THE NATURE OF ACTIVATION HEATS. A CALCULATION OF THE HEAT OF ACTIVATION FROM BAND SPECTRA DATA

BY DONALD STATLER VILLARS

RECEIVED AUGUST 7, 1929 PUBLISHED MAY 8, 1930

When one compares the heat of activation in a chemical reaction with the heats of dissociation of one of the reacting molecules into its component parts (*cf.* Tables I, II and 111), the conclusion may be drawn that activation is not, in general, a dissociation but must be essentially an interaction between two molecules, in which both take part and which could not occur except for the presence of the second molecule. In the present paper this idea will be applied in detail to the hydrogen iodide decomposition, as the

TABLE I

DISSOCIATION ENERGETICS

Activation heats taken from Hinshelwood, "The Kinetics of Chemical Change in Gaseous Systems," Oxford, 1926. Heats of dissociation calculated from data in Tables II and III. Value for Cl + ClO taken as one-half "atomic" heat of formation of Cl_2O. Value in parentheses for H + I indicated from convergence limit [Tingey and Gerke, THIS JOURNAL, 48, 1838 (1926)], but uncorrected for the fact that absorbing molecules may be in a higher quantum state than the zero-th. Heat of activation for ammonia estimated (Hinshelwood, p. 93). Heat of activation for N_2O_5 decomposition given in parentheses corrected to ten degrees of freedom by formula

$$E_{\text{corr.}} = E_{\text{obs.}} + 2.303RT[((n/2) - 1)]$$

Substance	Products	Heat of dissociation, kg. cal.	Homogeneous heat of activation
N_2O_5	$N_2O_4 + O$	71	24.7
	$N_2O_3 + O_2$	20.2	
	$2NO + O$	251	
	$NO + NO_2 + O_2$	28.5	(30.4)
	$N_2O + 2O_2$	18.4	
	$N_2 + 2O_2 + O$	68	
N_2O	$N_2 + O$	48	59.4
	$N + NO$	110.5	
O_3	$O_2 + O$	35	26.0
Cl_2O	$Cl_2 + O$	52	21.4
	$Cl + ClO$	(55)	
HI	$H + I$	68.9 (64.4)	44.7
NH_3	$NH + H_2$	64.8	(70.0)

experimental data[1,2] for this reaction are the most accurate, and it will be shown that we can account qualitatively for its heat of activation if we make use of certain simple principles taught by the quantum mechanics.

These principles are the following. First, Franck[3] has shown that the electronic excitation of a molecule takes place instantaneously compared to its vibrational period, and that the separation of the nuclei can be considered to remain unchanged during the light absorption.[4] Condon[5] extended this principle by assuming that, for most of the time, the nuclei occupied those positions at the extremities of their vibrations, as it was here that the velocity of their motions was least. He was successful in explaining certain peculiarities of the intensity distribution in band spectra which had been mystifying up to that time, and has since shown how these considerations are in harmony with the quantum mechanics.[6]

Second, one of the characteristic differences between the quantum mechanics and the classical mechanics has been that the former takes account of degeneracy introduced by the fact that an electron, for example, in the H_2^+ ion may belong as well to a second similar atom as to the first one and have the same energy value. This degeneracy causes a probability distribution of the electron between the two atoms; if we think of the separate atoms and not the molecule, as a whole, the electron can be considered as belonging to one atom at one moment; at a later moment it may

change its allegiance to the other atom, although it does not change its position nor its energy. This idea may be extended to a system of atoms and it is just as reasonable to expect that two of these atoms may change their allegiance, provided the energy of the second state is equal to that of the first. Thus, in the decomposition of hydrogen iodide, if two molecules, H_aI_a and H_bI_b collide, two kinds of allegiance exchange are possible. After the collision, H_a may owe allegiance to I_b and H_b to I_a. This is similar to the case mentioned above of the molecular hydrogen ion. The energy perturbation arising in this case of degeneracy will account, in part, for the van der Waals attraction between the two molecules. But a second case is possible, where H_a may owe its allegiance to H_b and I_a to I_b. If this occurs, a chemical reaction has taken place.[7]

Our picture, then, of chemical activation, or rather of chemical reaction, for activation is concomitant with reaction, is that of a collision in which the nuclear separations of the atoms are such that the latter can change allegiance without changing their total energy content. Expressed in an equation, chemical reaction can occur only when

$$x + y - 1.4 = a + b \qquad (1)$$

where x and y are the internal energies of the two colliding hydrogen iodide molecules, a and b the internal energies of the hydrogen and iodine molecules, respectively, and -1.4 is the heat of reaction.[8] In the following calculations these energies are considered as representing vibrational energy only; they are the values obtaining at the moment just before and just after the exchange and do not account for any attractive or repulsive force between the hydrogen iodide molecules. Kinetic energy of the molecules after collision is considered equal to that before collision, since the probability of energy transfer by a collision of the second kind rapidly diminishes with increasing difference in the total kinetic energies.[9] Obviously, the energy of activation is

$$A = x + y + F \qquad (2)$$

where F is the potential energy due to repulsion of two hydrogen iodide molecules.

The calculation itself was a cut and try process. The vibrational potential energy curves were plotted for hydrogen, iodine and hydrogen iodide. The iodine nucleus defined the origin in the hydrogen iodide curve and was considered to be at rest. A one-dimensional collision was then depicted (Fig. 1) by bringing a templet of a second hydrogen iodide curve up within a definite distance of the first, corresponding to a possible nuclear

separation of the iodine molecule. The energy value of b was read from the iodine curve (Fig. 2). Then, by means of a pair of dividers, the separations of the two hydrogen atoms, consistent with Equation 1 were found for different values of y ranging from 0 to 60 kg. cal.

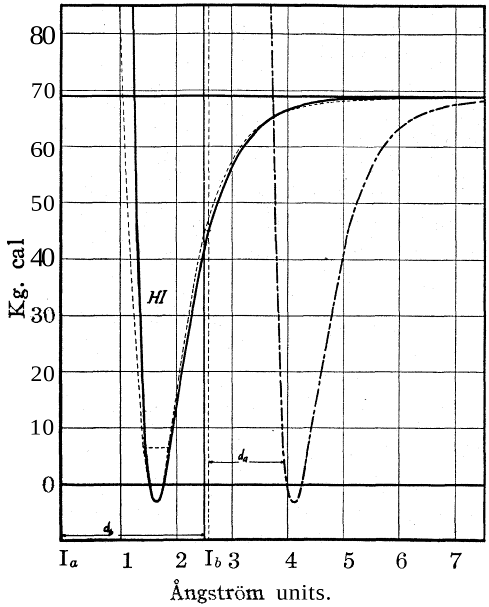

Fig. 1.—Vibrational potential energy curves of two colliding hydrogen iodide molecules. Heavy lines, Morse function. Dotted right branch, inverse power function. Dotted left branch, harmonic force function. Minimum distance of separation of iodine nuclei at collision d_b, is equivalent to b = 4 kg. cal., vibrational energy of I_2 molecule (See I_2 curve). In case first HI molecule has 45 kg. cal. vibrational energy ($y = 45$), second HI molecule must have x = 4 kg. cal., in order for relation $x - a = 1.4 + b - y$ and distance apart of H nuclei, d_a (equivalent to a = 43.5—see H curve) to be compatible. $A' \equiv x + y = 49$. First vibrational quantum level represented by dotted line. Band spectra constants used from Czerny, Z. Physik, **44**, 250 (1927). $\omega_0'' = 2272$ cm.$^{-1}$, $I_0'' = 4.309 \times 10^{-40}$ g. cm.^{2}; $r_0'' = 1.616 \times 10^{-8}$ cm.

Potential energy curves for hydrogen, iodine and hydrogen iodide were plotted by making use of band spectra constants which give us the various derivatives of the curve at the equilibrium position of the nuclei.[10]

By expressing the potential energy in the form of an inverse power series

$$V = (a_6/r^6) + (a_7/r^7) + (a_8/r^8) + (a_9/r^9) + (a_{10}/r^{10}) \qquad (3)$$

one can readily obtain the constants and calculate points for large nuclear separations.[11] This series is no longer convergent for small nuclear separations; the curve actually has several minima, some of which are lower than that corresponding to the stable state of the molecule. When data for iodine are substituted in the equations, the constant a_6 turns out to be positive, which is impossible.[12]

Morse[13] has proposed a new function

$$V = A + De^{-2a(r - r_e)} - 2De^{-a(r - r_e)} \qquad (4)$$

which has the advantage of having only one minimum point (at $r = r_e$), is of a form similar to those required by Heitler and London and

others, and the Schroedinger equation of which gives energy levels corresponding to those empirically observed. In this function, A is the heat of dissociation of the molecule, D the heat of dissociation plus the half quantum of vibrational energy associated with the lowest state of the molecule, r_e is the equilibrium separation of the nuclei in Ångström units, and

$$a = 2\pi\omega_e\sqrt{\frac{\mu}{2D}\frac{c}{h}} = 0.006547\ \omega_e\sqrt{M/D}$$

where ω_e is in cm.$^{-1}$, M the reduced mass in atomic weight units, and D is in kg. cal. This function has been used throughout these calculations and compares very favorably with the inverse power function (see Figs. 1 and 2).

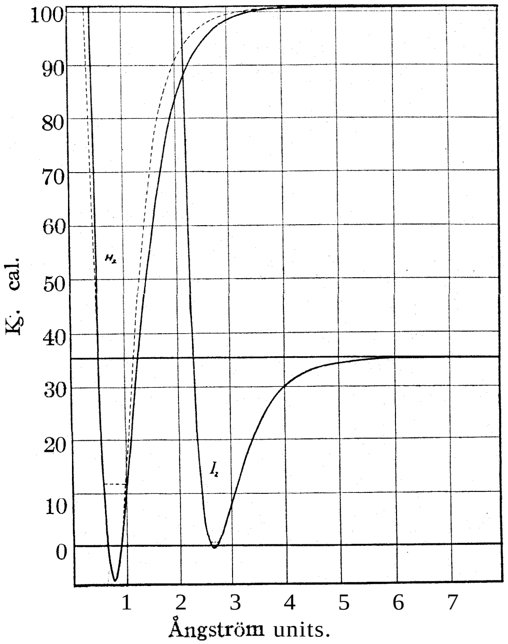

Fig. 2.—vibrational potential energy curves for hydrogen and iodine. Heavy lines, Morse function. Dotted right branch, inverse power function. Dotted left branch, ascending powers function. First vibrational quantum level represented by dotted line. Band spectra constants used: Hydrogen [Hori, *Z. Physik*, 44,834 (1927)]—$\alpha'' = 2.7$; $\omega_0'' = 4415.2$ cm.$^{-1}$; $I_0'' = 0.467 \times 10^{-40}$ g. cm.^{2}; $r_0'' = 0.75 \times 10^{-8}$ cm.; Iodine [Loomis, *Phys. Rev.*, 29, 119 (1927)]—$\alpha'' = 0.00012$; $\omega_0'' = 213.9$ cm.$^{-1}$, $I_0'' = 742 \times 10^{-40}$ g. cm.^{2}, $r_0'' = 2.66 \times 10^{-8}$ cm.

In the calculation procedure outlined above, there is a certain arbitrariness. One may note that rotation has been left out of consideration. This was done mostly to avoid complication, the postulate being made that the total rotational energy (as well as kinetic energy of translation) be the same after as before the collision. When we recall that hydrogen iodide molecules have a dipole moment,[14] it is seen that a rotation from the considered orientation at collision, I^--$H^+ \longleftarrow$ I^--H^+, through 180° to I--H f $\longleftarrow$ H^+-I^- would require the transformation of some of the available energy into orientation energy. This would have to be corrected for. Moreover, the faster the rotation, the less time is going to be spent by the molecule in those particular positions where reaction is favored, and hence the probability of reacting under such circumstances becomes negligibly small. A few cases were calculated corresponding to this 180° orientation away from the natural posi-

(i = inner branch)
(o = outer branch)

tion. It may be seen that sometimes the sum $A' \equiv x + y$ is smaller than the experimental heat of activation, but the difference is of the proper order of magnitude to be accounted for by the dipole repulsion.

Besides the repulsive force originating from a re-orientation of the molecule, there is a van der Waals attractive force between the molecules. The order of magnitude of the corresponding energy may be very roughly estimated from the latent heats of vaporization and fusion. The former is 4.7 (at −36°) kg. cal. and the latter 0.7[15] (at −51°). The density of the liquid at the boiling point is 2.799; this corresponds to an average separation of the molecules of 4.23 Å. A rough estimate of the separation of the molecules in the crystal lattice yields the same value.

The final results are summarized in Table IV. According to Bodenstein[1] the experimental heat of activation is 44 kg. cal. The minimum calculated values of A' lie in the neighborhood of 50 kg. cal. If we take $F = -5$ kg. cal., the agreement is very gratifying. In those cases where the vibrational quantum number of one of the molecules is very small, inaccuracies are especially prone to creep in, as the displacement of the nuclei has a much wider probability range than usual. The reader has, of course, recognized that quantization of vibration has also been neglected. In those cases of 180° relative orientation where some of the potential energy curves run parallel, it is especially difficult to pick the correct displacements, for here a small error makes a large energy difference. When we remember how rough the Condon working principle is, that the molecule spends all its time at the two extremities of vibration, the agreement in the calculated minimum values of A is very good and indicates that we have gained a better insight into chemical processes than has hitherto been possessed.

That enough molecules of these high vibrational energies exist to account for the observed reaction rate can be demonstrated by Hinshelwood's calculation.[16] He, it is true, made this on the assumption that it was translational energy alone (two degrees of freedom) which effected activation. One need only re-interpret his equations to mean vibrational energy alone and the same calculations hold.

Note of January 25, 1930.—Polyani has found some generalizations in regard to activation energies in reactions involving free atoms,[17] which may be understood in the light of the above theory. According to him, an exothermic reaction between a molecule and an atom demands no activation energy; on the other hand, an endothermic reaction between a

---

[16] Hinshelwood, "The Kinetics of Chemical Change in Gaseous Systems," Oxford, 1926, p. 92.

[17] Cf. also Nernst, "Die Grundlagen des neuen Wärmesatzes," Wilhelm Knapp, Halle, 1918, p. 133; Herzfeld, *Z. Elektrochem.*, 25, 301 (1919); *Ann. Physik*, 59, 635 (1919), in regard to bimolecular metatheses involving a free atom.

molecule and an atom will proceed with an activation energy equal to the heat of reaction. Thus, in the reaction

$$\begin{aligned} &H + \overset{69}{HI} = \overset{101}{H_2} + I + 32 \\ &y + 32 = a \end{aligned}$$

it is easy to find a collision distance at which the above equation will hold for $y = 0$.

On the other hand, in the reaction

$$\begin{aligned} &I + \overset{69}{HI} = H + \overset{35}{I_2} - 34 \\ &y - 34 = b \end{aligned}$$

it is obvious that in order for b to have positive values $y > 34$, and it is again easy to find a collision distance at which this equation will hold. The difference between this case and that taken up in the body of the paper lies in the extreme limitations to which we are subjected when we must satisfy the geometry of the *second* molecule taking part in the process.

Summary

Chemical reaction is most probable when the kinetic energy of the resulting molecules equals that of the reacting molecules, and will occur only in those cases where the sum of the potential energies of the colliding molecules plus the heat of reaction equals the sum of the potential energies which the resulting molecules would have if their respective nuclei undergo no change in position during the change in allegiance. The heat of activation, then, is the sum of the vibrational energies of the colliding molecules plus their heat of repulsion at the distance at which collision occurs. The foregoing principles have been applied to the hydrogen iodide decomposition with satisfactory numerical results.

THE ANALYTICAL CHEMISTRY OF ELEMENT 91, EKATANTALUM, AND ITS DIFFERENCE FROM TANTALUM

BY ARISTID V. GROSSE

RECEIVED OCTOBER 31, 1929 PUBLISHED MAY 8, 1930

In 1871 Mendelejeff,[1] on the basis of his periodic law, predicted the existence of a metal between thorium and uranium and named it ekatantalum (symbol Et). At present three isotopes of ekatantalum are known, all of them radioactive: brevium (Bv), discovered by Fajans[2] in 1913, protoactinium (Pa) and uranium Z (UZ, O. Hahn).[3]

Henceforth the author proposes to use as a synonym for element 91 the term "ekatantalum" (Et), meaning by it *all* of the isotopes of element 91. Under the term "protoactinium," according to its original meaning, will be understood only the parent substance of actinium, and by "brevium" only the disintegration product of UX_1.[4]

Brevium and uranium Z are very short-lived isotopes, their average life periods being 1.65 minutes and 9.7 hours. Naturally it is, and probably always will be, impossible to isolate them in pure form. Of the three isotopes, protoactinium is by far the most important, since it is the parent substance of actinium and all of the radio-elements of the actinium series. It was discovered in 1917 by Hahn and Meitner[5] in Germany, and simultaneously in England by the distinguished pioneer in radioactivity, Soddy in collaboration with Cranston.[6] Of the numerous radio-elements found since the splendid discovery of Mme. Curie, protoactinium is, in addition to radium, the only representative of a new radioactive chemical element which occurs in nature in considerable quantities. According to the author's latest determinations of the half-life period of protoactinium,[7] any uranium ore contains 0.6 g. of protoactinium for each gram of radium.

Until recently all attempts to concentrate and isolate the new element have been unsuccessful. These attempts have been based on the assumption that an analogy exists between the properties of ekatantalum and

[4] In this way the difference between the element "ekatantalum" and its isotope "protoactinium" will be emphasized, and such expressions as "protoactinium, free from brevium (or UZ)," or "brevium, free from protoactinium," will be definite.

[7] Their description is in preparation. The most reliable value for the half-life period of protoactinium is *32,000* years ±10%.

tantalum similar to that between radium and barium. This assumption has been supported by the authority of many prominent chemists and was one of the principal reasons for failure in attempts to isolate ekatantalum. The fallacy of this assumption has been demonstrated in the course of this investigation, and therefore it will be discussed here in greater detail.

Fajans,[8] in 1913, worked on this assumption during the discovery of the first isotope of ekatantalum—brevium—and shortly afterward Hahn and Meitner[9] concluded that any analytical reaction of tantalum can be used for the separation of element 91 from other metals. In the same year A. Fleck,[10] at the suggestion of Soddy, made a thorough study of the chemistry of the radio-elements, and wrote: "The chemistry of UX_2 (element 91) remains extremely vague. Tantalum is generally recognized by chemists to be a very difficult substance to work with, and an element of higher atomic weight occupying a position in the same group is not likely to have more distinctive reactions."

The attempts of Hahn and Meitner[11] to discover the parent of actinium in pitchblende by adding tantalum and recovering it by the acid and hydrogen peroxide method, and similar efforts of Göhring[12] to separate the then hypothetical protoactinium together with tantalum from solutions of alkali tantalates obtained from pitchblende gave negative results.

In 1917 success was attained in the long search for protoactinium and it was found in tantalum preparations. The supposedly close analogy between element 91 and tantalum appeared to be confirmed, so that Paneth and Hevesy remarked in their well-known manual on radioactivity; "The chemical properties of protoactinium are exactly those which should be anticipated from a higher homolog of tantalum; accordingly, its separation from tantalum is difficult."[13]

Soon after their discovery, Hahn and Meitner succeeded in obtaining highly radioactive preparations, but these contained at most only 0.01 to 0.1% by weight of the new element.[14] These preparations consisted generally of varying amounts of oxides and phosphates of zirconium, hafnium, tantalum, columbium, titanium and some other metals. All efforts to raise the protoactinium concentration proved futile, and in 1926 Hahn,[15] emphasizing the importance of isolating element 91, stated: ". . . . but

protoactinium, as a homolog of tantalum, evidently has in an exceptionally high degree its annoying chemical properties. Instead of normal chemical reactions of precipitation and substitution, colloidal precipitations, peptizations and as yet insufficiently explained adsorptions take place. In addition, the quantities are always very small, as compared with the accompanying elements, tantalum, niobium, titanium, zirconium and others, so that until now it has not been possible to obtain protoactinium in a highly concentrated state."

Such was the situation when the author took up the problem at the end of 1926. Inasmuch as the law of Mendelejeff had been employed advantageously in previous work on the chemistry of metal-organic compounds,[16] it was also applied in this case, and in November, 1926 the writer presented to Professor O. Hahn a report entitled "The Properties of Protoactinium and its Compounds, Calculated According to the Periodic Law."[17] The principal deductions were as follows. (1) Element 91, ekatantalum, will have its own characteristic properties and analytical reactions, differing from those of tantalum and columbium, just as its neighbors, thorium and uranium, differ greatly in their properties from their lower homologs, hafnium and zirconium, and tungsten and molybdenum. (2) Ekatantalum pentoxide (Et_2O_5) will have basic properties (similar to UO_3 and ThO_2) and form salts with acids, as contrasted with tantalum pentoxide (Ta_2O_5), which is a weak acid anhydride.

These predictions were verified recently through the isolation by the writer of 2 mg. of element 91 in pure form as its oxide.[18] Ekatantalum pentoxide, like tantalum pentoxide, is a heavy white powder with a very high melting point. The ignited oxide is practically insoluble in concentrated sulfuric, nitric or hydrochloric acid.

The author has recently succeeded in extracting about 40 mg. of element 91.[19] Part of this material has been used in the experiments described herein, which aimed at a more detailed study of the analytical reactions of ekatantalum and especially a comparison with tantalum.

The Reactions of Element 91 and Tantalum

The analytical reactions of the two elements were carried out with comparable quantities (10–50 mg.) of the pure oxides. Thus the quan-

tities of element 91 used were not very much smaller than the amounts used in ordinary quantitative analysis. In small beakers (10–25 cc.), the reactions of this rare metal may be observed and studied as easily as those of any of the commoner elements.

1. Material and Apparatus.—All chemicals were E. Merck's guaranteed pure reagents. All operations with hydrofluoric acid and molten sodium bisulfate were carried out in platinum dishes. Pyrex or Jena glassware was used.

The ekatantalum pentoxide (Et_2O_5) was part of the first **30** mg. of the pure material recently separated by the author. It had been freed from all other metals and especially purified for a new determination of the average life of the protoactinium atom. The β-activity of the oxide was taken as a criterion of its purity; it remained constant throughout the various purification processes.[20]

The tantalum pentoxide (Ta_2O_5) was a sample of pure oxide from Merck and contained only traces of columbium and titanium. For further purification it was dissolved in 40% hydrofluoric acid, potassium carbonate added, the potassium fluotantalate separated and washed with 1% hydrofluoric acid. This material was then fractionally crystallized three times from 1% hydrofluoric acid in platinum dishes, the first and last fractions being discarded each time. The product was treated with sulfuric acid to expel the hydrofluoric acid, fused with sodium bisulfate, the melt dissolved in cold water and the precipitated tantalum pentoxide washed with boiling water until free from alkali metals. The oxide was then dried and ignited to constant weight.

Procedure.—Dissolved or insoluble matter was determined by difference in weight (using a micro-balance) or, in the ease of element 91, also by estimating the amount of protoactinium electroscopically.[21]

Results

(a) Dissimilar Reactions

1. Reaction with Sodium Bisulfate and Sulfuric Acid.—Each oxide (10–50 mg.) was well mixed with 6–8 "times its weight of powdered anhydrous sodium bisulfate and carefully melted in a platinum crucible until all of the oxide had dissolved and the melt was absolutely clear. The cooled melt was then treated with 10–50 cc. of 3% sulfuric acid at room temperature. In the case of *ekatantalum* almost all of the oxide *goes into solution,* leaving only a small residue (I, 6%; II, 4%); while in the case of *tantalum* only a small part of the oxide dissolves, most of it *remaining* as a fine, white powder (residue: I, 84%; II, 79%).

2 and **3.** Reaction with Potassium Carbonate and Water.—Each oxide (10–50 mg.) was mixed with six times its weight of dry powdered potassium carbonate, melted and held in fusion with continuous stirring for ten to fifteen minutes. The oxide of *ekatantalum* is *insoluble* in the molten carbonate and remains suspended as a powder, giving the melt a milky appearance; *tantalum* pentoxide *dissolves completely* and clearly to give potassium tantalate.

---

[20] The details of the purification methods will be published later.

[21] The method for exact determination of protoactinium and other isotopes of element 91 will be described in detail shortly.

The cooled melt was dissolved in 10–25 cc. of warm water (60–80°). The *ekatantalum* pentoxide remains as a fine, white *insoluble* powder (I, 99.9%; II, 99.8%), while the potassium *tantalate dissolves* to a clear solution with no residue.

4. *Reaction with Hydrogen Peroxide.*—*Ekatantalum* pentoxide hydrate is *completely precipitated* (99.9%) by an excess of hydrogen peroxide from a warm (40–60°) 2% sulfuric acid solution. On the other hand, a mixture of sulfuric acid and hydrogen peroxide *completely dissolves tantalum* pentoxide hydrate freshly precipitated from a potassium tantalate solution by sulfuric acid.

5. Reactions with Phosphoric Acid.—*Ekatantalum* pentoxide in solution in 20–30% hydrochloric acid, 15–20% sulfuric acid or in nitric acid, with or without hydrogen peroxide, is *completely precipitated* (99.9%) by an excess of phosphoric acid. A stable solution of *tantalum* pentoxide in concd. hydrochloric or sulfuric acid, with or without hydrogen peroxide, remains *absolutely clear* on the addition of an excess of phosphoric acid.

(b) Similar Reactions

6. Reaction with Ammonia.—*Ekatantulum* and *tantalum* in solution in mineral acids (hydrochloric, nitric, sulfuric and others) are *completely precipitated* on boiling with a slight excess of ammonia: Et_2O_5, 99.95%; Ta_2O_5, 99%. In the presence of *hydrofluoric acid or fluorides* the precipitation is incomplete (varying according to the concentration of ammonia, fluoride ion, etc.), owing to the formation of water-soluble double ammonium fluorides.

7. *Reaction with Hydrofluoric Acid.*—*Both oxides* are *completely dissolved* by 40% hydrofluoric acid on slow gentle warming, the ekatantalum pentoxide dissolving the more rapidly.

Discussion

A consideration of the reactions given above shows that except for the precipitation by ammonia, a reaction characteristic of almost all metals, *ekatantalum* and *tantalum* have *only one reaction in common*—*the* solubility of their oxides in hydrofluoric acid. (It is to be expected, of course, on the basis of the periodic law, that other reactions common to both will be discovered.)

Reaction 2 shows why Göhring[12] failed to isolate the hypothetical protoactinium together with tantalum, since actually he was purifying his tantalum preparations from the last traces of protoactinium which they may have adsorbed. Similarly, Reaction 4 indicates why the first attempts of Hahn and Meitner[11] were unsuccessful.

The behavior of the pentoxides of the two metals toward various reagents shows that while tantalum pentoxide is a feeble acid anhydride and forms more stable compounds with alkalies, ekatantalum pentoxide is a weak but decidedly basic oxide with no acidic properties.

All in all it may be said that the predictions made by the writer in 1926 as to the analytical properties of element 91 have thus far been proved by experiment; the expected characteristic properties of ekatantalum have been demonstrated. Once more Mendelejeff's law has proved its usefulness, and its application has rendered comparatively simple the solution of an apparently difficult task.

Summary

1. The unsuccessful attempts to isolate and obtain element 91—ekatantalum—were based on the assumption that it resembles its lower homolog—tantalum—just as radium resembles barium. The origin and development of this assumption and its contradiction to conclusions derived from the periodic law are discussed.
2. A study of the analytical chemistry of ekatantalum has been made with adequate amounts of its pure oxide. Its difference from tantalum predicted by the author on the basis of Mendelejeff's law, has been proved experimentally.
3. The behavior of ekatantalum toward different reagents is, in most of the cases observed, opposite to that of tantalum.
4. Ekatantalum pentoxide (Et_2O_5) is a distinctly, though feebly, basic oxide without acidic properties, whereas tantalum pentoxide (Ta_2O_5) is an acid anhydride and readily forms stable salts with basic oxides.

THE BOILING POINTS OF CONSTANT BOILING HYDROCHLORIC ACIDS

BY WALTER D. BONNER AND ROLAND E. WALLACE

RECEIVED DECEMBER 5, 1929 PUBLISHED MAY 8, 1930

In connection with the work on the composition of constant boiling hydrochloric acid, recently published from this Laboratory,[1] we have made a precise determination of the boiling points of these acids over the same pressure range. The samples used were those whose analyses are given in the previous paper.

Foulk and Hollingsworth have shown[2] that the variation in boiling point of the acid which distils unchanged in composition at 750 ± 0.2-mm. pressure is not more than 0.003°, though they were not able to fix the temperature of boiling. In the work reported here a precision of 0.1 mm. was

---

[1] Bonner and Titus, THIS JOURNAL, 52, 633 (1930).

[2] Foulk and Hollingsworth, *ibid.*, 45, 1224 (1923).

attained in the pressure control. This corresponds to a precision of temperature measurement of 0.021° at the lowest pressures, 50 to 150 mm. Above this pressure the boiling point curve rapidly flattens out, so that at 370-mm. pressure the temperature measurement has a precision of 0.007°, and at 760-mm. pressure one of 0.004°.

This is not, of course, so great a precision as that with which the vapor pressure of water is known. On the other hand, it is interesting to observe that with the apparatus we used it is much easier to obtain reproducible measurements with these acids than with either water or benzene. We suggest that this may be due to the binary solution overheating less readily than does a pure substance. Whatever the reason, it is an experimental fact that these acids yield more convenient fixed thermometric points than does water.

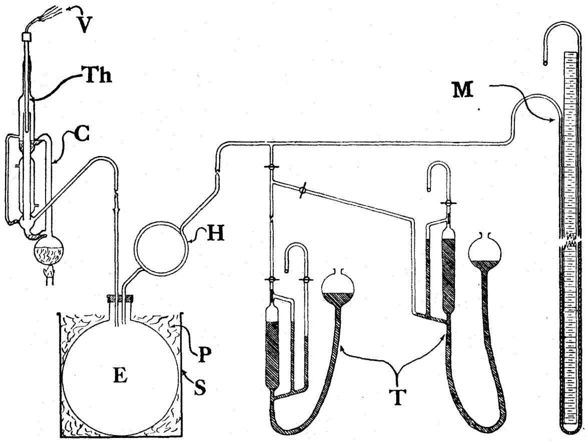

Fig. 1.—Apparatus. V, to bridge; Th, thermometer; C, boiling flask; H, glass spiral; P, paper packing; S, stone crock; E, 5-liter equilibrium flask; T, Toepler pumps; M, manometer.

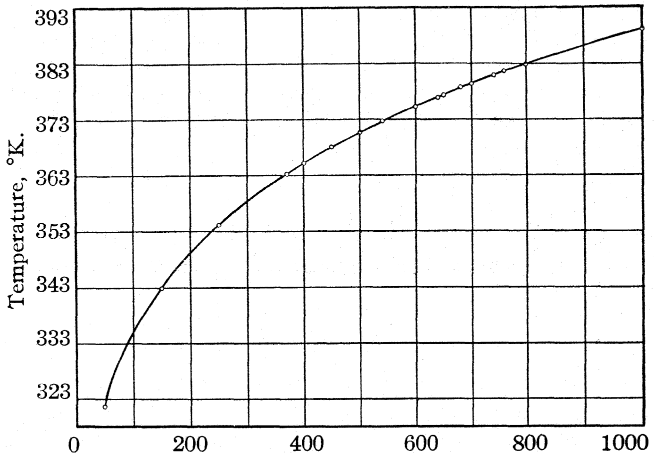
Experimental

The apparatus, shown diagrammatically in Fig. 1, consisted of a pressure control device, a boiling flask and a platinum resistance thermometer. The pressure control device was essentially two Toepler pumps, the one to force air into the apparatus, the other to pump it out. The entire apparatus was of pyrex. All joints were either sealed or ground, with the exception of the entrance of the resistance thermometer, which was made tight with wrappings of rubber dam. The boiling flask was very kindly supplied by Professor C. A. Kraus, of Brown University. It was designed to minimize loss of distillate and to prevent superheating. The resistance thermometer was calibrated by the United States Bureau of Standards.

It was checked by us at the steam point and found to be exact. It was calibrated and used as a four-lead potential terminal resistor, with current reversing commutator. For this latter purpose we used a very heavy three-pole double-throw switch. Care was taken to have the leads from the commutator to the bridge heavy and of the same length. A radiation shield was not used, but the boiling point apparatus was carefully wrapped with heavy asbestos cord over the part containing the thermometer. Resistances were determined to 10^{-5} ohms by means of a calibrated Leeds and Northrup temperature bridge, of the Mueller type. The check on the steam point of the resistance thermometer was taken to be also a check on the calibration of the bridge. A high sensitivity D'Arsonval galvanometer, with lamp and scale at a distance of four feet, was used as the null instrument. The manometer in the pressure control device was very carefully made and calibrated. The mercury was twice distilled before being put into the apparatus. The two meter scale, of flat grained maple, was compared over its entire length with a standard meter. In making our calculations we have taken into account all essential corrections. The barometer used was of the Fortin type, carefully calibrated, and compared with the United States Weather Bureau instrument in Salt Lake City.



Pressure in millimeters of mercury.

Fig. 2.

Each sample of hydrochloric acid was introduced into the clean, dry boiling flask. After sealing the apparatus, the pressure was roughly adjusted to within 5 mm. of the pressure at which the sample had been prepared. When the sample had boiled for ten to fifteen minutes, the pressure was very carefully adjusted to within 0.1 mm., all essential calibrations and corrections being considered. The sample was then allowed to boil for an hour before any readings were attempted. In that time the thermometer had assumed the temperature of the condensing acid vapors, and its resistance was therefore constant. From the resistance of the thermometer the temperature was calculated, in accordance with the constants of the instrument and Callendar's equation. The boiling points so obtained are given in Table I and in the graph, Fig. 2.

Résumé

We have determined the boiling points of constant boiling hydrochloric acid at pressures between 50 mm. and 1220 mm. Pressure was maintained constant to 0.1 mm. and resistances were determined to 10^{-5} ohms. The temperatures given are precise to 0.02° for the lowest pressures and to 0.004° for pressures in the neighborhood of 760 mm.

A METHOD FOR THE DETERMINATION OF SURFACE AND INTERFACIAL TENSION FROM THE MAXIMUM PULL ON A RING

BY WILLIAM D. HARKINS AND HUBERT F. JORDAN

RECEIVED DECEMBER 6, 1929 PUBLISHED MAY 8, 1930

1. Introduction

Although many thousands of measurements have been made to determine the pull necessary to detach a ring from the surface of a liquid, it is a surprising fact that *until three years ago there was no "ring method" for the measurement of surface tension.* Thus in "International Critical Tables," nine experimental methods for surface tension are listed but a ring method is not included, since the procedure which had been designated by this term did not supply even one single measured value of surface tension of these tables.

The failure of the ring procedure was due to the fact that the theory had not been sufficiently developed to permit its use as a method of measurement, although an incomplete theory had been developed by Cantor,[1] Lohnstein,[2] Lenard,[3] Tichanowsky[4] and MacDougall.[5]

In 1926 Harkins, Young and Cheng,[6] on the basis of the well-justified assumption that the capillary height method, properly applied, gives correct values for the surface tensions of suitable liquids, showed how the ring procedure could be used as a moderately accurate method for such measurements. In the present paper the method is given a still higher degree of accuracy (about 0.25%).

In a third paper from this Laboratory, Drs. B. B. Freud and Henrietta Zollman Freud convert this into an absolute method, since by the use of the fundamental differential equation of Laplace they have been able to calculate the shapes of the surfaces upheld by rings. It is of considerable interest that their theoretical and our experimental procedure agree within approximately the limits of accuracy of either, that is, to about 0.25%, where the two have been compared.

Symbols

γ = surface tension in dynes per centimeter
a = square root of the capillary constant

---

[6] Harkins, Young and Cheng, *ibid.*, 64, 333 (1926).

M = weight of liquid raised above the free surface of the liquid; M = maximum value of M
P = total pull on the ring in dynes = Mg; $\mathrm{P} = Mg$
p = P divided by $4\pi R$; $\mathrm{p} = \mathbf{P}/4\pi R$
R = radius of the ring measured from the center of the ring to the center of the wire
r = radius of the wire
V = the volume of liquid raised above the free surface of the liquid, or $M/(D - d)$ V = maximum volume
D = density of the liquid
d = density of air saturated with vapor of the liquid
S = shape of the surface
h = the "pressure height" or the vertical distance from the point in the meniscus under the center of the ring to a point in the liquid where the pressure is equal to that in the vapor at the same level

In much of the earlier work the entirely false assumption was used that the maximum pull (p) per cm. on the ring is equal to the surface tension of the liquid-or

$$\mathrm{P} = Mg = 4\pi R\mathbf{p} = 4\pi R\gamma \qquad (1)$$

in which $\mathbf{P}$ is the total maximum pull on the ring as determined by the balance.

The results obtained by the use of this entirely incorrect equation vary from 30% too high to 30% too low, and even more. The high values are commonly obtained for surface, and the low for interfacial, tensions.

