature hot-plate, kept at 110" by means of an electric regulating apparatus. The hot-plate is the top of an evacuated chamber, the lower portion of which is filled with water (W) and heated by the electric heater (H). When the water (W) boils and produces steam above atmospheric pressure, the diaphragm (D) is pushed down, forcing down the electric contact (C) and thus breaking the circuit and cutting off the heat.

The pyrex tube furnace shown in Fig. 5 is reduced in size stepwise so as to accommodate nickel boats of different sizes. The platinum spiral is heated by the electric current from a transformer in which the voltage may be varied by turning a knob (Franklin Transformer Company, Minneapolis). It may be heated by means of a gas flame below the tube, but there is more danger of softening the pyrex. The spiral is heated so as to be luminous in a darkened room but not perceptibly luminous in a brightly lighted room. The oxy-gas torch has an opening made by driving a needle through the oxygen tube, thus directing a stream of oxygen forward so as to supply oxygen to the platinum spiral and complete the combustion of gases. The torch itself has the gas cut down to a small rate and the oxygen supplied in excess so that the heated urine residue will burn with a dazzling luminosity. In case an electrically heated platinum loop is substituted, an attached tube carries oxygen, which is directed toward the loop. The loop is plunged into the urine residue and moved slowly backward until all is ignited.

If any tarry film condenses on the pyrex tube it is burned off by placing a gas flame under it.

At the end of the combustion the ash has a light gray color or is almost white. The ash is ground for one hour in a 250-cc. ball mill with 100 cc. of 95% alcohol, followed by one hour with 100 cc. of 80% alcohol, and the combined extracts are centrifuged and decanted. The extracts, sulfite solution and washings of the tube are evaporated in a porcelain dish to a small volume and, if necessary, centrifuged again and transferred to a nickel boat, evaporated to dryness, and ignited in the smaller pyrex tube (Fig, 2). The analysis is then continued as in analysis of iodine in fat.

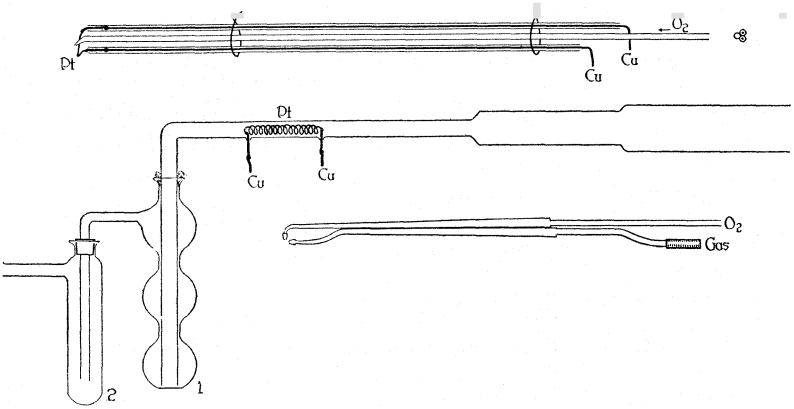

Fig. 5.—Apparatus for burning urine residue. The urine is placed in a nickel boat and is inserted into the pyrex tube which is narrowed stepwise. The boat is placed in the narrowest portion which will conveniently receive it. The platinum spiral (Pt) is heated by means of the copper connection (Cu) in the middle of the figure. The pyrex combustion tube is bent down into a tripartite absorption flask (1) and the joint closed with asbestos. The second absorption flask (2) is closed by means of a rubber stopper. Heat is supplied by means of the oxy-gas torch, shown below, with an extra opening in the oxygen tube, allowing oxygen to pass forward, or by means of the apparatus shown above. To show the details the binding wires are loosened so that the three parts are shown separately. The middle tube (O) carries oxygen, which is directed toward the platinum loop (Pt) and in each of the other tubes is a pyrex tube containing a copper wire, which is welded onto a large platinum wire, which, in turn, is connected onto the platinum loop of finer platinum wire (Pt), which is heated to a white heat by means of an electric current. The gas or electric torch is held in the hand and inserted inside the pyrex combustion tube in order to burn the urine residue.

In order to determine the behavior of the apparatus, relatively large quantities of iodide were added to small samples of iodine-free substances and burned in the tube. Ten mg. of iodine (as potassium iodide solution) was added to 50 cc. of iodine-free urine treated as above described, and burned in the tube. There was recovered

8.10 mg. in the ash in the boat
0.49 mg. in the washings of the tube
0.47 mg. in the 1st absorption tube
0.055 mg. in the 2nd absorption tube

Total, 9.115 mg. of iodine recovered

On repeating this experiment the following values were obtained

3.07 mg. in the ash in the boat
0.375 mg. in the washings of the tube
5.562 mg. in the 1st absorption tube
0.762 mg. in the 2nd absorption tube

Total, 9.769 mg. of iodine recovered

Ten mg. of iodine (as potassium iodide solution) was added to 5 g. of iodine-free starch and burned in the tube with the following recovery

7.94 mg. in ash in the boat
1.26 mg. in 1st absorption flask (none found in 2nd absorption flask)
0.13 mg. in washings of tube

Total, 9.33 mg. of iodine recovered

This experiment was repeated, with the following results

9.66 mg. in the ash in the boat
0.52 mg. in the 1st and 2nd absorption flasks
0.05 mg. in the washings of the tube

Total, 10.23 mg. of iodine recovered

The recovery was within the limits of accuracy of the pipet in which the iodide solution was measured. The variations in the distribution of iodine in different parts of the apparatus were probably due to variations in temperature, duration of heating and rate of suction of air and exhaust gases through the apparatus. If potassium iodide is heated in a test-tube over a Bunsen burner, elemental iodine is evolved. It is not necessary to raise the temperature sufficiently to sublime the iodide in order to carry over iodine into the absorption flasks. If there is not sufficient sulfite in the absorption flasks, iodine will color the solutions in them (and some be lost, passing into the suction pump), and the color disappears on adding more sulfite.

Eight (24-hour) urine specimens of Minnesota men who used ordinary non-iodized salt ranged between 0.008 and 0.011 mg. (av. 0.00956) of iodine. Nine (24-hour) urine specimens of Minnesota men who used iodized salt ranged from 0.068 to 0.295 (av. 0.1213 mg.). The great variability is probably due to variability of intake of iodine. The average iodized salt contains about 1.4 mg. of iodine per 100 *g.* of salt. The amount used by the subjects was not controlled. In two determinations on days following strenuous exercise, the iodine excreted in the urine was double that on other days, but the iodine intake was not investigated. In one determination day-urine contained about twice as much iodine as night-urine (12-hour day urine, 0.09, and 12-hour night urine, 0.05 mg. of iodine).

[a] Way following heavy exercise.

Summary

1. Foodstuffs and urine are burned with oxygen in a silica or pyrex tube furnace, using an atomizer for oils and a screw feed device for solid substances. Heat is applied from the outside by gas burners or from the inside by electrically heated platinum wires or oxy-gas torches. Urine is freed from urea with urease and burned in a pyrex tube furnace.

2. Sodium sulfite solution is used to absorb the iodine, and hydrazoic acid to free it from excess nitrite. The iodide is oxidized with a known quantity of nitrite to iodine and shaken out with carbon tetrachloride.

THE HEAT CAPACITY AND ENTROPY OF POTASSIUM PERCHLORATE FROM 12 TO 298° ABSOLUTE. THE HEAT OF SOLUTION OF POTASSIUM PERCHLORATE. THE ENTROPY AND FREE ENERGY OF PERCHLORATE ION

BY WENDELL M. LATIMER AND J. ELSTON AHLBERG[1]

RECEIVED SEPTEMBER 3, 1929 PUBLISHED FEBRUARY 6, 1930

This work is a continuation of the program[1a] for the evaluation of entropies of aqueous ions and constitutes an example of the application of these values to the determination of the free energy of a negative ion which is not readily obtained by the ordinary equilibrium or electromotive-force methods.

The following measurements were made: (1) the heat capacity of po-

---

[1] Du Pont Fellow in Chemistry.

[1a] For references to the general theory see (a) Latimer and Buffington, THIS JOURNAL, 49, 2297 (1927); (b) Latimer, *ibid.*, 48, 2868 (1926); (c) Latimer and Greensfelder, *ibid.*, 50, 2202 (1928); (d) Latimer and Kasper, *ibid.*, 51, 2293 (1929); (e) Latimer, *J. Phys Chem.*, 31, 1267 (1927).

tassium perchlorate from 12 to 298°K., (2) the heat of solution of potassium perchlorate at 208.1°K. These values have been used in the calculation of the entropy of potassium perchlorate and the entropy and free energy of perchlorate ion.

Material.—The potassium perchlorate used was Baker's "C. P.," which was recrystallized four times and dried for 100 hours under vacuum. Analysis indicated the purity to be at least 99.9%.

Measurement of Heat **Capacity.**—The experimental method follows the general plan used by Latimer and Greensfelder" and reference may be made to their paper for a description of the experimental technique. In cooling the calorimeter to the lowest temperature, ll.S°K., the three-stage vacuum pump described by Giauque and Johnston[2] was used. All runs were timed by a stop watch calibrated before and after measurements with watches at the University Observatory. The values obtained for the specific heat and the molal heat capacity are given in Table I in calories per degree K. The high value at 274.75°K. may be explained by the assumption of less than 0.1% of water occluded inside the crystals. The mean deviation of the values excluding the lowest and the ice points is ±0.3%.

[2] Giauque and Johnston, THIS JOURNAL, 51, 2300 (1929).

Entropy of Potassium **Perchlorate.**—Figure 1 gives the plot of C_p against log T, from which the entropy may be obtained graphically as the integral $S = \int C_p \, d \ln T$. The extrapolation at low temperatures was carried out by fitting the lower points to a Debye function. In this region the curve is rapidly approaching the T^3 law. The value which we found from the integration is $S_{298.1} = 36.1 \pm 0.3$ cal./deg.

Heat of Solution.—The measurements of the heat of solution were made in a calorimeter which consisted of a vacuum-walled flask of about a liter capacity fitted with a stirrer and resistance thermometer. The resistance thermometer contained about 300 ohms of number 40 copper wire and served also as the heating coil for the determination of the heat capacity of the calorimeter. A small tube in the neck of the flask contained a definite weight of the solid potassium perchlorate, which could be dumped into the water by an outside control. The whole apparatus was submerged in a 25° thermostat constant to 0.01°. The value obtained for the heat of solution of one mole of potassium perchlorate in 1800 moles of water at 298.1°K. was 12,115 ± 30 cal.

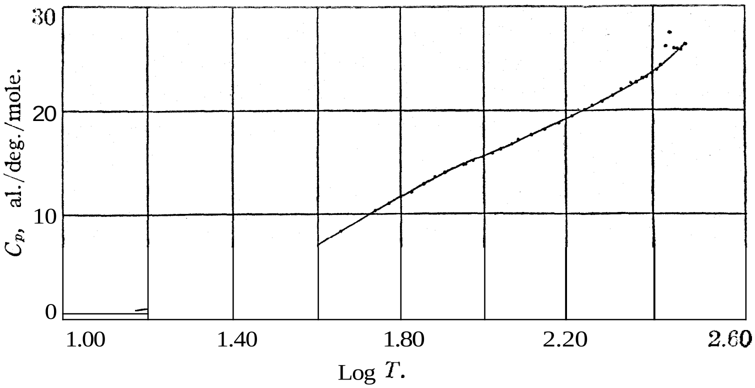

Fig. 1.—Molal heat capacity of potassium perchlorate.

Entropy of Perchlorate Ion.—We may now calculate the entropy change for the process: solid potassium perchlorate to give a hypothetical one molal solution of its ions, from the relations

$$\Delta S^\circ = \frac{AH - AF^\circ}{T} \quad \text{and} \quad \Delta F^\circ = -RT \ln (\gamma m)^2$$

This requires in addition to the heat of solution AH a knowledge of the solubility, m, and the activity coefficient, γ. The former has been carefully determined by a number of investigators;[3] their results, agreeing

[3] (a) Noyes, Boggs, Farrell and Stewart, THIS JOURNAL, 33, 1650 (1911); (b) Noyes and Sammet, *Z. physik. Chem.*, 43, 534 (1903); (c) Rothmund, *Z. physik. Chem.*, **69**, 538 (1909).

to within 0.3%, give $m = 0.148$ mole per liter at 298.1°K. The activity coefficient in the saturated solution is not readily determined experimentally, as the ordinary freezing-point method encounters as a difficulty the small solubility of the salt at low temperatures. From the conductivity measurements of Noyes and Sammet,[3b] the value α_λ for the saturated solution at 298.1°K. is 0.78, and since this value agrees closely with the value for potassium nitrate, we feel justified in assuming the activity coefficient as given by Lewis and Randall[4] for the latter salt, namely 0.70 ± 0.05. This then gives

$$\Delta F^\circ_{298}, = -1364\ 9 \log (0.148 \times 0.70)' = +2690 \pm 100 \text{ cal.}$$

and

$$\Delta S^\circ_{298}, = \frac{12{,}115 - 2690}{298.1} = +31 \text{ ti entropy units}$$

Using our value for the entropy of the solid, 36.1, we obtain for the sum of the entropies of potassium and perchlorate ions, 67.7. Latimer and Buffington gave 22.0 for the entropy of potassium ion as the average of two methods. This now becomes 21.5 when we use the recent value of Lange[5] for the heat of solution of potassium chloride which entered into one of the calculations. Hence we obtain for the entropy of perchlorate ion in the hypothetical one molal solution at 298.1°K, $S^\circ_{298.1} = 46.2$.

Free Energy of Perchlorate **Ion.**—Berthelot[6] found as the average of two methods for the reaction,

$$KClO_4 = KC1 + 202 \quad . \quad A\,H = +7600 \text{ cal.}$$

Combining this with our experimental heat of solution of potassium perchlorate and with Lange's value for the heat of solution at infinite diiution of potassium chloride, +4157 calories, we obtain

$$ClO_4^- = Cl^- + 2O_2 \qquad AH = -358 \text{ cal.}$$

Then from the value of the entropy of perchlorate ion obtained above, the entropy of chloride ion,[1b] 15.6, and the entropy of oxygen,[2] 49.03, we obtain for the same reaction, $\Delta S^\circ_{298.1} = 67.5$. Hence

$$ClO_4^- = Cl^- + 202 \qquad \Delta F^\circ_{298.1} = -358 - 298.1 \times 67.5$$
$$= -20{,}480 \text{ cal.}$$

We can also calculate, as a check, the free energy of this reaction by another path which does not involve the ionic entropies. Thus using the entropy of potassium chloride,?19.7, together with that for potassium perchlorate and oxygen, we obtain

$$KClO_4 = KCl + 2O_2 \qquad \Delta F^\circ_{298.1} = +7600 - 298.1 \times 81.7$$
$$= -16{,}755 \text{ cal.}$$

---

[4] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Kill Book Co., New York, **1923.**

[5] Lange, *Z.* Elektrochem., 35, 29 (1929).

[6] Berthelot, *Ann. chim. phys.,* [5] **27,** 226 (1882).

[7] Lewis and Gibson, THIS JOURNAL, 39, 2554 (1917).

Combining this value with the free energy of solution of potassium perchlorate, +2688, and of potassium chloride,[8] −936, gives

$$ClO_4^- = Cl^- + 2O_2 \qquad \Delta F^\circ_{298.1} = -20{,}379 \text{ cal.}$$

Using −20,430, the average of the two methods, and the Lewis and Randall[4] value for the free energy of chloride ion, −31,367, we obtain for the *free energy of perchlorate ion*, $F^\circ_{298.1} = -10{,}937$ cal.

The error in this value is determined very largely by the accuracy of the heat of decomposition of potassium perchlorate measured by Berthelot. Although this is difficult to estimate, we judge it is within ±500 cal.

For many purposes it is more convenient to express the free energy of perchlorate ion in terms of the reduction potential referred to the H_2–H^+ couple as zero. Using the Lewis and Randall[4] value for the free energy of water, we find

$$\tfrac{1}{2}Cl_2 + 2H_2O = ClO_4^- + 8H^+ + 7E^-;\ E^\circ = -1.333 \pm 0.005$$

Summary

The specific heat–temperature curve and the heat of solution of potassium perchlorate have been determined. These values have been used in the calculation of the entropy and free energy of perchlorate ion.

CERIC SULFATE AS A VOLUMETRIC OXIDIZING AGENT. XII. THE DETERMINATION OF TELLUROUS ACID

BY H. H. WILLARD AND PHILENA YOUNG

RECEIVED SEPTEMBER 5, 1929 PUBLISHED FEBRUARY 6, 1930

Introduction

An excellent survey of the volumetric methods proposed for tellurium up to the year 1926 has been given by Lenher.[1] The electrometric titration of tellurate with titanous chloride either in a hydrochloric or a sulfuric acid solution has been described recently.[2] The volumetric method based upon the oxidation of tellurous acid by dichromate, proposed first by Brauner[3] and modified by Moser and Miksch,[4] Lenher and Wakefield,[5] and Schrenk and Browning,[6] appears to be the most satisfactory and is applicable in the presence of selenious acid. The oxidation, if carried out at room temperature in hydrochloric acid solution,[5] is rather slow and

the concentration of hydrochloric acid must be carefully controlled. If too low, the speed of the reaction is retarded; if too high, hydrochloric acid and telluric acid react to give free chlorine. Schrenk and Browning[6] carried out the oxidation at room temperature in a sulfuric acid solution, forty-five to sixty minutes being required for complete oxidation. They did not study the reaction in hot solution.

This paper describes a rapid and accurate volumetric procedure for tellurium, based upon the oxidation of tellurous acid by excess standard ceric sulfate in the presence of chromic sulfate as catalyst, and electrometric titration of the excess ceric sulfate with standard ferrous sulfate.

Experimental

The potassium tellurite solution was prepared by dissolving pure basic tellurium nitrate in dilute potassium hydroxide, and was approximately 0.09 N. It was standardized by the method of Lenher and Wakefield[5] against dichromate of known purity, the excess of dichromate being titrated electrometrically with ferrous sulfate. A 0.1 N selenious acid solution was prepared from high grade selenious acid. The ceric sulfate solution was a part of a large supply made by the method described by the authors[7] from high-grade ceric oxide and was 0.5 M in sulfuric acid. It was standardized against sodium oxalate.[8] The ferrous sulfate solution was standardized electrometrically against standard ceric sulfate.[8]

The oxidizing action of ceric sulfate on selenious acid and tellurous acid was first tested. Measured portions of 0.1 N selenious acid were diluted with water, 25 cc. of 0.09611 *N* ceric sulfate and sulfuric acid (sp. gr. 1.5) to 200 cc., heated to boiling, held just below the boiling point

over a small flame for the time indicated, then cooled to 30–35°, and the excess of ceric sulfate titrated electrometrically with standard ferrous sulfate. The results are shown in Table I.

These results indicate that selenious acid is not oxidized by ceric sulfate in a hot solution of moderate acid concentration and only very slightly oxidized in a solution of low acidity.

Measured portions of a 0.9 N tellurite solution were diluted with water, acid and 25 cc. of 0.09611 N ceric sulfate to 200 cc., and treated in the same way as the solutions for the experiments in Table I. The results obtained are shown in Table II

Thus tellurous acid is only slightly oxidized under the conditions used in these experiments.

Since dichromate may be used, either in a hydrochloric or a sulfuric acid solution, to determine tellurous acid in the presence of selenious acid,[4,5,6] and since ceric sulfate may be used to oxidize chromic salt quantitatively to chromic acid in sulfuric acid solution,[9] it seemed obvious that

[9] Willard and Young, THIS JOURNAL, 51, 139 (1929).

chromic salt should catalyze the reaction between ceric sulfate and tellurous acid. Ceric sulfate oxidizes the small amount of chromic salt to chromic acid, which, after oxidizing tellurous acid, would be reoxidized by the ceric sulfate. To test this point, solutions were prepared as for the experiments in Table II, except that additions were made of chromic sulfate, and in some cases of selenious acid and copper sulfate, and the volume of the solution at the time of oxidation was varied. The treatment of the solutions was the same as for the experiments in Table II. Results are shown in Table III.

The above data show that the oxidation of tellurous acid by ceric sulfate in the presence of chromic salt as catalyst is quantitative over wide variations in acid concentration, excess of oxidizing agent and time of its action, volume of solution in which the oxidation is carried out, amount of chromic salt as catalyst and tellurous acid content. Selenious acid does not interfere if the sulfuric acid concentration at the time of oxidation is not too high. Cupric salts are without effect. The method offers a much wider possibility of variation in conditions than does the oxidation of tellurous acid by dichromate in hydrochloric acid solution, and is more rapid. The same is true in comparing it with the oxidation of tellurous acid by dichromate in sulfuric acid solution, though the experiments in Table III show that a much wider range of conditions could be developed for this latter method than those described by Schrenk and Browning.[6]

Also, preliminary experiments have shown the possibility of using chromic salt as catalyst in many oxidation reactions in which ceric sulfate alone is not effective, for example, in the oxidation of certain organic substances.

Summary

1. Selenious acid is not oxidized by ceric sulfate in hot sulfuric acid solution. Tellurous acid is oxidized only to a very slight extent under the same conditions.

2. A rapid quantitative method for tellurous acid has been developed, based upon its oxidation in hot sulfuric acid solution by ceric sulfate in the presence of chromic sulfate as catalyst. Selenious acid and cupric salts do not interfere.

3. Attention is called to the possibility of using chromic sulfate as catalyst in other oxidation reactions in which ceric sulfate alone is not effective, especially in the oxidation of certain organic substances.

CERIC SULFATE AS A VOLUMETRIC OXIDIZING AGENT. XIII. THE DETERMINATION OF MERCUROUS MERCURY

BY H. H. WILLARD AND PHILENA YOUNG

RECEIVED SEPTEMBER 5, 1929 PUBLISHED FEBRUARY 6, 1930

Introduction

Few of the volumetric oxidation or reduction methods for mercurous mercury afford a separate estimation of it in the presence of mercuric ion. Among the procedures which accomplish this may be mentioned (1) its reduction by potassium iodide to mercury, followed by addition of excess standard iodine solution, and determination of the excess iodine with thiosulfate;[1] (2) its precipitation as mercurous oxalate by excess standard oxalate, the excess oxalate in the filtrate being determined with permanganate;[2] **(3)** its oxidation with excess standard permanganate, followed by addition of excess standard ferrous sulfate and back titration with permanganate;[3] (4) its precipitation by excess standard sodium chloride solution, followed by filtration, precipitation of the mercuric salt with hydrogen sulfide, filtration, removal of hydrogen sulfide by boiling and titration of the excess sodium chloride with standard mercurous nitrate, using diphenylcarbazide as indicator[4]—obviously a tedious process; (5) its titration in strong hydrochloric acid solution with potassium iodate, using chloroform as indicator.[5] This last method appears to be the one most widely used.

The present paper is a study of the oxidizing action of ceric sulfate on mercurous ion and describes a volumetric procedure for mercurous mercury, applicable in the presence of large amounts of mercuric salts.

Experimental

Mercurous sulfate was made by adding slowly a solution of mercurous perchlorate to dilute sulfuric acid. The precipitate was thoroughly washed, then suspended in 0.1 *M* sulfuric acid. This mixture, after being stirred for five to six hours, was filtered. The mercurous sulfate solution thus obtained was standardized gravimetrically by precipitating the mercurous mercury as chloride and drying the precipitate to constant weight over phosphorus pentoxide. The results of three experiments gave 0.0295, 0.0295 and 0.0296 g. of mercury per 100 cc. The filtrate from the mercurous chloride gave no test for mercury when made ammoniacal and treated with hydrogen sulfide and solid ammonium chloride.

The ceric sulfate solution was part of a large supply made by the method described by the authors[6] from high grade ceric oxide and was 0.5 *M* in sulfuric acid. It was standardized against sodium oxalate.[7] The ferrous sulfate solution was standardized electrometrically against standard ceric sulfate.[7]

Measured portions of the standard mercurous sulfate were taken, diluted with water, sulfuric acid (sp. gr. 1.5) and 0.09611 N ceric sulfate to a definite volume, heated to boiling and held just below the boiling point over a small flame for the time indicated. The solutions were then cooled to 30–35° and titrated electrometrically with standard ferrous sulfate. The results of a number of experiments are indicated in Table I.

If more than 30–35 mg. of mercurous mercury is present in a sample, it is always necessary to run a blank determination, using the same quantities of reagents and the same procedure

---

[6] Willard and Young, THIS JOURNAL, 51, 149 (1929).

[7] Willard and Young, *ibid.*, 50, 1322 (1928); see also Furman, *ibid.*, 50, 755 (1928).

as for the unknown. An amount of mercuric sulfate, free from mercurous ion, approximately equal to that in the unknown should be added to the blank before heating. Mercuric ion in considerable amount tends to cause a slight decomposition of ceric sulfate in hot solution.

The experiments in Table I show that mercurous ion is quantitatively oxidized to mercuric ion provided that a large excess of ceric salt is used, that the acidity of the solution is not too great and that the oxidizing agent is allowed to act in hot solution for thirty to sixty minutes. A moderate amount of perchloric acid causes no interference but nitric acid produces a slight effect. A large amount of mercuric ion does not interfere if a blank correction is made for its slight action on ceric sulfate in hot solution.

Summary

An accurate method has been developed for mercurous mercury, based upon its oxidation in hot sulfuric acid solution by excess ceric sulfate and titration of the excess electrometrically with standard ferrous sulfate. Mercuric ion in large amount does not interfere.

PHOTOCHEMICAL STUDIES. XI. THE QUANTUM EFFICIENCY OF OZONE FORMATION IN THE FLUORITE REGION

By William E. Vaughan and W. Albert Noyes, Jr.

Received September 9, 1929 Published February 6, 1930

The photochemistry of the range of wave lengths below those transmitted by quartz has received scant attention. The difficulty of obtaining monochromatic radiation of sufficient intensity to produce measurable chemical effects in this region of the spectrum is great. In a recent article the photochemical decomposition of ammonia was studied in the fluorite region.[1] By a comparison of the rate of ozone formation with the rate of decomposition of ammonia under the influence of those wave lengths transmitted by fluorite but not by quartz, it was possible to calculate the quantum efficiency of the latter reaction by making the following assumptions: (I) that the photochemical decomposition of ammonia is represented by the equation $2NH_3 = N_2 + 3H_2$; (2) that the absorption of ammonia is identical with that of oxygen in this range of wave lengths; **(3)** that two molecules of ozone are formed per quantum of radiation absorbed by oxygen. With these assumptions it was possible to show that the average quantum efficiency of ammonia decomposition is about 0.7 for the approximate spectral region 150mμ to 190mμ.

---

[1] Kassel and Noyes, This Journal, 49, 2495 (1927).

Since the publication of this work, additional confirmation has been received for the validity of the second assumption.[2] The validity of the first assumption is not so certain,[3] since some of the decomposition products may not appear in the gas phase. The possible formation of hydrazine as an intermediate product hardly offers a satisfactory explanation of the discrepancy.[1,4] The quantum efficiency would, therefore, be slightly higher than 0.7.

The present research was undertaken with the object of investigating the validity of the third assumption, namely, that two molecules of ozone are formed from oxygen per quantum absorbed. The work has been carried out at atmospheric pressure. Since oxygen has a region of continuous absorption below 175mμ,[5] this reaction is a convenient one for measuring light intensities in the range of wave lengths transmitted by fluorite but not by quartz. This investigation, it is hoped, will establish the quantum efficiency of this reaction so that it may be used in the future.

I. Experimental Procedure

The first requisite for the determination of the quantum efficiency of ozone formation is an accurate method of analysis. After a review of the literature and an investigation of the various methods for the quantitative determination of small amounts of ozone,[6] it was decided that the most reliable method was by absorption of the ozone in a solution of potassium iodide. The solutions were acidified and to each one was added a definite quantity of starch freshly prepared each few days. All of the calculations are based on the equation

$$2H^+ + O_3 + 2I^- = O_2 + I_2 + H_2O \qquad (1)$$

Some uncertainty exists as to the exactness of this equation, but it undoubtedly represents the main course of the reaction. In basic solution there may be some simultaneous reaction of the type $I^- + O_3 = IO_3^-$.

The source of radiation was a condensed discharge through hydrogen at a pressure of about 0.1 mm. Current was supplied from the secondary of a 1-kw. transformer with a peak voltage of 30,000. The dimensions of the discharge tube are given in Fig. 1. The electrodes (A) were made of iron. The windows (B) and (C) were of fluorite. The ends of the discharge tube were carefully ground, so that there was little contact between the hydrogen and the picein wax used. A continuous flow of hydrogen was maintained through the discharge tube. Hydrogen was prepared in an ordinary electrolytic gen-

erator and passed continuously over heated platinized asbestos, sodium hydroxide sticks and phosphorus pentoxide before being admitted to the discharge tube through the capillary (I)). (F) was attached to a mercury diffusion pump backed by an oil pump. The pressure of hydrogen in the tube remained quite constant.

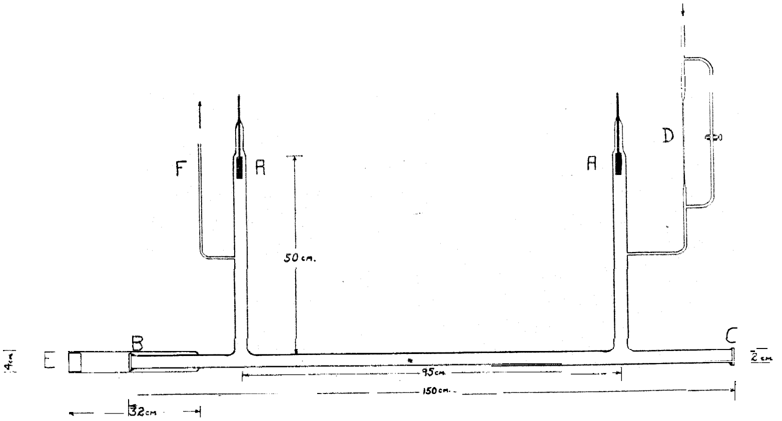

Fig. 1.

The radiation given out by the discharge tube formed a slightly diverging beam. The intensities were measured by means of two different thermopiles, both calibrated by a radiation standard furnished by the Bureau of Standards.

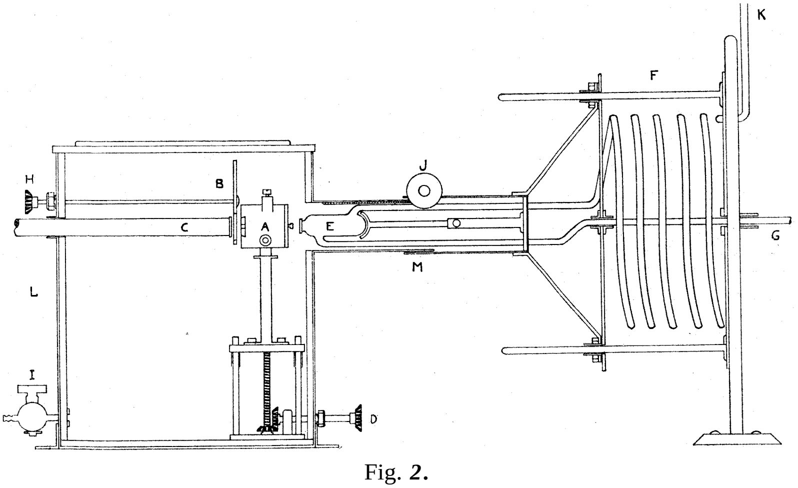

Fig. 2.

One end of the discharge tube (C) projected into the box shown in Fig. 2. This box was constructed of brass and no oil was used on any of the bearings. The box was not, of course, vacuum tight, but it was kept under slight positive pressure of gas transparent to the region of the spectrum under consideration. At first helium was tried, but it was found impossible to purify commercial helium satisfactorily at the rate of flow necessary. Consequently, attempts were made to use hydrogen and nitrogen. After many measurements of absorption in the fluorite region it was found that it was easier to obtain nitrogen of reproducible purity and this gas was used to fill the box in all of the final measurements.

The nitrogen was obtained from a cylinder. It was water-pumped and of 99.7% purity. It was passed first over heated copper turnings, then partially dried by sodium hydroxide sticks and finally passed through a charcoal trap immersed either in liquid air or in carbon dioxide snow and ether. The distance traversed by the radiation through the nitrogen was about 1.4 cm.

The thermopile (A) was fitted with a fluorite window and was arranged so that it could be lowered and raised by turning the handle (D). The reaction vessel (E) was 7.4 cm. in length and 2 cm. in internal diameter. It was arranged so that when the thermopile was lowered it could be moved forward to such a point that the window was the same distance from the discharge tube as the elements of the thermopile. The glass spiral (F) was of such length and flexibility that the reaction vessel could be moved without introducing any rubber tubing into the apparatus. The shutter (B) had three openings. On one was placed a piece of crystal quartz 3 mm. in thickness with the optical axis such that there was no polarization of the radiation traversing it. On the second opening was cemented a piece of optically plane pyrex 3 mm. in thickness. The third opening was left vacant.

The oxygen was streamed through the reaction vessel at various rates. It had already been shown[1] that the amount of ozone formed was independent over quite wide limits of the amount of oxygen passing through the reaction vessel in unit time. This is in agreement with tests made during the present experiments.

The oxygen was passed first over heated platinized asbestos, partially dried by passing over sodium hydroxide sticks and finally passed through a trap immersed in carbon dioxide snow and ether. It entered the reaction vessel through the spiral (F). The tube (G) was attached to two Fischer wash bottles containing either 0.01 or 0.001 M potassium iodide and 0.0013 M sodium hydroxide.

The first runs (shown in Table I) were made in the following manner: the thermopile (A) was raised to the position shown in Fig. 2 and the intensity of the radiation measured. The discharge tube had been allowed to run until the current through the transformer became constant. The intensity of the radiation transmitted by 1.4 cm. of nitrogen without filter through quartz and through pyrex was determined before each run. The thermopile was then lowered and the reaction vessel (E) moved forward. The oxygen was allowed to pass through the reaction vessel for a definite length of time, the rate of flow being determined by a flowmeter (not shown). Following the run the intensity of the radiation was determined. Good agreement between the initial and final intensity readings was found in nearly every case. The rate of flow of oxygen was varied by a factor of about forty without causing a definite trend in the amount of ozone found.

A definite fraction (50 cc. out of 152 cc.) of the potassium iodide solution from the first wash bottle was acidified with 6 cc. of 0.05 M sulfuric acid and 2 cc. of a clear starch solution was added. The mixture was well shaken and allowed to stand for about ten hours. A sample from the second wash bottle was treated in exactly the same manner. In a few cases a third wash bottle was also used. In no case did the solution in the third wash bottle give any test for iodine liberated and usually the amount in the second wash bottle was small.

The intensity of coloration was compared in Nessler tubes with standards made in exactly the same manner except that a carefully measured (by pipet) amount of 2.48×10^{-5} M solution of iodine dissolved in potassium iodide was added. These standards were allowed to stand for the same length of time as the unknown.

The fraction of the total radiation absorbed by the oxygen was determined in two different manners In one the other end of the discharge tube (B) (Fig 1) was used. The tube at (E) was attached to an iron cylinder by wax. A thermopile was placed in the iron cylinder The cylinder was evacuated to a pressure of about 10^{-5} mm. by mercury diffusion pumps. Mercury vapor was excluded by a trap immersed in liquid air. The absorptions of nitrogen and of oxygen were determined for a 19-cm. path In this manner it was found that **3.3%** of the radiation was absorbed by oxygen that was not absorbed by nitrogen. The absolute measurement of the amount of radiation seemed to have little significance.

The second method was to replace the reaction vessel by a tube of exactly the same length fitted with fluorite windows at both ends. A thermopile without fluorite windows was placed directly in back of the absorption tube. The tube was evacuated and the deflection measured. The deflection was measured again when thr tube was filled with oxygen. When the fluorite window used on the reaction vessel was interposed, three determinations gave 3.0, 3.5 and 3.1 as the percentage decrease in the deflection when the tube was filled with oxygen.

The calculation of the fraction of the incident radiation absorbed can only be made by an indirect method. Let us consider a perfectly parallel beam of radiation. Then we may make the following comparisons, where I represents intensity.

Through oxygen

I_1 Fluorite window I_2 oxygen I_3 Fluorite window I_4

With cell evacuated

I_1 Fluorite window I_2 vacuum I_2 Fluorite window I_5

The fraction $(I_5 - I_4)/I_5$ is measured directly in the experiments. Put $I_1/I_2 = a$, $I_3/I_4 = b$ and $I_2/I_5 = c$. The fraction of the incident radiation absorbed by the oxygen is $(I_2 - I_3)/I_1 = X$. Put $(I_5 - I_4)/I_5 = Y$. We now find that

$$X = [c-(1-Y)b]/ac \qquad (2)$$

The measurement of the quantities a, b and c was accomplished by removing the windows from the absorption cell and determining the absorption of the fluorite when the radiation had traversed nitrogen and the proper length of column of oxygen. In this way it was found that $a = 1.160$, $b = 1.134$ and $c = 1.137$, each value being the average of a large number of readings. Hence

$$X = (1.137 - 0.968 \cdot 1.134)/1.160 \cdot 1.137 = 0.030$$

Table I gives a summary of the data obtained in preliminary runs made by the method described above.

Another series of measurements was made in which the cell used previously to determine the absorption was used as a reaction vessel. Since this cell could not be moved, the light intensity back of the cell (through oxygen) was measured during the run. The procedure for the determination of ozone was the same as that used previously, except that in half of the runs an acid solution of potassium iodide was used in place of a basic solution.

TABLE I

PRELIMINARY DETERMINATION OF QUANTUM EFFICIENCY

Iodine solution, 0.0000248 M. Thermopile, 14.3 ergs/mm.^{2}/sec./cm. Area of window, 154 mm.^{2} Wave length (av.), 175mμ. Fraction absorbed, 0.03

Run	Total cc. of I_2	Length of run, hrs.	Av. defl., cm.	Molecules of O_3	No. of quanta	M/N
1	9.4	3	1.09	1.41×10^{17}	$6\ 92 \times 10^{16}$	2.0
2	9 9	3	1.08	1.49×10^{17}	6.85×10^{16}	2.2
3	13 6	4	1.13	2.04×10^{17}	9.57×10^{16}	2.1
4	12.2	3	1.19	1.83×10^{17}	7.56×10^{16}	2.4
5	8 5	3	11.96	1.28×10^{17}	$6\ 03 \times 10^{16}$	2.1
						Av. 2 2

Since a different fluorite window was used at the front of the reaction vessel in these experiments, it was necessary to redetermine the absorption. Table II gives the data obtained in making these determinations.

TABLE II

ABSORPTION OF OXYGEN

Defl. av. vacuum, cm.	No. of readings	Defl. av. oxygen, cm.	No. of readings	Fraction $(I_5 - I_4)/I_5$ av.
1.70 (0)	14	1.62 (2)	12	
1.70 (1)	12	1.61 (5)	10	
1.69 (3)	14	1.63 (1)	11	
1.70 (0)	10	1.60 (3)	11	
1.69 (6)	10	1.61 (4)	10	0.048 ± 0.006

By the use of Equation 2 it is found that the fraction of the incident radiation absorbed by the oxygen is 0.044.

Since the radiation intensity is measured back of the cell through oxygen, it is necessary to find the factor by which it must be multiplied to obtain the incident intensity. Since the beam was not perfectly parallel, but diverged somewhat, this factor could not be calculated directly. However, this factor was obtained by removing the reaction vessel and obtaining the ratio of the deflection at 1.4 cm. from the discharge tube to the deflection at 8.8 cm. Eight determinations gave 4.9 as the average ratio. The observed intensity must be multiplied, therefore, by $4.9 \cdot 1.137 \cdot 1.134/$-0.952 or 6.64. Direct measurement of this factor gave 6.6.

Table III gives the data obtained in this manner. Absorption of the ozone was carried out in acid (with hydrochloric acid) solution of potassium iodide in the last three runs. It has been shown previously[7] that ozone has an apparently higher oxidizing power in acid solution than in neutral or basic solution. This fact was studied[6] and it was found that within the experimental error 1.25 times as much iodine was liberated when ozone was absorbed in acid solution as when it was absorbed in neutral or basic

[7] Mellor, "Comprehensive Treatise," Longmans, Green and Co., London, 1922. Vol. I, p. 905.

solution and then acidified. The number of molecules of ozone obtained by direct calculation in the last three runs in Table III is multiplied by 0.8.

TABLE III

QUANTUM EFFICIENCY OF OZONE FORMATION

Iodine solution, 0.00005 *M*. Thermopile, 2 8 ergs/mm.^{2}/sec./cm. Area of window, 73 mm.^{2} Wave length (av.), 175mμ. Fraction absorbed, 6 64·0.044

It is difficult to form a very precise idea of the probable accuracy of the values obtained for the quantum efficiency. The determination of the number of molecules of iodine liberated is undoubtedly the main cause for variation among the various results. On the average these values should be good to better than 10%. The error in the calibration of the thermopile is undoubtedly small compared to other errors. The determination of Y in Equation 2 is somewhat uncertain, but the values used should be accurate to somewhat better than 10%. The quantities *a*, b and *c* in Equation 2 are of importance; a and *c* are each known with a probable error not exceeding 1%, but small errors in *c* and b would produce a relatively large error in X. These values were carefully determined and when all the factors entering into Equation 2 are considered, it is probable that the value of X is accurate to within 15%.

It seems safe to state that the quantum efficiency of ozone formation for radiation transmitted by fluorite is 2.0 ± 0.3.

It should be pointed out that the error in choice of the average wave length of the active radiation is certainly small compared to other errors. It is recognized that the quantum efficiency is not obtained for monochromatic radiation. A discussion of the possible effect of change of wave length will be given in the next section. However, since no lenses were used errors due to such factors as chromatic abberration are negligible.

Using a different type of discharge, Kassel and Noyes[1] showed that approximately **3.5** times as much ozone is formed when fluorite windows are used as with quartz. One attempt was made in these experiments to determine the amount of ozune formed by radiation transmitted by quartz, but the inaccuracies in the determination of the ozone and in the measurement of the light absorption were so great that the matter was not pursued further. Since absorption would not be complete (about

15%[8] for the shortest wave length transmitted by quartz) whereas no greatly increased absorption was observed for a 19-cm. path, it seems probable that a very large fraction of the radiation absorbed in these experiments lies below the limit of transmission of quartz. Except for certain isolated bands, nitrogen is quite transparent to the region of the spectrum under consideration. There are several bands near 170mμ and stronger bands at 145mμ.[9] The limit of transmission of the nitrogen is probably determined by the impurities it contains. The fluorite used transmitted to about 140mμ. The probable limits of the spectrum involved in the above experiments are from about 190mμ to somewhat less than 170mμ.

II. Theoretical Discussion

It has been shown that the oxygen molecule is normally in a $^3\Sigma$ level and that this is the ground level for both the atmospheric absorption bands and the Schumann–Runge bands.[10] The interpretation of the atmospheric absorption bands is now quite satisfactory[11] and is found to involve a $^3\Sigma - {}^1\Sigma$ transition. The $^1\Sigma$ level lies only 1.62 volts above the normal level and combines with it exceedingly weakly. To all intents and purposes oxygen at ordinary pressures and thicknesses is practically completely transparent to radiation of wave lengths found in the atmospheric absorption bands.

The Schumann bands are found to involve in all probability a $^3\Sigma - {}^3\Sigma$ transition.[12] They involve, in absorption, a transition from the normal to a 6.09-volt electronic level. The convergence limit of this series of bands occurs at 175.1mμ, or a little over 7 volts. Dissociation of the molecule should, therefore, be brought about by radiation of wave length shorter than this value. The products of dissociation should be one normal and one excited atom. The exact state in which this excited atom will leave the molecule is uncertain[13] but it may lie between 1.5 and 2.0 volts above the normal level.[14] Due to the fact that no exact determination of the heat of dissociation of oxygen by calorimetric methods has been made, this level cannot be calculated indirectly.

In the range of wave lengths longer than the convergence limit, excited molecules in a $^3\Sigma$ state are produced by absorption of radiation. Ozone is, however, produced in this region of the spectrum. Warburg[15] has studied the quantum efficiency of ozone formation at relatively high pressures at 207mμ and 253mμ and finds values of about 2 at about 47 atmospheres, becoming lower at higher pressures. The quantum efficiency is lower at the longer wave length.

In view of the present knowledge of band spectra the primary process in the region of the Schumann bands at wave length greater than 175mμ is the production of an excited molecule and this may be followed by some such reaction as

$$O_2' + O_2 = O_3 + O \quad (3)$$

A second molecule could be produced by the reaction

$$O_2 + O = O_3 \quad (4)$$

However, this latter reaction, in accord with well recognized principles, can only take place as the result of triple collisions or on the walls, since otherwise the molecule would still possess energy adequate to produce redissociation. Similarly, the reaction

$$O + O = O_2 \quad (5)$$

could only take place in this fashion. Enough is not known to permit an adequate calculation of the relative probabilities of Reactions 4 and 5, but unless the light intensity were exceedingly great the chance of Reaction 5 would be small. Also, the formation of ozone by Reaction 4 would be less exothermic than Reaction 5, so that the probability of its occurrence would be greater. Hence it would not be surprising if two molecules of ozone were produced by wave lengths longer than the convergence limit.

In the region of continuous absorption below the convergence limit, two oxygen atoms, one of which is excited, are produced. There are now several possibilities. The normal atom may undergo Reaction 4 by triple collision. The excited atom may lose its energy by radiation and subsequently undergo Reaction 4. In this event the quantum efficiency would be two in this region of the spectrum. If the energy of the excited atom is sufficiently large, it might lose its energy to an oxygen molecule by a collision of the second kind, thereby raising the latter to some higher vibration state of either the normal or the 1.62 electron level. In either event the excited molecule produced could not undergo Reaction **3.** As a result of a triple collision with molecules in higher vibration states it might undergo the reaction

$$O_2'' + 2O_2 = 2O_3 \quad (6)$$

Since the production of two molecules of ozone from three molecules of oxygen involves the absorption of energy corresponding to about 2.5 volts,

---

[15] Warburg, *Z.* Elektrochem., **27,** 133 (1921). See Wulf, THIS JOURNAL, 50, 2596 (1928), for a discussion of the possible relationship of this work to the existence of O_4.

the two oxygen molecules in the normal state must possess an energy of 2.5 − E_1 volts, where E_1 represents the energy of the molecule O_2'' above the normal. Since E_1 is not known, it is impossible to make any definite statement in this connection. Reaction 6 must not be considered as impossible, however.

Still one other possibility may be mentioned. Since Reaction 4 is exothermic and can occur only as the result of triple collisions, the third molecule involved may be raised to a higher vibration or electronic level. However, since the energy available by Reaction 4 only slightly exceeds 1 volt, this possibility would seem to be of small importance.

As a result of these considerations we see that the quantum efficiency of ozone formation to be expected from theoretical consideration agrees with experiment well within the experimental error. A value slightly greater than two would not be impossible.

Eucken[16] has studied the formation of ozone by short wave length radiation and finds a negative temperature coefficient. This effect is particularly noticeable at low oxygen pressures. Eucken attempts to explain this phenomenon by assuming that the mean life of activated molecules in high rotation states is shorter than when the rotational quantum number is less. Another effect may also be of importance. The oxygen atoms produced by Reaction 3 may have time to diffuse to the walls and be removed before undergoing the triple collision necessary for Reaction 4. This effect would be particularly noticeable at low pressures. Since third order reactions have, in general, negative temperature coefficients, the necessary triple collisions might occur more often at low temperatures. In the region of continuous absorption the temperature coefficient should be unity unless the effect of the walls in removing the oxygen atoms is of importance. Since this removal process may be more important at low than at high temperatures, this effect cannot be neglected.

Summary

1. Approximately two molecules of ozone are formed per quantum absorbed by oxygen in the fluorite region.

2. A short theoretical discussion is given. The value found is in agreement with theory, although a slightly higher value would not he impossible.

DETERMINATION OF MERCURY AS METAL BY REDUCTION WITH HYDRAZINE OR STANNOUS CHLORIDE

BY H. H. WILLARD AND A. W. BOLDYREFF

RECEIVED SEPTEMBER 12, 1929 PUBLISHED FEBRUARY 6, 1930

Introduction

The principal errors in determining moderate and large amounts of mercury gravimetrically by reduction to metal are caused by: (1) loss through volatility during the process of reduction, if it is carried out at an elevated temperature; (2) loss in the process of filtration—fine particles going through the filter; (3) loss through volatility in the process of drying. The loss of mercury from hot solutions of its salts, from suspensions of fine particles of mercury, and from metallic mercury on drying has been sufficiently emphasized by Howard[1] as early as 1904. Therefore, the reaction and the conditions for reduction, filtration and drying must be so chosen that the whole process can be carried out at room temperature, that the precipitated mercury is not in too fine a state of division and that the time of drying is as short as possible.

The following reducing agents were tested: sodium arsenite, phosphorous acid, hypophosphorous acid, hydrogen peroxide, stannous chloride, hydroxylamine and hydrazine. Hydrazine hydrate in an ammoniacal solution and stannous chloride in a hydrochloric acid solution were found most satisfactory.

Hydrazine Reduction.—Jannasch[2] has shown that mercury can be separated from such metals as copper, bismuth, lead, cadmium, arsenic, antimony, zinc and metals of the iron group by reduction with hydrazine in an ammoniacal or a weakly acid solution. However, on account of the danger of loss he weighed the mercury as sulfide.

The separation of mercury from other metals by reduction with hydrazine has also been studied by Knoevenagel and Ebler.[3]

In their work on the atomic weight of mercury, Easley and Brann[4] and later Honigschmid, Birckenbach and Steinheil[5] removed mercury from the solutions of its halides by reduction with hydrazine. The former found that some of the precipitated mercury was always in such a fine state of division that it passed through the densest filters.

Duccini[6] applied the reaction to the quantitative determination of mer-

cury, weighing it as metal. Briefly, his procedure consisted in precipitating mercury from a potassium hydroxide solution with an excess of hydrazine sulfate, filtering through a small paper filter after six to eight hours' standing, washing first with dilute hydrochloric acid, then with water, alcohol and ether, drying for five to six hours in a desiccator over calcium chloride and weighing. Under these conditions the finely divided mercury settles very slowly, and this method of drying can hardly be recommended.

In this work the question of drying precipitated mercury was first studied. Dick[7] recommends washing precipitates with alcohol and ether, followed by drying in a vacuum desiccator. This procedure was not considered advisable, because it requires two wash solutions, the use of a vacuum desiccator, and because even pure ether usually contains enough peroxide to tarnish the surface of mercury. It is strange that the use of acetone in preference to alcohol and ether has not found a wider application for drying precipitates. Barnebey[8] in a note on the use of acetone for drying chemical utensils, recommended it in place of alcohol and ether. Easley[9] showed that a single globule of mercury could be dried without loss by washing with acetone and warming up to 30–35° for half an hour.

Experimental

In this work the method of drying was as follows: the crucibles and precipitates were washed five times with redistilled acetone and air-dried at room temperature on the suction flask by sucking through them for five minutes air previously dried by calcium chloride (see Fig. 1).

The reproducibility of the weights is shown in Table I. A slight difference between the "acetone-dried weight" and the "oven-dried weight" is undoubtedly due to a trace of acetone being adsorbed by the pores of

the crucible. Whenever the chemical nature of the precipitate permits the use of acetone, and especially when heating must be avoided, the use of this simple and rapid method is recommended.

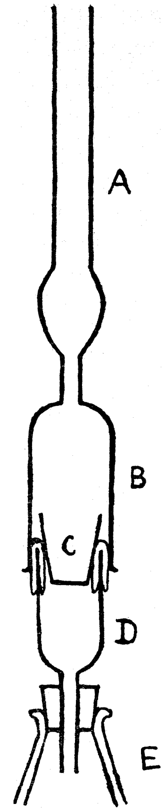

Fig. 1.—Apparatus used in drying crucibles. A, calcium chloride tube; B, glass adapter sealed to the calcium chloride tube and fitting tightly over the rubber Gooch tubing of the crucible holder; C, crucible; D, crucible holder; E, suction flask.

Attention was next turned to the process of filtration. The precipitation was always carried out in the cold. Filtered concentrated ammonium hydroxide was first added, and then roughly twice the theoretical amount of hydrazine hydrate. The rate of precipitation was found to increase with the hydroxyl-ion concentration. The speed of settling and the coarseness of the particles of precipitated mercury increased at first, but decreased with further increase in concentration of ammonium hydroxide, due, undoubtedly, to adsorption of hydroxyl ions on the surface of the particles of mercury, preventing them from coalescing.

For optimum conditions, 10 cc. of freshly filtered ammonium hydroxide (sp, gr. 0.90) should be added to every 50 cc. of the neutral solution. The precipitation is most conveniently carried out in a tall narrow beaker. It is preferable to keep the volume of the solution as small as possible (50 to 100 cc.).

Under these conditions the precipitate settles completely in one to two hours, but may stand longer if preferred. The heavy gray powder can be filtered as it is or changed into droplets (to facilitate transfer and filtration) by adding to the solution 35 cc. of concentrated hydrochloric acid, stirring for a minute and making ammoniacal again. When time is an important factor, the precipitation is carried out in a centrifuge cup, the solution stirred for a minute to ensure complete reduction, and centrifuged for five minutes. All the mercury then collects into one or two large globules, except a few milligrams, which always remain in the form of a fine gray powder.

The precipitate is conveniently filtered through a porcelain filtering crucible, type A1,[10] previously dried with redistilled acetone and dry air, as already described. A Gooch crucible with asbestos or with precipitated gold mat and a Munroe crucible were used with equal success, but the porcelain filtering crucibles were finally used exclusively, because their weight is most reproducible.

After filtering, the precipitate is thoroughly washed with cold water.

---

[10] Manufactured by the Staatliche Porzellanmanufaktur, Berlin.

The mercury in the crucible can be caused to collect into one drop by gently shaking the crucible, thus simplifying the washing; a few milligrams of mercury will, however, always remain in the form of a fine gray powder sticking to the pores of the crucible. The water is then washed out with pure redistilled acetone and the crucible air-dried for five minutes, as described above. After standing in the balance case for two minutes the crucible can be weighed.

The analyses of pure mercuric chloride solutions (prepared from 99.98% pure $HgCl_2$) and of nitrate solutions (prepared by dissolving specially redistilled mercury in nitric acid) are given in Table II.

TABLE II

DETERMINATION OF MERCURY BY REDUCTION WITH HYDRAZINE HYDRATE IN AN AMMONIACAL SOLUTION

	Mercury, g			
No.	Taken	Found	Corrected	Error, mg.
		Chloride Solutions		
1	1.8821	1.8801	1.8814	−0.7
2	1.3662	1.3652	1.3665	+ .3
3	1.2416	1.2405	1.2418	+ .2

7	.1751	.1739	.1752	+ .1
8	.1533	.1519	.1532	− .1
9	.1132	.1120	.1133	+ .1
10	.0700	.0686	.0699	− .1
		Nitrate Solutions		
1	2.2247	2.2232	2.2245	− .2
2	1.8285	1.8282	1.8295	+1.0
3	1.5168	1.5146	1.5159	−0.9
4	0.8045	0.8033	0.8046	+ .1

From this table it is evident that the amount of mercury found is always less than the theoretical by a practically constant amount. That this loss was due only to volatility was proved by testing in each case the original beaker, the filtrate and the washings with ammoniacal sulfide, after first adding concentrated nitric acid to dissolve the mercury. In every case the transfer of the precipitate from the beaker to the crucible was found to be complete, and no mercury could be detected either in the filtrate or washings. Furthermore, in several experiments the air with which the mercury was dried was passed through a gas wash-bottle containing nitric acid. This was tested for mercury, and a distinct test could be obtained in every case. Because of the constancy of this loss over a wide range of conditions, it was considered justifiable to apply a correction for it; this correction, calculated from the average of twelve analyses, is +1.3 mg. The results corrected for volatility in this manner are quite accurate, the error seldom exceeding 0.1%.

Stannous Chloride Reduction.—The determination of mercury by reduction to metal with stannous chloride was described as early as 1839 by Rose.[11] More recently it was used by Farup[12] and by Schumacher,[13] who filtered mercury on a gold-asbestos filter, but the method has been unfavorably criticized and little used. Thus Fresenius[14] finds that "this method gives accurate results only when conducted with the greatest care. In general, a little mercury is lost," while Howard[15] states that "stannous chloride is not at all a suitable reducing agent for the estimation of mercurial salts, as the reduction takes place very slowly and is apt to give variable results."

In this work the conditions were found under which this method gives accurate results. Using a large excess of stannous chloride, in a strongly acid solution, the reduction was found to be strictly quantitative and practically instantaneous, the precipitate was easy to filter and the results were accurate both in pure mercuric chloride solution and in the presence of nitrate, sulfate, iron, lead, cadmium, copper, antimony or bismuth.

TABLE III

DETERMINATION OF MERCURY BY REDUCTION WITH STANNOUS CHLORIDE IN AN ACID SOLUTION

No.	$HgCl_2$, g	Mercury, g			Error, mg	Remarks
		Found	Corrected	Calcd.		
1	1.7002	1 2544	1.2554	1.2559	−0.5

---

[11] Rose, "Handbuch des anal. Chem.," 2d ed., 1839, Vol. II, pp. 169–172.

[12] Farup, *Arch. expt. Path. Pharm.*, 44,272 (1900).

[13] Schumacher, *Z. anal. Chem.*, 39, 12 (1900).

[14] Frescnius, "Quant. Chem. Anal.," translation of the 6th German ed. by Cohn, John Wiley and Sons, New York, 1904, Vol. I, p. 366.

[15] Howard, *J. Soc. Chem. Ind.*, 23,151 (1904).

The preferred procedure is as follows: to 50 cc. of the cold neutral solution add 25 cc. of concentrated hydrochloric acid and 5 cc. of freshly filtered stannous chloride solution, containing 1.125 g. of $SnCl_2 \cdot 2H_2O$ per cc., dissolved in hydrochloric acid (sp. gr. 1.09) and kept over metallic tin. Stir and let settle (or centrifuge). Settling is usually complete in thirty minutes to an hour. Filter through a filtering crucible, previously dried with acetone and dry air, wash with 1:1 hydrochloric acid to prevent hydrolysis of tin salts, then with water and finally with acetone. Dry for five minutes by sucking through the crucible air dried by calcium chloride and weigh. The volatility correction in this method, determined from the average of twenty analyses, is +1.0 mg.—somewhat lower than in the hydrazine method. This may be due to the larger size of the particles. The results are shown in Table III.

Summary

1. Conditions are given for the accurate gravimetric determination of mercury after reduction to metal by hydrazine in ammoniacal solution or by stannous chloride in hydrochloric acid solution.
2. In the latter method iron, cadmium, bismuth, copper, lead, antimony, nitrate and sulfate do not interfere.
3. There is always a definite constant loss due only to volatilization of mercury during filtration and drying, for which an accurate correction can be made.
4. A rapid method of drying is described, using acetone and dry air.

THE SODIUM PEROXIDE–CARBON FUSION FOR THE DECOMPOSITION OF REFRACTORIES

BY GEORGE G. MARVIN WITH WALTER C. SCHUMB

RECEIVED SEPTEMBER 14, 1929 PUBLISHED FEBRUARY 6, 1930

The usual methods for decomposing refractory materials are far from being ideal, in that they require considerable manipulatory skill, are time-consuming, and frequently do not effect complete decomposition in a single treatment; in fact, for some commercial refractories several types of fusions must be used in succession to obtain this result. Alkaline and acid fusions are frequently carried out in platinum crucibles, entailing considerable expense where a number of analyses must be carried on at once, while nickel, iron or porcelain crucibles are usually badly attacked under similar circumstances. The temperatures obtainable in a fusion are in general limited to those furnished by a gas flame or an electric heating element, commonly not above 1100°. In view of these considerations, a method of fusion which would eliminate some of the objections mentioned is desirable.

Sodium peroxide has been used in the decomposition and analysis of organic compounds for a number of years.[1] In 1925 W. F. Muehlberg[2] described "An Explosion Method for Peroxide Fusion," which showed great possibilities. The metal crucibles would last indefinitely and a number of samples could be fused nearly simultaneously and with a minimum of effort. The cooled melt separated from the crucible very readily and its acidified solution was always clear. The application of the method to the analysis of ferrosilicon was outlined. In a private communication Mr. Muehlberg kindly suggested several lines of further investigation; namely, that aluminum oxide and corundum might be studied with a view to extending the possibilities of this type of fusion. Previous to the work of Muehlberg, we have found no reference to the use of sodium peroxide with sugar carbon for the decomposition of inorganic compounds. From a quantitative aspect it seemed desirable to investigate the efficacy of this method of fusion in the case of a variety of highly refractory materials, such as alundum, cassiterite, zircon, rutile, beryl, mullite, carborundum, graphite, etc.

The following method of study was adopted: (1) to prepare a series of mixtures of sodium peroxide with sugar carbon in varying proportions, and after explosion of these mixtures to determine, if possible, the most advantageous ratio of the components; (2) to use this mixture with an analyzed sample of a refractory material; to vary the proportion of fusion mixture to sample in an effort to determine the proper ratio of mixture to sample, as well as the proper method of mixing, and to determine the amount of unfused residue in each case; (3) to try other organic substances in place of sugar carbon; (4) to fuse a variety of highly refractory materials and in each case to determine the amount of unfused residue, as well as to determine whether or not the unfused material is changed, *i. e.*, whether or not there is any selective action by the sodium peroxide; (5) to determine the maximum temperatures obtained in the case of representative fusions.

Experimental Work

An aluminum tray 12 × 6 × 1 inches was prepared for cooling the crucibles after a fusion. Fitting over the top of this tray was a metal plate with six holes, $1^5/_8$ inches in diameter. A 60-cc. nickel crucible placed in one of the holes would be held firmly in position while resting on the bottom of the tray. Cold water was allowed to run into the bottom of the tray and overflowed at the top.

[2] Muehlberg, *Ind. Eng. Chem.*, **17,** 690 (1925).

To obtain a uniform sample of sodium peroxide, the contents of six cans of approximately 150 g. each were thoroughly mixed and placed in glass-stoppered bottles. The purity of the sodium peroxide was tested by acidifying with hydrochloric acid and dehydrating to determine silica. A 15-g. sample thus yielded a residue of 0.003 g.

The sugar carbon used was from Eimer and Amend, bearing the note "prepared from cane sugar." It was somewhat lumpy and was ground in an agate mortar until it passed through a 100-mesh screen. It was noted that when the carbon had been ground to about 50-mesh it assumed a flaky character, resembling that of graphite. This condition made subsequent grinding a tedious operation. Using an automatic grinding apparatus, about 200 g. of 100-mesh carbon was prepared. The purity of the sugar carbon was tested by the ignition of several 2-g. samples in a muffle furnace, addition to the residue of a mixture of sulfuric and hydrofluoric acids, evaporation and ignition. Three samples thus gave residues after the first ignition of 0.0041, 0.0041 and 0.0044 g., respectively. These residues proved to be practically pure silica when subjected to the hydrofluoric acid treatment.

Seven mixtures of sodium peroxide and sugar carbon were prepared, containing, for each 150 g. of peroxide, 7.5, 8.0, 8.5, 9.0, 9.5, 10.0 and 11.0 g. of carbon, respectively. In a preliminary experiment 15 g. of each of these mixtures was fired under identical conditions with no added substance present, the method of firing being as follows. The mixture was weighed into a 60-cc. nickel crucible, then tamped down gently with a glass rod flattened at one end. The crucible was placed iii the metal trough with cold tap water circulating in it, and the mixture was fired by means of the glowing end of a piece of cotton string, inserted through a small hole in the cover of the crucible. The speed of the combustion process increased with increasing proportion of carbon present in the mixture from a slow, but complete combustion, to a very rapid one. The solid mass left in the crucible after the fusion was readily transferred from the crucible to a beaker by tapping and about 60 cc. of cold water was added. After the resulting reaction was complete, the solution was diluted to about 300 cc., cooled, acidified with hydrochloric acid and filtered; the residue was washed with hot water, ignited and weighed. The residues so obtained from the seven mixtures, run in duplicate, varied from 0.0006 to 0.0015 g., and no one of the mixtures could be said to be superior to any other.

In order to determine which of the fusion mixtures was most satisfactory for general use, an analyzed sample of feldspar prepared by the Bureau of Standards and marked "sample 70" was selected, particularly because of its high silica content (66.66% SiO_2), and because it was not especially difficult to decompose. A one-gram sample of this feldspar was mixed with 15 g. of each of the fusion mixtures, care being taken to prevent the sample from coming into contact with the sides of the crucible. This was accomplished by transferring the weighed sample into a conical depression made in the fusion mixture and carefully stirring the sample and fusion mixture with a small spatula, while not disturbing the lining on the sides of the crucible. The entire crucible contents were finally tamped down with the flattened end of a glass stirring rod. On ignition of the seven samples thus prepared, the first three, containing the lowest proportions of sugar carbon, were found unsatisfactory because the reaction was too slow and incomplete; the seventh was discarded as being too rapid for personal safety. The range of mixtures was thus narrowed to the fourth, fifth and sixth, and while no considerable difference in the behavior of these three was noted, Mixture 6, containing 1.50 g. of sodium peroxide to 10.0 g. of sugar carbon was adopted for later use as being the most satisfactory from the point of view of completeness and speed of reaction and ease of preparation.

In the treatment of the contents of the crucible after fusion with water and subsequently with hydrochloric acid, in each case a large quantity of silicic acid gel formed, the filtration of which in the usual way would have been tedious. To obviate this difficulty, the following expedient was employed. After the usual 60 cc. of cold water had been added to the fusion product to decompose the unchanged sodium peroxide, water was added to a volume of about 400 cc. and the whole allowed to stand; after settling, the supernatant liquid was decanted and the solution again diluted to 400 cc. and allowed to settle. After the fourth decantation the solution was acidified and filtered, and the residue washed, ignited in platinum and weighed. Much time was saved by this procedure, inasmuch as the greater part of the sodium silicate had been eliminated before the solution was acidified, thus eliminating the necessity of filtering a gelatinous precipitate. In three typical fusions, using one gram of feldspar with 15 g. of fusion mixture, by the above treatment, residues of 0.0079, 0.0087 and 0.0073 g. were obtained upon ignition. To each of these in platinum crucibles a few drops of concentrated sulfuric acid and about 1 cc. of hydrofluoric acid were added, the whole evaporated to dryness and ignited. Losses of 0.0024, 0.0040 and 0.0015 g., respectively, were observed, thus indicating that the greater part of the unfused residues consisted of undecomposed feldspar.

This conclusion was wholly confirmed by examination of the residues obtained above, as well as the original sample, with a petrographic microscope; the unfused material showed the typical twinning of crystals of feldspar, and possessed the same refractive index as the original material. Whereas the grains of the original material showed sharp broken edges, the grains of the unfused residue had rounded ends with no sharp edges, indicating that incipient fusion by the sodium peroxide treatment had occurred.

It was now obviously a question of determining how best to reduce the amount of unfused residue to a minimum. First, very thorough grinding of the sample in agate was tried, until all the sample would pass through bolting cloth, approximately 100-mesh. The amount of residue obtained from a one-gram sample after fusion and subsequent treatment as already described—0.0082 g.—showed that grinding alone would not suffice to bring about complete fusion.

Various expedients were tried in modifying the method of mixing the sample and fusion mixture, both within and outside the crucible, and the ratio of mixture to sample was raised to 25:1, but the unfused residues remained unsatisfactorily large, until it was discovered that the cause of the large residues was due to spattering of material during fusion on to the sides and cover of the crucible. Thus, it was found, when the spattered material and the solid fused mass in the crucible were separately treated after fusion, that approximately 80% of the residue came from the spatterings, the rest—about 1 mg.—from the solid lump. The spattering could not be eliminated entirely by any of the several expedients tried, although a covering of about 5 g. of sodium carbonate applied to the contents of the crucible before firing was found to reduce this considerably. Thus, using a one-gram sample of feldspar in the usual method of procedure, but employing the sodium carbonate covering, three samples gave residues as follows: (a) from the solid mass in the crucible, 0.0004, 0.0008 and u.0005 g.; and (b) from the spatterings, 0.0038, 0.0024 and 0.0021 g., respectively.

Several mixtures of organic compounds with sodium peroxide were tried with a view to determining whether or not the carbon might be replaced by a compound, and the necessity of grinding the carbon thus eliminated; but of the substances tried, in varying proportions, with the peroxide—benzoic acid, oxalic acid and tartaric acid—none gave as satisfactory results as the ground sugar carbon. It is possible that certain pure, solid hydrocarbons, such as triphenylmethane, would prove to be satisfactory substitutes for the carbon, but further work along these lines was not attempted.

It was thought desirable to determine, at least approximately, the maximum temperature attained in this method of fusion. For this purpose the use of a thermocouple or optical pyrometer seemed impracticable, as the high temperature obtained lasts but a few seconds. Strips of silver foil and copper foil melted readily in the fusion mixture so that a temperature of at least 1100° was indicated. By the use of flake graphite in place of sugar carbon the combustion progressed more slowly, requiring about thirty seconds for completion, so that an optical pyrometer could be employed. With this instrument typical fusion mixtures on firing showed temperatures of approximately 1-1-50". It seems probable that with the faster burning charcoal temperatures considerably in excess of this are attained.

The following highly refractory materials, after grinding in agate, were now fused in succession, employing the usual procedure outlined above: 1, fused kaolin brick; 2, ignited crucible, largely zirconium oxide; 3, sipylite, chiefly erbium columbate; 4, commercial product of fused alumina and magnesia; 5, commercial product of fused alumina and silica; 6, alundum; 7, cassiterite; S, corundum; 9, rutile; 10, zircon concentrates; 11, beryl; 12, ilmenite; 13, mullite, a commercial product of fused alumina and silica; 14, carborundum; 15, flake graphite.

In certain cases grinding of the sample to 100-mesh was found desirable, so that residues of only a few milligrams should result after fusion and subsequent treatment. For example, one-gram samples of alundum and corundum gave the following residues.

		Without careful grinding of sample, g.	Sample ground to pass 100 mesh, g.
I Alumina	Residue from fusion	0.0020	0.0016
	Residue from spattering	.0020	.0005
II Corundum	Residue from fusion	.0073	.0010
	Residue from spattering	.0058	.0004

In nearly all cases, when careful grinding was employed, the total residue obtained from a one-gram sample did not exceed 0.0025 g. and was usually much less than this.

In the case of the carborundum sample, the procedure was modified in order that the reaction might not be too violent. About 10 g. of fusion mixture was placed in the bottom of the crucible and above it 10 g. of sodium peroxide was introduced, into which the 0.5-g. sample of carborundum (100-mesh) was stirred. The whole was covered with about 5 g. of fusion mixture and fired. The results obtained were very satisfactory.

In the case of the graphite, the sugar carbon was entirely omitted and the one-gram sample mixed directly with 15 g. of sodium peroxide. The residue after acidification was filtered through a Gooch crucible instead of being ignited in the muffle furnace, since in the latter the graphite residue was observed to burn down to an ash.

The fact that the sodium peroxide–carbon fusion does not have a selective action on the refractories studied was determined by microscopic examination of the crystal grains, before and after fusion. For example, Sample 13, mullite, before and after fusion gave the appearance seen in the photomicrographs. Before fusion the grains were not uniform in size and showed sharp edges—in the sample shown in the photomicrograph the smaller grains were washed away by decantation and only the larger ones remained; after fusion, the fragments of residue obtained were more nearly uniform in size and the edges appeared rounded—in preparing the photograph of the fused material the decanting of the lighter particles was not carried out. Consequently, the fusion appears to have entirely consumed the smallest particles and uniformly eroded the surfaces of the larger ones—facts that indicate no selective action on the part of the fusion medium. In calculating the results of an analysis, it, therefore, would seem to be justifiable merely to subtract the weight of residue from that of the original sample.

Before fusion.

After fusion.

Summary

A quantitative study of the sodium peroxide–carbon method of fusion has been made in the case of fifteen highly refractory materials, including both naturally occurring minerals and artificial products. The results show that, properly executed, this fusion may well replace any of the customary methods for the decomposition of refractories, being more complete in many cases, and far superior in point of speed and ease of manipulation; being carried out in nickel, it obviates the need of platinum crucibles. No loss in weight of the nickel crucible is detected after repeated use.

Details are given for the proper method of procedure in preparing the sample and the fusion mixture, as well as the proper proportions of mixture to sample, the mode of charging, firing and cooling the crucible and the subsequent treatment of the fusion product.

It is shown that the unfused residue from a one-gram sample, ground to at least 100-mesh, need not exceed two milligrams, and that this small residue consists of particles of the original sample and, therefore, may be subtracted from the original weight.

ACTION OF SULFURIC ACID ON TMIOCYANATES

BY B. S. SHARMA

RECEIVED SEPTEMBER 19, 1929 PUBLISHED FEBRUARY 6, 1930

Thiocyanic acid can be prepared by the action of dilute sulfuric acid on alkali thiocyanates, with subsequent distillation under reduced pressure, collecting the distillate in a receiver kept in a freezing mixture.[1] At ordinary room temperature RSCN polymerizes to $(HCNS)_2$ and $(HCNS)_3$. With dilute sulfuric acid persulfocyanic acid, $H_2C_2N_2S_3$, is obtained. Decomposition with sulfuric acid is represented as

$$\text{(Dilute sulfuric acid)}\ 2HSCN + 2H_2O \longrightarrow 2NH_3 + CS_2 + CO_2$$
$$\text{(Strong sulfuric acid)}\ HCNS + H_2O \longrightarrow COS + NH_3$$

Persulfate and other oxidizing agents, according to Pawlewsky[2] and Goppelsroeder,[3] with thiocyanates yield $C_3N_3S_3H$. Concentrated sulfuric acid[1c] acts vigorously with solid thiocyanates and evolves acrid vapors consisting of formic acid, sulfur dioxide and carbon dioxide, and sulfur separates out.

While estimating the composition of the precipitate formed by treating ammonium thiocyanate solutions with sulfuric acid, it has been noticed that the composition of the precipitate varies according to the strength of ammonium thiocyanate and sulfuric acid solutions used. It has also been noticed that the stronger the sulfuric acid used, the lower became the sulfur content of the precipitate. The reaction of concentrated sulfuric acid on thiocyanates described by Allen does not seem to take place when solid ammonium thiocyanate is treated with concentrated sulfuric acid in the cold.

Anal. Calcd. for $H_2C_2N_2S_3$: C, 16; H, 1.3; N, 18.7; S, 64.0. Calcd. for $C_3N_3S_3H$: C, 20.6; H, 0.6; N, 24.0; S, 54.9.

Experimental

The composition of the precipitates obtained by using solutions of different strengths of ammonium thiocyanate and sulfuric acid was found to vary as follows—C, 13.01 to 17.6; H, 0.9 to 2.8; N, 18.4 to 21.3; S, 57.0 to 65.5.

The precipitate obtained by using a saturated solution of ammonium thiocyanate and 20% sulfuric acid in equal quantities gave the following results—C, 15.9 to 15.95; H, 1.01 to 1.1; N, 19.0 to 20.3; S, 62.5 to 65.5.

The precipitate obtained by treating solid ammonium thiocyanate

[2] Pawlewsky, *Ber.*, **33**, 164 (1903).

[3] Goppelsroeder, **J.** Chem. *Soc.* (Abstracts), **48**, 109 (1885).

with 50% sulfuric acid with gentle heating gave as analytical results—C, 16.4 to 16.5; H, 0.76 to 1.1; N, 19.2 to 20.0; S, 57.0 to 57.0.

Some of the precipitates were found to leave a little residue on combustion (mostly of iron oxide).

When solid ammonium thiocyanate was treated with concentrated sulfuric acid in the cold, a white precipitate was formed which was not sulfur. It dissolved after a few days, producing a sirupy liquid which did not give the characteristic red coloration with ferric chloride.

Concentrated hydrochloric acid produced a yellowish-white precipitate. It dissolved in water and the solution became turbid on heating.

All attempts to obtain these precipitates in a pure state have failed.

The acids used were Kahlbaum's pure reagents.

Discussion.—The analytical results show that the precipitates obtained by treating ammonium thiocyanate with sulfuric acid are generally mixtures of varying composition, depending on the strength of ammonium thiocyanate and sulfuric acid used. A study of the sulfur and carbon results shows that sulfuric acid has a variable oxidizing influence on thiocyanates, depending on the strength of acid used.

This work has been carried out at the Government College Chemical Laboratories, Lahore, India. Thanks are due to Dr. Dunnicliff for suggesting the problem.

Conclusions

1. The thiocyanate-sulfuric acid precipitates are generally mixtures.
2. There seem to be two factors which influence the formation of the precipitate: the strengths of (a) the ammonium thiocyanate solution and (b) of the sulfuric acid.
3. Sulfuric acid, besides its hydrolyzing effect, appears to have an oxidizing influence on thiocyanates; the stronger the acid the more marked is the effect.

POTENTIOMETRIC TITRATIONS OF PHOSPHATES, ARSENATES AND ARSENITES WITH SILVER NITRATE[1]

BY M. HUME BEDFORD, FRANCES ROBERTS LAMB AND W. EDWARD SPICER

RECEIVED SEPTEMBER 21, 1929 PUBLISHED FEBRUARY 6, 1030

Introduction

Neither Treadwell and Weiss[1a] nor Pinkhoff[2] were able to carry out the potentiometric titration of phosphates and arsenates with silver nitrate. Kolthoff and Furman[3] suggest the use of a buffer solution to keep the hydrogen-ion concentration low enough to cut down the solubility of the silver phosphate and arsenate.

In this investigation various salts of weak acids and stronger bases were used as buffers with varying degrees of success. However, successful results were obtained by using a 0.1 N solution of sodium or potassium hydroxide for a secondary titration to keep the solution at a constant hydrogen-ion concentration. This method gave consistent results with alkali phosphates, arsenates and arsenites and with phosphate rock and arsenate insecticide.

By using a Leeds and Northrup student potentiometer the potentials were measured between silver and normal calomel electrodes.

Materials

Approximately 0.1 *N* solutions of $AgNO_3$, $NaNH_4HPO_4$, Na_2HAsO_4, Na_2HAsO_3, and NaH_2PO_4 were made and standardized. The $AgNO_3$ solution was standardized by electrolytically depositing the silver;[4] the $NaNH_4HPO_4$ by using a definite weight of the salt; the Na_2HAsO_4 by precipitation and weighing as Ag_3AsO_4;[5] the Na_2HAsO_3 by using a definite quantity of As_2O_3; the NaH_2PO_4 by precipitation and weighing as magnesium pyrophosphate.[6]

Experimental

Sodium bicarbonate[3] and ammonium acid succinate were tried as buffer solutions to neutralize the nitric acid formed during the titration.

$$Na_2HAsO_4 + 3AgNO_3 = Ag_3AsO_4 + 2NaNO_3 + HNO_3$$

---

[1] An abstract of theses submitted in partial fulfilment of the requirements for the Degrees of Master of Science at the University of Kentucky, 1928 and 1929.

[1a] Treadwell and Weiss, *Helv. Chim. Acta*, **2**, 680 (1919).

[2] Pinkhoff, "Over de Toepassing der Elektrometrische Titraties," Dissertation, Amsterdam, **1919.**

[3] Kolthoff and Furman, "Potentiometric Titrations," John Wiley and Sons, Inc., New York, **1926**, p. 179.

[4] Edgar F. Smith, "Electro-analysis," P. Blakiston's Son and Co., Philadelphia, **1907**, p. 107.

[5] Georg Lunge and Arnest Berl, "Chemisch-technische Untersuchungsmethoden," 6th ed, **1910**, p. 716.

[6] Treadwell and Hall, "Analytical Chemistry," Vol. II, Quantitative Analysis, John Wiley and Sons, Inc., New York, **1924**, p. 379.

However, silver succinate and silver carbonate seemed to be precipitated and end-points were not obtained. The titration curve showed a break corresponding to excess silver nitrate or silver in solution when the small amounts of nitric acid resulting from the reaction were successively neutralized with 0.1 N sodium hydroxide, using one drop of 0.1 N phenolphthalein indicator to each 50 cc. of solution. This suggested the use of sodium phenolphthalate as a buffer. In this case the titration curves showed breaks, but varying end-points were observed with different amounts of the buffer.

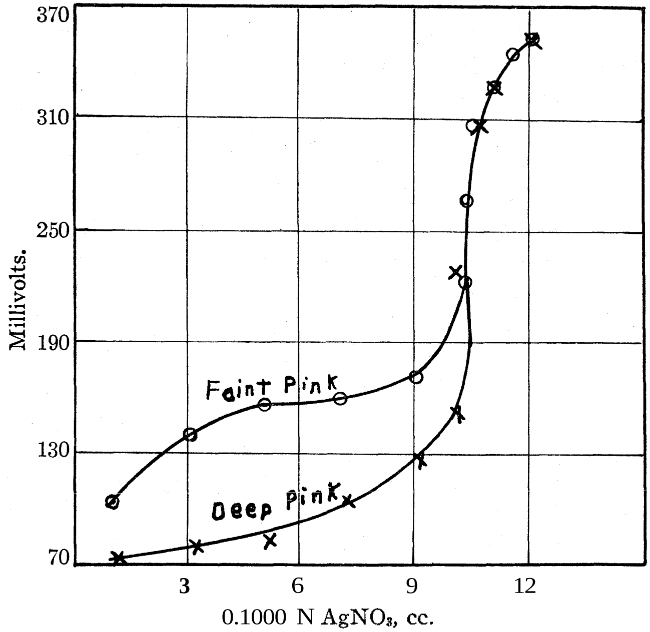

Fig. 1.—Titration curves of two portions of the same solution, one titrated with NaOH until the color of the solution due to the indicator was faint pink; the other until the color was deep pink.

The remaining experimental work was restricted to the use of sodium hydroxide for a secondary titration to the alkaline reaction. The use of the additional buret offered no disadvantage or difficulty. It was not necessary to record the readings of this buret. The solution containing the silver phosphate or arsenite could be neutralized without discontinuing the stirring of the solution. However, as the color of the silver arsenate precipitate is a brick-red, the stirring of the solution was stopped occasionally and the precipitate allowed to settle to make certain that the liquid itself retained a rose-pink color. The volume of the titrated solution was always kept under 300 cc.

Since the question might arise as to whether the sodium hydroxide solution should be added until the phenolphthalein assumed a faint or a deep pink color, the effect on the potential of small variations in the quantity of sodium hydroxide used was studied at different intervals in the titration. While even one drop of 0.1 N sodium hydroxide produced considerable change in the potential before the end-point was reached, the effect of an equal quantity immediately after the end-point had been passed was negligible (Pig. 1).

TABLE I

EFFECT OF SODIUM HYDROXIDE AFTER END-POINT

	Arsenate	Arsenite	Phosphate
Initial potential, v.	0.309	0.340	0.3060
After 1 drop 0.1 N NaOH, v.	.309	.340	.3060
After 2 drops 0.1 N NaOH, v.	.309	.340	.3055
After 3 drops 0.1 *N* NaOH, v.	.308	.339	.3045

Also, in this connection a comparative study was made of the total quantity of silver nitrate required for the various substances when the color of the solution was a faint or a deep pink.

TABLE II

EXPERIMENTAL RESULTS

	Sample, cc.	$AgNO_3$, cc. (faint pink)	$AgNO_3$, cc. (deep pink)
Arsenate	25	25.28	25.33
Arsenite	10	10.08	10.09
Phosphate	10	10.40	10.40

Three slight variations of the drop method were compared. The first variation consisted of adding silver nitrate drop by drop and neutralizing the solution with very dilute (0.01 N) sodium hydroxide after

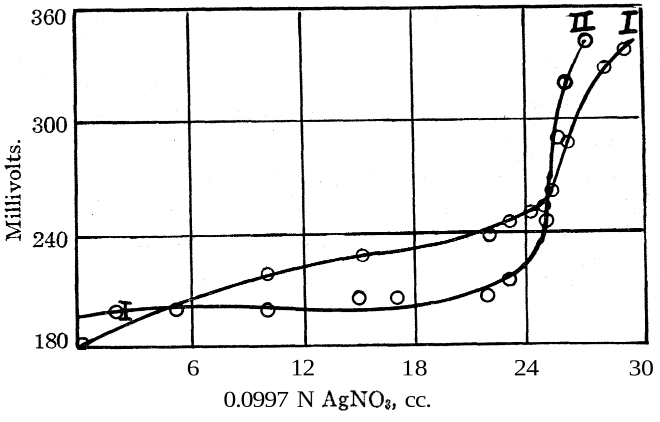

Fig. 2,—Titration curves: I, 25 cc. of 0.1031 N NaH_2PO_4; II, 25 cc. of 0.1011 N $NaHAsO_4$.

each one or two drops. The second required the addition of a drop of silver nitrate followed by a drop of 0.07 N sodium hydroxide. In the third, sodium hydroxide was present in excess before the addition of silver nitrate by drops so that no more sodium hydroxide had to be added.

The results obtained by the potentiometric method have been compared with the results obtained by the standard methods (Table V). In the tables the first column contains the results obtained when using the calculated equivalence potential; the second column, when using the drop method; the third, when using the experimentally determined equivalence potential. The equivalence potentials for these first columns were determined from the solubility products, using the formula[7]

$$E = e_0 - 2.303\frac{RT}{NF(x + y)}\left(P_{S_{B_xA_y}} - \log\frac{x}{y}\right)$$

where $e_0 = 0.798$ volt for the silver electrode; $T = 294°$ absolute, room temperature; $x = 3$ and $y = 1$, since $xB^{n+} + yA^{m-} = B_xA_y$.

Two sets of determinations were made with the microcosmic salt, the second of which was titrated after being boiled with sodium hydroxide. The difference in results is such as might be expected due to the presence of the ammonium group.

TABLE V

RESULTS OF EXPERIMENTS

Sample taken, cc.		% Error in comparison with standard values when the end-point was determined by		
		Calcd. potential	Drop method	Experimental potential
Na_2HAsO_4	10	0.4	0.3	0.5
	25	0.2	0.1	0.3

	25	−0.8	1.7	0.7

A rough comparison between the actual quantities of sodium hydroxide required completely to neutralize the nitric acid formed by the reaction and the theoretical quantities has been made. This comparison shows that a relatively large amount of the sodium hydroxide is used in replacing the ammonium group.

TABLE VI

0.1 *N* SODIUM HYDROXIDE USED FOR 25 CC.

	Experimentally, cc.	Calculated, cc.
0.1011 *N* Na_2HAsO_4	9.2	8.7

0.1000 *N* $NaNH_4HPO_4$	13.3	8.3
0.1000 *N* $NaNH_4HPO_4$ (boiled with NaOH)	18	16.7
0.1031 *N* NaH_2PO_4	18.3	16.7

Since excess sodium fluoride does not interfere with the precipitation of silver arsenate,[8] the calcium in samples of phosphate rock and calcium arsenate insecticide was precipitated with excess sodium fluoride (4%) and the phosphate and arsenate titrated with silver nitrate. In this procedure the nitric acid solution of the calcium phosphate or arsenate was neutralized with sodium hydroxide to the point at which the precipitate just barely redissolved, then the excess sodium fluoride was added and the titration started with silver nitrate. Before the addition of alkali, readings were made until a potential of approximately 0.24 volt was reached, then the sodium hydroxide was added to produce the pink color and the titration continued. By this method all the calcium was precipitated as calcium fluoride instead of calcium phosphate or calcium arsenate and results were obtained which agreed with those from standard methods of analysis of the same samples.

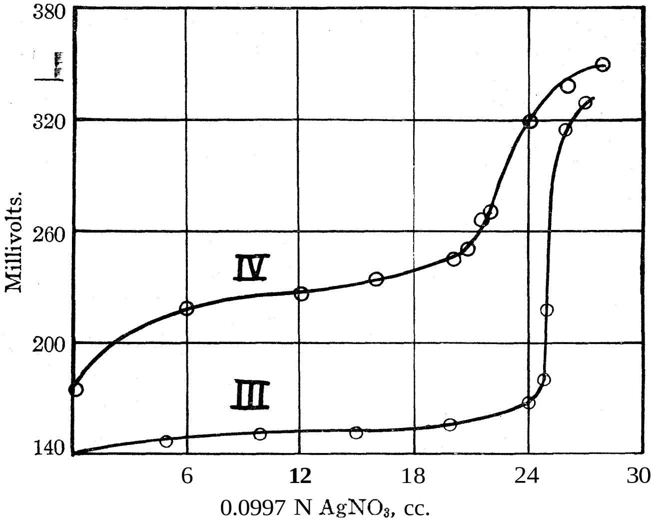

Fig. 3.—Titration curves: III, 25 cc. of 0.1000 *N* Na_2HAsO_3; IV, 20 cc. of 0.1000 N $NaNH_4HPO_4$.

Summary

The potentiometric titration of phosphates, arsenates and arsenites with silver nitrate has been accomplished by making use of a secondary titration with sodium hydroxide to maintain the desired low hydrogen-ion concentration. The phosphate titration proved the least satisfactory.

THE POTENTIAL OF LEAD–LEAD ION

BY MERLE RANDALL AND JESSIE Y. CANN

RECEIVED SEPTEMBER 23, 1929 PUBLISHED FEBRUARY 6, 1930

The potential of the lead–lead ion electrode was taken as 0.122 volt by Lewis and Randall,[1] who based their calculations largely upon measurements of the lead–lead chloride electrode and a fairly satisfactory guess of the activity coefficient of lead chloride in the saturated solution. New methods of evaluating the activity coefficients, new values of the reference electrodes and the results of the solubility measurements of Randall and Vietti[2] make it desirable to restudy the older measurements and to determine the potential by an independent method.

The Cell: Pb (in sat. amalg.), $Pb(NO_3)_2$ (aq) | KNO_3 (aq) | KC1 (aq), AgCl (s), Ag (s).—The activity coefficient of lead nitrate was measured by Randall and Scott[3] by the freezing point method, and since the uncertainty in the potential of the flowing liquid junction with a common ion at the same equivalent concentration of salts is not large, we have measured the cell Pb (in sat. amalg.), $Pb(NO_3)_2$ (aq) | KNO_3 (aq) | KC1 (aq), AgCl (s), Ag (s).

The Cell.—The electrode vessels were of the usual form. The flowing junctions were an all-glass modification of the type described by Randall and Langford.[4] The complete cell of pyrex glass is shown in Pig. 1. The dropping funnels A, B and C contained the solutions of lead nitrate, potassium nitrate and potassium chloride. The reservoirs D, E and F were filled with the corresponding solutions and served to bring the temperature of the solutions to the temperature of the thermostat. During measurements Stopcocks G and H were open and I and J were adjusted so that there would be the same flow from the tips K and L. The flow was regulated by means of the stopcocks of the dropping funnels. The rods M and N were raised, the flow from tips K and L regulated, then the rods were lowered and contact was made through the film of solution around the rods. Waste solutions were continuously removed by means of suction applied to small tubes inserted nearly to the bottom of O and P.

The warmed lead amalgam was poured rapidly in succession through a series of clean, dry, pyrex glass test-tubes, which removed all traces of the slight surface film of oxides, and was immediately introduced into the

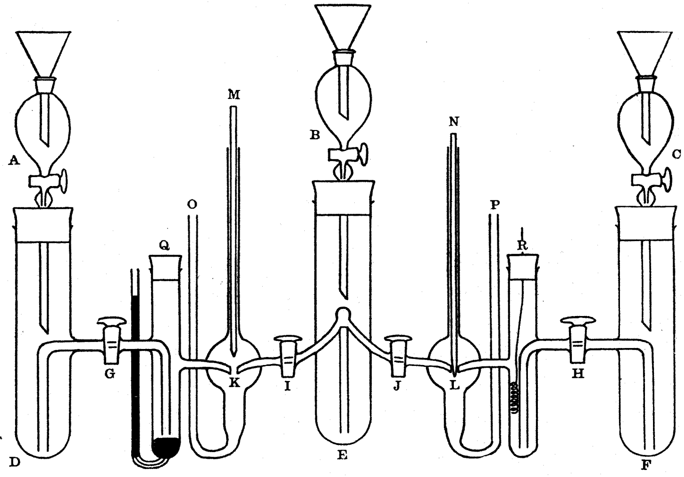
[4] Randall and Langford, unpublished.

cell, Q, and covered quickly with the solution that was to be used. This was done after the whole apparatus had been flushed with hydrogen. The surface of the amalgam was just below the tip of the connecting tube. The cell was placed in the usual oil thermostat, and measurements were made with a shielded Leeds and Northrup Type K potentiometer.

Materials.—The solutions were made up by weight (moles per 1000 g. of water in vacuum) from high grade "analyzed" salts and conductivity water. Pure hydrogen was bubbled through the solutions to remove traces of oxygen.



Pig. 1.—Cell with two flowing junctions.

The saturated two-phase lead amalgam was made by heating together in vacuum 5 g. of "analyzed" test lead and 100 g. of distilled mercury according to the method of Gerke.[5] This amalgam had a slight film of oxide which was removed as described above.

The silver–silver chloride spiral electrodes were made in the same way as those used by Randall and Young.[6] Before introducing into the electrode vessel, the spirals were placed in the solution to be used and evacuated for about thirty minutes with gentle heating, or until all bubbles ceased to appear at the surface of the spiral. Complete removal of oxygen by the above means and by flushing the solutions and apparatus with hydrogen was found to be necessary in order to obtain steady and concordant potentials.

The Standard Potential of the Lead–Lead Ion Electrode.—The molality of the solutions used and the potentials obtained are shown in the first four columns of Table I.

TABLE I

Pb (IN SAT. AMAL.), $Pb(NO_3)_2$ (AQ.) | KNO_3 (AQ.) | KCl (AQ.), AgCl(s), Ag(s) AT 25°

m Pb-$(NO_3)_2$	m KNO_3	m KCl	E volt	E $Pb(NO_3)_2$ | KNO_3	E KNO_3 | KCl	E less liquid	$E^\circ_{298 \cdot 1}$	$\mu^{1/2}$	log γ + const
0.025	0.05	0.05	0.4760	−0.0062	0.0013	0.4809	0.3361	0.2738	−4.0188
.05	.10	.10	.4545	− .0078	.0017	.4606	.3367	.3873	−4.0910
.10	.20	.20	.4327	− .0098	.0023	.4402	.3368	.5477	−4.1621

The values of the potential given in Col. 4 represent the average of several hundred measurements with various rates of flow of the solutions in the liquid junctions, with several solutions and different electrodes for each series. The flowing liquid junctions proved quite reproducible, the principal error being introduced by alteration of the temperature of the solutions when the rate of flow was great. About forty drops per minute was found to be the best rate. The potentials of the liquid junctions were calculated by means of the Lewis and Sargent[7] formula, the conductivities being taken from the compilation by Holborn[8] from the work of Kohlrausch and others at 18°. The ratio of the conductivities at 18 and 25° was assumed to be the same.

The cell reaction after elimination of liquid potentials may be written

$$\text{Pb(in sat. amalg.)} + 2\text{AgCl(s)} = 2\text{Ag(s)} + \text{Pb}^{++}\,(\text{in Pb(NO}_3)_2\ (\text{aq.}) + 2\text{Cl}^-\ (\text{in KCl (aq.)}) \quad (1)$$

in which, formally, aqueous lead chloride is produced, not with an activity coefficient which is that of lead chloride, but one which is the geometric mean of the activity coefficients of lead and chloride ions in lead nitrate and potassium chloride, respectively. As an approximation, which is not wholly justified, we may assume the hypothesis of the independent activity coefficient of the ions,[9] whence the activity coefficient of this hypothetical lead chloride is given by

$$\gamma_\pm(\text{Pb}^{++}\ (\text{in Pb(NO}_3)_2\ (\text{aq.}))\ 2\text{Cl}^-\ (\text{in KCl (aq.)}) = [\gamma^3(\text{Pb(NO}_3)_2)\ \gamma^4\text{KCl}/\gamma^4\text{KNO}_3]^{1/3} \quad (2)$$

Whence, substituting the values of the activity coefficients taken from the work of Randall and Scott,[3] for lead nitrate, of Randall and White[10] for potassium chloride, and of an unpublished summary of activity coefficients, we find by the usual equation[11] the values of E° given in the eighth column of Table I, from which we choose the average value

$$E^\circ = 0.3367 \text{ v.}; \quad \Delta F^\circ_{298 \cdot 1} = -15{,}538 \text{ cal.}$$

---

[7] Lewis and Sargent, THIS JOURNAL, 31, 363 (1909).

[8] Landolt, Bornstein, Roth, Scheel, "Tabellen," Springer, Berlin, 1923, Vol. II, pp. 1079–1080.

[9] Ref. 1, p. 380.

[10] Randall and White, THIS JOURNAL, 48, 2514 (1926).

[11] (a) (Ref. 1, p. 396); (b) Randall, Trans, *Faraday Soc.*, 23, 505 (1927).

We may make an independent extrapolation of the activity coefficient of this hypothetical aqueous lead chloride by means of the equation[11b]

$$\log \gamma + \text{const.} = -\mathbf{E}/0.088725 - \log m^* \tag{3}$$

The values of the square root of the ionic strength and of log γ +const. in Equation 3 are given in the last two columns of Table I. Plotting on transparent paper, log γ +const. on the standard scale against $\mu^{1/2}$ and referring to the standard plot of activity coefficients as was done by Randall and Vietti,[2] we obtain constant = –3.8000 or $\mathbf{E}^\circ$ = 0.3372 v.; but the value 3.7938, corresponding to $\mathbf{E}^\circ$ = 0.3366 seems from the plot to be a reasonable value.

For the potential of saturated lead amalgam we take[12]

$$\text{Pb(s)} = \text{Pb(in sat. amalg.)};\ \mathbf{E}^\circ_{298.1} = 0.00586;\ \Delta F^\circ_{298.1} = -270 \text{ cal.} \tag{4}$$

whence

$$\text{Pb(s)} + 2\text{AgCl(s)} = \text{Ag(s)} + \text{Pb}^{++} + 2\text{Cl}^-;\ \mathbf{E}^\circ_{298.1} = 0.3424\text{ v};\ \Delta F^\circ_{298.1} = -15{,}801 \text{ cal.} \tag{5}$$

and combining with Gerke's value for the free energy of formation of silver chloride (ΔF°_{298}, = –26,220), and the new value of the chloride ion of Randall and Young[7] ($\Delta F^\circ_{298.1}$ = –31,345) we find

$$\text{Pb} = \text{Pb}^{++} + 2E^-;\ \mathbf{E}^\circ_{298.1} = 0.1203 \text{ v};\ \Delta F^\circ_{298.1} = -5551 \text{ cal.} \tag{6}$$

The relation of this potential to that determined from the potential of lead–lead halide electrodes will be discussed in another place.

Summary

The potential of the lead–lead ion electrode has been determined by measurements of the lead amalgam–lead nitrate electrode, combined through flowing junctions, with a silver–silver chloride electrode. The standard potential of lead ion is found to be 0.1203 v., and the free energy of formation to be –5551 cal. at 25°.

THE TEMPERATURE COEFFICIENT OF THE SYNTHESIS OF HYDROGEN CHLORIDE BY LIGHT AND BY ALPHA-RADIATION

BY S. C. LIND AND ROBERT LIVINGSTON

RECEIVED OCTOBER 8, 1929 PUBLISHED FBBRUARY 6, 1930

In 1926, Porter, Bardwell, and Lind[1] compared the rates of hydrogen chloride synthesis by light and by a-rays at 25°. The method consisted in circulating the same mixture of hydrogen and chlorine through a light chamber and through an a-ray chamber, employing in the latter radon in a thin a-ray bulb. The principal result was the discovery that any change in sensitivity of the gas mixture toward one form of activation was exactly the same as for the other. This result is readily interpreted in terms of chain mechanism, as meaning that by no matter what agency a chain is initiated, its further propagation depends only on the gas mixture and its sensitivity (concentration of inhibitors which terminate the chains). This primary result is confirmed in the present work.

The absolute value of the ratio of the yield per ion pair to that per light quantum, which Porter, Bardwell and Lind[1] found equal to nearly 4, has not been wholly confirmed, but a value approximating unity has been obtained. This discrepancy may be partly due to the fact that in the present photochemical experiments a strictly monochromatic source was used for the quantum yield measurements, whereas in the work of Porter, Bardwell and Lind a considerable fraction of the chlorine absorption band was involved. As Allmand and Beesley[2] have recently shown, the different wave lengths absorbed are by no means equal in efficiency in causing synthesis of hydrogen chloride. When correction is made by using Allmand and Beesley's data[2]", the values are reduced from unity and 3.7 to slightly less than unity and to approximately 2.5, respectively. We have at present no explanation for this three-fold discrepancy.

In the paper of Porter, Bardwell and Lind[1] it was found that the photochemical yield per quantum increased about two-fold in the interval 25–100°. On the assumption that the a-ray reaction, in analogy to most of the other reactions previously studied, would be independent of temperature, it was concluded that the M/N and $M/h\nu$ yields might approach each other at high temperatures. Experiment has shown the danger of faulty analogy, since sight was lost of the fact that none of the supposedly analogous a-ray reactions had chain mechanisms, and that if the temperature coefficient is largely determined by the chain part of the reaction, as predicted by Cremer,[3] then the a-ray and light reactions should possess

---

[1] Porter, Bardwell and Lind, THIS JOURNAL, 48,2603 (1926).

[2] (a) Allmand and Beesley, Nature, 123, 164 (1929); see also (b) Coehn and Jung, *Z. physik. Chem.*, 110, 705 (1924).

[3] E. Cremer, *ibid.*, 128, 285 (1927).

identical temperature coefficients. The present experiments show this to be the case for white light.

This conclusion must be contrasted with Tolman's[4] theory of the temperature coefficient as a function of the primary rather than the secondary step in the reaction. If each wave length has its own temperature coefficient, the greater the smaller the quantum, then only by accident will any one of these or the average of all coincide with the α-ray temperature coefficient. More drastic comparison with "green light" ($NiSO_4$ filter) over the same temperature range showed a temperature coefficient of 1.3 for a 10° interval, which is distinctly higher than 1.2, the value for white light in the same region of sensitivity. This may mean that Tolman's theory[4] is not incorrect in principle, but that actually the temperature coefficient is determined almost entirely by one or more steps in the chain mechanism rather than in the primary step.

Porter, Bardwell and Lind[1] also found that the temperature coefficient is a function of the sensitivity, becoming greater the higher the sensitivity. This has been confirmed, but their case of an actual negative coefficient at very low sensitivity could not be substantiated. The actual value of the 10° coefficient is higher by about 0.1 than that of Porter, Bardwell and Lind; the maximum is lower than that of Padoa and Butironi[5] for white light, but is in good agreement with the average of Bevan's values.[6]

Apparatus and Calibration

The apparatus used was a modified Bunsen and Roscoe actinometer,?similar to that employed by Porter. Bardwell and Lind[1] The essential part of the apparatus, a diagram of which is given in Fig. 1, are an electrolytic generator, a capillary U-tube trap containing a few drops of water, a magnetic circulating pump, an absorption vessel, two reaction chambers in separate thermostats and a graduated capillary actinometer. The entire apparatus was made of pyrex glass.

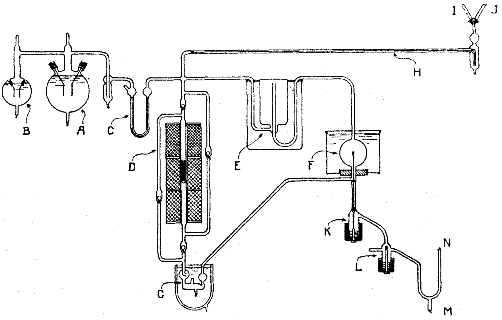

Fig. 1.—Diagram of the apparatus.

The generator **A** contains concentrated hydrochloric acid. The electrodes are of platinum–iridium alloy and are introduced through small rubber stoppers, which are covered outside by mercury seals. The generator B contains dilute sulfuric acid and was used to generate a hydrogen-oxygen mixture, when it was desired to decrease the sensitivity of the gaseous mixture. Since the amount of oxygen added was always a

small fraction of the total amount of gas, the effect of the hydrogen added simultaneously was negligible.

The trap C was used to isolate the generator while measurements were being made. The capillary U-tube is constricted at one point so that a drop of solution can be held there by surface tension.[8] By immersing the trap in liquid air a plug of solid chlorine and ice is formed, which permits the reaction system to be pumped out, through J, without affecting the generator.

The photochemical reaction cell E is similar in design and size to that used by Porter, Bardwell and Lind.[1] The radiochemical reaction cell is a sphere 5.0 cm. in (inside) diameter, having an a-ray bulb mounted at its center. In order that it might be sealed to the apparatus the a-ray bulb was made of pyrex. This can be done quite readily by a technique differing only slightly from that described by Lind.[9] The bulbs were blown in a quartz furnace heated with a gas–oxygen flame, using compressed air (at approximately 6-lb. pressure) instead of a foot bellows.

Radon was introduced into the apparatus sealed in a thin capillary, which was placed through the "eye" in the top of the central steel rod in the breaking vessel L. The capillary was broken by revolving the rod, which extended through a hard rubber stuffing gland and a double mercury seal. After breaking the capillary the radon was condensed just below the reaction bulb by means of liquid air in a Ramsay liquid air funnel. The mercury was then brought just below the radon, before it was released by warming, to minimize absorption or trapping along the wall. The setting valve F is a modification of that described by Lind.[9]

The circulating pump was of the type described by Livingston,[10] and was capable of producing a rapid regular rate of flow.

The capillary used for the actinometer was selected for uniformity by measuring the length of a thread of mercury at different points along its length. It was calibrated by determining the length of a thread of mercury of known weight.

The quantity of radon used was determined by the gamma-ray method by comparison with a standard tube certified by the Bureau of Standards.

A 75-watt gas-filled tungsten lamp, situated one meter from the reaction cell was used as a secondary standard in the determination of the temperature coefficient of the radiochemical reaction. In the determination of the temperature coefficient of the photochemical reaction 75- and 200-watt lamps were used. They were run on 109 volts a. c., the voltage across the lamp being maintained by a hand regulated series resistance. In some of the experiments blackened copper gauzes were used to reduce the intensity of the light.

The monochromatic source, used as a radiation standard, consisted of a quartz mercury arc, equipped with the lenses and diaphragms necessary to produce a gradually converging pencil of light. The light beam passed through Corning filters *G585* and G38 and a crown glass absorption cell containing a 5% copper chloride solution. The emitted radiation was practically pure monochromatic light of 4358 Å. The arc was run at 52 volts and 3.0 amperes d. c. Variations in the line voltage and the room temperature were counterbalanced by an adjustable series resistance and forced ventilation of the lamp housing. The constancy of energy emitted was checked by direct measurement on several occasions during the course of the work.

The energy measurements were made with a Moll thermopile and a sensitive low-

resistance Leeds and Northrup galvanometer. Deflections were observed on a ground glass scale placed one meter from the galvanometer. The system was calibrated by means of a radiation standard lamp furnished by the Bureau of Standards, for which the total radiation in absolute units at two meters distance in a given direction was known for various values of the current. When the calibrations were made a 15-ohm resistance was put in series with the galvanometer to reduce the deflection. Following the explicit directions furnished with the lamp, the results summarized in the following table were obtained.

TABLE I

CALIBRATION OF THE THERMOPILE AND GALVANOMETER

Amperes through filament[a]	Ergs mm.^{2} sec.[b]	Average deflection	Ergs/per mm. deflection mm.2 sec.
0.250	4.26	20.20	0.02109
.300	6.27	29.87	.02099
.350	8.67	41.00	.02115
		Av.	.02108 ± 0.00007

[a] The ammeter used in these measurements was kindly calibrated by Professor **A.** Zeleny of the Department of Physics. [b] Calibration of the Bureau of Standards for flux at *2* meters' distance from the lamp.

The deflections given in Column 4 are the averages of a large number of observations. The inside diameter of the thermopile horn is 2.60 cm. Assuming that all of the light falling in the horn is reflected onto the elements[11] the sensitivity of the system may be computed directly, as 0.02108 X (26.0/2) X π = 11.19 ergs/sec. per mm. deflection. Since the thermopile was equipped with a fluorite window, it is necessary to apply a correction for its absorption of the total radiation incident. If we take an approximate value for the transmission as 91%, the corrected value for the sensitivity is 10.18. Since the measurements of the energy of the monochromatic source were made with no extra resistance in the circuit, a correction must be applied for the 15 ohms used in calibration. A series of direct comparisons showed this factor to be equal to 0.677. The final value for the calibration is 6.89 ergs/sec. per mm. deflection.