Harkins, Young and Cheng considered that the size of the surfaces outside and inside the ring is determined mostly by the size of the ring (R), and that its shape is determined by the surface tension and density of the liquid, the radius of the ring (R) and of the wire (r), and certain other variables. In order to determine the form of the functional relation they used the principle of similitude, which in this case indicates that the shape of each surface supported by the pull of the ring depends entirely, when at rest, upon a few simple dimensionless variables. These are (1) the ratio (R^3/V) of the cube of the radius of the ring to the volume of the liquid; (2) the ratio (R/r) of the radius of the circular ring to the radius of the circular wire of which it is made, and (3) the ratio (h^3/V) of the cube of the "pressure height" to the volume of liquid which the ring supports. Thus, the shape S is given by

$$S = f\,(\mathbf{R}^3/V,\ R/r,\ h^3V), \text{ or}$$
$$S = \varphi(R/a,\ R/r,\ h/a)$$

The surface tension is a function of the shape, and, therefore, of these same variables, and its value is given by the equation

$$\gamma = \frac{Mg}{4\pi R} \times f_1(R^3/V,\ R/r,\ h^3/V)$$

Since the volume upheld by the ring becomes a maximum at a certain definite shape for which the value of h^3/V is determined by the values of R^3/V and R/r

$$\gamma = \frac{\mathbf{M}g}{4\pi R} \times \alpha(R^3/V,\ R/r), \text{ or}$$
$$\gamma = \frac{\mathbf{M}g}{4\pi R} \times \frac{\gamma}{\mathbf{p}} = \frac{\mathbf{M}g}{4\pi R} \times F$$

The values of F may be determined experimentally by determining the true surface tensions of various liquids by the capillary height or drop weight methods, and comparing with the values of **p** as shown in the above equation.

A number of values of F were determined experimentally by Harkins, Young and Cheng, and it was shown that if R/r is held constant by regulating the dimensions of the rings, F varies with R^3/V along a smooth curve, regardless of the values of R. However, this work was not sufficiently extensive or precise for general use with accurate data.

2. Outline of Procedure

The present work is a thorough investigation of the technique of the ring method, and the accurate determination of the correction curves which were found in a preliminary way by Harkins, Young and Cheng.

The general method of procedure was to determine the surface tension of water, of benzene and of bromobenzene by the capillary height method, and the values of **p** for these liquids by the use of sixteen different rings, with values of R between 0.4 and 1.8 cm., of r between 0.009 and 0.05 cm. and of R/r between 13.9 and 78.3. The quantities $\gamma/\mathbf{p}$ and $R^3/\mathbf{V}$ were calculated and plotted against each other, and the curves so obtained for the various rings were corrected to even values of R/r. Thus curves for R/r equal to 30, 40, 50, 60 and 80 were obtained. Interpolated curves were also obtained for intermediate values of R/r.

The liquids water, benzene and bromobenzene were chosen for the standardization for the following reasons: first, because their contact angles against glass and against platinum also are zero, and their surface tensions may, therefore, be accurately determined by the capillary height method; and second, because they are easily purified and kept in the pure condition. While pure liquids were not required for the purposes of standardization as long as the same sample of liquid was used throughout and its true surface tension known, it was considered desirable to use pure liquids so that the surface tension values may be compared with those obtained by others.

3. Determination of the Surface Tension of Liquids by the Capillary Height Method

The surface tension of each liquid used in this investigation was determined by capillary height measurements made on very pure liquids. The method applied was similar to that of Richards and Coombs, Harkins and Brown and Young and Gross. The apparatus was exactly that of the last-named investigators, except that a special stopcock (S, Fig. 1) was inserted between the trap (T) and the large tube (I,), to facilitate the drying of the capillary. The average radius of the capillary, a 3-cm. section of a tube selected by Harkins, and Brown, and Davies, was 0.02557 cm. and of the large tube 1.805 cm. The mean diameter of this tube had been determined by these investigators, but was recalibrated by us at 26 levels by a determination of the capillary height with pure water at 25°, at which temperature its surface tension is 71.97 dynes per cm.

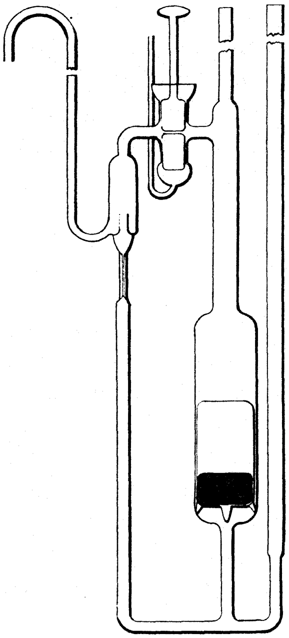

Fig. 1.—Capillary height apparatus.

The observed heights were corrected by adding $^1/_3\ r$ to correct for the volume of the small meniscus, and by adding 0.0018 cm. to correct for the rise in the larger tube when water was used. This latter correction was negligible with the other liquids.

Six values for the surface tension of benzene at 25° were obtained as follows: 28.19, 28.24, 28.23, 28.24, 28.24, 28.23, with a mean value of 28.22 dynes per cm. The density 25/4° was 0.8733, and $D - d = 0.8718_7$ was used.

For bromobenzene the values are: 35.75, 35.73, 35.75, 35.73, 35.75, 35.73, 35.75, 35.76, 35.77, 35.77, or a mean of 35.75, at 25°. The density was 1.4887 (25/4°), and $D - d$ was taken as 1.4875.

4. Apparatus for the Ring Method

The rings were made of platinum–iridium wire containing 10% iridium to give the wire stiffness, with the exception of rings 15 and 16. These contained no iridium, and proved to be unsatisfactory for practical purposes. It was found necessary to use wire of this alloy, as platinum wire bends too easily and rings made of it soon lose their shape through handling. The rings were constructed by bending the wire around a brass rod turned down to the exact inner diameter desired, and welding the ends of the wire together with a spot welder. This has to be done with extreme care or the wire will be flattened at the spot of the weld. The stirrups were then welded on to the top or side of the ring, and all protuberances and unevenness removed with a fine file and emery paper. In four of the rings, made with fine wire, silver solder was used instead of welding. The loop at the top of the stirrup was made in the form of an ellipse with the least possible radius of curvature at the uppermost part, so that the ring would always hang in the same position. All the rings with radii greater than 0.8 cm. were made with two stirrups whose planes were at right angles to each other.

It was found that the DuNoüy tensiometer is too inaccurate for measurements of the high precision desired in the present investigation. Therefore, a chainomatic balance, sensitive to 0.05 mg., was adapted for the work. The left pan was removed and a hole three-eighths of an inch in diameter was bored in the base of the balance directly under it, through which an aluminum rod connected the ring with the beam of the balance. The righ-hand pan was replaced by a very light aluminum pan, in order that the momentum of the beam and pan might be reduced to a minimum. The pan rest was disconnected, as it was found to be troublesome in making measurements.

In order to prevent ripples in the surface of the liquid, which might have been formed by lowering the level of the liquid or the containing vessel, a machine was devised to lower and raise the balance with great ease and smoothness. While such a machine is not essential to measurements by the ring method, it was deemed advisable to use it in this work in order to remove the source of error mentioned above. The machine is represented diagrammatically in Fig. 2. It consists essentially of four heavy upright steel rods, which are screwed into a heavy cast-iron base provided with leveling screws. Fitted onto these rods are two heavy bronze castings. The lower one is fastened to the rods, and supports the set of gears which raise and lower the upper movable casting. To the upper casting are attached the balance platform and its counterweight. Frictional effects were reduced to a minimum by a delicate counterbalancing of weights throughout. For example, the balance is counterbalanced by the movable weight W′. These and the casting which supports them are. in turn, counterbalanced by the weight W. This is connected to the upper casting by a steel piano wire which runs over a stationary pulley. The smoothness of operation was also increased by reducing the bearing surface of the movable casting to a minimum The balance platform is provided with two large oval-shaped openings, through which the rod connecting the ring with the balance beam passes.

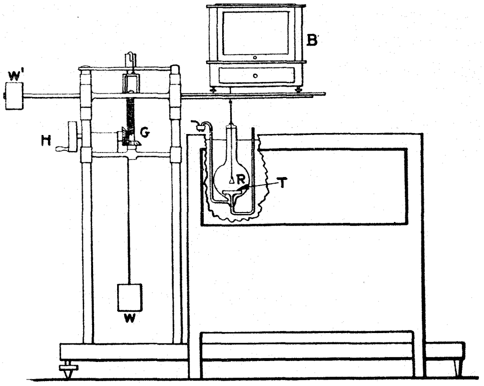

Fig. 2.—Apparatus for determination of surface tension by the ring method.

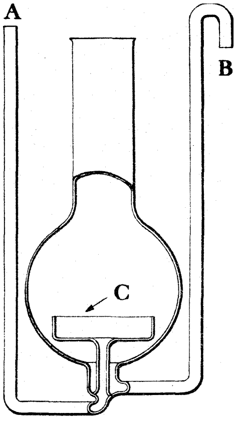

Fig. 3.—Flask for the ring method.

The flask used in the measurements is illustrated in Fig. **3.** The principle involved in the design is to provide a means of overflowing the surface to prevent surface contamination. The flask was constructed by sealing a cup (C) 7.5 cm. in diameter and 2 cm high near the bottom of a two-liter flask, and by replacing the neck with a longer and wider one The liquid is introduced in the side-arm **(A)** and the excess withdrawn through (B).

5. Measurement of Rings

Since the correction factor $(\gamma/p$ or $F)$ is a function of the variable R/r, it is necessary to have very accurate measurements of the radii of the wires of which the rings are made, as well as of the radii of the rings.

The diameters of the rings were measured by a screw micrometer carrying a microscope with *a* magnification of ten diameters. One division on the screw head corresponds to 0.0005 cm. The instrument had been originally calibrated by Dr. E. H. C. Davies, by comparison with a standardized invar scale by a series of 5000 measurements, and later checked by Mr. Frank Frese. In order to make precise measurements it is necessary to illuminate the ring from below, and the method was as follows, A reading glass about two and one-half inches in diameter was mounted in a hole in the top of a box, and within the box at the principal focus of the lens was placed a 100-watt lamp painted black with the exception of a spot about a centimeter in diameter. This provided for practical purposes a point source, with parallel light coming through the lens. Above the lens and about two inches away from it was placed the leveling table containing the ring. This was constructed as is shown in Fig. 4. It may be leveled with leveling screws, or, with the leveling screws removed, may be attached to a microscope by removing the microscope platform. In the top of the cylinder in the table was mounted a transparent celluloid disk (D), roughened with emery paper. The disk had two slits cut in it at right angles to each other (S) through which the stirrups were passed, and on it were scratched a series of concentric circles (C) to aid in centering the ring. Measurements on the rings were made across twelve evenly spaced diameters from the outer edge of the ring on one side to the inner edge on the other. Readings were taken at the point where the cross-hair, which had been previously made perpendicular to the direction of travel, became tangent to the edge of the ring.

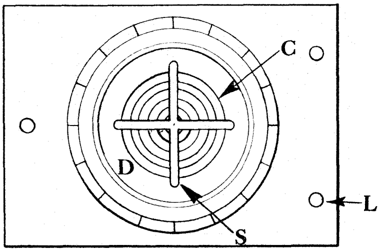

Fig. 4.—Apparatus for measurement of diameter of rings.

The measurements of the radii of the wires were made with a microscope, with a magnification of ten diameters and provided with a micrometer eyepiece. This was calibrated by comparison with an invar scale standardized by the Bureau of Standards. One division on the micrometer screw head corresponds to 0.0001 cm. at this magnification. In these measurements the leveling table was attached to the microscope in place of the microscope platform by means of a special adapter, and the illumination from below was used as in the previous measurements. In place of the celluloid disk a piece of bond paper was stretched over the top of the cylinder. In order to make the ring appear very black and the edges sharp, a narrow strip of thin cardboard with a slit very slightly wider than the diameter of the wire was slipped under the wire to cut down the extra light. This method gives excellent illumination, and precise measurements of the wire can be made in this manner. Measurements at twelve different, evenly spaced points on the ring were made and the average of these was used. The values for the radii of the rings and the radii of the wires are given in Table I.

[a] Ring number 10 was the ring furnished with a DuNoüy Tensiometer.

6. Measurement of Surface Tension by the Ring Method

The difficulties involved in making precise measurements by the ring method are far more numerous than most investigators have assumed. Any rigorous theory of the ring method would require: (1) that the wire of the ring lie in one plane; (2) that the plane of the ring be horizontal; (3) that the vessel containing the liquid under investigation be large enough so that any curvature of the free surface of the liquid would not be great enough to affect the shape of the liquid raised by the ring; (4) that the surface of the liquid be free from wave motion; (5) that there be no motion of the ring except an infinitesimally slow upward motion; (6) that there be no evaporation and consequent cooling of the surface; and (7) that the ring be round. These are requirements that are inherent in the proper technique of the ring method, and must be approximated as nearly as possible. Of these sources of error, the last is probably the least important.

The most important source of error arises from the ring not being horizontal. This was investigated in a quantitative way by measuring the pull on the ring when tipped by various amounts. The stirrup was bent so that the plane of the ring was not horizontal, and the difference in height between the two sides was measured with a cathetometer. From this the angle made between the plane of the ring and the horizontal was calculated. Ring Number 12 was used, and the data, which are given in the table below, are illustrated in Fig. 5.

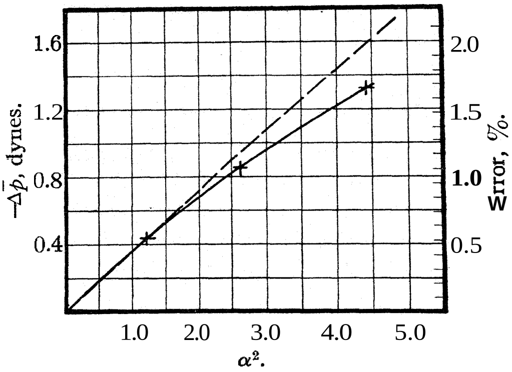

Fig. 5.—Error due to tipping of ring.

TABLE II

DATA WITH RING 12

Angle, α	α^2	P	Δp	Error, %
0.00	0.00	84.05	0.00	0.00
1.10	1.21	83.61	0.44	0.52
1.62	2.62	83.20	0.85	1.01
2.10	4.42	82.73	1.32	1.57

It is seen from the graph of the above data that for small angles such as are liable to be encountered in practice, the error introduced is proportional to the square of the angle. Δp is, therefore, expressed by the equation

$$-\Delta p = k\alpha^2$$

In the present case the equation holds for angles not greater than 1.5 degrees, and k has the value 0.36. From the graph it may be seen that for the error due to this source to be less than 0.1% the angle of tip must be less than 0.47 degree, and for an angle of 1 degree the error introduced is 0.43%.

The effect of the curvature of the meniscus and the size of the vessel was studied by making measurements of water contained in crystallizing dishes of various sizes. The crystallizing dish was placed on a glass desiccator triangle in a 2-liter beaker, and overflowed from the top, thus insuring uniformly clean surfaces. To prevent evaporation the top of the beaker was covered with a plate of glass in which a hole was bored. Measurements could not be made when the diameter of the dish was less than 7 cm., as the curvature of the meniscus was so great as to cause the ring to cling to the side of the dish. Ring Number 12 was used. The data are given in Table III.

TABLE III

OBSERVATIONS ON MENISCUS CURVATURE

Diam. of dish, cm.	7	8	9	10	12
P	83.96	84 03	84.08	84 05	84 06

While this effect is not great for dishes more than 7 cm. in diameter in the measurement of surface tension, it becomes of much greater importance in the measurement of interfacial tension.

The error caused by not having the wire all in the same plane cannot be measured quantitatively with any accuracy, but it was observed that this was an important source of error. This results in a consistently lower pull on the ring, and is one of the troublesome factors in measurements with the larger rings made of fine wire. In straightening the wire a small brass plate was used in which a groove was cut. The ring was set on the plate with the portion of the ring to be straightened across the groove, and then tapped gently with a small brass rod rounded at the end. While this method is not entirely satisfactory, it was the best of a number that were tried.

7. Method of Measurement of Surface Tension

The method of measurement was as follows. The flask was cleaned with hot cleaning solution (10 *cc.* of saturated potassium dichromate solution and 990 *cc.* of concd. sulfuric acid) and the solution was allowed to stand in the flask for fifteen minutes. The flask was then rinsed thoroughly with conductivity water. In the case of measurements on liquids other than water it was also dried by circulation of air, previously dried over sulfuric acid, and by gentle heating on the outside with a steam jet. The flask was then filled with the liquid (already at the temperature of the thermostat) to be measured and allowed to stand in the thermostat for three-quarters of an hour before measurements were made.

The ring was leveled as follows. It was suspended over a small gold plated brass table, fitted with leveling screws and polished to a mirror finish on top. The table was made level by a small right angle level, and the ring was lowered to within a half millimeter of the top of the table. By sighting between the top of the table and the ring in two mutually perpendicular directions, and by looking at the ring and its mirror image at the same time, considerably less then 30′ of tilt could be determined. The stirrup of the ring was bent until the plane of the ring appeared to be perfectly horizontal. It was then cleaned by heating to red heat in a flame. In the case of three or four of the rings in which the stirrups were silver soldered to the ring, the ring was cleaned by dipping into warm cleaning solution, rinsing thoroughly in conductivity water, and drying at some distance above a gas flame:

The flask was then put in position under the balance so that the plane of the inner cup was as nearly horizontal as possible. The ring was then connected with the fine aluminum rod from the left-hand stirrup of the balance beam by a jointed aluminum rod composed of links about two inches in length. On its end was a hook, the inner circumference of which was beveled to a knife edge to allow free motion of the stirrup loop over it. An inverted Erlenmeyer flask with a hole about 1 cm. in diameter blown in the bottom was placed in the top of the measuring flask to prevent evaporation.

The weight of the ring suspended in air was determined and taken as the zero weight. The cup in the flask was overflowed with plenty of liquid to insure a clean surface, and enough liquid withdrawn through the side-arm (A) (Fig. 3) to cause the liquid in the cup to become level instead of concave upward. With large rings the initial surface was made slightly convex upward, to such an extent that the outer part of the surface becomes plane when the ring is lifted to the height of detachment. The balance was lowered until the ring met the liquid, and then slowly raised while weights were added to determine the approximate maximum pull. In this procedure the addition of weights to the pan was made with the beam rest supporting the beam as in ordinary weighing, and during the addition of weight by the chain the rest was lowered only enough to allow the pointer to swing three divisions in either direction The final addition of weight and the raising of the balance were so regulated as to keep the pointer always at the scale zero. In check determinations the beam of the balance was raised and lowered again when the pull was about 10 mg. less than the maximum to insure its proper position, and the additional weight was added very slowly. When the maximum weight is reached, the balance pointer suddenly swings to the left and the liquid may or may not become detached from the ring, but any attempt to raise the balance---to bring the pointer back to zero--causes detachment of the liquid. The maximum weight was taken as the weight required to make the pointer suddenly move to the left, and which cannot be compensated by raising the balance without detachment of the liquid from the ring.

8. Experimental Results

The experimental results obtained by the ring method for water, benzene and bromobenzene are given in Tables IV, V and VI.

In the treatment of the results above the first problem was to find the variation of $\gamma/\mathbf{p}$ with R/r when R^3/V is kept constant at various values, so that the values of $\gamma/\mathbf{p}$ found experimentally could be converted into those of the closest even value of R/r. While the values could have been read from the $\gamma/\mathbf{p} - R^3/V$ plots of the values above, it was found that in the case of the smaller rings the curvature of the plot was so great that this could not be done accurately. Other functions were then resorted to

in order to reduce this inaccuracy. The values for rings with R^3/V between 0 and 1.0 were determined by plotting V/R^3 against $\gamma/\mathbf{p}$, and the values for rings with R^3/V values above 1.0 were determined by plotting log R^3/V against log $\gamma/\mathbf{p}$. In this way the curvature of the graphs was decreased to a minimum, and the accuracy greatly increased. When the resulting values of $\gamma/\mathbf{p}$ are plotted against R/r, the series of curves shown in Fig. 6 is obtained. The values of $\gamma/\mathbf{p}$ were then corrected to those of the closest value of R/r. These values are 30, 40, 50, 60 and 80. The corrected experimental values are given in Table VII.

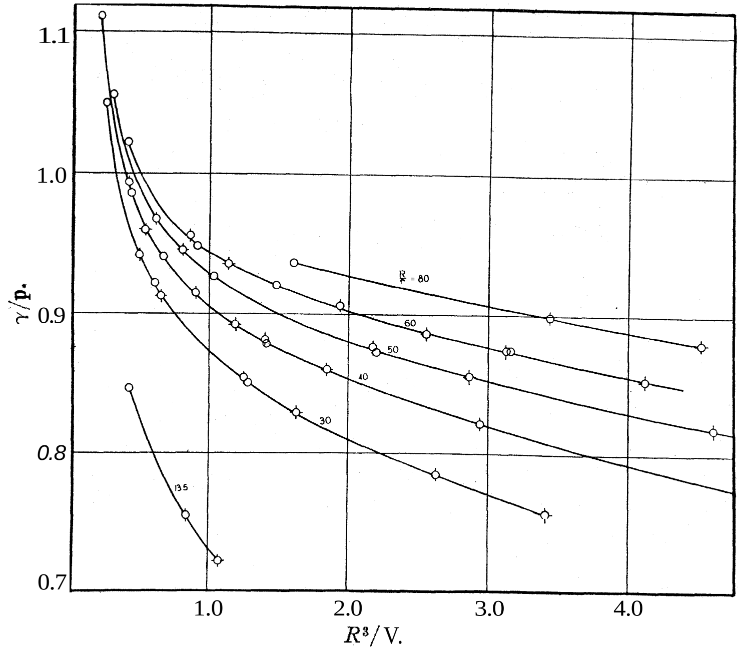

Fig. 7.—Correction curves for ring method.

The curves obtained by plotting the values above are shown in Fig. 7. Those obtained by plotting the values logarithmically are shown in Fig. 8. It is seen that the curvature is greatly reduced by plotting the values in the latter way. By use of the $\gamma/\mathbf{p} - R/r$ graphs, curves were also obtained for intermediate values of R/r, from which were read the values that compose the table mentioned in the following section.

9. Ring Method Correction (F) for the Shapes of the Surfaces

In order to avoid the necessity of plotting the corrected experimental values for use in actual work, a table was constructed for a number of intermediate values of R/r as well as the even values. The values of $\gamma/\mathbf{p}$ given in the tables for R/r (except for too low values of R^3/V) equal to 30, 40, 50, 60 and 80 are considered accurate to 0.3% with a probable error of less than 0.2%, while those for the intermediate values of R/r are considered accurate to 0.4% with a probable error of less than 0.3%. The values are given in Table VIII.

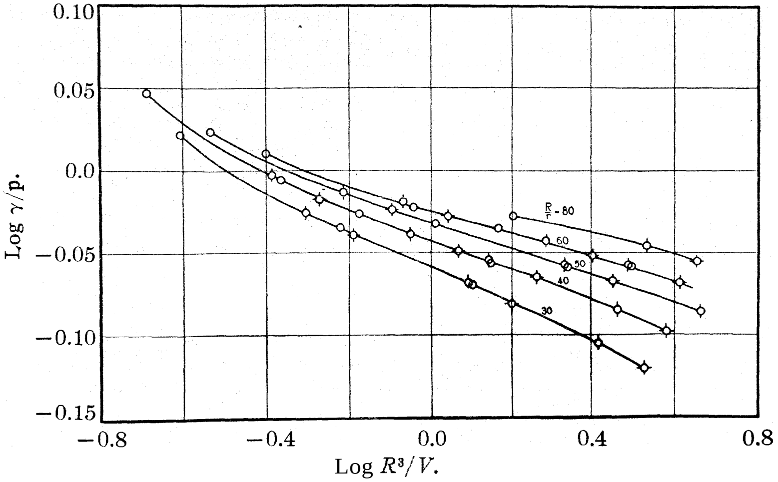

Fig. 8.—Correction curves for ring method.

10. Weights of the Residual Drops on the Rings

There has been a discussion concerning the importance of the drops of liquid which adhere to the ring after it has been pulled out of the liquid. Klopsteg[7] suggested that the zero weight should be taken at the weight of the ring plus the weight of the drops of liquid which adhere to it, while MacDougall[8] considers that such a correction is not justified. As a result manufacturers have printed instructions that in the use of their apparatus the intial reading be taken at the weight of the ring in air plus the weight of the adhering drops, and suggest that additional accuracy is acquired. Since, as may be seen from the experimental data presented in this paper, most of the values for surface tension (p) obtained by the

pseudo-ring method are too high, the values seem to be improved, but this is done only by introducing a second error. The theory indicates that the zero point should be taken at the weight of the dry ring in air. The weight of liquid which adheres to one of our rings is constant if the air is saturated with vapor, and values of the weights of liquid which adhere to some of the rings are given in Table IX.

11. The Variation of the Pull on the Ring with the Height of the Ring above the Free Liquid Surface

Dorsey[9] has recently suggested that many workers, particularly those using the DuNoüy tensiometer, might be measuring the pull of a film of liquid upon the ring rather than the maximum pull of the liquid. It was therefore considered important to study the variation of the pull on the ring with the distance it is raised above the free surface of the liquid. The values, which are shown graphically in Fig. 9, are given in Table X. Ring 10 was used.

TABLE X

RESULTS

Pull in grams	Height in cm.	Pull in grams	Height in cm.
0.3064	0.062	0.5894	0.290

[9] Dorsey, *Science,* 69, 187 (1929).

It is evident that as the ring is pulled out of the liquid the pull on it increases to a maximum and then decreases.

It is at once evident that there is no danger of measuring any other than the maximum pull with the balance with the technique used, since great difficulty was experienced in measuring points beyond the maximum. After the maximum pull had been reached, the balance pointer swung to the left and could be made to return only by decreasing the weight by fifteen or twenty milligrams, when it would swing quickly to the right and remain there. During this time its motion was restricted by the beam rest to one division in either direction from the scale zero. In order to make any measurements of even low precision beyond the maximum it was necessary to attach a stop which would allow the pointer to swing from zero to a point one-half scale division away in one direction at a time. The weight that would just suffice to make the pointer leave zero in one direction and then the weight to make it leave in the other direction were determined. In this way the limits of the pull on the ring were determined for the heights above the height of maximum pull.

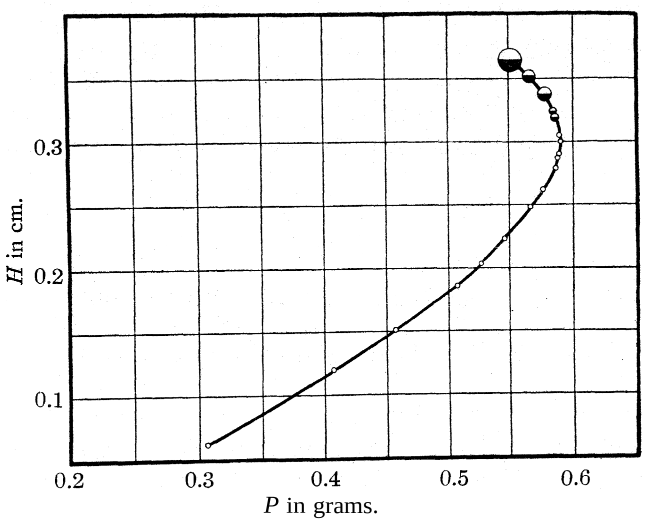

Fig. 9.—Variation of pressure with height of ring.

It was noticed, particularly in the case of the smaller rings, that the liquid column had a tendency to adhere to the ring and be pulled out into a film after the pointer had swung to the left, signifying that the maximum pull had been reached. If, however, the beam rest is further released from under the balance beam the liquid breaks. Until the maximum pull is reached the edge of the liquid meniscus appears to be attached to the ring.

12. Preliminary Application of the Ring Method to Interfacial Tension

Measurements of the interfacial tension between water and benzene were also made in order to see whether the ring method is a practical one for such measurements.

The general method of measurement was the same as for surface tension with only slight modifications. The measurements were carried out in a 2-liter Erlenmeyer flask provided with a special long neck. The ring was connected with the aluminum rod running up to the balance beam by means of a length of platinum wire 0.1 mm. in diameter. This was quite fine, in order to reduce the effect of surface forces and the effect of buoyancy. The layer of benzene was several centimeters deep, so that the ring and its stirrups were completely immersed throughout the measurements. The initial weight was the weight of the ring completely immersed in benzene. The results obtained with Rings 7 and 5 are given in Table XI. The interfacial tension is calculated by use of the correction factors (F).

TABLE XI

RESULTS

King	M	P	V	R^3/V	γ/p	γ
7	0 5345	34.33	4 335	0.4132	0 995	34.16
5	.4190	32 23	3 398	.3070	1.051	33.91

t, 25°; $(D - d) = 0.1233$; γ by the drop weight–volume method, 34.71.

On account of the steepness of the correction curves in this region, better results could probably be obtained with larger rings (of as small or smaller wire).

In the ring method the angle of contact between the interface and the ring must be zero, a condition which is more difficult to meet, in general, with interfacial than with surface tension.

There are probably a number of additional factors to be considered in the measurement of interfacial tension by the ring method, but the deviations from the standard value are not greater than is to be expected from the first preliminary determinations.

Measurements were also made with smaller rings and the values of γ/p

TABLE XII

DATA

γ, 34.71; $(D - d) = 0.1233$.

were calculated by assuming that the interfacial tension measured had the standard value. The purpose of this was to show the magnitude of the error that may be introduced by neglect of the correction factors. The data are given in Table XII.

It is seen that as high as 45% error may be incurred by this neglect in the measurement by the use of a moderately small ring, since R^3/V is very small, and the curvature in this region of the curve is very great. The neglect of the correction with the ring furnished with the Cenco Tensiometer gives results which are 20% too low, which accounts for the extremely inaccurate results which have been obtained in the measurement of interfacial tension by the "ring method."

Summary

1. Until three years ago there was no *ring method* for the *measurement* of surface tension, since, in general, all that was determined was the pull on a ring, and this pull was incorrectly assumed to be equal to the surface tension multiplied by twice the mean circumference of the ring. Even in cases in which attempts were made to use the incomplete theory of the ring method, it was found that rings of the dimensions required by the theory were incapable of use. Three years ago Harkins, Young and Cheng applied the principle of similitude to this problem, and determined the values of the function F in the correct equation

$$\gamma = \frac{Mg}{4\pi R} \times f(R^3/V, R/r) = \frac{Mg}{4R} F$$

In this paper a larger number of values of F, determined to a higher degree of accuracy, are given. These were obtained by determining the values of the maximum pull ($P = Mg$) for sixteen rings with radii from 0.4 to 0.8 cm. made from wire with radii between 0.009 and 0.05 cm. and with values of R/r between 13.9 and 78.3.

2. The values of the maximum pull were determined for three liquids: water, benzene and bromobenzene. Accurate determinations of the surface tension by the capillary height method gave for the liquids used 28.23 dynes per cm. for benzene and 35.75 for bromobenzene at 25°.

3. Various sources of error in the experimental methods were investigated. (a) The error introduced when the plane of the ring is not horizontal is proportional to the square of the angle of tip when the angle is small. An angle of 0.4 degree causes an error of 0.1% and 1.0 degree of 0.45%. (b) The diameter of the vessel which confines the surface of the liquid should be not less than 8 cm. (c) An error is introduced if the ring does not lie in a plane.

4. An apparatus for the accurate determination of surface tension by the ring method is described. This consists of a chainomatic balance, supported by a machine which raises or lowers it with a minimum amount

of vibration, and a special flask, designed to give a clean liquid surface, buried under the water of a thermostat.

5. It was found that the accuracy of measurement of the dimensions of the rings depends greatly upon the method of illumination employed, and apparatus for these measurements was developed.

6. It was shown that at a certain height above the surface of the liquid the pull on the ring reaches a maximum. This maximum pull is what was determined in the measurements reported.

7. A necessary condition of the ring method is that the angle of contact between the ring and the liquid be zero.

8. Preliminary measurements indicate that the ring method may be used for the determination of interfacial tension.

A THEORY OF THE RING METHOD FOR THE DETERMINATION OF SURFACE TENSION

BY B. B. FREUD AND H. Z. FREUD

RECEIVED DECEMBER 3, 1929 PUBLISHED MAY 8, 1930

The most convenient method for the determination of surface tension is perhaps what is known as the ring method. It has been used extensively, for example, by DuNoüy[1] in the case of numerous biological liquids. It is convenient because the experimental procedure necessary to obtain a fair degree of accuracy can be made very simple, although of course it becomes much more complicated when a higher degree of accuracy is sought. The essentials of the procedure are a ring, capable of being wetted by the liquid whose surface tension is to be measured, suspended horizontally in the flat surface of that liquid, and some device to measure the force necessary to separate ring and liquid. That the applied force may be changed gradually, a torsion balance is often used but a beam balance of the chainomatic type is also satisfactory. From this measured force, expressed as a weight, a quantity which many assume to be the value of the surface tension is often obtained from the relationship

$$W = 4\pi R\gamma \qquad (1)$$

where R is the radius of the ring, γ the surface tension and W the maximum weight of liquid held up or the pull on the ring at the instant of rupture. Modifications have been introduced into this equation, such as the substitution of $(R_1 + R_2)/2$ for r, where R_1 and R_2 are the inner and outer radii of the ring. But the validity of this relationship is not at all obvious. An experimental study of it by Harkins, Young and Cheng[2] and

[2] Harkins, Young and Cheng, Science, 64, 93 (1926).

a later one by Harkins and Jordan[3] indicate that it is in error in some cases by as much as 30% in either direction, plus or minus. The experiments of Harkins and his collaborators are expressed in the form of a series of empirical curves which involve the value of the surface tension as determined by a so-called absolute procedure and which must be used to correct the value given by the above relationship. It should be noted in this connection that a precisely analogous correction for the drop weight procedure for measuring surface tension was proposed by Harkins and Brown.[4] The purpose of this paper is to establish a theoretical basis for these empirical correction curves to the ring procedure, so that the values of surface tension as thus obtained may be accepted with that additional confidence which is given to a procedure based on a solid theoretical foundation. A similar study of the theoretical basis for the corrections to be used with the drop weight procedure made by Freud and Harkins[5] should be consulted for certain details of the mathematical analysis. These two studies are interrelated.

The ring method, and for that matter many other methods for the determination of surface tension, depends upon the equilibrium forms assumed by liquid surfaces under the combined action of their own surface tension and some external forces, of which gravity usually is the dominant one. The capillary rise method is usually considered an absolute procedure largely because it is affected by the shape of the liquid surface less than any of the others. In this procedure it enters only as a correction in estimating the volume of liquid in the meniscus. The shapes taken by liquid surfaces play a much more significant role in the bubble pressure, sessile drop, hanging drop and drop weight procedures, none of which accordingly have been regarded as fundamental. As was indicated in our study of the shapes of hanging and of detaching drops, the drop weight procedure alone of those just mentioned involves the properties of a dynamic system, the others being stable even though some of them are at the very limit of stability. It is only in drop weight procedure that the theory is not complete; in this case the weight of the detached drop involves changes in the shape of the drop during the process of detachment, which, of course, cannot be explained by any theory of static liquid surfaces. A dynamic theory has been proposed by us[5] but it proved much too complicated to be applied. The ring procedure, as this paper shows, is another that may be adequately based on sound theory. There is no fundamental reason why it too should not be regarded as an absolute method.

A fundamental equation for the shapes of liquid surfaces, credited to Laplace, is

$$\frac{1}{R_1} + \frac{1}{R_2} = \frac{P}{\gamma} \qquad (2)$$

where P is the pressure and R_1 and R_2 are the two principal radii of curvature at any point in the surface. For $1/R_1$ and $1/R_2$ may be substituted their equivalents, $\mathrm{d}u/\mathrm{d}x$ and u/x, in the special case of liquid surfaces of revolution. Here x is the horizontal distance of the point from the axis of symmetry, and u is the sine of the angle which the tangent to the surface at the point makes with the x-axis. The latter is, in the notation of this paper, coincident with the level of the undisturbed surface of the liquid. For P may be substituted $\pm ygd$, the sign depending upon the particular surface involved. P is really a composite of several factors such as barometric pressure, gas pressure, head of liquid above the point and possibly others. All, however, may be included in the term ygd if the x-axis is taken at what may be termed the "ideal level" of the surface, and y is the vertical distance of the point from this level. The question of the proper sign for these terms is important. It has been found convenient, in this paper, to hold the convention that R_1 and R_2 are positive when the osculatory circle is on the liquid side of the surface, and negative when on the gaseous side. This usually can be determined by inspection. $\mathrm{d}u/\mathrm{d}x$ and u/x are numerically equal to $1/R_1$ and $1/R_2$ but are like them in signs only when the original choice of u or v, the cosine of the angle of which u is the sine, is such as to make them so. The signs of $\mathrm{d}u/\mathrm{d}x$ and u/x can also be told by inspection. If they do not agree with those of $1/R_1$ and $1/R_2$, this fact must be formulated by preceding $\mathrm{d}u/\mathrm{d}x$ and u/x, in the equation, with negative signs. The sign of the ygd term also can be told by inspection. It depends upon whether the "ideal level" is above or below the point in question. If the effect of the weight of the column of liquid is a push on the surface from the liquid side, the absolute value of the weight is positive; if it is a pull, the absolute value is to be given the negative sign. For the quantity gd/γ may be substituted its equal by definition, $2/a^2$, where a^2 is the capillary constant of the liquid; and a^2 may be eliminated by the device of changing the variables from x and y to $a\bar{x}$ and $a\bar{y}$, thus eliminating all characteristics of any particular liquid. The equation in this form becomes

$$\frac{\mathrm{d}u}{\mathrm{d}\bar{x}} + \frac{u}{\bar{x}} = \pm 2\bar{y} \qquad (3)$$

This equation describes the surfaces of a very diverse set of phenomena: pendent drops, drops of fluid in a medium of greater density on a tip pointing upward, menisci, both convex and concave, the surface of a liquid surrounding a vertical rod whether or not the rod is wetted, the liquid surface raised by a disk, bubbles of a fluid in a heavier medium on a tip pointing downward, and sessile drops—in fact all liquid surfaces of revolution. The fact that this equation applies only to surfaces of revolution excludes its application to such forms, for example as are produced when a wetted rectangular plate is raised from the surface of a liquid.