The Temperature Coefficient of the Photochemical Reaction.—The apparatus used in the determination of the temperature coefficient of the photochemical reaction differed from that represented in Fig. 1 in that a second photochemical vessel (similar to the first) was introduced in place of the radiochemical vessel. These vessels were surrounded by separate thermostats, one of which was kept at room temperature, while the other was maintained at either room temperature or at 94°.

Reaction velocity measurements were made by illuminating alternately the first and second reaction vessels. In order to avoid the lag which follows a change in the intensity of activation, the method which Porter, Bardwell and Lind used for slow reactions[12] was not employed. The following method was adopted. Reaction Vessel I was illuminated, and the time required for the meniscus to move through a certain 50 cm. length

---

[11] This was demonstrated for this instrument by B. Lewis, J. Phys. *Chem.*, 32, 278 (1928).

[12] Ref. 1, p. 2611.

of the actinometer capillary was determined; the illumination on Vessel I was shut off and Vessel II was illuminated; the meniscus was displaced by admitting more gas from the generator, and the time required for the meniscus to move through the 50 cm. length was taken. At least five such successive measurements were performed, and the average value of the ratio of the recorded times, with Vessel I and with Vessel II illuminated, was computed. The following typical computation will illustrate the method of taking the average.

TABLE II

COMPUTATION OF THE AVERAGE

A	B	C	D	E	
	201.5				
197.5		147		1.34	A/C

	183		131.5	1.39	B/D
		131			
			Av.	1.39	

Columns B and C give the times in seconds observed when Vessels I and II, respectively, were illuminated. Column A gives the averages between successive values in B, and Col. D gives the averages for C. As is indicated by the arrangement, values of B and C were determined alternately. Values of the ratio of the time required when Vessel I was illuminated are given in Column E. This term is equal to the ratio of the two reaction velocities, or, since the illumination was constant, to $(M/q)_{\mathrm{I}}/(M/q)_{\mathrm{II}}$, where M/q is the number of molecules reacting per quantum absorbed.

Rapid changes in sensitivity were never observed during the course of an experiment. A slow uniform drift in sensitivity was commonly observed (compare Table I), but did not appreciably affect the accuracy of the values of the ratio. We were unable to determine what factors were responsible for the sudden changes in sensitivity observed by Porter, Bardwell and Lind.[13] By the use of the two electrolytic generators the sensitivity could be controlled over a wide range. To increase the sensitivity the reaction system was first pumped out and then refilled by starting the hydrogen–chlorine generator (A). To reduce the sensitivity, the hydrogen–oxygen generator (B) was run for a few seconds.

To evaluate the temperature coefficient values of $(M/q)_{\mathrm{I}}/(M/q)_{\mathrm{II}}$ must be determined, first when both reactions occur at the same temperature, and second when one of them (I) occurs at a different temperature (94°). Since $(M/q)_{\mathrm{II},\,25^\circ}$ differs from $(M/q)_{\mathrm{I},\,25^\circ}$ only in the number of chains started per second (*i.e.*, by a constant factor), we may write

---

[13] **Ref.** 1, p. 2611.

$$\frac{(M/q)_{94^\circ}}{(M/q)_{25^\circ}} = \frac{(M/q)_{\mathrm{I},\,94^\circ}}{(M/q)_{\mathrm{II},\,25^\circ}} \times \frac{(M/q)_{\mathrm{II},\,25^\circ}}{(M/q)_{\mathrm{I},\,25^\circ}}$$

The average variation of the reaction velocity per 10° interval over the range 25 to 98°, K_{10}, is given by the equation

$$\log K_{10} = \frac{10^\circ}{94 - 25^\circ} \log \frac{(M/q)_{94^\circ}}{(M/q)_{25^\circ}}$$

In computing values of K_{10} the measured room temperature, which varied from 21 to 27°, was used instead of 25°. A few measurements, Numbers 20 to 22, Table III, were made at 52°. The differences between the temperatures of the two thermostats (ΔT) is given in Col. 5. The values of $(M/q)_{94^\circ}/(M/q)_{25^\circ}$ listed are each based upon a series of measurements similar to that quoted in Table II. Only those series which showed a uniform drift in sensitivity, not greater than 6% between successive measurements, are recorded. The values of $(M/q)_{\mathrm{I},\,25^\circ}/(M/q)_{\mathrm{II},\,25^\circ}$ used in computing $(M/q)_{94^\circ}/(M/q)_{25^\circ}$ are each the average of from six to ten series of measurements.

In order to obtain an absolute value for the chain length, M/q, at which the temperature coefficient measurements were performed, a cylindrical absorption cell was sealed into the apparatus in place of one of the reaction vessels. The cell is 16.0 cm. long and has plane sealed-on ends 3.0-mm. thick. The monochromatic source was adjusted to throw a narrow pencil of light which passed through the cell and converged into the horn of the thermopile. Measurements were made of the energy passing through the cell when it was evacuated to less than a mm. pressure and when the reaction mixture circulated through it at one atmosphere pressure. The galvanometer deflection corresponding to the absorption by the gas was 3.20 cm. This corresponds to a rate of absorption of 6.89 ergs./sec. mm. × 32.0 mm. = 220.5 ergs./sec. This value must be corrected for the absorption by the second pyrex plate of the cell. Direct measurements with this plate, and measurements with 11.7 mm. of pyrex, gave a value for the transmission of the plate of 91%.[14] The absorption of the fluorite window for light of this wave length is practically negligible. Correcting for the absorption by the pyrex, the amount of energy absorbed is 243 ergs./sec. The energy per quantum is

$$E = \frac{6.56 \times 10^{-27} \times 3 \times 10^{10}}{4.36 \times 10^{-8}} = 4.51 \times 10^{12}\ \text{ergs. per quantum}$$

Therefore, the rate of absorption of quanta is $2.43 \times 10^2/4.51 \times 10^{-12} = 5.40 \times 10^{13}$ quanta per second.

By comparing the reaction velocity due to the monochromatic source with the velocities due to the white light sources used, the number of

---

[14] This corresponds to a considerably lower value for the coefficient of absorption than that based on measurements of the transmission of a plate 0.77 mm., made by Gibson and McNichols in 1919, Bureau of Standards., Technical Paper 119 (1919).

quanta absorbed by the chlorine from the latter may be computed. *Since quanta of different frequencies are not equally effective in starting reaction chains,*[2] *the number of the quanta determined in this way is not equal to the actual number of quanta absorbed from the white light, but rather to the number of quanta of λ4358 Å. which would be required to maintain the same rate.* The values of M, used in computing M/q, were obtained from the calibration of the actinometer capillary; 1.00 cm. displacement corresponds to 0.0504 cc. By combining this factor with Avogadro's number and the observed rate of displacement of the meniscus (in cm. per sec.), M, the number of molecules reacting per second can be obtained. The detailed results of the comparison of the monochromatic source with the 75-watt lamp are given in Table III.

TABLE III

COMPARISON OF A 75-WATT LAMP WITH THE MONOCHROMATIC SOURCE

In Fig. 2 the values of K_{10} are plotted (as black dots) against the average chain length, M/q. As may be readily seen from this plot, the value of K_{10} depends on the sensitivity, or average chain length. It is least for low sensitivities and rises to a constant value or flat maximum for M/q equal to 10^5.

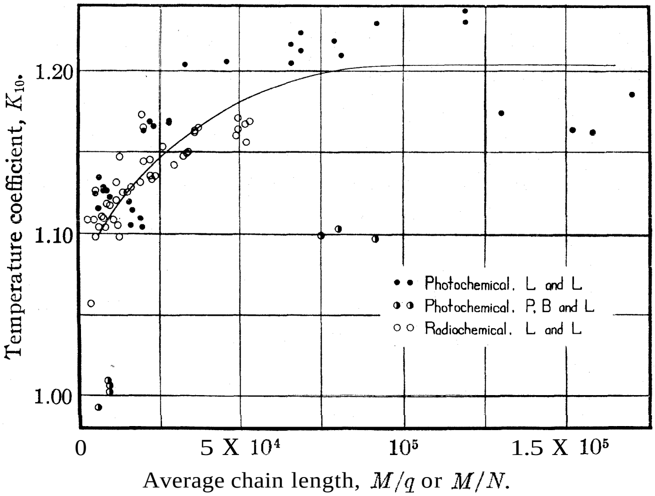

Fig. 2.—The temperature coefficient.

Since it proved difficult to attain the highest sensitivities, comparatively few measurements were made for chain lengths greater than 10^5, and it is possible that the values of K_{10} corresponding to the highest sensitivities are less accurate than those in the intermediate range. It should be noted that these values are not in agreement with those published by Porter, Bardwell and Lind[1] (which are indicated by half-blackened circles in Fig. 2), although both sets of data show the same trend with sensitivity. The explanation of this discrepancy is not known.

It should be of interest to compare the values of the temperature coefficient given here with those published by other investigators.[1,5,6] Since these measurements were made for different temperature intervals, probably the simplest way of comparing them is to plot the logarithm of the reaction velocity against the absolute temperature. Such a plot is given in Fig. **3**. Arbitrary quantities have been added to each of the several series of values of log v such that they coincide at T = 29S°K. The values taken from Table IV are the average of Numbers 20, 21 and 22 for 52°, and Number 23 for 94°; these values correspond to an average chain length of about 68,000. All of the values plotted represent experiments with white light. The values taken from the work of Porter, Bardwel and Lind correspond to a chain length of about 80,000. Except for the values of Porter, Bardwell and Lind, all of the results are in as good agreement as could be expected, particularly when it is remembered that the sensitivity of the mixtures used by Bevan[6] and by Padoa and Butironi[5] are not known. The data also indicate that the Arrhenius equation holds at least approximately for this reaction. In view of the complex nature of the reaction, this latter result is rather surprising.

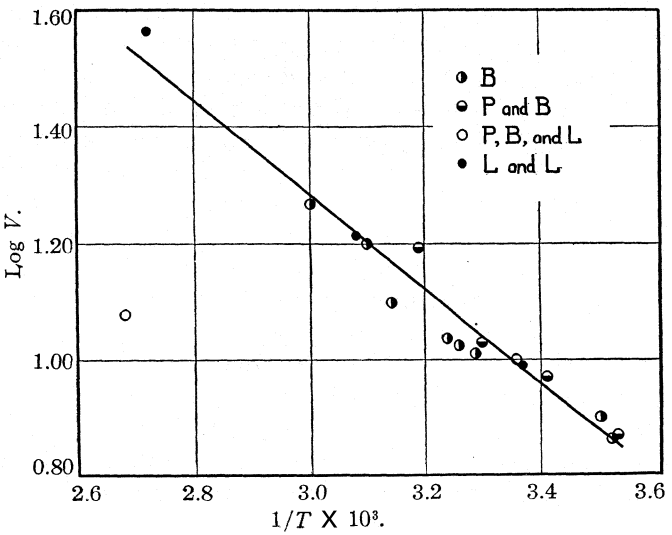

Fig. 3.—Comparison of rate measurements at different temperatures.

The results of Padoa and Butironi[6] indicate that the value of K_{10} is greatly affected by the wave length of the absorbed light. To test this result a few measurements were made with a 100-watt light and a 5-cm. filter of saturated nickel sulfate solution. The values of the temperature coefficient so obtained were unmistakably larger; about 1.29 for $M/q = 10^5$. However, this is much smaller than the value of 1.5 obtained by

Padoa and Rutironi. The results of these latter experimenters may be influenced by their experimental conditions. If their reaction was preceded by an induction period of measurable length, then reducing the number of effective quanta absorbed per second, as in going to light of longer wave length by means of filters, would very probably produce an apparent increase in the temperature coefficient. In a recent preliminary report, Allmand and Beesley[2] state that "experiments carried out at 19.7 and 25° showed the relative temperature coefficients of the quantum efficiency to increase slowly, but unmistakably, with λ between 313 and 436mμ."

In view of the fact that Franck[15] has shown that chlorine dissociates into an excited and a normal atom as a primary act on absorption of a quantum of frequency greater than the convergence frequency of chlorine (which corresponds to λ4785 Å.), it is difficult to explain the results of Allmand and Beesley.[2] However, if a quantum of light, of wave length greater than 4785 Å. but still containing nearly enough energy to dissociate a chlorine molecule, is absorbed, it is quite probable that the resulting activated molecule can be dissociated by means of a collision.[16] It is very probable that activation of this type does possess a relatively large temperature coefficient.[17] This fact may be responsible for the higher temperature coefficient observed when "green" light (or monochromatic light of 5460 Å.) is used; but it does not explain Allmand and Beesley's result for shorter wave lengths. Since they determined the amount of absorption by measuring the incident intensity and computing the absorption from von Halban and Siedentopf's data,[18] it is possible that the explanation of their results lies in the effect of temperature on the absorption coefficient of chlorine for the several frequencies used.[19]

Temperature Coefficient of the Radiochemical Reaction.—The methods used in determining the temperature coefficient of the radiochemical reaction were similar to those used in the study of the photochemical reaction. The apparatus is represented in Fig. 1. The thermostat surrounding the photochemical vessel was kept at room temperature or at 98°.

Reaction velocity measurements were made alternately, when the activation was due to a-rays alone, and when it was due to both a-rays

[17] Compare, however, the results of Jost [*Z. physik. Chem.*, 134, *92* (1928)], who found no difference in the efficiency of light from either side of the bromine convergence in producing the synthesis of hydrobromic acid.

[18] Von Halban and Siedentopf, *ibid.*, 103, 80 (1923).

[19] The effect of this phenomenon on the observed values of the temperature coefficient of photochemical reactions has been discussed by Kistiakowsky, Ref. 16, pp. 248–251.

and light. The experimental procedure and the method of averaging have been described in connection with the photochemical reaction. In this case, however, the average so obtained is the ratio of the sum of the two reaction velocities to that of the radiochemical reaction. In order to reduce a series of such values to a common basis, it is necessary to correct for the decay of radon.

$$e^{-\lambda t}\left(\frac{v_q + v_\alpha}{v_\alpha} - 1\right) = e^{-\lambda t}\,\frac{v_q}{v_\alpha} = \frac{(M/q)_{25^\circ}}{(M/N)_+}$$

Since the work of Porter, Bardwell and Lind demonstrates that the ratio $(M/N)/(M/q)$ is not dependent on sensitivity, these values may be used to obtain $(M/N)_{98^\circ}/(M/N)_{25^\circ}$ by the method already described. The values so computed are not an exact measure of the temperature coefficient, since the total ionization is not independent of the temperature. The ionization is proportional to the density of the gas or inversely proportional to the absolute temperature. Therefore

$$\frac{371^\circ}{298^\circ} \times \frac{(M/N)_{98^\circ}}{(M/N)_{25^\circ}\text{ obs.}} = \frac{(M/N)_{98^\circ}}{(M/N)_{25^\circ}\text{ corr.}}$$

The corrected values were used in computing K_{10}.

To determine the number of ion pairs formed per second per millicurie with the a-ray bulb and reaction sphere used, the sphere was sealed into a manometric system, 182.3 millicuries of radon was placed in the bulb, and the reaction system was filled with a stoichiometric mixture of hydrogen and oxygen at atmospheric pressure. The pressure change was followed for five days, and kE_0/λ was determined, by plotting $\log P_{H_2 + O_2}$ against $e^{-\lambda t}$, to be equal to 0.723. This corresponds to 3.23×10^{15} ion pairs per second per millicurie, in a stoichiometric mixture at N. T. P. If it is assumed that the total ionization in the sphere is proportional to the specific ionization of the gas,[20] it follows that the number of ion pairs formed per second per millicurie in an equimolar hydrogen–chlorine mixture is $(1.33/0.527)10^{-3} \times 3.23 \times 10^{15} = 8.15 \times 10^{12}$. At 22° and 740-mm. pressure (average values for the room temperature measurements) the corresponding value is 7.35×10^{12}. The method of computing M has already been outlined. The values of $(M/N)_{98^\circ}$ were corrected to 25° by dividing by the corresponding values of $(M/N)_{98^\circ}/(M/N)_{25^\circ}$.

A plot of K_{10} against $(M/N)_{25^\circ}$ is included in Fig. 2, the experiments being represented as circles. As in the case of the photochemical reaction, the temperature coefficient is a function of the sensitivity.

The Relative Efficiency of Photons and Ions.—The experimental data,

---

[20] This assumption is not in general justifiable. However, Porter, Bardwell and Lind[1] point out that the work of Bardwell and Doerner [THIS JOURNAL, *45*, *2593 (1923)*] shows that for spheres of less than 3 cm. radius the intensity of ionization is very nearly constant along this path. Therefore, although the method of calibration used here is not exact, the results are probably not in error by more than *10%*.

summarized in Tables IV and V, demonstrate that the value of the temperature coefficient of the reaction rate is practically the same for the photo- and radiochemical reactions. This, as well as the fact that the temperature coefficient is a function of sensitivity, indicates that the temperature coefficient is determined by the secondary or chain mechanism[21] and that this mechanism is independent of the form of activation. Additional evidence for this latter point has been presented by Porter, Bardwell and Lind,[1] who have demonstrated that the ratio of the yield per ion pair to the yield per absorbed quantum is independent of the sensitivity of the mixture. For measurements at 25° they find the value of this ratio to be 3.72. They assume that K_{10} for the radiochemical reaction is equal to unity and therefore that the ratio is a function of temperature, probably equal to 2.0 at 100°. However, the measurements of the temperature coefficient presented here indicate that the ratio is independent of the temperature, at least for the range 25 to 100°.

In the determination of the radiochemical temperature coefficient, a number of values of $(M/N)_{25°}/(M/q)_{25°}$, in arbitrary units, were determined. By introducing the number of ion pairs produced per second and the number of quanta absorbed per second (Table III) this ratio may be converted into absolute units.

$$\frac{(M/N)_{25°}}{(M/q)_{25°}}\ \text{absolute} = \frac{q}{E_t \times 7.35 \times 10^{12}} \times \frac{(M/N)_{25°}}{(M/q)_{25°}}\ \text{arbitrary}$$

where 7.35 × 10^{12} is the number of ion pairs per second per millicurie. The average value of $(M/N)/[E_+ \times (M/q)]_{\text{arbitrary}}$ for three series of measurements (involving three separate charges of radon in the same bulb, 27 determinations in all) is 1.36 ± 0.21. The corresponding value of $(M/N)_{25°}/(M/q)_{25°\,\text{absolute}}$ is 0.92. Since this determination involves an indirect measure of the number of quanta absorbed, as well as possible uncertainties in the quantity of radon, the measurement was repeated under more definite conditions.

A new radiochemical vessel was calibrated by means of the hydrogen–oxygen reaction, and was found to give 9.45 × 10^{12} ion pair per millicurie for an equimolar mixture of hydrogen and chlorine at 740 mm. and 22°. Without removing the charge of radon this vessel was sealed into a circulating system containing the light absorption cell. The radon was allowed to decay to about 7 millicuries. It has already been shown that under the experimental conditions employed 5.40 X 10^{13} quanta per second of λ4358 were absorbed by the chlorine. Using a reaction mixture of low sensitivity (M/N about 4000), three series of measurements of $(M/N)/(M/q)$ were made. Two days later, when an attempt was made to repeat the measurements using a more sensitive mixture an explosion ensued which wrecked the entire apparatus. The average value of $(M/N)_{25°}/(M/q)_{25°}$ abs. based upon the three experiments is 1.18. This is in good agreement with the value obtained by the indirect comparison, but is about three-fold smaller than that published by Porter, Bardwell and Lind.

Very recently Allmand and Beesley[2a] have published a preliminary

---

[21] Compare Cremer, Ref. 3.

notice of work which indicates that quanta of different wave lengths differ materially in their chemical efficiency. They state that the efficiency curve has a maximum at 4050 Å. If the factor for 4050 Å. is taken as unity, the value for 4358 Å. is 0.67. Therefore, if monochromatic light of 4050 Å. instead of 4358 Å. had been used in these experiments, the values for $(M/N)/(M/q)_{\text{abs}}$. would have been $0.92 \text{ X } 0.67 = 0.62$ and $1.18 \times 0.67 = 0.79$, within the limits of experimental error still equal to unity. A similar correction must be applied to Porter, Bardwell and Lind's value of 3.72. However, there are apparently two errors in the computation of this value which should be corrected for first. The total number of ion pairs per a-particle should be $2.47 \times 3.72 \times 10^4 = 9.19 \times 10^4$ not $8.45 \text{ X } 10^4$.[22] Correcting this to 25°

$$9.19 \text{ X } 10^4 \text{ X } 273/298 = 8.41 \times 10^4 \text{ ion pairs per particle.}$$

This corresponds to $1.003 \times 10^{18} \times 8.41 \times 10^4 = 8.44 \times 10^{12}$ ion pairs/sec. per millicurie, for the total ionization in the bulb. Repeating their graphical determination of the mean wave length of the light absorbed by the chlorine results in a value of 4350 Å., not 4100 Å. as published. In this computation we have used Priest's[23] values for the energy distribution from a 500-watt tungsten lamp.

There appears to be considerable uncertainty in the published values for the extinction coefficient for copper sulfate solution. The values used were graphical averages of the data of Martens and Grunbaum[24] for 0.62 M solution, of van der Gon[25] for 1.15 M solutions, and of Mecke and Ley[26] for 0.50 M solutions. The method of taking the average (particularly in the region 3600 to 5000 Å.) has a large effect on the values for the average wave length of the light absorbed by the reaction mixture, and a still greater effect on the average efficiency term (Allmand's factor). It is apparently one of the chief sources of uncertainty in the corrected value for $(M/N)/(M/q)$ based upon the work of Porter, Bardwell and Lind.[1] No correction was made for the absorption of crown glass, partly because it is practically independent of the wave length for the region 4000 to 6000 Å. and partly because the thickness of the glass in the optical path is not given. The absorption of chlorine is taken from the work of von Halban and Siedentopf.[18]

From these data a curve of the energy absorbed (in arbitrary units) against wave length was plotted. The corresponding curve of relative

---

[22] Ref. 1, p. 2609.

[23] Priest, J. Opt. *Soc. Am.*, *6*, 27 (1922). The filament (color) temperature of this 500-watt lamp was 2848°, not 2700°K. as used by Porter, Bardwell and Lind. However, if 2700° were used it would result in an even greater value than 4350 Å. for the mean wave length.

[24] Martens and Grunbaum, *Am.* **Physik,** 12,1004 *(1903).*

[25] Van der Gon, *Arch. ne'erl,* 7, *140* (1923).

[26] Mecke and Ley, *Z. physik. Chem* , 111,385 (1924)

number of quanta absorbed against wave length was plotted, and a mean value (4350 Å.) which divided the area under the curve into two equal parts was determined. The corrected value for $(M/N)/(M/q)$ is

$$3.72 \times \frac{4350}{4100} \times \frac{7.84 \times 10^{12}}{8.44 \times 10^{12}} = 3.67$$

Using Allmand and Beesley's[2a] table of efficiency factors and the plot of relative number of quanta absorbed, a curve of relative number of "effective quanta" was plotted against wave length. The ratio of the total areas under these two curves is the efficiency factor (in terms of λ4050 Å.). Using this factor (0.71), Porter, Bardwell and Lind's value of $(M/N)/(M/q)$ reduces to 0.71 X 3.67 = 2.6.

The average of these three values for $(M/N)/(M/q)$ is 1.3. Although the close agreement between this value and unity is apparently fortuitous, it is fairly certain that the correct value is not greater than 2.0, and is quite probably unity.

The Mechanism of the Reaction.—While the results presented here indicate that the chain mechanism is independent of the form of activation, they do not offer any direct evidence in regard to the nature of that mechanism. However, it is possible to draw certain conclusions about the mechanism of activation. It is now generally accepted that photochemical activation, by light of wave length less than 4785 Å., can be represented as

$$h\nu + Cl_2 = Cl + Cl'$$

A possible corresponding mechanism for the activation by α-rays is

$$Cl_2^+ + (-) = Cl + Cl' \text{ or } Cl_2^+ + Cl_2^- = Cl_2 + Cl + Cl' \text{ or } Cl_2 + (a) = Cl + Cl^+ + (-)$$

These two equations would indicate a value of unity for the ratio $(M/N)/(M/q)$. If the correct value for this ratio were 2.0, a corresponding activation involving negative molecular ions could be assumed

$$Cl_2^+ + Cl_2^- = 2Cl + 2Cl'$$

Of course, both of these processes might occur simultaneously. The experimental evidence seems to indicate that the latter process occurs less frequently than the former.

There is an apparent inconsistency between the results presented here and by Porter, Bardwell and Lind,[1] which show that an ion is very effective in starting a chain, and the results of Allmand and Beesley,[2a] which show that a quantum of *ultraviolet* light is a relatively inefficient source of activation.

Summary

1. The photochemical (white light) and radiochemical synthesis of hydrogen chloride have temperature coefficients which are identical within the limits of experimental error.

2. The temperature coefficient of this reaction varies with the sensitivity of the reacting mixture. The 10° coefficient has a value of about

1.10 for an average chain length of 2×10^3, and rises to a constant value, or flat maximum, of about 1.20 for an average chain length of 8×10^4.

3. It has been shown qualitatively that the temperature coefficient has a value about 10% higher when "green light" (a $NiSO_4$ filter) is used as the source of activation.

4. An absolute value, of approximately *unity,* for the ratio of the yield per ion pair to the yield per absorbed quantum was obtained using monochromatic light of λ4358 Å. The results of Porter, Bardwell and Lind[1] are discussed, and a correction based upon the work of Allmand and Beesley[4] has been applied.

5. **A** mechanism of activation, consistent with the results presented here, is outlined.

THE OXIDATION OF IODIDE ION BY PERSULPATE ION. III. THE IODIMETRIC ESTIMATION OF PERSULFATES

BY CECIL V. KING AND ERIC JETTE

RECEIVED OCTOBER 8, 1929 PUBLISHED FEBRUARY 6, 1930

In the second paper of this series the velocity of the reaction between persulfate and iodide ions in alkaline solutions was reported. The iodine produced disappears almost as fast as formed, producing iodate and iodide (through the intermediate formation of hypoiodite); the liberation of iodine on acidifying was assumed to be quantitative. Some of our experiments suggested that the amount of iodine recovered was slightly low. Consequently the iodimetric estimation of persulfate in neutral and alkaline solutions was carefully compared.

A number of previous investigations have proved that persulfate liberates iodine from potassium iodide with quantitative precision in neutral solution[1] and we have fully confirmed this. The reaction is slow, but can be hastened enormously by inert salts, special catalysts, etc., as shown in the papers mentioned.

Experimental

(1) Liberation of Iodine in Neutral Solution.—We first compared the amount of iodine liberated by potassium permanganate in acid solution with that liberated by an equivalent amount of potassium persulfate in neutral solution. The permanganate was carefully standardized, and the concentrations and conditions used in liberating iodine were well

---

[1] See Miiller and Ferber, Z. anal. *Chem.,* 52, 195 (1913); Muller, *ibid.,* 52, 299 (1913); Schwicker, *ibid.,* 74, 433 (1928); Zombory, *ibid.,* 73, 217 *(1928).* References to other literature will be found in these papers.

within the limits recommended by Bray and Miller, who have concluded that the permanganate method for standardizing thiosulfate solution is accurate to one part per thousand.[2] Potassium persulfate was recrystallized three times between 50 and 0° and dried over sulfuric acid. Standard solutions were made by weighing out the crystals; 0.008 and 0.04 M solutions of persulfate were used. Samples of these solutions, potassium iodide and potassium chloride (to hasten the reaction) were sealed in glass bulbs (to avoid loss of iodine by volatilization) and allowed to stand for one to three hours. Several series of experiments showed agreement to one part per thousand between the two methods. For example, using 0.008908 *M* permanganate ($\pm 0.03\%$) a thiosulfate solution was 0.009841 *M* ($\pm 0.04\%$); using 0.008 *M* persulfate to liberate the iodine, the thiosulfate was 0.009847 *M* ($\pm 0.05\%$). Other trials gave equally good agreement.

(2) The Reaction in Alkaline **Solution.**—Müller and also Schwicker[1] have claimed quantitative results when iodine is liberated by persulfate in alkaline solution which is later acidified just before titration. Most of Müller's titrations show 1 to 2 parts per thousand less iodine than the theoretical, but it is hard to tell from Müller's paper whether this is significant or not. Schwicker reports most of his titrations only to 0.1 cc. and consequently his degree of precision is doubtful. We feel that our experiments are comparable in accuracy to those of Bray and Miller[2] on the use of permanganate in standardizing thiosulfate solutions.

Our very carefully made comparisons show that the iodine liberated in alkaline solution is invariably 2 to 5 parts per thousand lower than the amount which is liberated in neutral solution. The following example from a series of twenty comparisons made will illustrate: neutral solution, 25 cc. of 0.008 M persulfate + 5 cc. of M KI + 4 g. of KCl required 40.11, 40.14, 40.13, 40.12 cc. of thiosulfate solution; alkaline solution, 25 cc. of 0.008 M persulfate + 5 cc. of M KI + 10 cc. of M NaOH (from sodium), acidified later, required 40.03, 40.04, 40.02, 40.03 cc. of the same thiosulfate solution. In all other experiments, with persulfate 0.008 M and 0.04 M, the results were similarly low. The difference is quite outside experimental error. We recommend that if the alkaline solution method is used, the results be increased by three parts per thousand to be in agreement with the very accurate neutral solution method.

(3) Investigation of this Inaccuracy.—It has apparently been taken for granted that when iodine solution is made alkaline and then acidified, the iodine is quantitatively recovered. However, we have found that this is not the case. In a series of comparisons it was found that the iodine recovered was almost invariably 2 to 5 parts per thousand lower than that in the same sample titrated directly with thiosulfate. For example:

---

[2] Bray and Miller, This Journal, 46, 2204 (1924).

25 cc. of 0.00880 *M* iodine (in 0.1 *M* KI) titrated directly required 20.57, 20.59, 20.55, 20.60 cc. of thiosulfate. The same sample + 5 cc. of 3 N sulfuric acid required 20.60 and 20.58 cc. of thiosulfate. The same sample run into 20 cc. of 3 M NaOH (from sodium), immediately acidified, required 20.52, 20.53 and 20.53 cc. of thiosulfate; acidified after standing for one hour, 20.49 and 20.50 cc. of thiosulfate. About fifty other samples run at widely different times, with different lots of materials, with iodine from 0.005 to 0.02 M and NaOH from 0.5 to 1.5 M, gave results 2 to 5 parts per thousand low in the alkaline solutions.

We are sure that these results are not due to experimental error. All precautions were taken to avoid loss of iodine by volatilization. Sodium hydroxide which had been purified by alcohol was avoided (see Müller, Ref. 1). Comparisons were made under exactly similar conditions. The inaccuracy of the liberation of iodine by persulfate in alkaline solution is undoubtedly due to the same cause as the loss of iodine when the solution is made alkaline and then acid.

The only reasonable explanation seems to be that hypoiodous acid or hypoiodite ion decomposes in some manner such that part of the iodine does not reappear on acidifying. Hypoiodous acid, being more of a base than an acid, exists to an appreciable extent in alkaline solution; it may decompose as follows

$$2HIO \longrightarrow 2I^- + 2H^+ + O_2\text{, or perhaps } 2IO^- \longrightarrow 2I^- + O_2$$

The yellow color (which does not disappear immediately on making the solution alkaline) and the odor presumably indicate the presence of hypoiodous acid in the alkaline solution.

Summary

1. The amount of iodine liberated from potassium iodide by persulfate in neutral solution is shown to agree within one part per thousand with that liberated by an equivalent amount of permanganate in acid solution. Persulfate is therefore recommended as an oxidimetric standard in iodimetry.
2. When the liberation is carried out in alkaline solution which is acidified just before titration, the results are 2 to 5 parts per thousand low; no way has been found to eliminate this error.
3. When a solution of iodine in potassium iodide is made alkaline, then acidified, 2 to 5 parts per thousand of the iodine are lost. This probably explains conclusion (2).

THE HEAT CAPACITY OF SATURATED LIQUID ETHANE FROM THE BOILING POINT TO THE CRITICAL TEMPERATURE AND HEAT OF FUSION OF THE SOLID[1]

BY R. WIEBE,[2] K. H. HUBBARD[3] AND M. J. BREVOORT[4]

RECEIVED OCTOBER 14, 1929 PUBLISHED FEBRUARY 6, 1930

The data presented in this paper are the results of further work on a series of investigations that are being carried out on the properties of ethane.[5] Measurements on the heat capacity of saturated liquid ethane have recently been made by A. Eucken and F. Hauck,[6] but their results are 10 and in some instances even 20% higher than ours; we shall discuss the relative merits of the data later.

The purpose of this investigation is to gain additional knowledge of the thermal properties of one of the constituents of natural gas from which helium is being extracted.

Preparation of Ethane.—The preparation of large quantities of pure ethane was difficult. At low temperatures 2.3 moles were necessary to fill the calorimeter, and altogether more than 12 moles of the substance were made.

Ethane was generated by electrolyzing a solution of potassium acetate as outlined by Murray.[7] The gas was passed successively and repeatedly through 30% solution of sodium hydroxide, fuming sulfuric acid, concentrated sulfuric acid, 30% solution of sodium hydroxide, potassium hydroxide sticks and phosphorus pentoxide. The liquefied gas was finally fractionated twice under stirring in a cryostat; the first and last portions were rejected. Before the final fractionation, several portions had been rejected during the process of chemical purification. From the heat effect associated with premelting and lowering of the melting point, the purity was estimated to be about 99 mole per cent. Two batches of ethane were initially prepared. The second batch showed signs of only slightly higher purity than the first one, even though considerably more care was used in its preparation. The fillings for the steel calorimeter were taken from the second batch and should have been of progressively greater purity as the amount of ethane in the calorimeter decreased.

Apparatus.—The apparatus for temperature control, similar to that used by Gibson and Giauque[8] is shown in Fig. 1.

The copper cylinder, B, weighing 3.8 kg., was suspended from the steel top of a vacuum-tight container, A, made from a solid brass cylinder. A lead gasket, D, was

found quite satisfactory even at liquid–air temperatures, although it was necessary to tighten the nuts on the stud screws occasionally. The pressure was ordinarily less than 3×10^{-5} mm. of mercury. H and J were heating elements connected in series. The heater, J, was added to the apparatus after it was found that the temperature of the top lagged considerably behind the temperature of the body of the copper cylinder because of poor contact. One of the thermometer terminals is shown at G; F is a bakelite tube for thermocouple leads. The Wood's metal seal, E, insured good thermal contact with the steel tube leading to the calorimeter. The places marked TC indicated the positions of different thermocouples.

Two calorimeters as shown in Fig. 1 were used, a steel calorimeter, C, primarily for pressures above 1 atmosphere, and one made of copper, P, for low pressures.

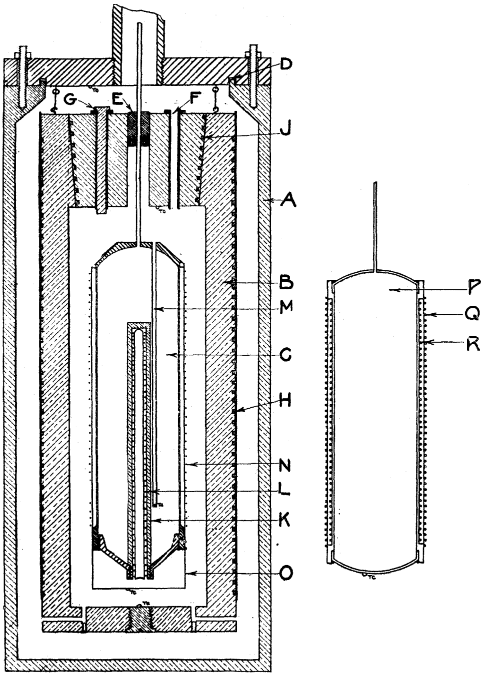

Fig. 1.—Apparatus for specific heat measurements.

The cylindrical steel calorimeter, C, had a wall thickness of 1.0 mm. The height was 14 cm., the diameter 3.8 cm. and the volume 123.3 cc. The bottom steel cap was screwed into the body of the calorimeter and the joint was made pressure tight by silver-soldering in a groove left for that purpose. A central heater tube, K, 10 cm. in length, made of a solid copper cylinder with twelve radial vanes cut out in a milling machine, was screwed and silver-soldered into the bottom cap. The heater, L, was wound around a thin copper tube closed on one end and in thermal contact with the central heater tube by means of Rose metal. A thermocouple well, M, of copper was extended from the top.

The steel calorimeter, C, was surrounded by a copper shell, O, 1.5 mm. thick, in order to equalize rapidly the outside temperature. The copper resistance thermometer, N, was wound on this copper sheet. The latter made contact only at the top and bottom of the cylindrical portion, which eliminated any strain in the thermometer due to differential expansion.

The copper calorimeter, P, had a wall thickness of 0.75 mm. The height was 13 cm. and the diameter 3.8 cm. Sixteen radial vanes of copper served to distribute the heat rapidly throughout the calorimeter. Ethane was introduced through a steel tube (O.D. 0.25 cm. and I.D. 0.19 cm.). Resistance thermometer Q and heater R were separate. The former was made of No. 40 B. and S. gage copper wire and had a resistance of 240 ohms at 0°. The resistance thermometer was wound on the outer shell which was soldered to the calorimeter, while the heater, made of No. 32 B. and S. gage manganin wire, was wound around the body of the calorimeter. The resistance of the heater was 620 ohms at room temperature and remained very constant because of the small temperature coefficient of manganin wire. In using a copper resistance thermometer we followed Onnes and Holst,[9] Meissner[10] and others. The volume of the copper calorimeter was 144.8 cc.

The container was surrounded by a silvered pyrex Dewar flask 14 cm. in diameter. The storage cylinder used to keep and weigh the ethane under its saturation pressure was made of stainless steel (Allegheny metal, composition: C less than 0.2%; Cr, 17–20%; Ni, 7–10%; Fe, 70–76%). The weight of the storage cylinder was 690 g. and its volume 360 cc.

Measurements.—Both energy and temperature measurements were made with a White double potentiometer, *A*, Fig. *2*. The electrical connections are shown in Fig. *2*, and were essentially the same as those used by Gibson and Giauque? B indicates the resistance thermometer and C the heater of the calorimeter. **A** constant thermometer current was obtained by discharging six lead storage cells, N, continuously through a 50,000-ohm resistance, J, in series with the thermometer. The potential drop across the 100-ohm standard resistance, H, gives the value of the thermometer current, amounting to about 0.00024 ampere. The e.m.f. of the thermometer was measured directly across its terminals. In order to obtain the heat input, the potential drops across F and O were read; the former gave the current directly while the latter was a known fraction of the total drop. The parallel lead correction and also the correction for heat generated in the lead wires between the calorimeter and copper cylinder were made; the latter was in most cases negligible. Energy was

obtained from a set of lead storage batteries, M. The rheostat, L, was used to stabilize the heating current; the ammeter, K, gave its approximate value. E was a mercury master switch, D a mercury reversing switch for thermocouples, and Q and P the two independent circuits of the White double potentiometer. An attempt was made to heat the copper cylinder simultaneously with the calorimeter, but for the runs with the copper calorimeter, this had to be abandoned, since a decided temperature lag was noticed in the cover of the copper cylinder. For the runs with the steel calorimeter an extra heating element was wound around the cover, and the two thermocouples, one near the bottom of the cylinder, and the other at the bottom of the cover, registered a simultaneous rise. Since the rates of heating of the calorimeter and cylinder were not always identical, the heat leak correction for the steel calorimeter was made graphically by plotting the temperatures of the copper block and the outside of the steel calorimeter against time and obtaining the area between the two curves by means of a planimeter; from the area and the rates of heating before and after each run, the heat leak was calculated.

An additional correction discussed by Giauque and Wiebe[11] was not necessary in case of the steel calorimeter, since the temperature difference between calorimeter and copper cylinder remained very nearly the same at all times and a check made by means of the thermocouple inside the well showed no discrepancies in the two temperature rises. The check runs at lower temperatures made with the steel calorimeter did not indicate any discrepancies with respect to the runs made with the copper calorimeter, beyond the experimental error.

For the lowest temperatures liquid nitrogen boiling under reduced pressure was used; otherwise liquid nitrogen, air, oxygen or ethyl bromide cooled by means of liquid nitrogen served as the bath liquid in the Dewar.

The average run lasted ten minutes.

All standard resistances, the standard cell of the potentiometers and the stop-watch were checked by the U. S. Bureau of Standards before and after the measurements.

The stop-watch showed a discrepancy of less than 0.02% for a ten-minute interval between the two calibrations, and we place our accuracy of time measurement at 0.05%. For the heat capacity measurements on the empty calorimeter, hydrogen was introduced in order to speed up the attainment of equilibrium; a small correction was applied to take into account the heat capacity of this gas.

Each batch was weighed when put in and when taken out of the calorimeter. The discrepancy between the two weighings was less than 0.005%.

Temperature Scale.—The thermocouples used were calibrated at approximately ten-degree intervals against platinum resistance thermom-

---

eter No. 2[12] of the laboratory. The calibration was made in a cryostat described by Walters and Loomis.[13] In their work the boiling point of liquid oxygen was assumed to be −183.00°, while according to the recent international agreement[14] the boiling point has been fixed at −182.97'. We have applied the necessary correction to the melting-point temperature only, since in specific heat determinations we are concerned with temperature differences primarily. The absolute temperature is probably correct to 0.07' except below −185°, where it may or may not be better than 0.10°. The ice point of the resistance thermometer was found to check the original value within the accuracy of the instrument. The copper resistance thermometers were calibrated in place by means of the thermocouples attached to the calorimeter. The calibration was checked repeatedly.

Heat Capacity Data

The results are given in Table I and Fig. 3. The data of Eucken and Hauck lie on a straight line and, therefore, approach our data at low and high

temperatures. It will be seen from Table II and Fig. **3** that the discrepancies between the values reported by Eucken and Hauck[6] and the values presented here are outside any experimental inaccuracy or impurity. As a matter of fact, it is not thought that their ethane was of higher purity than ours if we take into account the purity of some of the other substances they used and the difficulty of purification. The points in our favor are improved calorimetric design and from 20 to **30** times larger amounts. Since other measurements have been made with the same apparatus and values of other observers have been checked, it is believed that the measurements pre-

sented here are the more reliable. The accuracy is estimated to be 0.5% for the liquid below the boiling point and 1% at higher temperatures. The few measurements of solid ethane are probably not more accurate than to within 1 to 2%.

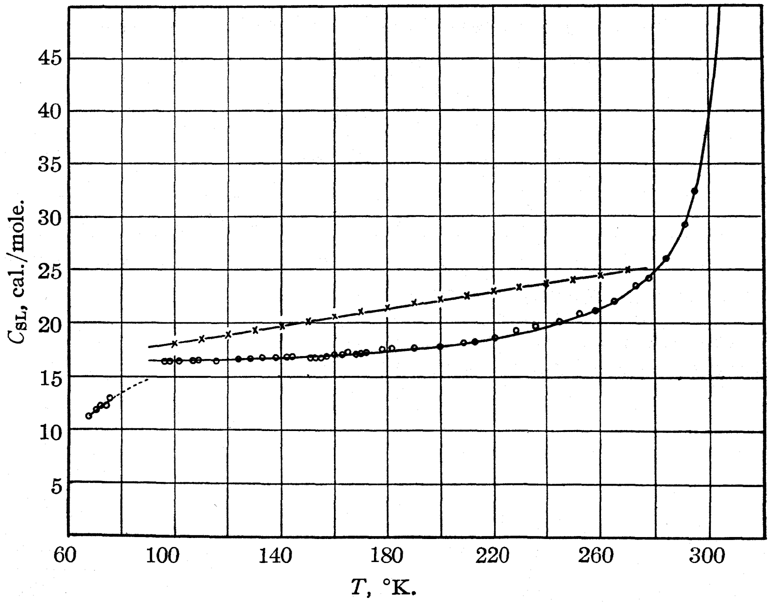

Fig. 3.—Heat capacity in calories per mole of saturated liquid ethane.

The method outlined by Osborne and Van Dusen[15] was used to calculate the heat capacity of the saturated liquid. The heats of vaporization

---

[15] N. S. Osborne and M. S. Van Dusen, Sci. Papers, Bureau of Standards, No. **313** **(1917).**

were taken from Porter[6] and from Dana and co-workers.[16] The liquid and vapor densities have been measured by Porter,[5] Kuenen[17] and Maass and McIntosh[18] and Maass and Wright.[19]

The critical data have been summarized by Pickering,[20] who selected the following values for ethane: T_c, 305.2°K.; P_c, 48.8 atm.; d_c, 0.21 g./cc. The following data are given as a typical example for the calculation of the heat capacity.

Sample Calculation.—Potentiometer reading across F, Fig. 2, is 0.0265856 volt.

$$I_{\text{av.}} = \frac{0.0807261 + 0.0807088}{2} = 0.0807175 \text{ amp.}$$

Time, 601.8 sec.

Energy added to calorimeter plus that lost in parallel resistance and lead wires

$$\frac{10014}{10} \times 0.0265856 \times 0.0807175 \times 601.8 \times 0.23895 = 309.017 \text{ cal.}$$

Energy lost in parallel resistance

$$\frac{10014}{10^2} \times (0.0265856)^2 \times 601.8 \times 0.23895 = 10.178 \text{ cal.}$$

Lead wire correction, 0.084 cal.

Energy supplied to calorimeter = 309.017 − 10.178 − 0.084 = 298.755 cal.

Initial resistance 225.9667 ohms. Final resistance 230.4005 ohms

Rate of warming in ohms per minute

Before starting run	0.00103
After close of run when equilibrium was attained	0.00127
Equilibrium period, 10 minutes	

Resistance interval correction calculated graphically from initial and final rates, initial and final temperature differences between calorimeter and surroundings, and special rate determinations

Correction for period during the run, ohms	0.0193
Correction for equilibrium period, ohms	0.0127
	0.0320
Initial temperature, °C.	−30.551
Final temperature, °C.	−26.602
Uncorrected temperature rise, °C.	3.949
Temperature interval correction	−.028
Corrected temperature rise	3.921

[a] Extrapolated values.

Since C_{SL} was measured, C_{SV} was calculated from the Clausius relation

$$C_{SV} - C_{SL} = \frac{dL}{dT} - \frac{L}{T}$$

where L is the heat of vaporization. In order to calculate the temperature coefficient of the heat of vaporization, the following equation was found satisfactory

$$L = 483.2\,(T_c - T)^{1/2} - 16.45\,(T_c - T)$$

The entropy and heat content of the saturated liquid and vapor are given in Tables III and IV and Figs. 4 and 5. The normal boiling point of ethane, 184.47°K., was taken as zero for both the entropy and heat content. The heat content is defined by the equation

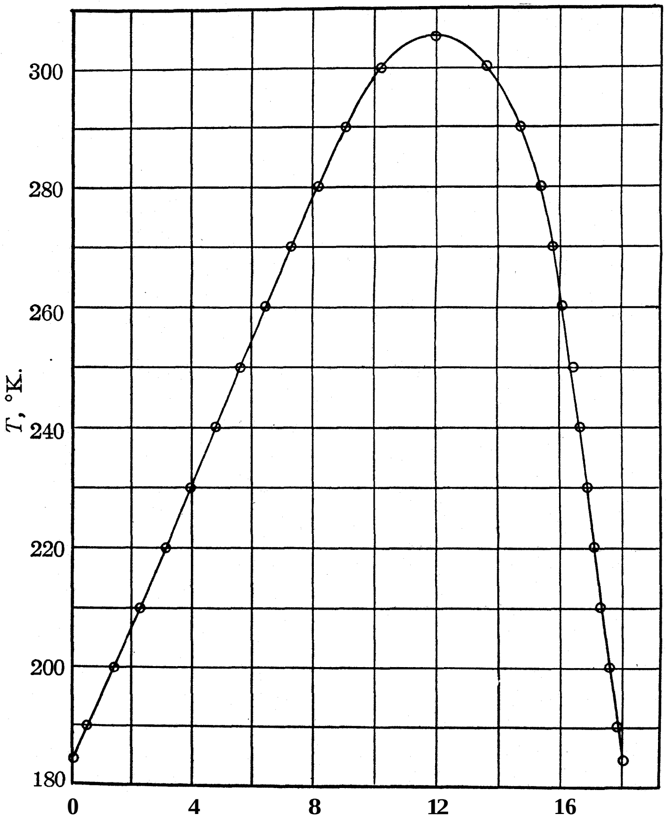

Fig. 4.—Temperature-entropy diagram for ethane.

$$H = E + pv$$

where E is the internal energy of the system.

As will be seen in the Table, C_{SV} is negative. A general rule for ascertaining whether a substance has positive or negative values of C_{SV} cannot be given, but approximate calculations by van der Waals[21] show that in the case of mono-, di- and triatomic substances a positive value of C_{SV} is entirely excluded, while substances with more than three atoms may have positive values over part of the range before and after which they are negative. Ether is an example showing positive values for the heat capacity of the saturated vapor.

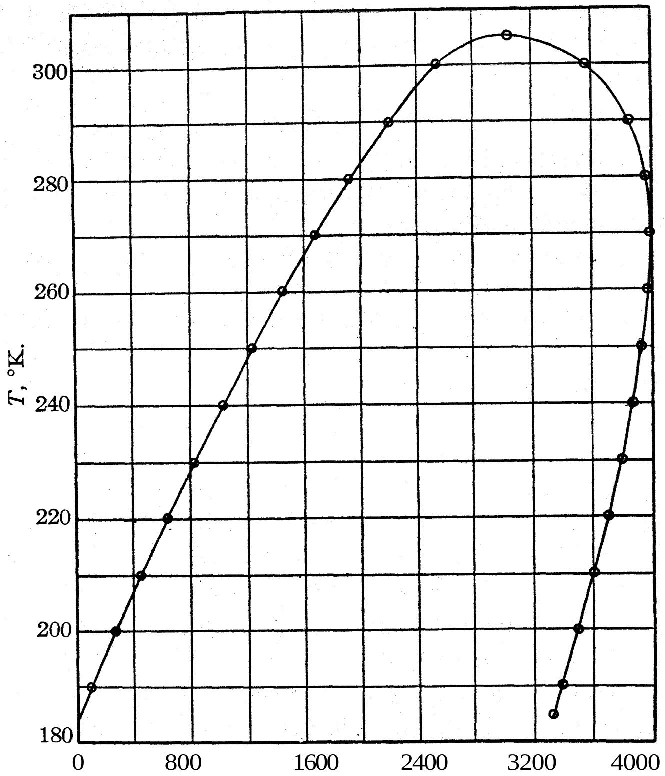

Fig. 5.—Mollier diagram for ethane.

Heat of Fusion and Melting Point.—The amount of heat consumed in premelting below the initial temperature of the run was determined graphically in each case and added as a correction to the heat of fusion. Table V gives the results of six determinations.

---

[21] Van der Waals-Kohnstamm, "Lehrbuch der Thermodynamik," Vol. I, p. 70.

The average value of the heat of fusion is 667.5 ± 3 cal. per mole of ethane. The melting point was found to be −183.65 ± 0.10°C. Ladenburg and Krügel[22] give −172.1° and Lebeau[23] remarks that ethane is still liquid at −195°.

We wish to express appreciation to Dr. C. W. Kanolt, formerly in charge of the Cryogenic Laboratory, Bureau of Mines, for the interest he has shown in our work, and to thank Messrs. Rowe and Schmidt of the instrument shop of the Pittsburgh Station for their excellent construction of the apparatus used in this study.

Summary

One low-pressure and one high-pressure calorimeter for determinations of heat capacities of liquids below room temperatures under their saturation pressure have been described.

Measurements of the heat capacity of saturated liquid ethane and the heat of fusion are presented.

Calculations of the entropy and heat content of the saturated liquid and vapor have been made.

THE HEAT CAPACITY OF SATURATED LIQUID NITROGEN AND METHANE FROM THE BOILING POINT TO THE CRITICAL TEMPERATURE[1]

BY R. WIEBE[2] AND M. J. BREVOORT[3]

RECEIVED OCTOBER 14, 1929 PUBLISHED FEBRUARY 6, 1930

Three papers have recently been published on the thermodynamic properties of nitrogen.[4,5,6] Since large discrepancies exist between the results of the different workers, it was thought desirable to obtain accurate experimental values in order to decide the question.

Keesom and Houthoff[5] have recently prepared temperature–entropy and Mollier charts of methane utilizing the results of Keyes, Smith and

Joubert.[7] Their work involves several uncertainties due to lack of data, and confirmation was needed.

No heat capacity measurements of saturated liquid nitrogen or methane above 1 atmosphere were in existence, but several observers[8] have made determinations up to the boiling point. Their data have been incorporated for comparison.

Nitrogen and methane are two of the main constituents of helium-bearing natural gas, and it is of importance to know accurately their thermal behavior.

Preparation.—The purest commercial nitrogen available was used as crude material. The gas was passed successively through tightly packed copper leaf heated to about 350°, fused potassium hydroxide and phosphorus pentoxide. The liquefied gas was fractionated several times, the first and last portions being rejected each time.

Two different batches of methane were prepared. The Grignard method was used for the first. Dry methyl iodide in small quantities was added to fresh turnings from an ingot of magnesium in an excess of dry ether. The heat of reaction caused the ether to boil, and the vapors were condensed by means of a water-cooled reflux condenser placed vertically above the flask. A calcium chloride tube at the top of the condenser prevented the entrance of moisture. Water was then added to decompose the Grignard reagent, and the methane given off was passed successively through a condensation bulb to eliminate the ether, fuming sulfuric acid, concentrated sulfuric acid, 30% sodium hydroxide solution, potassium hydroxide sticks and phosphorus pentoxide. The liquefied gas was then ,fractionated several times, the first and last portions being rejected each time, The second batch was prepared by the method outlined by Gladstone and Tribe? who prepared methane by the action of a copper–zinc couple on methyl iodide. The gas was purified in the same way as in the Grignard method. The melting point was determined to be **–182.9** ± 0.1°; a slight variation indicated some impurity. The value given in "International Critical Tables" is –184°.

Measurements.—The apparatus used has been described in detail in a previous paper.[10] The measurements were made in the steel calorimeter exclusively. The method outlined by Osborne and Van Dusen[11] was used

[8] Klaus Clusius, Z. *physik Chem.*, **3B, 41 (1929).** In this article Clusius criticizes the temperature scale used by W. F. Giauque and R. Wiebe in their work on the heat capacity of hydrogen chloride [THIS JOURNAL, 50, **109** (1928)]. The authors of the latter article wish to call attention again to the passage on page **111:** "However, since the results deviate in only one direction, it is improbable that the difficulty can be due primarily to inaccurate temperature scale. Even an approximate knowledge of the extremes of the temperature range investigated would mean that if some results were too high, others would necessarily be made too low." In other words, if the extremes of the temperature range are known accurately and the size of the "degrees" is incorrect, it follows that some "degrees" must be too small and some too large and, therefore, some measurements too low and some too high.

in making the necessary corrections in order to obtain the heat capacity of the saturated liquid. The gases were weighed in a steel cylinder at about 60 atmospheres' pressure. The average error is estimated to be about 1%; a few points are off slightly more, but all the rest fall well within this limit when a smooth curve is drawn through the results. The probable distribution of the percentage error is as follows

Weighing	0.1	Heat leak correction	0.1
Time measurement	0.1	Vapor space correction	0.1
Temperature interval	0.5	Heat cap. of empty calorimeter	0.1

The thermocouples were calibrated against the platinum resistance thermometer No. 2.[12]

Heat Capacity Data.—The following definitions are used in this article, subscripts L and V referring to the liquid and vapor state, respectively. C_S = heat capacity of the saturated state per mole; H = heat content per mole; S = entropy per mole and L = heat of vaporization per mole. Thermodynamics gives the following relations between these quantities

$$C_S = C_P - T\left(\frac{\partial v}{\partial T}\right)_P \frac{dP}{dT_{sat.}} = C_P - \left(\frac{\partial v}{\partial T}\right)_P \frac{L}{\Delta v}$$

$$H = E + pv \qquad S_L = \int \frac{C_{SL}}{T}\,dT \qquad S_V = S_L + L/T$$

The results are shown in Table I and II and are plotted in Figs. 1 and 2.

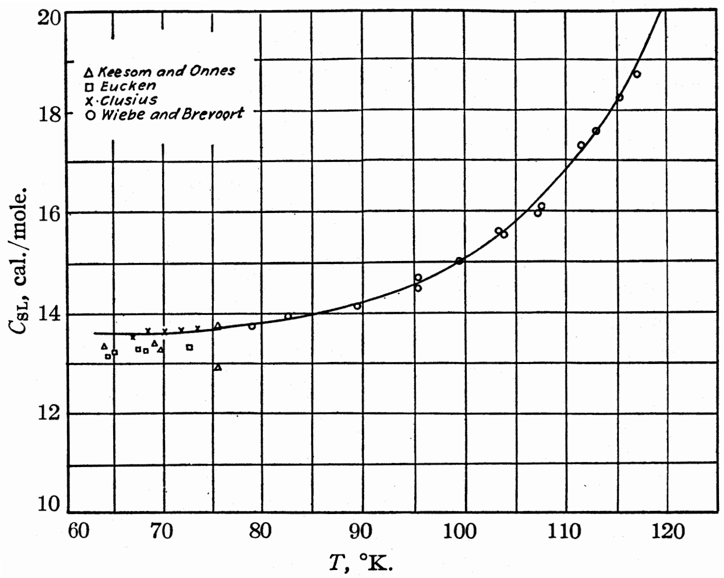

Fig. 1.—Heat capacity of saturated liquid nitrogen.

The measurements of previous investigators[8] have been included. Our extrapolated curve for nitrogen passes well through the values of Clusius and one point of Keesom and Onnes. The other points of the latter and

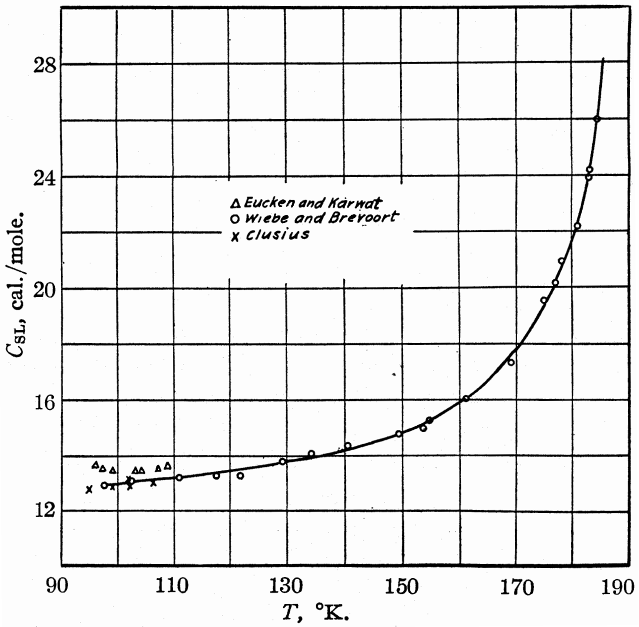

Fig. 2.—Heat capacity of saturated methane.

of Eucken are slightly lower. In case of methane, we also check the results of Clusius, while the determinations of Eucken and Karwat are too high.

Heat Content and Entropy.—Tables III and IV show the calculations made from the experimental data of the authors.

^{a} Extrapolated values.

The heats of vaporization for nitrogen were taken from a smooth curve drawn through the values given by Burnett[13] and Keesom and Houthoff.[14] Near the boiling point we inclined toward the values of the former, since the heat of vaporization at the boiling point has been determined experimentally,[15] while at higher temperatures the values of Keesom and Houthoff appeared to us more reasonable with regard to entropy and heat content especially at 125°K.

The densitites of the co-existing phases for nitrogen have been determined by Mathias, Kammerlingh Onnes and Crommelin.[16] The heats of vaporization and densities of the co-existing phases for methane were taken from the work of Keyes, Smith and Joubert.[7] Pickering[17] has summarized the critical constants of various gases obtained by different observers and selected the following values for nitrogen and methane.

	Nitrogen	Methane
T_c, °K.	126.0	190.6

obtained by Millar and Sullivan,[6] Burnett,[13] Keesom arid Houthoff[4] and the authors for nitrogen.

Burnett had obtained his values frotn two empirical equations expressing the heat content along the 50% quality line

$$H_{50} = 1090 - 1.5486\,(T_c - T)^{1.375}$$

and the heat of vaporization

$$L = H_V - H_L = 331\,(T_c - T)^{0.375} - 0.404\,(T_c - T)^{1.375}$$

The former was arrived at by adjusting values derived from Keyes' equation of state in the neighborhood of the critical point to conform to the known behavior of other gases and thus obtaining values for the change in heat content between different P–T points in the superheat field and the

120	6.727	5.18	11.91
125	8.28	2.06	10.34
126	9.32	0.00	9.32

corresponding points on the saturation curve. By combining the two equations of Burnett, we obtain

$$H_V = [1090 - 1.5486\,(T_c - T)^{1.375}] + [165.5\,(T_c - T)^{.375} - 0.202\,(T_c - T)^{1.375}]$$
$$H_L = [1090 - 1.5486\,(T_c - T)^{1.375}] - [165.5\,(T_c - T)^{.375} - 0.202\,(T_c - T)^{1.375}]$$

Burnett chose 70°K. as his reference zero, and we subtracted $H_L\,77.4 - H_L\,70$ from his values. We have given two values for the heat content at the critical point; one was obtained by completing the dome plotted from the H_L and the H_V values against temperature, while the other and probably more correct value was found by extrapolating the heat content of the 50% quality line.

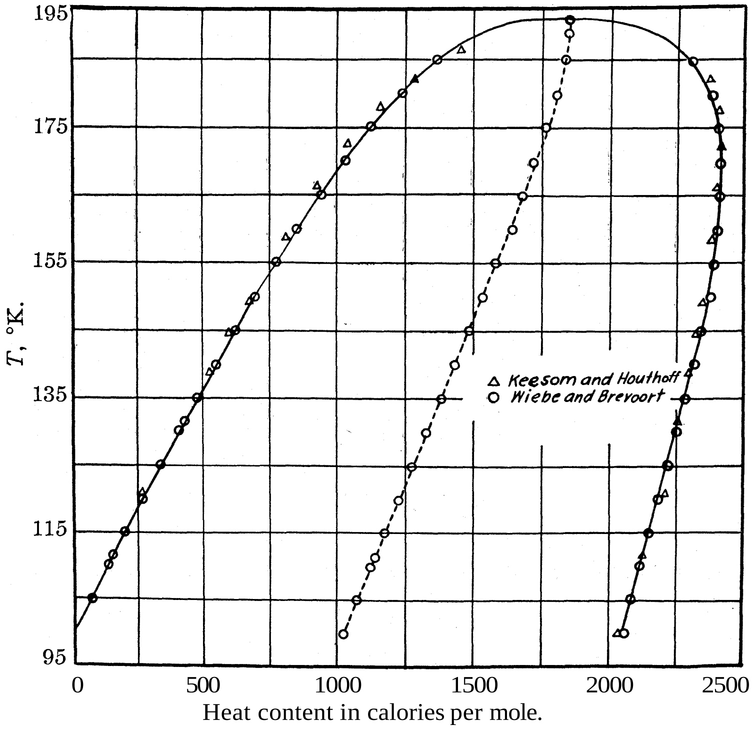

Fig. 4.—Mollier diagram for methane.

Figure 4 shows a comparison between the heat content values of Keesom and Houthoff and those calculated from our experimental data. The agreement is good except in the neighborhood of the critical point, where their values deviate slightly.

Tables VI and VII give the entropy values calculated from our experimental values and Table VIII and Fig. 5 give a comparison between the values of Millar and Sullivan, Keesom and Houthoff, Rodebush, Andrews and Taylor and the authors for nitrogen.

Entropies of the vapor by Rodebush, Andrews and Taylor were calculated by adding our entropies of vaporization to their liquid entropies taken from a smooth curve through their data.

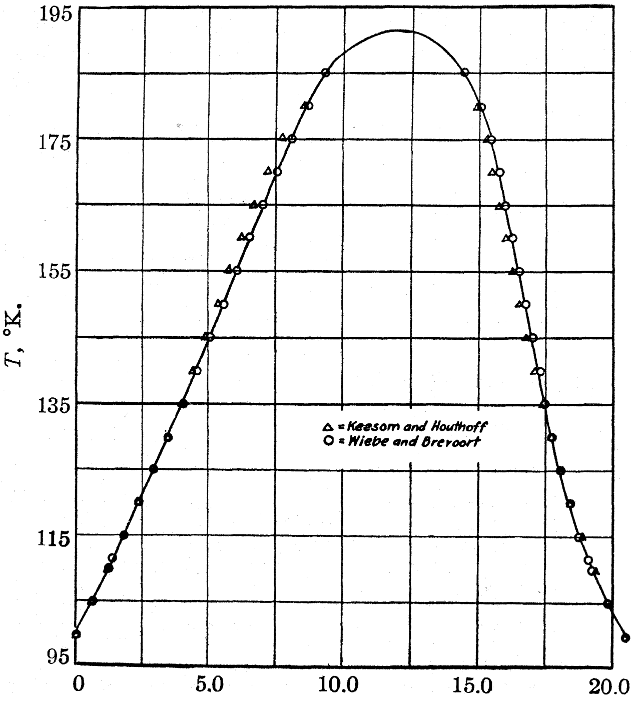

Fig. 6.—Temperature–entropy diagram for methane.

The results of Rodebush, Andrews and Taylor seem to indicate that their vapor was contaminated with liquid spray, which made their percentages too high. A more efficient baffle system would probably reduce or even eliminate the danger of contamination.[18] The entropy values of Keesom and Houthoff and the authors are shown in Fig. 6.

The authors wish to express their appreciation to Mr. G. St. J. Perrott, Superintendent of the Pittsburgh Experiment Station, U. S. Bureau of Mines, and to Dr. David F. Smith of the physical chemistry section for permitting the work of this investigation to be carried out at the Pittsburgh Station.

Summary

The specific heats of saturated liquid nitrogen and methane from the boiling point to the critical temperature have been measured.

The entropy and heat content of the saturated state have been calculated.

THE COMPOSITION OF CONSTANT BOILING HYDROCHLORIC ACID AT PRESSURES OF 50 TO 1220 MILLIMETERS[1]

BY WALTER D. BONNER AND ALBERT C. TITUS

RECEIVED OCTOBER 15, 1929 PUBLISHED FEBRUARY 6, 1930

Since Hulett and Bonner[2] published their paper on the preparation of standard hydrochloric acid solutions from constant boiling hydrochloric acid, their acidimetric standard has been checked by others, and its use has become fairly common.[3]

However, the only precise determinations of the compositions of these acids so far published are those made near sea level, and those made at the rather low barometric pressures near 640 mm.[4] The experiments of Roscoe and Dittmar, published 70 years ago,[5] remain the only work covering a considerable range of pressures. We have, therefore, determined the compositions and densities of various hydrochloric acids of constant boiling point between the pressures of 50 and 1220 mm. The procedure used was much that of Foulk and Hollingsworth[4] except that the pressure control apparatus was filled with mercury rather than with water. The compositions were determined gravimetrically, by means of silver chloride. The silver nitrate used was very carefully purified. The

[18] This was suggested to the authors by Mr. E. S. Burnett.

acid sample for each analysis was weighed, the samples being such that the weight of silver chloride was always about 2 g. The total volume of mother liquor and washings was always less than 1 liter, under which condition the correction to be made for dissolved silver chloride is negligible.[6] All weighings are reduced to vacuum and the weights used were carefully calibrated. The compositions given are each the mean of at least three concordant analyses, and the maximum deviation from the mean is never greater than 0.05%. They agree remarkably well with those given by Foulk and Kollingsworth[4] for 760-mm. pressure, and with those previously presented from this Laboratory for 640 mm.[4]

Densities were determined at 25 ± 0.02°, by means of an Ostwald–Sprengel type of pyknometer. The densities given are the means of never fewer than three independent experiments, and are precise to 0.01%. There is, however, a discrepancy of 0.1% between the density given here for the 640 mm. acid, and that given in the paper already referred to, for the same acid. We are unable to assign a cause for this, but we are convinced that the error lies in the previous data. Our density for the 760 mm. acid agrees within less than 1 part in 5000 with that given by Hulett and Bonner for the same acid. The barometer used was carefully compared with the U. S. Weather Bureau instrument in Salt Lake City. All necessary corrections have been applied, both to the barometer and to the pressure control apparatus. Pressures were maintained constant to within 1 mm. The following table gives the data assembled.

TABLE I

DENSITIES AND COMPOSITIONS

Pressure, mm.	Density	HCl, %	Pressure, mm.	Density	HCl, %
50	1.1118	23.42'	600	1.0980	20.638[b]
150	1.1073	22.520[b]	640	1.0973	20.507
250	1.1042	21.883	700	1.0966	20.360[b]
350	1.1019	21.437	760	1.0959	20.222[b]
400	1.1010	21.235[b]	800	1.0955	20.155
450	1.1002	21.075[b]	1000	1.0933	19.734
500	1.0993	20.916	1220	1.0915	19.358
540	1.0987	20.777"			

[a] Result of a single analysis. [b] Interpolated.

When the percentage of hydrochloric acid in these acids is plotted as abscissas, using the corresponding densities as ordinates, the resulting graph is a straight line whose equation is

$$x = \frac{Y - 0.9966}{0.004912}$$

This equation is precise to about 0.05% within the range of ordinary barometric pressures. It is thus possible to prepare a sample of constant boiling hydrochloric acid at any convenient atmospheric pressure, deter-

---

[6] See Richards and Wells, THIS JOURNAL, 27, 486 (1905).

mine its density at 25°, and at once compute its hydrochloric acid content with a precision sufficient for any ordinary volumetric work. Any reference to the pressure of the distillation is thus avoided, it being only necessary to see that the barometric pressure is not changing rapidly during the preparation of the constant boiling acid.

Foulk and Hollingsworth, in the work already cited, found that the composition of the constant boiling acid was influenced markedly bv the rate of the distillation. We have been unable to corroborate this. We have made, at various pressures, series of distillations in which the rate was varied from 1.7 cc. to 4.9 cc. per minute. These distillates were compared by determining the densities, and in no case did we find *a* difference in density as great as 1 part in 10,000. For example, in a set of ten such distillates, the mean density was 1.09709, with an average deviation of 0.00004 and a maximum deviation of 0.00009. We would conclude that the rate of distillation has a negligible effect on the composition. However, for the sake of convenience, we carried out all of our distillations at the uniform rate of 4.5 cc. per minute.

Résumé

We have determined the composition and density of constant boiling hydrochloric acid between pressures of 50 and 1220 mm.

We have given an equation by the aid of which the composition of any constant boiling hydrochloric acid may be computed from its density, at 25". The use of this acid as a primary standard in acidimetry is thus simplified.

SALT LAKE CITY, UTAH

NOTES

An Inorganic Stopcock Lubricant.—Up to the present time there has been no inorganic material discovered which compares favorably in all respects with stopcock grease, although there are many types of research in which such a material would be extremely valuable. The two main makeshift substitutes which have been used are moist phosphorus pentoxide and moist metaphosphoric acid, both of which leave much to be desired as lubricants for high vacuum work. The former tends to leak and to "freeze," while the latter "freezes" unless the stopcocks are turned very frequently.

During attempts to develop a more satisfactory lubricant for use in work at present in progress, the writer discovered that a thick, sirupy liquid with practically no tendency to crystallize on standing could be obtained by preparing a solution of the three phosphoric acids in one another. This mixture may be prepared with almost any desired viscosity by simply varying the proportions of the components. Due to the hygroscopic nature of the material, it must, of course, be protected from moisture but this can easily be done by using mercury seal stopcocks. Absorption of water causes crystallization to take place, with a simultaneous thinning of the remaining liquid phase.

It must be admitted that this mixture is not as satisfactory a lubricant as grease, and stopcocks on standing under vacuum tend to "freeze" to a certain extent. However, they can be loosened very readily by warming gently with a flame. This latter operation should be performed, if possible, when the system is not evacuated but can be performed under vacuum, if necessary. In the latter case the tendency to "freeze" is increased but in the former it is not.

Due to this slight tendency to "freeze" the stopcocks, it is advisable to re-grind the latter with fine emery powder before using with the phosphoric acid lubricant. If one takes the additional precaution of finishing with rouge, "freezing" will be reduced to a minimum.

For high vacuum work the following directions will yield a mixture that has been found by the writer to be very satiefactory. On heating the mixture of ortho- and metaphosphoric acids above the decomposition point of the former, there will also be formed some pyro acid. This increases the complexity of the mixture and probably hinders crystallization.

Directions.—Add 18 g. of metaphosphoric acid to 35 g. of 85% orthophosphoric acid, containing a drop or two of concentrated nitric acid, to destroy reducing substances. Heat to 300° in a platinum crucible, over a period of fifteen minutes, then hold at 300° for. fifteen minutes. Cool to about 100° and transfer equal portions to three or four small bottles equipped with rubber stoppers. (Division into three or four portions is recommended because the lubricant is usually spoiled by the admission of moist air into the bottle before it is nearly all used.)

A New Regulator Allowing Rapid Changes in the Temperature Setting **of** the Thermostat.—In the course of an investigation involving the use of a thermostat at widely different temperatures, the author has designed a vapor-pressure regulator that made possible rapid changes from one temperature setting to another. Although many forms of vapor-pressure regulators have been used before, it is believed that certain new features in the construction and operation of the device justify a detailed description of it.

The filling of the apparatus is carried out by a suitable application of vacuum and tilting. When ready for operation, it has both ends sealed. The bulb (Fig. 1) contains a vapor phase devoid of air, a suitable liquid and a layer of mercury. The space in the inclined tube above the mercury is evacuated. The whole rests on an iron bar (not shown in the figure) bent to fit the tube and capable of rotation around an axis at O.

As the thermostat is heated, the mercury level in the tube rises. When the desired temperature is reached, the upper wire from the relay is attached to the nearest electrode (tungsten wire sealed into the pyrex glass), and the apparatus is tilted to just make or break contact. After this the regulator will work for weeks without requiring any attention.

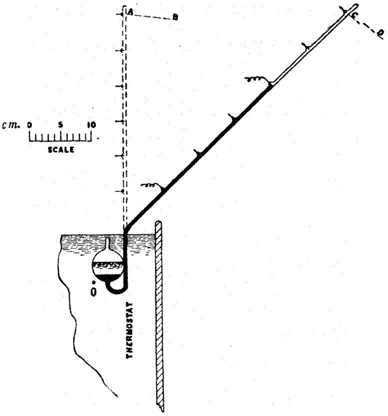

Fig. 1.

Using aniline as the source of vapor pressure, the author was able to obtain any temperature within the range 110 to 160" by using the proper electrode. The temperature was kept constant to within 0.1".

It will be noticed that the tube is bent through an angle of about 45°. With the apparatus fixed, to every electrode there corresponds a certain temperature. Intermediate values are obtained by tilting, at which time all points move along inclined arcs CO. Were the tube made vertical, the points of contact would move along nearly horizontal arcs AB, necessitating much larger angles of rotation for the same temperature shift. Incidentally, the sensitiveness of the regulator is increased by a factor of about 1.4.

The chief advantage of this apparatus lies in the ease with which the thermostat temperature setting can be changed. Furthermore, contact is made in a sealed tube, with no air present, thus eliminating any possibility of contamination.

A METHOD OF DETERMINING THE ARSENIC CONTENT OF ORGANIC ARSENICALS

BY F. E. CISLAK[1] AND CLIFF S. HAMILTON

RECEIVED MARCH 7, 1929 PUBLISHED FEBRUARY 6, 1930

Numerous methods have been proposed for the estimation of the arsenic content of organic compounds containing arsenic. Bunsen[2] estimated the arsenic content by difference; Dumas[3] determined the increase in weight of the combustion tube after the elementary analysis of the organic arsenical and ascribed this increase to the presence of arsenious oxide. In other procedures[4] the compound was oxidized by fusion and the arsenic weighed as magnesium pyroarsenate. Monthulé[5] destroyed the organic matter present by nitric acid. The work of F. A. Norton and A. E. Koch[6] gave rise to numerous volumetric methods. Among the most widely known of these methods may be mentioned those of Lehmann,[7] Ewins[8] and Robertson.[9]

In all the above volumetric methods a standard iodine solution is used as the titrating solution with starch as an indicator. Rather exacting conditions are required in order to get reliable and reproducible results by these methods.[10]

A means of determining arsenic in inorganic compounds by the potentiometric method has been proposed by Zintl and Wattenberg.[11] The authors adapted this method to the determination of the arsenic content of organic compounds. The method is described below.

Details of Method

A saturated calomel electrode was used as the cathode, and a piece of platinum

wire sealed into a T-tube served as the anode; these electrodes were connected directly to a Leeds and Northrup portable potentiometer. A slow stream of carbon dioxide was passed through the anode above (not into) the solution. A mechanical stirrer was provided. An approximately 0.05 *N* solution of potassium bromate was used as the titrating solution.

Procedure.—Between fifteen hundredths and two-tenths of a gram of the substance was weighed out and introduced into a Kjeldahl flask of 300-cc. capacity. Twenty grams of potassium sulfate, 0.2 to 0.3 g. of starch, and 20 cc. of concentrated sulfuric acid were then added to the sample in the flask and the mixture was warmed gently over a small flame for about thirty minutes; then the size of the flame was increased very slightly and the heating continued for another thirty minutes, when the flame was increased to a fairly good size and the digestion continued until the solution became clear and colorless.[12] The flask was removed as soon as the solution became colorless, allowed to cool to about 80° and diluted with approximately 70 cc. of distilled water. The solution was transferred quantitatively into a beaker of 600-cc. capacity and to this solution 30 cc. of concentrated sulfuric acid was added and sufficient water to make the total volume of the solution about 400 cc. The solution was then ready for titration.

The arm of the calomel half-cell was rinsed with distilled water and then about 10 cc. of the potassium chloride solution from the reservoir was run through the cell. The platinum wire was also rinsed with water. The two electrodes were then immersed in the solution which was to be titrated and connected to the potentiometer. A slow stream of carbon dioxide was turned on and the stirrer started.

The resistance of the potentiometer was adjusted so that there was no deflection of the galvanometer when this instrument was thrown into the circuit. The bromate solution was then added slowly from a buret. At this stage of the titration the solution was added at the rate of about 4 cc. per minute.[13] After the addition of each cubic centimeter of the standard solution the galvanometer was thrown into the circuit and the deflection of the galvanometer needle observed. The deflection, at this point, was so slight that by merely increasing the resistance a very small amount, corresponding to one to two hundredths of a volt, the null point was again reached. When the end-point was only about 2 cc. away,[14] the rate of addition was slowed down to such an extent that it was possible to observe the deflection of the galvanometer needle after the addition of each drop. When the end-pint was reached, one drop of the bromate solution caused a rather complete deflection of the galvanometer needle. This single drop threw the needle to one side so strongly that resistance

---

[12] The heating should not be prolonged after the solution has cleared as there is a tendency for the hot sulfuric acid, in the absence of any other reducing matter, to oxidize the trivalent arsenic.

[13] The addition of the bromate solution should not be too rapid as the reaction is not extremely fast in reaching equilibrium even in the presence of so high an acid concentration.

[14] In this method of determining the end-point of the reaction, there is no indication of an approach to it. Hence, in order not to go past the end-point, one must either add the reagent very slowly during the entire course of the titration or else have an idea as to the amount of reagent the given sample will require.

corresponding to at least 0.200–0.400 volt was **necessary** to balance the circuit.[15]

Experimental

A large number of organic arsenicals was analyzed by the method herein described; the results of a few of these analyses are given in Table I.

TABLE I

TESTS OF THE METHOD

Compound	Arsenic trioxide		Arsanilic acid		*n*-Butylarsonic acid		Diphenylamine-*o*-arsonic acid	
Sample, g.	0.1002	0.1013	0.2022	0.2009	0.1986	0.1987	0.2095	0.2199
As found, %	75.76	75.78	34.59	34.58	41.26	41.24	25.62	25.54
As calcd., %	75.75	75.75	34.56	34.56	41.21	41.21	25.57	25.57
Deviation, %	+0.01	+0.03	t0.03	+0.02	+0.05	+0.03	+0.05	−0.03

Summary

The arsenic content of organic compounds can be determined readily and accurately by digesting the compound with hot sulfuric acid in the presence of potassium acid sulfate, diluting the solution thus obtained and titrating electrometrically with potassium bromate.

THE CATALYTIC "COUPLING" OF MANGANESE DIOXIDE WITH PHOSPHORIC OR SULFURIC ACID AS AN OXIDIZING AGENT. THE EFFECT OF ACIDITY ON THE OXIDATION OF BUTYRIC ACID WITH HYDROGEN PEROXIDE

BY EDGAR J. WITZEMANN

RECEIVED MAY 13, 1929 PUBLISHED FEBRUARY 6, 1930

The results given in this paper constitute a part of a study of the influence of a few chemical variables upon the oxidation of butyric acid.[1] This report concerns the influence of the amount and nature of the acids present on the oxidation of butyric acid by hydrogen peroxide.

The Influence of Phosphoric Acid.—Since previous work had brought out the catalytic properties of dialkali phosphate in the oxidation of butyric acid, attention was first given to phosphoric acid, in studying the effect of acidity upon this oxidation, especially in view of the fact that it is possible that the catalytic effects of dialkali phosphates may be due to the intermediate formation of a perphosphate.

[15] When this 0.200–0.400 volt increase in e.m.f. caused by a single drop of the bromate solution is compared to the increase of 0.01–0.03 volt caused by one cubic centimeter of the solution, it is obvious that the end-point is extremely easy to recognize.

[1] (a) Witzemann, *J. Biol. Chem.*, **35**, 83 (1918); 49,123 (1921); (b) THIS JOURNAL, 48,202,208,211 (1926); 49,987 (1927).

Experiments were, therefore, set up with free phosphoric acid: 100 cc. of solution contained 50 cc. of 3% hydrogen peroxide, 0.25 g. of butyric acid as the potassium salt and phosphoric acid as indicated below. These experiments were allowed to stand at room temperature for forty-two to forty-five hours before analysis for acetone. The methods of analysis used were those previously described.[2]

	1	2	3	4	5	6	7
H_3PO_4 (85%), g.	0.0	0.066	0.198	0.33	0.66	1.32	3.3
Molarity, M	....	0.0057	0.0171	0.0285	0.057	0.014	0.285
Acetone, g.	0.0011	0.0010	0.0022	0.0034	0.0020	0.0128	0.0588

Calculated acetone yield, 0.164.

In the above experiments, the results of which are typical, an increasing yield of acetone was associated with increasing acidity.

The use of manganese dioxide during distillation had been adopted as a routine procedure in oxidations with hydrogen peroxide in order to obtain distillates free from hydrogen peroxide. It had become customary to add about **3** to 4 g. of manganese dioxide for this purpose. Such high yields of acetone as those indicated in (6) and (7) were obtained when no more than this was used. Under these conditions the mixture in the distilling flask becomes gray in (6) and (7) before distillation is complete and the mixture foams freely throughout the distillation. If a large excess of manganese dioxide is added the mixture remains black, tends to bump during distillation and no more acetone is obtained than in (4) and (5).

Data Concerning the Phosphoric Acid–Manganese Dioxide Catalysis.—The facts that the manganese dioxide was reduced with the formation of manganese phosphate and that the addition of large excess of manganese dioxide led to a striking decrease in the yield of acetone, suggested that manganese dioxide is vitally concerned in this process. Special test experiments brought out the following facts. When phosphoric acid and manganese dioxide but no hydrogen peroxide were allowed to act upon potassium butyrate as usual, no acetone whatever was obtained. Although it is generally stated that dilute sulfuric acid does not liberate oxygen from manganese dioxide, a suitably arranged test experiment was made with this acid as well as with phosphoric acid. No oxygen was evolved in the course of a week. When phosphoric acid and hydrogen peroxide were used with potassium butyrate and the peroxide was decomposed by making the solution alkaline and adding precipitated calcium carbonate, very little acetone was obtained. Moreover, the hydrogen peroxide concentration remained unchanged in the experiments containing phosphoric acid, butyric acid and peroxide, for as long as three weeks, as was shown by permanganate titrations.

---

[2] Witzemann, *J. Biol. Chem.*, 49, 123 (1921).

These and other test experiments developed the fact that this catalysis is dependent upon the presence of two components and that both the hydrogen peroxide and the manganese dioxide are reduced when the best results are obtained.

The only well-known reaction in which an acid interacting with manganese dioxide causes the decomposition of hydrogen peroxide with the reduction of the manganese dioxide is the following

$$H_2SO_4 + MnO_2 + H_2O_2 \longrightarrow MnSO_4 + 2H_2O + O_2$$

Nothing could be found in the literature concerning oxidations brought about by this system.

Test experiments showed that sulfuric acid may be replaced with phosphoric acid. Small concentrations of phosphoric acid were used (comparable with those in Nos. 5, 6 and 7 above) with a considerable excess of manganese dioxide. It was noted that the presence of the phosphoric acid very materially retarded the time rate of oxygen evolution upon addition of manganese dioxide. The volume of oxygen evolved was measured in each case. The results showed that at the lower concentrations all of the phosphoric acid reacted apparently as follows

$$2H_3PO_4 + 3MnO_2 + 3H_2O_2 \longrightarrow Mn_3(PO_4)_2 + 6H_2O + 3O_2 \qquad (1)$$

The excess hydrogen peroxide not required for this reaction was decomposed thus

$$MnO_2 + 2H_2O_2 \longrightarrow MnO_2 + 2H_2O + O_2 \qquad (2)$$

In any case the observed volume of oxygen corresponded closely with the volume calculated on this assumption. With higher concentrations of phosphoric acid not all of the phosphoric acid entered reaction according to (1) and so the observed volume of oxygen was less than that calculated on this assumption. This suggests that at the lower concentrations all of the phosphoric acid enters into some complex relation with hydrogen peroxide before the reaction is over.

These experiments furnish a clew for the interpretation of the catalytic oxidations of butyric acid described below.

The Influence of Sulfuric and Boric Acids on Butyric Acid Oxidation.—Having learned that phosphoric acid interacts like sulfuric acid with manganese dioxide and hydrogen peroxide, it was of interest to learn how sulfuric acid influences the oxidation of butyric acid. Flasks containing 100 cc. of solution of which 50 cc. was 3% hydrogen peroxide and 0.25 g. butyric acid, containing also sulfuric acid as indicated below, were otherwise treated as in the phosphoric acid experiments and upon analysis the contents gave the results shown

Sulfuric acid, g.	0.28	0.56	1.12	2.80
Molarity of acid, M	0.03	0.06	0.11	0.28
Acetone yield, g.	0.0036	0.0053	0.0052	0.0053

Such negative results were obtained several times until suddenly data similar to those given below were obtained by changing the conditions slightly in some way.

An experiment like the last of this group was set up containing 500 cc. of 0.28 *M* sulfuric acid, 500 cc. of **3%** hydrogen peroxide, 2.50 g. of butyric acid in 50 cc. of water and 1.59 g. of potassium hydroxide in 50 cc. of water. After standing for forty-five hours the mixture was distilled in portions of 110 cc. with 50 cc. of distilled water using various catalysts for the decomposition of the peroxide.

(a) and (b) Added 3 to 4 g. of manganese dioxide (Baker's analyzed) and distilled slowly. Acetone found, 0.0514 g. (31.3% of the possible yield) and 0.0552 g., respectively.

(c) Repeated (a) with a much less dense form of manganese dioxide and found 0.0464 g of acetone.

(d) Repeated (a) with three times as much managnese dioxide. The evolution of oxygen was more rapid and only 0.0036 g. of acetone was found.

(e) Added a teasponful of unglazed porcelain chips and distilled as slowly as possible. Hydrogen peroxide was not present in the distillate and 0.0335 g. of acetone was found.

(f) Added a teaspoonful of 60-mesh quartz sand and distilled slowly as in (e). Acetone found, 0.0340 g.

These results show that the influence of sulfuric acid on this oxidation is at least roughly similar to that of phosphoric acid.

Boric Acid.—Boric acid was selected for some additional experiments because in some respects it is so different from either of the two acids previously used. The reaction mixture was made up as follows: 250 cc. of 0.28 M boric acid, 250 cc. of **3%** hydrogen peroxide, **1.25** g. of butyric acid in 25 cc. of water and 0.80 g. of potassium hydroxide in 25 cc. of water.

(a) After standing for two days at room temperature, 110 cc. of the above with 50 cc. of water was distilled slowly with about 2 g. of manganese dioxide. The manganese dioxide was not visibly changed and no peroxide distilled over. The acetone obtained was 0.0029 g. or 1.7% of the possible yield.

(b) The preceding distillation was repeated with 1 g. of manganese dioxide with slow heating in the beginning. The results were the same--0.0031 g. of acetone.

(c) When (a) was repeated using a teaspoonful of unglazed porcelain chips and no manganese dioxide, 0.0823 g. of acetone or a 50.2% yield was obtained. A repetition gave 0.01023 g. of acetone or a 62.3% yield.

The hydrogen peroxide content of the solution was practically unchanged after standing for a month in the laboratory.

It seemed that manganese dioxide must necessarily catalyze this oxidation as well as porcelain chips, but a good many trials failed to give the desired result.

The Fate of the Butyric Acid Used in These Oxidations.—The preceding data suggest that a considerable portion of the butyric acid is oxidized in these experiments. Some more definite data were desired.

The oxidation mixture with phosphoric acid was set up as follows:

250 cc. of 0.285 *M* phosphoric acid, 250 cc. of 3% hydrogen peroxide, 1.25 g. of butyric acid in 25 cc. of water and 0.8 g. of potassium hydroxide in 25 cc. of water. The hydrogen peroxide content of this solution was 1.36%, as determined by titration with potassium permanganate; after standing at room temperature for about three weeks it was unchanged.

Two hundred and twenty cc. of the mixture with 50 cc. of water and 3 to 4 g. of manganese dioxide were distilled slowly. The distillate was made up to 300 cc.; 125 cc. of this analyzed for acetone gave 0.147 g. of acetone for the entire distillate, a yield of 44.8%.

A portion of 110 cc. with 50 cc. of water and 2 g. of manganese dioxide was treated similarly. The distillate was made up to 225 cc. and fractionated in four 50-cc. portions, which neutralized 0.1 N alkali as follows: (1) 10 cc., (2) 6.4 cc., (3) 5.07 cc., (4) 3.13 cc., (residue) 1.87 cc., total 26.47 cc. This result indicated that considerable unchanged butyric acid was present.[3] These solutions were united, acidified with phosphoric acid and again distilled. The distillate was made up to 240 cc.; 120 cc. was then distilled off. This neutralized 16.53 cc. of 0.1 N alkali. The residue in the flask required 8.8 cc. of alkali.

In order to determine approximately how much butyric and acetic acid was present, it was desired to use the method of Wiegner and Magasanik[4] as applied by Virtanen.[5] In order to do this effectively the distillation constants for very dilute solutions of these acids were determined in our own apparatus. It was found that when 240 cc. of dilute acid (equivalent to 15 to 25 cc. of 0.1 N sodium hydroxide) was distilled, the first 120 cc. of distillate when acetic acid was used required 36.0% of the total alkali, while with butyric acid it required 71.6%. These figures are slightly lower than those given by Virtanen for the apparatus used by him.

Using the above data we have the following simultaneous equations

$$\begin{matrix} A + B = 25.33 \\ 0.360\,A + 0.716\,B = 16.53 \end{matrix} \quad \left\{ \begin{matrix} \text{A and B are the alkali equivalents of acetic} \\ \text{and butyric acids, respectively.} \end{matrix} \right.$$

Solving for A and B we obtain A = 4.49 cc., B = 20.84 cc.; *i. e.*, 74.4% of the butyric acid was recovered unchanged in this experiment.

Virtanen reports that this method serves also as a criterion of the purity of the substances used. In order to check the qualitative nature of the mixture being analyzed, a synthetic mixture of pure acetic and butyric acids was prepared in 240 cc. of water having the supposed composition of the unknown. The half distillate neutralized 16.80 cc. of 0.1 N alkali, while the residue required 8.85 cc. The total acidity, therefore, corresponded to 25.65 cc. of 0.1 N alkali. When these data were calculated

---

[3] Witzemann, THIS JOURNAL, 41, 1946 (1919).

[4] Magasanik, *Chem.-Ztg.*, 43, 656 (1919); *Analyst*, 45, 24 (1920); *C. A.* 14, 1947 (1920).

[5] Virtanen, *Soc. Scient. Fennicae, Comm. Phys. Math.*, 1, No. 36 (1923); see also THIS JOURNAL, 50, 3138 (1928).

by the above equations, the acetic acid found neutralized 4.38 cc. of 0.1 N alkali, while the butyric acid neutralized 21.27 cc. This corresponds very nearly to the amounts added and gives good agreement with the data for the unknown mixture.

A simultaneous determination of acetone and carbon dioxide was made using a method previously described;[2] 110 cc. of the original mixture with 50 cc. of water and 1 g. of manganese dioxide and a few porcelain chips were heated slowly in the apparatus: 0.0657 g. of acetone or 40.1% and 0.155 g. of carbon dioxide or 31.0% were obtained. One-fifth of the distillate diluted to 100 cc. was treated with silver oxide (from 5 g. of silver nitrate) and 4 cc. of concentrated ammonium hydroxide in a sealed magnesium citrate bottle in a warm water-bath for about four hours.[6] On filtering off the silver residues, acidifying with hydrochloric acid and distilling, 0.0456 g. or 27.8% of acetone was obtained. Quite *a* little silver chloride was precipitated, indicating that a corresponding amount of acid formation had occurred.

When the above and other results not given are summarized, a fairly good account can be rendered of the butyric acid used in spite of the general variations in the results of the oxidation. Forty per cent. or more of the butyric acid used was recovered unchanged; as much as 28% was oxidized to acetone and carbon dioxide; enough more carbon dioxide was formed to account completely for **23%** of the butyric acid; quite a little acetic acid was also found.

With Sulfuric Acid.—The oxidation mixture was set up as follows: 500 cc. of 0.28 M sulfuric acid, 500 cc. of hydrogen peroxide, 2.5 g. of butyric acid in 50 cc. of water and 1.59 g. of potassium hydroxide in 50 cc. of water. The peroxide titer remained unchanged three days later.

Aliquot portions of this solution were analyzed by the methods used above. On the basis of the butyric acid originally present, this solution yielded 0.139 to 0.20 g. of acetone, *i. e.*, a minimum of 42.1%. Fractionation and analysis of the volatile acids present showed that about 23.7% of the butyric acid was recovered unchanged, while the remainder of the volatile acid was apparently pure acetic acid, as shown by fractionation of controls having the same acid titer and presumably the same composition. In some analyses smaller amounts of volatile acids were obtained, but unchanged butyric acid was always present.

The acetone as determined in the crude distillate varied from **35** to 60%, but in the former case dropped to 23.8% after treatment with silver oxide and ammonia.

---

[6] Portions of a solution containing about 0.05 g. of pure acetone in 50 cc. were treated with silver oxide, etc., at the same time. These solutions showed 0.045 g. of acetone upon analysis, whereas the untreated solution gave 0.046 g. of acetone. This showed that acetone is not materially influenced by this treatment.

From 28.8 to 44.3% of the carbon in the butyric acid was converted into carbon dioxide, which was recovered as barium carbonate.

The results obtained with sulfuric acid correspond to those obtained with phosphoric acid, except that very small amounts of unchanged butyric acid are recovered. The transformation is much more profound in this case. More undetermined products are formed, and the results do not so adequately account for the butyric acid used as was the case with phosphoric acid.

Summary

The influence of the presence of considerable amounts of free acids (phosphoric, sulfuric and boric) upon the oxidation of butyric acid with hydrogen peroxide was studied. Under these conditions the concentration of hydrogen peroxide remains unchanged indefinitely and no oxidation occurs unless or until a suitable catalyst is added. The catalyst most frequently used was manganese dioxide. It is thought that the oxidation observed arose from the action of this compound upon the peroxide compound of the acid, although this point was not proved. Under these conditions the butyric acid present is often largely oxidized, with the formation of much acetone, carbon dioxide and acetic acid. The volatile acid products consisted of acetic acid and unchanged butyric acid.

No adequate interpretation of this unexpected catalytic system was developed.

This catalytic oxidation of butyric acid, unlike that brought about by ammonia and sodium phosphate, is a very rapid reaction.[1b,2]

THE ACTION OF BROMINE ON PHENOLPHTHALEIN. FURTHER EVIDENCE OF THE TAUTOMERIC CHARACTER OF PHENOLPHTHALEIN

BY ALLAN R. DAY

RECEIVED JUNE 28, 1929 PUBLISHED FEBRUARY 6, 1930

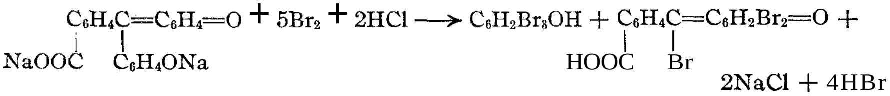
It was noted during the course of previous work[1] that the action of bromine (as generated by acidifying a bromate–bromide mixture) on phenolphthalein varied greatly with conditions. In the presence of a solvent such as chloroform tetrabromophenolphthalein was always formed. This, of course, is the usual and well-known reaction. The lack of color of this derivative indicates its lactoid structure. An attempt was made to make this bromination the basis of a quantitative determination but the results obtained varied from the theoretical by 1 to 2%.

---

[1] **Day** and Taggart, *Ind. Eng. Chem.*, **20**, **545** (1928).

When the phenolphthalein was dissolved in sodium hydroxide and the resulting solution acidified with hydrochloric acid, in the presence of an excess of bromate and bromide, a brownish-yellow precipitate was formed. It was found, by adding potassium iodide and titrating the liberated iodine with thiosulfate, that the formation of the brownish-yellow precipitate was accompanied by the loss of five molecules of bromine. The directive groups present in the original molecule seemed to eliminate the possibility that the fifth bromine molecule reacted by substitution. The brownish-yellow color of the precipitate indicated the possible presence of a quinoid structure. It was with the hope that a study of this reaction would furnish more evidence of the chromoisomerism of phenolphthalein that this investigation was undertaken.

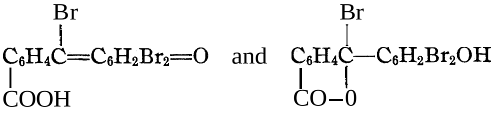
The brownish-yellow material on being carefully heated yielded a sublimate of long, colorless needles and finally a brownish residue remained from which no further sublimate could be obtained. The sublimate consisted entirely of tribromophenol. (Baeyer noted[2] that when dry phenolphthalein was rubbed together with an excess of bromine, tribromophenol was obtained as one of the products. Baeyer, however, did not investigate the reaction.) Further investigation showed that for every molecule of phenolphthalein brominated, one molecule of tribromophenol split off. On the basis of this evidence the following reaction was assumed to take place



$$\underset{\substack{|\\ NaOOC}}{C_6H_4}\underset{\substack{|\\ C_6H_4ONa}}{C}{=}C_6H_4{=}O + 5Br_2 + 2HCl \longrightarrow C_6H_2Br_3OH + \underset{\substack{|\\ HOOC}}{C_6H_4}\underset{\substack{|\\ Br}}{C}{=}C_6H_2Br_2{=}O + 2NaCl + 4HBr$$

Such a reaction is not an unusual one as many cases are known in which a substituent ortho or para to an OH group is readily replaced by bromine, for example, o- and *p*-hydroxybenzoic acids yield tribromophenol.

The quinoid compound, illustrated above, should be capable of existing in two forms



$$\underset{\substack{|\\ COOH}}{C_6H_4}\overset{\substack{Br\\ |}}{C}{=}C_6H_2Br_2{=}O \quad \text{and} \quad \underset{\substack{|\\ CO-}}{C_6H_4}\overset{\substack{Br\\ |}}{\underset{\substack{|\\ O}}{C}}{-}C_6H_2Br_2OH$$

Colored Colorless

This was found to be the case. After dissolving the colored form in alcohol, it was recovered, by very slow evaporation, only in the colorless or lactone form. The bromine content of both forms proved to be somewhat less than the theoretical, due to incomplete bromination. An attempt was made to overcome this difficulty by dissolving the yellow form in sodium hydroxide and acidifying the solution with hydrochloric acid in the presence of bromate and bromide. The precipitate obtained,

---

[2] Baeyer, *Ann.*, **202**, 78 (1880).

however, was not what was expected. It was reddish-brown in color and its bromine content had increased about 15%. It is hoped, in later work, to be able to prepare these compounds by different methods and conclusively prove the structure of the quinoid and lactone forms.

Tetrabromophenolphthalein when brominated under similar conditions yielded the same products. It is probable that tetrabromophenolphthalein is an intermediate product in the reaction under investigation.

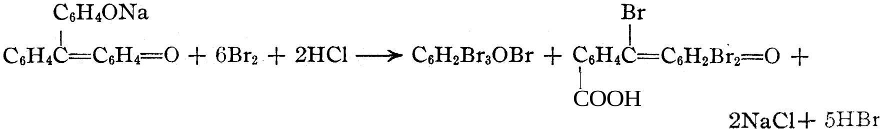
Experimental Part

Bromination of **Phenolphthalein.**—Five grams of phenolphthalein was dissolved in a little more than the calculated amount of 3 N sodium hydroxide. To this was added a solution containing 5 g. of potassium bromate and 18 g. of potassium bromide and the resulting solution was then diluted to one liter. The solution was then vigorously shaken or stirred and 15–20 cc. of 12 N hydrochloric acid slowly added. The precipitate at first was very voluminous but after shaking for ten to thirty minutes it settled very nicely and was easily filtered. The brownish-yellow precipitate was dried between filter paper. The precipitate on drying becomes coated with tiny colorless needles of tribromophenol and a small amount of bromine is given off, the latter probably being due to the decomposition of $C_6H_2Br_3OBr$ to $C_6H_2Br_3OH$.

Identification of Sublimate.—The sublimate was obtained, by carefully heating (50–75") the dried precipitate from above, in the form of long colorless needles. The sublimate melted at 92°. The bromine content determined by a sodium peroxide fusion method was 72.39%. These results check very well the melting point and bromine content of tribromophenol, 92° and 72.48%.

In two other cases the brownish-yellow precipitate, as first obtained, was suspended in water and treated with sulfur dioxide to reduce the $C_6H_2Br_3OBr$ to $C_6H_2Br_3OH$. The dried precipitate from this treatment was subjected to careful sublimation. The sublimate melted at 92° and the bromine content was 72.30%.

Determination of the Total Bromine Consumed in the Reaction.—Half a gram of phenolphthalein was dissolved in a slight excess (1–2 cc. in excess) of 3 N sodium hydroxide and the resulting solution diluted to 250 cc. A 25-cc. aliquot was pipetted into a 500-cc. iodine flask, followed by 25 cc. of 0.2 N bromine solution (75 g. of potassium bromide and 5.6 g. of potassium bromate per liter). Five cc. of 12 N hydrochloric acid was added and the flask stoppered at once. It was vigorously shaken and allowed to stand for one hour with occasional agitation. The flask was then cooled and 5 cc. of 40% potassium iodide solution introduced. After vigorous shaking the liberated iodine was titrated with 0.1 N thiosulfate solution. The results from a series of analyses, based on a bromine equivalent of $5Br_2$, varied from 98 to 99.5%. The essential equations for the reaction may be represented as follows



$$C_6H_4\overset{\displaystyle C_6H_4ONa}{\overset{|}{C}}{=}C_6H_4{=}O + 6Br_2 + 2HCl \longrightarrow C_6H_2Br_3OBr + \underset{\displaystyle COOH}{\underset{|}{C_6H_4}}\overset{\displaystyle Br}{\overset{|}{C}}{=}C_6H_2Br_2{=}O + 2NaCl + 5HBr$$

$$C_6H_2Br_3OBr + 2HI \longrightarrow C_6H_2Br_3OH + I_2 + HBr$$

Estimation of Tribromophenol Formed.—The tribromophenol was determined by weighing the sublimate obtained from the bromination of a known amount of phenolphthalein. The results in all cases indicated the formation of one molecule of tribromophenol for one molecule of phenolphthalein. It was found necessary to repeat the bromination in order to complete the reaction. For example, 1.1283 g. of phenolphthalein was brominated as usual. The precipitate was next suspended in water and treated with sulfur dioxide. The dried precipitate was then subjected to careful sublimation. When sublimation had ceased, the residue was again dissolved in sodium hydroxide and the bromination repeated. In this particular case three brominations followed by sublimation were necessary before no more sublimate was formed. The 1.1283 g. of phenolphthalein yielded 1.1629 g. of tribromophenol; theoretical, 1.1736 g.

Analysis of the Quinoid Form.—The brownish-yellow precipitate as first formed was dried, washed with ether and finally heated carefully until sublimation had completely stopped. The bromine content of the residue varied from 48 to 51.08%; theoretical, 51.80%. The low results were undoubtedly due to incomplete bromination. This was demonstrated in the previous paragraph. All attempts to rebrominate the product have failed, as some other reaction (perhaps further substitution or oxidation) resulted. The substance melted at 229–236° with decomposition. It dissolved in sodium hydroxide, forming a greenish-yellow solution which finally became yellow.

Analysis of the Colorless or Lactone Form.—The yellow form, purified as above, was shaken with a large volume of absolute alcohol. It dissolved very slowly, forming a yellow solution which quickly became colorless. When this solution was evaporated almost to dryness, a colorless apparently crystalline material was obtained. This material, after drying, melted at 270–273° with some decomposition. The bromine content checked very well with that of the yellow form. For example, the bromine content of one sample of the yellow was found to be 49.62%. A portion was then changed to the colorless form and the bromine content was now found to be 49.75%. The colorless form dissolved in sodium hydroxide to form a colorless solution. A slight violet color appeared at first but quickly disappeared. Whether this trace of color was due to the lactone form or to the presence of a trace of tetrabromophenolphthalein cannot be answered at present.

Discussion

Friedländer,[3] in 1893, assigned a quinone structure to phenolphthalein salts. About the same time Meyer and Spengler proved it to be a dibasic acid. The tautomeric character of phenolphthalein has been demonstrated since then by various workers, including Stieglitz,[4] Acree and Slagle,[5] Green and King,[6] Hantzsch and Meyer,[7] Meyer and Marx,[8] Orndorff, Gibbs and McNulty,[9] and Gibbs and Shapiro.[10] It was shown by some of these investigators that esters could be prepared from phenolphthalein. They showed that the labile quinoid modifications were yellow or orange, but rearranged in the process of crystallization to give the colorless, stable lactoid form.

According to the views expressed by these papers, the appearance of color during the process of salt formation, with phenolphthalein, would indicate that the color change depends upon changes in constitution rather

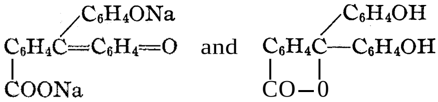
[9] Orndorff, Gibbs and McNulty, THIS JOURNAL, 48, 1994 (1926).

[10] Gibbs and Shapiro, *ibid*, 50, 2978 (1928); Proc. *Nat.* Acad. *Sci.*, 14, 251 (1928).

than upon the formation of ions. Any ions which may form can possess color only if the non-ionized molecules from which they come are colored. The sodium salt is assumed to have a quinoid structure, while free phenolphthalein has a lactone structure



$$\begin{array}{l} \quad\diagup C_6H_4ONa \\ C_6H_4C{=}C_6H_4{=}O \\ | \\ COONa \end{array} \quad \text{and} \quad \begin{array}{l} \quad\diagup C_6H_4OH \\ C_6H_4C{-}C_6H_4OH \\ |\quad\ | \\ CO{-}O \end{array}$$

The results presented in this paper can only be explained on the basis of a quinone structure for phenolphthalein in alkaline solution. It is evident that the phenolphthalein must have been brominated before it could change to the lactone structure. If this were not the case, one would naturally expect bromination to proceed as usual with the formation of tetrabromophenolphthalein. That the yellow precipitate first formed is similar to the quinone structure for phenolphthalein is shown by the readiness with which it changes to the colorless or lactone form. The lactone form may be regarded as a derivative of phthalide and the yellow form as the corresponding labile or quinoid structure.

Attempts to prepare these compounds in pure form have not been successful, but it is hoped that later work will overcome some of the difficulties.