The ring method involves two of these shapes, the meniscus and the surface raised by a disk. Shapes of menisci are not too difficult to obtain. They are determined by mechanical integration of the equation exactly as described in our previous study of hanging drops, with the difference that if u is considered positive, increasing from 0 to 1 as $\bar{x}$ increases from 0, $\bar{y}$ must be considered negative in the equation, as $du/d\bar{x}$ and $u/\bar{x}$ do not agree in sign with $1/R_1$ and $1/R_2$, and the weight of the liquid causes a pull on the surface. The tables of Bashforth and Adams[6] give the data for a few of the menisci in Fig. 1. Unfortunately these tables do not include data for menisci for which ? at the y-axis is smaller than 0.1414. The numerical integration is exactly as originally described by Lohnstein,[7] with the change in sign mentioned above.

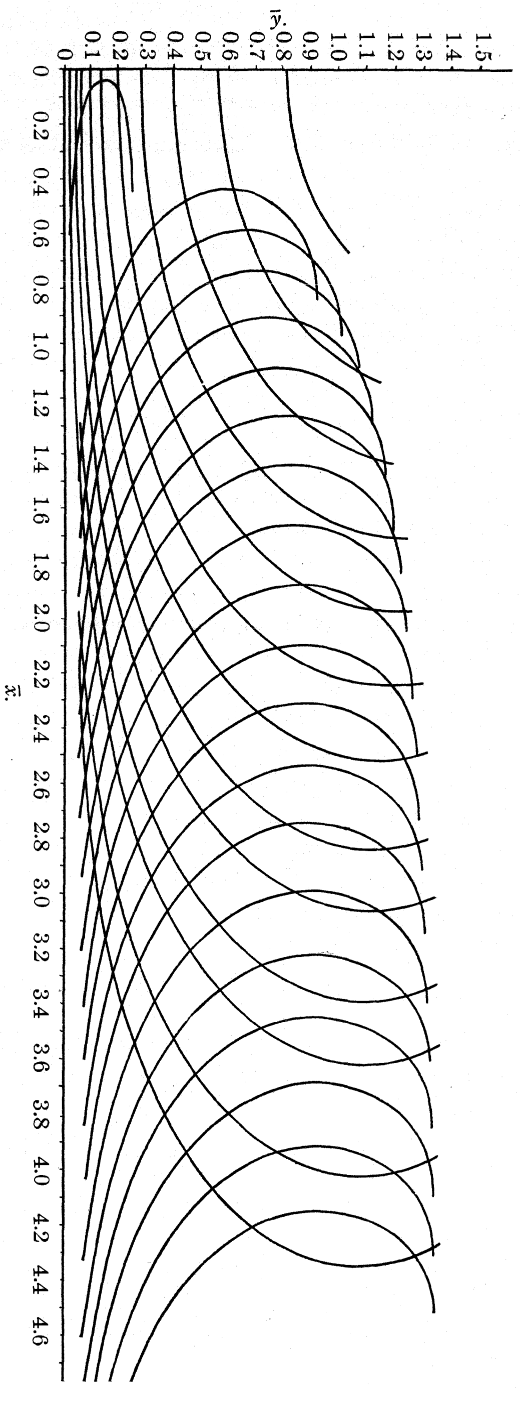

Fig. 1.—Meniscus and disk curves. Expansion of $du/d\bar{x} + u/\bar{x} = \pm 2\bar{y}$.

[6] Bashforth and Adams, "Attempt to Test Theories of Capillary Action," Cambridge University Press, 1888.

[7] Lohnstein, *Ann. Physik*, [4] **20,237**, 606 (1906).

In the case of the outside surface sloping away from the ring, however, the problem is less simple. It must be recalled that this equation cannot be integrated, and even mechanical integration requires that $\bar{x}$, $\bar{y}$ and u be known for some particular point in the surface. In the cases of a stable pendent drop and a meniscus, it is known that at the very bottom u equals zero because at this point the tangent to the surface is parallel to the Z-axis, and $\bar{x}$ and $\bar{y}$ may be known from a suitable choice of the coordinate system. In the case of the surface raised by a disk, however, no point is really known except at infinite distance from the disk, that is, in the undisturbed level of the surface. Here $\bar{x} = \infty$, $\bar{y} = 0$ and $u = 0$. Because one of the coördinates of this known point has the value of infinity, the method of numerical integration, using Taylor's theorem, is inapplicable. However, we also know that $\bar{y}$ and u become very nearly equal to zero before $\bar{x}$ becomes very large. We have considered it sufficiently precise to assume that $\bar{y}$ and u become equal to 0.00001 units at distances from the axis of symmetry varying from 7.5 to 12.0 units. These distances were chosen because the resulting curves lay in the region experimentally investigated by Harkins and his collaborators. One curve starting much closer to the y-axis is given, but was not used in any of the calculations. This approximation involves an error so small that conclusions can nevertheless be made with a precision quite equal to that given by the best experimental technique.

It will be observed that our choice makes the sign of u positive for these outside surfaces, and thus fixes the signs to be used in Equation **3.** As $\bar{y}$ and u both increase with decreasing $\bar{x}$, the tangents u/v and $du/d\bar{x}$ are both negative, thus making v also negative; $u/\bar{x}$ is positive. Inspection shows that $1/\bar{R}_1$ is negative and $1/\bar{R}_2$ is positive according to our convention. Since these agree in sign with $du/d\bar{x}$ and $u/\bar{x}$, and the weight of the liquid column causes a pull on the surface, the equation to be used for these outside surfaces, thus, is

$$\frac{du}{d\bar{x}} + \frac{u}{\bar{x}} = -2\bar{y} \tag{4}$$

Had a negative sign been chosen for u, $d\bar{y}/d\bar{x}$ and $u/\bar{x}$ would have been negative and $du/d\bar{x}$ and v positive. In this case $du/d\bar{x}$ and $u/\bar{x}$ do not agree in sign with $1/\bar{R}_1$ and $1/\bar{R}_2$, so the equation would have been

$$-\frac{du}{d\bar{x}} - \frac{u}{\bar{x}} = -2\bar{y}, \text{ or} \tag{5}$$

$$\frac{du}{d\bar{x}} + \frac{u}{\bar{x}} = 2\bar{y} \tag{5'}$$

Mechanical integration of Equations 4 and 5 gives the same curve.

The two families of surfaces obtained in these ways are given in Pig. 1. The left edge of the figure, the y-axis, is the axis of symmetry, and the lower edge, the Z-axis, is the level of the undisturbed liquid. The family of curves crossing the axis of symmetry represents the shapes of the menisci obtained with various rings for the different heights to which they are raised above the surface. The family reaching apparently to infinity at the right edge of the figure represents the shapes of the outside surfaces formed by the raised rings. If a ring made of wire with a rectangular cross section, one of whose edges is in the plane of the ring, is lifted from the Z-axis in such a way that its lower edge alone is wetted, the plane of the ring remaining parallel to the flat surface of the liquid, the various portions of the family of meniscus curves intersected by the lower left corner of the wire give the shapes of the crater-like formations at the center of the raised liquids. Similarly, those portions of the other family of curves intersected by the lower right corner of the wire give the outside slopes of the mountain-like formations pulled up by the ring.

If the ring is made of wire having a circular cross section and is pulled out, keeping the plane of the ring parallel to the undisturbed surface, the two curves, one from each family, which are at any particular position tangent to it, the meniscus on the inside and the other on the outside, give the shapes of the inner crater and the outer slope of the liquid raised by the ring in that particular position. The last statement involves an approximation. It is assumed that the material of the ring is wetted by the liquid. While it is accordingly to be expected that a film of liquid covers the whole of the ring, this film must be very thin where the ring is not immersed, for the attraction which causes it to adhere extends only a very short distance from the surface. The volume of this film, then, must be small. It is assumed in this discussion that it is negligible in comparison with that held up by the surface tension itself. Those curves that are tangent to the ring are the ones selected because the fact that the ring is wetted implies a zero angle of contact.

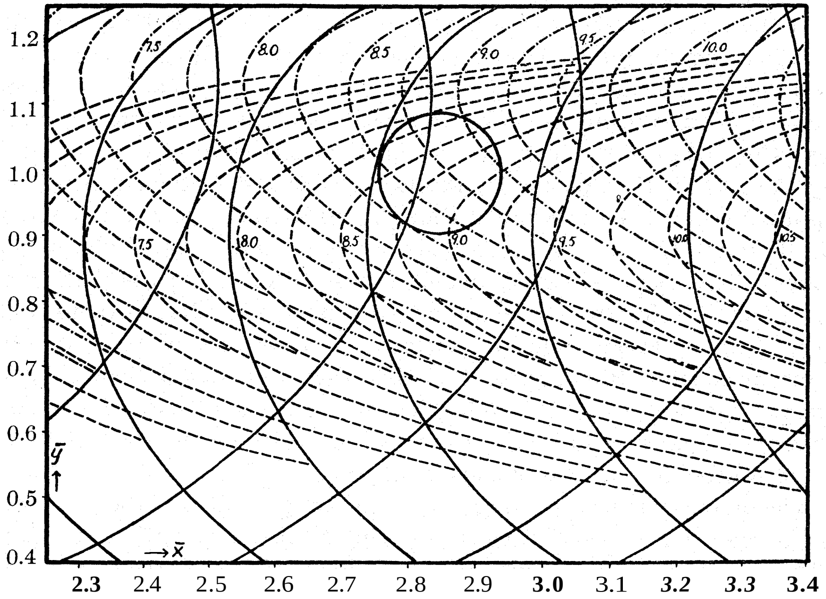
The quantity measured in the experimental procedure of the ring method is the weight necessary to cause the ring to break away from the liquid. This is usually the maximum weight of liquid held up by the ring. It may be calculated from our graphs of Equation **3.** After the capillary constant has been eliminated from the equation, that which corresponds to the volume of the liquid held up by the ring in a particular position will be designated by $\overline{V}$. Its value is found as follows. Integration of Equation **3** gives for the volume below any horizontal section through the outer surface, for example, below the section through the point of tangency of curve and ring

$$\overline{V}_1' = \pi\bar{x}_1^2\bar{y}_1 + \pi u_1\bar{x}_1 \tag{6}$$

and for the volume below any similar horizontal section cutting the meniscus surface

$$\overline{V}_2' = \pi\bar{x}_2^2\bar{y}_2 - \pi u_2\bar{x}_2 \tag{6'}$$

where subscripts 1 and 2 refer, respectively, to the points of tangency of the outer and meniscus surfaces with the ring, and the corresponding $\bar{V}'$ accordingly represents the volume below this section. For the outer curve it is the volume generated by revolving about the axis of symmetry the area bounded by the Z-axis, the y-axis, the line $\bar{y} = \bar{y}_1$ and the curve; for the meniscus it is the volume generated similarly by the area bounded by the y-axis, the line $\bar{y} = \bar{y}_2$ and the curve. This is shown in Fig. **3.** $\bar{V}_1$, the volume outside of the line $\bar{x} = \bar{x}_1$ corrected as discussed below, is obtained by subtracting the volume of the cylinder $\pi\bar{x}_1^2\bar{y}_1$ from $\bar{V}'_1$. From Equation 6 $\bar{V}_1$ is thus seen to be equal to $\pi u_1\bar{x}_1$. From Equation 6' it is seen that $\bar{V}_2$, the volume held up by the ring inside of the line $\bar{x} = \bar{x}_2$ properly corrected, is given by subtracting $\pi\bar{x}_2\bar{y}_2$ from $\bar{V}'_2$, and making the necessary change in sign.



—— Meniscus and disk curves; – – – constant $\pi u_1\bar{x}_1$ (dirk); —·— constant $\pi u_2\bar{x}_2$ (meniscus).

Fig. 2.—Portion of Fig. 1 with constant $\pi u\bar{x}$ lines.

The volume labeled $\bar{V}_3$ in Fig. 2, between the limits $\bar{x} = \bar{x}_2$ and $\bar{x} = \bar{x}_1$, is obtained, allowing for a small correction, by finding the volume generated by revolving the area under *a* curve about an axis. In this case the curve is the cross section of the wire between the points $\bar{x}_2$, $\bar{y}_2$ and $\bar{x}_1$, $\bar{y}_1$ and the axis of revolution is the y-axis. It is accomplished as follows. For convenience the bars above all symbols are dropped in the following derivation. R is the radius of the ring, r is the radius of the wire and h is the height of the bottom of the ring above the x-axis.

$$V_3 = 2\pi \int_{x_2}^{x_1} x\{(h + r) - \sqrt{r^2 - (R - x)^2}\}\mathrm{d}x$$

$$\int_{x_2}^{x_1} x(h + r)\mathrm{d}x = \frac{x^2(h + r)}{2}\Big]_{x2}^{x1}$$

$$\int_{x_2}^{x_1} x\sqrt{r^2 - (R -} \qquad = -\int_{x_2}^{x_1} (R - x)\sqrt{r^2 - (R - x)^2}\,\mathrm{d}x + \int_{x_2}^{x_1} R\sqrt{r^2 - (R - x)^2}\,\mathrm{d}x$$

$$= -\frac{1}{3}\{r^2 - (R - x)^2\}^{3/2}]_{x2}^{x1} - \frac{R}{2}(R - x)\{r^2 - (R - x)^2\}^{1/2}]_{x2}^{x1} - \frac{R}{2}r^2 \sin^{-1}\frac{R - x}{r}\Big]_{x2}^{x1}$$

$$\therefore V_3 = \pi\{(h + r)(x_1^2 - x_2^2) + \frac{2}{3}[(h + r - y_1)^3 - (h + r - y_2)] + R(R - x_1)(h + r - y_1)$$

$$-R(R - x_2)(h + r - y_2) + Rr^2\left(\sin^{-1}\frac{R - x_1}{r} - \sin^{-1}\frac{R - x_2}{r}\right)\} \qquad (7)$$

Of the terms in Equation 7 only the first and last are of appreciable significance in most cases, and just these two were usually used in the calculations. In some cases, however, it was necessary to use the third and fourth.

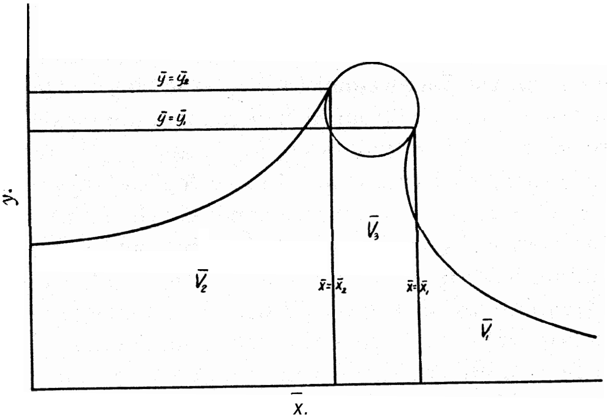


Fig. 3.—Vertical section of liquid raised by ring.

It may seem that another correction should be made for the small volume of the ring which may be inside of the line $\bar{x} = \bar{x}_2$ or outside of that $\bar{x} = \bar{x}_1$. However, this is already allowed for in the calculation of $\bar{V}_3$, when $\sin^{-1}\frac{R - x_1}{r}$ or $\sin^{-1}\frac{R - x_2}{r}$, as the case may be, is greater than $\pi/2$. When these angles are less than $\pi/2$, the lines $\bar{x} = \bar{x}_2$ and $\bar{x} = \bar{x}_1$ cut the surfaces, and the correction is made in the corresponding value of $\pi u \bar{x}$, that is, $\bar{V}_1$ or $\bar{V}_2$. These corrections are, in general, so small as to be negligible in all cases except when R/r is very small.

The total volume held up by the ring in any position is given by

$$\bar{V} = \bar{V}_1 + \bar{V}_2 + \bar{V}_3$$

To facilitate the use of Fig. 1 in these calculations, constant $\pi u\bar{x}$ curves, isochors, for the two families of surfaces have been calculated, and superposed upon Fig. 1. Thus at any point on the map $\bar{V}_1$ and $\bar{V}_2$ may be read off. Unfortunately the necessary interpolations are such as to introduce an error into the conclusions, but this is inherent in the graphical method of solution. Of course, the error may be reduced below any desired limit if enough surfaces are calculated. To attain the precision of the experimental values of Harkins and Jordan more curves than we have provided are needed, although it is estimated that our procedure gives results of the same order of precision as their experimental method. We have been sufficiently precise to convince ourselves of the adequacy of the underlying theory proposed.

A small portion only of the map is reproduced in this paper as Fig. 2. The whole would be quite unintelligible, as well as unusable, because of the reduction necessary for publication, but the portion reproduced serves adequately to demonstrate our procedure. The heavy circle is the cross section of the wire of the ring. In the actual procedure we lay upon the map, which is an enlarged Fig. 1 bearing the constant volume lines, a metal template of this cross section made, of course, to scale, and place its center at a distance from the y-axis equal to $\bar{R}$ for the ring. The points of tangency of the two curves, one from each of the two families of surfaces, with the wire are noted. These points are $\bar{x}_1$, $\bar{y}_1$ and $\bar{x}_2$, $\bar{y}_2$, respectively, and $\bar{V}_1$ and $\bar{V}_2$ are read from the map. $\bar{V}_3$ is calculated approximately from the formula $\pi(\bar{x}_1^2 - \bar{x}_2^2)(\bar{h} + \bar{r})$, thus using merely the first term of Equation 7, which is written as $\bar{V}_{3a}$. $\bar{V}_1 + \bar{V}_2 + \bar{V}_{3a}$ gives an approximate value of the total volume held up. The procedure is repeated, varying $\bar{h}$, that is, moving the template parallel to the y-axis. It is found that as $\bar{h}$ increases, the approximate value of $\bar{V}$ goes through a maximum. This maximum value and a few on either side of it are recalculated more precisely using additional terms of Equation 7. The maximum thus precisely calculated is taken as the maximum volume capable of being held up by the ring, and its weight is what is measured by the ring method.

Harkins and his collaborators plot their values for the corrections to be applied to the usual ring method on a diagram using R^3/V and γ/p as the coordinates, where R is the radius of the ring and $p = W/4\pi R$, a procedure quite analogous to Harkins and Brown's correction curve for the drop weight determination. The corresponding terms in our procedure are $\bar{R}^3/\bar{V}$ and $2\pi\bar{R}/\bar{V}$. $\bar{R}^3/\bar{V}$ is identical with R^3/V because the a^3 in numerator and denominator cancels. $2\pi\bar{R}/\bar{V}$ corresponds to γ/p by virtue of

$$\frac{\gamma}{p} = \frac{4\pi R\gamma}{W} = \frac{4\pi R\gamma}{Vgd} = \frac{4\pi Ra^2}{2V} = \frac{2\pi\bar{R}a^3}{\bar{V}a^3} = \frac{2\pi\bar{R}}{\bar{V}}$$

These quantities have been calculated by the procedure just outlined. The curves given by these variables are found to coincide with the experimental curves within the accuracy of the calculations. Por comparison particular points so calculated are shown in Pig. 4. We are certain that any discrepancies are due entirely to the difficulties inherent in a graphical method and in the fact that enough surfaces have not been calculated; but only those who have made such numerical integrations can appreciate the labor involved in producing even a single curve.

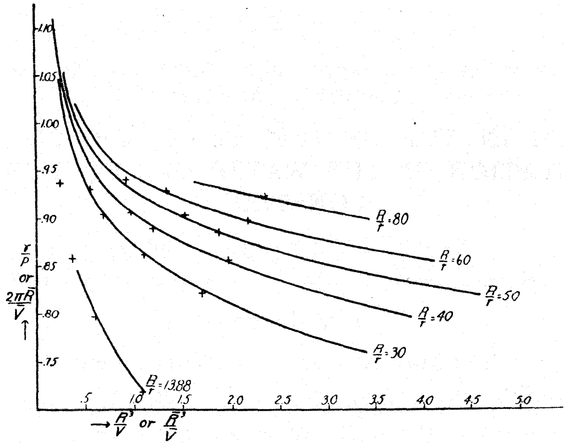

Fig. 4.—Comparison of theory and experiment: ——, experiment (Harkins and Jordan); +, theory (Freud).

The remarkable agreement between the calculated and the experimental values shows that, within the small error of both methods, the same values of the surface tension are obtained, whether the relative corrections of Harkins and his collaborators, or the absolute corrections as calculated by us are used. Thus the ring method, as described by Harkins, Young and Cheng, may now be considered as an absolute method, since by it the surface tension may be determined without reference to any other method.

Conclusions

1. A theory for the ring method of determining surface tension, based on the fundamental Laplace equation describing stable liquid surfaces, has been proposed.

2. This equation has been integrated numerically, thus giving data describing the shapes of the surfaces formed by raising a wetted ring out of a liquid. These data are represented in the paper by a graph of two families of curves. They may be used to supplement the tables of Bashforth and Adams.

3. From these curves it is possible to find certain ratios which are analogous to the dimensions of any particular ring and to the volume of any liquid held up by it. The relationship between three suitable functions of these ratios gives a set of curves which are analogous to those

determined experimentally and which are quite independent of any measurement of surface tension.

4. These curves are found to agree with the analogous experimental curves.

5. The ring method may thus be considered an absolute one for the determination of surface tension.

EQUILIBRIUM IN THE SYSTEM $Co-CO_2-CoO-CO$. INDIRECT CALCULATION OF THE WATER GAS EQUILIBRIUM CONSTANT

BY P. H. EMMETT AND J. F. SHULTZ

RECEIVED DECEMBER 19, 1929 PUBLISHED MAY 8, 1930

Introduction

A survey of the literature reveals marked disagreement concerning the value of the equilibrium constant K_1 for the reaction

$$CO + H_2O = CO_2 + H_2 \quad K_1 = (P_{CO_2})(P_{H_2})/(P_{CO})(P_{H_2O}) \qquad (1)$$

Hahn,[1] Haber and Richardt,[2] and finally Neumann and Kohler[3] have obtained directly values for the equilibrium constant. However, Eastman[4] and his collaborators, by measuring the equilibrium in each of the reactions

$$FeO + H_2 = H_2O + Fe \quad K_2 = P_{H_2O}/P_{H_2} \qquad (2)$$
$$FeO + CO = CO_2 + Fe \quad K_3 = P_{CO_2}/P_{CO} \qquad (3)$$
$$SnO_2 + H_2 = Sn + H_2O \quad K_4 = P_{H_2O}/P_{H_2} \qquad (4)$$
$$SnO_2 + CO = Sn + CO_2 \quad K_5 = P_{CO_2}/P_{CO} \qquad (5)$$

and by making use of the relations $K_1 = K_3/K_2 = K_5/K_4$, obtain indirectly a value for the water gas equilibrium constant that differs by about 40% from the directly determined one. The evidence for the validity of the indirect calculation has seemed particularly strong in view of the fact that the results obtained in the $Sn-SnO_2$ system agree so excellently with those in the $Fe-FeO$ system. Accordingly, since we have already determined and published[5] the value of the equilibrium constant for the reaction

$$CoO + H_2 = Co + H_2O \quad K_6 = P_{H_2O}/P_{H_2} \qquad (6)$$

it seemed of interest to determine experimentally the equilibrium constant for the reaction

$$CoO + CO = Co + CO_2 \quad K_7 = P_{CO_2}/P_{CO} \qquad (7)$$

and thus to obtain an additional set of data from which the water gas equilibrium constant could be calculated.

Experimental

A flow method similar to that described in the previous paper[5] was used in the present experiments. It consisted in passing known carbon dioxide–carbon monoxide mixtures over a large volume of catalyst held at constant temperature and determining the CO_2–CO ratio in the effluent gas. Equilibrium was approached from both the high and low CO_2/CO sides at each temperature; readings were continued until a constant and reproducible value was obtained.

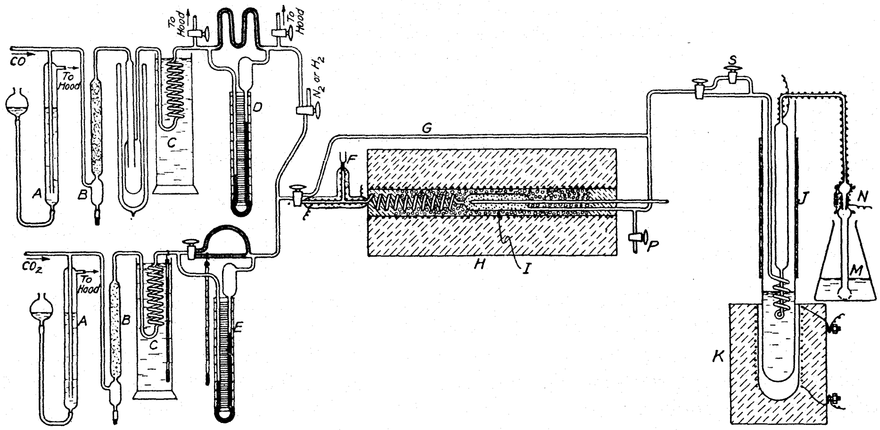

Fig. 1.

The apparatus can best be described with the help of Fig. 1. Commercial carbon dioxide, after being dried by phosphorus pentoxide, was passed through a flowmeter into the catalyst chamber. Carbon monoxide, especially prepared by Thompson in a manner already described,[6] was passed through a liquid-air trap to free it from $Fe(CO)_5$, which experience has shown is likely to accumulate when, as in the present case, the carbon monoxide had been stored for some time in a steel cylinder. The carbon monoxide was then passed through a flowmeter into the catalyst chamber. Necessary overflow bubblers as well as means of conducting to hoods any excess carbon monoxide were also employed as shown. The furnace was the same as that previously used and consisted of a nichrome wound alundum tube packed into a larger iron cylinder with "85% magnesia." The reaction chamber was packed into the center of the alundum tube with mossy copper. A thermocouple well extending along the axis of the glass reaction tube permitted the temperature to be measured throughout the entire length of the Co–CoO mass. The gradient thus obtained did not exceed 3°. The temperature was measured with a calibrated alumel-chromel thermocouple, together with a portable

Leeds and Northrup potentiometer indicator. The cold junction correction on the instrument was set correctly several times each day.

In the course of the experiments, streams of pure hydrogen, pure nitrogen and steam were required. Separate stopcocks connected the system to supplies of nitrogen and of hydrogen that had each been purified by passage over hot copper. The steam boiler was sealed off when not needed.

The carbon dioxide flow was measured by means of a carefully calibrated flowmeter. Two methods of calibration were used to avoid any uncertainty as to the rate of carbon dioxide passage. The flowmeter was first calibrated by collecting the carbon dioxide over a saturated sodium chloride solution. Many points were obtained at several flows varying from **10** to **100** cc. of the gas per minute. This calibration curve was checked by a second method that consisted in absorbing the stream of carbon dioxide in a potassium hydroxide weighing bulb and noting the increase in weight per unit time for a given setting of the flowmeter. The agreement obtained in the two calibrations is shown in Table **I**. In actual runs only flowmeter settings were used for which the calibrations in Table **I** were made.

TABLE I

CALIBRATION OF CARBON DIOXIDE FLOWMETER

	Small capillary		Large capillary		
Height of flowmeter liquid, cm.	11.0	27.6	9.0	10.8	18.4
Cc./min., Method 1[a]	10.26	25.75	50.41	60.56	101.29
Cc./min., Method 2[b]	10.33	25.94	50.05	60.17	100.22
Cc./min., average of 1 and 2	10.30	25.85	50.23	60.37	100.76

[a] Carbon dioxide was collected in potassium hydroxide and weighed.

[b] Carbon dioxide was collected over saturated sodium chloride solution and the displaced liquid measured.

The carbon monoxide content of the exit carbon dioxide–carbon monoxide mixture was determined by passage over iodine pentoxide, absorption of the liberated iodine in potassium iodide solution, and titration with **0.001** *N* sodium thiosulfate solution.[7] An approximate entering flow of carbon monoxide was obtained by a flowmeter equipped with a capillary sufficiently small in diameter to permit the passage of only **6** or 7 cc. of carbon monoxide per minute, under a head of **40** cm. of Nujol.

The **0.001** N sodium thiosulfate was standardized by titration against carefully checked **0.00121** *N* potassium permanganate solution. The agreement obtained as shown in Table II between the titrated carbon monoxide and measured carbon monoxide in calibration of the carbon monoxide flowmeter serves as an additional check of the fact that the titrimetric carbon monoxide determination could not be grossly in error. The normality of the thiosulfate was checked daily. The efficiency of the iodine pentoxide toward the oxidation of carbon monoxide was determined at frequent intervals by running blanks on the entering CO_2–CO ratios. In addition, a final check of the efficiency of the iodine pentoxide was obtained at the end of the series of equilibrium measurements by comparing the efficiency of the iodine pentoxide tube held at **100**° with that of two iodine pentoxide tubes in series, the first at **100**° and the second at **140**°. The agreement of the carbon monoxide as determined in these experiments is shown in Table II. It was considered sufficient proof that all carbon monoxide was being quantitatively oxidized to carbon dioxide by the iodine pentoxide in the equilibrium runs.

For the small concentrations of carbon monoxide used in the present experiments it was found entirely satisfactory to maintain the iodine pentoxide at a temperature of

[a] These "inlet CO" flows were taken from an extrapolated calibration curve obtained by measuring volumetrically the carbon monoxide at flows of five and ten cc. per minute. It should be accurate to 5%.

100". Quantitative oxidation of the carbon monoxide with liberation of iodine was thereby obtained without causing any thermal decomposition of the pure iodine pentoxide. Stopcock S was adjusted to produce the same back pressure in the line during the intervals between runs that was produced by the potassium iodide absorption solution during a run. Thus by turning the gas stream through S during the interval between runs a practically constant rate of flow could be produced.

The exit of the iodine pentoxide tube was electrically heated in order to prevent the condensation of iodine. A ground-glass joint was provided in the exit line permitting the portion dipping into the potassium iodide solution to be removed and washed free of any condensed iodine. By such means all traces of iodine evolved in a particular run could be washed into the potassium iodide solution and titrated.

The cobaltous oxide used in the present experiment was the same sample that had been used in a previous determination of the steam–hydrogen equilibrium over cobalt–cobaltous oxide already referred to.[6] It was originally prepared by igniting to 500° some recrystallized cobaltous nitrate containing 0.98% of nickel, reducing this material almost completely with hydrogen, and partially reoxidizing it to cobaltous oxide by a long steaming process at 500°. Its weight as Co_3O_4, at the completion of the ignition in air, was 23 g. Its apparent volume was 30 cc.

At the beginning of the series of runs the cobalt–cobaltous oxide mixture was steamed at 500° until 75% oxidized. Then about 400 cc. of hydrogen was passed through to insure the presence of ample cobalt surface. The hydrogen–steam mixture was removed by flushing with nitrogen. At each of the three temperatures studied, carbon dioxide-carbon monoxide mixtures were passed over the resulting material at such rates of flow as were necessary to obtain equilibrium. From time to time the surface of metallic cobalt was restored by reduction with about 400 cc. of hydrogen. Equilibrium was approached from both sides and readings were taken over a sufficient interval of time to assure the reaching of steady state conditions and to exclude the possibility of temporary surface effects influencing the equilibrium values. In each run readings were taken of the temperature of the air immediately surrounding the capillary of the carbon dioxide flowmeter, temperature of the water-bath through which the carbon dioxide line passed before reaching the capillary, temperature of the reaction tube, time of passage of carbon dioxide, barometric pressure, and back pressure in the reaction system resulting from placing potassium iodide absorption solution on the exit of the iodine pentoxide tube. The volume of carbon monoxide as determined by the thiosulfate titration was also recorded. The CO_2–CO ratio in equilibrium with Co–CoO at each of the three temperatures employed was calculated from these data.

Experimental Results

The values of $K_7 = P_{CO_2}/P_{CO}$ obtained at 450, 515 and 570° are 489.6, 245.9 and 148.4, respectively. Attempts to obtain values at 330° were abandoned because of the sluggishness with which equilibrium was reached at so low a temperature.

In Tables III, IV and V are shown a few typical runs at each of the three temperatures studied. They consist of several groups of consecutive runs taken from a longer series of runs at each of the temperatures. In Col. 2 is

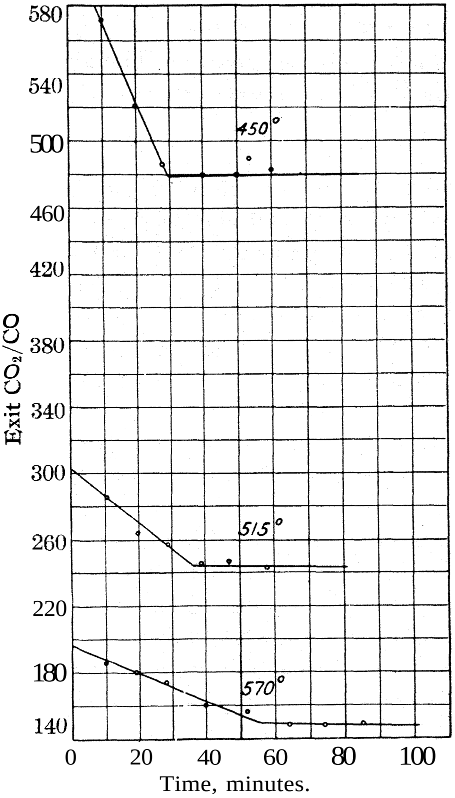
listed the rate of flow of carbon dioxide (S.T. P.) per minute into the reaction vessel. Corrections have been applied as explained later for the temperature of the flowmeter capillary and for the barometric pressure. Column **3** contains the approximate values for the entering flow of carbon monoxide, obtained as described in the footnote to Table II. Column 4 represents the time during which an analytical sample was taken. The total carbon monoxide shown in Col. 5 is that calculated from titration with the sodium thiosulfate. The average of the exit CO_2/CO ratios in Col. 6 of the tables differs slightly from the average of all runs made. This is inevitable, of course, in choosing only a small number of representative runs out of a large number taken.

It was noticed in the course of the work that the first few runs made after a reduction of the oxide surface by hydrogen yielded low values for the CO_2–CO ratio, when pure carbon dioxide was passed over the oxide–metal mixture. Furthermore, the first few runs made after complete oxidation of the surface to cobaltous oxide yielded abnormally high CO_2/CO values, even though the entering CO_2–CO ratio was much less than the normal equilibrium value. Figure 2 gives a few typical curves illustrating this latter effect. In each instance the entering CO_2–CO ratio was 30 to 50% less than the normal equilibrium value. The value of K_7 decreases with time until the normal value results. This is entirely analogous to the effect noted in the determination of the H_2O–H_2 ratio necessary to oxidize cobalt to cobalt oxide.[5]



Pig. 2.—Typical curves Lowing the effect of "surface oxide" on the CO_2–CO equilibrium value. The three series of runs shown were taken immediately after oxidation of the cobalt surface to CoO. The entering CO_2–CO ratios in the 570, 515 and 450" runs shown were 102, 194 and 325, respectively.

The accuracy of the above equilibrium values will depend upon the reliability of the volume of carbon dioxide passing the reaction tube per unit time, the volume of carbon monoxide passing the reaction tube in the same time and the temperature of the reacting cobalt–cobaltous oxide.

Accordingly, each of these determinations will be briefly considered with a view to fixing the maximum and probable errors of the final equilibrium values.

Four possible sources of error in the determination of the carbon dioxide are (1) the uncertainty in corrections for the pressure and temperature variations from the temperature and pressure at which the flowmeter was originally calibrated; (2) the reading error on the flowmeter; (3) the uncertainty in the calibration of the flowmeter; and (4) the uncertainty of the exact temperature of the flowmeter capillary through which the carbon dioxide passed. The first of these sources of error was corrected for by the equation

$$\frac{V_1}{V_2} = \frac{\eta_2 T_2 P_1}{\eta_1 T_1 P_2}$$

where V_1 is the volume of gas (S. T. P.) that passed the flowmeter during calibration when the height of the flowmeter liquid was h_1, the capillary of the flowmeter was at T_1 and the pressure at the exit of the flowmeter P_1; η_1 is viscosity of carbon dioxide at T_1; V_2 is volume of gas (S. T. P.) passing the capillary when the latter is at T_2, the pressure at the flowmeter exit P_2 and the height of the flowmeter liquid again h_1; η_2 is viscosity of carbon dioxide at T_2.

The values for the viscosity of carbon dioxide in the "International Critical Tables" (Vol. V, p. 4) are 147.1 at 23° and 137 at 0°. In making corrections by the above formula, η_2 and η_1 were obtained by extrapolating these viscosity values to the temperature range 25–33°, over which the capillary varied during the series of runs. When, as in the above measurements, T_1 is 29°, P_1 is 750 mm., $(T_1 - T_2) \gtreqless 4°$ in absolute value, and $P_1 - P_2 \gtreqless 10$ mm. in absolute value, it is believed the uncertainties of this correction should be very small, probably ±0.2%. (2) The uncertainty of the flowmeter reading will not exceed 1 mm. This represents an error of ±0.6% at the rates of flow used for most of the runs. (3) From the calibration data of Table I the uncertainty of the carbon dioxide calibration seems to be about ±0.3%. (4) It is assumed that the temperature of the capillary of the flowmeter does not differ by more than ±0.5° from that of the thermometer hanging in air beside it. The summation of the possible errors in the carbon dioxide values thus amounts to *1.3%.

The two sources of error in the carbon monoxide determination are the series of standardization determinations against potassium permanganate and the individual titration in each regular run. The first of these seems not to exceed ±0.3%. Assuming the end-point in the final thiosulfate–iodine titration to be accurate to ±0.2 cc., a maximum error of about ±1.2% would result. Hence the maximum individual error in the carbon monoxide determinations was about ±1.5%.

From a plot of the logarithm of the equilibrium constant against the reciprocal of the absolute temperature, the variation of each constant per degree of temperature variation is readily found to amount to approximately 1% per degree. The temperature was noted at the beginning and end of each run and an average value recorded. The portable potentiometer could be read to ±1°. It is probable, therefore, that errors due to temperature variation did not exceed ±1%. However, in the present maximum error calculation an uncertainty in temperature of ±3° causing a possible error of ±3% in the equilibrium constants for any specified temperature has been assumed.

The summation of the maximum errors that could conceivably be involved in any one reading is thus about 6%. An examination of all the data obtained, however, shows that the maximum deviation from the mean was very much smaller than this calculated possible maximum error. In fact, the maximum deviation of any one reading from the average was 3.9% at 570°, 3.6% at 515° and 2% at 450°. The average deviation was between 1 and 1.3% for the three temperatures. Probable errors calculated by the usual formula on a basis of all of the readings obtained at each temperature (except, of course, those immediately following fresh reduction or oxidation of the catalyst surface) amount to about ±0.3%.

The Equilibrium Constant for the Water Gas Reaction.—The values of K_6 already reported[5] for the temperatures 450, 515 and 570° are 67, 57.5 and 50.3, respectively. From the above K_6 values and the K_7 values determined in the present work, the values of $K_1 = (P_{CO_2})(P_{H_2})/(P_{CO})(P_{H_2O})$ can be readily calculated to be 7.31, 4.31 and 2.94 at 450, 515 and 570°, respectively. Most workers have expressed their results in terms of $K_{wg} = 1/K_1$. The present calculated values of K_{wg} are accordingly the reciprocals of the above and equal to 0.137, 0.232 and 0.340 at the above temperatures. These values agree closely with 0.140, 0.232 and 0.345 obtained in the direct measurements of Neuman and Kohler. In Fig. 3 are plotted values for log K_{wg} against $1/T$. The results of the direct determination of K_{wg} by Hahn,[1] by Haber and Richardt[2] and by Neumann and Kohler[3] are included for comparison. The indirectly determined values of Eastman and Evans[4] are also indicated.

A consideration of the maximum errors that could reasonably be included in the equilibrium values both in the system Co–H_2O–CoO–H_2 and the system Co–CO_2–CoO–CO indicates that the excellent agreement between the values of the water gas constant indirectly determined with the help of Co–CoO mixtures and the directly determined values is truly significant and not a coincidence resulting from experimental error. Assuming a temperature reading accurate to ±3°, and an error of ±0.5% in reading the hydrogen, the values given in the previous paper for the H_2O–H_2 ratio in equilibrium with cobalt–cobaltous oxide are accurate to

±1.5%. Accordingly, the summation of all the maximum errors for the two sets of experiments could not, it seems, exceed 7.5%. The probable errors, as calculated from all readings taken in both systems, total ±0.5%. The conclusion seems warranted that the cobalt–cobaltous oxide system affords a reliable indirect means of obtaining values for the water gas constant. The reaction both with steam–hydrogen and with carbon dioxide–carbon monoxide is remarkably free from complications. No oxides other than cobaltous oxide are present, as was established by x-ray powder photographs of the samples used. Tests for carbon or carbide in the cobalt after the carbon dioxide–carbon monoxide equilibrium were practically negative, 0.06% carbon only being found in each of two samples analyzed.

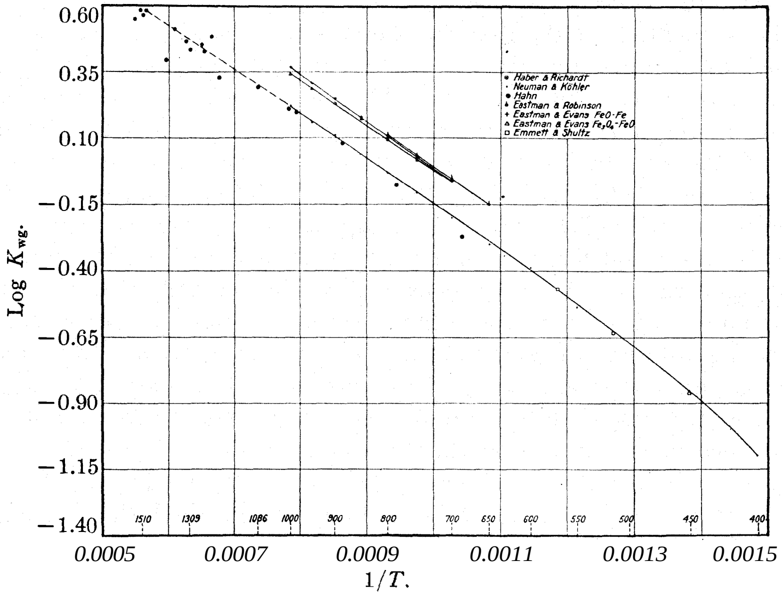


Fig. 3.—Variation with $1/T$ of $\log K_{wg}$ where $K_{wg} = (CO)(H_2O)/(CO_2)(H_2)$. The values of Haber and Richardt, Neumann and Kohler and Hahn are all directly measured values; those of the other authors are the indirect, calculated ones.

In view of the fact that the indirectly determined values of K_{wg} obtained from equilibria of Reactions 6 and 7 were calculated from experimental data obtained over the temperature range 450 to 570°, one cannot, strictly speaking, compare the values so obtained with those obtained by indirect means at higher temperatures. Since it does not seem reasonable, however, to expect sudden changes with temperature in the values of the equilibrium constants of Reactions 6 and 7, between 570 and 700°, one can conclude that the present indirectly determined values of K_{wg} not only verify the directly determined water gas values of Neumann and

Kohler below 570°, but also add a very considerable weight to their direct determinations at higher temperatures.

It is not the purpose of the present paper completely to review all of the other indirect determinations of the water gas equilibrium constant or to attempt therein to explain the discrepancies that now seem to exist. Nevertheless, a few observations will perhaps be worth while.

The experimental work of Eastman and Robinson[4b] upon the determinations of the equilibria of Reactions 4 and 5 in the $Sn-SnO_2$ system seems to have been carefully and accurately done. We are unable to suggest at present any plausible reason why the resulting indirectly calculated water gas constant should be in error. The fact that one of the phases involved in the two equilibria was a liquid and might possibly have been appreciably different in composition in Reaction 5 than in Reaction 4, due to possible dissolved tin carbide, or oxide, offers a slight but entirely unconfirmed source of difficulty.

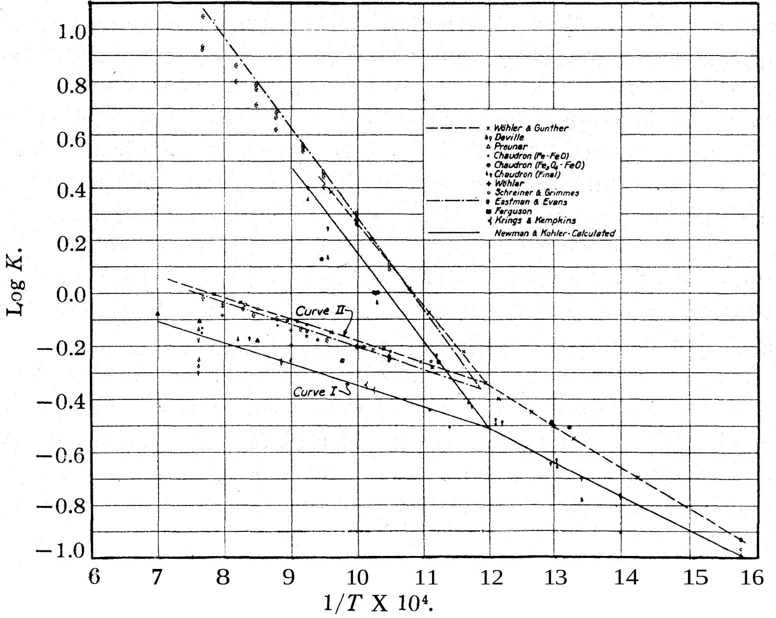

Fig. 4.—Variation with I/T of log K, where $K = (H_2O)/(H_2)$ in equilibrium with $FeO-Fe$, $FeO-Fe_3O_4$ or $Fe-Fe_3O_4$. Curve I is calculated by combination of equilibrium constants for the Fe–C–O system and the direct water gas constants of Neumann and Kbhler. Curve II is the experimental curve of Wohler and Giinther.

It has seemed to us, however, that indirect calculaton of the water gas constants involving the equilibrium constant for Reaction 2 are more open to question. In Pig. 4 are plotted the principal determinations that have been made of the ratio of steam to hydrogen in equilibrium with Fe–FeO at various temperatures. Curve I has been calculated by combining the generally recognized best values for Reaction 3 as chosen by Eastman[8] with the directly determined water gas equilibrium constants of Neumann and Kohler. Any experimental points for the steam–hydrogen equilibria of Reaction 2 will, assuming always the correctness of the Fe–C–O diagram of Eastman, give indirectly calculated values of the water gas constant in perfect agreement with the direct. It can be seen at a glance that the experimental values for the most part fall into two groups. Those of Chaudron,[9] of Deville,[10] of Preuner,[11] of Ferguson[12] and of Krings and Kempkens[13] all agree fairly well with Curve I. The values of the other workers[14,4a] shown in the diagram agree much more closely with Curve II drawn by Wohler and Günther[15] as a representative locus of their own experimental points. We believe it is especially significant that the recent experimental values for the equilibrium constant reported by Krings and Kempkens were obtained by a flow system and are in good agreement with Curve I. Work is now being carried on in this Laboratory to test a possible source of difficulty that has thus separated the experimental observations to date into the two groups. Further discussion of these results will accordingly be deferred to a later paper.

It seems, then, that a correct and fair statement concerning the value of the water gas equilibrium constant must admit of the following.

1. The direct determinations by Neumann and Kohler are in fair agreement with those of Hahn, and of Haber and Richardt. They seem to have been carefully done and are not open to any apparent sources of gross error.

2. The present indirect calculation of the water gas constant from the equilibria for the systems Co–H_2O–CoO–H_2 and Co–CO_2–CoO–CO at temperatures of 450 to 570° agrees well with the directly determined values of Neumann and Kohler. The solid phases seem free of solid solution effects and carbide formation. It is believed the agreement is real and significant.

3. The indirect calculation by Eastman and Robinson involving the Sn–SnO_2 equilibria of Reactions 4 and 6 give values about 40% higher than the directly determined values. No probable cause of the discrepancy is as yet apparent.

4. The indirect calculations involving the Fe–H_2O–H_2 equilibria fall principally into two groups, the one agreeing fairly well with the directly measured values, the other being some 40% higher.

Summary

The value of the equilibrium constant $K_7 = CO_2/CO$ for the reaction $CoO + CO = Co + CO_2$ has been determined by a flow system at 450, 515 and 570°, to be 489.6, 245.9 and 148.4, respectively. Combination of these values with the previously determined constant $K_6 = H_2O/H_2$ for the reaction $CoO + H_2 = Co + H_2O$ gives indirect values for the water gas constant $K_{wg} = (CO)(H_2O)/(CO_2)(H_2)$ that are in good agreement with the values determined directly by Neumann and Kohler. The present status of the disagreement between some of the indirectly determined values for K_{wg} and the direct values of Neumann and Kohler is summarized.

A SCREENED BRIDGE FOR THE MEASUREMENT OF ELECTROLYTIC CONDUCTANCE. I. THEORY OF CAPACITY ERRORS. II. DESCRIPTION OF THE BRIDGE

BY THEODORE SHEDLOVSKY

RECEIVED DECEMBER 26, 1929 PUBLISHED MAY 8, 1930

Introduction

Kohlrausch's classical method for measuring the electrical conductance of solutions has had the benefit of numerous improvements by many workers. The researches of Washburn[1] were particularly valuable in stimulating accurate conductance work in this country. Morgan and Lammert[2] have discussed some of the sources of error in the electrical arrangement used in the method, with valuable references to previous work. Of particular importance from the standpoint of precision measurements has been the comparatively recent introduction of vacuum tube alternating current generators and amplifiers for providing currents of symmetrical wave form, on the one hand, and increasing the sensitivity of the detector on the other.[3] Jones and Josephs[4] have described in a very detailed paper a direct reading alternating current bridge embodying these new features.

[4] Jones and Josephs, *ibid.*, 50, 1049 (1928).

Their paper also includes a valuable and comprehensive study of various sources of error from the electrical standpoint in the Kohlrausch method as it has been generally used.

Important features of Jones and Josephs' bridge are the abandoning of the circular slide wire (which is capable of introducing a disturbing unsymmetrical inductance in the measuring circuit) and the use of a suitable earthing device for the bridge for minimizing disturbing earth capacity effects. They have, however, condemned the use of electrostatic screening of the bridge.[5] The use of screening, when properly designed, for the entire bridge has decided advantages. Since the readings are unaffected by the movements of the observer, a screened bridge is more convenient to operate than an unscreened one. Without adequate shielding, delicate balances are difficult to make due to shifting capacities introduced by the hands of the observer, etc. Also, with suitable screening, measurements of high precision are possible under conditions existing in modern laboratories in which other electrical work is certain to be in progress. Under such conditions the use of an unshielded bridge is at times troublesome if not impossible.

In Part I of this paper the theory of disturbing capacity effects in an alternating current Wheatstone bridge circuit is discussed, with reference to the underlying principle of the apparatus as a measuring instrument. Also, the basis for designing proper screening is developed.

In Part II, a shielded alternating current bridge for measuring electrolytic conductance with a high degree of precision is described. The main problem in the design of such a bridge is the fixing and the proper balancing of "stray couplings" in the apparatus.

PART I. THE THEORY OF EARTH CAPACITY ERRORS IN THE A. C. WHEATSTONE BRIDGE

1. **Stray** Couplings.—When a direct current flows through a conductor, leakage can take place only through inadequate insulation. With alternating currents, the case is more complicated because the current may also leak away through electrostatic and electromagnetic linkings, commonly known as "stray couplings" with the surroundings. Such stray couplings may be electrostatic capacities between the parts of the cirduit and capacities between these parts and the ground. There may also be mutual inductive effects due to linkages with stray magnetic fields. The effects produced by these couplings vary with the frequency, being more troublesome at higher frequencies.

Stray electromagnetic couplings are particularly important in the case

---

[5] Their conclusions are based on tests made with a screen placed near one branch of the bridge network, which introduced an *unbalanced* earth capacity effect into the circuit. Such a test does not prove, however, that electrostatic screening cannot be used without error if it is properly designed.

of parts of circuits, such as transformer coils, which have appreciable inductance. These mutual inductive couplings may be reduced by using materials of high permeability in the cores of the transformers, by shielding stray fields with screens of high permeability, or by sufficiently separating the branches of the circuit having high inductances from each other. In the case of a Wheatstone bridge for measuring electrolytic conductance, the only branches in the network capable of very serious inductive coupling with each other are the detector and the oscillator. The best plan is to avoid the necessity of electromagnetic screening, which is always difficult and seldom completely satisfactory. This is readily accomplished by removing the oscillator to a sufficient distance from the detector, which is more conveniently located near the bridge, and avoiding as much as possible the introduction of stray inductance in the bridge itself. A distance of 10 to 15 feet between the detector and the oscillator is usually sufficient.

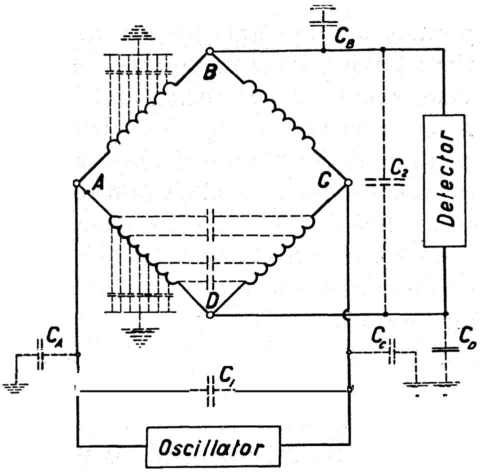

Fig. 1.

Electrostatic couplings existing between various branches of a circuit, directly or to ground, cannot be eliminated entirely in this simple manner without introducing another difficulty. The difficulty is that excessive separation of all the branches of the bridge from each other and from ground, besides being inconvenient, introduces additional inductance into the network because of the increased length of leads required. The result of this increased looping is that although capacitative couplings are reduced, inductances capable of disturbing the bridge balance are thus added, since the bridge balance may be changed by the inductive effect of varying stray fields enclosed.

In Fig. 1 is shown a diagram of a bridge supplied with alternating current, indicating the position of some of the capacitative couplings. The capacity paths from one lead of the oscillator to the other, either directly (C_1) or through ground (C, and C_c in series), merely shunt the current input, and do not affect the bridge balance. Similarly, the coupling between the leads to the detector does not influence the bridge reading, merely shunting the detector. However, couplings are possible which may disturb the balance of the bridge. For example, current leaking from the branch AD, through CB to the terminal B, and back to the oscillator through the branch BC, would have an effect on the bridge balance. (It should be pointed out that the bridge terminals A, B, C and D include the leads appended to them since if they are not too long their resistance is usually negligible.) Although some of these numerous possible paths will tend to neutralize each other, the effects of these paths must be controlled; otherwise, the bridge readings will depend on the relative positions of the units in the circuit and on the surroundings.

Precise measurements are not possible unless these troublesome couplings are neutralized by being made symmetrical with respect to the terminals of the detector. It is not possible to avoid electrical asymmetry entirely in the construction of the apparatus, particularly if the bridge is used for measurements with various frequencies of current, requiring readjustments in the oscillator, or perhaps different oscillators. Neither is it practicable to reduce these couplings so as to make them negligible, especially at the higher frequencies, and in the measurement of dilute solutions having large resistances. For these reasons it is necessary to provide means for controlling and balancing these disturbing effects. This is accomplished (a) by properly designed shielding[6] and (b) by the "Wagner earthing device," both of which will be discussed below. Shielding makes it possible to fix definitely and to control the possible interbranch capacities. Before discussing the effect of capacity couplings on the bridge as a whole, it is first necessary to consider the effect on the impedance of *a* single branch due to the capacity between it and the ground (or a surrounding screen).

2. Effect of Earth Capacity on a Conductor.—In general, with a conductor carrying alternating current, there will be present a distributed capacity of total magnitude c to earth, or to a surrounding screen, as indicated in Fig. 2a, where OR is the conductor of impedance[7] R, and S is the ground or screen. In Fig. 2b is shown a special condition which will help in the consideration of a more general case. In this special case the total capacity from OR to S is concentrated at some point P, between O and R. Let [x] be the impedance from O to P, [y] the impedance from P to R and [z] the impedance from P to S. Let us now substitute for the

---

[6] The necessity of electrostatic screening for measurements at frequencies of, say, above 10,000 cycles is generally recognized. See for example G. A. Campbell, "The Shielded Balance," *Electrical World,* April, 647 *(1904);* W. S. Shackelton, "A Shielded Bridge for Inductive Impedance Measurements," *Bell System Technical Journal, 6,* 142 (1927); J. G. Ferguson, "Shielding in High Frequency Measurements," *ibid.,* 8, 560 (1929).

[7] Ohm's law can be applied to sinusoidal alternating currents if vector symbols instead of scalar symbols are used. On this basis the impedance operator, which is analogous to resistance in D. C., is defined as the vector voltage divided by the vector current. See B. Hague, "A. C. Bridge Methods," pp. 32–35; R. M. Wilmotte, *Phil. Mag.,* 6, 788 (1928).

arrangement connecting the points O, R and S as in Fig. 2b, the arrangement shown in Fig. 2c. which we shall prove can be made equivalent by the "Kennelly $\tau - \pi$ transformation."[8] In Fig. 2c $[\alpha]$,$[\beta]$ and $[\gamma]$ are the impedances connecting the three terminals of interest, O, R and S. By equivalence of the two circuits (shown in Figs. 2b and 2c) is meant that the potentials of O, R and S are the same at any instant in both arrangements. Thus, for example, the impedante operators x + y must be equal to α and $\beta + \gamma$ in parallel. (The letters in brackets [x], $[\alpha]$, etc., refer to impedances; x, α, etc., refer to the corresponding impedance operators.) We consequently get the following relations

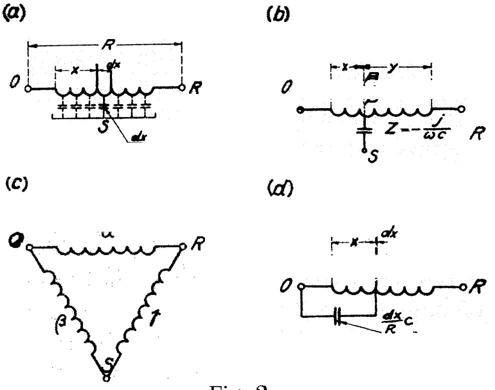

Fig. 2.

$$\frac{1}{x+y} = \frac{1}{\alpha} + \frac{1}{\beta+\gamma} \tag{1}$$

$$\frac{1}{x+z} = \frac{1}{\beta} + \frac{1}{\alpha+\gamma} \tag{2}$$

$$\frac{1}{y+z} = \frac{1}{\gamma} + \frac{1}{\alpha+\beta} \tag{3}$$

Solving, we obtain the equations

$$\alpha = x + y + \frac{xy}{z} \tag{4}$$

$$\beta = x + z + \frac{xz}{y} \tag{5}$$

$$\gamma = y + z + \frac{yz}{x} \tag{6}$$

(a) Capacity Concentrated at the Midpoint.—Now, referring again to Fig. 2b, if we consider R a resistance with its total capacity to the ground (S) concentrated at the midpoint, $x = y = R/2$; $z = -j/\omega c$, where c is the total capacity to ground. $\omega/2\pi$ is the frequency and j is the "reactance" operator.[9] Substituting these values in (4), (5) and (6) we obtain

$$\alpha = R + j\,\frac{R^2wc}{4} \tag{7}$$

$$\beta = \gamma = \frac{R}{2} - j\left(\frac{1}{\omega c/2}\right) \tag{8}$$

---

[8] This transformation has been used by Butterworth [*Proc. Phys. Soc.*, **33**, 312 (1921); *ibid.*, **34**, 8 (1922)] and more recently by Bartlett [*J. Sci. Instruments*, **6**, 277 (1929)] in dealing with the effects of earth capacities.

[9] $(j)^2 = -1$. The reactance due to a capacity c is $-(j/\omega c)$; the reactance due to an inductance L is $j\omega L$. See, for example, B. Hague, "Alternating Current Bridge Methods," p. 35.

That is, due to earth capacity effects, the resistance R between the points O and R is modified by a reactance $R^2\omega c/4$ (this may be considered to be an inductance of magnitude $R^2c/4$ in series with the resistance R) and by the impedances (8) from O and R to ground (S) (these may be considered to be capacities of magnitude $c/2$ in series with a resistance $R/2$).

(b) Capacity Uniformly Distributed.—The more general case of a distributed capacity, as shown in Fig. 2a, is somewhat more complicated to deal with rigorously. However, the values of α, β and γ for this case are approximately represented by Equations 7 and 8. This assumes, of course, the approximation that the total distributed capacity is represented by a single capacity from the middle of the arm to the screen. If the capacity is uniformly distributed, the effect on α due to the differential capacities $(dx/R)(c)$ from the differential proportions dx/R (see Fig. 2) is obtained from Equation 4 to a first approximation by integration as follows[10]

$$d\alpha = x + R - x + j \,\text{''}\frac{(R - x)\omega c dx}{R} \tag{9}$$

$$\alpha = R + \int_0^R \frac{x(R - x)\omega c dx}{R} = R + j\frac{\omega R^2 c}{6} \tag{10}$$

Equation 10 shows that the resistance of OR, due to the distributed earth capacity effect, behaves as a resistance R in series with an inductance $R^2c/6$.

(c) Impedance Directly Connected to Earth or Screen.—Another case of interest is one in which the ground or screen S is connected to one terminal of the impedance (Fig. 2d), since screens are often so connected, and bridges are frequently grounded directly from one terminal. The effect due to the capacity from a differential section to the screen S (or earth) is a shunting impedance [dz]. As before, $-j(R/\omega c dx) = dz$.

The total impedance operator, then, from O to R is

$$Z_{(OR)} = \frac{1}{\frac{1}{x} + j\frac{\omega c dx}{R}} + R - x = x - j\,\omega c x^2 dx + R - X = R - j\frac{\omega c x^2 dx}{R} \tag{11}$$

neglecting terms of higher order.[11] Integrating from $x = O$ to $x = R$

$$Z_{OR} = R - j\frac{\omega c r^2}{3} \tag{12}$$

---

[10] For a more rigorous treatment of this uniformly distributed case, see **A. E.** Kennelly, "Electric Lines and Nets," McGraw-Hill Book Co , New York, pp. 61, 395. The method of integration (Equations 9 and 10) used below for obtaining α in this distributed case amounts to neglecting higher order terms in the rigorous treatment which involves the use of hyperbolic functions. However, no such approximations are involved in obtaining Equations 7 and 8.

[11] This derivation involves the approximation that the differential capacity effects act independently. For a more rigorous derivation see R. Davis, **J** *Sci. Instruments*, *5*, 306 (1928).

In this case we see that the earth capacity effect introduces a negative inductance in series with it of magnitude $\boldsymbol{R^2c/3}$.

3. Earth Capacity Effect on the **Bridge** Circuit.—In the light of the discussion in the previous section we may now view the effect of "stray couplings" on the bridge network. We shall assume that direct couplings between the branches have been avoided by shielding. Assuming, then, that the branches of the bridge are so shielded from each other by screens, and making the Kennelly $\tau - \pi$ transformation for every branch, the bridge with its capacity couplings to ground can be represented as in Fig. **3.** The segments L_1, L_2, etc., represent the inductive effects discussed above produced in the branches by the earth capacities. AE, BE, CE and DE are the impedances from the four bridge terminals to ground at E. Each of these impedances includes the separate earth capacity effects from the three branches (corresponding to the various β and γ terms, Equation 8) meeting at each terminal of the bridge network. In addition, there are the capacities to earth from the terminals (and leads) A, B, C and D. For instance, (1) is a resistance in series with a capacity due to AB; (2) is a similar, though not necessarily equal, impedance due to AD; **(3)** is another one due to the oscillator branch; and (4) is a capacity from A to E, due largely to the lead from the oscillator. All these in parallel constitute AE.

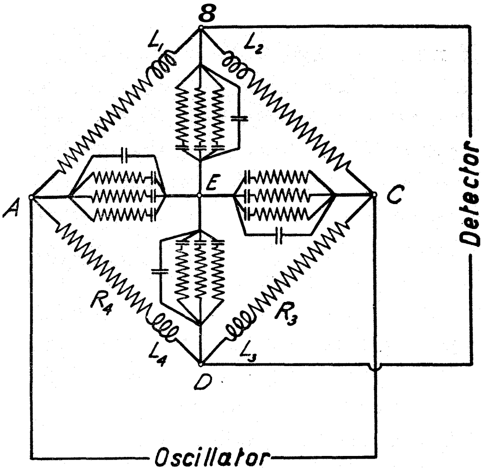

Fig. 3.

It should be noted that the representation of the bridge in Fig. **3** takes into account the distributed dissipations of current from the branches in the circuit to the screens and earth. The advantages of the artifice used in this representation are that it shows the effects produced on the branch impedances from the standpoint of the four terminals of the bridge, making clear the necessary conditions for proper bridge balance, and shows the limitations which must be observed in designing suitable screening so as not to introduce errors in the measurements.

When the bridge is balanced, the terminals B and D are at the same potential, both in magnitude and in phase. That is, the potentials are equal at every instant and no current flows between the two points through the detector. Referring to Fig. **3,** if V is the potential between two points at balance

$$V_{AB} = V_{AD} \text{ and } V_{BC} = V_{DC} \tag{a}$$

This gives by the Vector Ohm's Law[12]

$$\frac{I_{AB}Z_{AB}}{I_{BC}Z_{BC}} = \frac{I_{AD}Z_{AD}}{I_{DH}Z_{DC}} \tag{b}$$

where I is the current and Z the impedance. Now, if the points B and D are brought to the same potential as the ground E, there will be no current flowing in either BE or DE, and the conditions

$$I_{AB} = I_{BC} \text{ and } I_{AD} = I_{DC} \tag{c}$$

will be fulfilled. (There are only three possible paths for current from B or D, when no current flows in the detector.)

Then

$$\frac{Z_{AB}}{Z_{BC}} = \frac{Z_{AD}}{Z_{DC}} \tag{d}$$

If no errors are to be introduced into the measurements, the ratio arms (AD and CD) should be identical in all respects in the case of a direct reading (equal ratio) bridge ($Z_{AD} = Z_{DC}$). Not only must the resistances R_4 and R_3 be equal, but the inductances L_4 and L_3 must also be equal. The latter need not, however, necessarily be negligible, since it is quite feasible to have two equal coils, of similar construction, similarly screened so that, practically, $R_4 = R_3$ and $L_4 = L_3$, in which case $Z_{AD} = Z_{DC}$. Nevertheless, slight differences, in resistance particularly, are likely to occur. This, as well as slight unbalances in the I, terms due to screen capacity, are automatically corrected for if two readings are taken, one with the ratio arms reversed. The average value (strictly speaking, the geometric mean) gives the correct measurement.

However, the characteristics of the measuring branch and of the unknown (cell) cannot be considered identical as in the case of the ratio arms. That is, it is not possible to shield the two with relatively close screens, and feel assured that the capacity effects are similar in both cases. However, shielding is desirable from the standpoint of screening out external influences which may affect the circuit. The correct procedure, therefore, is to shield these branches not closely, but at a sufficient distance to make the effect of the capacity on the impedance negligible under the limiting conditions existing in measurements. If the upper frequency range does not exceed 4000 cycles, direct test showed that a separation of 2.5 inches between the coils of the resistance box (or cell) and the shield introduces a negligible error. That is, the terms L_1 and L_2 in Fig. 3 are negligible.

If these conditions for the ratio arms and the other two branches in the bridge are fulfilled (L_1 and L_2 negligible, $L_3 = L_4$, $R_4 = R_3$, no current in BE or DE) then Equation d reduces to

$$Z'_{AB} = Z'_{BC} \tag{e}$$

---

[12] See Hague, Ref. 9, p. 32.

(2' is the impedance free from earth or screen effect)[13] which is the correct balance condition for an equal ratio bridge without error. Jones and Josephs[4] state in their paper that the necessary condition for the validity of Equation e is that no current whatever escape from any of the bridge parts. Of course, if that is so, correct balance is obtained at once. Practically this is not possible. However, as shown above, correct balance, without error in the measurements, is quite attainable when the proper precautions are observed in spite of a certain amount of current leakage from at least some of the branches.

4. The Wagner Earthing Device.—One of the conditions for the validity of Equation e is that the terminals B, D and E (Fig. 3) be at the same potential. This may be done by adjusting the earth impedances AE and CE until no current flows in the detector connected from E to B (or D), when the main bridge (ABCD) is also balanced. That is, $Z_{AE}/Z_{CE} = Z_{AB}/Z_{CB} = Z_{AD}/Z_{CD}$. This is the principle of the device. Since Z_{AE} and Z_{CE} are mixed impedances, consisting of resistance and capacity, the adjusting impedance must similarly comprise a variable resistance and reactance. The reactance may be either a capacity or an inductance, or both, since any impedance may be balanced by such combinations. It is merely necessary to adjust the impedances Z_{AE} and Z_{CE} to the proper ratio.

The scheme used by Jones and Josephs,[4] who, however, do not discuss the theoretical basis of the device, is a very convenient one. It consists of shunting AE and CE with resistances permitting of sufficient variation in adjustment, and a variable condenser from A to E, or C to E, as required. The advantage of their method lies principally in the fact that for the same delicacy of adjustment condensers of lower capacity can be used than would be required with series resistance and capacity combinations.[14]

An examination of Fig. 3 shows the limitations of connecting the ground point E directly to B or D, and securing balance by the adjustment of a condenser in parallel with the necessary branch. Evidently, except in the case of accidental balancing between AE and CE, the bridge reading will not be free from error. The magnitude of the error will depend on the magnitudes of AE and CE and on the extent of their unbalance. It is, however, possible to determine the unbalance between AE and CE, and then to calculate the error thus introduced in the measurements.

---

[13] This impedance may be a pure resistance. The somewhat more complicated case of a cell for measuring electrolytic conductance will be discussed in a later paper. However, if the cell impedance is of sufficiently low-phase angle, it can be regarded as a resistance.

[14] Jones and Josephs deserve the credit for describing the proper use of the earthing device for balancing the earth admittances in *a* conductance bridge for work with solutions, although the underlying principle of the method is due to Wagner.

This scheme, though feasible in certain types of impedance measurements, is inconvenient since it requires an estimation of the earth capacity with subsequent calculations. For a bridge designed to measure electrolytic conductance the Wagner device is simpler and preferable.

PART II. A SCREENED ALTERNATING CURRENT WHEATSTONE BRIDGE

The shielded bridge, which was discussed from the theoretical standpoint in Part I, is shown diagrammatically in Fig. 4. The detector and oscillator are connected to the bridge by duplex cables inclosed in flexible copper shielding which is grounded. The oscillator and the earthing circuit W_R, W_C are connected directly to terminals of the measuring branch and of the conductivity cell, at M and N.

1. Balancing Condensers.—A twin (double) variable air condenser K is connected across the measuring resistance (MS) and the cell (BN) as shown, for balancing out the reactance of the cell, due to polarization at the electrodes. The ordinary type of single variable condenser has a disadvantage. It is sometimes impossible to get complete balance in the bridge with it, owing to the fact that the residual zero capacity is too large for the required setting. The twin type, which makes it possible to remove. capacity from one side, adding it to the other, avoids this difficulty, and does not require a switch for shifting the condenser from one branch to the other. The entire condenser K consists of two such twin condensers. One is of 250$\mu\mu$f. capacity, easily reconstructed from the "tandem type" condenser made by the General Radio Co. The other, connected in parallel witli the first, is similarly constructed from two micro condensers. The latter has a maximum capacity of about 10$\mu\mu$f. and it is provided with a "Vernier" control knob, allowing of very delicate adjustment.

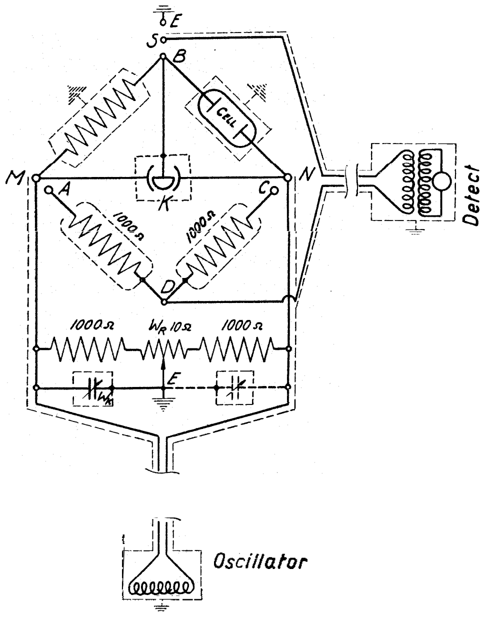

Fig. 4.

2. Ratio Arms.—The ratio arms are connected to the bridge by means of a double pole double throw reversal switch (not shown in Fig. 4). In making determinations the mean of readings with the ratio arms in the two reversed positions is taken. This procedure corrects for slight variations in the resistances (and reactances) of the ratio coils, and avoids the necessity of adjusting them to perfect equality. The ratio coils are surrounded by local symmetrical shields connected to the junction point D. The shield localizes the total distributed capacity of the ratio arms at point D, and avoids the possibility of any stray couplings directly with these important branches of the bridge.

The ratio arms consist of two closely matched Ayrton–Perry coils of 1000 ohms resistance which are wound on flat bakelite cards. It has been shown in Part I that the effect of the distributed capacity in these coils will add an inductance of magnitude $-cR^2/3$ to them. For this reason it is important to make shielding the same around the two ratio arms. In our arrangement the flat coils are mounted parallel to each other, symmetrically between three parallel copper plates spaced 1.5 inches apart. The plates are soldered to a copper strip joining the two resistance coils.

3. The Detector.—The detector consists of a two-stage audio transformer coupled amplifier with sensitive telephones. The output from the bridge is fed into the primary winding of the first transformer. By means of the switch S in Fig. 4, the detector may be connected across DB, for recording the balance in the main bridge, or across DE, for the earthing adjustment.

4. The Earthing Circuit.—The earthing circuit consists; of two 1000-ohm bifilar coils (Leeds and Northrup) and a 10-ohm rheostat (W_R) connected as shown in Fig. 4 to the ratio arm extremities, and to ground. In addition, there is a variable air condenser, with a "Vernier" control knob connected between the earth E and the point A (or C, as required).

Various parts of the bridge, including the oscillator and detector, are shielded from external electrostatic disturbances by the earthed metal shields surrounding them. The various earth points E are all brought together by soldered connections.

The ratio arms, earthing resistances, condensers K, and the reversal and detector switches ("Federal Anti-capacity Switches") are mounted in a grounded copper screened box, as shown diagrammatically in Fig. 5. The top of the box consists of a brass plate in which the terminals are mounted with adequate insulation of transparent bakelite.