Summary

1. It has been shown that the action of bromine (as generated by acidifying bromate–bromide mixtures) upon phenolphthalein varies greatly with conditions. In the absence of a special solvent such as alcohol, chloroform, etc., tetrabromophenolphthalein is not formed. The reaction is accompanied by the loss of five molecules of bromine. Four molecules react by substitution and one by addition.

2. It has been pointed out that the interpretation of the reactions offers further evidence that phenolphthalein possesses a quinoid structure in alkaline solution.

THE SYNTHESIS OF BETA-BROMO-ALKYL ETHERS AND THEIR USE IN FURTHER SYNTHESES[1,2]

BY LLOYD C. SWALLEN AND CECIL E. BOORD

RECEIVED JULY 1, 1929 PUBLISHED FEBRUARY 6, 1930

Introduction

The remarkable difference in the reactivity of halogen when substituted in the alpha- or beta-position of an aliphatic ether makes it seem desirable to investigate further these derivatives. The present paper describes the preparation of several β-bromo-alkyl ethyl ethers and their use in further syntheses. An adaptation of the method of Houben and Führer[3] was selected as having the most general application. The synthesis consists of a three-stage process, as indicated by the following reactions

$$CH_3CHO + C_2H_5OH + HCl = CH_3CHClOC_2H_5 + H_2O \quad (1)$$
$$CH_3CHClOC_2H_5 + Br_2 = CH_2BrCHBrOC_2H_5 + HCl \quad (2)$$
$$CH_2BrCHBrOC_2H_5 + RMgBr = CH_2BrCHROC_2H_5 + MgBr_2 \quad (3)$$

The initial step was first described by Wurtz and Frapoli[4] and later improved by Gauthier.[5] The second step consists in the bromination of α-chloro-ethyl ethyl ether. The bromination of this compound has been described by Madinaveitia and Puyal[6] as yielding the α-chloro-β-bromoethyl ether. The present authors do not obtain the same results. Carefully repeated analyses of the product and a study of the yield values show our product to be the dibromo derivative. The final step is an adaptation of the method used by Houben and Führer[3] for the synthesis of β-chloro ethers applied to the preparation of the corresponding bromo derivatives. The yields are good.

The Synthesis of β-Ethoxy-alkyl Mercaptans.[7]—The β-halogenated ethers are remarkable for their lack of chemical reactivity toward some reagents. The β-bromo ethers herein described may be distilled over solid caustic soda without appreciable decomposition. They do, however, react readily with the alkali metal hydrosulfides, forming the corresponding mercaptans. The β-ethoxy-alkyl mercaptans when freshly pre-

[6] Madinaveitia and Puyal, *Anales soc. españ. fís. quím.*, **16,** 329–337 **(1918).**

[7] While this work was in progress two of the compounds herein described were also prepared by Rojahn and Lemme, *Arch. Pharm.*, **263, 612 (1925).**

pared have a not unpleasant odor closely resembling that of the corresponding chloro ethers. Upon standing they develop the usual mercaptan characteristics as to odor but are quite stable. They are easily converted into the corresponding disulfides and mercaptide chloride derivatives by the usual methods. Ethoxy-ethyl mercaptan readily condenses with acetone to form the corresponding mercaptol and is easily oxidized to ethoxyethylsulfonic acid. The latter compound has been converted into the corresponding sulfochloride and sulfonamide.

β-Bromo Ethers in the Malonic Ester Synthesis.—p-Ethoxy-ethylmalonic ester has been previously described by Byk,[8] who obtained it by the action of β-iodo-ethyl ethyl ether upon malonic ester. It is now shown that an appreciable yield of the same product results even when the β-chloro ether is used. β-Ethoxy-*n*-butyl bromide also reacts readily with malonic ester to form β-ethoxy-*n*-butylmalonic ester in good yield. The latter compound readily yields γ-ethoxy-*n*-caproic acid.

β-Bromo Ethers in the Williamson Reaction.—The β-ethoxyphenetole formed by the action of sodium phenolate upon β-chloro-ethyl ethyl ether is identical in every respect with the product described by Henry[9] as having been derived by the action of sodium alcoholate upon β-chlorophenetole.

Reaction with Aniline.—Cretcher and Pittenger[10] have shown that morpholines are formed by the action of β,β′-dichloro-diethyl ether upon aniline. In an analogous way the monoethoxy-alkylanilines are now produced by the action of aniline upon the β-halogenated alkyl ethyl ethers.

Reaction with Metals.—The most interesting reaction and one which promises to be of great value in synthesis is the decomposition of the β-halogenated ethers in the presence of metals.

Wislicenus[11] observed that β-chloro-acetal reacts with sodium above its melting point to form ethyl vinyl ether as one of the principal products. Wohl and Berthold[12] have also shown that metallic sodium reacts with β-chlorophenetole to form chiefly sodium phenolate and ethylene. Grignard[13] found that β-bromophenetole formed an alkylmagnesium bromide which rapidly decomposed to give phenoxy magnesium bromide and ethylene. In agreement with these facts it is now found that the β-bromo-alkyl ethyl ethers react with magnesium to form olefins as the principal product. In the experimental part of this paper it will be

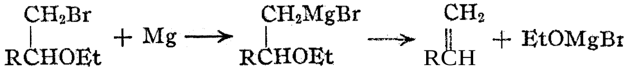
[10] Cretcher and Pittenger, THIS JOURNAL, 47, 163 (1925); Cretcher, Koch and Pittenger, *ibid.*, 47, 1173 (1925).

[11] Wislicenus, *Ann.*, 192, 106 (1878).

[12] Wohl and Berthold, *Ber.*, 43, 2177 (1910).

[13] Grignard, *Compt. rend.*, 138, 1048 (1904).

shown that β-ethoxy-*iso*heptyl bromide reacts with magnesium in the presence of anhydrous ether to yield α-*iso*heptene. The course of the reaction can be easily understood upon the basis of the following mechanism



$$\begin{matrix} CH_2Br \\ | \\ RCHOEt \end{matrix} + Mg \longrightarrow \begin{matrix} CH_2MgBr \\ | \\ RCHOEt \end{matrix} \longrightarrow \begin{matrix} CH_2 \\ \| \\ RCH \end{matrix} + EtOMgBr$$

The significance of this decomposition lies in the fact that the β-bromo-alkyl ethyl ethers may be synthesized readily as indicated above. The yields are good and the reaction seems to be of quite general application. The process promises well as a method for the synthesis of olefins with a definite constitution. The application to the synthesis of olefins has been Further developed and will be offered for publication at an early date.

Experimental Part

Preparation of β-Chloro Ethers.—Several previously described β-chloro ethers were prepared by new or modified methods. The yields and physical constants of these products are shown in Table I.

TABLE I

β-CHLORO ETHERS

Formula	Yield, %	B. p., °C.	d^{20}_{20}
$CH_3—O—CH—CH_2Cl$[14,15]	27	89.5–90.5	1.0659
$C_2H_5—O—CH_2—CH_2Cl$[15,16]	61.7–66	108–109	1.0210
$C_2H_5—O—CHCH_3—CH_2Cl$[17]	54	116–118	0.9798
$C_2H_5—O—CHC_2H_5—CH_2Cl$[17,3]	84	138–139	0.9547
$C_2H_5—O—CHC_6H_5—CH_2Cl$[3]	53	100–105	1.1035

β-Chloro-ethyl methyl ether was prepared by heating a mixture of 80 g. of ethylene chlorohydrin and 120 g. of dimethyl sulfate in a distilling flask over an oil-bath at 145–165° as long as any product distilled. The crude distillate was washed, dried and fractionated.

β-Chloro-ethyl ethyl ether was prepared by dropping slowly a mixture of 175 g. of ethylene chlorohydrin and 350 g. of alcohol into a mixture of 50 cc. of concd. sulfuric acid and 50 cc. of alcohol kept at a temperature of 145–150°. The crude distillate was dried and fractionated using an efficient column, the major portion distilling between 106–110°.

The other three β-chloro ethers of the general type $C_2H_5—O—CHR—CH_2Cl$ were prepared by the method of Houben and Führer. This method consists in adding an ether solution of the appropriate alkylmagnesium bromide to an ether solution of α,β-dichloro-ethyl ethyl ether. Purification was effected in the usual manner.

The Preparation of β-Bromo Ethers.—All attempts to prepare β-bromo ethers by the action of the alkyl hypobromite upon ethylene or of the sodium alcoholate upon ethylene bromide were unsuccessful. A very

[17] Lieben and Bauer, *Ann*, **123**, 130–136 (1862).

satisfactory general method for their preparation was found in an adaptation of the method used by Houben and Fuhrer for the preparation of the β-chloro derivatives. The yield values, analyses and physical constants of six β-bromo ethers prepared by this method are given in Table II.

A. Preparation of a-Chloro-ethyl Ethyl **Ether,**[4,5] $CH_3—CHCl—O—C_2H_5$.—A mixture of 100 g. of paraldehyde and 100 g. of ethyl alcohol was cooled in a freezing mixture and treated with 100 g. of dry hydrogen chloride. The reaction mixture separated into two layers. The upper layer was dried over calcium chloride and fractionally distilled. The portion boiling at 93–96" weighed 162 g., corresponding to a 69% yield. **A** second run using 200 g. of paraldehyde, 210 g. of alcohol and 226 g. of hydrogen chloride yielded 297 g. (64%).

B. Preparation of a,@-Dibromo-ethylEthyl **Ether,**[18] $C_2H_5—O—CHBr—CH_2Br$. Bromination of a-Chloro-ethyl Ethyl Ether.—The a-chloro-ethyl ether, prepared as described above, was cooled in an ice-bath and the theoretical amount of bromine added in small portions. The reaction mixture was allowed to become decolorized or nearly so, after each addition. The reaction proceeded rapidly at first, but quite slowly toward the end. The gas evolved proved to be almost wholly hydrogen chloride. The crude reaction product was submitted **directly** to distillation at diminished pressure. Almost the entire product distilled between 92 and 95° (17 mm.). The yields from two successive runs were 91 and 88.4%. Further fractionation yielded a product boiling at 90–91° (20 mm.); d_{20}^{20} 1.7350.

Anal. Calcd. for $C_4H_8OBr_2$: Br, 68.93. Found: Br, 69.08.

The Bromination Reaction.—The yield and analysis as given above leave no doubt as to the identity of the product as α,β-dibromo-ethyl ethyl ether. These results, however, do not correspond to those obtained by Madinaveitia and Puyal,[6] who have described the bromination product of a-chloro-ethyl ether as the α-chloro-β-bromo derivative. In order to secure additional evidence for the correctness of our conclusions the following experiment[19] was made to determine whether the hydrogen halide was hydrogen chloride.

A portion of a-chloro-ethyl ethyl ether was carefully brominated by the procedure described. The gases evolved were absorbed in water. Twenty cc. of the solution thus obtained was treated with an excess of standard silver nitrate solution. The precipitated silver halides were filtered through a Gooch crucible, washed, dried and weighed. The excess silver nitrate in the filtrate was determined by titration with standard ammonium thiocyanate using ferric ammonium alum as an indicator. From these data the relative amounts of silver bromide and silver chloride in the precipitate were calculated. The results were as follows: ***Anal.*** AgX, 0.2837, 0.2909; cc. of 0.09976 N $AgNO_3$, 23.82, 23.88; cc. of 0.1197 *N* NH_4CNS, 3.32, 3.26; AgCl, calcd., 0.2835, 0.2855; AgBr, calcd., 0.0002, 0.00054. These results indicate that the hydrogen halide evolved is almost quantitatively hydrogen chloride and support the view that the bromination product is a dibromo derivative.

C. Preparation of **β-Bromo** Ethers. Condensation of **α,β-Dibromo-ethyl** Ether with an **Alkylmagnesium** Halide.—The Grignard reagents were prepared in the usual

---

[18] Wislicenus, *Ann.*, 192, 111 (1878).

[19] This experiment is taken from the unpublished work of Dr. Harry B. Dykstra.

manner from the corresponding alkyl bromides. The α,β-dibromo ether was mixed with about twice its volume of anhydrous ether and placed in a two-liter flask surrounded by an ice-bath. The flask was provided with a reflux condenser and the Grignard reagent added dropwise, with constant shaking. The reaction took place instantaneously and with a hissing sound. The rate at which the reagent was added was regulated so as to avoid undue loss of ether by volatilization through the condenser. A slight excess of the alkylmagnesium halide not only served to increase the yield but also to render the product more easily purifiable. The reaction mixture was decomposed by pouring on ice and acidifying with dilute hydrochloric acid. The ether layer was separated, dried over calcium chloride and the ethyl ether removed by distillation. The product was then transferred to a smaller flask, about 5% of its weight of solid sodium hydroxide added and fractionated.

β-Ethoxy-*n*-propyl bromide and β-ethoxy-*n*-butyl bromide were distilled at atmospheric pressure, but the remaining compounds were distilled under diminished pressure. Further purification was effected by refractionation, sometimes over solid alkali, using an efficient column.

The bromine determinations were made by decomposing the compounds by the Bacon–Stephanow procedure and titrating the halogen by the Volhard method, using ferric nitrate as an indicator.

TABLE II

β-BROMO-ALKYL ETHYL ETHERS, $C_2H_5O—CHR—CH_2Br$

β-Ethoxy- ( )-bromide	R-	Yield, %	B. p., °C.	d^{20}_{20}	Bromine, %	
					Found	Calcd.

Ethyl-β-iodo-ethyl Ether,[20] $C_2H_5—O—CH_2—CH_2I$.—The methods described by Baumstark and by Henry for the preparation of this compound were tried but the following procedure was found to be much superior.

A mixture of 35 g. of anhydrous sodium iodide, 35 cc. of 95% alcohol and 24 g. of β-chloro-ethyl ethyl ether was refluxed on the water-bath for five hours. The reaction mixture was diluted with water, causing the separation of an oily layer. The aqueous layer was extracted with chloroform, the extract added to the oily layer and the solution thus obtained dried and fractionally distilled. Ten g. of the chloro ether was recovered. The yield was 24 g. or 89% of the theoretical based on the amount of chloro ether actually used. After further purification the ethyl β-iodo-ethyl ether boiled at 154.5–155° (corr.); d^{20}_{20} 1.7032. Demole gives the same boiling point. Henry gives the density as d^0 1.6924.

Preparation of β-Ethoxy-alkyl Mercaptans and their Derivatives

β-Ethoxy-alkyl Mercaptans, $C_2H_5—O—CHR—CH_2SH$.—A solution of potassium hydrosulfide was prepared by saturating a solution of potassium hydroxide in methyl alcohol with hydrogen sulfide. The appropriate β-chloro-ether was added to this solution in such amounts as would leave the hydrosulfide in approximatey 100% excess. The combined solutions were placed in pressure bottles in 100–150-cc. por-

---

[20] Baumstark, *Ber.*, 7, 1172 (1874); Demole, ibid., 9, 746 (1876); Henry, Bull. *soc. chim.*, 44, 459 (1885); *Compt.* rend., 100, 1007 (1885).

tions and heated in a water-bath for the time indicated. The reaction mixture was diluted with water, causing a large part of the product to separate as an oily layer. The aqueous portion was extracted with petroleum ether and the extract added to the main product. Usually it was found advantageous to dissolve the mercaptan in caustic soda solution and reprecipitate with hydrochloric acid. When the reaction had been carried quite to completion this solution and reprecipitation proved unnecessary. The crude mercaptan was finally dried and fractionally distilled. A small amount of the sulfide was always formed as a by-product. The experimental conditions and yield values are shown in Table III.

TABLE III

β-ETHOXY-ALKYL MERCAPTANS, $C_2H_5—O—CHR—CH_2SH$

β-Ethoxy-( )-mercaptan	Formula	Chloro ether, g.	Temp., °C.	Time, hours	Yield, % mercaptan	Yield, % sulfide
Ethyl[7]	$C_2H_5OCH_2CH_2SH$	100	65	24	74	13
n-Propyl	$C_2H_5OCH(CH_3)CH_2SH$	25	..	50	36[a]	..
n-Butyl	$C_2H_5OCH(C_2H_5)CH_2SH$	50	90	60	61	14

[a] Eight grams of chloro ether recovered.

The β-ethoxy-alkyl mercaptans are colorless liquids, readily obtained in a high degree of purity. The boiling points are remarkably constant. These ethoxy mercaptans form insoluble salts of both mercury and lead but all attempts to obtain such salts in the crystalline condition failed.

Mercury β-Ethoxy-alkyl Mercaptide Chloride, $C_2H_5—O—CHR—CH_2SHgCl$.—The mercuric chloride derivatives were readily prepared by mixing an alcoholic solution of mercuric chloride with that of the mercaptan. The salt is deposited slowly as a crystalline white powder. These deposits were filtered off, washed first with alcohol and then .with ether, dried and submitted directly to analysis.

Bis-(β-ethoxy-alkyl) Disulfide, $(C_2H_5O—CHR—CH_2)_2S_2$.—The ethoxy mercaptans were oxidized quantitatively to the disulfides by shaking with the theoretical amount of iodine in either aqueous or alcoholic solution. The oily products which separated were washed with water, dried over calcium chloride and distilled under diminished pressure.

The physical constants and analyses of the β-ethoxy-alkyl mercaptans and their derivatives are summarized in Table IV.

TABLE IV

Bis-(β-Ethoxy-ethyl) Sulfide, $(C_2H_5O—CH_2—CH_2)_2S$.—A solution of 20 g. of sodium hydroxide in 100 cc. of 70% alcohol was saturated with hydrogen sulfide. To this solution 25 g. of α-ethoxy-ethyl chloride was added and the reaction mixture heated at the boiling point for three hours. As no effort was made to prevent the escape of hydrogen sulfide the active agent was sodium sulfide. After cooling the reaction mixture was diluted with water, causing the product to separate as an oily layer. The aqueous layer was extracted with ether and the extract added to the main product. The ether solution was dried and the product purified by fractional distillation. The yield was 51%; b. p. 229° (corr.); d_{20}^{20} 0.9840.

Anal. Subs., 0.1483: $BaSO_4$, 0.933. Calcd. for $C_8H_{18}O_2S$: S, 17.99. Found: S, 17.90.

Formation of Ethylene Sulfide.—Six g. of β-ethoxy-ethyl mercaptan was heated with 12 g. of 48% hydrobromic acid on a water-bath for three hours. A white solid separated, which was proved to be a mixture of the polymers of ethylene sulfide by complete conversion into diethylene disulfide by depolymerization with phenol.

Acetone **β-Ethoxy-ethyl** Mercaptol, $(CH_3)_2C(SCH_2—CH_2OC_2H_5)_2$.—A mixture of 11 g. of β-ethoxy-ethyl mercaptan and 5 g. of acetone was saturated with dry hydrogen chloride. The reaction mixture became warm and water separated. The mercaptol was washed with water, dried over calcium chloride and distilled *in vacuo*. The yield was 80%; b. p. 134° (7 mm.); d_{20}^{20} 1.0044.

Anal. Subs., 0.2173: $BaSO_4$, 0.4070. Calcd. for $C_{11}H_{24}O_2S_2$: S, 25.41. Found: S, 25.72.

Sodium **β-Ethoxy-ethyl Sulfonate,**[21] $C_2H_5—O—CH_2—CH_2SO_3Na$.—Fourteen grams of β-ethoxy-ethyl mercaptan was placed in a flask under a reflux condenser. While the contents of the flask was kept at the boiling point, a solution of 30 g. of concd. nitric acid in 100 cc. of water was added in small portions during the course of an hour. The digestion was continued at the boiling point until the reaction mixture became homogeneous. The solution was concentrated on the steam plate, neutralized with sodium hydroxide solution and evaporated to dryness. The sodium sulfonate was extracted with 90% alcohol. Evaporation of the alcoholic extract yielded 21 g. of crude product. Recrystallization from alcohol gave a pure product. The sodium was determined by ashing a weighed sample, treating with sulfuric acid and igniting.

Anal. Calcd. for $C_4H_9O_4SNa$: Na, 13.06. Found: Na, 13.64.

The sodium salt of β-ethoxy-ethyl sulfonic acid is very soluble in water, moderately soluble in 90% alcohol, but only slightly soluble in absolute alcohol. The free acid was not obtained in the pure condition.

β-Ethoxy-ethyl Sulfochloride, $C_2H_5—O—CH_2—CH_2SOCl$.—Twenty-one grams of dry, finely pulverized sodium β-ethoxy-ethyl sulfonate was mixed with 27 g. of phosphorus pentachloride in a round-bottomed flask. The reaction proceeded with the evolution of heat. The flask was arranged for vacuum distillation and heated gently at first but more strongly as the reaction neared completion. The portion distilling above 100° under strongly diminished pressure was washed with water, dried over calcium chloride and twice distilled *in vacuo*. A yield of 8 g. boiling at 118–122° (26 mm.) was obtained. The product was not pure since analysis showed a chlorine content of 21.64% while the calculated value is 20.54%.

A benzene solution of the β-ethoxy-ethyl sulfochloride described above was saturated with dry ammonia gas. The solution was filtered from the ammonium chloride and evaporated. The product obtained was an oil which crystallized after several

---

[21] Hübner, *Ann.*, **223,** 218 (1884).

days standing as large colorless crystals, m. p. 41°. This substance, apparently the amide, was not obtained in sufficient purity for analysis.

Use of β-Halogen Ethers in the Malonic Ester Synthesis

β-Ethoxy-ethyl Malonic Ester,[22] $C_2H_5OCH_2—CH_2—CH(COOC_2H_5)_2$.—Seven and one-half grams of sodium was dissolved in 100 cc. of anhydrous alcohol and 50 g. of pure malonic ester added. The flask was shaken vigorously to break up the lumps of the sodium salt and 35 g. of β-chloro-ethyl ethyl ether added with warming and shaking until a clear solution was obtained. The reaction mixture was heated on the water-bath for three hours. The alcohol was distilled off, water added and the product extracted with petroleum ether. Two fractionations under diminished pressure yielded 11.4 g. (14%) of β-ethoxyethylmalonic ester boiling at 134–138° (15 mm.), d^{20}_{20} 1.0430. The boiling point given in the literature is 136° (13 mm.).

β-Ethoxy-*n*-butylmalonic Ester, $C_2H_5O—CHC_2H_5—CH_2—CH(COOC_2H_5)_2$.—A similar reaction was carried out using 50 cc. of anhydrous alcohol, 3 g. of sodium, 22 g. of malonic ester and 18.1 g. of α-bromo-β-ethoxy-*n*-butane. The product boiled at 146–150° (12 mm., uncorr.). Titration of the aqueous solution for ionized halogen showed only 64% of the bromo ether to have been destroyed. The reaction mixture was also quite alkaline, indicating that the heating should have been continued for a longer time. The yield was 58% on the basis of bromo ether actually destroyed. The product was not analyzed but was carried directly to the following preparation.

Calcium β-Ethoxy-*n*-butylmalonate, $C_2H_5O—CHC_2H_5—CH_2—CH(COO)_2Ca$.—The entire product from the preceding preparation was hydrolyzed by heating on the water-bath with a solution of sodium hydroxide (5 g. in 10 cc. of water) until the oily layer had disappeared. The solution was neutralized with concd. hydrochloric acid and the calcium salt precipitated by the addition of a concd. solution of calcium chloride. The salt was filtered off, washed and dried; yield, 6.5 g.

A portion of the salt recrystallized from a mixture of equal parts of methyl alcohol and water was obtained as a white crystalline powder. Calcium was determined by igniting a weighed sample, treating with sulfuric acid and re-igniting.

Anal. Calcd. for $C_9H_{14}O_5Ca$: Ca, 16.54. Found: Ca, 16.33.

γ-Ethoxy-*n*-caproic Acid, $C_2H_5—OCHC_2H_5—CH_2—CH_2—COOH$.—Eight cc. of concd. hydrochloric acid was added to the remainder of the calcium salt obtained in the previous preparation and the free substituted malonic acid extracted with ether. Upon evaporation of the ether, β-ethoxy-*n*-butylmalonic acid was obtained as a thick sirup which could not be induced to crystallize. The product was heated at 180" on an oil-bath as long as any gas was evolved (fifteen minutes); r-ethoxycaproic acid, b. p. 138–140° (8 mm.) uncorr., d^{20}_{20} 0.9816, was obtained in a yield of 3.3 g.

The barium salt was prepared by neutralizing a solution of barium hydroxide with *a* slight excess of the acid and carefully evaporating the solution. It is very soluble in water, alcohol and acetone. Barium was determined by ashing a weighed sample and igniting with sulfuric acid.

Anal. Calcd. for $C_{16}H_{30}O_6Ba \cdot H_2O$: Ba, 29.01. Found: Ba, 29.10.

The Williamson Reaction

β-Ethoxyphenetole, $C_6H_5—O—CH_2—CH_2—OC_2H_5$.—Ethyl β-chloro-ethyl ether was heated with an excess of an alcoholic solution of sodium phenolate for ten days. The greater part of the alcohol was removed by distillation and the residue diluted with water. The oily layer which separated was washed with dilute caustic soda solu-

---

[22] German Patent 285,636; *Chem. Zentr.*, II, 639 (19151.

tion, dried and fractionally distilled. The product was obtained as a colorless liquid; b. p. 230–232° (corr.); d_{20}^{20} 1.0057.

Bentley, Haworth and Perkin,[23] who obtained the same product by an application of the malonic ester synthesis, give the b. p. as 230°. Henry,[9] who obtained the compound by the action of sodium ethylate upon β-chlorophenetole, gives the boiling point as 230°; d 1.018.

Reaction with Aniline

β-Ethoxy-ethylaniline, $C_6H_5NHC_2H_4—O—C_2H_5$.—Fifty grams of ethyl β-chloroethyl ether and an equal weight of aniline were heated at the boiling point for about ten hours. The temperature rose to 180°. The reaction mixture was decomposed by dilute sodium hydroxide solution and the mixture of bases separated, dried and submitted to fractional distillation. Repeated fractionation was necessary to separate the products. Mono-β-ethoxy-ethylaniline was obtained as a colorless liquid, b. p. 262–263° (corr.), d_{20}^{20} 1.0156. It darkens on standing and develops a disagreeable odor.

Anal. Subs., 0.3798: required 22.7 cc. of 0.10006 N H_2SO_4. Calcd. for $C_{10}H_{15}ON$: N, 8.49. Found: N, 8.36.

Mono-β-ethoxybutylaniline, $C_6H_5NH—CH(C_2H_5)—CH_2—OC_2H_5$.—This compound was prepared in an analogous manner but with much greater difficulties in purification, due to the formation of tarry substances. The compound boils at 264–269° (corr.) and has a density of d_{20}^{20} 0.9830.

Reaction with Magnesium

Preparation of **1,2-*Iso*heptene,** $(CH_3)_2CH—CH_2—CH_2—CH{=}CH_2$.—Thirty-five grams of β-ethoxy isoheptyl bromide was added in small portions to 12 g. of magnesium turnings covered with 75 cc. of dry ether. The magnesium soon became coated with a gummy white substance which rendered it somewhat inactive. After warming for five hours on the water-bath, the ether was distilled off using an efficient column. The remaining liquid was decanted from the residue and distilled until the temperature reached 120°. Further fractionation of the distillate yielded 5 g. of isoheptene boiling between 80 and 85°, mainly at 85°. The product was identified by conversion into the dibromide.

1,2-*Iso*heptene Dibromide, $(CH_3)_2CH—CH_2—CH_2—CHBr—CH_2Br$.—The *iso*heptene from the preceding preparation was dissolved in chloroform and treated with a slight excess of bromine. The crude dibromide was washed successively with concd. sulfuric acid, dilute sodium hydroxide and water and then dried. The product which distilled in *vacuo* with slight decomposition was obtained in a yield of 8 g., b. p. 95" (13 mm.), d_{20}^{20} 1.5083.

Anal. Calcd. for $C_7H_{14}Br_2$: Br, 61.96. Found: Br, 60.29.

Summary

The method of Houben and Fuhrer has been adapted to the synthesis of β-bromo-alkyl ethyl ethers and six new compounds of this type are described.

It is shown that, notwithstanding the relatively low chemical reactivity of the β-halogenated ethers in comparison with the a-halogenated derivatives, the β-bromo-alkyl ethers may be used advantageously in certain syntheses. They react readily with the alkali hydrosulfides to form β-ethoxy-alkyl mercaptans, which in turn may be converted into the corre-

---

[23] Bentley, Haworth and Perkin, J. *Chem. Soc.*, 69, 171, 1503 (1896).

sponding disulfides, sulfonic acids and related derivatives. The β-bromo-alkyl ethers may be used in the same way as ordinary alkyl halides in the malonic ester synthesis, Williamson's reaction and in the formation of ethoxy-alkylanilines.

β-Bromo-alkyl ethyl ethers react in ether solution with magnesium to form olefins. Isoheptene is prepared in this way.

PICTET AND GAMS' BERBERINE SYNTHESIS

BY JOHANNES S. BUCK AND ROSE M. DAVIS[1]

RECEIVED JULY 15, 1929 PUBLISHED FEBRUARY 6, 1930

The synthesis of the alkaloid berberine by Pictet and Gams[1a] has long been regarded as classic. Some doubt as to its accuracy has, however, recently arisen.

Buck and Perkin[2] in attempting to synthesize *epi*-berberine (2,3-dimethoxy-9,10-methylenedioxyprotoberberine)[3] by the method of Pictet and Gams[1] obtained only the isomeric pseudo-*epi*-berberine (2,3-dimethoxy-10,11-methylenedioxyprotoberberine). Haworth, Perkin and Rankin[4] in repeating Pictet and Gams' synthesis of berberine (2,3-methylenedioxy-9,10-dimethoxyprotoberberine) obtained exclusively the isomeric pseudoberberine (2,3-methylenedioxy-10,11-dimethoxyprotoberberine), the second ring closure taking place so as to give the 10,11- and not the 9,10-dimethoxy compound. A search of the literature showed that Pictet and Gams' alleged ring closure to give the 9,10 compound is unique, at least when the ring substituents are methoxyl or methylenedioxy groups. Pictet himself expresses astonishment that berberine and not the isomer should be formed. The only departure from the general rule is the formation of both tetrahydropalmatine and nor-coralydine from tetrahydropapaveroline, recorded by Spath and Kruta.[5] Here, however, hydroxyl, not alkoxyl, groups were the substituents.

It therefore appeared necessary to investigate the synthesis further, in order to detect any error, if such were present. The authors believe that they have definitely shown the synthesis to be erroneous.

Pictet and Gams[1] on heating homoveratroylhomopiperonylamine with

---

[1] The material presented in this paper is from a dissertation submitted by Rose M. Davis to the Graduate School of Arts and Sciences of Duke University in partial fulfilment of the requirements for the degree of Doctor of Philosophy, 1929.

[1a] Pictet and Gams, Ber., **44**, 2480 (1911).

[5] Späth and Kruta, Monatsh., 50, 341 (1928).

phosphorus pentoxide, obtained an amorphous glassy mass, melting at 68–70', which they considered to be 6,7-methylenedioxy-3′,4′-dimethoxy-3,4-dihydroprotopapaverine. Haworth, Perkin and Rankin,[4] carrying out the same cyclization, obtained a white crystalline compound, melting at 88°, and this was shown[6] to be rapidly oxidized in air to give 6,7-methylenedioxy-3′,4′-dimethoxy-9-keto-3,4-dihydroprotopapaverine. It may, therefore, be safely inferred that Pictet and Gams' product contained considerable amounts of this oxidized base, especially as it had been exposed in a desiccator. 6,7-Methylenedioxy-3′,4′-dimethoxy-3,4-dihydroprotopapaverine, as has clearly been shown by Haworth and co-workers,[4,6] gave only 6,7-methylenedioxy-3′,4′-dimethoxy-1,2,3,4-tetrahydroprotopapaverine on reduction, and this, on treatment with methylal or formaldehyde, results exclusively in 2,3-methylenedioxy-10,11-dimethoxytetrahydroprotoberberine (pseudoberberine). The obvious inference is that Pictet and Gams mistook tetrahydropseudoherberine for tetrahydroberberine. The authors constantly obtained tetrahydropseudoberberine on repeating Pictet and Gams' work. The other source of error is the presence of the oxidized cyclized material, which had been overlooked by Pictet and Gams. This has been shown by Ruck and co-workers[6] (and carefully checked by the present authors) to give rise to 6,7-methylenedioxy-3′,4′-dimethoxy-9-ketoprotopapaverine under the action of alkalies, with surprising ease. As far as is possible to see from Pictet and Gams' meager account, this compound is identical with their "veratryl-nor-hydrohydrastinine," the supposed reduction product of 6,7-methylenedioxy-3′,4′-dimethoxy-3,4-dihydroprotopapaverine. The compound is incapable of reacting with methylal, the requisite imino group being absent. Pictet and Gams' analysis is correct for veratryl-nor-hydrohydrastinine.

It is true that Pictet and Gams reduced their crude cyclization product before treating it with alkali, but the authors have observed that 6,7-methylenedioxy-3′,4′-dimethoxy-9-keto-3,4-dihydroprotopapaverine is not reduced under the conditions employed. It would seem highly probable, therefore, that Pictet and Gams obtained not veratryl-nor-hydrohydrastinine (6,7-methylenedioxy-3′,4′-dimethoxy-1,2,3,4-tetrahydroprotopapaverine) but 6,7-methylenedioxy-3′,4′-dimethoxy-9-keto-protopapaverine on cyclization, reduction and treatment with alkali. As before stated, this cannot react with methylal. It is concluded, therefore, that Pictet and Gams never isolated veratryl-nor-hydrohydrastinine, but obtained the oxidized side product, a compound closely related to xanthaline. Their tetrahydroberberine must, therefore, have been actually tetrahydropseudoberberine and have been obtained by operating with crude reaction mixtures.

---

[6] Buck, Haworth and Perkin, *J. Chem. Soc.*, **125**, 2176 (1924)

There remained one possibility, that Pictet and Gams had by chance obtained some unknown reduction product capable of giving tetrahydroberberine on treatment with methylal. The authors therefore carefully investigated the reduction products of 6,7-methylenedioxy-3′,4′-dimethoxy-9-keto-3,4-dihydroprotopapaverine and of 6,7-methylenedioxy-3′,4′-dimethoxy-9-keto-protopapaverine. From the first, 6,7-methylenedioxy-3′,4′-dimethoxy-9-hydroxy-1,2,3,4-tetrahydroprotopapaverine was obtained and from the second, 6,7-methylenedioxy-3′,4′-dimethoxy-9-hydroxyprotopapaverine. This, analogous to the compound papaverinol described by Stuchlik,[7] cannot react with methylal. 6,7-Methylenedioxy-3′,4′-dimethoxy-9-hydroxy-1,2,3,4-tetrahydroprotopapaverine indeed reacts with methylal or formaldehyde, giving rise to an interesting compound described in the experimental part, but this compound is very different from the tetrahydroberberine.

Experimental

Veratryl-nor-hydrohydrastinine (6,7-Methylenedioxy-3′,4′-dimethoxy-1,2,3,4-tetrahydroprotopapaverine).—The details given by Pictet and Gams regarding this compound are meager. A number of experiments, following as closely as possible the procedure given, were carried out with the uniform result that the material obtained on cyclizing homoveratroylhomopiperonylamine with phosphorus pentoxide and then reducing with tin and hydrochloric acid, detinning with hydrogen sulfide and liberating the bases by alkali, was found to be a mixture of 6,7-methylenedioxy-3′,4′-dimethoxy-1,2,3,4-tetrahydroprotopapaverine (melting at 84° and described by Haworth and co-workers[4,6]) and 6,7-methylenedioxy-3′,4′-dimethoxy-9-keto-protopapaverine, melting at 208°. The former has been dealt with in another place; the latter cannot react with methylal (this was checked experimentally).

Authentic 6,7-methylenedioxy-3′,4′-dimethoxy-3,4-dihydroprotopapaverine when reduced with tin and hydrochloric acid gave 6,7-methylenedioxy-3′,4′-dimethoxy-1,2,3,4-tetrahydro-isoquinoline, melting at 84° (see above), together with varying amounts of 6,7-methylenedioxy-3′,4′-dimethoxy-9-keto-3,4-dihydroprotopapaverine, melting at 151° and formed by air oxidation of unchanged material. If alkali had been used (sodium hydroxide) in liberating the base, then in place of the latter compound (and formed from it) 6,7-methylenedioxy-3′,4′-dimethoxy-9-keto-protopapaverine melting at 208° was found. Neither this nor the dihydro compound is capable of reacting with methylal.

Pictet and Gams' Preparation of Tetrahydroberberine.—The preparation of tetrahydroberberine described by Pictet and Gams was very carefully repeated a number of times, following the rather vague directions as closely as possible except that the reduction was carried out immediately on the cyclized product and no attempt was made to isolate the supposed veratryl-nor-hydrohydrastinine, m. p. 208" (see above). After cyclizing homoveratroylhomopiperonylamine, reducing, detinning and treatment of the base with methylal, the pseudotetrahydroberberine (2,3-methylenedioxy-10,11-dimethoxytetrahydroprotoberberine) of Haworth and co-workers, melting at 168°, was always obtained. Mixed with authentic tetrahydroberberine, m. p. 167°, the mixture showed a considerable depression (10°). If the original cyclization product had been kept in a desiccator, as described by Pictet and Gams, or any other oppor-

---

[7] Stuchlik, *Monatsh*, **21**, 814 (1900).

tunity for air oxidation given, then 6,7-methylenedioxy-3',4'-dimethoxy-9-keto-protopapaverine, m. p. 208°, was also found.

In connection with compounds of the foregoing types, the authors have frequently found that mixed melting point determinations of their salts, especially the picrates, are quite unreliable. This point seems to have escaped some workers.

6,7-Methylenedioxy-3',4'-dimethoxy-9-hydroxy-1,2,3,4-tetrahydroprotopapaverine.—6,7-Methylenedioxy-3',4'-dimethoxy-9-keto-3,4-dihydroprotopapaverine was reduced in 10% sulfuric acid solution with powdered zinc, a little copper sulfate being added to the mixture. When the reaction slackened, the whole was heated on a water-bath for one hour. After cooling, the mixture was filtered and treated with sodium hydroxide solution to liberate the bases. A gummy crystalline mass separated and was carefully fractionated from alcohol. Three compounds were found: (1) unchanged material, (2) 6,7-methylenedioxy-3',4'-dimethoxy-9-keto-protopapaverine, melting at 208°, and formed from the unchanged material by the action of the alkali and (3) a base $C_{19}H_{21}O_5N$. The latter, 6,7-methylenedioxy-3',4'-dimethoxy-9-hydroxy-1,2,3,4-tetrahydroprotopapaverine forms white glittering broken prisms melting at 161–162° to a yellow liquid. It is moderately soluble in alcohol and benzene, readily soluble in chloroform and slightly soluble in ether. Acetic anhydride and hydrochloric acid give colorless solutions.

Anal. Calcd. for $C_{19}H_{21}O_5N$: C, 66.4; H, 6.1. Found: C, 66.3; H, 6.2.

It was not found possible to obtain the above compound by reduction with tin and hydrochloric acid, unchanged material being always recovered, although there was some destruction. The failure is doubtless due to the separation of the highly insoluble tin double salt.

The catalytic method of reduction of Adams and co-workers (hydrogen–platinum oxide) was found to give excellent results with acetic acid as solvent, four atoms of hydrogen being smoothly absorbed. No compound other than that described above was isolated.

2,3-Methylenedioxy-10,11-dimethoxy-13-hydroxytetrahydroprotoberberine.—6,7-Methylenedioxy-3',4'-dimethoxy-9-hydroxy-1,2,3,4-tetrahydroprotopapaverine, dissolved in methyl alcohol, was mixed with sodium bicarbonate and 40% formaldehyde solution gradually added. The mixture was heated on the water-bath and then precipitated with water and salt. The product was heated with concentrated hydrochloric acid for a few minutes. Upon cooling yellow crystals formed and these were recrystallized from hot dilute hydrochloric acid. These were decomposed with potassium carbonate solution and the product recrystallized from methyl alcohol. A mass of fine yellow needles separated, melting at 153°. When methylal was substituted for formaldehyde, the product was obtained with considerable difficulty and in very poor yield. It is readily soluble in chloroform, moderately soluble in alcohol and benzene and sparingly soluble in ether.

Anal. Calcd. for $C_{20}H_{21}O_5N$: C, 67.6; H, 5.9. Found: C, 67.5; H, 6.0.

The test suggested by Robinson[8] to distinguish between 1,2,3,4- and 1,2,4,5-ring closures was applied to the above compound and indicated it to be a 1,2,4,5-derivative.

6,7-Methylenedioxy-3',4'-dimethoxy-9-hydroxyprotopapaverine.—6,7-Methylenedioxy-3',4'-dimethoxy-9-keto-protopapaverine was reduced in hot acetic acid solution by the catalytic method of Adams. Two atoms of hydrogen (maximum) were absorbed. After diluting and filtering, excess of ammonia was added and the gummy product which separated was recrystallized several times from alcohol. The

---

[8] Kaworth and Perkin, *J. Chem. Soc.*, **127**, 1448 (1925).

compound forms fine white needles from alcohol, melting at 161°. It is very soluble in chloroform, moderately soluble in benzene and fairly soluble in ether.

Anal. Calcd. for $C_{19}H_{17}O_5N$: C, 67.3; H, 5.0. Found: C, 67.3; H, 5.1.

Summary

The synthesis of berberine described by Pictet and Gams is in all probability erroneous, the error arising from overlooking the 6,7-methylenedioxy-3′,4′-dimethoxy-9-keto-3,4-dihydroprotopapaverine formed by air oxidation of their cyclized product. The "veratryl-nor-hydrohydrastinine" described by them is 6,7-methylenedioxy-3′,4′-dimethoxy-9-keto-protopapaverine, which cannot react with methylal. Any product which was obtained by the action of methylal must have been pseudoberberine and have been obtained by operating with crude reaction mixtures.

STUDIES IN THE DIPHENYL SERIES. SOME ARSENIC DERIVATIVES OF DIPHENYL

BY DAVID E. WORRALL

RECEIVED JULY 19, 1929 PUBLISHED FEBRUARY 6, 1930

Diphenyl, a substance now available in quantity at a low cost, is the starting point for the preparation of arsenic-containing compounds of possible therapeutic value Yet despite the vast amount of attention received by arsenicals during the past two decades, apparently only one paper has appeared in the literature on diphenyl derivatives of arsenic. Adams and Bauer[1] developed a method of entering this series, using the method of Bart with benzidine. Consequently a study has been made of tri-biphenylarsine and related compounds.

The actual starting material used in this investigation was *p*-bromoaniline, which was converted into 4-bromodiphenyl through the diazo reaction.[2] A pure product was obtained, but the process is time consuming, especially if the bromo-aniline has to be prepared, and the final yield is not particularly inspiring. Since then 4-chlorodiphenyl has appeared in the market and at a price much lower than bromo-aniline. While only one experiment was conducted, chlorodiphenyl appeared to be just as effective as the bromo derivative for a synthetic reagent. Several general methods have long been known for the preparation of arylated arsenic from aryl halides. One of these was ruled out because of inability to obtain biphenylmercuric acetate, while poor results attended the use

---

[1] Adams and Bauer, THIS JOURNAL, 46, 1925 (1924).

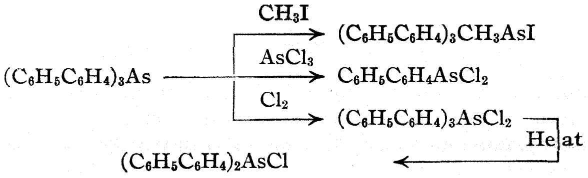
[2] Gomberg, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1928, Vol. VIII, p. 42.

of magnesium. Excellent results, however, were obtained with sodium, over 80% in some instances.

$$AsCl_3 + 3C_6H_5C_6H_4Br + 6Na = As(C_6H_4C_6H_5)_3 + 3NaCl + 3NaBr$$

It was found that benzene could be substituted for ether in the synthesis. An unexpected result was the discovery of diphenyl in working up the mother liquors from the purification of tri-biphenylarsine. It does not seem likely that diphenyl formation could have resulted from the action of moisture on tri-biphenylarsine, for the latter was found to be insensitive to water at 80° in the presence of alkali. Neither does it appear at all probable that nascent hydrogen resulting from the interaction of water and sodium could replace bromine with hydrogen. It is possible to interpret the appearance of diphenyl as evidence of the formation of free biphenyl which subsequently picked up hydrogen.

The following diagram indicates how the various classes of organic derivatives were prepared from tri-biphenylarsine.



The chlorine and bromine addition products are not sensitive to moisture when free from solvent, but when hydrolysis does take place both halogen atoms are involved. Thus if tri-biphenylarsine dibromide is mixed with a small volume of alcohol, it quickly dissolves and in a few minutes a crystalline precipitate forms. It contains bromine but the amount is approximately one-half of the theoretical, assuming that tri-biphenylarsine hydroxy bromide was formed. The halogen content varies in different preparations, but some bromine persists after recrystallization. The product may be regarded as a mixture of the hydroxide and hydroxy bromide, although the latter was not isolated.

Experimental

Tri-biphenyl.—To 4.2 g. of granulated sodium suspended in **150** cc. of *dry* benzene were added 21 g. of 4-bromo-diphenyl and 5.5 g. of arsenic chloride. As the initial reaction was somewhat sluggish, it was speeded up by heating the mixture under a reflux condenser. The source of heat was removed as soon as boiling started. A vigorous reaction ensued and continued spontaneously for over half an hour. Heat was again applied for some time, after which the mixture while still warm was filtered by suction. The residue was washed with 100 cc. of hot benzene, the combined filtrate concentrated to approximately 35 cc. and **25** cc. of ordinary alcohol added. The resulting bulky crystalline precipitate was filtered, washed thoroughly with cold ethyl alcohol and dried; yield, **12** g. of fairly pure material.

Anal. Calcd. for $C_{36}H_{27}As$: As, 14.0. Found: As, 13.8.

This last filtrate was evaporated to dryness and the residue steam distilled. About one-half a gram of residual tri-biphenylarsine was found. The distillate contained **2.6** g.

of a substance identified by its odor and properties as diphenyl. It evidently contained traces of 4-bromodiphenyl as it responded to the Beilstein test for halogen and the melting point was low (68–69°) even after recrystallization from alcohol. However, the melting point was not changed after mixing with diphenyl, while on nitration a substance was obtained identical in all respects with a known sample of 4-nitrodiphenyl.

Tri-biphenylarsine was also obtained in good yield by substituting 4-chlorodiphenyl for the bromo compound in the above preparation. Less desirable results attended the use of the reagent of Grignard. Thus in one experiment to 10 g. of 4-iododiphenyl in ether solution was added 1 g. of magnesium turnings. Precautions were taken to have the reagents dry and the apparatus was swept out with dry air. Activated magnesium was added, but the resulting action was slow and incomplete. Barely enough heat was evolved to warm the mixture, to which arsenic chloride was added after standing overnight. This caused some heat evolution, and the formation of a bulky precipitate. Previous to decomposition with water the mixture was heated under a reflux condenser for an hour, then it was steam distilled. Diphenyl, 1.2 g. in amount, came over first followed by approximately 5 g. of iododiphenyl. The two substances were easily distinguished as the latter, melting as it does above the boiling point of water at atmospheric pressure, formed a sublimate. The difference in vapor pressure of the two substances at this temperature made a separation practicable. The residue (2 g.) was found to contain tri-biphenylarsine. Similar results were obtained with bromodiphenyl.

Tri-biphenylarsine dissolves readily in hot glacial acetic acid, methyl iodide, benzene and chloroform. It is less soluble in ether and practically insoluble in cold ethyl alcohol. It dissolves in about two volumes of hot benzene, separating in aggregates of tiny needle-like crystals melting at 182–183° with preliminary softening. At the boiling point decomposition takes place with the formation of free arsenic.

Action of Water.—The interpretation of some of the results obtained necessitated a knowledge of whether or not hydrolysis of tri-biphenylarsine took place. It was found that hydrolysis did not take place on heating the substance for many hours under a reflux condenser with alcoholic potash. At higher temperatures and pressure, on the contrary, positive results were obtained with dilute hydrochloric acid. A gram of tri-biphenylarsine was heated in a sealed tube with water containing hydrochloric acid to 250" for twelve hours. On opening the tube and steam distilling the contents a sufficient amount of volatile material was collected to be identified by the odor and a mixed melting point as diphenyl.

Tri-biphenylarsine-dibromide.—To 5 g. of tri-biphenylarsine dissolved in 40 cc. of pure dry chloroform was added 1.5 g. of dry bromine. Instant absorption took place with considerable heat evolution. The resulting cream-colored precipitate of flattened needles was filtered and dried; yield, 5.5 g.

Anal.[3] **Calcd** for $C_{36}H_{27}AsBr_2 \cdot CHCl_3$: Br, 19.7. Found: Br, 19.8.

The dibromide has no definite melting point, gradually softening above 200°. It was not obtained free from chloroform of crystallization. An excess of bromine inhibits completely crystal formation in the preparation of the dibromide, while the presence of moisture brings about tar formation. Once formed and freed from the solvent the solid substance is surprisingly insensitive toward moisture, perhaps because it is so insoluble in water. At any rate, it is unaffected by cold water or long standing exposed to the atmosphere. It is decomposed by hot water and by ordinary alcohol at room temperature.

---

[3] A weighed amount of the substance after short. heating with alcoholic ammonia was evaporated to dryness, extracted with water containing a few drops of nitric acid and the filtered solution used in the regular way.

Tri-biphenylarsine-dichloride.—On bubbling chlorine through a chloroform solution of 5 g. of tri-biphenylarsine until no further absorption took place, a white crystalline precipitate quickly formed; yield, 6 g.

Anal. (for labile chlorine). Calcd. for $C_{36}H_{27}AsCl_2{\cdot}CHCl_3$: Cl, 9.8. Pound: Cl, 9.8.

The chlorine addition product melts at 272–273° with preliminary softening. It is only sparingly soluble in cold chloroform; accordingly an excellent yield is obtainable.

Action of Water.—The dichloride or dibromide was changed to a gum, which subsequently became crystalline on boiling with water. Chloroform was set free as well as halogen acid. Similar changes took place in cold alcohol, except that the new substance separated out directly in the solid phase. It was identified as tri-biphenylarsine dihydroxide, although an impure form as halogen was present even after recrystallization from alcohol. No evidence was found of the existence of the hydroxy bromide of tri-biphenylarsine.

Tri-biphenylarsine Dihydroxide.—Several grams of dichloride was heated on a steam-bath for a few minutes with a small volume of alcohol containing a few drops of ammonium hydroxide solution. The substance promptly dissolved, but a crystalline precipitate quickly appeared. It was purified by dissolving in the minimum amount of hot alcohol and adding water drop by drop until a slight turbidity resulted.

Anal. Calcd. for $C_{36}H_{29}O_2As$: As, 13.2. Found: As, 13.1.

It is sparingly soluble in alcohol, separating in microscopic prismatic needles melting at 262–263° with preliminary softening. It is easily dissolved by chloroform. Tri-biphenylarsine dihydroxide is also formed by the action of potassium permanganate on tri-biphenylarsine.

Tri-biphenylarsine Sulfide.—This was prepared by running hydrogen sulfide into an alcohol solution of the dihydroxide. The resulting precipitate of small rod-shaped crystals was filtered, washed and dried.

Anal. Calcd. for $C_{36}H_{27}AsS$: S, 5.7. Found: S, 5.5.

The sulfide is insoluble in most of the common solvents with the exception of chloroform, from which it is precipitated by alcohol as a crystalline powder melting at 239–240". Both the sulfide and dihydroxide are reduced by tin and hydrochloric acid in glacial acetic acid to tri-biphenylarsine.

Tri-biphenylmethylarsonium Iodide.—Obtained by heating for several hours under a reflux condenser 1 g. of tri-biphenylarsine dissolved in benzene with an excess (3 molar equivalents) of methyl iodide. Crystal formation started in a few minutes if the mixture was seeded, otherwise an oil separated out at first; yield, 0.8 g.

Anal. Calcd. for $C_{37}H_{30}AsI$: I, 18.8. Found: I, 18.9.

The arsonium compound is sparingly soluble in hot alcohol, separating in glittering gold-yellow plates melting at 151–152° with foaming. It decomposes at the melting point into methyl iodide and tri-biphenylarsine.

Tri-biphenylmethylarsonium iodochloride was obtained by bubbling chlorine through a warm solution of the arsonium iodide.

Anal. Calcd. for 0.1 g. of $C_{37}H_{30}AsICl_2$: AgI + AgCl, 0.0696 g. Found: AgI + AgCl, 0.0708.

It crystallizes from alcohol as a yellow powder melting at 86–88".

Tri-biphenylarsonium Hydroxide.—Two grams of the arsonium iodide derivative was shaken in alcohol with moist silver oxide, The mixture was filtered after the disappearance of the yellow color and evaporated in *vacuo* over sulfuric acid to a brittle colorless glass-like solid. This material probably contained some carbonate and sulfate picked up during the manipulation.

Anal. Calcd. for $C_{37}H_{31}OAs$: As, 13.3. Pound: As, 12.8.

No definite melting point was observed. It gradually softens on heating and foams at 120°, at which point it decomposes into methyl alcohol and tri-biphenylarsine. It is alkaline, absorbing carbon dioxide from the air on standing and turning red litmus paper blue.

Di-biphenylarsenious Chloride.—Ten grams of tri-biphenylarsine dichloride was heated to melting in a beaker; then the temperature was carefully raised until gentle boiling took place. Chloroform and chlorodiphenyl vapors were evolved. After several minutes of heating at this temperature the mixture was cooled and the resulting tar repeatedly extracted with absolute alcohol. A yellowish gummy material was deposited as the alcoholic extract cooled. The resulting solution was colorless and on concentration a white precipitate of small needle-like crystals usually was obtained. Altogether less than a gram of substance was obtained. Approximately a gram of diphenyl was isolated by the steam distillation of the residues.

Anal. Calcd. for $C_{24}H_{18}AsCl$: Cl, 8.5. Found: Cl, 7.8.

The chloride obviously was not obtained in a pure form. The substance as isolated softened above 110°, melting at 123°. It decomposes at the boiling point *in vacuo* and is easily dissolved by benzene or chloroform. It is sparingly soluble in alcohol. It is rapidly attacked by hot water, more slowly by ordinary alcohol, changing into the oxide and liberating hydrochloric acid. The hot vapors of the substance are irritating to the throat, but have no apparent effect on the skin.