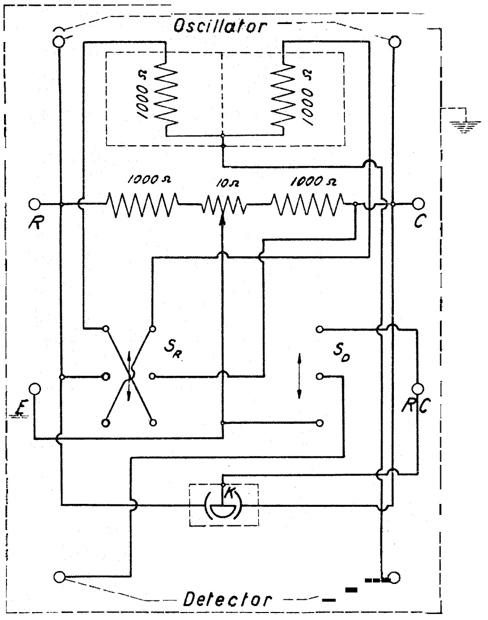

Fig. 5.

5. Measuring Resistance.—The resistance standard MB (Fig. 4) consists of three parts. A five-dial box of bifilar coils containing decades of 1/100, 1/10, 1, 10 and 100 ohm steps, is mounted in a shielded box. The screening in the box has a clearance of not less than 2.5 inches from any of the coils or contacts. This spacing proved to be sufficient by actual test to make the effect of the screen capacity on the resistance negligible for our purposes. The control knobs for operating the resistance dials are on the outside of the box, over a brass plate which forms a part of the shielding. They are fastened to the dials through stout bakelite rods. Complete shielding of these lower resistance dials as well as of the condenser K (Fig. 5) is of great convenience in entirely eliminating "hand effects" in measurements.

The effect of temperature on the resistance coils of higher values is not negligible in work requiring readings to 0.01 ohm and is not the same on every coil, so that corrections are not readily made. For this reason we found it desirable to control the temperature of the 1000-ohm step decade and the 10,000-ohm coils. These coils, of a woven type, forming one loop, are made by the Leeds and Northrup Co. They are practically reactance-free, compact and more constant in resistance than the card-wound type, being subject to very slight mechanical strain.

The 1000-ohm decade is mounted in air in a glass jar which is immersed in the metal shielded, oil-filled thermostat which holds the conductivity cell. The 10,000-ohm coils are mounted separately in large test-tubes, which are sufficiently spaced in a wooden frame, and also immersed in the thermostat. The 1000-ohm decade is permanently connected to the resistance box with a stiff heavy wire, avoiding close screening. The required connections in the thermostat, of the cell and measuring resistance are made with short heavy strands of bare copper wire through mercury cups. To avoid appreciable "dead end effects" the 10,000-ohm coils are appended one at a time as needed. Connections to the "bridge box" (Fig. 5) of the various units are made with flexible copper screened stranded wire, the screening being grounded.

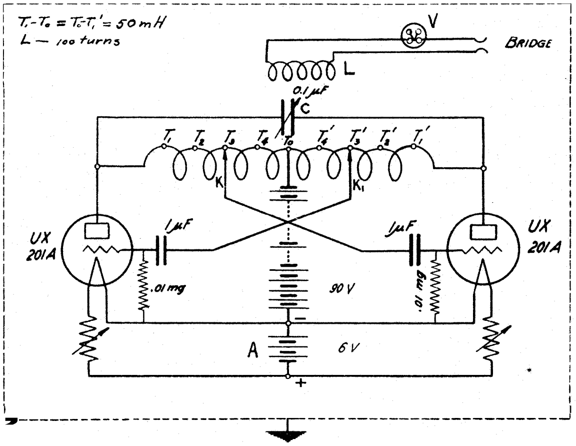

Fig. 6.

6. The Oscillator.—We are indebted to Dr. N. Frank of the Massachusetts Institute of Technology for furnishing us with the specification for an improved type of vacuum tube oscillator, designed by Eccles and Jordan. It consists of a double balanced oscillating circuit which has the advantage of giving an alternating current of very good wave form and of more constant frequency and intensity than that generated by the usual type of one-tube oscillator. The circuit is shown in Fig. 6. In varying the magnitude of the capacity C, which is made up of mica condensers which can be thrown in parallel by a system of switches (not shown in Fig. 6), the instrument can be made to give currents of frequencies ranging from about 600 to about 8000 cycles. The filament supply from the 6-volt storage battery **A** can be thrown on or off by means of a switch located near the bridge, so that the oscillator can be started or stopped conveniently during the measurements. The voltage supplied may be varied by looser coupling of the "pick up" coil L, or by changing the connections of K and K' to the taps T_1, T_2, T_3 and T_1', T_2', T_3', respectively. It is important to use separate batteries for the oscillator and detector circuits; otherwise, troublesome inductive couplings will occur. A calibrated vacuum thermocouple (V) is included in the apparatus for measuring the current supplied to the bridge.

7. Tests and Calibrations.—The resistance box, 100-ohm step decade, and the 10,000-ohm coils were calibrated with direct current against Bureau of Standards resistance standards, by the Carey Foster method, using an auxiliary resistance box. This was done directly with the bridge described above, using a high sensitivity galvanometer, and then checked on a well calibrated direct current Wheatstone bridge. The individual 10,000-ohm coils and various parallel combinations of them were also measured with the shielded bridge, at frequencies of 1000, 2000 and 3000 cycles, and with direct current. The variations from the direct current values obtained were less than 0.002% at 3000 cycles for 10,000 ohms, and entirely negligible at 1000 cycles, or for lower resistances.

The quality of the insulation, which is particularly important for the higher resistance measurements, was tested by connecting a 45-volt battery between the various binding posts, leads and screens, with a sensitive galvanometer in series. It was found to be well over 500 megohms across the important paths. The resistances of the metal contacts, important for the comparatively low resistance measurements, were also tested. A film of vaseline on the terminals and switch points made the resistance of the contacts reproducible and negligible (under 0.01 ohm).

In using the bridge, measurements are made by alternately adjusting R and K for the main balance, and W_R and W_K in the earthing circuit, with the detector in the correct position for each. The unknown and standard are then interchanged by throwing the reversed switch, and the procedure is repeated. The mean of the two readings gives the desired value.

No difficulty is found in making the adjustments, which may be made rapidly with a sensitivity of 0.001% directly without interpolation in measuring resistances of 1000 ohms or over. It is possible to use the bridge for measurements of high precision under conditions in which the use of an unshielded bridge would be quite difficult or impossible due to disturbances from other electrical circuits.

Measurements made with this bridge on the conductance of mixtures of potassium and sodium chlorides have already been reported.

The author wishes to express his gratitude to Dr. D. A. MacInnes for his helpful suggestions both during the progress of the work and in the preparation of the manuscript.

Summary

Part I. The theory of earth and shield capacity effects on alternating currents is discussed, and the results are applied to the Wheatstone bridge. The principles for the design of an electrostatically screened bridge for precision work are developed.

Part II. An alternating current, shielded bridge for precise electrolytic conductance measurements is described.

A CONDUCTIVITY CELL FOR ELIMINATING ELECTRODE EFFECTS IN MEASUREMENTS OF ELECTROLYTIC CONDUCTANCE

BY THEODORE SHEDLOVSKY

RECEIVED DECEMBER 26, 1929 PUBLISHED MAY 8, 1930

The electrolytic conductivity of a solution is ordinarily determined by measuring its resistance, with alternating current, in a cell previously calibrated with a solution having a known specific conductance. The product of this specific conductance and of the corresponding cell resistance is the "cell constant." Values of the specific conductance of other solutions are obtained by dividing the cell constant by the resistance measured in the cell.

Parker[1] has compared measurements on solutions of potassium chloride and hydrochloric acid, obtained in several cells over a range of concentrations. He found that determinations with different cells would lead to somewhat different conductance values. That is, there seemed to be an apparent variation in "cell constant" when the nature or concentration of the measured solutions was varied. Randall and Scott[2] found similar variations on measuring in two cells the conductance of solutions of several substances. These workers found very surprising variations, which in some cases were as high as 0.5%. Such large variations evidently make precision work impossible, and the following study was made with the purpose of eliminating them.

We have made a number of intercomparisons between several cells and have also observed apparent variations in cell constants, although considerably smaller ones than those found by the above investigators. In our work the variations were never greater than 0.2% with bright platinum electrodes, and were always under 0.1% with platinized electrodes. This smaller variation is due, we believe, to the fact that our measurements were made with a bridge[3] which gave readings free from certain sources of error possible in the arrangements these workers used.

Parker has suggested that the variations of cell constants are due to adsorption at the electrode. However, adsorption would be less on bright electrode surfaces, which, as we have just seen, give the largest variations. Therefore, adsorption cannot entirely account for the observations. In addition, the bridge readings with bright electrodes showed fluctuations of a nature suggesting variable polarization effects. Such fluctuations disappeared when the electrodes were lightly platinized, but it is quite pos-

sible that such polarization was made constant by this procedure, rather than eliminated.

In this paper is described a cell which was designed for studying means of eliminating any effects at the electrodes which would disturb conductance measurements. The results of test measurements with the cell are also reported. To anticipate the conclusions, these results indicate that cell constant variations disappear if electrode effects are completely eliminated.

The Cell

The cell is shown diagrammatically in Fig. 1. It is provided with two end, or conducting, electrodes O and D, and the three loop, or detector, electrodes a, b and e. The electrodes O and D are hollow cones of platinum foil, made as nearly alike as possible, and a, b and c are loops of platinum wire. All the electrodes are sealed directly to the inner surface of the cell and are very lightly platinized. The cell is constructed from Jena glass 16^{III}, which may be sealed directly to platinum. This glass also has a very low solubility.

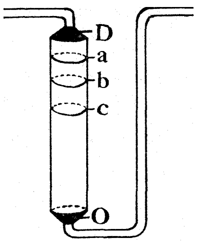

Fig. 1.

Such a cell may be connected into the Wheatstone bridge circuit in a number of different ways. For instance, measurements may be made in the ordinary manner between various electrode pairs. We have used the pairs OD, ab, bc, and ac in this way. This is obviously equivalent to an intercomparison between four ordinary cells. One of the purposes of this investigation was to see whether variations of the cell constant would disappear if similar electrodes were included in two arms of the bridge during measurement. The arrangement is shown in Fig. 2. It was hoped that the disturbing variations would be eliminated if measurements were made with one of the loop electrodes (a, b or c) connected to the detector, electrode O to one end of the current source, and the electrode D to a resistance box in the other arm of the bridge. Thus, for example, the portion of the cell (aO) with the electrode effect from O is balanced by the resistance box in series with the electrode effect from D, and the portion of the cell (aD) K is the condenser for balancing the resistances in the two arms, and the two 1000-ohm coils are the ratio arms. This particular arrangement we have called [a]. [b] and [c] are similar arrangements with the detector connected to (b) or (c) instead of to (a).

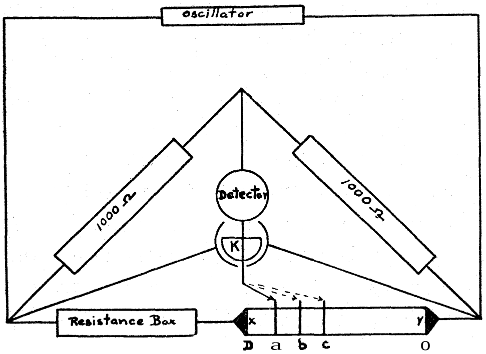

Fig. 2.

Parker,[1] who has made some excellent determinations of absolute conductance values for potassium chloride solutions, partially corrected for electrode effects by subtracting measurements made in two different cells provided with similar electrodes. He hoped that the electrode effect would be eliminated from the measurements if all determinations were made with the same two cells and the difference between the two readings were always taken as the resistance value. This would be so if the electrodes in the two cells behaved in exactly the same manner in all measurements. The method of making measurements by arrangements [a], [b] and [c] was chosen for obtaining directly the results given by Parker's two cell scheme. The difference between two of our measurements, ab, ac, bc, using the various pairs of loop electrodes as ordinary cells, corresponds to Parker's actual scheme. In Table II these arrangements are represented by (ac) (ab) and (ac)-(bc).

Referring once more to Fig. 2, let us call x the effect on the resistance due to the electrode D, and y the effect due to the electrode O. The current density at these electrodes depends on whether the detector is connected to a, b or c; that is, on the resistance between the detector electrode and the current source terminals, other things being equal. We found that a ten-fold change in current density attained by altering the voltage supplied to the bridge had no effect on the value of a particular measurement, so that it is fair to assume that x and y remain essentially the same whether the detector is connected to a, b or c. Let us call R_a, R_b, R_c the resistance box readings for the arrangements [a], [b] and [c], respectively. Since the loop or detector electrodes draw no current when the bridge is balanced, it seems plausible to assume that there is no effect at such electrodes that influences the readings.

We can write the following equations representing the conditions of balance in our bridge for the arrangements [a], [b] and [c]

$$\begin{array}{lll} [a] & R_a + x + \rho_{Da} = \rho_{oa} + y; & R_a = \rho_{oa} - \rho_{Da} + Y - x \\ [b] & R_b + x + \rho_{Db} = \rho_{ob} + y; & R_b = \rho_{ob} - \rho_{Db} + y - x \\ [c] & R_c + x + \rho_{Dc} = \rho_{ac} + y; & R_c = \rho_{ac} - \rho_{Dc} + y - x \end{array}$$

where ρ_{Da} is the resistance of the solution between D and a, etc. The actual reading observed, for instance R_a, corresponds to the difference between the two fixed portions of the solution Oa and Da, modified by the effects from the electrodes. If x = y, this method of measuring conductances is free from these electrode errors. However, if x and y are not equal, the electrode effects can be entirely eliminated by taking the difference between any two of the measurements [a], [b] and [c]. Thus

$$\begin{array}{ll} [a] - [b] & R_a - R_b = \rho_{oa} - \rho_{ob} + \rho_{Da} + \rho_{Db} = 2\rho_{ab} \\ [a] - [c] & R_a - R_c = 2\rho_{ac} \\ [b] - [c] & R_b - R_c = 2\rho_{bc} \end{array}$$

Thus, for instance, the difference $R_a - R_b$ is equal to twice the resistance of the solution between a and b, without error due to effects at the conducting electrodes.

The Measurements

Measurements were made with the cell described in the various ways discussed above. Four series were carried out at 1000, 2000 and 3000 cycles. First the cell was filled with potassium chloride solution (approx. 0.005 N) and then with three different concentrations of hydrochloric acid (approx. 0.001, 0.002 and 0.004 N). The cell was immersed in an oil thermostat which maintained a temperature regulation accurately to ±0.001°. The temperature was measured with a platinum resistance thermometer sensitive to about 0.0002°. A shielded bridge. described in another paper,[3] supplied with current from a balanced vacuum valve oscillator, and a detector amplifier was the measuring apparatus. 'She resistance box used in the measurements was calibrated to 0.01%.

The data are summarized in Tables I and II. The figures shown in Table I represent the resistances corresponding to the various arrangements when the cell was filled with approximately 0.005 N potassium

chloride. Table II gives the corresponding resistance ratio, i. e., $R_{\text{HCl (c)}}/R_{\text{KCl (0.005 }N\text{, approx)}}$ for the three hydrochloric acid solutions measured. These values are, therefore, proportional to the specific resistance of the three hydrochloric acid solutions as obtained from the various types of measurements, after calibrating with a potassium chloride solution.

It is evident that the arrangements [a] − [b], [a] − [c], [b] − [c], which are free from conducting electrode effects, as shown above, give the most consistent values. These figures show practically no variations with frequency, nor of "cell constant," the average deviation being within 0.01%, which is the precision to which the resistance box is calibrated. We have, therefore, assumed as correct the values obtained by making measurements in this manner. The percentage error of the values obtained from the other arrangements on this basis is indicated in Table II to the nearest 0.01%.

Discussion

Since electrodes O and D were made as nearly alike as possible both in construction and in the subsequent platinizing, we should expect smaller variations in the arrangements [a], [b] and [c] in which these two electrodes are in opposite arms of the bridge than in the ordinary arrangement OD, if the cause of the variations is due to simple adsorption. This does not seem to be generally true, which suggests that besides adsorption there is superimposed another effect. Referring to the equations [a], [b] and [c], the results seem to indicate that x and y may have opposite signs, so that their effect on the measurements may increase instead of decreasing when they appear in opposite branches of the bridge. Such may be the case if there is a definite difference between the rates of building up and decaying of the e. m. f. at the electrode surfaces for the oxidation and reduction parts of the current cycle.

It appears from our results that conductance values, free from errors due to effects at electrodes which tend to change the apparent cell constant, can be obtained with a four electrode cell. The measurements for the arrangements [a] – [b], [a] – [c] and [b] – [c] represent a comparison between three such four electrode cells and lead to consistent conductance values.

Cells of the ordinary type (with two electrodes), which may be more convenient for routine work, can be calibrated by comparison with a four electrode cell.

Summary

1. A multiple electrode cell for studying the elimination of electrode effects in conductance measurements is described.

2. Data obtained with one potassium chloride solution and three hydrochloric acid solutions of different concentrations, using various measuring arrangements of electrodes, are given for three frequencies.

3. The assumption of adsorption at the electrodes does not entirely explain the variations in "cell constant" which are observed.

4. A four electrode arrangement is found to give consistent results at the three frequencies without variations in "cell constant."

THE USE OF ORTHO,PARA-DIHYDROXY-AZO-PARA-NITROBENZENE AS A TEST FOR THE MAGNESIUM ION

BY EDWARD WILLIAM ENGEL

RECEIVED DECEMBER 26, 1929 PUBLISHED MAY 8, 1930

The azo dye *o,p*-dihydroxy-azo-*p*-nitrobenzene has been reported by K. Suitsu and K. Okuma[1] as rendering a very sensitive test for the magnesium ion. A recently published note by Ruigh[2] gives the method of preparation and use. A 0.5% solution of the dye in 1% sodium hydroxide solution is stated to be the proper concentration to employ. The test depends upon the formation of a blue lake with the azo dye in dilute sodium hydroxide solution. It is also stated that ammonium salts render the test less sensitive, while the presence of nickel or cobalt, cations which form similar lakes with the dye, invalidates or confuses the test.

Numerous tests with this reagent have been made in this Laboratory, and it is believed that a more sensitive and more convenient method for its use has been developed. In addition, this usage has the advantage of being very simply conducted and, with very few exceptions, can be carried out, if desired, without the preliminary, time-consuming removal of interfering anions or cations. The classical magnesium ammonium phosphate method of determining magnesium is often confusing, inasmuch as aluminum hydroxide, silicic acid, strontium phosphate and calcium phosphate often precipitate at this point in the ordinary qualitative analysis schemes. Methods of removing these substances usually involve several time-consuming separations which are, in addition, generally not very sensitive.

'She method which was found to be the most practicable, involves the evaporation of the unknown solution to a small volume, or to dryness if the quantity of magnesium is very small and if substances such as organic material (which would char under such treatment) are absent. A clean porcelain crucible is essential for this test and the evaporation should be conducted within it. Five or ten ml. of 6 *N* sodium hydroxide is now added to the porcelain crucible or casserole and finally one drop of the dye reagent. In about ten seconds or more, depending upon the concentration of the magnesium ion, a light blue stain will appear upon those portions of the casserole which had been in contact with the solution containing magnesium. This stain adheres quite tenaciously to the surface of the casserole. If the supernatant liquid is now poured from the casserole and the stain washed twice with 5 to 10 ml. of water, the stain turns green in color but does not disappear. If the same test is carried out with nickel alone, the stain does not form as rapidly, adheres less tenaciously and turns red-

[1] **Suitsu** and **Okuma,** *J. Soc. Chem. Ind.* Japan, 29, 132–138 (1926); C. *A.* **20,** 3000 (1926).

[2] Ruigh, THIS JOURNAL, **51,** 1456–1457 (1929).

brown in color upon washing with water. If a similar procedure is followed with cobalt, no stain whatever forms, although a blue lake will appear.

Treatment of the stains with concentrated ammonium hydroxide is also characteristic. In the case of magnesium, the stain is not affected, but in the case of nickel the stain dissolves readily. If desired, this solution could be tested for nickel in the usual manner, that is, by the addition of dimethylglyoxime to the solution with the formation of a precipitate of nickel dimethylglyoxime.

Quantitative investigation indicates that in the absence of de-sensitizing material, 3×10^{-6} g. of magnesium can be readily detected with this technique. If, therefore, the magnesium test is applied in its customary place in the fourth or fifth group of the commonly employed qualitative analysis schemes, this small quantity of magnesium will be capable of detection.

Experiments were also conducted to determine the validity of this test in the presence of the cations commonly met with in qualitative analysis either tested singly or in any possible combination. In the presence of these cations, tested individually, no interference in any case was obtained. A great many combinations were tested, and, in general, any grouping of cations which form colored precipitates (particularly blue precipitates) upon the addition of sodium hydroxide, renders the test somewhat uncertain. Portunately, however, only a few such conflicting combinations were found. Copper and aluminum illustrate a case in point, the cupric hydroxide apparently being absorbed by the aluminum hydroxide, thereby forming a cbnfusing lake not readily soluble in concentrated ammonium hydroxide.

Further investigation indicates that acetates, tartrates and ammonium salts render the test less sensitive but that if magnesium be present in sufficient quantity (and in the case of organic material such as tartrates) evaporation is not carried to complete dryness (to prevent charring), the test is still valid. The quantity of these conflicting substances determines, quite naturally, the amount of detectable magnesium. Quantitative tests show that with 1 g. of these substances present only 3×10^{-4} g. of magnesium can be detected. Consequently, when great sensitivity is required, organic matter and ammonium salts should be first removed and the solution then evaporated to dryness before applying the stain method technique.

Summary

A new technique for the use of *o,p*-dihydroxy-azo-*p*-nitrobenzene as a test for the magnesium ion has been described.

With this technique the test is valid in the presence of any one of all of the common cations met with in qualitative analysis and in a ***great*** many combinations of these cations.

Nickel, cobalt or both do not confuse the test.

Acetates, tartrates and ammonium salts do not interfere but decrease the sensitivity of the test.

The test can be used most efficiently as a substitute for the classical magnesium ammonium phosphate test commonly employed in qualitative analysis procedures. Used in this way, 3×10^{-6} g. of magnesium can be detected.

THE INTERPRETATION OF THE COLLIGATIVE PROPERTIES OF WEAK ELECTROLYTES

BY MERLE RANDALL AND CLYVE ALLEN

RECEIVED JANUARY 11, 1930 PUBLISHED MAY 8, 1930

Introduction

Although the importance, in the study of solutions, of the activities or activity coefficients[1,2] of the components has been most emphasized in the field of strong electrolytes, these quantities are, of course, of no less importance to the study of weak electrolytes and of non-electrolytes. Moreover, although the methods of determining the activity coefficients[1,2] have been most widely studied in the case of strong electrolytes, these methods are, of course, equally applicable to weak electrolytes and non-electrolytes. The application of these methods is illustrated by the work of Randall and Failey[3] in determining the activity coefficients of gases, of non-electrolytes, and of the undissociated part of weak electrolytes in solutions of electrolytes.

In the study of electrolytes it has been customary to regard as strong those completely or practically completely dissociated in dilute aqueous solution, and as weak those incompletely dissociated at finite concentrations. The question as to the actual extent of dissociation of a strong electrolyte in a given solution is of importance from a kinetic standpoint and has received considerable attention. To account for apparent evidences of incomplete dissociation of strong electrolytes consisting of small ions or those having "un-centrally located charges," Bjerrum[4] suggested a modification of the inter-ionic attraction theory of Debye and Hückel[5] whereby such ions, of opposite charge, when closer together than a certain minimum distance (dependent upon the dielectric constant of the medium and the absolute temperature) would be regarded as associated—behaving

osmotically as though undissociated. Mueller,[6] Gronwall,[7] and, more recently, Gronwall, LaMer and Sandved,[8] have shown, however, that Bjerrum's practical results can be explained by a more thorough consideration of the postulates of Debye and Hückel.

Whether or not we consider an electrolyte as completely dissociated, especially for thermodynamic treatment, is largely a matter of convenience. For example, it has been convenient for a long time to consider such substances as ammonium hydroxide, acetic acid and mercuric chloride as mostly undissociated in solution and to consider a definite equilibrium between the ions and undissociated portions. On the other hand, with substances as strong as dichloro-acetic acid it is perhaps more convenient to consider them strong electrolytes but having activity coefficients less than those of the typically strong electrolytes.

It is not the purpose of this paper to discuss the colligative properties of weak electrolytes on the basis of any particular mechanistic theory, but rather to indicate methods whereby the activity of weak electrolytes may be calculated from measurements of the activity of the solvent, and to clarify our conceptions of the thermodynamic treatment of "so-called" incompletely dissociated substances.

Theoretical

For clearness we shall confine our discussion entirely to an aqueous solution of a univalent electrolyte. We shall use the symbols employed by Lewis and Randall[1] and by Randall and Failey.[3]

The stoichiometrical molality of the electrolyte will be denoted by m, the molality of the undissociated portion by m_u, that of the negative ion by m_- and that of the positive by m_+; a_u, a_- and a_+ will represent the corresponding activities, and a_1 that of the solvent. Also we will for simplicity call $m_+ = m_- = m_\pm$, so that $m = m_u + m_\pm$ and call $m_\pm/m = \alpha$, the degree of dissociation in the usual sense.

Now, if we use the basis of treatment which we have used for strong electrolytes,[1,2] the activity of the solute, a_2, is equal to the product a_+a_-, or $a_\pm = a_2^{1/2}$. For slightly weak electrolytes, or weak electrolytes at very low concentrations (if the effect of the ions of the solvent upon the dissociation is neglected), the activity of the solute is more nearly equal to the square of the mean molality of the ions than to the molality of the undissociated substance.

We therefore define the following activity coefficients:

$$\gamma_0 = a_2/m, \quad \gamma = a_2^{1/2}/m, \quad \gamma_u = a_u/m_u, \quad \gamma_\pm = a_\pm/m_\pm$$

where γ_0 is the stoichiometrical activity coefficient of a solute considered as undissociated; γ is the stoichiometrical activity coefficient of a univalent

electrolyte, regardless of whether or not the electrolyte is completely dissociated, and, moreover, by our conventions, is the stoichiometrical mean activity coefficient of the ions; γ_u is the activity coefficient of the undissociated portion of the solute, and $\gamma_{\pm}$ the mean activity coefficient of the ions. By these definitions

$$\gamma \equiv \alpha\gamma_{\pm}; \;\; \log \gamma = \log \alpha + \log \gamma_{\pm} \qquad (1)$$

By virtue of the rapid interconvertibility of the solute constituents, we have also the relation[1]

$$\mathrm{HA} = \mathrm{H}^+ + \mathrm{A}^-; \;\; K = a_{\pm}{}^2/a_u \qquad (2)$$

where K is the dissociation constant.

For an aqueous solution of a binary electrolyte, the general partial molal equation[1] in the form

$$m\, d\ln a_2 = -55.51\, d \ln a_1 \qquad (3)$$

is equivalent to

$$d \ln \gamma_0 = -(55.51/m)\, d \ln a_1 - d\, m/m \qquad (4)$$
$$d \ln \gamma = -(55.51/2m) d \ln a_1 - d\, m/m \qquad (5)$$

At the freezing point of the solution, these equations become[1]

$$\mathrm{d} \ln \gamma_0 = \mathrm{d}\,\theta/\lambda m + \theta\, \mathrm{d}\,\theta/\lambda'' m + \ldots - \mathrm{d}\, m/m \qquad (6)$$
$$\mathrm{d} \ln \gamma = \mathrm{d}\,\theta/2\lambda m + \theta\, \mathrm{d}\,\theta/2\lambda'' m + \cdots - \mathrm{d}\, m/m \qquad (7)$$

where $\lambda = 1.858$ and $\lambda'' = (0.00057)^{-1}$ are constants, and θ is the freezing point lowering.

Introducing the Lewis and Randall divergence functions[1]

$$1 - \theta/\lambda m = j_1, \; (\nu = 1) \text{ and } 1 - \theta/2\lambda m = j_2, \; (\nu = 2)$$

and integrating, we have

$$n\, (\gamma_0/\gamma_0') = -(j_1 - j_1') - \int_{m'}^{m} (j_1/m) \mathrm{d}\, m - \int_{m'}^{m} (\theta/\lambda'' m) \mathrm{d}\,\theta \ldots \qquad (8)$$

and, following Randall and White[9]

$$\ln\, (\gamma/\gamma') = -(j_2 - j_2') - 2\int_{m'}^{m} (j_2/m^{1/2})\, \mathrm{d}\, m^{1/2} - \int_{m'}^{m} (\theta/2\lambda'' m)\, \mathrm{d}\,\theta \qquad (9)$$

For a binary electrolyte at infinite dilution

$$\underset{m \to 0}{\text{Limit}}\, (a_2/m^2) = 1; \;\; \underset{m \to 0}{\text{Limit}}\, (\gamma_0/m) = 1; \;\; \underset{m \to 0}{\text{Limit}}\, (\gamma) = 1 \qquad (10)$$

By definition, if we wish to use the quantity γ_0 in a region in which the divergence function using $\nu = 1$ is most convenient, we may refer γ_0 to a proper standard state by the relation

$$\log \gamma_0 = \log\, (\gamma)^2 + \log m \qquad (11)$$

and where we wish to use the quantity γ, in the region in which $\nu = 2$ is most convenient, we have

$$\log \gamma = -0.4343\, [j_2 + 2\int_{0}^{m} (j_2/m^{1/2})\, \mathrm{d}\, m^{1/2} + \int_{0}^{m} (\theta/2\lambda'' m)\, \mathrm{d}\,\theta + \cdots] \qquad (12)$$

Equation 12 may be easily evaluated by means of Equation 1 if we also know the α, $\gamma_{\pm}$ and m relations (in dilute solutions).

---

[9] Randall and White, This Journal, 48, 2514 (1926).

Application of Foregoing Considerations.—Our correlation of γ_u, $\gamma_\pm$ and α with the empirical freezing point lowering equations of Lewis and Randall is to facilitate the treatment, in certain cases, of weak electrolytes in very dilute solution. Similar relations, of course, hold for the generalized divergence function of Randall and White.[2,9] Moreover, it is fully as important as in the case of strong electrolytes to adopt a consistent and logical standard state for the activity of weak electrolytes. (Values of quantities proportional to the activity coefficients have recently been obtained for several weak acids[10] by measurements of the freezing point lowering in concentrated solution. These quantities were given on the basis of an activity coefficient equal to unity in one molal solution. Such a standard state is not to be recommended and must ultimately cause confusion.) It is our immediate purpose to show that, on the basis of complete dissociation of the electrolyte at infinite dilution, we may evaluate the activity coefficients of weak electrolytes in dilute solution and that where K is known this is facilitated.

To this end we shall examine the consequences of two postulates: (1) that the mean activity coefficient of the ions of a partially dissociated univalent electrolyte at small molalities is the same as that of hydrochloric acid[11] at the same ionic strength and that the activity coefficient of the acid would not be considerably affected by the presence of small amounts of undissociated substance. (If the effect on the dielectric constant of dilute hydrochloric acid due to small additions of non-electrolyte were thought considerable, it could, of course, be corrected for on the basis of the interionic attraction theory.)

(2) That in sufficiently dilute solution the freezing point lowering or other similar colligative property due to the ions, $2\theta_i$, is the same as it would be if the undissociated part were not present; that the freezing point lowering of the undissociated part, θ_u, is the same as that if the dissociated part were not present, and that the total freezing point lowering is the sum of these two quantities.

The validity of Assumption 1 has to a large extent been demonstrated,[3] by methods which give directly the activity of the solute. If, as Randall and Failey found, the quotient, logarithm of activity coefficient of undissociated part of weak electrolyte by ionic strength, is approximately constant for weak electrolytes in salt solutions (the constant varies with the weak electrolyte or salt being considered), then in sufficiently dilute solution

$$(\ln \gamma_u)/\mu = k', \quad \gamma_u = e^{\mu k'} = 1 + \mu k' + (\mu k')^2/2 + \ldots \doteq 1 \qquad (13)$$

Furthermore, we offer here the possibility of verification of Assumption 2 by a correlation of the activity of the undissociated portion of an electrolyte with the activity of the solvent.

---

[10] Jones and Bury, Phil. Mag., [7] 4, 841 (1927).

[11] For bases we would take sodium hydroxide as a type strong base.

Inasmuch as the apparent dissociation constant from conductivity measurements, extrapolated to infinite dilution, K_A°, must be equal[1] to K (the correct interpretation[12,13] of α will give us K) we are frequently in *a* position to utilize this quantity, by the relations developed in the present section, to evaluate activity coefficients of weak electrolytes from measurements which give directly the activity of the solvent.[14]

[13] MacInnes, *ibid.*, 48,2068 (1926).

[14] The following experimental methods all give the activity of the solvent: freezing point lowering, vapor pressure lowering, boiling point raising, osmotic pressure, "dew-point" lowering, distribution ratio of the solvent and, in the case of a few solvents, measurements of the electromotive force in which the solvent is the substance involved in the electrode reactions. See Ref. 2.

[15] Randall and Young, THIS JOURNAL, 50,989 (1928).

$$K = (\gamma_{\pm}m_{\pm})^2/\gamma_u m_u \doteq (\gamma_{\pm}m_{\pm})^2/m_u; \ m_u = (\gamma_{\pm}m_{\pm})^2/K;$$
$$m \doteq m_{\pm} + (\gamma_{\pm}m_{\pm})^2/K \quad (14)$$

Although we use the assumption that the freezing point lowering caused by the undissociated part is the same as that of a perfect solution

$$\theta = 28, + 8, \doteq 28, + \lambda m_u \quad (15)$$

j_1, j_2, etc., are independent of this assumption.

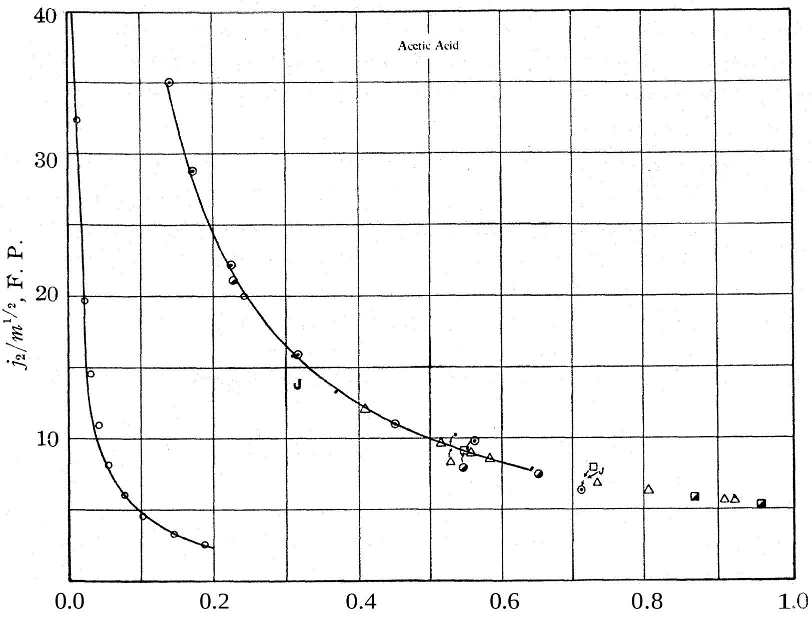

Fig. 2.—Freezing point function for acetic acid. ○ Hausrath, ◐ Jahn, A Jones and Bury, J Jones and Getman, □ Kendall, ◪ Kendall and King, ◉ Ostwald, • Roth.

In Figs. 1 and 2 are given the plots of $j_2/m^{1/2}$ thus calculated for univalent electrolytes of various dissociation constants.

In Fig. 1 we have also placed the points, $j_2/m^{1/2}$, calculated from the data of three investigators,[16] of the freezing point lowering of dichloroacetic acid. These points are evidently in very poor agreement among themselves. According to the dissociation constant at 18°, K_{291} = 0.0583,[17] and the heat of dissociation given by Steinwehr,[18] K_{273}, should be approximately 0.07. In cases of this sort, where the freezing point data

---

[17] Schreiner, *Z. anorg. allgem. Chem.*, 122,201 (1922).

[18] Steinwehr, *Z. physik.* Chem., 38, *185* (1901).

are very discordant, curves of this type serve to indicate the probable accuracy of the data.

In Fig. 2 are given the points, $j_2/m^{1/2}$, calculated from all the available data[19] of the freezing point lowering of acetic acid. These points show excellent agreement among themselves and, in turn, lie very closely along the curve for $K = 2 \times 10^{-5}$, which according to the extrapolation by Lewis and Randall of the data of Noyes and Cooper,[20] very likely represents the true K of acetic acid within 4 or 5%.

The curves of j_1/m for weak electrolytes are not given, as these, of course, rapidly approach extreme negative values in dilute solution, as is always the case when the value of ν assigned the substance is less than the true value (see Randall and Cann).[21]

Regarding the sharp peaks shown in the $j_2/m^{1/2}$ curves for weak electrolytes of low dissociation constant,[22] we see from our previous discussion that in just the region where they manifest themselves and graphical integration becomes laborious (very dilute solution) we may place most confidence in our postulates.

According to our discussion, we should have the relations

$$\log (\alpha\gamma_{\pm}/\alpha'\gamma_{\pm}') = -0.4343\left[(j_2 - j_2') + 2\int_{m'}^{m} (j_2/m^{1/2})\text{d}\, m^{1/2}\right] \qquad (16)$$

and

$$\log \alpha\gamma_{\pm} = -0.4343\left[j_2 + 2\int_{0}^{m} (j_2/m^{1/2})\text{d}\, m^{1/2}\right] \qquad (17)$$

true in very dilute solution where the integral of the θ term is negligible and our postulates should almost certainly be valid. As we have drawn our curves of Figs. 1 and 2 from our values of $m_{\pm}$, $\gamma_{\pm}$ and θ_i, and m's calculated from the K's, satisfaction of Equations 16 and 17 in these cases is, of course, to be expected.

Higher accuracy in determining the activity coefficients of weak electrolytes from freezing point lowering data is to be gained by higher accuracy in the values of the dissociation constant at 0°, as well as in the freezing point measurements.

The values of γ_0 and γ for acetic acid at round values of $m^{1/2}$ at the freezing point are given in Table I.

It will be noted that the values of γ_0 are very near the value of K, namely, 2×10^{-5}. The quotient γ_0/K given in the third column of the table shows

[22] It is a characteristic of the curves of Fig. 1 that the maximum appears in more and more dilute solution the smaller the value of K.

TABLE I

THE ACTIVITY COEFFICIENT OF AQUEOUS ACETIC ACID AT THE FREEZING POINT

$m^{1/2}$	$\gamma_0 \times 10^5$	γ_0/K	γ
0.1	1.910	0.955	0.0440
.15	1.940	.970	.0295
.2	1.956	.978	.0220
.25	1.964	.982	.0175
.3	1.970	.985	.0143
.35	1.974	.987	.0121
.4	1.976	.988	.0108

that in solutions as strong as 0.1 M the effect of ionization of the acid may be disregarded. The quotient is easily interpolated and convenient for this purpose. When using this value of γ_0, however, we in effect make the same convention as in the case of a strong electrolyte, namely, that the standard state of aqueous acetic acid is one which is defined by the infinitely dilute solution; moreover, it is so defined that the standard free energy of the aqueous acid is the same as the sum of the free energies of the ions. The value of γ is as is to be expected very nearly the value of the degree of dissociation as ordinarily used, being the product of this quantity and $\gamma_\pm$, the activity coefficient. Since the effective ionic strength is very small, $\gamma_\pm$ is nearly unity.

It will be seen that the effect of our definitions is to make a distinction between the quantities γ and $\gamma_\pm$ as formerly employed by Lewis and Randall, who made these quantities as well as m and $m_\pm$ identical for a univalent electrolyte. We have retained that part of their convention which makes the activity of the solute the geometrical product of the activities of the ions.

Regarding the possibility of testing the validity of the assumption $\gamma_u = 1$ from measurements of the activity of the solvent, we should be able to subtract the calculated quantity $2\theta_i$ from observed freezing point depressions, form the function $j_u/m_u = [1 - (\theta_u/\lambda m_u)]/m_u$ and examine its approach to constancy in dilute solution. (A plot of $2\theta_i$ and $m_\pm$ against m for the electrolyte studied, K = 2.0×10^{-5} in this example, is useful for the purpose.)

Table II shows j_u/m_u for acetic acid, calculated from the data of Hausrath[16a,23] and Jones and Bury,[19c] probably as accurate data as any in existence in their respective ranges of molality. The values are of the expected order of magnitude[3a] (see Equation 13) except in the most dilute solutions. Such a test is exacting and enormously magnifies the experimental errors.[24]

It might be pointed out that our postulates have intrinsically rather a wide field of applicability. That is, the assumption that the ions of weak

---

electrolytes act like those of hydrochloric acid (at the same ion molality) makes little difference in electrolytes of K < 0.01, because the important thing is how far the undissociated portion departs from the ideal. On the other hand, with electrolytes of K > 0.5, the assumption of $\gamma_u = 1$ makes little difference. Of course, such assumptions should not be employed and are not needed except in quite dilute solution. Our postulates appear to be very nearly valid in the case of acetic acid up to about 0.4 M, far beyond the range in which they are needed.

Curves of the type shown in Fig. 1, in addition to serving as a criterion for the accuracy of data, may also be employed for the detection of and estimation of the degree of dissociation. Inasmuch as freezing point measurements are frequently not dependable in solutions more dilute than 0.01 M, we may employ a simple modification of the curves of Fig. 1 as an aid in evaluating divergence functions in more dilute solutions. For example, values of $j_2/m^{1/2}$ at m = 0.01 (Fig. 1 and Table III) are plotted against log K as illustrated in Fig. 3, giving us a plot whereby we may determine probable values of K from a single value of the freezing point lowering at 0.01 M. Thus if we have a single measurement

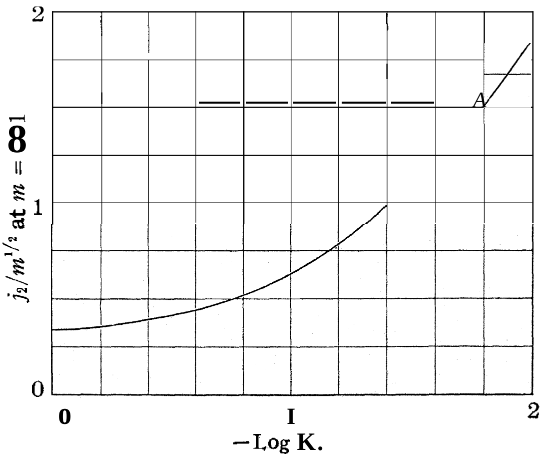

Fig. 3.—Freezing point function at 0.01 M for univalent acids of various dissociation constants.

of the freezing point at 0.01 *M*, we may calculate the value of $j_2/m^{1/2}$ and by interpolation along the curve of **Fig. 3** we find the value of log K, or, having K, may complete the divergence function in the very dilute range. This method is most valuable in the range of $K > 10^{-3}$.

Summary

The methods of Lewis and Randall for determining activity coefficients from freezing point measurements or from other measurements of the activity of the solvent are formally reviewed for weak univalent electrolytes.

The logarithm of the activity coefficient of a weak electrolyte (basis of strong electrolytes) is equal to the sum of the logarithm of the degree of dissociation and the logarithm of the activity coefficient of the ions as such.

Use of the dissociation constant, $K = a_\pm^2/a_u$, in evaluating the divergence functions of weak electrolytes in very dilute solution is introduced.

The procedure to be followed in determining the activity coefficient of acetic acid in dilute solution from measurements of the activity of the solvent is shown as an example of the treatment of a typical weak electrolyte.

In dealing with weak electrolytes it is expedient to have an easily interpolated activity coefficient for employment where dissociation is inappreciable and one for use where dissociation is considerable. These should be thermodynamically related and should permit of evaluation in very dilute solution. In addition, these coefficients should reduce in the limiting cases, on the one hand to the activity coefficient of a non-electrolyte, and on the other to that of a completely dissociated electrolyte. They should also be defined so that the reference solution is the same for solvent and solute. These requirements are entirely satisfied by the methods described in this paper.

A method of determining the dissociation constant of moderately weak electrolytes from a single measurement of the freezing point at 0.01 *M* is given.

THE DIELECTRIC POLARIZATION OF LIQUIDS. VIII. ACETIC AND BUTYRIC ACIDS

BY C. P. SMYTH AND H. E. ROGERS

RECEIVED JANUARY 11, 1930 PUBLISHED MAY 8, 1930

The fatty acids have been so extensively investigated from many points of view that their dielectric behavior should be of unusual interest. Solutions of acetic acid in benzene and in ether were studied some years ago by Dr. S. O. Morgan and one of the writers, but, as the results were peculiar and as some doubt arose as to the purity of the acetic acid which had been employed, no use was made of the data. The measurements have been repeated with carefully purified acetic acid over a wider range of temperature and extended to butyric acid. The apparatus, with which the dielectric constant was determined at a wave length of 600 meters, has been described previously.[1]

Preparation of Materials

Benzene.—Benzene was purified in the usual manner, being finally dried and distilled over sodium; b. p. 80.1°; n_D^{20} 1.50135.

Ether.—U. S. P. ether was shaken several times with a strong sodium chloride solution containing a little sodium hydroxide, washed with water, dried over calcium chloride and distilled; b. p. 35.1°; d_4^{20} 0.7137.

Acetic Acid.—Merck's C. P. glacial acetic acid was crystallized twelve times, the final melting point being 16.6° and the refractive index n_D^{20} 1.37175. This sample was fractionally distilled; b. p. 117.8°; d_4^{20} 1.0491; n_D^{20} 1.37175.

Butyric Acid.—n-Butyric acid obtained from the Eastman Kodak Company was fractionally distilled, the fraction boiling between 163.2 and 163.4° being taken for the measurements; d_4^{20} 0.9591.

Experimental Results

For the acetic acid solutions and the pure substance the dielectric constants ϵ were measured at temperature intervals of approximately 10° and the densities d at intervals of about 15°. The values given for them in Table I were obtained by graphical interpolation. The butyric acid measurements were made at three fixed temperatures, which make interpolation unnecessary. The polarizations, P_2, of the acids were calculated by means of the equations

$$P_{12} = \frac{\epsilon - 1}{\epsilon + 2} \times \frac{c_1M_1 + c_2M_2}{d} \text{ and } P_2 = \frac{P_{12} - P_1}{c_2} + P_1$$

in which P_{12} is the polarization of the mixture, and c_1 and c_2, M_1 and M_2, and P_1 and P_2 are, respectively, the mole fractions, molecular weights, and polarizations of the individual components.

In the case of pure acetic acid slightly supercooled to 16.4°, a resistance

of 3.6 ohms had to be inserted in series with the condenser in the opposite arm of the bridge to balance the small conductance of the liquid. At 85.1' the dielectric constant was 7.11 and the compensating resistance 41.5 ohms, and at 100.0° ϵ was 8.05 and the resistance 60.0 ohms. For the benzene solution containing a mole fraction 0.7912 of acetic acid, the resistance required at room temperature was negligible, but rose to 6.6 ohms at 90.6'. In the less concentrated solutions the conductance was negligibly small. In the ether solutions the conductances were small, as the temperature of measurement was not above 30°, but were detectable at concentrations of acid down to mole fraction 0.3549.

Discussion of Results

The acetic acid data in Table I do not agree precisely with the earlier unpublished values, but the small differences observed are no greater than might be expected in view of the difference in the material used and are insufficient to affect the conclusions to be drawn. When these earlier measurements were made upon acetic acid, the increase in the dielectric constant of the pure liquid with rising temperature was thought to be the first observed case of such a phenomenon, although it was known that the polarization of pure ethyl bromide increased with rising temperature. Since these first measurements were made, similar behavior has been observed for a number of secondary and tertiary octyl alcohols.[2] As the dielectric constants of the dilute benzene solutions decrease in the normal manner with rising temperature, there is an intermediate region of concentration within which the temperature coefficient of the dielectric constant is very small. Thus, the solution containing 0.6134 mole fraction of acetic acid shows a slight increase in ϵ with rising temperature up to 40° followed by an even more gradual decrease. The values of P_{12} which

---

[2] Smyth and Stoops, THIS JOURNAL, 51,3330 (1929).

are not shown in Table I increase with temperature throughout the entire range of concentration, although the increase is very slight in the dilute solutions where the effect of the almost constant polarization, P_1, of the benzene predominates. As the polarization P_2 of the acetic acid in the dilute solutions is lower than that of benzene, the P_{12}–c_2 curves pass through a flat minimum in a region where there is little change of P_{12} with concentration.

The reason for this peculiar behavior is to be sought in the strong molecular association which is known to occur in acetic acid. Freezing point and partition coefficient measurements show that the apparent molecular weight of acetic acid in dilute solution in benzene is close to 120, the weight which it would have if polymerized into double molecules.[3] X-ray investigations indicate that the molecules of the higher fatty acids in the solid state are paired[4] end to end with their carboxyl groups in contact and a similar conclusion has recently been drawn for the liquid.[5] Such a pairing should bring the electric moments of the single molecules into opposition with resultant partial or complete cancellation of one another's effects. It is easy to picture the acetic acid in dilute solution in benzene as consisting largely of these double molecules possessing little or no electric moment. The concentration of single molecules is so low in the solutions here measured that extrapolation of the P_2 values to $c_2 = 0$ gives not the polarization of the molecules existing singly but rather their polarization when paired in the double molecules. Since these values of P_∞ increase with rising temperature, presumably because of increasing dissociation into single molecules, it is evident that they are not wholly free from the effect of the small number of single molecules present. It may be concluded, however, that the polarization of the molecules in this complex state is not far from 20. The molar refraction of acetic acid for the sodium D line is 13.0.[6] The difference between this and 20 is little, if any, larger than the value which the atomic polarization P_A might be expected to have. Consequently, the dipole contribution to the polarization, P_M, must be close to zero, if not actually zero, the electric moments of the single acetic acid molecules being practically canceled in the complex molecules. This conclusion is in agreement with results privately communicated some years ago by Dr. L. Ebert, who obtained 18.85 as the value of P_∞ for acetic acid in benzene and 19.4 for the molar polarization of the solid measured at 0° with a wave length of 5 meters. As there is no dipole contribution to the polarization of the solid measured under

these conditions, it is evident that P_∞ is made up of the electronic and atomic polarizations only, that is, $P_\infty = P_E + P_A$ and $P_M = 0$, which is equivalent to saying that the molecular complexes in the dilute benzene solutions possess no electric moment.

Apparently, when the concentration increases, these complexes, in spite of their lack of electric moment, affect one another sufficiently to cause increase of polarization. It seems possible that the higher dielectric constants of the more concentrated solutions may further the dissociation of the complexes into single molecules and so increase the polarization. The fact that the polarization increases with rising temperature would seem to support the attribution of the increase to the separation of single molecules rather than to the formation of a different type of complex. The absence of electric moment in the complexes in the dilute solutions and the closeness of the apparent molecular weight to that of a double molecule point to a polymerization to double molecules in which the carboxyl groups are in contact as indicated by the x-ray results. However, the mere assumption of the existence of single and double molecules without effect upon one another is inadequate to explain the observed phenomena. The freezing point measurements of Trautz and Moschel[3] give an apparent molecular weight of 117.5 for acetic acid when the mole fraction in the benzene solution is 0.0288, increasing to 124.9 when the mole fraction is 0.0650. This and similar results may indicate the formation of definite complexes containing more than two molecules, but it appears possible to explain the observed phenomena in terms of single and double molecules and strong intermolecular forces.

In the hope of reducing the intermolecular forces and the extent of the association, a solvent of higher dielectric constant than benzene was sought. Ether was adopted as being the only liquid of higher constant which, when dissolved in non-polar solvents, showed a polarization independent of concentration. Unfortunately, however, ether may form an addition compound with acetic acid and thus complicate the situation. The polarization of the acetic acid, P_2, calculated on the assumption that the polarization of the ether, P_1, is unaffected by the presence of the acid, shows a normal behavior, although the values for the dilute solutions contain errors larger than usual because of loss of ether by volatilization. The P_{12}–c_2 curve passes through a flat maximum in the region of high dilution where the apparent polarization of the acetic acid is higher than that of the ether. The value of P_M is calculated by subtracting from P_∞ the approximate value 20 found for $P_E + P_A$ and, from P_M, the electric moment 1.40×10^{-18} is obtained for the single acetic acid molecule. This value cannot be regarded as certain since it may be really the moment of an addition compound of acetic acid and ether, but there is some evidence in its favor.

In order to investigate the question of a definite equilibrium between single and double acetic acid molecules in ether solution, Mr. C. H. Lindsley has measured the distribution of acetic acid between water and ether at 25° over a range of concentration of 0.086 to 1.644 moles of acetic acid per liter of ether, a range within which lie the four most dilute solutions in Table I. The most constant value of the distribution coefficient was obtained when an equilibrium between single and double molecules was assumed. If a is the total number of moles per liter of acetic acid, all the acid being calculated as having molecular weight 60.04, and x is the concentration of single molecules, the equilibrium constant $K = x^2/(a-x)$. The mean value obtained for K was 2.7.

Since it has been shown that the double molecules have practically no moment and do not, therefore, contribute to the orientation polarization P_M and, since it has been assumed that the P_∞ obtained from the ether solutions is the polarization of the single molecules, the value of P_M observed at any concentration should be the orientation polarization for the single molecules $P_{M\infty}$ multiplied by the fraction of the acetic acid which is present as single molecules, that is, $P_M = (x/a)P_{M\infty}$. The values of P have been obtained by interpolation at 25° and those of P_M by subtracting from them $P_E + P_A = 20$. From the value $P_{M\infty} = 41$ thus obtained, the values of P_M have been calculated by means of K and the values of a and x calculated from it. The difference between the observed and calculated values of P_M is large at $c_2 = 0.1039$ and $c_2 = 0.1269$, but for the other solutions and the pure acid the average difference is only 1.9.

Since the value of K determined in the distribution measurements may be affected by the water with which the ether layer is saturated and since it may be different in the concentrated solutions and the pure acid from what it is in the dilute solutions, too much significance should not be attached to the agreement between the observed and calculated values of P_M. It may be said, however, that the entire behavior of acetic acid which has been described is consistent with the theory of its existence in single and double molecules, the force fields of which may affect one another and cause further abnormalities. As the moment of acetic acid might be expected to be not very different from that of methyl acetate, for which Williams[7] has found a value of 1.67×10^{-18}, the value 1.4×10^{-18} seems reasonable, but it must be borne in mind that there is a possibility that this is really the moment of an addition compound of acetic acid and ether.

The behavior of butyric acid is very similar to that of acetic. The dielectric constants of the pure liquid and the most concentrated solution increase with rising temperature. The dielectric constant is lowered

---

[7] Williams, *Physik. Z.*, **29,** 174 (1928).

by the lengthened hydrocarbon chain, which reduces the number of dipoles in unit volume so that pure butyric acid behaves much like a benzene solution containing 0.6 to 0.7 mole fraction of acetic acid. The two methylene groups which differentiate butyric from acetic acid have a combined refraction for the sodium D line of 9.2, which is their contribution to P_E for the compound. This is very nearly the difference between the values of P_∞ for the two substances. The larger proportion of hydrocarbon in the butyric acid molecule lessens the rate of increase of the polarization with decrease in the concentration of benzene in the mixture so that pure butyric acid happens to have the same polarization as acetic.

The close resemblance of butyric acid to acetic is what would be expected from freezing point and partition coefficient measurements and the indication of double molecules by x-ray studies. The single butyric acid molecules must have approximately the same moment as those of acetic acid and form similar complexes in which the carboxyl groups are in contact with one another, canceling their moments.[8]

Summary

The dielectric constants and densities of solutions of acetic and butyric acids have been measured at different temperatures, and the data have been used to calculate the polarizations of the substances.

The dielectric constants of the pure acids behave abnormally in that they increase with rising temperature instead of decreasing.

The results are shown to be consistent with the theory of the existence of the acids in single and double molecules, the latter of which have little or no electric moment. It must be supposed, however, that the molecular force fields may affect one another and cause further abnormalities.

PRINCETON, NEW JERSEY

---

[8] Since the submission of the manuscript of this paper for publication, Dr. *C.* T. Zahn has communicated to the authors a value 1.4 X 10^{-18} for the moment of acetic acid measured as vapor at high temperatures and low pressures where it must have existed as single molecules. This may be regarded as excellent confirmation of the value for what was thought to be the single acetic acid molecule in ether solution. Wolf, in a paper just published [*Physzk.* Z., 31, *227* (1930)], obtains a value of 0.74 X 10^{-18} for acetic acid from measurements in benzene solution at 22°, a value of 0.68 × 10^{-18} for butyric acid and 0.63 × 10^{-18} for both propionic and isovaleric acid. In calculating these results he used an estimated value of P_A equal to 15% of the molar refraction, which the evidence cited above shows to be much too small in the case of acetic acid. If $P - P_E$ in our results is used to calculate the moments of acetic and butyric acid, the values obtained are close to those calculated by Wolf. As it has been shown that $P - P_E$ consists mainly of the atomic polarization P_A for molecular complexes, the values calculated for moments from these differences and attributed to single molecules would seem to have little significance. These results also cast doubt upon the moment assigned to the carboxyl group in aromatic compounds from measurements upon the strongly associated benzoic acid in benzene solution [Williams, *Chem. Rev.*, 6, 589 (1929)].

THE DIELECTRIC CONSTANTS OF BINARY MIXTURES. X. THE ELECTRIC MOMENTS OF SIMPLE DERIVATIVES OF CYCLOHEXANE AND OF DIOXAN

BY JOHN WARREN WILLIAMS

RECEIVED JANUARY 16, 1930 PUBLISHED MAY 8, 1930

In the previous papers of this series there has been discussed the relation between electric moment data and the structure of benzene and a number of its derivatives. Another article[1] has been devoted to a study of the structure of derivatives of methane and ethane. It was thought that the extension of this type of study to cyclohexane and its derivatives would lead to a number of interesting conclusions, particularly because considerable information is now available concerning the structures of the mono- and di-substitution products of benzene.

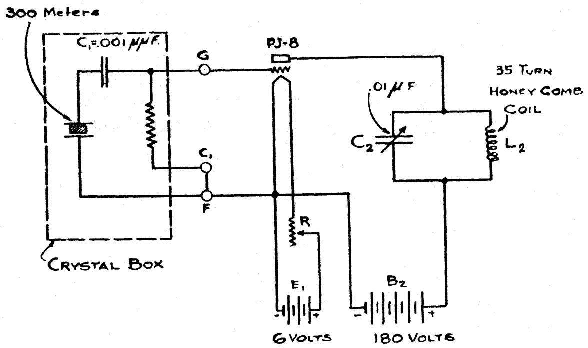

Fig. 1.—Crystal oscillator.

Experimental Method

The method of determining the electric moment of a solute molecule from dielectric constant and density data of a suitable binary mixture has been completely described in a number of places[2,3] and will not be repeated here. The measurement of the dielectric constants was made using an apparatus which was improved in several details over that previously described. A quartz crystal controlled circuit (frequency, 10^6 cycles) was used as the standard oscillator and a resistance-coupled three-tube detector and amplifier circuit replaced the transformer-coupled arrangement of the earlier investigations. The actual method of measurement of the dielectric constant of a solution was not changed from that which

has already been described. A diagram of the circuits used is given in Figs. 1 to 3.

Results

All chemicals used were carefully purified and their boilng points checked with those given in the "International Critical Tables." All dielectric constant and density measurements were made at 25°. The frequency 10^6 cycles was used for the dielectric constant determinations. The dielectric constant of benzene under these conditions was assumed to be 2.280.

The dielectric constant and density data for the various binary mixtures are given in Table I.

TABLE I

DIELECTRIC CONSTANT AND DENSITY DATA FOR MIXTURES

The symbols used have the following significance: f_1 is mole fraction of the solvent, in this case benzene; d_4^{25} is density of the solution; ϵ is dielectric constant of the solution; $P_{1,2}$ is molar polarization of the solution $= (\epsilon - 1)/(\epsilon + 2) \times [(f_1M_1 + f_2M_2)/d] = f_1P_1 + f_2P_2$; P_2 is molar polarization of the solute molecule.

In this table, P_2 is molar polarization of the solute molecule; P_2'' is polarization due to deformation of the molecule; P_2' is polarization due to orientation of the molecule; μ is electric moment of the molecule.

the total polarization which is due to the deformation of the molecule is given by the Lorentz–Lorenz formula, using the refractive index for the "D" line. The results of these calculations are believed to be correct to within **0.1** $\times$ 10^{-18} e. s. u., with the possible exception of dioxan, whose moment cannot be distinguished from zero by the method used. These data are presented in Table II.

Since the dielectric constants of but few of these derivatives of cyclohexane are to be found in the literature, measurements were made upon certain of the more common ones. The measurements were made in the manner described in the earlier papers of this series, using the apparatus which has just been described. It is evident that this method neglects the effect of any change in the absorption of energy in the liquid dielectric as the position of the rotor plates of the measuring condenser is changed. When substances like benzene and dilute solutions of polar molecules in benzene are studied, the absorption of energy is so low that corrections for this effect are not necessary. This is not the case, however, when appreciable and different amounts of energy are absorbed, and for precision measurements not only capacity changes but also resistance changes should be accounted for. For this reason the data, presented in Table III, are recorded to the nearest tenth of a unit only, since it was not possible to make the proper corrections. The results for the last four substances given are certainly the only ones which could be at all affected by this difficulty, and even in these cases the error introduced must be small.

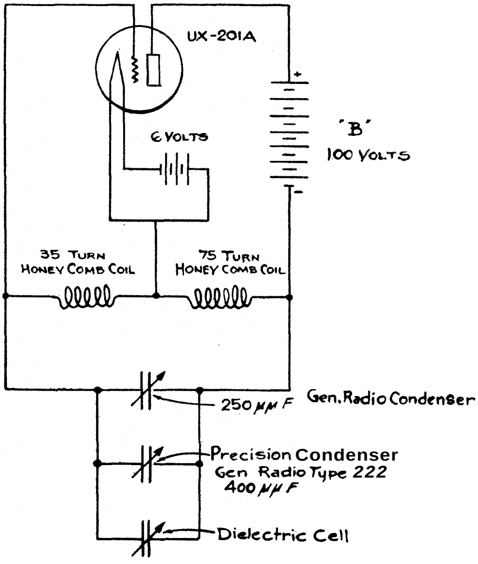

Fig. 2.—Variable oscillator.

TABLE III

DIELECTRIC CONSTANT DATA FOR CYCLOHEXANE AND ITS DERIVATIVES

Temperature, 25°. **Frequency, 10^6 cycles**

Molecule	Dielectric constant	Molecule	Dielectric constant
Cyclohexane	2.0	Bromocyclohexane	7.9
Methylcyclohexane	2.1	Cyclohexanol	15.0
1,4-Dioxan	2.2	Cyclohexanone	18.1
Chlorocyclohexane	7.6		

Discussion

There are now sufficient electric moment data for various mono-substitution products of cyclohexane, methane and benzene to be able to compare the effect produced by substituting a simple atom or group of atoms into these various parent substances. The data are collected in Table IV, in which those figures marked by the asterisk have been taken from other observers.[4]

TABLE IV

DATA FOR SUBSTITUTION PRODUCTS OF SIMPLE HYDROCARBONS

	Electric Moment X 10^{18}				Electric Moment X 10^{18}		
Atom or radical	For $C_6H_{11}\alpha$	For $C_6H_5\alpha$	Por $CH_3\alpha$	Atom or radical	For $C_6H_{11}\alpha$	For $C_6H_5\alpha$	For $CH_3\alpha$
H	0	0	0*	OH	1.9	1.65	1.65
Cl	2.3	1.5	2.0*	NO_2		3.9	3.1*
Br	2.3	1.5	1.9*	CH_3	0	0.4	0*
I		1.3	1.6	NH_2		1.5	1.2*
CN		3.85	3.4				

As one would expect, cyclohexane itself is a symmetrical molecule. When a CH_3 group is substituted into it, an electrically symmetrical molecule is again formed, since methylcyclohexane has a zero moment as well.

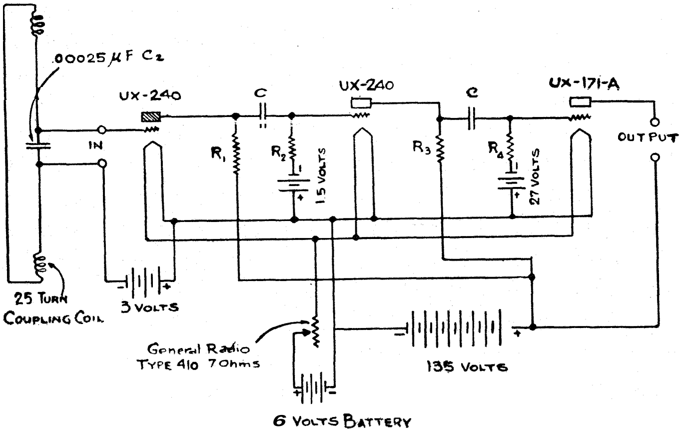

Fig. 3.—Detector-amplifier. CF $0.01\mu\mu$F.; R_2F 5 megohms; $R_1 = R_3$F 0.25 megohms; R_4F 5 megohms.

Thus cyclohexane behaves like methane and not like benzene on the substitution of a CH_3 group. Toluene is a slightly polar substance. Furthermore, Raman spectra for benzene and for toluene indicate distinct differences in energy levels which are not found in methane hydrocarbons and presumably will not be found in cyclohexane hydrocarbons,[5] so that

[4] Debye, "Polare Molekuln," Table of Dipole Moments, Hirzel, Leipzig, 1929.

[5] Kohlrausch and Dadieu, *Physik. Z.*, 30, 385 (1929); Reynolds and Williams, THIS JOURNAL, article submitted March, 1930.

these two types of study lead to similar conclusions involving two different carbon to carbon linkages.

The electric moments for chlorocyclohexane and bromocyclohexane are practically identical. This might have been predicted since the corresponding derivatives of methane and of benzene, respectively, also have like values. The moment produced in the cyclohexane derivatives is distinctly higher than that of the other compounds in question. Also, the substitution of an hydroxyl group in cyclohexane produces a more polar molecule than the substitution of the same group into benzene or methane. This appears to be a matter of internal compensation of charges about which little is known in a quantitative way at present.

The data for cyclohexane carboxylic acid are to be compared with those previously reported[6] for benzoic acid. In each case the molar polarization of the solute molecule is constant over a considerable range of concentration. This is a surprising result, because, at least for benzoic acid and presumably for cyclohexane carboxylic acid as well, the molecular weight of the solute in benzene solution increases as its concentration is increased. In other words, the degree of association of the solute is increasing with increasing concentration and, therefore, according to the explanation given this phenomenon by Debye,[3] the molar polarization of the dissolved molecule should either increase or decrease, the latter being more probable. The same reservation must be made for the value of the electric moment reported for cyclohexane carboxylic acid as was made for benzoic acid, namely, that it is difficult to state exactly what the effect of this association will be upon the result. The moment reported is to be considered of the right order of magnitude only. It is possible that measurements over a range of temperature would be of material assistance in assigning more definite values for the electric moments of these two compounds.

The data for the methylcyclohexanols are of interest in connection with the data for the cresols.[7] For the latter it will be recalled that each had a smaller moment than phenol, and that the moments for the meta and para compounds were practically identical. The electric moments of the three methylcyclohexanols are in every case of identical magnitude with that of cyclohexanol itself and are all three practically identical. The fact that all four molecules have nearly identical moments is not surprising. The moment is characteristic of the OH group alone and is quite independent of the presence of the CH_3 group. This result was to have been expected from the zero moment found for methylcyclohexane. It is also true that these substances, bought under the names used in the tables from the Eastman Kodak Co., may be mixtures of isomers; in that event the electric moments reported are average values for equilibrium

[6] Williams and Allgeier, THIS JOURNAL, 49, 2416 (1927).

[7] Williams, *Physik. Z.*, 29, 683 (1928).

mixtures. Because of the possibility of isomerism it is evident that any extension of dipole moment studies to disubstituted cyclohexanes will be considerably more difficult and involved than the corresponding study of benzene derivatives has been. Nevertheless it should be an interesting problem.

There are included in Tables I and II the results of measurements for solutions of 1,4-dioxan in benzene. Dioxan is found to have an electric moment which can differ but slightly, if at all, from zero ($\mu = 0.4 \times 10^{-18}$ e. s. u.) in spite of the fact that there must be two very active parts in the molecule. This interesting chemical, though not classed as a derivative of cyclohexane, has a ring structure and has certain properties in common with cyclohexanol and cyclohexanone. Since it is such an unusual solvent and at the same time a molecule of extremely low polarity, it was thought that it might serve as as uitable solvent for the determination of the electric moments of substances insoluble in the usual nonpolar solvents. This idea will form the basis of the next article of this series.

Summary

1. Dielectric constant and density data at 25° have been obtained for dilute benzene solutions of cyclohexane, chlorocyclohexane, bromocyclohexane, cyclohexanone, methylcyclohexane, cyclohexanol, 1,4-dioxan, 2-methylcyclohexanol, 3-methylcyclohexanol, 4-methylcyclohexanol and cyclohexane carboxylic acid. The electric moments of the solute molecules have been calculated.

2. Certain improvements, shown only by diagram, have been made in the apparatus used to measure the dielectric constants.

3. The electric moment data for the various derivatives of cyclohexane have been compared with those for the corresponding derivatives of benzene and methane.

THE DIELECTRIC CONSTANTS OF BINARY MIXTURES. XI. THE USE OF DIOXAN AS A SOLVENT FOR ELECTRIC MOMENT STUDIES

BY JOHN WARREN WILLIAMS

RECEIVED JANUARY 16, 1930 PUBLISHED MAY 8, 1930

There are at present two methods by which the electric moment of a molecule may be determined, as follows: (1) from the temperature coefficient of the dielectric constant of a gas or vapor;[1] (2) from dielectric constant and density data for suitable binary mixtures.

The previous articles of this series have utilized the second of these methods, for while it is perhaps not as sound theoretically as the first one, it is easier from an experimental viewpoint and does give a result which is in good (though not exact) agreement with that of the first method. The latter statement has now been amply verified. It has been the purpose of these articles to show the application of a new physical method to the study of the structure of molecules—an important chemical problem.

Both methods have difficulties inherent in them. For example, the electric moments of a number of organic molecules may never be determined by the first method because these substances are unstable in the vapor state. The second method is not as yet a general one because for it there are required "suitable" binary mixtures. A suitable binary mixture is defined as one in which one of the components, the solvent, is non-polar, that is, its electric moment is zero. Benzene, carbon tetrachloride, carbon bisulfide and hexane are liquids having no moment and considered to be suitable solvents for electric moment determinations of this sort. Unless other solvents can be found the second method will then be applicable only to those substances which can be dissolved in these solvents to the extent of something like 1%, using the best apparatus now available for the dielectric constant and density determinations. Measurements have been made for substances having lower solubilities, but the results cannot be considered to be entirely dependable. Thus the electric moment of the water molecule has been calculated from dielectric constant and density data for a saturated solution of water in benzene,[2] but it can only be claimed that the result is of the right order of magnitude.

Several recent articles have discussed the solvent properties of 1,4-dioxan.[3,4] It is found to be an excellent solvent for a large number of

---

[1] Dielectric constant measurements on gases and vapors at a single temperature have also been utilized for this purpose.

[2] Williams, *Physik.* Z., 29, 204 (1928).

[3] Anschutz and Broeker, *Ber.*, **59B,** 2844 (1926).

[4] Reid and Hofmann, Ind. Eng. *Chem.*, 21, 695 (1929)

substances, inorganic as well as organic. Its electric moment, reported in the previous article of this series,[5] is not greater than $\mu = 0.4 \times 10^{-18}$ e. s. u. This value is so small that it is indistinguishable from zero by the method used; therefore it seemed possible that dioxan might act as a non-polar solvent, in spite of the fact that it is a molecule containing two very active groups. Dielectric constant and density data at 25° were obtained for dilute solutions of chlorobenzene, water, chlorocyclohexane and *o*-diethyl phthalate in 1,4-dioxan, and the molar polarizations of the respective solute molecules were calculated, making the assumption that the polarization due to the solvent dioxan was always exactly proportional to its mole fraction in the solution. The electric moments were calculated from the molar polarizations in the usual manner. These four substances were chosen at random to represent different types of molecules. In the interest of a saving of space the dielectric constant and density data for the four mixtures have not been included. The results of the calculations of the electric moments of the solute molecules are presented in Table I. The symbols used have been defined completely in the previous article.[5]

TABLE I

ELECTRIC MOMENT DATA FOR SOLUTE MOLECULES

Molecule	P_2	P_2''	P_2'	$\mu \times 10^{18}$ e s u.
Chlorobenzene	80	31	49	1.5
Water	82	4	78	1.9
Chlorocyclohexane	146	33	113	2.3
o-Diethyl phthalate	226	60	166	2.8

Electric moment data for chlorobenzene, water and chlorocyclohexane are available in the literature. The electric moment of o-diethyl phthalate was determined from dielectric constant and density data (Table II) for this substance in dilute benzene solution.

TABLE II

DIELECTRIC CONSTANT AND DENSITY DATA FOR BINARY MIXTURE BENZENE–*o*-DIETHYL PHTHALATE

f_1 (Benzene)	•	d_4^{25}	$P_{1,2}$	P_2
100.00	2.280	0.8731	26.77	206
99.64	2.316	.8756	27.37	202
99.29	2.360	.8782	28.10	209

Finally, there is given in Table III the comparison of the polarization and electric moment data for the four solute molecules obtained from benzene solution and from dioxan solution.

The only conclusion to be drawn from this table is that dioxan is just as good a solvent as benzene for determinations of the electric moments of these particular molecules. For chlorobenzene and chlorocyclohexane

---

[5] Williams, THIS JOURNAL, 52, 1831 (1930).

TABLE III

COMPARISON OF DATA USING DIOXAN AND BENZENE AS SOLVENTS

Molecule	Solvent	P_2	P_2'	$\mu \times 10^{18}$
1 Chlorobenzene	C_6H_6	82	51	1.5
	$C_4H_8O_2$	80	49	1.5
2 Water	C_6H_6	64	60	1.7[2]
	$C_4H_8O_2$	82	78	1.9

Electric moment of water, calculated from temperature coefficient of dielectric constant of water vapor = 1.85–1.87.[6]

Molecule	Solvent	P_2	P_2'	$\mu \times 10^{18}$
3 Chlorocyclohexane	C_6H_6	143	110	2.3
	$C_4H_8O_2$	146	113	2.3
4 o-Diethyl phthalate	C_6H_6	205	145	2.7
	$C_4H_8O_2$	226	166	2.8

the results are identical, within the limits of experimental error. Dioxan would appear to be the more desirable solvent for the determination of the electric moment of the water molecule, since the value obtained using it, $\mu = 1.9 \times 10^{-18}$ e. s. u., is identical, to two significant figures, with the commonly accepted value obtained from the temperature coefficient of the dielectric constant of the vapor. The molar polarization value for o-diethyl phthalate obtained from the dioxan solution is somewhat higher than the corresponding value obtained from the measurements in benzene solution. Indeed, there is good reason to believe that in a number of cases the resulting molar polarization obtained in dioxan solution will be somewhat higher than they should be. Since dioxan contains two very active groups in the molecule, one might expect segregation and orientation effects upon solute molecules which happen to be within a certain distance of these more active centers.[7] These orientation effects would result in an additional polarization contributing to the total polarization. In this case the assumption could hardly be made that the polarization due to the dioxan (as solvent) is always exactly proportional to its mole fraction in solution.