Di-biphenylarsenious Oxide.—Prepared by heating the chloride with alcoholic ammonia, recrystallizing from alcohol.

Anal. Calcd. for $C_{48}H_{36}As_2O$: As, 19.3. Found: As, 19.4.

It is soluble in hot alcohol, separating as an oil in which crystalline aggregates form on standing. It gradually softens above 90° without any definite melting point.

Di-biphenylarsenious Sulfide.—Obtained as an amorphous powder by the action of hydrogen sulfide on an alcohol solution of the oxide. No definite melting point was observed, the substance gradually softening above 110".

Anal. Calcd. for $C_{48}H_{36}As_2S$: S, 4.0. Found: S, 4.5.

Di-biphenylarsinic acid was produced by passing moist chlorine through the chloride dissolved in chloroform. The oil resulting from evaporation of the solvent was dissolved in dilute sodium hydroxide solution, filtered and precipitated as an amorphous powder by dilute sulfuric acid. It was heated to melting and on cooling became crystalline.

Anal. Calcd. for $C_{24}H_{19}O_2As$: As, 9.1. Found: As, 9.1.

It softens above 95°, partially melting at 110°. This acid is soluble in alcohol and in water containing alkali-forming water-soluble salts.

Mono-biphenylarsenious Oxide.—A solution of 10 g. of tri-biphenylarsine in 50 g. of arsenic chloride was heated in a sealed tube to 300° for thirty-six hours. The mixture was then distilled up to 300° to remove arsenic chloride. Some diphenyl was also removed by this treatment. The residue (12 g.) was first washed with water containing hydrochloric acid to remove arsenious oxide; then it was extracted with alcohol. By this process any unchanged tri-biphenylarsine was left behind. The alcohol extract was concentrated and steam distilled to remove traces of diphenyl. A cream colored residue of 6 g. was obtained. It was finally purified by concentration of an alcohol solution.

Anal. Calcd. for $C_{12}H_9AsO$: As, 30.7. Found: As, 30.4.

It separates from alcohol, in which it is readily soluble, as an amorphous white powder melting at 163–165° with preliminary softening.

Mono-biphenylarsenious sulfide was prepared by the action of hydrogen sulfide on a dilute alcohol solution of the oxide. Ball-like aggregates of microscopic needles separated out. No definite melting point was observed, the substance softening above 108°.

Anal. Calcd. for $C_{12}H_9AsS$: S, 12.3. Found: S, 12.0.

Mono-biphenylarsenic Acid.—To a gram of the arsenious oxide derivative suspended in water containing a little ethyl alcohol was conducted a slow stream of chlorine for an hour. Then an excess of dilute sodium hydroxide solution was added and the mixture saturated with carbon dioxide. It was filtered and hydrochloric acid added. The resulting bulky precipitate was filtered with difficulty by suction and precipitated from alcohol by water.

Anal. Calcd. for $C_{12}H_{11}O_3As$: As, 27.0. Found: As, 27.2.

The new acid separates from alcohol as an amorphous powder partially melting at 180–181° with preliminary softening.

It is planned to continue work with these substances, also to investigate the diphenyl derivatives of antimony and bismuth.

Summary

It has been found that tri-biphenylarsine is obtainable in good yield from the interaction of arsenic chloride, 4-bromodiphenyl and sodium. Using tri-biphenylarsine as a starting point, some representative tri- and pentavalent arsenic derivatives have been prepared containing one, two and three biphenyl groups.

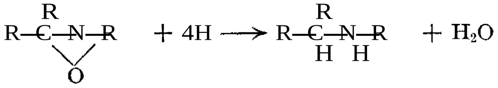
CATALYTIC REDUCTION OF O-ALKYL SUBSTITUTED OXIMES[1]

BY LAUDER W. JONES AND RANDOLPH T. MAJOR

RECEIVED JULY 23, 1929 PUBLISHED FEBRUARY 6, 1930

The reduction of N-alkyl substituted oximes was studied about thirty years ago by Dunstan and Goulding,[2] who found that sodium amalgam in absolute alcohol converted them into dialkylamines, according to the eauation



$$R{-}\underset{\diagdown\;\diagup \atop O}{\overset{R}{C}{-}N}{-}R + 4H \longrightarrow R{-}\underset{H}{\overset{R}{C}}{-}\underset{H}{N}{-}R + H_2O$$

The corresponding reduction of the O-alkyl substituted oximes apparently has not been investigated.

It has long been known, however, that oximes could be reduced to primary amines by the use of a number of different reducing agents.[3] Re-

---

[1] presented at the Columbus meeting of the American Chemical Society, May, 1929.

[2] Dunstan and Goulding, *J. Chem. Soc.*, **79**, 639, **640** (1901).

[3] Meyer and Jacobson, "Lehrbuch der Organischen Chemie," Verlag von Veit and Company, Leipzig, **1907**, Vol. I, Part 1, p. 349.

cently Vavon and his co-workers[4] have shown that hydrogen in the presence of a platinum catalyst reduced the hydrochlorides of oximes in dilute alcohol to N-substituted hydroxylamine hydrochlorides.

It was thought, therefore, that by using somewhat similar methods it might be possible to reduce O-alkyl oxime hydrochlorides to O,N-dialkylhydroxylamine hydrochlorides according to the equation

$$\text{R—CR=NOR·HCl} + \text{H}_2 \xrightarrow{\text{Pt}} \text{RHCR—NHOR·HCl}$$

Solutions of the O-alkyl oxime hydrochlorides were prepared in two ways. The first was to dissolve the O-alkyl oxime in a solution of the calculated amount of hydrogen chloride in 65% alcohol. The other method was to add the calculated amount of the carbonyl derivative to a solution of O-alkylhydroxyl-ammonium chloride in 65% alcohol, and to allow the solution to stand long enough to come to equilibrium, usually about an hour. However, it was found that it did not make any difference in the reductions which way the O-alkyl oxime hydrochloride was prepared.

The reductions were carried out by agitating the solution containing the platinum catalyst at room temperature in an Adams Reduction Apparatus.[5] When the solution had absorbed the calculated amount of hydrogen the platinum was removed by filtration and the alcohol and most of the water evaporated. By means of alkali the free bases were obtained from the hydrochlorides, which remained as residues. In this way O-methyl-N-amyl-3-hydroxylamine, $(C_2H_5)_2CH·NHOCH_3$, O-methyl-N-isopropylhydroxylamine, $(CH_3)_2CH·NHOCH_3$, O-methyl-N-heptyl-4-hydroxylamine, $(C_3H_7)_2CH·NHOCH_3$, and O-ethyl-N-*iso*propyl-hydroxylamine, $(CH_3)_2CH·NHOC_2H_5$ were prepared.

To serve as a means of identification, several derivatives of these compounds were made. The chloroplatinates of all of these substituted hydroxylamines except O-methyl-N-heptyl-4-hydroxylamine, which did not yield a solid chloroplatinate, were prepared. In addition, the phenyl isocyanate addition products, which have the general formula $RRCH·NOR·CO·NHC_6H_5$, of all of them except O-ethyl-N-*iso*propylhydroxylamine were formed. Also, the phenyl mustard oil addition product of O-methyl-N-amyl-3-hydroxylamine, which has the formula $(C_2H_5)_2CH·NOCH_3·CS·NHC_6H_5$, was made.

It was found that the properties of the O-ethyl-N-*iso*propylhydroxylamine that was made in this manner were identical with those ascribed to this compound by Hecker, who made it in another way.[6] O-Methyl-N-amyl-3-hydroxylamine and O-methyl-N-*iso*propylhydroxylamine, which

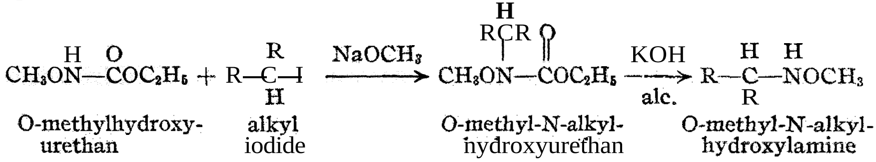
[6] Hecker, *Am. Chem. J.*, 50, 455 (1913).

previously had not been described, were also prepared, according to the equations



$$\overset{\text{H}}{\text{CH}_3\text{ON}}\!-\!\overset{\text{O}}{\text{COC}_2\text{H}_5} + \text{R}\!-\!\underset{\text{H}}{\overset{\text{R}}{\text{C}}}\!-\!\text{I} \xrightarrow{\text{NaOCH}_3} \text{CH}_3\overset{\overset{\text{H}}{\text{RCR}}}{\text{ON}}\!-\!\overset{\text{O}}{\text{COC}_2\text{H}_5} \xrightarrow[\text{alc.}]{\text{KOH}} \text{R}\!-\!\underset{\text{R}}{\overset{\text{H}}{\text{C}}}\!-\!\overset{\text{H}}{\text{N}}\text{OCH}_3$$

O-methylhydroxyurethan — alkyl iodide — O-methyl-N-alkylhydroxyurethan — O-methyl-N-alkylhydroxylamine

The properties of the hydroxylamines synthesized in this manner were the same as those of the corresponding compounds synthesized by reducing the O-alkyl oximes.

Another reaction always accompanied the formation of the O,N-dialkylhydroxylammonium chlorides when O-alkyl oxime hydrochlorides were reduced. Ammonium chloride, a ketone and an alcohol were always formed. This side reaction was most pronounced in the case of the reduction of methyl and ethyl acetoxime hydrochlorides, when about 75% of the oximes were transformed into these products. Also, O-methylacetaldoxime hydrochloride, when reduced in the same way, gave almost a quantitative yield of ammonium chloride. Presumably the formation of these products depends upon the fact that in the solution there is an equilibrium of the type shown in the equation

$$\text{R—CR=NOR·HCl} + \text{H}_2\text{O} \rightleftarrows \text{R—CR=O} + \text{RONH}_2\text{·HCl}$$

That this is probable is suggested by the fact that the usual method used to hydrolyze the O-alkyl oximes is to warm them with dilute hydrochloric acid. In this way they yield the carbonyl derivative and O-alkylhydroxylammonium chloride.? The reverse reaction of forming O-alkyl oxime hydrochlorides from carbonyl derivatives and O-alkylhydroxylammonium chlorides is indicated by some of the experiments described in this paper. In addition it was found that a solution of 0-methylacetoxime hydrochloride in dilute alcohol gave a faint test for acetone. The formation of ammonium chloride, therefore, probably depends upon the reduction of the O-alkylhydroxylammonium chloride. This has been shown to proceed quite readily, according to the equation

$$\text{RONH}_2\text{·HCl} + \text{H}_2 \xrightarrow{\text{Pt}} \text{ROH} + \text{NH}_4\text{Cl}$$

The relative amounts of ammonium chloride and O,N-dialkylhydroxylammonium chloride formed evidently might then depend in the main upon three factors: first, the percentage of the products of hydrolysis which are present at equilibrium, second, the relative ease of reduction of the O-alkylhydroxylammonium chloride and the O-alkyl oxime hydrochloride and, third, the readiness with which the system comes to equilibrium when one or more of its products are removed. The first factor mentioned must play *a* very unimportant role, since it was found that in

[7] Dunstan and Goulding, J. *Chem. Soc.*, 79, 631, 635 (1901).

the case of O-methylacetoxime hydrochloride the percentage of the carbonyl derivative in the solution at equilibrium was very small. It was also established that O-methylhydroxylammonium chloride was reduced more rapidly than any of the oximes investigated. However, it was found that, among themselves, the rate at which the oximes absorbed hydrogen varied considerably, being relatively rapid for O-methyl-diethylketoxime and slow for O-methylacetoxime, O-ethylacetoxime and O-methyl-dipropylketoxime. Another difference in the various oximes which must affect the relative amounts of ammonium chloride and O,N-dialkylhydroxylammonium chloride formed is the third factor previously mentioned, namely, the ease with which the equilibrium is reestablished after it has been disturbed. The greater general chemical activity of acetaldehyde and acetone than that of the higher ketones is in harmony with this explanation of the relatively larger amounts of ammonium chloride formed in the reduction of the substituted oximes of acetaldehyde and acetone than those of diethyl ketone and dipropyl ketone.[8]

When a solution of O-methylbenzaldoxime in dilute alcohol containing one equivalent of hydrogen chloride was reduced in the same way with one mole of hydrogen, no hydroxylamine was found among the products of reduction but instead the hydrochlorides of benzyl- and dibenzylamine and considerable unchanged O-methylbenzaldoxime were identified. These results may be represented by the following set of equations

$$C_6H_5CH{=}NOCH_3 + HCl + H_2 \xrightarrow{Pt} (C_6H_5CH_2\overset{H}{N}OCH_3{\cdot}HCl) \xrightarrow{H_2} C_6H_5CH_2NH_2{\cdot}HCl + CH_3OH$$

$$C_6H_5CH{=}NOCH_3 + HCl + H_2O \leftrightarrows C_6H_5CH{=}O + CH_3ONH_2{\cdot}HCl$$

$$C_6H_5CH{=}O + C_6H_5CH_2NH_2{\cdot}HCl \leftrightarrows C_6H_5CH{=}NCH_2C_6H_5{\cdot}HCl \xrightarrow{H_2} (C_6H_5CH_2)_2NH{\cdot}HCl$$

$$CH_3ONH_2.HCl + H_2 \xrightarrow{Pt} CH_3OH + NH_4Cl$$

In support of a mechanism of the formation of benzylammonium chloride which involves the intermediate formation of O-methyl-N-benzylhydroxylammonium chloride it may be noted that Vavon suggested, in connection with the reduction of oximes, that the protection afforded by hydrochloric acid against further reduction to an amine of the first formed hydroxylamine becomes less as the basicity of the hydroxylamine becomes smaller.[4] It is very probable that O-methyl-N-benzylhydroxylamine would be a much weaker base than any of the hydroxylamines that we have previously mentioned.

In a somewhat similar manner a solution of O-ethylacetaldoxime in acetic anhydride was reduced to ethyl acetate and ethyl acetamide, according to the equation

---

[8] Stewart, *J. Chem. Soc.*, 87, 185, 410 (1905).

$$CH_3CH{=}NOC_2H_5 + 2(CH_3CO)_2O + 2H_2 \xrightarrow{Pt} CH_3CH_2NH{—}CO{—}CH_3 + CH_3COOC_2H_5 + 2CH_3COOH$$

Experimental Part

Reduction of O-Alkylald- and Ketoxime Hydrochlorides. Method I.—One-fifth of a mole of the carbonyl derivative was added to a solution which had been made by adding the calculated amount of 5 *N* hydrochloric acid to 0.2 of a mole of O-methylhydroxylamine (Eastman Kodak Company) in 150 cc of alcohol. After this solution had been stirred and had stood for an hour, it was catalytically reduced by shaking it with hydrogen in an Adams reduction apparatus, using a pressure of 1 to 3 atmospheres of hydrogen. About 0.2 g. of a platinum catalyst was used, which was prepared by reducing with hydrogen a platinum oxide catalyst which was made according to the method of Adams and Shriner.[9] When necessary, in order to complete the reduction, more of the same catalyst was added to the solution which was being reduced. After the calculated amount of hydrogen had been absorbed, the platinum was removed by filtration and then the alcohol and nearly all of the water was evaporated on a water-bath.

Investigation of the Products Formed in the Reduction of 0-Methyl, Diethyl- and Dipropyl-ketoxime Hydrochlorides.—After the residue left from evaporating the reduced solution had been cooled it was found to consist partly of an oil and partly of a solid. Absolute alcohol was added to a little of the solid portion. That part of the solid which did not dissolve was washed with more alcohol and dried. It was shown to be ammonium chloride by its behavior on being heated, by the fact that its solution in water gave a test for the chloride ion, also that with alkalies a strong odor of ammonia was released and fourth that when benzoyl choride was shaken with an aqueous solution of it to which alkali had been added, a white solid separated, m. p. 128°, which did not lower the melting point of benzamide, m. p. 128°, when the two were mixed.[10]

The rest of the residue from which the alcohol and water had been evaporated was treated with somewhat more than the calculated amount of caustic soda. An oil was extracted from the alkaline solution with ether. The ethereal solution was dried with anhydrous sodium sulfate and then fractionated.

The O-methyl-N-alkylhydroxylamines were colorless oils, which possessed a peculiar terpene-like odor. They were readily soluble in alcohol, ether and ligroin but only slightly soluble in water.

TABLE I

ANALYTICAL AND OTHER DATA

Substituted hydroxylamine	Catalyst, g.	Time of reduction, hours	B. p., °C.	Yield, %	Nitrogen, %	
					Calcd.	Found
$(C_2H_5)_2CH{\cdot}NHOCH_3$	0.2	7	124	48	11.96	11.97
$(C_3H_7)_2CH{\cdot}NHOCH_3$	.6	44	164–166 or 88–89° at 60 mm.	38	9.64	9.68

O-Alkylacetoxime Hydrochloride.—The residue that remained when the reduced solution was evaporated was partly solid and partly an oil. A little of the solid portion was isolated and found to be ammonium chloride. It was possible to isolate in this process a yield of 70 to 80% of ammonium chloride.

In order to isolate the substituted hydroxylamine, the rest of the solid-oil residue mentioned above was made alkaline with concentrated potassium hydroxide and the

free base condensed after water had been removed from it by passing the vapors through solid pieces of potassium hydroxide kept at a temperature of 97°. In order to remove dissolved ammonia air was blown for a short time through the liquid which condensed. It was then redistilled. The substituted hydroxylamines obtained were clear, colorless liquids. O-Methyl-*iso*propylhydroxylamine had a terpene-like odor, but it was not as pronounced as was that of O-methyl-N-amyl-3-hydroxylamine. However, O-ethyl-N-isopropylhydroxylamine had an odor more like ethylamine.

[a] Hecker, Am. Chem. J., 50, 455 (1913), gives 78° as the b. p

O-Methylacetaldoxime Hydrochloride.—The reduction of 0.2 of a mole of O-methylacetaldoxime hydrochloride in the presence of 0.2 g. of platinum catalyst required four hours. Evaporation of the reduced solution left almost pure ammonium chloride, which was identified in the manner previously described.

O-Methylbenzaldoxime in a Solution of Hydrogen Chloride in Dilute Alcohol.—The reduction of 0.1 of a mole of O-methylbenzaldoxime in 0.1 of a mole of hydrogen chloride in dilute alcohol in the presence of two successively added portions of 0.2 g. of the platinum catalyst required forty-five hours. The reduced solution was concentrated on a water-bath until precipitation started. A white solid appeared when it was cooled, which was filtered off and recrystallized from hot butanol; m. p. 263" corr.;[11] yield, 1.2 g. A test for the chloride ion with silver nitrate was positive. It was only slightly soluble in benzene and ether but more readily soluble in water and alcohol. *Anal.* Calcd. for $(C_6H_5CH_2)_2NH\ HCl$: Cl, 15.20. Found: Cl, 15.20. In order to establish the identity of this hydrochloride more completely, its base was isolated by means of alkali, this solution extracted with ether and the ether solution dried with sodium sulfate. An oil was left, when the ether was distilled, which was dissolved in alcohol. Approximately the calculated amount of phenyl isothiocyanate was then added and the solution was warmed for a few minutes. After it had been cooled a white solid was precipitated from it by the addition of petroleum ether; m. p. 145–146°. It possessed all of the properties ascribed by Dixon[12] to α-phenyl-β,β-dibenzylthiourea.

Water was added to the filtrate from which the above-mentioned hydrochloride, m. p. 263°, was removed. An oil separated which was extracted with ether; the ether solution was dried with anhydrous sodium sulfate and then fractionally distilled. After the ether had passed over, all of the oil that remained, aside from a very small amount of a very high-boiling liquid which was unidentified, distilled from 187–194°; yield 2 g. Since this liquid was insoluble in water and dilute acid and since its boiling point was about that of O-methylbenzaldoxime, which boils at 191°,[13] it seemed probable that it was this substituted oxime. In order to hydrolyze it a portion of this liquid was accordingly dissolved in concentrated hydrochloric acid. As it stood at room temperature an oil gradually separated which had the odor of benzaldehyde. After a day this

---

[11] Limpricht, Am., 144, 314 (1867), gives 256° (probably uncorrected) as the m. p. of dibenzylammonium chloride.

[12] Dixon, *J.* Chem. Soc., 63, 539 (1893).

[13] Traube, *Ber.*, 53, 1486 (1920).

oil was extracted with ether. A solution of *p*-nitrophenylhydrazine hydrochloride in water was shaken for several minutes with this ether solution. Evaporation of the ether left a reddish-brown solid, which was recrystallized from alcohol; m. p. 193°.[14] The aqueous solution from which the benzaldehyde was extracted was evaporated to dryness on a water-bath. A white solid remained which was recrystallized by dissolving it in absolute alcohol and reprecipitating it with dry ether; m. p. 148°.[15] When alkali was added to this hydrochloride the characteristic odor of O-methylhydroxylamine was noted.

The aqueous solution from which the O-methylbenzaldoxime was extracted was made alkaline with caustic soda. An oil separated which was extracted with ether. After the ether solution had been dried with sodium sulfate it was fractionated. An oil which boiled at 184–185° was obtained; yield. 1 g.[16] To a solution of a small amount of this oil in benzene was added the calculated amount of phenyl isocyanate. After this solution had stood overnight a white solid was found, which was recrystallized from alcohol; m. p. 170–171°. α-Phenyl-β-benzylurea made from benzyl isocyanate and aniline according to the method of Letts[17] also melted at 170–171°. In addition, a mixture of these two solids melted at 170–171°, which indicates that the liquid which boiled at 184–185° was benzylamine.

Method II

Preparation of O-Methylketoximes, $R_2C{=}NOCH_3$.—To 0.2 of a mole of O-methylhydroxylamine was added 0.2 of a mole of the ketone. After the solution had stood for four days anhydrous calcium chloride was added to it to absorb water. The unabsorbed oil was decanted, again dried with calcium chloride and fractionated. O-Methylacetoxime boiled at 72–74°;[18] yield, 20%. O-Methyldiethylketoxime distilled at 116–117°; yield, 66%. It was readily soluble in alcohol, ether and ligroin but insoluble in water.

Anal. Calcd. for $C_6H_{13}ON$: N, 12.17. Found: N, 12.36.

Reduction of O-Methylketoxime Hydrochlorides.—The calculated amount of 4 N hydrochloric acid necessary to neutralize it was added to the O-methylketoxime and then sufficient alcohol was added in order to unite the two liquid layers which were at first present. The solution was reduced in the manner described previously for the reduction of the O-methyldialkylketoxime hydrochlorides prepared by the other method

Ammonia and O-methyl-N-amyl-3-hydroxylamine, b. p. 124°, with its characteristic terpene-like odor were obtained from the reduction products of O-methyldiethylketoxime hydrochloride in the same way as was described previously.

When the reduction of the 0-methylacetoxime hydrochloride was complete the solution gave a distinct qualitative test for methyl alcohol with guaiacol sulfate,[19] and for acetone with sodium nitroprusside.[20] The presence of acetone was also proved

---

[14] Rosenthaler, "Der Nachweis organischer Verbindungen," Verlag von Ferdinand Enke, Stuttgart, 1914, p. 132, gives 192–193° as the m. p. of benzaldehyde-*p*-nitrophenylhydrazone.

by the formation of its *p*-nitrophenylhydrazone when p-nitrophenylhydrazine hydrochloride was added to the solution which had been reduced. It melted at 149" and did not lower the melting point of acetone-p-nitrophenylhydrazone; m. p. 149°.[21] When the reduced solution was evaporated, a white solid and a small amount of oil were obtained. The solid portion was proved to be ammonium chloride by tests which have been mentioned previously.

α-Phenyl-*β*-methoxy-*β*-amyl-3-thiourea, $C_6H_5NHCS{\cdot}N(OCH_3){\cdot}CH(C_2H_5)_2$.—To a solution of 2.7 g. (0.02 mole) of phenyl isothiocyanate in benzene was added 2.4 g. (0.02 mole) of O-methyl-N-amyl-3-hydroxylamine, which was obtained from the reduction products of O-methyldiethylketoxime hydrochloride. After the solution thus formed had stood at room temperature for a day the benzene was evaporated. A white solid remained which was recrystallized from 50% alcohol; m. p. 57". It was soluble in alcohol, benzene and ligroin, but insoluble in water.

Anal. Calcd. for $C_{13}H_{20}ON_2S$: N, 11.11. Found: 11.61.

Reduction of O-Methylhydroxylammonium Chloride.—The calculated amount of 4 N hydrochloric acid was added to 0.2 of a mole of 0-methylhydroxylamine. It was reduced in one hour by hydrogen in the presence of 0.2 g. of the platinum catalyst in the usual manner. The solution which had been reduced gave a strong test for methanol with guaiacol sulfate.[19] Ammonium chloride was left as a residue when the reduced solution was evaporated to dryness. It was identified in the same way as was the ammonium chloride formed in the reduction of the O-alkylacetoxime hydrochlorides which has been previously described.

Partial Hydrolysis of 0-Methylacetoxime Hydrochloride.—A solution prepared by mixing equivalent proportions of O-methylhydroxylamine, hydrochloric acid and acetone in dilute alcohol. in the same way as was that prepared for reduction, was allowed to stand for half an hour. At the end of this time it was tested for acetone with sodium nitroprusside.[20] The depth of color produced in this test was compared with the color produced in standard solutions of acetone in dilute alcohol which were treated in the same way. By such comparisons it was found that the solution being tested contained a little acetone but that the amount was less than 5% of that originally added. However, when it was heated rapidly, cooled and then retested, the percentage of acetone was considerably higher for a short time.

Reduction of O-Ethylacetaldoxime in Acetic Anhydride.—A solution of 3.4 g. of O-ethylacetaldoxime in 10 cc. of acetic anhydride was reduced with hydrogen in the usual way in the presence of 0.2 g. of platinum catalyst. Somewhat more than one molecular equivalent of hydrogen was absorbed in fifty minutes. When the reaction bottle was opened at the end of the experiment, the odor of ethyl acetate was quite pronounced. In order to hydrolyze the solution it was refluxed for an hour with a solution of 20 g. of potassium hydroxide in 40 cc. of 50% alcohol and then the volatile portion distilled into dilute hydrochloric acid. This acid solution was evaporated almost to dryness on a water-bath. A concentrated solution of potassium hydroxide was added to the residue and the free base which was released was condensed after it had been passed through solid potassium hydroxide at 97°. When it was redistilled it boiled under 25". A white solid formed when it was shaken with ethyl oxalate, m. p. 181°. The melting point was not changed when it was mixed with diethyloxamide.[22]

O-Methyl-N-Alkylhydroxylamines from O-Methyl-N-Substituted Hydroxyurethans

Preparation of O-Alkylhydroxyurethan, $RONHCOOC_2H_5$.—O-Methyl- and O-ethyl-hydroxyurethans were prepared by a modification of the method used by Major

---

[21] Bamberger and Sternitzki, *Ber.*, 26, 1306 (1893).

[22] Schiff, *ibid.*, 17, 1034 (1884), gives 179" as the m. p. of diethyloxamide.

and Fleck[23] to prepare O,N-dialkylhydroxyurethans and small amounts of O-alkylhydroxyurethans. In order to increase the amount of O-alkylhydroxyurethan, only 2.1 moles of dialkyl sulfate and 600 cc. of a 20% solution of potassium hydroxide were used instead of the 4.25 moles of the former and the 3200 cc of the latter which were used by these investigators. Otherwise the preparation of the O-alkylhydroxyurethans was carried out as it is described by these authors: O-methylhydroxyurethan, yield, 29%, b. p. 186–188°; O-ethylhydroxyurethan, yield, 43%, b. p. 195–196°.

Preparation of **O-Methyl-N-alkylhydroxyurethan, $CH_3ONRCOOC_2H_5$.**—One molecular equivalent of sodium dissolved in absolute methanol was added to a solution of one molecular equivalent each of O-methylhydroxyurethan and of alkyl iodide. After this mixture had been well shaken and had stood at room temperature for a day a rather large white precipitate had formed. In order to complete the reaction the mixture was refluxed for five hours. At the end of this time most of the methanol was distilled off and water was added to the residue in order to dissolve the white solid. This aqueous solution was then extracted repeatedly with ether. Then, in order to remove unchanged O-methylhydroxyurethan, the ether solution was in turn extracted several times with a dilute solution of sodium hydroxide. The ether solution was dried with anhydrous sodium sulfate, the ether distilled and the oil that remained was fractionated. O-Methyl-N-*iso*propylhydroxyurethan boiled at 164–167° (at 734 mm.); yield, 49% (31 g.). O-Methyl-N-amyl-3-hydroxyurethan boiled at 196°; yield, 16% (3 g.).

Anal. Calcd. for $C_7H_{15}O_3N$: N, 8.70. Found: N, 9.22. Calcd. for $C_9H_{19}O_3N$: N, 7.41. Found: N, 8.09.

Preparation of **O-Methyl-N-*iso*propylhydroxylamine, $(CH_3)_2CH{\cdot}NHOCH_3$.**—A solution of 0.125 mole of O-methyl-N-*iso*propylhydroxyurethan in 50% alcohol containing 0.475 mole of potassium hydroxide was refluxed for three hours. The volatile portion was then distilled into dilute hydrochloric acid. This acid solution was evaporated to dryness on a water-bath. An oily hydrochloride was left as a residue, from which the free base was obtained by warming it with potassium hydroxide. The vapors which formed were passed through solid potassium hydroxide at a temperature of 97°. Redistillation gave a light liquid with a terpene-like odor; b. p. 75–76°; yield, 60%.

Preparation of **O-Methyl-N-amyl-3-hydroxylamine, $(C_2H_5)_2CHNHOCH_3$.**—A solution of 2.4 g. (0.013 mole) of O-methyl-N-amyl-3-hydroxyurethan in 50% alcohol containing 3 molecular equivalents of potassium hydroxide was refluxed for four hours. The volatile portion was then distilled into dilute hydrochloric acid. This acid solution was evaporated to dryness on a water-bath. Sufficient cold caustic soda to more than combine with all of the chloride ion was added to this residue. Then the alkaline solution was extracted with ether, the ether solution was dried with sodium sulfate and then fractionally distilled. After the ether had been distilled, an oil remained which boiled at 124" and possessed the characteristic terpene-like odor of O-methyl-N-amyl-3-hydroxylamine; yield, 32%.

Chloroplatinates of **O-Alkyl-N-alkylhydroxylamines.**—Somewhat more than the calculated amount of hydrogen chloride was passed into a solution of the O-alkyl-N-alkylhydroxylamine in absolute alcohol. To this solution was added the calculated amount of a concentrated solution of chloroplatinic acid in absolute alcohol. When dry ether was added an orange-colored precipitate formed. In order to purify it, it was redissolved in absolute alcohol and reprecipitated with dry ether in the form of orange-yellow colored needles.[24]

[23] Major and Fleck, THIS JOURNAL, 50, 1479 (1928).

[24] It was necessary to fractionally precipitate the chloroplatinate formed from the O-methyl-N-isopropylhydroxylamine which was obtained when O-methylacetoxime

TABLE III

CHLOROPLATINATES OF THE O-METHYL-N-ALKYLHYDROXYLAMINES WHICH WERE FORMED BY THE HYDROLYSIS OP O-METHYL-N-ALKYLHYDROXYURETHANS

Substituted hydroxylamine	M. p., °C. with dec.	Platinum, % Calcd.	Pound
O-Methyl-N-*iso*propyl-	183	33.19	32.93
O-Methyl-N-amyl-3-	161	30.30	30.10

TABLE IV

CHLOROPLATINATES OF THE O-ALKYL-N-ALKYLHYDROXYLAMINES WHICH WERE OBTAINED FROM THE REDUCTION PRODUCTS OF O-ALKYLKETOXIME HYDROCHLORIDES

Substituted hydroxylamine	M. p., °C. with dec.	Platinum, % Calcd.	Found
O-Methyl-N-*iso*propyl-	183[a]	33.19	32.74
O-Ethyl-N-*iso*propyl-	174	31.68	31.65
O-Methyl-N-amyl-3-	161[b]	30.30	30.54

[a] A mixture of the chloroplatinates of the O-methyl-N-*iso*propylhydroxylamine which was obtained from the reduction product of O-methvlacetoxime hvdrochloride and of that formed in the hydrolysis of O-methyl-N-*iso*propylhydroxyurethan also melted with decomposition at 183°.

[b] A mixture of the chloroplatinate which was obtained from the reduction product of O-methyldiethylketoxime hydrochloride and that formed in the hydrolysis of O-methyl-N-amyl-3-hydroxyurethan also melted with decomposition at 161°.

α-Phenyl-β-methoxy-β-alkylureas, $C_6H_5NHCONROCH_3$.—α-Phenyl-β-methoxy-β-amyl-3-urea was prepared by letting a solution of equimolecular proportions of O-methyl-N-amyl-3-hydroxylamine and phenyl isocyanate in benzene stand for five hours. When the benzene was evaporated, an oil remained as a residue, which solidified after it had stood overnight in a vacuum desiccator. In order to purify it, it was dissolved in freshly distilled petroleum ether, extracted with dilute hydrochloric acid and then the petroleum ether was evaporated. The solid was dried in a vacuum desiccator containing sulfuric acid and solid potassium hydroxide. It was readily soluble in all ordinary organic solvents but insoluble in water.

The other α-phenyl-β-methoxy-β-alkylureas were formed when a solution of equimolecular proportions of the O-methyl-N-alkylhydroxylamine and phenyl isocyanate in petroleum ether had stood for an hour. The white solid precipitated from the petroleum ether was recrystallized from hot ligroin.

The α-phenyl-β-methoxy-β-*iso*propylurea which was made from the O-methyl-N-*iso*propylhydroxylamine that had been obtained from O-methyl-N-isopropylhydroxyurethan melted at 73°.

Anal. Calcd. for $C_{11}H_{16}O_2N_2$: N, 13.46. Found: N, 13.79.

---

hydrochloride was reduced. The first portion of the precipitate which formed when ether was added to the solution of the chloroplatinate in alcohol did not melt sharply and analysis revealed that it contained a lower percentage of platinum than that calculated for O-methyl-N-*iso*propylhydroxylamine chloroplatinate. The larger fraction of the chloroplatinate which was precipitated when more ether was added to the filtrate melted sharply and as may be seen from the following table it yielded, within the experimental error the calculated percentage of platinum for the chloroplatinate of O-methyl-N-*iso*propylhydroxylamine. The fraction which first precipitated probably contained a very small amount of ammonium chloride. This was probably formed due to the presence of a small amount of dissolved ammonia in the O-methyl-N-*iso*propylhydroxylarnine.

TABLE V

α-PHENYL-β-METHOXY-β-ALKYLUREAS THAT WERE FORMED FROM THE O-METHYL-N-ALKYL-HYDROXYLAMINES WHICH HAD BEEN OBTAINED FROM THE REDUCTION PRODUCT OF O-METHYLKETOXIME HYDROCHLORIDES

Alkyl group	M. p., °C.	Nitrogen, %	
		Calcd.	Found
Isopropyl-	73[a]	13.46	13.43
Amyl-3-	59	11.86	12.11
Heptyl-4-	109	10.41	10.74

[a] A mixture of the α-phenyl-β-methoxy-β-*iso*propylureas that were obtained from the O-methyl-N-*iso*propylhydroxylamine formed from the reduction product of O-methylacetoxime hydrochloride and that which was formed from O-methyl-N-*iso*propyl-hydroxyurethan also melted at 73°.

Summary

1. Several O-alkylketoxime hydrochlorides have been catalytically reduced in dilute alcohol to O-alkyl-N-alkylhydroxylamine hydrochlorides, ammonium chloride and other products. The mechanism of the formation of these compounds has been discussed.

2. The corresponding O-alkyl-N-alkylhydroxylamines have been synthesized by the hydrolysis of O-alkyl-N-alkylhydroxyurethans, which were made by the action of alkyl iodides on O-alkyl-hydroxyurethans in the presence of sodium methylate.

3. A number of derivatives of these substituted hydroxylamines have been prepared.

4. The only nitrogen-containing compound that was isolated when O-methylacetaldoxime hydrochloride was catalytically reduced was ammonium chloride, but when O-ethylacetaldoxime dissolved in acetic anhydride was reduced, ethyl acetate and ethyl acetamide were obtained.

5. When O-methylbenzaldoxime was catalytically reduced in a solution of hydrogen chloride in dilute alcohol, benzyl- and dibenzylammonium chlorides were formed. The mechanism of the formation of these compounds has been discussed.

STUDIES ON PYRETHRUM FLOWERS. II. THE RELATION BETWEEN MATURITY AND PYRETHRIN CONTENT

BY C. B. GNADINGER AND C. S. CORL

RECEIVED JULY 23, 1929 PUBLISHED FEBRUARY 6, 1930

Handlers of *Pyrethrum* flowers have quite generally held the opinion that the immature or closed flowers have greater insecticidal power than open or mature flowers. So firmly fixed has this idea become, that closed Dalmatian flowers command a premium of five to six cents a pound over half-closed flowers, which in turn, cost two to three cents a pound more than open flowers. At the present time, Dalmatian open flowers are slightly higher in price than Japanese flowers, which are not graded as closed and open.

In a previous paper[1] the writers described a method for determining the percentage of active principles in *Pyrethrum* flowers. By the application of this method to flowers in different stages of maturity, it has been possible to determine the comparative value of open and closed flowers.

Experimental Part

Difficulty was experienced in obtaining suitable material, because *Pyrethrum* flowers are not grown commercially in the United States. Through the courtesy of Mr. E. B. Fischer of the College of Pharmacy, University of Minnesota, a plot of *Pyrethrum roseum* was made available for this work. Samples were collected from these plants, which were three to five years old, at intervals throughout the flowering season, and the flowers were carefully shade dried. The analyses of the samples are presented in Table I.

Before the buds were formed, the roots, leaves and stems did not contain any pyrethrins. As the buds formed and developed, their pyrethrin content gradually increased. The last and most mature sample contained four times the percentage of pyrethrins found in the unexpanded buds. Samples four and six represented closed flowers at the same stage of development but collected at different times; sample six contained considerably more active material than number four, indicating that the pyrethrin content depends on the maturity of the plant as well as on the development of the flowers. The average weight of the open flowers was two to three times that of the closed flowers, and the pyrethrin content of the former was about double that of the closed flowers. Therefore, the yield of pyrethrins from a given unit of land can be approximately quadrupled by merely allowing the flowers to mature.

---

percentage of closed, half-closed and open flowers was determined. A portion of the original sample was then ground and analyzed. From the remainder of the original sample, the closed and open flowers were carefully separated, selecting only complete flowers and rejecting those from which parts were missing. The pyrethrin content of the closed and open flowers was determined. The results obtained are compared in Table II.

The open flowers contained from 18 to 61% more active principle than the closed flowers from the same lots.

It is well known that certain parts of the Pyrethrum flower-head contain more active principle than others,[2] but the distribution of the pyrethrins in the different flower parts has not been determined accurately heretofore. A sample of uncompressed Japanese flowers was carefully separated into the principal parts, using for this purpose flowers from which none of the parts were missing. The analyses of these parts are given in Table III.

TABLE III

DISTRIBUTION OF ACTIVE PRINCIPLE IN JAPANESE PYRETHRUM CINERARIAEFOLIUM

Sample No. 25	Composition of flowers, %	Pyrethrins, %	Percentage of total pyrethrins
Achenes	34.2	2.27	92.4
Receptacles	11.3	0.26	3.5
Involucral scales	11.5	0.15	2.0
Disk florets	25.8	Trace	..
Ray florets	17.2	Trace	..
Original sample	..	0.84	..
Stems	..	0.15	..

---

[2] U. S. Dept. Agr., "Insect Powder," Bulletin 824 revised, 1926.

The achenes contained 92.4% of the total pyrethrins; the receptacles and scales contained 3.5 and 2.0%, respectively, while the disk and ray florets contained mere traces. Analysis of the original sample showed 0.84% of pyrethrins, while calculation of the total pyrethrin content from the analyses of the parts gave a pyrethrin content of 0.82%. It would seem, therefore, that a high pyrethrin content depends on the development of the achenes.

The fact that the receptacles and scales and other outer parts of the flower-head contain only a small proportion of pyrethrins is of some importance. Should an attempt be made to increase the apparent pyrethrin content, obtained by the use of the method,' by coating or spraying flowers with a petroleum-ether soluble, copper reducing material, the adulteration could be detected by the high pyrethrin content of the outer parts of the flower. This is apparent from Table IV, in which the pyrethrin content of the outer parts of five samples of flowers is reported.

TABLE IV

PYRETHRIN CONTENT OF RECEPTACLES AND INVOLUCRAL SCALES

No.	Rind of flowers	Pyrethrins, in recept.,[a] %	Recept.[a] in flowers, %	Percentage of total pyrethrins in recept.[a]	Pyrethrins in orig. flowers, %
20	Japanese	0.27	25.0	7.0	0.96
25	Japanese	.20	22.8	5.4	.84
25	Japanese (closed)	.26	30.8	10.5	.76
23	Dalmatian	.17	31.1	10.0	.53
24	Dalmatian	.17	30.0	9.8	.52

"Scales included.

Summary

Contrary to popular belief, the pyrethrin content increases as the flowers mature, so that open flowers contain more active principle than closed flowers from the same plants. There is also some evidence that the earlier flowers produced contain less pyrethrins than the later flowers but this was not proved conclusively. Open flowers from commercial samples contained from 18 to 61% more active principle than closed flowers from the same lots.

The average weight of the open flowers is about double that of closed flowers. Therefore, the pyrethrins produced from a given tract of land can be increased three to four times by merely allowing the flowers to mature.

The roots, stems and leaves contain no pyrethrins before the flower buds are formed.

In the sample analyzed the achenes contained more than 90% of the active material. The receptacles and involucral scales contained most of the remainder. The disk and ray florets yielded only traces of pyrethrins. The low pyrethrin content of the outer parts of the flower is important because it affords a means for detecting certain types of adulteration.

STUDIES ON PYRETHRUM FLOWERS. III. THE PYRETHRIN CONTENT OF DIFFERENT COMMERCIAL VARIETIES

BY C. B. GNADINGER AND C. S. CORL

RECEIVED JULY 23, 1929 PUBLISHED FEBRUARY 6, 1930

The three species of *Pyrethrum* flowers that have insecticidal value are *Pyrethrum cinerariaefolium, Pyrethrum roseum* and *Pyrethrum carneum;* of these *Pyrethrum cinerariaefolium* is by far the most important. In 1928 more than eleven million pounds of *Pyrethrum cinerariaefolium* were imported into the United States from Europe and Japan, the latter country supplying about five times as much as all other sources combined. The amount of *Pyrethrum roseum* imported is negligible, but it is widely grown in this country for its ornamental flowers. *Pyrethrum carneum* is of no commercial importance.

The two principal commercial varieties of flowers, Dalmatian and Japanese, belong to the species *Pyrethrum cinerariaefolium.* There are several commercial grades of these flowers and it has been shown[1] that the trade preference for certain grades is unwarranted. The purpose of this paper is to show the comparative value of the different commercial varieties of *Pyrethrum* flowers.

Experimental

Twenty-eight commercial samples of whole flowers were collected from dealers in the United States and also from agents in Japan and Europe. Twenty samples of powdered commercial flowers were kindly supplied by Dr. C. C. McDonnell, Chief, Insecticide Control, United States Department of Agriculture. These powders had been kept in air-tight containers for two or three years. Two samples of *Pyrethrum cinerariaefolium* grown in Virginia were obtained through the courtesy of Dr. A. F. Sievers, Senior Biochemist, Bureau of Plant Industry, United States Department of Agriculture. Five samples of Minnesota and Iowa grown *Pyrethrum roseum* were collected and ten samples of ground or powdered commercial lots were obtained from large manufacturers of *Pyrethrum* sprays. Samples of *Pyrethrum carneum* could not be obtained.

The flowers were examined to determine the proportion of closed, half-closed, and open flowers and stems. Some of the Japanese flowers were com-

pressed so that such a separation could not be made. The Department of Agriculture samples (numbers 31 to 50 inclusive) had been examined, before powdering, by Mr. George L. Keenan, Microanalyst, Food, Drug and Insecticide Administration. The results showing the percentage of achenes, disk florets, ray florets and receptacles in the twenty powdered samples are Mr. Keenan's and are published by permission. The whole flowers were ground to about 40-mesh, taking care to avoid heating during the grinding.

The pyrethrins, or active principles, were determined by the method previously described;[2] the analyses are reported in Table I and are summarized in Table II.

There was little or no difference in the pyrethrin content of the different grades of Dalmatian flowers. In general, the closed flowers yielded more color and extractive than the open flowers. Some of the samples that had been powdered for several years yielded almost colorless extracts but the pyrethrin content was as high as that of freshly ground new flowers. The pyrethrin content of the Dalmatian flowers ranged from 0.38 to 0.58%. Staudinger and Harder[3] found 0.4 to 0.6% of pyrethrins in the Dalmatian samples they analyzed.

The Japanese flowers contained from 0.58 to 1.21% of pyrethrins and averaged twice the pyrethrin content of the Dalmatian flowers.

It is interesting to note that American grown *Pyrethrum cinerariaefolium* is richer in active principle than Dalmatian and equal to Japanese. American grown *Pyrethrum roseum* averaged higher than Dalmatian *P. cinerariaefolium* and lower than Japanese. Ten commercial samples averaged 0.63%. No connection could be found between the appearance of the flowers and the pyrethrin content.

Summary

Japanese *Pyrethrum cinerariaefolium* has about twice the insecticidal value of Dalmatian flowers. Flowers equal to the Japanese can be grown

in America. The pyrethrin content of P. *roseum* is about the same as that of P. *cinerariaefolium*.

ALKALI METAL DERIVATIVES OF PHENYLATED METHANES AND ETHANES

BY CHARLES BUSHNELL WOOSTER[1] AND NEWELL WILSON MITCHELL[2]

RECEIVED JULY 29, 1929 PUBLISHED FEBRUARY 6, 1930

The fact that many of the colored organo-alkali compounds conduct the electric current in ether and in liquid ammonia solution,[3] and behave in other ways as salts, implies that the corresponding hydrides should exhibit an acidic character, albeit an exceedingly weak one. In fact, it has been shown that they may react with the ammono-base, potassium amide, in liquid ammonia solution to form the potassium salts. Thus triphenylmethane forms potassium triphenylmethide[4]

$$(C_6H_5)_3CH + KNH_2 \longrightarrow NH_3 + (C_6H_5)_3CK \qquad (1)$$

and potassium benzhydrolate yields dipotassium benzophenone[5]

$$(C_6H_5)_2CHOK + KNH_2 \longrightarrow (C_6H_5)_2CKOK + NH_3 \qquad (2)$$

This behavior indicates that these hydrides are ionized to a greater degree than the solvent ammonia, for otherwise reaction would be expected to proceed in the opposite direction corresponding to an ammonolysis of the salts. In the case of the alkali alkyls and alkali phenyls[6] such an ammonolysis does occur, demonstrating that the corresponding hydrocarbons are ionized to a less degree than ammonia.[7] Accordingly it is impossible to obtain organo-alkali compounds by the action of potassium amide upon these hydrocarbons.

[7] Strictly speaking the ionization of ammonia does not constitute a sharp line of demarcation between hydrocarbons whose salts are completely stable and those whose salts are completely ammonolyzed. Hydrocarbons whose ionization lies either closely above or below that of ammonia would be expected to yield salts whose ammonolysis would reach an equilibrium when appreciable amounts of both the salt and hydrocarbon were present. In all cases considered in this paper, however, the salt was either formed in very large proportions or else in amounts so minute as to escape detection. Thus it is permissible to conclude that the ionization of these hydrocarbons was either considerably above or considerably below that of the solvent.

It is not possible to apply the usual methods to determine the ionization constants of such very weak and sparingly soluble acids, but the facts just reviewed suggest the use of potassium amide in liquid ammonia to differentiate between those hydrides whose ionization is greater and those whose ionization is less than that of this solvent. The results of applying this test to a series of phenylated methanes and ethanes appear in Table I. The action of potassium metal upon the same hydrocarbons in liquid ammonia is also indicated.

TABLE I

THE ACTION OF POTASSIUM AND OF POTASSIUM AMIDE ON PHENYLATED METHANES AND ETHANES

No.	Hydrocarbon formula	Potassium	Potassium amide
1	$C_6H_5CH_3$	No action	No action
2	$(C_6H_5)_2CH_2$	Reacts	Reacts
3	$(C_6H_5)_3CH$	Reacts	Reacts
4	$(C_6H_5)_4C$	No action	No action
5	$C_6H_5CH_2CH_3$	No action	No action
6	$C_6H_5CH_2CH_2C_6H_5$	No action	No action
7	$(C_6H_5)_2CHCH_2C_6H_5$	Reacts	Reacts
8	$(C_6H_5)_3CCH_3$	Reacts slightly	No action
9	$(C_6H_5)_2CHCH(C_6H_5)_2$	Reacts	Reacts
10	$(C_6H_5)_3CCH_2C_6H_5$	Reacts slightly	No action
11	$(C_6H_5)_3CC(C_6H_5)_3$	Adds	...

From these data it is apparent that the ability of potassium amide to replace with potassium a hydrogen atom in hydrocarbons of this class is confined to those compounds (Numbers 2, 3, 7 and 9 in Table I) in which at least two phenyl groups are attached to a single carbon atom. Since no reaction occurs unless a hydrogen atom is also attached to the same carbon atom as are the two or more phenyl groups (see Numbers 4, 8 and 10), it is very likely that it is this hydrogen atom which is replaced. This circumstance may be of use as a principle for deciding the structure of hydrocarbons and organo-alkali compounds of these types.

In certain instances potassium metal is capable of reacting slightly with hydrocarbons on which the amide has no action. This may be due to addition to the carbon–carbon bond between the ethanic carbon atoms, for a similar action of sodium–potassium alloy and of 40% sodium amalgam has been reported by Ziegler and Thielmann and Conant and Garvey.[8] In this connection it is interesting to note that the metal is without action on tetraphenylmethane. This fact favors a negative answer to the question of the partial dissociation of this compound raised by Walden[9] in discussing the molecular weights obtained by Kraus and Kawamura.[10]

[10] Kraus and Kawamura, THIS JOURNAL, 45,2756 (1923).

The Relative "Electronegativity" of Organic Radicals.—The ionization of toluene is apparently intermediate between that of diphenylmethane and those of benzene and aliphatic hydrocarbons, for although toluene does not react with potassium amide, benzyl bromide and potassium metal yield potassium benzylide which is capable of a transient existence in liquid ammonia as evidenced by its red color and by its reaction with excess benzyl bromide to form dibenzyl. Under similar conditions the alkali phenyls and alkali alkyls are ammonolyzed too rapidly to show such reactions. Thus the ionization of methane (as hydrogen methide) appears to be progressively increased by the substitution of phenyl groups. This is in accordance with Lewis' idea as elaborated in his monograph and with the concepts of Lucas[11] but is the reverse of the series of radicals as arranged in the order of increasing "electronegativity" by Kharasch and Marker.

These authors criticize the conceptions of Lewis in the following terms[12]—"It seems to us, however, more logical that the phenyl radical would in virtue of its electronegativity attract the pair of electrons from the methyl carbon atom, become then negatively charged and repel other electrons from the methyl carbon atom, making the benzyl group much less electronegative than the methyl." In this logic they appear to have overlooked the fact that in attracting the electrons of the methyl carbon atom to a sufficient extent to become negatively charged, as they assume, the phenyl group must leave the former positively charged, with an increased ability to attract electrons, and thus, according to their own definitions more "electronegative."[13]

Moreover, it is difficult to reconcile their conclusions not only with the experimental results which appear in Table I, but also with such a fact as that the substitution of phenyl radicals in ethylene eventually renders the double bond inactive toward bromine but capable of readily adding the alkali metals.[14]

Also, in applying their concepts to the dissociation of free radicals these authors predict that the compound X_3C-CX_3 should be less stable and more highly dissociated than hexaphenylethane whenever the radical X is more "electronegative" than phenyl. This prediction is not supported

[11] (a) Lewis, "Valence and the Structure of Atoms and Molecules," American Chemical Society Monograph, The Chemical Catalog Co., New York, 1923; (b) Lucas, THIS JOURNAL, 48, 1828 (1926).

[12] Kharasch and Marker, *ibid.*, 48, 3138 (1926).

[13] Since this paper was submitted for publication an article by Smyth [ibid., 51, 2386 (1929)] has appeared in which attention is called to the same error in connection with the postulates of Kharasch and Darkis [*Chem. Rev.*, 5, 582 (1928)] regarding the influence of substitution on the polarity of the double bond.

[14] (a) Schlenk, Appendrot, Michael and Thal, ***Ber.***, 47, 473 (1914); (b) Schlenk and Bergmann, ***Ann.***, 463, 2–97 (1928).

by the behavior of dichlorotetraphenylethane,[15] $(C_6H_5)_2CClCCl(C_6H_5)_2$, dichlorotetrabiphenylethane,[16] hexanitroethane[17] and hexachloro-ethane,[18] none of which appear to be dissociated into free radicals. Accordingly, their view that "'. . . . the weight or complexity of the radical is of no significance—it is the electronegativity of the radical attached to the methyl carbon atom that is of paramount importance" is a too narrow one.

Such marked discrepancies cast doubt upon the general applicability of Kharasch and Marker's table of the relative "electronegativity" of organic radicals based upon the reactions between mixed organic mercury compounds and hydrogen chloride. In our opinion it is somewhat premature to draw any general conclusions regarding "electronegativity" from the course of a single class of chemical reactions until due allowance has been made for the influence of such factors as temperature, concentration, nature of solvent and solubility.

Experimental Part

Materials.—The toluene, diphenylmethane, triphenylmethane, ethylbenzene and dibenzyl were obtained from the Eastman Kodak Company and purified by crystallization or distillation. The other hydrocarbons were prepared by processes involving the use of liquid ammonia, as described below.