Furthermore, in spite of the fact that it is a stable substance it does form addition compounds with both organic and inorganic substances in solution. It is evident in the event of a compound formation between solvent and solute that the dielectric constant and density measurements would be of little significance.

---

[6] Jona, *Physik. Z.*, 20, 14 (1919); Sanger, in Debye, "Leipzig Lectures," S. Hirzel, Leipzig, 1929.

[7] These segregation and orientation effects are important not only in connection with measurements of molar polarization but also in connection with numerous chemical phenomena. For example, they will undoubtedly have to be considered in the study of solubility relationships and in the study of reactions in solution. These effects, now the subject of further investigation by us, have been defined by Langmuir [*Chem. Rev.*, 6, 451 (1929)].

It is not claimed as a result of this table that dioxan is a suitable solvent for the determination of the electric moment of any dissolved molecule in the same sense that either benzene or carbon tetrachloride is, However, it does appear possible that dioxan may be used to determine at least the correct order of magnitude of the electric moment of molecules which are difficultly soluble in the recogaized non-polar solvents. For example, if the electric moment of the water molecule could not have been determined by studying the temperature coefficient of the dielectric constant of its vapor, the value obtained from the dioxan solution would have indicated that the value obtained from the single solution of water in benzene could not be greatly in error. Indeed, it would be desirable to make comparison measurements in some solvent like dioxan in every case where the solute molecules are so difficultly soluble that measurements for only one (very dilute) solution can be made.

Another use of dioxan suggests itself. In a practical way it should be a suitable solvent in which to study the electrical properties of cellulose derivatives, gums, resins and other more complicated organic compounds, the idea being that certain information concerning the sizes and shapes of the various substances could be made available.

Summary

1. Dielectric constant and density data have been obtained for dioxan solutions of chlorobenzene, water, chlorocyclohexane and o-diethyl phthalate and for benzene solutions of o-diethyl phthalate.

2. The electric moments of the solute molecules calculated from the data in dioxan solution are compared with those obtained using the usual non-polar solvents, and found to be in good agreement.

3. It is suggested that while dioxan is probably not a suitable solvent for the determination of the electric moment of any dissolved molecule, it does offer interesting and important possibilities in cases where the usual solvents cannot be used.

THE SOLUBILITY OF GOLD IN MERCURY. II

BY ARTHUR A. SUNIER AND CHESTER M. WHITE

RECEIVED JANUARY 17, 1930 PUBLISHED MAY 8, 1930

Although several investigators[1] have worked on the system gold-mercury, the majority of the results have been confined to temperatures above 100°, and strangely enough the few values between 0 and 80° disagree remarkably with each other—differences of several hundred per cent. being common in this temperature range. Quite recently a rather precise piece of work was published by Sunier and Gramkee on the solubility of gold in mercury from 80 to 200°, using the tube of Sunier and Hess[2] slightly modified. It was thought advisable, therefore, to continue these measurements with the apparatus just mentioned. This paper will present results on the solubility of gold in mercury from 7 to 80°. In spite of the low apparent solubility (0.1 to 0.5%) in this temperature range, the precision of measurement is considered to be excellent, the average deviation from the mean for all the determinations being about 5 parts per thousand, which corresponds on the average to about 0.001 atomic %.

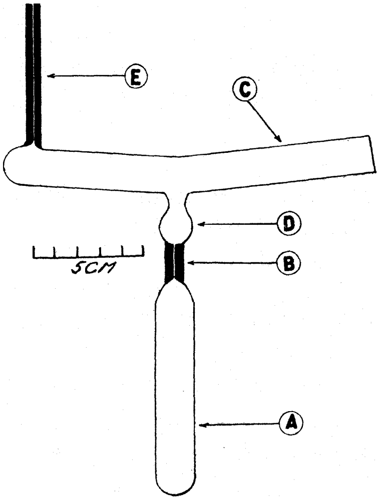

Fig. 1.—Solubility tube.

Materials.—Mercury was covered with a considerable amount of dilute nitric acid and air was aspirated through the mercury for a week; it was then distilled several times in an all-glass apparatus under diminished pressure, according to the method of Hulett and Minchin.[3] Samples of this mercury yielded no weighable residues when slowly evaporated at 270° in a current of air. The gold was used in the form of foil which had been rolled from a bar of gold said to contain less than 0.05% impurity.

Apparatus.—The solubility tube, Fig. 1, a modification of the one used by Sunier and Gramkee, was made of pyrex glass and consisted of a sample tube, A, capillary filter, B, a tube for preparing amalgams, C, the cup, D, and the capillary, E, both of which were used in filtering the amalgams. The dimensions of the tube were increased at lower temperatures to accommodate larger volumes of mercury.

The shaking and sampling apparatus differed considerably from that used in the

[2] Sunier and Hess, THIS JOURNAL, 50, 662 (1928).

[3] Hulett and Minchin, *Phys. Rev.*, 21, 288 (1905).

first research, and since it proved so satisfactory it will now be briefly described. The apparatus was designed with a view to making it possible to handle the low and high sides independently or simultaneously at will.[4] Figures 2 and 3 give front and side views, respectively, of the apparatus; these views correspond to the sampling and rotating positions, respectively. The apparatus is built in two units which are nearly identical; each unit is capable of carrying four solubility tubes; only one tube, however, is shown in Fig. 2 in order not to complicate the figure.

A large round piece of brass rod, R, was drilled to slip over the axle, G, and was fitted with suitable clamps to hold the tubes firmly in position. A cotter pin through G served to hold R in position. The axle G was supported by the square brass rod H, which in turn, was securely damped to rigid supports (not shown in Figs. 2 and 3). A smaller rod M was fixed to R in a manner indicated, and was connected by the long rod J to the eccentric; thus a motion could be given the tubes as indicated by the full and dotted lines in Fig. 3. The rods JJ could easily be detached from the eccentric and were used in rotating the tubes through 180° at the time of filtering.

The two units differ only in the rods H and I. Rod H was never removed from the bath and was always used to support the four tubes that corresponded to the high side. When the other unit (constituting the low side) was to be inserted in the bath, the peg N on the rod I was put in the hole in cated on the rod H; then the movable rod Q was pushed to the left until the two rods I and H were securely fastened together. It should be apparent then that each set of tubes could be inserted in the bath, rotated and sampled independently of the other set.

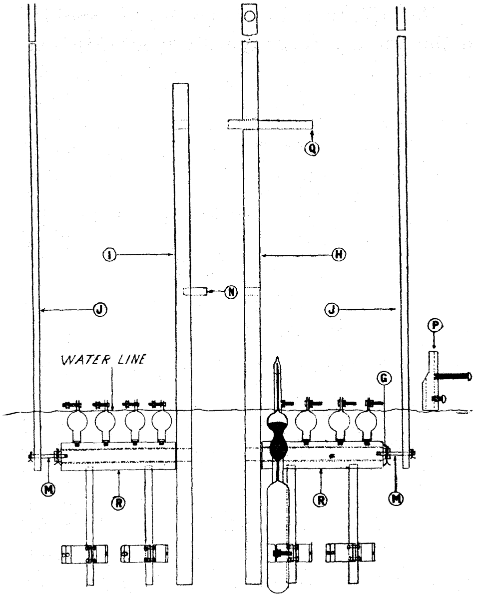

Fig. 2.—Shaking and sampling apparatus.

The tubes were immersed in a thermostat, which was very heavily lagged and contained 334 liters of water.[6] The top of the thermostat was partly covered in all the runs except in those at 70 and 80" where it was completely enclosed to prevent excessive evaporation of the water. Two or three centimeters of the sampling tubes projected above the water level in all the runs except in series I, where the entire tube was submerged. A revolving shaft, loaded with forty oil sample bottles, produced the necessary agitation within the bath. The bath could be heated by steam and by six 500-watt heaters; it could be cooled to temperatures below that of the room by running cold water through a special cooling coil, or by adding finely mashed ice directly to the water; this latter procedure was resorted to in run F (7°). In some of the runs a thermoregulator

---

[4] Mr. Law G. Weiner, working in the laboratory, first applied this idea (but his apparatus was necessarily quite different) in determining the solubility of gold in mercury at high temperatures.

[5] It is hoped to publish in another place further details concerning this type of thermostat, which has proved very satisfactory during the eight years of its use.

was used; in others hand regulation was resorted to. In either case variations of temperature as large as 0.1° occurred very rarely and only for a very short time. A Beckmann thermometer inserted in the bath was read at frequent intervals and indicated that the average temperature variation was about ±0.02°.

The temperatures were read from two mercury thermometers (graduated in tenths of a degree) which were compared with thermometers recently standardized by the Bureau of Standards. Temperatures are recorded to the nearest 0.02°, which was readable with ease. .

Experimental Procedure

A certain volume of mercury (depending on the temperature of the run) was charged in the tube D (Fig. 1) with about 100% excess of gold, using Britton and McBain's data as a guide, with the solubility tube in a horizontal position. A rubber tube and pinch clamp on the capillary E prevented the mercury from running out. After sealing off at D, the mixture was transferred to the opposite end of the tube and the capillary E was attached to a Cenco Hyvac pump. When the tube was thoroughly evacuated and outgassed, the capillary was sealed off and file marked.

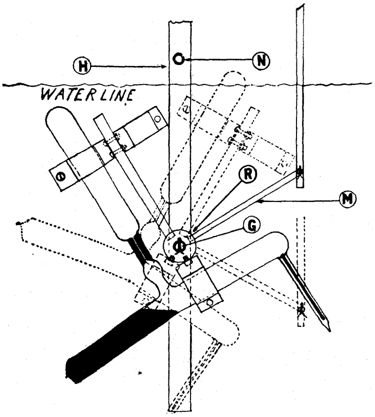

Fig. 3.—Shaking apparatus (side view).

To determine the solubility at a certain temperature saturation was (with two exceptions, Runs E and F) attained from both the high and the low sides. A total of eight tubes was made up and four were placed in each rack. One set was introduced and rotated for two and one-half to three hours when the bath was about 5° above the solubility temperature. This constituted the high side of the run. The temperature was then allowed to drop to the desired point when the remaining four tubes were inserted; all eight tubes were then shaken for three to four hours (in one case six hours) at constant temperature. By running the high and low side determinations together, considerable time was saved.

When it was time to sample, the connecting bars JJ were slipped from the eccentric and used as handles to rotate the tubes through 180°. Water was allowed to run out until the entire length of capillary E projected above the water level. A piece of brass rod (P), drilled to fit the capillary, was provided with two screws, one of which (lower) held the breaker fast while the second produced the necessary pressure above the file mark, which would break the capillary.[6] After filtration, the tubes were taken from the bath. The sampling tubes were cut off and their contents transferred to weighed crucibles. Some of the empty used tubes were cleaned thoroughly and repaired and were thus used for more than one determination.

To analyze the amalgams, the evaporation method was used which Sunier and Gramkee have shown to yield results 0.2% high if proper precautions are taken. Since it was known that hydrogen would not be available at all times during the course of this research, air was used in place of hydrogen. Carefully performed experiments seem to indicate that the results are identical in both cases. It should be noted that occasionally a small amount of a red powder was visible on the sides of some of the capsules when

---

[6] This improved breaker was designed and used by Mr. Law G. Weiner in another research.

held below 300°. On heating to about 550° this powder always disappeared, thus indicating that some mercuric oxide was formed at the lower temperatures. These observations appear to be in accord with the free energy changes for mercuric oxide given by Lewis and Randall,? who made use of data determined by Taylor and Hulett.[8] The capsules were placed on iron supports in a large pyrex tube, which was electrically heated. Air was passed through the tube, which was heated to 270° until no mercury was visible. Since the danger of bumping was lessened with these dilute amalgams, a higher evaporation temperature was employed. After heating the gold residues for ten to twelve hours at 450 to 550°, they were weighed and then reheated for three more hours when they were again weighed. If their weights differed by more than two-tenths of a milligram, the residues were further heated until this degree of constancy was obtained.

To test the entire experimental arrangement, six tubes were made up with weighed amounts of gold and mercury,[9] and were carried through the entire procedure. The results are given in Table I. The average differences in the values in columns four and five are seen to be a little less than 2 parts per thousand, which would appear to be very good, considering the small amount of gold weighed; furthermore, the averages of these two columns differ by less than one part per thousand.

TABLE I

ANALYSIS OF AMALGAMS OF KNOWN CONCENTRATION

No.	Gold taken, g.	Mercury taken, g.	Atomic % taken	Atomic % found	Diff., p. p. t.

I	7	80.40	.4647[a]	4.3

[a] Several years ago Mr. C. B. Hess, working in this Laboratory, made some determinations of the solubility of gold in mercury; his results, which were distinctly preliminary in character, are tabulated here

No. of detns.	Temp., °C.	Av. atomic % sol.
3	69.2	0.375
3	83.8	.498

The method of analysis was nearly identical with that used by Fitzsimmons; whose method was described in the first paper of this series. The temperatures were read from uncalibrated thermometers, hence it did not seem proper to include these results in Table II. It should be pointed out that the agreement in the two series of determinations is all that could be desired.

TABLE IV

SOLUBILITY OF GOLD IN MERCURY AT ROUNDED TEMPERATURES (FROM LOG N *vs.* $1/T$ PLOT)

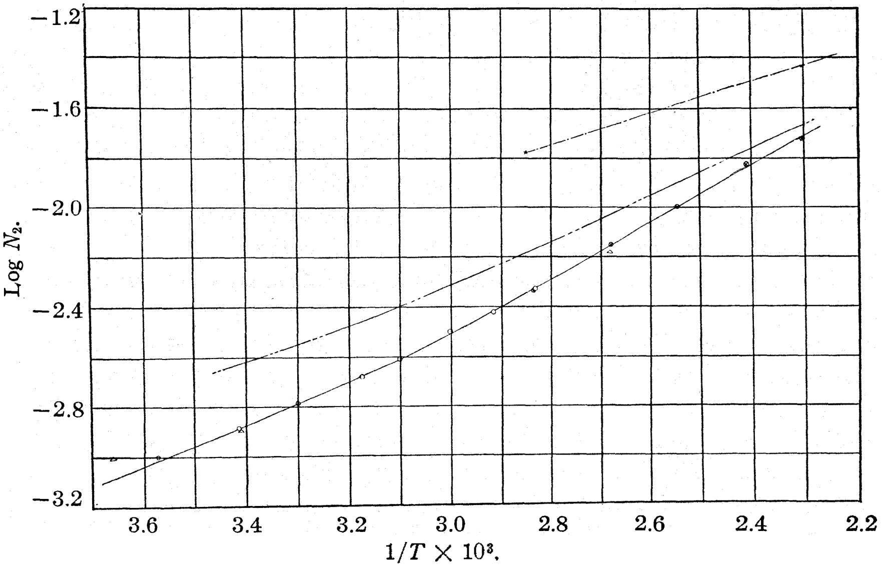
Temp., °C.	0	10	20	30	40
Atomic % sol.	(0.0813)[a]	0.1038	0.1306	0.1629	0.2014
Temp., °C.	50	60	70	80	
Atomic % sol.	0.2489	0.3076	0.3767	0.4614	

[a] Extrapolated value.

Of the fifty-six determinations, eight have been omitted, because the deviation of each was greater than four times the average deviation from the mean for that temperature. All solubilities are given in atomic per cent. (atoms of gold per 100 total atoms). Atomic weights as follows were used in the calculations: Au = 197.2, Hg = 200.61.

Discussion of Results

From the log N vs. $1/T$ plot (Fig. 4) it is seen that the present results are considerably lower than most of the previously published values. The present work appears to be in excellent agreement with the data presented by Sunier and Gramkee, the respective values reported at 80° being 0.4614% and 0.459%. The determination of Kasanzeff at 100° is in good agreement with the work of Sunier and Gramkee. Kasanzeff's three determinations were made about fifty years ago by an apparently crude method (the whole article of this author is really only an abstract, three paragraphs long). Britton and McBain's values are high at lower temperatures, but approach the authors' values as the temperature is raised.[10]



△, Kasanzeff; — - —, Parravano; — - - —, Britton and McBain; -⊗-, Sunier and Gramkee; -⊙-, Authors.

Fig. 4.—Solubility of gold in mercury.

Qualitative proof of the solubility at 25° was obtained from some preliminary experiments. Weighed quantities of gold and mercury, which corresponded to an average value of Britton and McBain's data at 18°,

---

[10] From unpublished work of Mr. Law G. Weiner, working in this Laboratory, it appears that these investigators are low at about 230". Incidentally, he does not find the maximum which they report.

were sealed in pyrex test-tubes and rotated for four hours at constant temperature (25°). At the end of this period, the gold foil was plainly visible, thus indicating that Britton and McBain's data are high at these lower temperatures. Braley and Schneider's results, which differ so radically from the present work, could not be conveniently plotted. It would seem that some serious error had been made in obtaining their data, which indicate a solubility of 15 atomic per cent. at 20°. Parravano has only two determinations in the temperature range plotted in Fig, 4; the results obtained in these determinations would appear to be much too high. It is well known that fusion curve methods often give high results if proper precautions are not taken.

The present results, however, are higher than the values which one gets from the equation of Sunier and Gramkee, $\log_{10} N = (-1167.4/T) + 0.996$, which was valid from 80 to 160°; consequently, when both sets of data are plotted, the resulting curve is not a straight line, nor was it possible to obtain a simple equation for this curve. Of the three possibilities, (1) solid phase may not be the one indicated, (2) an actual transition may take place at the temperature where the break occurs, (3) the latent heat of fusion of the solid phase is a function of the temperature, the last one seems to offer the best explanation; it should be mentioned, however, that the nature and composition of the solid phase in equilibrium with the solution has not been determined by any of the above-mentioned, investigators,[11] each (with one exception) suggesting a different compound. It would seem that evidence has been obtained in another research, unpublished but mentioned earlier, which tends to prove that the maximum in the solubility curve reported by Britton and McBain is quite likely in error, and thus the formula of the compound suggested by these workers is in error. Very recently Pabst[12] has published the results of an x-ray investigation of this system. Solid solutions appear to be present in the concentration range 0 to 15% mercury. Work in the range considered in this paper has apparently not been completed, but the author makes the general statement that there are several other phases of undetermined structure in the mercury-rich end of the diagram. It is to be hoped that these investigations may be continued and that other methods may be used in attempting to check the results that may be obtained.

At this point it might be well to mention the few sources of error in the apparatus and method. In the first paper attention was called to the error that might arise if the bore of capillary E was too large. In runs

---

[11] Since this was written it has been possible to look into the recent publication of I. N. Plaskin [*J. Russ. Phys.-Chem. Soc.*, **61**, 521 (1929)] who declares that the compound $AuHg_2$ is stable under the conditions existing in the experiments recorded in the present paper. It is hoped to discuss Plaskin's work more fully in the near future.

[12] Pabst, *Z. physik. Chem.*, **3B**, 443 (1929).

A to F, the only available capillary had such a diameter that a 2-cm. length contained about 0.6 g. of mercury; but since the tubes were made up twelve hours or more before being used (and the gold was always in contact with the mercury during this interval) the mercury may well have become saturated with gold at room temperature, which was 25° or a little higher. It should be quite evident that in the runs at 20 and 30° the concentration of gold in the mercury in the capillary was nearly the same as in the main body of the amalgam; the same was nearly true of the runs at 7 and 40°. In the runs at 50 and 60° the concentration of gold in the mercury in the capillary was about half (see Tables 111 or IV) that in the main body of the amalgam; thus the results at 50 and 60° may, at the *most*, be low by $(0.6/2/80)100 = 0.4\%$. The capillary available for the runs at 70 and 80° had a bore sufficiently fine so that no appreciable error arose from this cause.

In a few of the runs the folded strips of gold foil caught occasionally on the sides of the tubes and were not transferred with the amalgam every time; therefore, an excess of gold was not always in contact with the amalgams for the entire shaking period. Since the authors feel that a better technique was developed in the later runs, the first determination was not weighed as heavily as the succeeding ones. (The series numbers in Table III indicate the order in which the runs were made—A first, B next, etc.)

Run F (7") gave high results probably because the sampling tube was not long enough to contain the large volume of amalgam; consequently, some of it remained in the filter cup with the excess gold, after the tubes were taken from the bath. Possibly some of this more concentrated amalgam might have fallen into the filtered portion while the sampling tube was being broken. Three determinations were omitted from the average in this determination because their deviation was more than four times the average.

Throughout the temperature range 7 to 80°, the temperature coefficient of solubility was such that one-tenth degree corresponded to about 2 parts per thousand change in the solubility; since the temperature of the bath was held to ±0.02°, it would appear that no appreciable error arose from this cause.

In conclusion then it is felt that since the method of analysis of very dilute amalgams (described above) has proved so reliable and since the precision of measurement in the various determinations is so good, the values presented in Table IV appear to be considerably more accurate than those published heretofore.

Bearing of Data on **the** Metallurgy of Gold.—The amalgamation process for the mining of gold consists essentially of treating the crushed ore with mercury, which amalgamates with the gold and leaves impurities on the surface of the mercury. Later the solid amalgam which settles out, is distilled to remove the mercury from the metal.

The explanations which have been put forth to account for the extraction of gold by mercury are rather indefinite and somewhat confusing. Mellor[13] states, "The gold is miscible with mercury in all proportions. . . ." Evans[14] says, "Gold is soluble in mercury. . . .," and farther on he writes, "It should be pointed out that the actual catching of the gold grains by amalgamated plates is a process of surface adhesion; the dissolution of the adhering gold in the mercury to form an amalgam occurs slowly after the grains have been caught." From these quotations, it is seen that solubility is believed to play an important part in the formation of the amalgam. From the present results, however, the solubility appears to be 0.1306 atomic per cent. at 20°. A simple calculation shows that 100 pounds of mercury would only dissolve 2 ounces of gold (the amount found in a ton of some ores) which is far too small an amount to form a 10% amalgam which Schnabel[15] mentions as being fluid.

At present, therefore, the best mechanism seems to be that of surface adhesion followed by only very slight solubility effects. The gold particles, after being coated with mercury, settle to the bottom under gravity. The nature of this solid phase has not been determined as yet, as mentioned earlier.

Summary

1. Amalgams as dilute as 0.3% have been prepared and analyzed, by a method described, with a precision approaching one part per thousand.
2. An improved type of apparatus is described for shaking the solubility tubes and sampling the amalgams.
3. Fifty-six determinations of the solubility of gold in mercury have been made with the tube described earlier (with slight modifications). The results are lower and the precision of measurement is much higher than those previously reported.
4. The bearing of the present data on the well-known amalgamation process for mining gold is briefly discussed.

CALCIUM PERCHROMATE. A NEW TYPE OF RED PERCHROMATE

BY J. A. RAYNOLDS AND J. H. REEDY

RECEIVED JANUARY 24, 1930 PUBLISHED MAY 8, 1930

In spite of the very painstaking work of Riesenfeld[1], Wiede,[2] and others, our knowledge of the constitution of the perchromates is far from satisfactory. Their instability makes their isolation difficult, and no theory of the mechanism involved in their formation from chromates and peroxides has been advanced to prove their structure. The supposition that blue perchromic acid is formed in acid medium by a hyper-oxidation of chromates by means of hydrogen peroxide is hardly conclusive, when it is recalled that chromic acid is one of the strongest oxidizing agents and hydrogen peroxide in acid medium tends to behave as a reducing agent.

The red perchromates, which are formed when chromates and peroxides react in neutral medium, are more stable than the blue perchromic acid, and for this reason are better suited for isolation and analysis. Riesenfeld[3] has been the principal contributor to our knowledge of the red perchromates. From his analysis of the perchromates of the alkalies, he has proposed the type formula  $\begin{matrix}\text{M—O—O}\\ \text{M—O—O}\\ \text{M—O—O}\end{matrix}\!\!>\!\text{Cr}\!\begin{matrix}\nearrow\text{O}\\ \searrow\text{O}\end{matrix}$.

Experimental Part

Red Perchromic Acid.—A solution of what may be considered to be perchromic acid was prepared by the action at 0° of 30% hydrogen peroxide on freshly precipitated chromic hydroxide. The reaction is slow, an hour or more being required for its completion. The solution thus prepared has a brown to grape-juice color, and decomposes slowly upon standing at 0°, and very rapidly if the temperature is allowed to rise, giving a yellow solution of chromic acid. Up to this time, the product has not been isolated in a crystalline form. It is insoluble in organic solvents, and for this reason cannot be extracted from its water solution. Upon attempting to separate the excess water by freezing, the whole mixture congeals to a mushy mass. Upon acidification, the acid changes to the blue perchromic acid, and upon adding alkalies chromates are formed.

Calcium Perchromate.—This compound was first prepared by adding very slowly one volume of 30% hydrogen peroxide to three volumes of saturated calcium chromate, cooled to slightly below 0° by means of a bath of ice and salt. The mixture was allowed to stand at about −5° for an hour, and then the calcium salt was filtered off in a Gooch crucible. The product was washed with several portions of ice water, and finally with acetone, and dried on a clay plate in a desiccator. The yield was from 15 to 20% of the weight of the original calcium chromate.

Later it was found that calcium perchromate could be prepared by the action be-

tween calcium acetate solution and the red perchromic acid as prepared above. The products obtained by these two methods are identical in every respect.

Calcium perchromate is a buff-colored, fluffy powder, slightly soluble in water with slow decomposition, and practically insoluble in ether, alcohol and acetone. It is stable at ordinary temperatures, but decomposes explosively at about 100°, leaving a greenish residue of calcium oxide and chromic oxide. The purity of the salt is indicated by the failure of its water solution to give a precipitate with barium or lead acetate solutions. Upon acidification, the blue perchromic acid is formed.

Calcium perchromate prepared in this way was analyzed as follows. The calcium was determined by dissolving about 0.2 g. in dilute hydrochloric acid and boiling to destroy any peroxides. The calcium was then precipitated as calcium oxalate, and determined by titration with standard potassium permanganate solution.

The chromium was determined as barium chromate by the following procedure. About 0.2 g. was dissolved in very dilute acetic acid, the solution heated to boiling, and the chromium reconverted into the chromate form by means of sodium peroxide. After neutralization with acetic acid, barium acetate was added, and the precipitated barium chromate was filtered, ignited and weighed.

The available (or peroxide) oxygen was determined by dissolving about 0.1 g. in a mixture of potassium iodide and dilute sulfuric acid solutions and titrating the iodine liberated with standard sodium thiosulfate solution.

The water of hydration was determined by passing a current of dried air over samples of about 0.2 g. heated in a combustion tube, and absorbing the moisture evolved in *a* Swartz tube containing magnesium perchlorate trihydrate. On account of the explosive nature of the material, the charge was distributed over the length of the tube, and the heating was started at one end of the tube and slowly extended toward the other end.

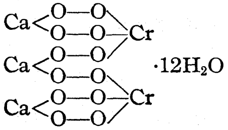
The results of these analyses have been collected in Table I.

TABLE I

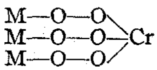
RESULTS OF ANALYSES

	Ca, %	Cr, %	Peroxide oxygen, %		H_2O, %	Oxygen (by difference), %
Experimental	18.74	16.37	15.27	15.19	34.56	
	18.70	16.42	15.25	15.26	34.46	
	18.69	16.34	15.21	15.23	34.49	
	18.70	16.39	15.22		34.57	
					34.43	
Average	18.71	16.38	15.23		34.50	15.17
Calcd. for $Ca_3Cr_2O_{12}\cdot 12H_2O$	19.01	16.45	15.18		34.18	15.18

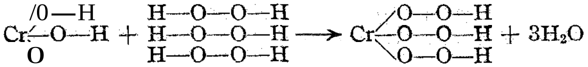
These analytical data indicate that the molecular formula for calcium perchromate is $Ca_3Cr_2O_{12}\cdot 12H_2O$. The only plausible configuration to represent this formula is



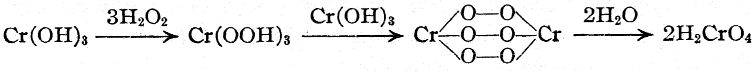
The type formula for univalent perchromates then should be



A very direct mechanism can be postulated to explain the formation of red perchromic acid:



The formation of chromic acid by the action of hydrogen peroxide on chromic hydroxide may, presumably, be represented



These methods are now being used to prepare other red perchromates, with a view to ascertaining if their formulas are analogous to that of the calcium salt.

Summary

1. A solution of red perchromic acid was prepared by the action of 30% hydrogen peroxide on freshly precipitated chromium hydroxide at temperatures near 0°.
2. Calcium perchromate is formed at low temperatures, either by the action of 30% hydrogen peroxide on saturated calcium chromate, or by the action between calcium acetate and red perchromic acid solutions.
3. Analysis of calcium perchromate indicates the formula, $Ca_3Cr_2O_{12}\cdot 12H_2O$.
4. A mechanism for the formation of chromates from chromium hydroxide by means of alkaline peroxides is suggested.

SYNTHESIS OF PHOSGENE BY LIGHT AND BY ALPHA RADIATION

By Hubert N. Alyea[1] and S. C. Lind

Received January 28, 1930 Published May 8, 1930

Extensive evidence shows that the initial step in a chemical reaction under alpha particle bombardment is ionization. In a great many reactions the subsequent formation of ion clusters[2] seemed sufficient to explain the resulting chemical reaction and yield per ion pair, which was in the neighborhood of two. Such a mechanism, involving ions, differs radically from the usual photochemical processes where the energy is insufficient for ionization. Among all the reactions studied, however, the union of hydrogen and chlorine was unique.[3] In this, many thousands of mole-

cules react per ion pair produced by radon, and since this is an historically famous photochemical chain reaction, it seemed probable that while the primary step might be different (ionization by alpha particles *versus* photochemical excitation of the chlorine molecules), the subsequent mechanism involving an atomic chlorine chain was identical in the two cases. This has been decisively confirmed by the very recent work of Lind and Livingston,[4] proving that not only has the yield per ion pair the same value as the yield per quantum absorbed, but also that the two reactions have the same temperature coefficient.

Since this hydrogen–chlorine reaction bridged the gap between alpha particle and photochemical chain mechanisms, it seemed timely to investigate other photochemical chain reactions to ascertain how general this analogy might be. Such a study has been made on a number of reactions, and is reported elsewhere.[4a] The present paper deals with one of them: the formation of phosgene from moist carbon monoxide and chlorine.

No previous work has been done on the formation of phosgene under alpha particle bombardment and it is scarcely necessary to review here the literature on the photochemical formation.[5] Suffice it to state that the photochemical formation is a chain reaction at least several thousand molecules in length,[3,5] and to emphasize, in particular, that the reaction rate is proportional to the square root of the number of quanta absorbed. It is generally accepted that the latter is an indication of an atomic chlorine chain mechanism,[6] and the question immediately arises whether the alpha particle reaction will give rise to atomic chlorine chains, and exhibit similar kinetics. This has been the objective of the present research.

Theoretical

The experimental conditions and calculations necessary for establishing the identity of the kinetics subsequent to the two types of activation in the reaction

$$CO + Cl_2 \longrightarrow COCl_2$$

are as follows: the kinetics of the photochemical reaction have been expressed by[3,5,6]

$$\frac{+dP_{COCl_2}}{dt} = K_p\sqrt{I_{abs.}}\cdot\sqrt{P_{CO}}\cdot P_{Cl_2} \qquad (1)$$

and the corresponding alpha particle reaction would be

$$\frac{+\mathrm{d}P_{\mathrm{COCl_2}}}{dt} = K_1\sqrt{i_p}\cdot\sqrt{P_{\mathrm{CO}}}\cdot P_{\mathrm{Cl_2}} \qquad (2)$$

in which the number of ion pairs, i_p, corresponds to the number of excited molecules produced photochemically, I_{abs}. Furthermore, $i_p = (i_{\mathrm{CO}}P_{\mathrm{CO}} + i_{\mathrm{Cl_2}}P_{\mathrm{Cl_2}})E_t$, in which i is specific ionizations, 1.00 for CO and 2.42 for Cl_2,[7] P is partial pressures, and E_t is number of curies of radon present.[8]

If the analogy is complete, the alpha reaction would he proportional to the square root of the radon concentration, which would give evidence of an atomic chlorine chain mechanism as discussed above. For simplicity in calculation, this was measured when the carbon monoxide pressure was the same as the chlorine pressure, *i*. e., where $P_{\mathrm{CO}} = P_{\mathrm{Cl_2}} = (P_{\mathrm{CO}} + P_{\mathrm{Cl_2}})/2$. Under such conditions, if $P = P_{\mathrm{CO}} + P_{\mathrm{Cl_2}}$, we have from Equation 2 above

$$\frac{+\mathrm{d}P_{\mathrm{COCl_2}}}{dt} = -{}^1/_2\,\frac{\mathrm{d}P_{\mathrm{CO+Cl_2}}}{dt} = K_1\sqrt{(1.00\,P_{\mathrm{CO}} + 2.42\,P_{\mathrm{Cl_2}})E_t}\,.\,\sqrt{P_{\mathrm{CO}}}\cdot P_{\mathrm{Cl_2}} =$$

$$K_1\sqrt{\frac{3.42}{2}\cdot P\cdot E_t}\cdot\sqrt{\frac{P}{2}}\cdot\frac{P}{2} = \frac{\sqrt{3.42}}{4}K_1\sqrt{E_t}\,P^2 \qquad (3)$$

The radon concentration E_t remained essentially constant under the normal experimental run of thirty minutes, and can be treated as a constant. In such a case, integrating Equation **3**, we obtain

$$K_1 = \frac{4}{2\sqrt{3.42}\,\mathrm{d}t\sqrt{E_t}}\int_{P_1}^{P_2}\frac{\mathrm{d}P}{P^2} = \frac{1.0815\,(1/P_2 - 1/P_1)}{\mathrm{d}t\sqrt{E_t}} \qquad (4)$$

where K_1 is the velocity constant for the alpha particle reaction. K_1 has been evaluated in the following results over an eighty-three-fold variation of the amount of radon and hence of the intensity of alpha radiation.

Our next step is to test kinetic Equation 2 by varying the carbon monoxide to chlorine ratio. Defining $k = P_{\mathrm{Cl_2}} - P_{\mathrm{CO}}$, three cases present themselves with the following solutions.

Case 1.—Where $k > 0$, **i**. e., where $P_{\mathrm{Cl_2}} > P_{\mathrm{CO}}$, from Equation 2

$$\frac{+\mathrm{d}P_{\mathrm{COCl_2}}}{\mathbf{dt}} = -\frac{\mathrm{d}P_{\mathrm{CO}}}{dt} = K_1\sqrt{i_p}\sqrt{P_{\mathrm{CO}}}\,.\,(P_{\mathrm{CO}} + k)$$

and therefore

$$\frac{-\mathrm{d}P_{\mathrm{CO}}}{(P_{\mathrm{CO}} + k)\sqrt{P_{\mathrm{CO}}}} = K_1\sqrt{i_p}\cdot\mathrm{d}t \qquad (5)$$

Considering $\sqrt{i_p}$ as constant during each successive interval (see Col. 5, Table IV) and integrating, we obtain

$$-\left[\frac{2}{\sqrt{k}}\tan^{-1}\sqrt{\frac{P_{\mathrm{CO}}}{k_1}}\right]_{P_1}^{P_2} = K_1\int\sqrt{i_p}\cdot\mathrm{d}t$$

---

[7] *i for chlorine,* 2.42. *See Porter,* Bardwell *and Lind, Ref.* **3.**

[8] *As is sometimes allowable* in *alpha particle calculations,* only ***the*** *ionization on the reactants is considered. See S. C. Lind,* **Ref.** 2, **p.** 100.

and since

$$\sqrt{i_p} = \sqrt{(1.00\,P_{CO} + 2.42\,P_{Cl_2})E_t} = \sqrt{(3.42\,P_{CO} + 2.42\,k)E_t}$$

we have

$$K_1 = \frac{\frac{\pi}{60 \times 180} \times \frac{2}{\sqrt{k}}\left[\tan^{-1}\sqrt{\frac{(P_{CO})_2}{k}} - \tan^{-1}\sqrt{\frac{(P_{CO})_1}{k}}\right]}{\int dt\,\sqrt{i_p}} =$$

$$\frac{5.82 \times 10^{-4}\left[\tan^{-1}\sqrt{\frac{(P_{CO})_2}{k}} - \tan^{-1}\sqrt{\frac{(P_{CO})_1}{k}}\right]}{\int dt\,\sqrt{k}\,\sqrt{(3.42\,P_{CO} + 2.42\,k)E_t}} \tag{6}$$

Case 2.—Where **k** $= 0$, *i. e.*, where $P_{Cl_2} = P_{CO} = (P_{CO} + P_{Cl_2})/2 = P/2$. This has been discussed above, Equation 4, where K_1 is evaluated.