1,1,1-Triphenylethane was obtained by the action of methyl iodide on potassium triphenylmethide in liquid ammonia. This salt was prepared from potassium and triphenylmethane, the hydrocarbon being used in preference to a halide, in spite of its higher cost, because it could be more readily obtained in a very pure state. The reaction was carried out in the apparatus shown in Fig. 1, consisting of a large Dewar flask C of 1500-cc. capacity, a stirring screw D, operated by a stirring motor, and a rubber stopper fitted with an inlet B and an outlet F for ammonia gas, an opening E for the addition of solid reagents and a dropping funnel A for introducing liquids. The flask was filled two-thirds full of liquid ammonia, the stirrer started and a slow stream of ammonia gas blown through the liquid. The potassium was then introduced and the triphenylmethane **(30 g.)** slowly added in 5-g. portions at about half-hour intervals. Additional pieces of potassium were dropped in from time to time whenever the free metal had entirely reacted, as indicated by a change in color of the solution from opaque blue-black to transparent red. After all of the triphenylmethane had been added and had reacted, methyl iodide was dropped in until the solution became colorless. The equations for the principal reactions are

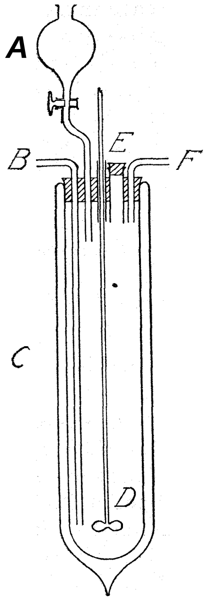

Fig. 1.—Apparatus for organic synthesis in liquid ammonia.

[18] Beilstein, "Handbuch der organischen Chemie," [4] I, 87 (1918); Erstes Erganzungswerk, [4] I, 26 **(1928).**

$$(C_6H_5)_3CH + K \longrightarrow (C_6H_5)_3CK + {}^1/_2H_2 \tag{3}$$

$$(C_6H_5)_3CK + CH_3I \longrightarrow (C_6H_5)_3CCH_3 + KI \tag{4}$$

and this type of synthesis is unique in that the preparation of a hydrocarbon from its next lower homolog is effected in a single process.

Although the liquid ammonia solution became colorless upon the addition of a slight excess of methyl iodide, part of the precipitate formed was light pink in color. This probably consisted of methylammonium triphenylmethide formed as a result of the reactions[19,20]

$$CH_3I + NH_3 \longrightarrow CH_3NH_3I \tag{5}$$

$$CH_3NH_3I + (C_6H_5)_3CK \longrightarrow (C_6H_5)_3CNH_3CH_3 + KI \tag{6}$$

By adding more potassium, continuing the stirring and then again adding a slight excess of methyl iodide, the major portion of this by-product was converted into the desired triphenylethane.

Most of the ammonia was allowed to evaporate. Water was then added to the residue and the aqueous solution filtered. The white solid on the filter paper was washed with water, dissolved in ether, the solution dried, filtered and evaporated and the product recrystallized from alcohol; yield, 85–94% of very pure product melting sharply at 95°.

1,1,1,2-Tetraphenylethane was prepared in a similar manner by the action of benzyl chloride on potassium triphenylmethide and a good yield of the hydrocarbon was obtained. The benzyl chloride was not very rapidly ammonolyzed so it was unnecessary to repeat the treatment with potassium as described in the preceding preparation.

1,1,2-Triphenylethane was obtained by reduction of triphenylethylene with sodium in liquid ammonia and decomposition of the resulting sodium addition product with ammonium chloride,

$$(C_6H_5)_2C{=}CHC_6H_5 + 2Na \longrightarrow (C_6H_5)_2C(Na){-}C(Na)HC_6H_5 \tag{7}$$

$$(C_6H_5)_2C(Na){-}C(Na)HC_6H_5 + 2NH_4Cl \longrightarrow \\ 2NaCl + 2NH_3 + (C_6H_5)_2CH{-}CH_2C_6H_5 \tag{8}$$
[21]

Sym.-tetraphenylethane was obtained from tetraphenylethylene by the method just described under 1,1,2-triphenylethane.

Tetraphenylmethane was prepared by the method of Kraus and Kawamura.[22]

Special Method of Purification.—Although the hydrocarbons prepared from triphenylmethane possessed sharp melting points and other attributes of a high degree of purity, they were always contaminated with exceedingly slight traces of triphenylmethane, just sufficient to interfere with the observation of their behavior with potassium and potassium amide. In the case of those hydrocarbons which react but slightly or not at all with potassium amide, the impurity may be removed by a thorough treatment of the product with this amide, which converts the triphenylmethane into its potassium salt. This salt may then be oxidized with a stream of dry air, forming triphenylmethyl peroxide, which is insoluble in ether and may thus be separated from the soluble hydrocarbons. (Tetraphenylmethane, which is itself almost insoluble in ether, may be freed from triphenylmethane by repeated crystallization from this solvent.)

The study of the hydrocarbons formed by attaching aliphatic radicals to the tri-

---

[19] Compare White, Morrison and Anderson, THIS JOURNAL, 46, 963 (1924).

[20] In a trial experiment this pink precipitate was found to decompose with loss of color upon warming to room temperature. The products are probably triphenylmethane and methylamine. This behavior is analogous to that of ammonium triphenylmethide (Ref. 10, p. 2758).

[21] Evidence that the disodium derivative is partly ammonolyzed to $(C_6H_5)_2C(Na)$-$CH_2C_6H_5$ will be presented in a forthcoming article.

[22] Kraus and Kawamura, Ref. 10, p. 2760.

phenylmethyl group which was made by Gomberg and Cone[23] was apparently rendered more difficult by the trouble of separating the product desired from the quantities of triphenylmethane also formed. The process just described promises to remove this difficulty satisfactorily.

The Action of Potassium and of Potassium Amide on the Hydrocarbons.—These reactions were carried out in a small reaction tube connected to an apparatus similar to that previously described.[24] Potassium metal was converted to the amide in liquid ammonia solution by the catalytic action of a piece of rusty iron. The hydrocarbon was then added to this pale yellow solution. In all cases but one[25] where reaction was observed, an intense red or orange-yellow coloration resulted in a very short time and most of the hydrocarbon was seen to dissolve In all cases where no action was reported, no change in color was observed after the mixture had been stirred for at least thirty minutes and the hydrocarbon was recovered unchanged at the end of the experiment. In studying the action of the metal itself, a mixture of the hydrocarbon and the solution of potassium was stirred for thirty minutes, the iron oxide catalyst then added and the color observed after all of the free metal had been converted into the amide.

The Action of Alkali Metals on Benzyl Bromide.—In 1923, Kraus and White[26] observed a reaction between sodium and benzyl chloride in liquid ammonia, but did not characterize the products. This experiment was repeated with benzyl bromide, adding one equivalent to a solution of two equivalents of sodium in liquid ammonia. Reaction took place rapidly, but the solution remained blue in color and, therefore, contained free sodium. More of the bromide was added until the blue color was discharged and replaced by a deep, rich, red color which gradually faded until the solution became entirely colorless. A white precipitate was then visible. The solid product obtained by extraction of the residue with ether could not be readily purified by crystallization, but upon subjecting it to sublimation from an oil-bath, crystals were collected which melted at 52° and proved to be dibenzyl. A similar reaction was observed with potassium. The red color of the liquid ammonia solution indicated the presence of sodium benzylide, which reacted with excess benzyl bromide to form dibenzyl.

Thus far the action of sodium on alkyl or aryl monohalides in liquid ammonia has always followed one of two distinct courses. When the hydrocarbon residue has been unable to form a sodium salt which is stable in ammonia, the product has consisted of the hydrocarbon and amines corresponding to the halide used. This has been the case when alkyl or phenyl[27] halides were employed[6] and is expressed in the equation

---

[24] Wooster, THIS JOURNAL, 51, 1856 (1929).

[25] The reaction between *sym.*-tetraphenylethane and potassium amide in liquid ammonia proceeds slowly. This is doubtless due to the exceedingly low solubility of the hydrocarbon, since the addition of toluene promotes the reaction. The best result was obtained when a toluene solution of the hydrocarbon was added to the liquid ammonia solution of the amide. The stability of toluene and ethylbenzene toward potassium amide cannot be ascribed to solubility influences since these substances are more soluble in ammonia than those hydrocarbons which react readily with the amide [Franklin and Kraus, *Am Chem.* J.,20,820 (1898)]. In all other instances where no action is reported the experiments were repeated using a toluene solution of each hydrocarbon but no difference in the results was observed.

[26] Kraus and White, Ref. 6a, p. 773.

[27] In this connection it must be noted that *traces* of biphenyl have been observed in a few instances.

$$2RCl + NH_3 + 2Na \longrightarrow RH + RNH_2 + 2NaCl \qquad (9)$$

although in practice, secondary and tertiary amines may also be formed.

On the other hand, when the hydrocarbon residue is capable of forming a sodium salt which is stable in ammonia, this salt results when the proportions of the reacting materials are correct.

$$RCl + 2Na \longrightarrow NaCl + RNa \qquad (10)$$

By further addition of the same or a different halide a synthesis of the Wurtz–Fittig type may be accomplished.

$$RNa + R'Cl \longrightarrow RR' + NaCl \qquad (11)$$

The reaction of benzyl bromide, therefore, presents an example of a new and intermediate case for although the sodium salt is unstable in ammonia, the reaction proceeds in such a manner that a synthesis of the Wurtz–Fittig type is possible. A further study of this reaction may yield considerable information regarding the mechanism of reduction by the alkali metals in liquid ammonia.

Summary

1. The acid character of hydrogen atoms in the side chains of aromatic hydrocarbons has been investigated. A table of the results has been prepared which illustrates the influence of the number and positions of the phenyl groups in the compound.

2. The influence of phenyl substitution upon the stability of certain organo-alkali compounds in ammonia is contrasted with the conclusions of Kharasch and Marker regarding the relative "electronegativity" of organic radicals.

3. Synthetic methods for the preparation of certain hydrocarbons in liquid ammonia solution are described.

STUDIES RELATING TO METHYL TIN DERIVATIVES. V. ACTION OF SODIUM TRIMETHYL TIN ON METHYLENE CHLORIDE

BY CHARLES A. KRAUS AND ARTHUR M. NEAL

RECEIVED AUGUST 3, 1929 PUBLISHED FEBRUARY 6, 1930

A. Di-Trimethylstannylmethane

Kraus and Greer[1] studied the action of methylene chloride on disodium dimethyl tin and found that the organic group combines with the dimethyl tin group to form a compound that has a marked tendency to polymerize. Kraus and Sessions[2] treated sodium trimethyl tin with symmetrical ethylene chloride. The products of reaction proved to be sodium chloride, trimethyl tin and ethylene. It seemed worth while to study the corresponding reaction between sodium trimethyl tin and methylene chloride in liquid ammonia. This reaction might be expected to proceed according to the equation

$$2(CH_3)_3SnNa + CH_2Cl_2 = [(CH_3)_3Sn]_2CH_2 + 2NaCl$$

Experiment showed that reaction takes place quantitatively, as was anticipated, but in attempting to characterize the compound by its reaction with sodium in liquid ammonia, certain unexpected reactions occurred. These were followed up further and are described in the next section.

Preparation.—A quantity of trimethyl tin bromide was dropped slowly into several hundred cubic centimeters of liquid ammonia contained in a Dewar flask. Sodium was then added until the compound was completely reduced to a sodium trimethyl tin. The end-point of the reaction is indicated by the appearance of a permanent blue color due to free sodium.

On now adding methylene chloride to the solution of sodium trimethyl tin, immediate reaction occurred with the formation of a liquid precipitate. When the reaction was completed, the supernatant liquid was colorless. The ammonia was allowed to evaporate and the oil was washed several times with distilled water, from which it was then separated. It was dried by filtering through anhydrous sodium sulfate in an atmosphere of nitrogen. Samples of the oil were introduced into weighed tubes and sealed under an atmosphere of nitrogen.

Analyses **and** Molecular Weight.—The compound was analyzed for tin by the Carius method. Subs. 0.3865, 0.6605, 0.6941: SnO_2, 0.3451, 0.5841, 0.6120. Calcd. for $[(CH_3)_3Sn]_2CH_2$: Sn, 69.50. Found: Sn, 70.33, 69.66, 69.45. The molecular weight was determined in benzene by the freezing-point method: solvent, 17.66, 20.85; solute, 0.7387, 0.9903; At, 0.590, 0.682"; mol. wt. found, 354.6, 348.2. Calcd. for $[(CH_3)_3Sn]_2CH_2$: 341.6.

Properties.—Di-trimethylstannylmethane is a colorless liquid which is quite fluid at liquid ammonia temperatures. It boils at 199–201° under normal pressure.

---

[1] Kraus and Greer, THIS JOURNAL, 47, 2568 (1925).

[2] Kraus and Sessions, *ibid.*, 47, 2361 (192.5).

The compound is readily iodized in benzene or chloroform solution. In two experiments 2.1 and 1.99 moles of iodine were required per mole of the compound. Reaction thus takes place according to the equation

$$[(CH_3)_3Sn]_2CH_2 + 2I_2 = 2(CH_3)_3SnI + CH_2I_2$$

After iodination in chloroform, the trimethyl tin iodide was precipitated by means of ammonia. Analysis of the product showed that it consisted of the ammonia complex $(CH_3)_3SnI{\cdot}NH_3$. From the filtrate there was obtained a product melting unsharply at 2°. This was evidently impure methylene iodide, which melts at 5.7°.

B. Action of Sodium on Di-Trimethylstannylmethane and Allied Reactions

In order to establish further the constitution of the compound whose preparation has been described in the preceding section, it was reduced with sodium in liquid ammonia and the resulting products were studied. In general, when a metallo-organic compound of the type R_4M is reduced with sodium in liquid ammonia, the following reaction occurs

$$R_4M + 2Na + NH_3 = R_3MNa + NaNH_2 + RH \qquad \text{(I)}$$

Reaction might also be expected to occur according to the equation

$$2R_4M + 2Na = 2R_3MNa + R_2 \qquad \text{(II)}$$

However, this latter reaction occurs infrequently, except when one of the substituents R is hydrogen.

Preliminary Experiments.—A weighed quantity of di-trimethylstannylmethane was treated with sodium in liquid ammonia. The metal was introduced, a little at a time, until the reduction was completed and the amount of sodium added was determined by weighing back. Gas evolved in the course of the reduction was collected over water and its volume and density were determined. Ammonium bromide was then added to the reaction mixture and the gas evolved in this reaction was collected over water and its volume and density were determined.

It was anticipated that, in the initial process of reduction, reaction would occur according to the equation

$$[(CH_3)_3Sn]_2CH_2 + 4Na + 2NH_3 = 2(CH_3)_3SnNa + 2NaNH_2 + \mathrm{CH_I} \qquad \text{(III)}$$

Since sodium amide is difficultly soluble in liquid ammonia, it was expected that it would be precipitated. A precipitate of sodium amide was, in fact, formed as the reaction proceeded. On adding ammonium bromide to the products of this reaction, it was anticipated that the sodium amide would be neutralized by the ammonium bromide, according to the equation

$$NaNH_2 + NH_4Br = NaBr + 2NH_3 \qquad \text{(IIIA)}$$

while the sodium trimethyl tin should be converted to the stannane, according to the equation

$$(CH_3)_3SnNa + NH_4Br = NaBr + (CH_3)_3SnH + NH_3$$

Two reactions were carried out in which, respectively, 6.4 and 6.8 m. moles of di-trimethylstannylmethane were treated with 21.6 and 23.2 m. atoms of sodium and 94.2

and 101.9 (4.2 and 4.6 m. moles) cc. of gas were evolved. The density of the gas indicated a mean molecular weight of 19.6 and 18.8, respectively. In the two experiments, 3.6 and 3.4 m. atoms of sodium were required per mole of compound in order to complete the reduction. According to Equation III, 4 atoms of sodium are required per mole of compound. The discrepancy is probably due to loss of the original material, which is appreciably volatilized in the course of the process of reduction. The molecular weight of the gas indicated that it was probably methane.

On adding ammonium bromide to the product of the above reductions, the solid (sodium amide) dissolved and a gas was evolved. In the two experiments, respectively, 12.7 and 14.1 m. moles of ammonium bromide were required to complete the initial stage of the reaction. This is approximately 2 moles of ammonium bromide per mole of the original compound. The density of the evolved gas in the two experiments corresponded to a molecular weight of 10.3 and 14.0, indicating that it consisted of hydrogen admixed with an impurity. On disappearance of the solid precipitate, a clear yellow solution remained. It was inferred that this color was due to sodium trimethyl tin. On further addition of ammonium bromide, no gas was evolved and a liquid was precipitated while the yellow color disappeared. The liquid proved to be trimethylstannane.

The appearance of hydrogen on addition of ammonium bromide to the products of reduction was unexpected. If ammonium bromide reacted with sodium amide according to Equation IIIA, no hydrogen would be produced, while any ammonium bromide reacting with sodium trimethyl tin is known to form trimethylstannane. The reaction between sodium amide and trimethylstannane has not been previously studied. It is known, however, that the alkali metal amides react readily with triphenylmethane according to the equation

$$(C_6H_5)_3CH + NaNH_2 = (C_6H_5)_3CNa + NH_3$$

Since sodium trimethyl tin is highly soluble and sodium amide is only sparingly soluble in liquid ammonia, it is to be expected that, on adding ammonium bromide to a mixture of the two in liquid ammonia, trimethylstannane would first be formed and that this compound would then react with the sodium amide present. Accordingly, it was found necessary to study the action of sodium amide on trimethylstannane.

The high values found for the molecular weights of the gases produced in the reactions described above indicated that volatile tin compounds were carried over with the escaping gases. Kraus and Sessions[2] found this to be the case in the reduction of tetramethyl tin. Accordingly, in subsequent experiments the evolved gases were passed through a strong solution of sodium in liquid ammonia, prior to collecting them over water. In order to establish the nature of the reduction process in the case of di-trimethylstannylmethane, the reaction between trimethylstannane and sodium amide was first studied. To establish the nature of this reaction fully, it was found necessary to study also the reaction between sodium amide and trimethyl tin. Finally, the reduction of di-trimethylstannylmethane was repeated and the products of reaction were identified.

Action of Sodium Amide on Tri-methylstannane.—A known weight of trimethyl tin bromide was introduced into a reaction tube and dissolved in liquid ammonia. The bromide was reduced to sodium trimethyl tin by means of sodium and this, in turn, was converted to trimethylstannane by addition of an equivalent quantity of ammonium bromide. To this preparation sodium amide was added until reaction was complete. Gas was evolved throughout this reaction; it was collected over water and its density determined. In a second experiment the evolved gas was passed through a solution of sodium in liquid ammonia prior to collecting over water.

In two experiments, respectively, 15.4 and 15.4 m. moles of trimethylstannane were treated with 20.8 and 14.3 m. moles of sodium amide with the evolution of 4.35 and 2.06 m. moles of gas. The density of the gas in the first reaction, collected directly over water, corresponded to a molecular weight of 28.1, while that of the second reaction washed through a sodium solution was 4.80. Because of the low solubility of sodium amide, an excess of this substance was added in both experiments in order to complete the reaction, and the proportion of this material to the stannane is without significance. However, in the first experiment, 0.28 mole of gas was evolved per mole of stannane, and in the second only 0.13 mole. Seemingly, several reactions occur in varying proportions, depending upon the conditions of the experiment. That the evolved gas was hydrogen is clearly shown by the low value of the molecular weight in the second experiment.

The reactions may be formulated as follows

$$(CH_3)_3SnH + NaNH_2 = (CH_3)_3SnNa + NH_3 \qquad \text{(IV)}$$

$$2(CH_3)_3SnH + NaNH_2 = (CH_3)_3SnNa + (CH_3)_3SnNH_2 + H_2 \qquad \text{(V)}$$

The proportion in which the two reactions take place probably depends upon the concentration and state of subdivision of the reacting materials.

Sodium amide is only slightly soluble in liquid ammonia, and in order to obtain a quantity of this material in a finely divided condition, the preceding experiment was repeated with some modification. Tetramethyl tin was treated with an equivalent quantity of metallic sodium. According to Kraus and Sessions,[2] this reaction leads to the formation of a solution of sodium trimethyl stannide and a finely divided precipitate of sodium amide in equivalent amount. Ammonium bromide was added to the resulting solution. Because of the relatively low solubility of sodium amide, and perhaps for other reasons, the ammonium bromide initially reacts with sodium trimethyl stannide to form trimethylstannane, which, in turn, reacts with sodium amide. The gas evolved, on addition of ammonium bromide, was passed through a concentrated solution of sodium in liquid ammonia prior to collecting it over water.

In this reaction 11.9 m. moles of tetramethyl tin were treated with 23.8 m. atoms of sodium, which resulted in the production of a solution containing 11.9 m. moles of sodium trimethyl stannide and 11.9 m. moles of finely divided sodium amide. This was treated with 13.3 m. moles of ammonium bromide; 83.0 cc. of gas was evolved, having a mean molecular weight of 5.01. The volume of gas corresponded to 3.7 m. moles, or 7.4 m. atoms of hydrogen. Therefore, 62% of the stannane formed in the course of the reaction was converted to sodium trimethyl stannide and trimethyl tin amine, according to Equation V.

The isolation of trimethyl tin amine involves many difficulties and its presence was accordingly shown by certain characteristic reactions. When sufficient ammonium bromide had been added to the initial reduction product to react with all the sodium amide, the solution, which was now transparent and of a pale yellow color, was treated with sodium. No gas was evolved but a finely divided precipitate was formed having the characteristics of sodium amide. Reaction occurred according to the equation

$$(CH_3)_3SnNH_2 + 2Na = (CH_3)_3SnNa + NaNH_2 \qquad \text{(VI)}$$

In order to show that the precipitate formed in this reaction was sodium amide, the mixture was treated with ammonium bromide. This was thus a repetition of Reaction V. On addition of ammonium bromide, a gas was evolved, and this evolution of gas continued until the precipitate had disappeared. This behavior is characteristic of a mixture of sodium trimethyl stannide and sodium amide. Further addition of ammonium bromide caused precipitation of trimethyl stannane.

Basing our calculation on the amount of hydrogen evolved in the preceding reaction, there were present in the solution 3.7 m. moles of trimethyl tin amine. To this solution were added 6.8 m. atoms of sodium and, on addition of excess ammonium bromide, there was evolved 31.8 cc. of gas, or 1.42 m. moles, having a mean molecular weight of 4.6. The amount of gas evolved corresponds to a reaction in which 75% of the product, formed according to Equation VI, reacted according to Equation V when ammonium bromide was added.

On adding ammonium bromide to a solution of sodium trimethyl stannide, in the presence of sodium amide, reaction takes place, initially according to the equation

$$(CH_3)_3SnNa + NH_4Br = (CH_3)_3SnH + NaBr + NH_3 \qquad \text{(VII)}$$

The trimethylstannane resulting from this reaction then reacts to the extent of about 70% according to Equation V, and 30% according to Equation IV.

Action of Sodium Amide on Trimethyl Tin.—In order to obtain some further data relative to trimethyl tin amine, the reaction between trimethyl tin and sodium amide was studied. Owing to the low solubility of both constituents in liquid ammonia, reaction takes place slowly according to the equation

$$[(CH_3)_3Sn]_2 + NaNH_2 = (CH_3)_3SnNa + (CH_3)_3SnNH_2 \qquad \text{(VIII)}$$

A slight excess of sodium amide was added in order to ensure completion of the reaction. The resulting solution exhibited the characteristic yellow color of sodium trimethyl stannide. Since trimethyl tin amine is volatile, its presence was shown by evaporating the ammonia solution into water, acidifying the aqueous solution with sulfuric and nitric acids and evaporating to dryness. As the result of this procedure, a small quantity of stannic oxide was obtained, indicating that a volatile tin compound was carried over with the ammonia vapors. In another experiment the ammonia was recondensed and sodium was added to the condensate. Immediate reaction took place, the solution acquired a yellow color, characteristic of sodium trimethyl stannide, and a finely crystalline precipitate was formed which resembled sodium amide. These observations would seem to demonstrate the presence of trimethyl tin amine as one of the products of reaction between sodium amide and trimethyl tin.

Final Reduction of Di-trimethylstannylmethane with Sodium.—With a knowledge of the action of sodium amide on trimethylstannane, it was possible to repeat the reduction of di-trimethylstannylmethane and to interpret the results with a reasonable degree of certainty. Sodium was added to a weighed quantity of the tin derivative in liquid ammonia until the end-point was reached, which was indicated by the appearance of a permanent blue color due to free metal. The data relating to this experiment are as follows: $[(CH_3)_3Sn]_2CH_2$, 1.4881 g. (4.35 m. moles); Na, 0.3505 g. (15.24 m. atoms); evolved gas, 66.95 cc. (2.99 m. moles); molecular weight of gas 15.99. On adding ammonium bromide, there was evolved a gas whose mean molecular weight was found to be 3.8.

As follows from these data, 3.5 atoms of sodium was used per mole of compound in the process of reduction. According to Equation III, 4 atoms are required. The discrepancy is doubtless due to unavoidable loss of material as a result of the volatility of trimethylstannane. The gas evolved in the course of reduction had a molecular weight corresponding closely to that of methane. The volume of methane obtained was somewhat low owing to the loss of some of the material. The gas evolved, on addition of ammonium bromide, was unquestionably hydrogen. The somewhat high value of its molecular weight was doubtless due to the presence of a small quantity of volatile tin compounds as impurities. It is almost impossible to avoid the presence of some of these compounds in the collected gases. Indeed, it was necessary to clean carefully all of the connecting tubes of the apparatus prior to carrying out an experiment; otherwise, much higher values were obtained.

The reaction evidently takes place according to Equation III. It probably occurs in two stages, as follows

$$[(CH_3)_3Sn]_2CH_2 + 2Na + NH_3 = (CH_3)_3SnNa + (CH_3)_3SnCH_3 + NaNH_2$$
$$(CH_3)_3SnCH_3 + Na + NH_3 = (CH_3)_3SnNa + CH_4 + NaNH_2$$

Summary

Di-trimethylstannylmethane, $[(CH_3)_3Sn]_2CH_2$, has been prepared and some of its properties investigated. It boils at 199–201° and has a normal molecular weight in benzene.

It has been shown that when sodium amide reacts with trimethylstannane in liquid ammonia, two reactions occur simultaneously. In one of these sodium trimethyl stannide and ammonia are formed, while in the other sodium trimethyl stannide, trimethylstannylamine and hydrogen are produced. The proportion in which these two reactions occur depends upon conditions, Sodium amide reacts with trimethyl tin to form sodium trimethyl stannide and trimethylstannylamine.

When ammonium bromide is added to a solution of sodium trimethyl stannide and sodium amide, hydrogen is evolved. For the most part, the ammonium bromide reacts with the stannide to form trimethylstannane, which in turn reacts with sodium amide, a portion to form sodium trimethyl stannide directly and another portion to form sodium trimethyl stannide, sodium trimethylstannylamine and sodium amide.

When di-trimethylstannylmethane is reduced with sodium in liquid ammonia, sodium trimethyl stannide is produced and methane is evolved.

THE MOLECULAR WEIGHT OF CASEIN. II

BY T. SVEDBERG, L. M. CARPENTER AND D. C. CARPENTER[1]

RECEIVED AUGUST 5, 1929 PUBLISHED FEBRUARY 6, 1930

In a former publication[2] the writers have described their experiments dealing with the molecular weight of casein prepared by the method of Hammarsten and that portion of Hammarsten casein which is soluble in hot acidified 70% alcohol. The first mentioned material was found by the ultracentrifuge to be a mixture of proteins of different molecular weights, while the latter was found probably to be a distinct chemical entity having a molecular weight of 375,000.

It was pointed out in the first paper that the casein that has furnished the starting point for experimental studies in late years has been usually prepared either by the precipitation method of Hammarsten[3] or by the method of Van Slyke and Baker.[4] In the former method the precipitation was effected by the slow addition of dilute acetic acid to milk, while in the latter method normal lactic acid or a mixture of normal acetic and hydrochloric acids was recommended. The latter workers also introduced rapid agitation as a means of distributing the added acid throughout the milk.

One of the principal differences between the two methods seems to lie in the time interval during which the milk is held in a state of partial coagulation. The other principal difference is that Hammarsten redissolves the precipitated casein in dilute alkali and reprecipitates with acid several times, with the hope of removing other substances carried down during the initial precipitation; while on the other hand, Van Slyke and Baker make no attempt to remove organic impurities by reprecipitation

of the casein. The latter workers seem to be more concerned with reducing the ash content than in separating one protein from another in pure form. These authors claim to produce a pure protein by a single precipitation from the very complex mixture of substances that are known to occur in milk. The work described in this paper will deal with casein prepared from cow's milk by the method described by Van Slyke and Baker.

Experimental Part

Preparation of Material.—We have carried out the precipitation process as described by Van Slyke and Baker using the acetic–hydrochloric acid mixture as precipitant, but have not attempted as yet to dry the material by their method, preferring for the present to make progress with material which had not been subjected to any drying process.

Freshly drawn milk was handled as described in our first paper[2] up to the point where it had passed through the separator. It was then, without diluting, precipitated by Van Slyke and Baker's method. After separating the precipitated casein centrifugally from the solution, the casein was beaten up with water, first to a thin paste by means of an electrically driven stirrer, and then more water was added and the stirring continued until the casein was well distributed throughout the whole of the wash water. After allowing to stand for an hour or so, the casein was separated centrifugally from the wash water. The washing was repeated in this manner five or six times, the washed casein finally being stored under water with toluene at 5°. Several such preparations were made at various times and used during the course of the work.

The same technique of preparing the casein solutions was used as was given in the first paper, namely, dissolving two grams of casein (dry basis) in 25 cc. of $M/15$ mixed phosphate buffer solution at PH 6.8 and diluting this to 100 cc., thereby producing a $M/60$ buffer salt concentration. The solution was prepared in the cold, slowly passed through the milk separator driven at a high speed and stored at 5° with toluene as preservative. The protein content of this solution was determined by evaporating *a* sample to dryness at 105° and correcting the weight of residue for the buffer salts present. Dilutions were made from the stock solution as required for the centrifuging work. No material changes were made in the centrifuging set-up or technique, which has already been described.

Determination of Molecular Weight.—In the experiments immediately following, the sedimentation velocity method was applied. Owing, however, to the fact that no constant diffusion value was obtainable from Van Slyke and Baker's casein, on account of its being a mixture, we are unable to use the usual molecular weight equation $M = RTS/D(1 - V\rho)$, where R is the gas constant, T the absolute temperature, S the specific sedimentation velocity or $1/\omega^2x\cdot dx/dt$, D the diffusion constant, V the partial specific volume of the protein, ρ the density of the solvent, x the distance from the axis of rotation, ω the angular velocity and t the time. We must, therefore, rely upon sedimentation velocity measurements entirely for a solution of the problem.

According to Stokes' Law for a spherical particle of radius r_1

$$^4/_3\pi r_1^3(\rho_1 - \rho_2) = 6\pi h r_1 s_1 \qquad (1)$$

and for any other spherical particle of radius r_2

$$^4/_3\pi r_2^3\ (\text{PI} - \rho_2) = 6\pi h r_2 s_2 \tag{2}$$

where $(\rho_1 - \rho_2)$ represents the difference in density between the particle and solvent and s_1 and s_2 represent the specific sedimentation velocities of the two particles of radius r_1 and r_2, respectively.

If we assume that the two particles have the same partial specific volume, then dividing (1) by (2) we obtain

$$\frac{r_1}{r_2} = \left(\frac{s_1}{s_2}\right)^{1/2} \tag{3}$$

However, where M_1 and M_2 represent the molecular weight of the respective species

$$\frac{M_1}{M_2} = \left(\frac{r_1}{r_2}\right)^3 \tag{4}$$

from which

$$\frac{M_1}{M_2} = \left(\frac{S_1}{S_2}\right)^{3/2} \tag{5}$$

In Tables I and II are given data on specific sedimentation velocity and diffusion, respectively, for a typical run at 1.0% protein concentration.

TABLE I

we have considered the break in the curves of this series to occur at the point of intersection with the line AB.

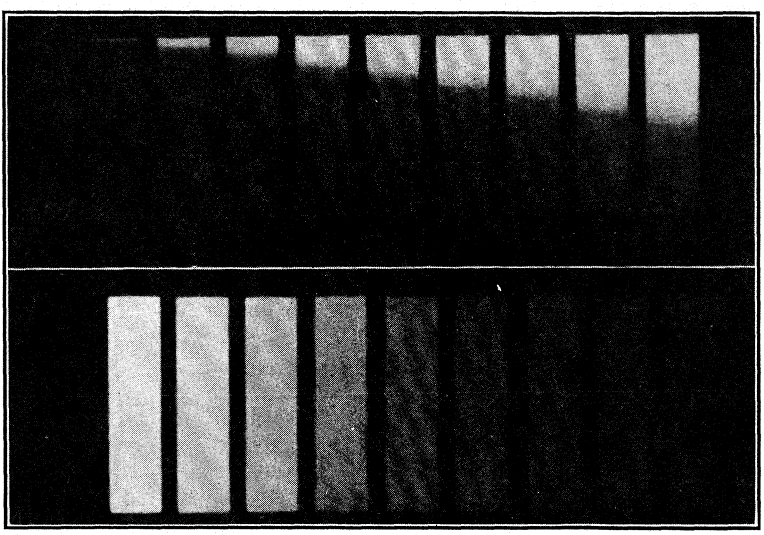

Fig. 1.

The shape of the sedimentation curves in Fig. 2 indicates that casein prepared by the method of Van Slyke and Baker is little or no improvement over the Hammarsten method. The material is definitely not one single protein substance but contains several kinds of molecules of different weights. The sedimentation values as shown in Table I are fairly constant, but the "apparent" diffusion values given in Table II show that as the experiment proceeds these values increase and are not constants such as we would have were we dealing with a homogeneous substance. The increase in the "apparent" diffusion is attributed to a spreading out of the boundary due to the effect of the centrifugal force on particles of different size. On the assumption that we are dealing with a spherical particle, we have calculated the theoretical distribution at the boundary after two hours of centrifuging of a monomolecular system having the specific sedimentation velocity we have found experimentally, and represented it as curve C in Fig. 2. As the above assumption involves the condition of minimum frictional resistance of the particle and consequently the maximum possible diffusion, we must conclude that there are protein molecules of at least three different sizes in Van Slyke and Baker's casein, one being larger and one considerably smaller than the main bulk of the material.

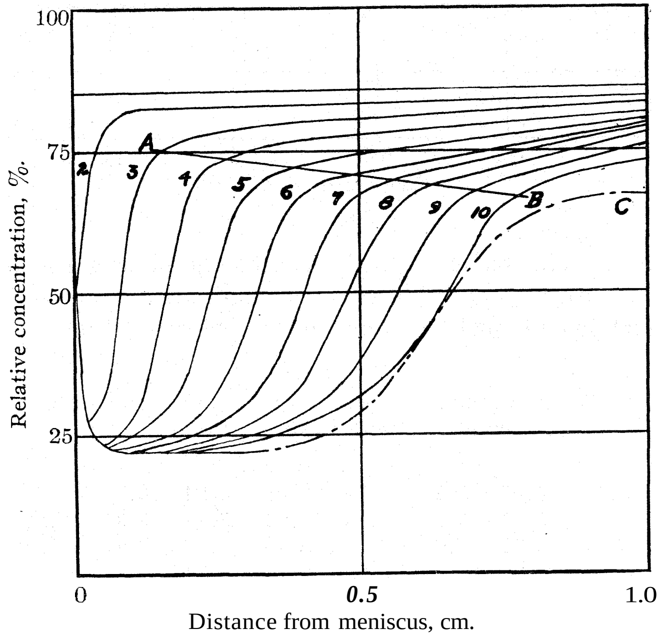

Fig. 2.

In Table III is given a summary of a large number of sedimentation velocity measurements on two different samples of Van Slyke and Baker casein at various protein concentrations. In Fig. 3 these data are shown graphically. It is to be noted that the influence of protein concentration on the sedimentation velocity is practically constant down to a concentration of about 0.50%, below which value the sedimentation velocity drops off rather rapidly. As the region between 0.50 and 2.00% seems to indicate a reasonably constant condition of the protein molecules, we will confine our attention largely to this region. Within this concentration range the main component of this protein mixture behaves very differently from the acidalcohol soluble casein which we described in a former publication.[2] The latter protein was more stable in dilute solutions (below 0.45%), while this protein appears to be more stable at concentrations above 0.50%. The buffer salt, the concentration and PH have been exactly alike with respect to both proteins, and identical procedures were used in dissolving the moist proteins in this buffer solution.

The two samples of Van Slyke and Baker casein shown in Fig. 3 show differences between themselves, one apparently being a purer specimen than the other. Some preliminary results which we have obtained by fractionating Van Slyke and Baker casein with potassium oxalate indicate that the purer of the two samples is the one having the smaller sedimentation velocity. For the purposes of the calculations of this paper, however, we have taken a mean of the 47 specific sedimentation velocity values recorded in Table III at concentrations of 0.50% and above, where the molecule is comparatively stable. This mean value is $S_{20^\circ} = 5.56 \times 10^{-13}$ and is probably somewhat greater than the true value representing the pure protein, on account of the fact that it represents an average obtained with specimens both of which contained a protein of rather high molecular weight as impurity.

It has been shown that for spherical particles having the same partial specific volume $M_1/M_2 = (S_1/S_2)^{3/2}$, where M_1 and S_1 represent the molecular weight and specific sedimentation velocity, respectively, of one chemical species and M_2 and S_2 the corresponding values of some other species. The egg albumin molecule has been deduced to be spherical in shape, to have a molecular weight of 34,500 and S_{20° equal to 3.32×10^{-13} and a partial specific volume of 0.748, almost identical with the value of 0.750 for casein.[5] Using this as a reference substance, from the above relationship we calculate that the molecular weight of Van Slyke and Baker casein cannot be less than 75,000.

Assuming a spherical particle and applying Stokes' Law $r = \sqrt{\frac{9}{2}\frac{hS}{(\rho_1 - \rho_2)}}$, where r equals the particle radius, h the viscosity of the solvent, S the specific sedimentation velocity and $(\rho_1 - \rho_2)$ the difference in density between particle and solvent, we calculate the molecular radius to be 2.75×10^{-7} cm. The majority of the proteins which have been examined to date, however, do not seem to have spherical shaped molecules, but are of some different shape which operates to increase the frictional resistance and the effective radius of the particle. We have calculated this in the case of acid-alcohol soluble casein and have found the ratio r_E/r_S to be 1.43. If we assume a similar ratio for the Van Slyke and Baker casein, we will have a molecular radius of 3.94×10^{-7} cm. and a corresponding diffusion constant, as calculated from Einstein's Law $D = \frac{RT}{N}\frac{1}{6\pi hr}$, of 5.41×10^{-7} cm. Solving the molecular weight equation with this diffusion value, we find the molecular weight of the bulk of the protein material of Van Slyke and Baker casein to be 100,300. This value corresponds very well with the molecular weight values 103,600 and 105,500, respectively, for serum globulin and phycocyan, which have been found to have S_{20° values of 5.57×10^{-13} and 5.59×10^{-13}, respectively. The S_{20° value we have found for the main protein component of Van Slyke and Baker casein is 5.56×10^{-13}, practically identical with the former of these last values. This S_{20° value, however, is no doubt somewhat high, as is also the molecular weight figure, due to the presence of the impurity of higher molecular weight, as we have mentioned before. There can be no doubt that the bulk of the casein prepared by Van Slyke and

---

[5] Svedberg, "Colloid Chemistry," 2d ed., Chemical Catalog Co., New York, 1928, p. 164.

Baker's method has a molecular weight between 75,000 and 100,000. Attention is again called to the fact that Van Slyke and Baker casein does not consist of a single molecular species.

Effect of Heat on the Casein Molecule.—Inasmuch as other investigators have paid little or no attention to the temperature conditions that have been employed in the preparation of their protein solutions, we have thought it advisable to compare casein solutions that had been heated to 40° during their process of solution in phosphate buffer with casein solutions that had been prepared by dissolving in the same buffer in the cold and which have just been described.

In these experiments casein prepared by the method of Van Slyke and Baker was dissolved in the same phosphate buffer solution and with the same technique as previously described, except that the protein and solvent were, in the present case, subjected to a temperature of 40° for one hour while the protein was going into solution. This solution was then passed slowly through the milk separator, which was operated at a high speed, and the solution stored at 5° with a few drops of toluene as preservative.

In order to show clearly the range of size of the protein particles existing in this solution and their respective molecular weights after the above treatment, we have examined the solution by the sedimentation equilibrium method. This method has been described in detail elsewhere and it is sufficient here to state that the molecular weight is given by the relationship

$$M = \frac{2RT \ln (C_2/C_1)}{(1 - V\rho)(X_2^2 - X_1^2)\omega^2}$$

where M represents molecular weight, R the gas constant, T the absolute temperature, C_2 and C_1 the protein concentrations at the distances X_2 and X_1, respectively, from the center of rotation after equilibrium is attained, V the partial specific volume of the protein, ρ the density of the solvent and ω the angular velocity.

The results of a run with Van Slyke and Baker casein which had been heated for one hour at 40° are given in Table IV. It will be seen that the bulk of the protein in the cell corresponds closely to a molecular weight of 188,000 and at the bottom of the cell we have a heavier constituent of molecular weight 370,000. This latter appears to be the acid–alcohol soluble casein described in our former communication. There is no sign of any protein material in this solution having a molecular weight around 100,000, such as we find the bulk of Van Slyke and Baker casein to consist of when it has not been subjected to the action of heat. From this we must conclude that the protein of molecular weight between 75,000 and 100,000 has been entirely converted into a different and a larger molecule by the action of the applied heat. The data indicate that the molecule after the

action of heat has at least twice the molecular weight that it had before such treatment. This suggests a polymerization or association of the molecules of molecular weight between 75,000 and 100,000 to form the larger molecules through the influence of heat. Our experiments do not show which of these suggested mechanisms is responsible for the changes in molecular weight which we have recorded. They do show, however, that in the case of casein, other factors remaining constant, the temperature at which the protein material is put into solution has a great influence on the state of the molecule.

It has often been noted that temperature changes and various other factors influenced certain physical properties of protein solutions. Such effects have been due largely to obscure causes and have been referred to as depending on "life history," etc., of the material in question. Evidence is here presented that in the case of casein the heat effect is a very definite one which results in at least doubling the molecular weight.[6]

Discussion of Results.—The experiments described in this paper with casein prepared from cow's milk by the method of Van Slyke and Baker have shown that this material is a mixture of protein substances of different molecular weight. Furthermore, samples from separate casein preparations made by this method of preparation, are shown to be different from each other, showing that not only a mixture of proteins is produced by the Van Slyke and Baker method, but a different mixture is to be found in different individual preparations. That little or no definite conclusions could be arrived at from researches based on such starting materials is entirely obvious.

[6] The authors are indebted to B. Sjogren for repeating and confirming our centrifuging results with the heated casein solutions described above.

There can be no doubt that the molecular weight of the main bulk of the protein separated by Van Slyke and Baker's method lies between 75,000 and 100,000.

In the equilibrium experiments where the casein solutions were subjected to a temperature of 40° while the moist casein was dissolving in the buffer solution, we have found that the protein of molecular weight between 75,000 and 100,000 has been altered to form larger molecules of molecular weight 188,000. That this represents an actual change in the molecules is evidenced from the fact that calculations of the specific sedimentation velocity of the 188,000 molecule yield an $S_{20°}$ value of 10.55 X 10^{-13} on the basis of a spherical molecule, and a similar value of 7.59×10^{-13} on the basis of a molecule of the same shape as the acid–alcohol soluble casein reported in the first paper. Neither of these values can be confused with or mistaken for the $S_{20°}$ value of 5.56×10^{-13} which we have obtained for the 75,000 to 100,000 weight molecule. We must be dealing, therefore, with another casein molecule in this casein which has been subjected to the influence of heat. In other words, the 100,000 molecule has been converted into the 188,000 weight type through the agency of heat. This change has been so complete that we do not find any of the 75,000 to 100,000 weight molecule even at the top of the sedimentation cell, where they would most certainly occur were any left unchanged in the solution.

Summary

1. Casein prepared by the method of Van Slyke and Baker has been examined at P_H 6.8 in phosphate buffer solutions at various protein concentrations by the centrifugal sedimentation velocity method, and found to consist of a mixture of protein substances of different molecular weight.

2. Different preparations made by this method were shown to be mixtures of proteins in different proportions. Not even a constant mixture was obtained by the Van Slyke and Baker method.

3. It was found that the bulk of the crude casein prepared by this method had a molecular weight between 75,000 and 100,000.

4. Crude casein subjected to a temperature of 40° during the time of dissolving in buffer solutions was found to have a molecular weight of 188,000 by the sedimentation equilibrium method. No molecules of molecular weight between 75,000 and 100,000 remained in the solution after this heat treatment.

STUDIES ON POLYMERIZATION AND RING FORMATION. IV, ETHYLENE SUCCINATES

BY WALLACE H. CAROTHERS AND G. L. DOROUGH

RECEIVED AUGUST 7, 1929 PUBLISHED FEBRUARY 6, 1930

Ethylene succinate as a typical example of a condensation polymer[1] has been submitted to further study with the view of gaining more information in regard to its structure. The presence of the structural unit,[1] I, in this ester has been established by the methods used in its synthesis,[2,3] by its chemical behavior, and by its analytical composition.[2,3]

$$—O—CH_2—CH_2—O—OC—CH_2—CH_2—CO— \qquad (I)$$

Of the various polymeric forms described in this paper, the apparent molecular weights indicate average values of 6 and 23, respectively, for the number of structural units contained in each molecule of the lowest and highest polymers. It is assumed that these units are joined together in a linear fashion by real primary valences, as in II. Since it is very improbable that there are free valences at the ends of the resulting chains, the problem of the structure of these polymers resolves itself into finding whether the end valences are mutually saturated with the formation of very large rings or are saturated by univalent groups of some kind.

$$—O—(CH_2)_2—O—OC—(CH_2)_2—CO—O—(CH_2)_2—O—OC—(CH_2)_2—CO—O— \\ (CH_2)_2—O—OC—(CH_2)_2—CO—, \text{ etc.} \qquad (II)$$

Any of the reactions by which this ester is prepared offers the formal possibility of establishing either rings (closed chains) of 8, 16, 24, ...(8)*n* members or of open chains corresponding to each of these rings. The observed molecular weights indicate the presence of 50 to 180 atoms in each chain. This fact and the physical properties of the ethylene succinates indicate the absence of more than traces of rings of less than 32 members. Since the same theoretical considerations[4,1] which predict the improbability of the formation in bifunctional reactions of rings of 8 to 32 members apply *a fortiori* to still larger rings, an open chain seemed much more probable than a cyclic structure, and our efforts were directed toward the detection of the univalent groups which would constitute the ends of the open chains. We have proved the presence of such groups, and the open-chain structure for the polymeric ethylene succinates is clearly established.

Neutral Ethylene **Succinate.**—This ester is prepared by heating suc-

cinic acid with excess glycol at 180° until the distillation of water ceases and then removing the excess glycol by heating in high vacuum at 200–250°. The ester is purified by crystallization and melts at 102°.[5]

Its apparent molecular weight is about 3000.

If this ester is an open chain, its method of formation and its observed molecular weight would lead one to assign to it the structure III, and it

$$\text{H—[O—(CH}_2)_2\text{—O—OC—(CH}_2)_2\text{—CO—]}_{22}\text{—O—(CH}_2)_2\text{—OH} \qquad \text{(III)}$$

should therefore show the reactions of a dihydric alcohol. The possibility of applying to it many of the typical reactions for the detection of primary alcohol groups was excluded for one reason or another. Thus the presence of ester linkages excluded any reactions which might result to hydrolysis. The fact that the compound is hygroscopic and insoluble in ether made it useless to attempt to apply any such methods as the Zerewitinoff. The compound crystallizes from acetic anhydride and is apparently unchanged even on long boiling in this solvent in the presence of catalysts, but in so large a molecule acetylation might occur without any apparent change in physical properties, and the amount of acetic acid which would be liberated on hydrolysis of even a completely acetylated product would be so small as to make its estimation difficult. The ester reacts very slowly and incompletely with phosphorus tribromide.

Six grams of the ester heated for five hours in 30 cc. of boiling chloroform with 6 cc. of phosphorus tribromide after thorough washing and repeated crystallization was found to contain 0.58% Br.

The ester was also recovered apparently unchanged after treatment with phenyl and naphthyl isocyanates under various conditions. These failures appear to be due to a reluctance of the hydroxyl groups to react, and they are not altogether surprising in view of the diminished reactivity which is frequently associated with increased molecular size.

Reaction occurred completely in the expected sense with succinic and with p-bromobenzoic anhydrides at elevated temperatures. These reactions led to the dibasic acid which agreed in properties and composition with the Formula IV, and to a *p*-bromobenzoyl ester which agreed in composition with Formula V.

$$\text{HO—OC—(CH}_2)_2\text{—CO—[—O—(CH}_2)_2\text{—O—OC—(CH}_2)_2\text{—CO—]}_{23}\text{—OH} \qquad \text{(IV)}$$

$$p\text{-BrC}_6\text{H}_4\text{—CO—[—O—(CH}_2)_2\text{—O—OC—(CH}_2)_2\text{—CO—]}_{22}\text{—O—(CH}_2)_2\text{—O—OC—C}_6\text{H}_4\text{Br-}p \qquad \text{(V)}$$

Preparation of IV.—Twelve grams of neutral ethylene succinate was heated with 3 g. of succinic anhydride at 175–180° for three hours. The reaction mixture was washed three times with hot water, dried, precipitated from chloroform with ether and crystallized 6 times from acetone. Its properties identified it as the dibasic acid IV, which would be formed by the reaction of each hydroxyl group of III with one molecule of succinic anhydride.

---

[5] Capillary tube melting point. See Carothers and Arvin, THIS JOURNAL, 51, 2560 (1929), for a description of the peculiar melting point behavior of this compound.

The ester III melted at 102°, had an apparent molecular weight of about 3000, was neutral and did not form a sodium salt. IV prepared from III melted at 98° and had an apparent molecular weight of 3110 (method of Menzies and Wright in ethylene chloride, observed values 3170, 3040) and a neutral equivalent of 1708. The action of sodium bicarbonate on IV led to a sodium salt which melted at 104° and contained 1.23% of sodium. The analytical data are given in Table I.

Preparation of Di-p-bromobenzoyl Derivative of **III.**—Two and one-half grams of III was heated for five hours with 0.75 g. of *p*-bromobenzoic anhydride at 175–185°. The reaction mixture was dissolved in chloroform and precipitated by ether, washed with hot water, dried and precipitated from acetone by ether. It melted at 93°. Analysis showed it to be the expected di-*p*-bromobenzoyl derivative, V, of III.

Anal. Calcd. for V as $C_{176}H_{172}O_{84}Br_2$: C, 49.30; H, 5.20; Br, 4.84. Found: C, 4947, 49.39; H, 5.59, 5.60; Br, 4.84, 5.01, 4.88, 4.91.

Acidic Ethylene Succinates.—If glycol and succinic acid would react completely in the proportions in which they are brought together, it would be possible to prepare chains of various lengths by using the glycol and acid in various ratios. In a number of experiments various excess amounts of succinic acid were allowed to react with glycol. The reactants were heated together at 180° until no more water was evolved and the temperature of the bath was then raised to 200–240° for one to five hours to make the reaction as complete as possible. Only traces of acid and glycol appeared in the distillates. The residues were always acidic and, when the excess of acid was large, always contained some unchanged succinic acid. Moreover, products of high molecular weight could be isolated from these residues even when the ratio of acid was as high as 2:1. This showed that under the conditions of these experiments complete control of the length of the chain produced was not possible by adjustment of the ratios of the reactants. On the other hand, this factor had some influence in controlling the lengths of these chains, and by making use of such control as it offered, together with fractional crystallization, it was possible to isolate samples of material representing chains of various lengths, each of which was quite homogeneous in its physical behavior. A comparison of the analytical data and molecular weights for these acidic ethylene succinates clearly indicates that their structure may be represented by VI, in which x has various average values for different fractions.

$$HO{-}OC{-}(CH_2)_2{-}CO{-}[{-}O{-}(CH_2)_2{-}O{-}OC{-}(CH_2)_2{-}CO{-}]_x{-}OH \quad \text{(VI)}$$

VIa, $x = 6$ VIb, $x = 9$ VIc, $x = 12$

Preparation of VI, a, b and c.—Ethylene glycol, 41 g., and succinic acid, 93.5 g. (20% excess), were heated at 200–210° for four hours, and the residual water was then removed as completely as possible by heating in *vacuo* The residue was dissolved in chloroform and precipitated with ether. The powder which resulted from the drying of this precipitate weighed 92.2 g. and melted at 87.5–90°. It was extracted several times with boiling water. The residue (59 g.) was dissolved in chloroform and precipitated by ether. It melted at 90°. This constituted fraction VIc. The hot aqueous extracts on cooling deposited 11 g. of solid which after drying melted at 73–74°.

In another similar experiment the acid and glycol were heated for two hours at 190–210° under ordinary pressure, and then immediately extracted several times with boiling water (3 × 300 cc.). The residue amounted to 10.5 g. After solution in chloroform and precipitation by ether, it melted at 82–83°. This constituted fraction VIb. On cooling, the aqueous extract deposited considerable white solid. This after precipitation from chloroform by ether melted at 73°. This material together with the fraction from the previous experiment melting at the same temperature constituted fraction VIa. By evaporation of the aqueous extracts from this experiment there was obtained another fraction melting at 86°. The analytical data for this fraction indicated that it lay between the 73° and the 82° fractions.

Fraction IV was prepared from III in the manner already indicated.

The analytical data for these fractions (see Table I) indicate that we are here dealing with a polymeric series in which the average values for the degree of polymerization vary from 6 up to 23. These fractions closely resemble each other in physical properties: they have the same appearance under the microscope, and they show similar solubility relations. All the fractions are soluble in cold chloroform and in hot 50% alcohol. The lowest fraction is quite soluble in hot water and the higher fractions only very slightly soluble. The melting points rise with increasing degree of polymerization.

All these fractions form sodium salts on treatment with sodium bicarbonate, and these resemble very closely in properties the acids from which they are derived. Thus they are readily soluble in cold chloroform and in warm acetone. They are only slightly soluble in cold water. All of them, however, are readily soluble in warm water, and in this respect the higher members are sharply differentiated from the corresponding acids. The magnitude of the change in properties which is produced by the transformation of the slightly polar carboxyl group into the completely polar sodium salt will be expected to vary with the size of the chains to which these groups are attached, but we found it somewhat surprising, nevertheless, that these sodium salts should melt only a few degrees above the melting points of the corresponding acids. This difference diminishes continuously with the increase in length of the chain and in the highest polymer, IV, amounts to only 6°.

The general plan of the structure of these acid esters is clearly established by the formation of the sodium salts. Attempts to prepare other derivatives from acids met with little success. Treatment with thionyl chloride and with phosphorus pentachloride under various conditions furnished products which contained chlorine, but it could not be established that these materials were really acid chlorides. Attempts to prepare amides by heating the sodium salts of the acids with *p*-toluidine hydrochloride led to the formation of N-*p*-tolyl succinimide. Heating the sodium salts with p-bromophenacyl bromide led to the formation of derivatives, but these contained less than the calculated amount of bromine. Thus the sodium salt of VIa led to a derivative, m. p. 73°, containing 8.66% of bromine, while the calculated value for a di-(*p*-bromophenacyl) ester of VIa is 11.61% Br. Similarly, the sodium salt of VIc led to a p-bromophenacyl derivative containing 4.12 instead of the calculated 7.13% of bromine.

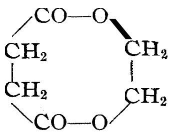
Mechanism of the Formation of Ethylene Succinate.—The formation of an open-chain poly-ester of the type exemplified by II might occur in either one of two ways. (1) The cyclic monomeric ester VII might first be formed, and this might then undergo A polymerization (self-addition) with the formation of II. (2) II might be formed directly from the acid and the glycol (C polymerization) by a series of successive reactions. That poly-esters of this general type may be formed by the first mechanism is clearly indicated by the fact[6] that the monomeric form of trimethylene carbonate can be isolated by the distillation of its polymer, and, by heating, the monomer can be changed to the polymeric form. This is also true of other poly-esters, but, so far as our information extends now, only of those in which the monomer is a 6-membered ring. The 5-ring esters do not polymerize; the poly-esters whose monomers would be larger-than-6-rings are not depolymerized; and, although monomers of this type are known[7] and are stable, none of them has ever been prepared by a bi-functional reaction. The general theory underlying these facts has already been discussed.[1,6]



VII

The evidence that ethylene succinate is formed by Mechanism 2 (C polymerization) rather than 1 is fairly conclusive. Experimental evidence

[7] Ruzicka and Stoll, *Helv. Chim. Acta*, 11, 1159 (1928).

in support of Mechanism 2 may be found in the fact that the molecules of ethylene succinate are open chains with functional groups at the ends. The supposition that the monomeric ring VII is first formed involves the tacit assumption that 8-rings are readily formed, but are unstable, whereas fact and theory alike indicate that such rings are formed only with great difficulty, but are stable when they have been formed. We have made a good many attempts to isolate the monomeric 8-ring, VII. All of these attempts have failed, and all of the observations which we have made are best interpreted on the assumption that the long chains are built up by a series of successive reactions and that rings are not formed at any stage of the process. Some light is thrown at one or two points on the details of the mechanism of the reaction by the following observations.

When glycol was allowed to react with succinic acid in the proportions of 1 to 2 moles, the product was found to be a mixture composed chiefly of unchanged succinic acid and poly-ester of fairly high molecular weight. The compound, $HO—OC—(CH_2)_2—CO—O—(CH_2)_2—O—OC—(CH_2)_2—CO—OH$, which might be expected to form under these stoichiometrical conditions was not found.

Neutral ethylene succinate was prepared by heating the acid with excess glycol and, after some time, distilling off the excess glycol as completely as possible at high temperature and under greatly reduced pressure. Under these conditions the formation of some di-β-hydroxyethyl succinate, VIII, might be expected. This ester was in fact formed, and it distilled

$$HO—(CH_2)_2—O—OC—(CH_2)_2—CO—O—(CH_2)_2—OH \qquad \text{(VIII)}$$

out of the reaction mixture when this was heatkd in *vacuo.* It was obtained in a state of approximate purity by redistillation in a carefully cleaned all-glass apparatus under high vacuum.

Di-(β-hydroxyethyl)-succinate.—Sixty-two grams of ethylene glycol (1 mole) and 39.3 g. of succinic acid ($^1/_3$ mole) in a pyrex Claisen flask fitted with ground-glass stoppers and provided with a receiver were heated for six hours by means of an oil-bath at 174–180°; 8.8 g. of water, b. p. 100–102°, n^{28}_{D} 1.3323, collected in the receiver. The residue was heated in vacuo finally to a temperature of 250° at 0.015 mm., until distillation ceased. The residue was a pale yellow viscous liquid which readily solidified on cooling. It was dissolved in 100 cc. of warm chloroform and precipitated as a powder by the addition of 250 cc. of benzene. After drying, this powder weighed 36 g (0.25 *g.* equivalent). Its instantaneous melting point was 98° and its slow melting point 105.5". The distillates were redistilled and yielded 9.97 g. or 0.648 mole of water, 33.9 g. or 0.548 mole of glycol and 14.5 *g.* or 0.07 mole of di-(β-hydroxyethyl) succinate. The total esters (0.7 mole + 0.25 *g.* equivalent) accounted for 0.32 mole of the 0.333 mole of succinic acid used, and these esters plus the glycol recovered accounted for 94.6% of the glycol used, while the water isolated was 87.5% of the calculated amount.

The di-(β-hydroxyethyl) succinate was never isolated in a state of purity. When distilled in a carefully cleaned all-glass (pyrex) Claisen flask, it boiled at 176–180° at 0.001 mm. as a colorless viscous liquid, leaving only a trace of residue.

The di-(phenylurethan) formed by the action of phenyl isocyanate on di-(β-hydroxyethyl) succinate and crystallized from a mixture of benzene and petroleum ether melted at 113°.

Anal. Calcd. for $C_{22}H_{24}O_8N_2$: C, 59.45; H, 5.41. Found: C, 59.40, 59.56; H, 5.53, 5.52.

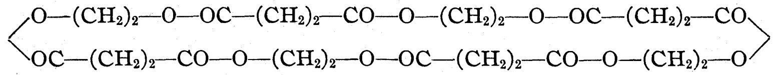
When heated slowly in *vacuo* di-β-hydroxyethyl succinate was completely converted into neutral (polymeric) ethylene succinate and ethylene glycol, the former appearing in the distillate and the latter remaining in the distilling flask.[7] This process evidently involves an ester interchange: glycol is eliminated between two molecules of the dihydroxy ester with the formation of a new dihydroxy ester containing two of the structural units of ethylene succinate. Repetition of this process finally results in such a molecule as III. It is evident that so long as one of the products of a possible ester interchange can be eliminated in this way, no merely stoichiometrical factors can set up a limit to the length of the molecules which might be produced. Nevertheless a fairly definite limit exists: polyintermolecular esterification has never led us to molecules of greater average length than about 200 atoms. No doubt various factors are involved in this point. There can be no question that the reactivity of functional groups diminishes with the size of the molecules which contain them. It is apparently this factor which accounts for the failure of the ester III to react with many of the typical reagents for hydroxyl groups. Moreover, as Staudinger has frequently emphasized,[8] the thermal stability of molecules must diminish with increase in their size. These two factors act in opposition. To force the completion of the reaction between succinic acid and glycol we have used high temperature (250°) to increase reaction velocity and high vacuum to remove the water as completely as possible. The ester produced under these conditions has a molecular weight of about 3000. It is interesting to observe that in the thermal polymerization of styrene the product formed at 250° also has an apparent molecular weight of about 3000, while the polystyrenes formed at lower temperatures have much higher molecular weights. And so also the A polymerization of trimethylene carbonate described in the previous paper,[6] although it also involves an ester interchange, leads to a poly-ester with a molecular weight considerably above 3000, since the reaction consists merely in self-addition and proceeds rapidly at 100°.

[8] See Staudinger, *Ber.*, 59, 3019 (1926).

Dimeric Ethylene Succinate.—Tilitschejew[9] has reported the isolation of a new ethylene succinate from the volatile materials formed by heating the product of the action of succinic acid on glycol (m. p. 88–89°) to 340–390° under 3–4 mm. pressure. The new product was distinguished from the usual form not only by its different melting point (129–130°), but by its definite macrocrystallinity. Cryoscopic data on acetic acid solutions of the new ethylene succinate indicated a double formula and, since Vorlander had already reported[10] that the old form was dimeric, Tilitschejew regarded his new ester as an isomer of the old. It has now been established that the usual form of ethylene succinate is not dimeric, but much more highly polymeric; the new compound cannot, therefore, be simply an isomer of the old. Aside from this, however, repetition of Tilitschejew's experiments has completely verified the correctness of his claims as to the nature of the new compound. It crystallizes in thin plates melting sharply at 130°. The analytical data clearly indicate that it is dimeric ethylene succinate.

Anal. Calcd. for $(C_6H_8O_4)_2$: C, 50.00; H, 5.50; mol. **wt.,** 288; saponification equivalent, 72. Found: C, 49.85, 50.00; H, 5.60, 5.57; mol. wt., in boiling ethylene chloride, 302, 299; in freezing benzene 279; saponification equivalent, 71.97, 71.95, 71.66.

Attempts to partially saponify this ester were unsuccessful—a part of the ester was recovered unchanged and the remainder was degraded to sodium succinate and glycol. Nevertheless, it seems fairly certain that this compound is the 16-membered ring, IX. No alternative formula seems



$$\begin{matrix} O-(CH_2)_2-O-OC-(CH_2)_2-CO-O-(CH_2)_2-O-OC-(CH_2)_2-CO \\ OC-(CH_2)_2-CO-O-(CH_2)_2-O-OC-(CH_2)_2-CO-O-(CH_2)_2-O \end{matrix}$$

(IX)

plausible. It is very improbable that this compound is present as such in the polymeric ester from which it is prepared. The dimer is quite soluble in hot absolute alcohol; the neutral polymer is quite insoluble. Continuous extraction of the polymer with hot absolute alcohol resulted in the solution of only a very small amount of material and this had the properties of the polymer not of the dimer. The dimer must therefore be formed during the process of thermal decomposition. The transformation of polymeric trimethylene carbonate into monomeric ethylene carbonate described in the previous paper[6] proceeds smoothly and practically quantitatively at about 200°. The formation of the dimeric tetramethylene carbonate, described in the same paper, and of dimeric ethylene succinate occurs only at a much higher temperature. Large amounts of gaseous and liquid products are formed as well as considerable

carbonaceous residue. The yields of the dimers are quite small, *e. g.*, 3–4% of the theoretical under the best conditions (Tilitschejew, however, reports 5.5%). In these respects the reaction resembles that used by Ruzicka for the preparation of the large cyclic ketones.[11] As yet we have not succeeded in isolating any monomeric ethylene succinate from the products of this reaction.

Ethylene Succinate and the Association Theory of High Polymers.—The discussion in this and the previous papers will, it is hoped, have amply demonstrated the adequacy of the ordinary structural theory of organic chemistry to deal with the poly-esters, a fairly complicated class of high polymers.

A possible explanation of the structure of the poly-esters which has not yet been considered is the following. The chemical unit or molecule of ethylene succinate is the monomeric 8-ring, VII. Because of the great strains in this structure, or for some other reason, it exhibits exceptionally strong residual or lattice forces, so that the osmotic unit becomes an aggregate of a great many of these ultimate chemical units. There is such a complete lack of any general theoretical justification for this view that there would be no need to consider it in connection with the poly-esters were it not that in the field of natural polymers such as cellulose, rubber, etc., in various slightly differing forms it has been defended at great length by so many investigators.[12]

Among the many facts which are quite incompatible with any association theory of the structure of poly-esters, the following deserve special mention.

(1) All of the known cyclic esters containing larger-than-6-rings are stable substances with definite properties corresponding with their simple formulas. They do not show any tendency to associate in solution.

(2) The polymeric esters corresponding to these monomers show no tendency to dissociate.

(3) In the polymeric ethylene succinates the chemical and osmotic units have been shown to be identical within the limits of experimental error, i. *e., ebullioscopic data give the same values for the molecular weights that are given by the determination of hydroxyl or carboxyl.*

The association theory is not clearly enough defined to permit any more crucial tests than these, but the following experiment at any rate agrees with these in the conclusions to which it leads.

If two different association polymers $(A)_n$ and $(B)_m$ are mixed in solution or in the liquid state so that they constitute a single phase, then

[12] See for example Bergman, Knehe and Lippmann, *Ann.*, **458**, 93 (1927); Hess, Trogus and Friese, *ibid.*, **466**, 80 (1928); Schlubach and Elsner, *Ber.*, **61**, 2358 (1928); Pummerer, Nielsen and Gündel, *ibid*, **60**, 2167 (1927).

since $(\mathrm{A})n \rightleftarrows n\mathrm{A}$ and $(\mathrm{B})m \rightleftarrows m\mathrm{B}$, the resulting mixture should be composed at least in part of (AB),.

Ethylene sebacate (m. p. 78°) and ethylene succinate (m. p. 103°) were melted together and thoroughly mixed. After cooling, the mass was extracted with benzene, which is a solvent for the sebacate but not for the succinate. The residue melted at 103° (unchanged succinate). To the benzene solution petroleum ether was added; the precipitated solid melted at 78–79° (unchanged sebacate). An ester was prepared by the action of glycol on equivalent amounts of succinic and sebacic acids. This was quite different in its properties from either the succinate or sebacate and it was homogeneous in its solubility behavior (m. p. 38–40°; mol. wt. 1540). This demonstrates the existence of a mixed polymer and the absence of any reversible relationship of association between it and the two corresponding simple polymers.

In the 6-ring esters a reversible relationship exists between the monomeric and polymeric forms, and some of the statements made above do not apply to these polymers. But it is possible, nevertheless, to account satisfactorily for the behavior of these esters without the assumption of any special or peculiar kinds of valence.[6]

The view that the ordinary structural theory of organic chemistry is adequate to deal with high polymers has been now for several years ably defended by Staudinger and his collaborators,[13] and recently the same view has been applied in a brilliant fashion to such natural polymers as cellulose, rubber, silk fibroin, etc., by Meyer and Mark.[14] So far as the minor differences[15] in the views of these two groups of investigators are concerned, our own experiments on poly-esters incline us to favor those of Staudinger. That is, we can find no real objection to referring to primary valence chains as molecules, and among the polyesters these molecules are experimentally identical with the osmotic units of their solutions.

The writers are indebted to Mr. W. H. Taylor for the molecular weight determinations and to Mr. G. A. Jones for the determinations of carbon and hydrogen.

Summary

The polymeric ethylene succinate previously described is shown to be a long chain made up of the recurring unit —O—(CH$_2$)$_2$—O—CO—

$(CH_2)_2$—CO— and bearing hydroxyl groups at its **ends.** Acidic ethylene succinates made up of similar chains of various lengths and bearing carboxyl groups at their ends have been prepared. Molecular weight determinations of these esters based on ebullioscopic measurements agree with those based on chemical evidence (estimation of hydroxyl or carboxyl).

A study of the ethylene succinate prepared by Tilitschejew verifies his claim that it is dimeric, and this ester is undoubtedly a 16-membered ring.

THE RELATIVE RATES OF ABSORPTION OF THE GASEOUS OLEFINS INTO SULFURIC ACID AT 25°[1]

BY HAROLD S. DAVIS[2] AND REUBEN SCHULER[3]

RECEIVED AUGUST 8, 1929 PUBLISHED FEBRUARY 6, 1930

This paper deals with measurements of the rates at which the gaseous olefins and the vapors of some liquid olefins are absorbed by sulfuric acid of various concentrations at 25°.

The quantity of acid used was always much larger than the molecular equivalent of the amount of olefin taken so that the data apply only to sulfuric acid in the initial stages of saturation, where its character was not perceptibly changed by dissolved olefin reaction products. Thus the absorptions were of the type which take place in gas analysis pipets except that they were carried out at constant volume instead of at constant pressure.

Apparatus.—The apparatus employed to measure the rates of absorption (Fig. 1) consisted essentially of a cylindrical glass reaction chamber connected to a glass manometer tube dipping in mercury. A measured volume of the olefin gas was introduced into the evacuated chamber which contained sulfuric acid. The progress of the absorption was followed by recording the gaseous pressure shown by the height of mercury in the manometer tube at successive periods of time. When desired the chamber could be turned on its major axis at a definite number of rotations per minute (r.p.m.), the manometer tube turning with it. A flexible piece

of rubber tubing connected the two, and a stopcock isolated the chamber between readings.

Three absorption chambers were used during the course of the experiments. The inside dimensions of Nos. 2 and 3 used in the final experiments were: length 15.9 cm., diameter 5.1 cm., volumes 289 and 284 cc., respectively, including the connecting tubes. All three were made from standard 50 × 400-mm. pyrex test-tubes.

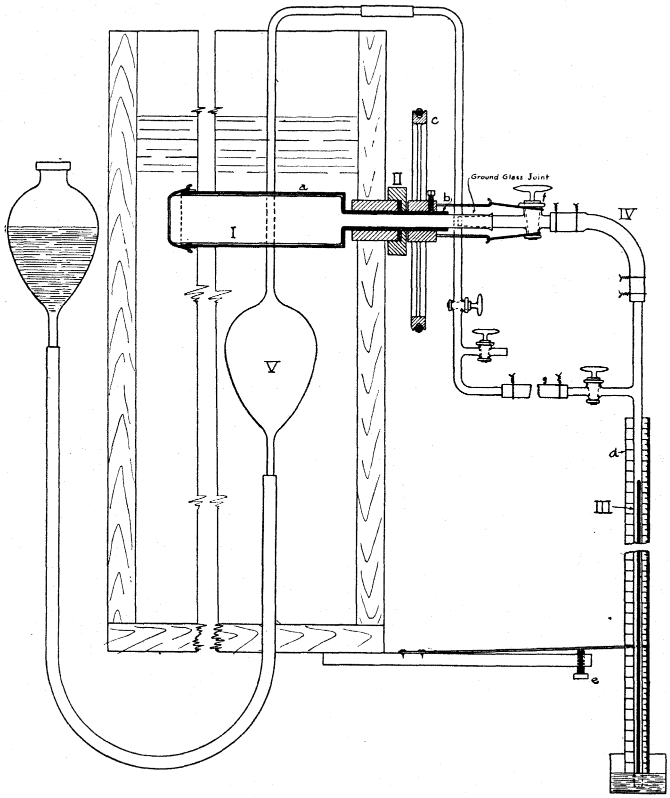

Fig. 1.—Apparatus for measuring the rate of absorption of an olefin gas into sulfuric acid. I.—Cylindrical glass reaction chamber, capacity 289 cc., in brass jacket "a," immersed in water-bath at *25".* 11.—Water-tight stuffing box through which passes exit tube "b" of brass jacket to driving wheel "c." 111.—Manometer tube dipping into mercury with a calibrated meter stick "d" adjusted to changing mercury level in cup by screw "e." IV.—Pressure tubing between chamber rotating horizontally and manometer rotating vertically. V.—Reservoir bulb for known volume of olefin gas to be introduced into reaction chamber "I" by mercury displacement.

Experimental Procedure.—Numerous preliminary experiments (1–12)

Table II, were necessary in order to develop our technique. These preliminary experiments contain, necessarily, many errors but they also contain material of such value that they have been included in the table of collected results.

The following discussion of the errors which were detected and of the methods used to overcome them throws light on the entire procedure. (1) In the preliminary experiments, the volume of the olefin gas was not measured before it was allowed to flow into the evacuated reaction chamber. Accordingly, it was not possible to gage the quantity absorbed by the liquid before the first pressure reading was taken. In the final experiments a definite volume of olefin gas, measured at atmospheric pressure and 25° in the reservoir bulb (V) was introduced into the evacuated chamber. From tests made with air and mercury in place of the olefin and the sulfuric acid, respectively, the pressure which the olefin gas would give in the reaction chamber if none dissolved in the acid was found. This calculated value represented the pressure reading at the beginning of an absorption, *i. e.*, $t = 0$. In no case was there any evidence of a rapid initial absorption which might have been attributed to physical solution of the gas in the acid.

(2) In the preliminary experiments care was not taken, during the addition of the acid, to prevent wetting the side walls and the ends of the chamber above the final level of the acid. However it soon became evident that a thin film of acid on the glass was, for a limited period of time, as effective for absorption as a similar area on the main body of the liquid. This error undoubtedly accounts for the wide variations in the preliminary results where the absorptions were measured with the chamber at rest [r.p.m. = 0]. In the final series the chamber was put in place as shown in the figure with the ground-glass joint open. The sulfuric acid was then poured into the center through a small funnel with a long bent stem. In this way wetting of the walls was largely avoided.

(3) Reaction chamber No. 1 was used in the preliminary experiments. It wobbled a little during rotation so that the sides were wetted unevenly and little waves were produced on the acid surface. Further, it had rounded ends, like an ordinary test-tube, from which at high speeds of rotation (100–200 r.p.m.) the acid drew away. Chambers 2 and 3 used in the final experiments were fitted inside a brass jacket which had been carefully centered to run true. Wobbling was thus cut down. Furthermore, their ends were flattened as much as possible which minimized, although it did not entirely eliminate, the errors caused by the round ends of No. 1.

(4) In the preliminary experiments no stopcock existed between the chamber and the rubber tube so that part of the olefin might have been absorbed, not into the acid but into the rubber. However, an analysis of the data shows that this error was much smaller than might have been expected. In all fast experiments it was negligible. For Expts. 50–80 a stopcock (F) was placed between the chamber and the rubber connection (IV). It was kept closed except when a pressure reading was taken. Any olefin in the manometer tube itself was removed by evacuating shortly after the start and replaced by air. The resulting apparatus held the olefin in the chamber out of contact with the rubber and even those absorptions could be safely followed which were so slow that they required several days for completion.

The Acid Surfaces and the Effects of Rotation.—Numerous experiments were carried out with the chamber at rest (r.p m. = 0). On rotation a fairly thick layer of acid was carried up one side. Part of this flowed back again but a thin film passed on to the other side. Here it met the surface layer of the liquid, which curved down several millimeters, and both were drawn under the liquid. Thus the surface of the film on the glass and that of the liquid itself were continuously renewed during rotation. A considerable mixing in the liquid also took place. If less than 10 cc. was used, the acid did not wet the surface uniformly on rotation but tended to form pools especially at high speeds. In the final experiments *20* cc. was used. Here the area of the film formed by rotation was nearly four times that of the liquid surface proper. Estimates were made of the average thickness of the acid films on the glass. This was done by measuring the change in the surface width of the acid, colored by purpurogallin, produced by rotation, and calculating its corresponding change in volume. For *70%* sulfuric acid the thickness was 0.1 to 0.3 mm., increasing with the speed of rotation. For concentrated acid it was somewhat greater.

Thin as these films were, they were thicker than the layers containing acid molecularly equivalent to all the gaseous olefins in the chamber, which were calculated to be only 0.04 mm. thick for *70%* acid and *0.023* mm. for concentrated.

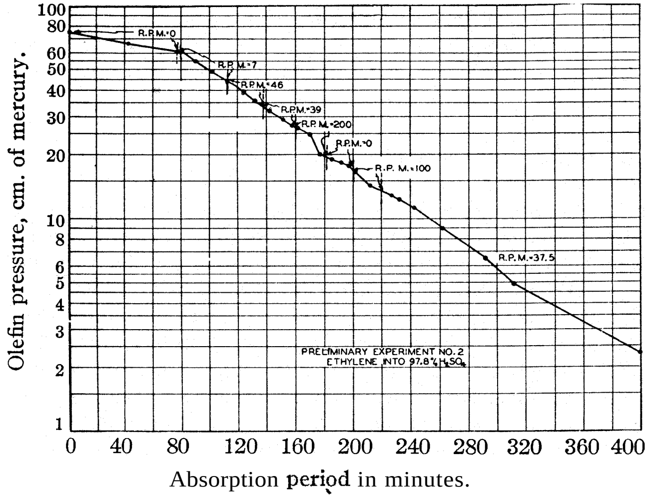

Fig. 2.

Calculations.—The actual variables measured in each experiment were (1) the length of the absorption period and (2) the gaseous pressure of the olefin. An examination of the absorption curves in Figs. 2 to 9, which are plotted on semi-logarithmic paper, shows that they tend to form straight lines over the greater part of the absorption. (The logarithm paper exaggerates the variations in the last period of absorption just as Mercator's projection makes Greenland seem larger than the United States on the map. Although the lower cycle is equal in width to the upper cycle, its range of values is only one-tenth.) That is, the logarithm of the olefin pressure decreased uniformly in proportion to the length of the absorption period and for each experiment the factor $1/t \ln 1/(1 - X)$ gave a fairly constant value of K (where X was the fraction of the olefin dissolved).

The magnitude of K was independent of the partial pressure of the gas and of the time of contact, To this extent its values are characteristic for the absorptions of the separate olefins.

Illustrative Calculations.—Preliminary experiment No. 2 (Fig. 2).

The absorption was followed for the first seventy-seven minutes with the chamber at rest. A straight edge placed on the absorption curve shows that it is sloping quite uniformly. The pressure would reach half value (37 cm.) in 300 min. Accordingly, K (for r.p.m. = 0) = $1/300 \times 60 \ln (1)/(1 - 0.5) = 0.39 \times 10^{-4}$.

The chamber was then rotated steadily at the rate of seven turns per minute. The absorption rate at once increased, due, as will presently appear, to the absorbing power of the acid film now formed on the glass surfaces. Nor was the rate much affected by a change in the speed of rotation. The variations in the slope seem to have been caused by experimental errors. (See discussion above of preliminary results.) As a whole, this absorption curve, for the tube rotating, lies around a straight line of such a slope that the pressure at any time would reach half value in about 70 min. Accordingly, K (chamber rotating) = $1/(70 \times 60) \times 0.693 = 1.65 \times 10^{-4}$.

In order to compare the absorption rates in cases where different areas of acid surface were exposed, or where different volumes of gas were used, it was found convenient to calculate from K in each case *a specific* ***absorption coefficient*** *C* which may be defined as the proportional change in volume at constant pressure which would take place in an infinitesimally short time when 1 cc. of the gas was in contact with 1 sq. cm. of an acid surface having the average absorbing power of the total acid surfaces

$$C = \frac{V\mathrm{d}p}{Ap\mathrm{d}t} \text{ at constant volume, or}$$

$$= \frac{dv}{A\mathrm{d}t} \text{ at constant pressure}$$

where A is the area of the absorbing surfaces.

At constant pressure, C is evidently equal to the average number of cc. of gas absorbed by 1 sq. cm. of acid surface in 1 sec.

The gas volumes for each experiment were easily found by subtracting from the total volume of the chamber, that of the acid used. The measure-

TABLE I

CALCULATED VALUES OF THE FACTOR *m* FOR THE VARIOUS EXPERIMENTAL CONDITIONS

	Chamber No. 1		Chamber No. 2		Chamber No. 3	
Vol. acid, cc.	At rest	Rotating	At rest	Rotating	At rest	Rotating
10	8.06	1.30				
20	6.11	1.25	5.50	1.12	5.40	1.09
25	5.69	1.23				
30	4.99	1.21				
90	2.73	0.887				

Completing the calculations started above for preliminary experiment No. 2 (ethylene + concd. H_2SO_4)

Chamber at rest $C = 0.39 \times 10^{-4} \times 4.99 = 1.95 \times 10^{-4}$

Chamber rotating $C = 1.65 \times 10^{-4} \times 1.21 = 1.99 \times 10^{-4}$

ments of the surface areas were more difficult: (a) the acid surface proper, area = width × average length. This constituted the whole absorbing surface at r.p.m. = 0. On rotation the following additional areas of absorbing surface were formed: (b) the acid film on the cylinder walls, area = average length × perimeter above acid surface, (c) the acid film on the ends, area = total area of ends − (area under acid + area not wetted)

$$C = mK \qquad \text{where } m = \frac{\text{Total cc. of gas}}{\text{Total area of absorbing surface}}$$

Discussion of Data

Reliability of the Measurements.—An examination of the figures shows that the absorption curves for check experiments usually lie very close to each other. The average deviation of K from the mean in 22 experiments in nine different types of absorptions was 1.6% (excluding Nos. 27 and 75 for 2-butene, where the deviation was 19%).

The Effects **of** Changes in the Rate of Rotation and in **the** Quantity of **Acid** Used.—For ethylene these effects are shown by Table VI.

TABLE V

EXPERIMENTAL RESULTS

The solutions of sulfuric acid were prepared from C. P. material and their concentrations were checked by titration

Olefin	Method of preparation[a]	B. p., °C.	F. p.,[b] °C.
Ethylene	"Refined" ethylene purchased from a well-known firm	......	...
Propene	Isopropanol and phosphorus pentoxide	−47.3 at 770 mm.	.....
1-Butene (A)	n-Butyl iodide and alcoholic potash	−6.0–−5.8	....
1-Butene (B)	Dehydration of n-butanol over alumina	−6.3–−5.1	.....
2-Butene (A)	*Sec.*-butyl iodide and alcoholic potash	1.8–2.2	−113
2-Butene (B)	2-Butanol and phosphoric acid	1.5–1.7	−122
Isobutene	*Tert.*-butanol and oxalic acid	−7.0–6.9	−140.3
Trimethylethene	*Tert.*-amyl alcohol and oxalic acid	38.4–38.45	−134
Isopropylethene	Dehydration of iso-amyl alcohol over alumina and treatment of product with dilute sulfuric acid	20.1–20.4	.....

[a] All the samples were finally purified by fractionation in a vacuum-jacketed spiral column. For details of the preparations see Davis, THIS JOURNAL, 50, 2769 (1928); Ind. *Eng.* Chem., Anal. *Ed.*, 1, 61 (1929). For isopropylethene the method of Norris and Reuter was used, THIS JOURNAL, 49, 2526 (1927). The sample of trimethylethene was supplied by Mr. George Thomson.

[b] The freezing-point curves were kindly made by Professor E. L. Skau of Trinity College, Connecticut, who also supplied the following information drawn from the freezing-point curves. The isobutene is really quite pure. The 2-butene from 2-butanol and phosphoric acid seems to be a mixture. That from *sec.*-butyl iodide and alcoholic potash is better but is still far from pure. However, it may be noted that all the freezing points are higher than those found by Coffin and Maass for these substances: *iso*-butene, 146.8°; 2-butene, −127° [THIS JOURNAL, 50, 1433 (1928)]. The samples of 1-butene and *iso*propylethene did not freeze in liquid air (Coffin and Maass, supra, Norris and Reuter, ibid.).

TABLE VI

ABSORPTION RATES PER UNIT AREA ($C \times 10^4$) FOR ETHYLENE INTO CONCENTRATED SULFURIC ACID AT DIFFERENT RATES OF ROTATION AND FOR DIFFERENT VOLUMES OF ACID

Expt.	H_2SO_4, cc.	R.p.m., 0	R.p.m., 7	R.p.m., 38–44	R.p.m., 100	R.p.m., 200
3	10	1.97	1.72	2.02	2.48	2.00
2	30	1.90	1.78	2.33	3.12	..
4	90	1.62	1.44	2.02	..	3.93

These results show that for the absorption of ethylene into concentrated sulfuric acid: (a) the film of acid on the glass absorbed as well per unit area as the surface of the acid itself, (b) the absorption rate was not greatly changed by the renewal of the surfaces or by the agitation in the liquid caused by rotation.[4] (c) The rate was hardly affected by a nine-fold change in the volume of the acid. Accordingly it must be concluded that the reaction between the ethylene and sulfuric acid took place entirely in a very thin film at the surface. The ethylene never reached the main body of the acid at all.

Similar conclusions hold for the absorption of ethylene into 80% acid and of isobutene into 70% acid (see Table III). In other cases the values for C at r.p.m. = 0 are quite different from those obtained with the chamber rotating. These divergencies might in part be attributed to errors in the former measurements, e. g., part of the glass surface is wetted by acid drawn up through surface tension. They are worthy of further study because of their bearing on the selection of methods for separating olefins in gas analysis by selective absorption in sulfuric acid.[5]

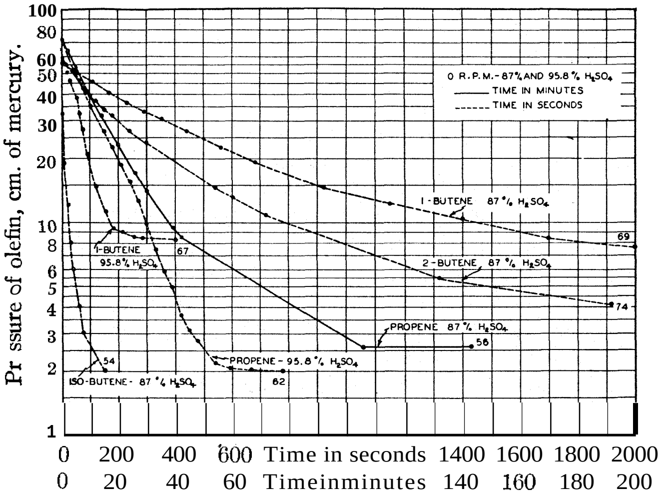

Fig. 3.

The Effect of Foreign Gases (Table II).—Propene was absorbed into 87% sulfuric acid from a 77% mixture with oxygen (No. 40) at the same rate, $C = 39.8$, as pure propene, $C = 38.2$. Nor was its absorption affected by the presence of an equal volume of ethylene (No. 41) $C = 39.9$. Tri-

---

[4] This very important conclusion has since been confirmed by absorption measurements in another apparatus where the liquid can be stirred without changing the area of its surface. Identical rates of absorption for ethylene into concentrated sulfuric acid were found when the rates of stirring were, respectively, 0, 90 and 480 r.p.m. Full details will be published later. On the other hand, Becker, *Ind. Eng. Chem.*, 16, 1236 (1924), showed that slow stirring (60 r.p.m.) increased the rate of absorption of oxygen into water 25 times.

[5] Unpublished data by Davis and Quiggle show that propene is absorbed about 1000 times faster than ethylene by 87% sulfuric acid in an Orsat pipet. Compare the corresponding ratios in Table IV, 550 at r.p.m. = 0 and 362 at r.p.m. = 28.

methylethene vapor was absorbed at the same rate when pure and when mixed with 96% of air (Nos. 43 and 44).

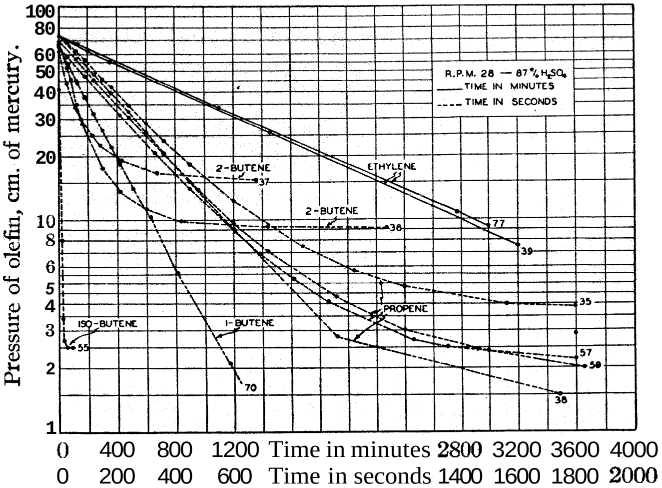

Fig. 4.

The Relation between the Acid Concentration and the Relative Rates of Absorption of Ethene and Propene (Table IV).—Considering only the measurements made on these two gases with the chamber rotating, those

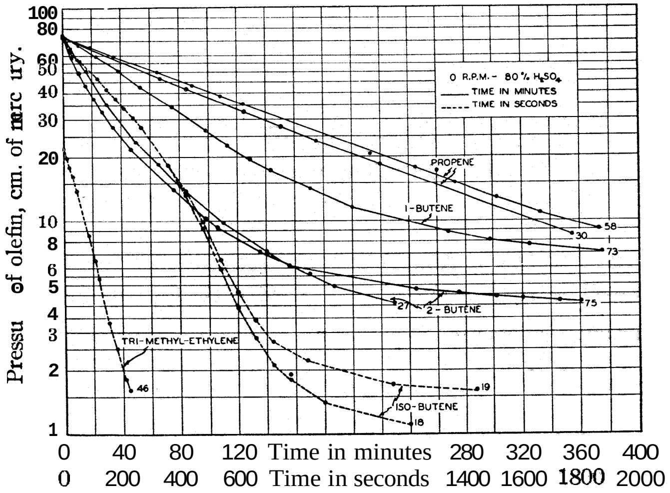

Fig. 5.

for 80 and 87% acid are the most reliable both because of the number of check experiments and because of the magnitudes of the pressure changes and of the periods of time involved. The values for propene in 95.8%

acid and for ethene in 60% acid are approximate only, because the former was a very rapid and the latter a very slow absorption.

It appears then that, within the accuracy of the measurements, the absorption rate of propene remained always about 300 times that of ethylene for concentrations of acid from 80% to concentrated, this in spite of the fact that the absolute values for the rates of both changed almost 200 times. This result is of importance in relation to the selection of the concentration of sulfuric acid most suitable for selectively absorbing propene from gases containing ethylene in the manufacture of *iso*propanol. It also raises doubt as to whether the superior merits claimed by Tropsch and Philippovich[6] for 87% acid in gas analysis absorptions for separating propene and its higher homologs from ethylene will hold for all types of pipets.

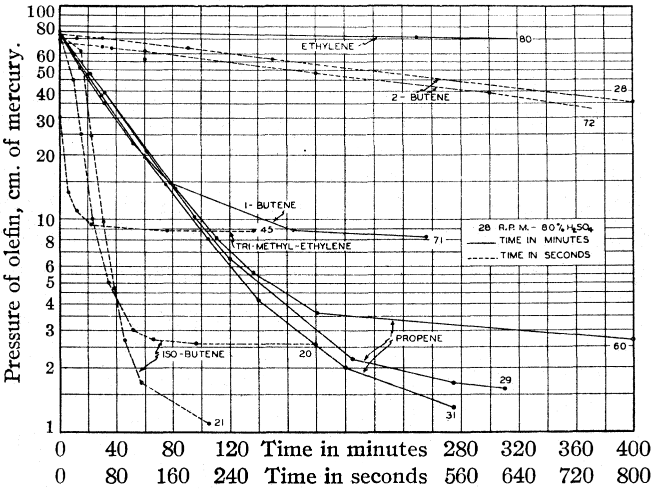

Fig. 6.

The Relative Rates of Absorption of Propene and the Three Butenes (Table IV).—The results show conclusively that propene and 1-butene

---

[6] Tropsch and Philippovich, *Brennstoff-Chem.*, **4, 147 (1923).** It may be noted that the following table prepared from the excellent data of these observers on absorptions from synthetic mixtures of ethylene and propene hardly supports their conclusion.

H_2SO_4 used, %	**99**	**90**	**88**	**87**
Contact in Hempel pipet with pearls, minutes	5	2	5	5
Relation of absorption to propene taken, %	100	104, 99.7, 99.5	102, 92	96.1, 100

Manning, King and Sinnatt, *Dept. Sci., Ind. Research* (Brit.), Technical Paper No. **19,** p. **8,** who used **87%** acid for this purpose in a standing pipet, found it necessary to correct for the ethylene absorbed. They state "It is interesting to note that the diminution in volume after ten minutes' absorption does often coincide with the true volume of the higher olefins as found by the above method (T. and P.), the small ethylene absorption compensating at that moment for the residual unabsorbed higher olefins."

dissolve at about the same rate in sulfuric acid of any concentration. Indeed for dilute acids it is uncertain which dissolves the faster. This question has considerable theoretical importance and is being investigated further. The somewhat higher rate of 1-butene, relative to propene, in concentrated acid may be due to its greater ease of polymerization.

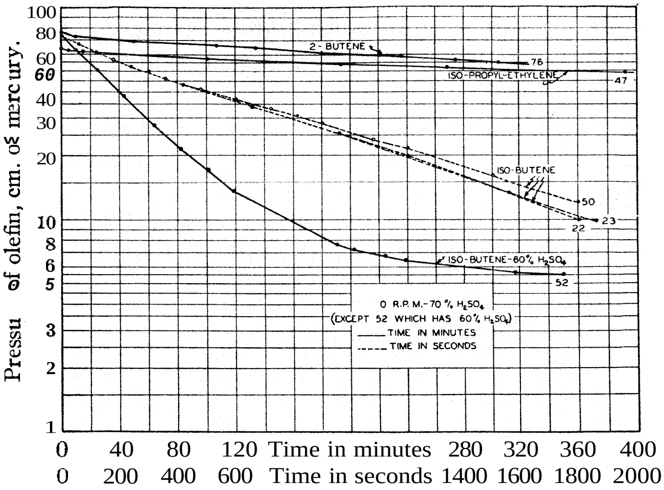

Fig. 7.

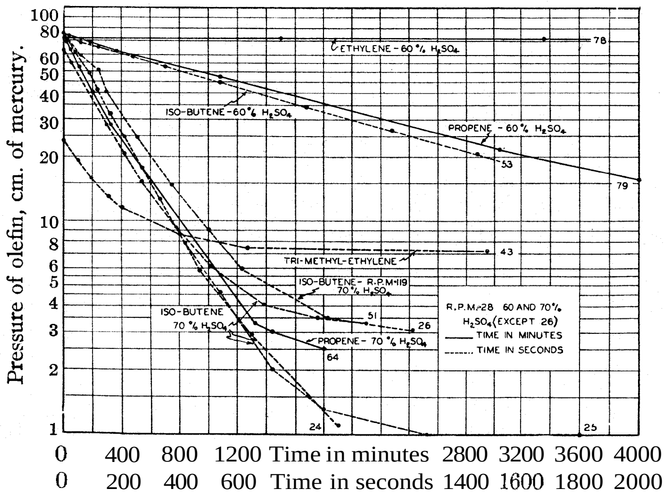

Fig. 8.

The ratio of the absorption rate of 2-butene to 1-butene is remarkably constant, 1.7 to 2.6 for 70 to 87% acid.

These facts show the unreliability of certain gas analysis methods which have been proposed involving the separation of the normal butenes from propene by selective absorption in sulfuric acid. This subject will be dealt with in another paper.

The values for isobutene vary in a puzzling manner However, it dissolved about 10 to 80 times as fast as 2-butene, which shows that it can be separated from propene and the normal butenes by selective absorption in sulfuric acid, although not as sharply as can propene from ethylene.

Isobutene and Trimethylethene (Table II).—According to our measurements, trimethylethene vapor was absorbed three to four times faster than gaseous isobutene into 80% sulfuric acid and 1.3 times faster into 70% acid. However Michael and Brunel[7] showed that when liquid

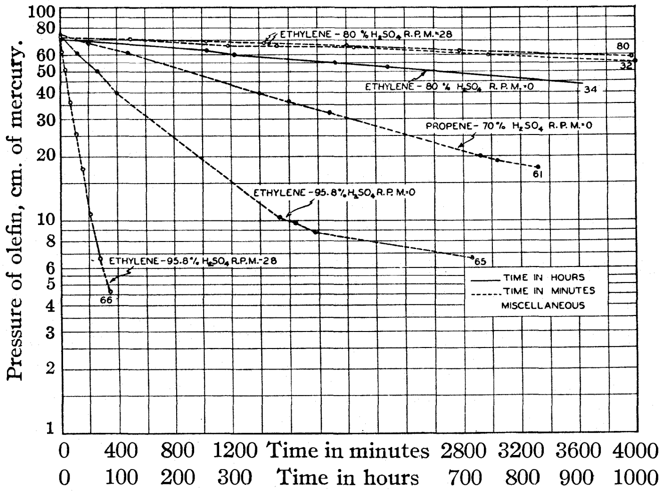

Fig. 9.

isobutene and trimethylene were shaken with 65% sulfuric acid or with more dilute acids in sealed tubes under similar conditions, isobutene dissolved at least three times as fast as trimethylethene.

Consideration must, however, be given to the differences in the conditions existing in the two methods of experimentation. In that of the writers the ratio of the absorption coefficients (C) of two olefins shows the ratio of the quantities which are dissolved when their gaseous partial pressures are equal. On the other hand, in the reaction tubes of Michael and Brunel the partial pressure of the isobutene (b. p. −6.8") must have been much larger than that of the trimethylethene (b. p. 38.4°).

From data obtained by the same experimental procedure, these investigators have compared relative rate of reaction with sulfuric acid for the two liquids cited above and also tetramethylethene (b. p. 71–72") and

---

[7] Michael and Brunel, *Am. Chem. J.*, **41, 118** (1909)

di-isobutene (b. p. 102–102.5°). When two liquids dissolve in and react with a solvent, to what extent are their relative rates of solution, on shaking, characteristic of their rates of reaction in the solution?

Isopropylethene.—The two measurements Nos. 42 and 47 indicate that this olefin is absorbed only slowly by 70% sulfuric acid at a rate comparable with that of propene.

The Researches of Michael and **Brunel.**[7]—These investigators measured the rates at which the individual butenes were absorbed when shaken with sulfuric acid of various concentrations in Hempel pipets. It has been pointed out by one[8] of us from their data that approximately the same fraction of the olefin was dissolved in unit time over the whole range of each experiment. This is also clearly shown by the fact that the absorption curves when plotted on semi-logarithmic paper are nearly straight lines (Fig. 10).

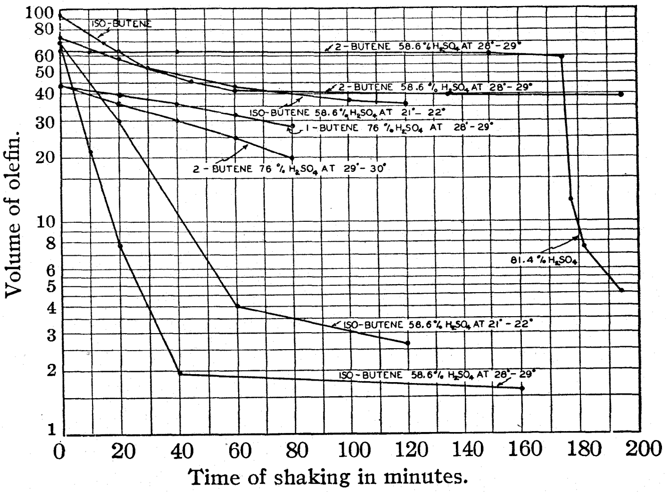

Fig. 10.—Michael and Brunel's absorptions in Hempel pipets.

This experimental fact could be explained if the amount of the absorption was always proportional to the area of the absorbing surface and if this area decreased proportionally with the gas volume. The actual relationships between the volumes of gas and the surfaces exposed in an ordinary Hempel pipet are shown in Table VII.

Michael and Brunel assumed that the rate of absorption of the olefin was proportional to the area of the liquid surface and corrected for variations in the sizes of their pipets on that basis. However, as has been shown above, a fresh acid film on the glass is as effective for absorption per unit area as the liquid surface itself, and moderate shaking wets the whole

[8] Davis, This JOURNAL, 50, 2780 (1928).

surface of a Hempel pipet if the gas volume is not excessive. As a first approximation the area of the absorbing surface may be taken as the sum of the liquid surface and of the glass above it with the pipet at rest. Table VII shows that this total area holds a more constant ratio to the gas volume than that of the liquid surface only.

TABLE VII

RELATIONS BETWEEN GAS VOLUMES AND ACID SURFACES FOR A SPHERICAL HEMPEL PIPET OF 175-CC. CAPACITY AT REST

r = radius. h = distance from center to liquid level

h cm.,	Volume of gas. cc. $\frac{2}{3}\pi r^3 - \pi\left(r^2h - \frac{h^3}{3}\right)$	Liquid surface sq. cm. $\pi(r^2 - h^2)$	Glass surface above liquid, sq. cm. $2\pi r(r - h)$	Total liquid and glass surface exposed, sq. cm.	Ratio of liquid surface/ vol of gas	Ratio of total surface/ vol. of gas
−1	124	35	97	132	0.28	1.16
0	88	38	76	114	.43	1.30
+0.5	69	37	65	102	.54	1.48
1	51	35	54	89	.68	1.74
1.5	34	31	43	74	.89	2.14
2	20	25	32	57	1 23	2.8
3	2.4	10	10	20	4 0	8 2

Nevertheless, for gas volumes from 70 to 20 cc. the ratio of the total surface to the volume changes about 100%, while some of the curves for the absorptions of Michael and Brunel remain fairly straight for even larger changes of gas volume. It appears that the course of their absorptions in Hempel pipets, moderately shaken, was much more uniform than would be predicted from the postulate that the quantity absorbed in unit time was always proportional to the total area of the liquid surface and the film on the glass measured at rest. This is not an academic problem. It is fundamental for the standardization of selective absorptions in gas analyses that the laws governing the absorption rates should be known for the various types of pipets.

To calculate the specific absorption coefficients C from the data of Michael and Brunel the constants $K = 1/t \ln (V_0/(V_0 - V_t))$ as calculated from the absorption curves, must be multiplied by the ratio of the volume of the gas to the area of the absorbing surface. Taking the ratio of total acid surface to volume existing for 50 cc. of gas, the following values were calculated in two cases where comparisons could be made with ours for the rotating absorber.

Absorption conditions	C
2-Butene into 81.4% H_2SO_4 in Hempel pipet at 28–29°.	55 X 10^{-4}
2-Butene into 80% H_2SO_4 in rotating absorber at 25°...	10.5 X 10^{-4}
Isobutene into 58.6% H_2SO_4 in Hempel pipet at 28–29°.	12 X 10^{-4}
Isobutene into 60% H_2SO_4 in rotating absorber at 25°...	9.7 X 10^{-4}

The agreement is rather remarkable. In the case of 2-butene they used a stronger acid at a higher temperature than we and a greater value for *C* would be expected. In the case of *iso*butene the effects of the differences in acid concentration and in temperature tended to counterbalance.

The Research of A. Dobrjanski.[9]—Instead of a Hempel pipet, this investigator used a glass cylinder of constant cross section for absorption into sulfuric acid. The olefin gas was introduced from a mercury buret, and in taking the separate volume readings as the absorption proceeded only part of the gas was withdrawn into the buret, apparently up to a fixed mark in the chamber. After a somewhat higher initial rate had subsided, each olefin gas dissolved at uniform speed for a long time. In each experiment an excess of acid 800 to 1000 times the theoretical was used.

Dobrjanski criticizes the use of Hempel pipets by Michael and Brunel for measuring absorption rates because, as pointed out above, the ratio of the area of the liqud surface to the volume of the gas changes as the absorption proceeds. For this reason he used a vessel of constant cross section 19.5 sq. cm. and tried to avoid wetting the upper surfaces during the volume readings. Unfortunately he does not seem to have recognized the high absorbing capacity of the acid films left on the glass and the errors from this source appear to have vitiated much of his otherwise valuable data.

He attributes the high initial rates of absorption to physcal solution of the gases in the acid. It seems more probable, however, that the observed effect was due to absorption into the film of acid left on the whole glass surface when the acid was forced down to admit the gas at the beginning.

For ethylene and propene the absorptions were carried out in three ways: first with the pipet at rest, second with the acid in the pipet tossed back and forth every five minutes, which about doubled the rate, and third with the pipet shaken continuously 120 times per minute, which increased the rate 5 to 28 times, depending on the concentration of the acid. The volume readings were taken every ten minutes. Evidently such procedures will give great variations in the total area of the absorbing surface and in the freshness of the acid film. It is not possible to calculate from Dobrjanski's data specific absorption coefficients comparable to ours and even his values for the relative rates of absorption of the different olefins appear to be only qualitative.

The present paper deals only with experimental investigations of the rates at which olefins are absorbed by sulfuric acid. The expression "rate of reaction" has been purposely avoided. The relationships between the rates of absorption of gases and the rates and types of the reactions which take place in solution need further consideration. The magnitudes of the physical solubilities of the gases and their rates of diffusion in the

solution are important factors. Nor should the possibility be overlooked that reactions may take place between the gaseous olefin molecules and the surface molecules of the acid.

Summary

1. Measurements have been carried out on the rates of absorption of olefin gases and vapors into sulfuric acid at constant volume by following the change in the gaseous pressure with time.

2. The logarithms of the olefin pressures plotted against periods of absorption form fairly straight lines. That is, the quantity absorbed in unit time was proportional to the partial pressure of the olefin.

3. When the reaction tube was rotated, the increase in the total absorption was largely proportional to additional area of acid surface formed on the glass.

4. Specific absorption factors (C) have been calculated on all the gaseous olefins into a large excess of sulfuric acid of various concentrations at 25° (Table III). They represent the cc. of gas absorbed, at constant pressure, by 1 sq. cm. of acid surface in one second and appear to be definite entities. They were often unaffected by the rate of renewal of the acid surface, by variations in the volume of the acid or in the degree of its agitation.

5. The reactions appeared to take place in a very thin film at the surface of the sulfuric acid. The gases never reached the main body of the liquid. Accordingly it seems advisable to use caution in drawing conclusions regarding the rates of reaction of gases with liquids in which they are sparingly soluble, from their rates of absorption.

6. Objections are raised to the practice of drawing conclusions regarding the relative rates of reaction of two liquids with another liquid from measurements of their relative rates of solution in it on shaking.

STUDIES IN AUTO-OXIDATION REACTIONS. I. OXIDATION OF ANETHOL, ETC.[1]

BY NICHOLAS A. MILAS[2]

RECEIVED AUGUST 8, 1929 PUBLISHED FEBRUARY 6, 1930

Introduction

In a very recent article[3] the author presented some evidence to show that "true" auto-oxidation reactions[4] are not only susceptible to inhibitory and accelerating action of small quantities of certain types of inorganic as well as organic substances, but are also capable of inducing the oxidation of other substances which ordinarily are not easily oxidized with molecular oxygen. Purthermore, it has been shown by Moureu and his collaborators[K] and more recently by the author[6] that auto-oxidation reactions induce the polymerization of unsaturated substances such as acrolein, styrene, iso-eugenol, etc.

Still another important characteristic which seems to be capable of generalization is the occurrence of a maximum oxygen absorption rate in all typical auto-oxidation reactions. The significance of this maximum rate was recently emphasized by the author,[7] who pointed out the existence of a definite'quantitative relationship connecting these maxima and the concentration of certain inhibitors such as anthraquinone and benzoquinone.

As a result of the tremendous interest shown recently in auto-oxidation reactions by various investigators, several methods have been developed for the measurement of oxygen absorption rates. Moureu and his coworkers: who carried out the principal part of the work in this field, employed a method which seems, in the opinion of the present author, to be inadequate for accurate quantitative measurements due to a failure of the investigators to observe the following facts.