Case 3.—Where **k** < 0, **i.** *e.*, where $P_{Cl_2} < P_{CO}$. Let $k' = -k = P_{CO} - P_{Cl_2}$. As in Equation 5, Case 1, we obtain

$$\frac{-dP_{CO}}{(P_{CO} - k')\,\sqrt{P_{CO}}} = K_1\,\sqrt{i_p}\cdot dt \tag{7}$$

in which

$$\sqrt{i_p} = \sqrt{(1.00\,P_{CO} + 2.42\,P_{Cl_2})E_t} = \sqrt{(3.42\,P_{CO} - 2.42\,k')E_t}$$

Expression 7 integrates into

$$K_1 = \frac{2.3026\left[\log\frac{\sqrt{P_2} - \sqrt{k'}}{\sqrt{P_2} + \sqrt{k'}} - \log\frac{\sqrt{P_1} - \sqrt{k'}}{\sqrt{P_1} + \sqrt{k'}}\right]}{\int dt\,\sqrt{k'}\,\sqrt{(3.42\,P_{CO} - 2.42\,k')E_t}} \tag{8}$$

K_1 has been evaluated experimentally in this paper for the three cases.

Returning to Equations 1 and 2, it remains to evaluate $\frac{\text{yield per ion pair}}{\text{yield per quantum}}$ Considering only the case where $P_{CO} = P_{Cl_2} = P/2$, let under the experimental conditions used: q = number of quanta absorbed at $P = 760$ mm. CO + Cl_2 and N = number of ion pairs produced at P = 760 mm. CO + Cl_2. Assume that $Pq/760$ = number of quanta absorbed at pressure P of CO + Cl_2,[9] let x = number of quanta equivalent to one ion pair. Substituting these values in Equation 2, we obtain

$$\frac{+dP_{COCl_2}}{dt} = \frac{-\tfrac{1}{2}dP_{CO+Cl_2}}{dt} = K_1\sqrt{i_p + \frac{q_{abs}}{x}}\cdot\sqrt{P_{CO}}\cdot P_{Cl_2} =$$

$$K_1\sqrt{\frac{NP}{760} + \frac{qP}{760\,x}}\cdot\sqrt{P_{CO}}\cdot P_{Cl_2}$$

Letting $K_2 = K_1/760 \times 2$, and integrating, we have

$$K_2 = \frac{2K_1}{2\sqrt{760 \times 2}} = \left(\frac{1}{dt\,\sqrt{N + q/x}}\right)\int_{P_1}^{P_2}\frac{dP}{P^2} = \frac{1/P_2 - 1/P_1}{dt\,\sqrt{N + (1/x)}} = \frac{k_{\alpha+L}}{dt\,\sqrt{N + (q/x)}}$$

---

[9] Incomplete light absorption. This simplifying assumption introduces an error, by not applying Lambert's law, which is less than 30% even in the most unfavorable experimental run in this paper. The error is small because $q_{abs.}$ and the photochemical rate were measured in the same region of chlorine pressure, and the pressure changes less than 30% during a light run.

The experimental method was to measure (1) alpha rate alone, (2) alpha plus light rate, during a single run with the same gas mixture. This gives the following solution for x, the number of quanta necessary to produce as much reaction as one ion pair

$$\frac{\text{Velocity}_{\text{alpha + light}}}{\text{Velocity}_{\text{alpha alone}}} = \frac{k_{\alpha+\mathrm{L}}}{k_\alpha} = \frac{\sqrt{N + (q/x)}}{\sqrt{N}}$$

Solving for x, we obtain

$$x = \frac{q}{N\left[\left(\frac{k_{\alpha+\mathrm{L}}}{k_\alpha}\right)^2 - 1\right]} \tag{9}$$

Or, for a comparison between (1) alpha rate alone, and (2) light rate alone, we have

$$\frac{k_\mathrm{L}}{k_\alpha} = \frac{\sqrt{q/x}}{\sqrt{N}} \text{ or } x = \frac{q}{N(k_\mathrm{L}/k_\alpha)^2} \tag{10}$$

This paper determines these values of x experimentally.

Experimental

The reaction vessel M, Fig. 1, was a pyrex bulb about 4 cm. in diameter, the pressure in which was indicated by the quartz spiral manometer V.[10] Alpha particles were supplied through the usual type of radon bulb *a*.[11] The stopcocks were treated with a special chlorine-resisting lubricant.[12] The evacuating system, H, consisted of a liquid-air trap, a refluxing mercury bath as a trap for chlorine, a McLeod gage, a mercury vapor pump and finally the oil pump, connected with the reaction vessel at H in the order named. The water pump, I, was used for removing chlorine-rich gases. Immediately before a run the reaction apparatus was flushed out five times by evacuating to 10^{-2} mm. of mercury, and filling with carbon monoxide through F. It was then evacuated to 10^{-3} mm. of mercury and chlorine admitted through valve J, until the spiral manometer indicated the partial chlorine pressure desired. The tubing between stopcocks F, G, J and K was then flushed out with carbon monoxide by several evacuations. Finally, carbon monoxide was allowed to flow in until the mixture of gases registered about an atmosphere pressure. K was immediately closed (time = 0), and pressure and temperature readings were taken every minute to follow the drop in pressure of the gases caused by the formation of phosgene from chlorine and carbon monoxide under alpha particle bombardment.

Carbon monoxide, purer than 99.7%,[13] was obtained by running c. p. 90% formic acid into concentrated sulfuric acid. Gentle heating of the generator, B, greatly accelerated the evolution of gas. Carbon dioxide was removed by the potassium hydroxide in vessel C. Initially the carbon monoxide apparatus was evacuated and thoroughly swept out with fresh carbon monoxide many times, and during the subsequent six months of measurements the apparatus was never again exposed to the air, since the generator could be nearly emptied by applying suction at A and recharged with fresh sulfuric acid without admitting any air. The carbon monoxide was freshly prepared about an hour before each run, and was delivered to the reaction vessel through

stopcock F by proper manipulation of stopcock D, controlling the potassium hydroxide solution in the storage bulb, E.

The chlorine was prepared according to the method described by Marshall.[14] Tank chlorine was bubbled through a tall water column, then through a tube at 260° packed with powdered glass to dissociate chlorine oxides and finally frozen out with liquid air. It was then redistilled under high vacuum, four times at −119° (ethyl bromide) into a receiver immersed in liquid air. The apparatus in the last two distillations and final storage bulbs had been thoroughly baked out in vacuo. They held at 5×10^{-6} mm. for more than six hours. During a single collection two two-liter storage bulbs were filled with chlorine at two atmospheres pressure, which sufficed for about fifty runs. The chlorine gas was delivered to the reaction vessel through a specially constructed capillary, J, described elsewhere,[15] which permitted the removal of small samples from time to time without contaminating the main gas supply.

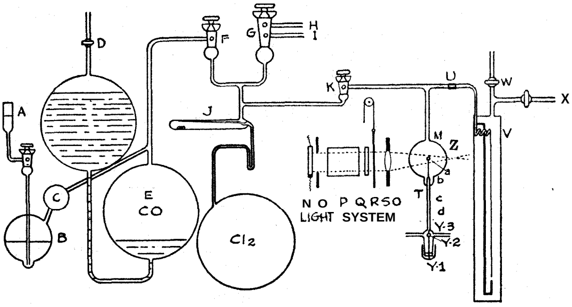

Fig. 1.—A, formic acid; B, sulfuric acid; C, KOH washing system, consisting of a tube of solid KOH, and several flasks of concentrated KOH solutions; E, carbon monoxide storage tank; H, to evacuating system; I, to water pump; J, special chlorine valve; M, reaction vessel; N, mercury Lab-arc lamp;* O, screens for definition of light beam; P, 5-cm. filter of 5% $CuSO_4$ solution; Q, Corning glass filter, G585;* R, shutter; S, lens; T, capillary to radon bulb; U, pyrex to quartz seal; V, quartz manometer, W, to suction pump; X, to mercury manometer; Y, to mercury level regulator; Y-1, nickel cup holding mercury seal around stuffing box; Y-2, hole in rod for holding and breaking radon capillary; Y-3, rod hollowed out for flexibility—holds mercury in capillary at fixed level; Z, focus of light; a, neck of alpha bulb; b, c, d, marked calibrated levels on capillary T.

* We are indebted to Dr. Stenstrom for the use of the Lab-arc, and to Dr. G. L. Glockler for the Corning glass filter.

In some runs it was desired to vary the radon concentration; this was accomplished by the device shown in T, Fig. 1. The volume of the small bulb to a, and of the capillary to marks b, c and d were obtained by measuring the loss in weight of a container from which mercury was sucked into the capillary up to the various marks. Accuracy

[15] Alyea, This Journal, 52, 1936 (1930).

was within 1%. The volume of the bulb was 0.00322 cc., the volume of the bulb and capillary to mark d, 0.0218 cc. By raising the mercury level to marks a, b, c or d, the volume occupied by the radon, and its subsequent pressure in the alpha bulb, could be varied. Since only the walls of the alpha bulb itself are thin enough to permit the passage of the alpha particles into the reaction sphere, this is a simple method for varying the effective radon concentration. For simplicity, in the tables which follow, only the *effective radon concentration* is given, that is, E_t is the radon present only in the bulb itself, disregarding how much radon may be in the capillary due to different mercury level settings. Unfortunately, measurements cannot be made until four hours after a new setting of the mercury level in the capillary[11] since Rn, RaA and RaC′, the sources of the alpha particles, must come to equilibrium. While this prevents making measurements on the same gas at different radon concentrations, fresh samples of gas gave reasonably reproducible results.

The apparatus used for the photochemical runs, N to S, Fig. 1, is self-explanatory. Spectral photographs of the light entering the reaction vessel, M, showed that the 3660 Å. mercury line comprised a large proportion of the light energy. The remaining 20% was also calculated in as if it were 3660 Å., since it was composed of approximately equal intensities of the 3130 Å. and 40404070 Å. mercury lines. The light radiation was expressed finally as the number of quanta absorbed in the reaction sphere by half an atmosphere of chlorine. For the calibration, the light energy was compared with a standard lamp, using a Moll thermopile. The cone of the thermopile received the light at point Z, Fig. 1. The galvanometer deflections were obtained for the light beam before and after its passage through the empty bulb, and through the bulb filled with chlorine at different pressures. There was no absorption with carbon monoxide. When the photochemical reactions were completed, the half of the bulb farthest from the light source was cut away, and the light coming through the remaining half of the bulb was measured. Similar measurements were made on the half of the bulb which had been cut away. These data enabled us to calculate in several different ways the original intensity of the beam, the percentage of light absorbed by, or reflected from, the walls of the reaction bulb and finally the number of quanta absorbed by the chlorine in the bulb.

In practice the normal alpha rate at equal carbon monoxide and chlorine pressures was measured for a few minutes and then the shutter R, shielding the reaction vessel from the ultraviolet light, was raised and pressure readings on the combined alpha and photochemical rates were taken at half-minute intervals. Five minutes later the shutter was dropped and once more the alpha rate alone was measured. The radon concentration and light intensity were so chosen as to give an alpha particle reaction several fold slower than the photochemical one, both to enhance the accuracy in measuring the photochemical reaction, and to prevent too much gas reaction before the photochemical measurements were begun.

In a few runs the experimental procedure was reversed, the photochemical–alpha reaction coming first, followed by the alpha alone, and finally checked by a second photochemical–alpha series of measurements.

Results

At Different Radon Concentrations.—Two typical runs are given in Table I. K_1 is calculated from Equation 4. In Run **36** and all runs at high radon concentrations an induction period, corresponding to the usual photochemical "clean up" of impurities in chain reaction,[16] is very

---

[16] Cf. Bodenstein, Refs. 3, 5 and 10, and Burgess and Chapman, J. *Chem. Soc.*, *89*, 1402 (1906).

evident. It is not noticeable, however, in Run 42 and similar runs at low radon concentrations. The smaller concentrations are undoubtedly unable to clean up the impurities during the first few minutes, and hence the induction period extends over the greater part of the run. The error so introduced was minimized by comparing velocity constants over the same initial pressure drops in the various runs (about 100 mm.), assuming the relations during the induction period to be the same as those obtaining afterwards. Thus in Run 36, the value 6.2 and not 7.2 was taken as the velocity constant, while 5.3 was used for Run 42. It is seen that the

velocity constant, calculated by assuming the reaction rate proportional to the one-half power of the radon concentration, is essentially the same in both runs, although the radon concentration has been varied eighty-three-fold (0.00834/0.000101). Table II summarizes the runs at different radon concentrations. In the seventh column, K_1 has been calculated from $K_1 = (1/P_2^{3/2} - 1/P_1^{3/2})/\Delta t E_t$, an expression derived by the same reasoning as in Equation 4, only that it assumes that the reaction is proportional to the first power of the radon concentration. From the last two columns it is at once evident that the reaction is proportional to the one-half and not to the first power of the radon concentration.

Variation of the Chlorine–Carbon Monoxide Ratio.—Tables III and IV show values of K_1 with one or the other gas in excess. Table V is a summary of the various runs, and shows that K_1 is essentially constant over a range of carbon monoxide pressures from 638.5 to 162.8 mm., the corresponding chlorine pressures having been increased from 95.5 to 587.1 mm. Runs 49 and 51 indicate that at still lower pressures of carbon monoxide the constant probably falls off. K_1 is calculated for the first seven minutes of a run, using about 0.005 curie of radon (Col. 4). This gives experimental conditions identical with certain runs in Table II, and makes the values in Tables II and V strictly comparable. If K_1 in Table V is taken over very long time intervals, the values are all about 20% higher, a fact which may be attributed both to the induction period and to the inaccuracy of our original kinetic equation in taking care of certain secondary factors in the phosgene reaction.

Quantum Efficiency Versus Yield per **Ion** Pair.—The first step in such a comparison was the calibration of the radiation intensities. The alpha radiation was calculated as the number of ion pairs produced per minute per curie of radon for a mixture of 380 mm. of chlorine and 380 mm. of carbon monoxide. Experimentally it involved evaluating the ionizing power of the alpha ray bulb, by measuring the velocity of a chemical reaction (the synthesis of water from electrolytic gas) for which the ratio of ionization to chemical reaction is known, carried out in the identical apparatus used for the phosgene reaction. The experimental procedure and calculations appear in the literature,[17] and the velocity constant $(k\mu/\lambda)^1 = [\log (P_1/P_2)]/[E_0 (e^{-\lambda t_1} - e^{-\lambda t_2})]$, where P is the pressure of hydrogen plus oxygen, had the experimental value of 2.03 in our apparatus. The volume of the reaction sphere was 49.2 cc. Since $(k\mu/\lambda)^1$ is "the number of times a given volume will completely react at any given pressure held constant during the decay of one curie of radon (5.55 days, average life) if the radon content were maintained constant,"[18] the number of molecules which reacted per minute, with one curie of radon under the experimental conditions, was

$$\frac{2.03 \times 49.2}{5.55 \times 24 \times 60} \times 2.46 \times 10^{19} = 3.08 \times 10^{16} \text{ molecules}$$

where 2.46×10^{19} is the number of molecules in one cubic centimeter of gas at 760-mm. pressure and 27°. Now for each ion pair six molecules react,[19] forming four molecules of water, and therefore the number of ion pairs formed per minute was $3.08 \times 10^{17}/6 = 5.13 \times 10^{16}$ ion pairs. The specific ionization in a gas mixture of chlorine and carbon monoxide at equal pressures, $i_{CO + Cl_2}$, is 171.0; and that in electrolytic gas, $i_{2H_2 + O_2}$ is 52.7. Hence *the total number of ion pairs produced in the chlorine–carbon monoxide mixture at 760-mm. pressure and 27° per curie of radon per minute* is $5.13 \times 10^{16} \times (171.0/52.7) = 1.66 \times 10^{17}$ ion pairs. Strictly speaking, the water synthesis should be made at pressures more than three times (171.0/52.7) greater than the phosgene runs, in order to have identical paths of ionization.[3] However, the size of the reaction vessel[20] permitted the standardization to be made at the same pressures, a fact experimentally verified when several runs made on phosgene at one-third of an atmosphere gave approximately the same velocity constant as at one atmosphere.

The light radiation was expressed as the number of quanta absorbed in the reaction vessel per minute by a gas mixture of 380 mm. of chlorine and 380 mm. of carbon monoxide. The standard lamp calibrated by the Bureau of Standards for 0.25, 0.30 and 0.35 ampere gave galvanometer deflections on a scale about 2.5 meters distant which corresponded to the following ergs of energy falling on the thermopile per minute per centimeter deflection on the scale: 1810, 1820 and 1780, giving an average of 1800 ergs. Comparable measurements on the light entering the reac-

[18] S. C. Lind, Ref. 2, p. 123.

[19] See S. C. Lind, THIS JOURNAL, 41, 531–559 (1919). In this paper, read before the American Chemical Society at Minneapolis, September 11, 1929, the error of dividing by four instead of by six led to the ratio of quantum efficiency: yield per ion pair of 0.5 instead of 0.78 as given in Table VII.

[20] Bardwell and Doerner, *ibid.*, 45, 2594 (1923).

tion vessel were then made. It was composed of 3600 Å., one quantum of which has ch/λ in cm. = $(3 \times 10^{10} \times 6.55 \times 10^{-27})/(3660 \times 10^{-8}) = 5.36 \times 10^{-12}$ ergs of energy, where 3×10^{10} is the velocity of light in cm. per second and 6.55×10^{-27} is the value of the Planck constant h. One centimeter deflection on the galvanometer scale, therefore, represented $1800/5.36 \times 10^{-12} = 3.35 \times 10^{14}$ quanta per minute. As mentioned earlier in the paper, the amount of light absorbed by and reflected from the walls of the reaction vessel, about 30% of the total light, was checked in several ways. The following is a great simplification of the actual data, but will suffice to show the experimental value obtained: (1) galvanometer deflection from the light entering the gas mixture after passing through the first wall of the reaction vessel, 15.2 cm.; (2) calculated galvanometer deflections after passage through (1) and 380 mm. of chlorine, 0.40 cm.; **(3)** calculated galvanometer deflection absorbed by 380 mm. of chlorine, or by a mixture of 380 mm. of chlorine plus 380 mm. of carbon monoxide, 14.8 cm. The deflection of 14.8 cm. represents $14.8 \times 3.35 \times 10^{14} = 4.95 \times 10^{15}$ *quanta per minute absorbed* by the chlorine–carbon monoxide gas mixture at 760-mm. pressure in the reaction vessel.

The results of a combined alpha particle–photochemical run made under these conditions of radiation are given in Table VI, where it is seen how the velocity constants for the run have been calculated. Table VII summarizes all of the runs. The final column calculates that 0.78 quanta produce as much reaction as one ion pair. The fact that this ratio remains approximately constant when the absolute rates have been cut down four-fold by the addition of oxygen is particularly interesting in the light of the recent studies of Bodenstein[5] where it was shown that at even these small oxygen concentrations the oxidation of carbon monoxide, photosensitized by chlorine, plays a prominent role. There is little doubt but that the photochemical reactions which he postulates between oxygen, chlorine and carbonyl chloride are taking place in the alpha particle reaction as well. The value 0.78, however, is at least 20% lower than the true experimental value, since Lambert's law was not applied in developing the expression $q/[N(A - 1)]$, Equation 9. Even after making this correction, the value of about 0.95 has been obtained under experimental conditions giving a large experimental error, and the best conclusion we can draw until measurements have been made with a more accurate apparatus is that the ratio of quantum yield to yield per ion pair is probably 1.

At any rate, the results leave little doubt that the secondary chain steps are identical under the two types of radiation, that the alpha particle bombardment also leads to atomic chlorine chains. From the kinetics above, the calculated chain lengths will vary as the square root of the radiation intensity. The photochemical chain length in Table VI is about 5000 molecules per quantum, while an alpha radiation 300 times less in-

tense, Table I, Run 42, gives a chain length of over 50,000 molecules per ion pair. The mechanism of the primary step in the alpha particle chain, however, can only be elucidated by further experiments. It probably involves an initial ionization by the alpha particle, while subsequent dissociation gives rise to chlorine atoms which may be produced at the time of ionization or later by collision of the ion with neutral molecules, or upon final neutralization of the ions by recombination; the steps which succeed this atomization mimic those of the photochemical reaction.

Summary

1. The photochemical systhesis of phosgene from carbon monoxide and chlorine has been expressed kinetically by

$$\frac{+dP_{COCl_2}}{dt} = k\sqrt{I_{\text{abs.}} \times P_{CO}} \times P_{Cl_2}$$

If the gas mixture is activated by alpha particle bombardment instead of by light, the reaction obeys this same kinetic equation, i_p, the number of ion pairs produced, being substituted for $I_{\text{abs.}}$, the number of quanta absorbed. This was tested over an eighty-three-fold range of radon concentration and a wide variation of the relative pressures of carbon monoxide and chlorine.

2. Simultaneous measurement of the alpha particle and photochemical reactions shows that the yield per ion pair is equal to the yield per quantum absorbed. This is also true in the presence of oxygen ($<10\%$) which inhibits the reaction.

3. With exceedingly weak radiation, yields as high as 85,000 molecules per ion pair were obtained: the more intense light radiations gave 5000 molecules per quantum absorbed.

4. The secondary steps in the phosgene synthesis involve an atomic chlorine chain mechanism and the above facts prove that this mechanism occurs independently of whether the primary step has been photochemical excitation or ionization by alpha particles.

THE PHOTOCHEMICAL HYDROGEN–OXYGEN REACTION

BY GEORGE B. KISTIAKOWSKY

RECEIVED FEBRUARY 3, 1930 PUBLISHED MAY 8, 1930

Several attempts have been made to elucidate the kinetics of the interaction of oxygen and hydrogen under influence of light. Andrejew[1] and Coehn and Grote[2] demonstrated the existence of a stationary state in the system water vapor–oxygen and hydrogen, illuminated by the short wave lengths of a mercury arc but did not investigate the details of the reactions involved. Tian[3] succeeded in showing the presence of hydrogen peroxide in illuminated hydrogen–oxygen mixtures and assumed that water is formed only through some intermediary steps involving hydrogen peroxide. Kistiakowsky[4] has shown that while at room temperature the quantum yield of water formation is not far from the value of two, reaction chains are set up in the temperature range where the thermal reaction becomes noticeable, the temperature coefficient of the photochemical water formation not following the Arrhenius equation. Reaction of hydrogen and oxygen photosensitized by mercury vapor has been studied by Marshall[5] and by Bates and Taylor.[6] It has been conclusively demonstrated that water is formed through a secondary decomposition of hydrogen peroxide. Bates and Taylor further noticed that in absence of mercury vapor only ozone is formed, hydrogen peroxide being completely

absent. In these latter experiments mainly the mercury line 1842 Å. must have been photochemically active. The present work is concerned with the mechanism of the un-sensitized reaction of oxygen and hydrogen in light of two spectral regions: 1854–1862 Å., by which according to Birge and Sponer,[7] excited oxygen molecules are produced and the region of 1719–1725 Å., which dissociates oxygen molecules in one elementary act, a normal and excited oxygen atom resulting.[8]

The experimental set-up consisted of a condensed spark burning between aluminum electrodes and of a thin-walled quartz vessel of about 100-cc. capacity, through which the reacting gases were passed at measured rates of flow. The reaction vessel was placed at 4-cm. distance from the spark and the space between was filled with streaming air or purified nitrogen. Oxygen in an air layer 4-cm. deep absorbs the strong aluminum spark lines in the neighborhood of 1720 Å. completely[9] while the strong line group 1854–1862 Å. reaches the reaction vessel only very slightly weakened.[9] The correctness of this assumption is proved by the observation that substitution of nitrogen instead of air increased the reaction velocity more than ten-fold. Accordingly, with a layer of nitrogen, more than 90% of the reaction is due to the initial formation of oxygen atoms, while with the air layer only the lines in the band absorption region of oxygen are effective. In order to determine the course of reaction the exit gases were passed through a neutral potassium iodide solution and the liberated iodine was titrated on acidification. This gave the total amount of ozone and hydrogen peroxide formed, since better than 90% of the latter, as established by special experiments, was retained in the wash bottles containing potassium iodide and reacted with it on acidification. Hydrogen peroxide alone was determined colorimetrically with the aid of titanium sulfate solutions. To determine the absolute rate of the reactions involved use was made of the work of Warburg[10] and of Noyes,[11] which shows that the quantum yield of ozone formation in oxygen is, independently of wave length, equal to two. Warburg's experiments indicate further that the yield remains unchanged on dilution of oxygen with nitrogen. Accordingly, in the following experiments the reaction rates in the oxygen–hydrogen mixtures are referred to the rates of ozone formation in similar oxygen–nitrogen mixtures, measured in the same vessel and under identical conditions of illumination. In Pig. 1 are plotted yields of ozone in light of the line group 1854–1862 Å. against the rate of gas flow. Circles refer to a mixture containing 20% O_2 and 80% N_2,

crosses to a mixture containing 80% H_2 instead of nitrogen. Determination of the hydrogen peroxide yield showed that this was formed at a rate of not more than 2×10^{-8} mole per minute (this being the sensitivity limit of the color test as here used) whether the gas flow was 700 or 30 cc./min. In calculating the points in Fig. 1 which were obtained with the highest rates of gas flow, averages have been taken of several experiments made. Since the effect on ozone yield of substitution of hydrogen for nitrogen is of importance for the discussion to follow, Table I presents complete data relating to this point.

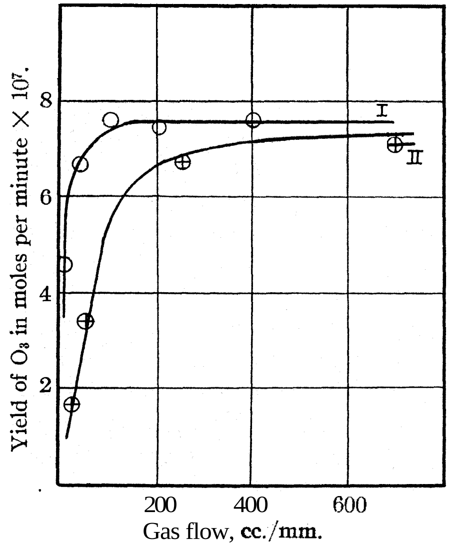

Fig. 1.—Yield of ozone in light of the (mean) wave length 1860 Å. Circles and Curve I, yields in the 1:4 oxygen–nitrogen mixture. Circles and Curve II, yields in the 1:4 oxygen–hydrogen mixture.

Figure 2 presents data obtained with the shorter wave lengths. Circles and Curve I represent ozone yields in the (1:4) oxygen–nitrogen mixture, crosses and Curve 2, ozone plus hydrogen peroxide yields in the (1:4) oxygen–hydrogen mixture, circles and Curve 3, finally, hydrogen peroxide yields alone. All points in Fig. 2 are averages of two or more experiments. The reproducibility of the results in the light of short wave lengths was not as good as in the experiments with the 1852–1864 Å. lines and can be best judged from Pig. 3, in which single experiments have been plotted. In this figure are plotted the relative yields of ozone (represented by circles)

TABLE I

OZONE YIELD

Gas mixture	Rate of gas flow, cc./min.	Ozone yield, moles per minute $\times 10^7$							
20% O_2 + 80% N_2	400	7.62	7.67	7.73	6.60	6.88	6.54	6.60[a]	
20% O_2 + 80% H_2	700	7.62	7.16		5.85	6.88	7.00	6.48	6.88

[a] This second series of determinations has been made with a slightly changed apparatus and was not used in drawing Fig. 1.

and of hydrogen peroxide (crosses) against the composition of the oxygen–hydrogen mixture, the ozone yields in the equivalent oxygen–nitrogen mixtures having been taken for 100%. The ozone yields in mixtures containing hydrogen were obtained by subtracting hydrogen peroxide yields from the total yield as determined by the iodine titration. All these data were obtained with a gas flow of 2000 cc./min. with oxygen–hydrogen and 1500 cc./min. with oxygen–nitrogen mixtures.

Figures 1 and 2 show that with increasing rate of gas flow the yields tend to constant values which represent undoubtedly the maximum yields in absence of secondary photochemical decomposition of either ozone or hydrogen peroxide. In view of all earlier work, it may be further assumed—with a considerable degree of certainty—that the ozone yields, in the oxygen–nitrogen mixtures, are equal to two molecules per quantum of absorbed light energy, irrespective of the wave length. With oxygen–hydrogen mixtures the effect of the two spectral regions is considerably different. While with the 1860 Å. line group practically the same yield of ozone is obtained whether the mixture contain nitrogen or hydrogen, with the short wave lengths and in the presence of hydrogen, the ozone yield is only 25% of that in the presence of nitrogen, but an equal amount of hydrogen peroxide is formed in addition. As Fig. 3 shows, ozone yields in presence of hydrogen are—at least roughly—proportional to the relative concentration of oxygen, whereas the yields of hydrogen peroxide are proportional to the concentration of hydrogen. Since it is well established that in the light of the 1720 Å. spectral region oxygen atoms are primarily formed, one can consider somewhat more in detail their reactions, of which not many are possible.

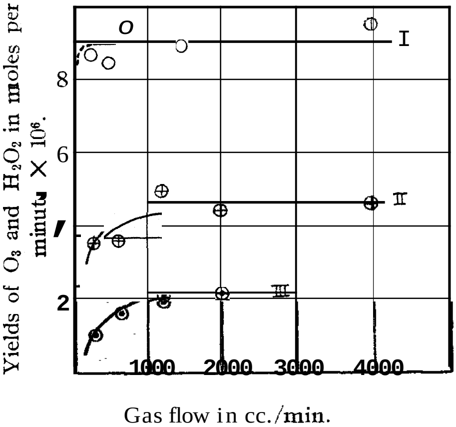

Fig. 2.—Yields of O_3 and H_2O_2 in light of the (mean) wave length 1720 Å. Circles and Curve I, O_3 in the 1:4 oxygen–nitrogen mixture. Crosses and Curve II, O_3 + H_2O_2 in the 1:4 oxygen–hydrogen mixture. Dots and Curve III, H_2O_2 alone in the 1:4 oxygen–hydrogen mixture.

$$O + O_2 + X = O_3 + X \tag{1}$$
$$O + H_2 + X = H_2O + X \tag{2}$$
$$O + H_2 = OH + H \tag{3}$$

X denotes here a molecule of oxygen or hydrogen. These three reactions are in qualitative agreement with the relations observed since they lead to an ozone yield which is proportional to the concentration of oxygen while the rate of the third reaction is proportional to the concentration of hydrogen. In this last reaction hydrogen atoms are produced, but, as was already suggested by Taylor and Marshall[12] and shown by Boehm and Bonhoeffer[13] hydrogen atoms react to form quantitatively hydrogen

---

[13] Boehm and Bonhoeffer, Z. *physik. Chem.*, 119, 385 (1926).

peroxide. According to Marshall,[5] or, the average not less than two molecules of this latter are produced by each hydrogen atom. While the first two reactions require three-body collisions and, therefore, should be relatively slow, the third reaction is free from this limitation and, being exothermic, should take place on every collision.[14] That this conclusion is incorrect is shown by the present experiments in which ozone yields equal to or in excess of hydrogen peroxide yields were obtained. Using data here recorded the probability of Reaction **3** can be estimated to 10^{-4} if, as the first approximation, the assumptions are made that all molecular diameters are equal ($\backsim 10^{-8}$ cm.) and that bimolecular collisions occur at atmospheric pressure 1000 times more frequently than termolecular ones (mean free path $\backsim 10^{-5}$ cm.). The only factor which might increase this value is the possibility that the three-body collisions leading to Reactions 1 or 2 occur more frequently than assumed, which means that the molecular effective cross sections are here larger than the kinetic values. The slowness of the reaction of oxygen atoms with hydrogen molecules finds a parallel in a similar reaction of chlorine atoms. By combining Bonhoeffer's[13] data on the reaction H + Cl_2 with calculations made by Trifonoff,[15] one finds that the probability of the reaction Cl + H_2 is somewhat less than 10^{-3} when water vapor is present and is presumably zero in completely dry gases. The hydrogen molecule shows thus a remarkable stability in reactions which should take place on every collision according to the theories of Herzfeld[14] and of others.

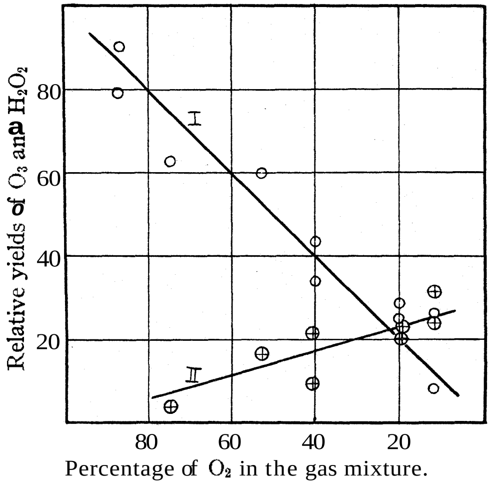

Fig. 3.—Dependence of the yields of O_3 and H_2O_2 on the composition of the gas mixture in light of the wave length 1720 Å. Circles and Curve I, O_3 yields. Crosses and Curve II, H_2O_2 yields.

In the dissociation of the oxygen molecule by light one of the oxygen atoms produced is in the normal ^3P state, whereas the other is, according to Herzberg,[8] in the ^1D metastable state, possessing some 30,000 cal. of excitation energy. The question is of considerable interest whether this difference in the energy levels influences the probability of reaction with hydrogen molecules. No definite answer can be obtained from the experiments with the short wave lengths alone. They can be accounted

---

[14] Herzfeld, *Ann. Physik*, 59, 635 (1919).

[15] Trifonoff, *Z. physik. Chem.*, *3B*, 195 (1929).

for by assuming equal probabilities. However, the later discussion will show that the assumption is more helpful that the oxygen atoms in the normal quantum state react with hydrogen molecules more slowly than the excited ones, for which alone the above estimated probability of 10^{-4} would then hold.

The occurrence of Reaction 2 has been so far, left out of consideration. That either this reaction or, and this is less probable, a recombination of oxygen atoms does take place in the hydrogen–oxygen mixture is shown by the observation that there is a deficit in the ozone plus hydrogen peroxide yield as compared with the ozone yield in the oxygen–nitrogen mixtures. Several attempts have now been made to identify water among the primary reaction products by freezing out the products in a liquid-air trap and analyzing the contents on weighing. These attempts failed, due to low yields and the very high gas flow velocities required, but further work under changed conditions is planned. As an indirect proof of the occurrence of Reaction 2 the experiments of Farkas, Goldfinger and Haber[16] may be considered. They succeeded in exploding $O_2 + H_2$ mixtures by introducing oxygen atoms in fairly high concentration. Formation of either ozone or hydrogen peroxide is not exothermic enough to cause explosion and a strongly exothermic reaction of the type represented by Reaction 2, eventually leading to short chains, must have occurred in these experiments.

It remains now to consider results obtained with the 1860 Å. spectral region. These experiments are not quite in accord with the data already discussed. The essence of the results obtained is that with the long wave lengths practically no reaction occurs between hydrogen and oxygen, ozone being quantitatively formed. If the secondary process on excitation of an oxygen molecule is its dissociation into atoms on collision—there is enough energy for the process—this result would be quite incomprehensible. The other possible process is

$$O_2 + O_2 = O_3 + O \tag{4}$$

the oxygen atom reacting then by 1, 2 or 3. But this scheme also requires a lower ozone yield and formation of hydrogen peroxide in presence of hydrogen even if the excited oxygen molecules do not react with hydrogen at all. In the 1:4 oxygen–hydrogen mixture one would expect (see Fig. 2) at most $50 + 25/2 = 62\%$ of ozone and at least $25/2 = 12\%$ of hydrogen peroxide as compared with the ozone yield in a similar oxygen–nitrogen mixture. The experiments show (Table I) that the sum of ozone and hydrogen peroxide formed is about 97–99%, while the hydrogen peroxide yield does not exceed 3%. This latter observation is, incidentally, in complete accord with the earlier mentioned results of Bates and Taylor. The difficulty in connection with the hydrogen peroxide yield is removed

---

[16] Farkas, Goldfinger and Haber, *Naturwissenschaften*, 17, 674 (1929).

if the suggestion be accepted that the probability of Reaction 3, which was calculated to 10^{-4} for excited atoms, is smaller in case of normal oxygen atoms, such as are produced in Reaction 4. But even with this assumption the excess of ozone yield over that calculated remains unexplained, since there are no reasons to assume that with normal oxygen atoms the ratio of the reaction velocities 1 and 2 is different than in case of excited atoms. This question, therefore, must be left open at present but it is hoped that further experiments now under way may bring a solution of this problem.

Summary

1. The oxygen–hydrogen reaction has been studied in light of the two spectral regions 1719–172.5 Å. and 1854–1862 Å.

2. The effect of these spectral regions is markedly different. While the longer wave lengths produce only ozone in an amount equal to that produced in similar oxygen–nitrogen mixtures, in light of shorter wave lengths the yields of ozone in the presence of hydrogen are smaller but hydrogen peroxide is formed in addition.

3. The probable reaction mechanism has been discussed. The probability of the reaction $O + H_2 = OH + H$ has been estimated to 10^{-4}, a much smaller value than that predicted theoretically.

THE VAPOR PRESSURE AND HEATS OF FUSION AND VAPORIZATION OF FORMIC ACID

BY ALBERT SPRAGUE COOLIDGE

RECEIVED FEBRUARY 8, 1930 PUBLISHED MAY 8, 1930

Introduction

In a recent paper[1] were given data on the density of formic acid vapor, together with some isolated vapor pressure data obtained in studying the process of purification. These data were obtained in order to make possible use of the Clapeyron equation in calculating heats of adsorption from equilibrium pressure data. The same equation should, of course, give the heats of evaporation of pure solid or liquid formic acid, when the corresponding vapor pressures are introduced. The case is interesting because of the wide deviation of the vapor from the perfect gas laws, produced by association. The only calorimetrically determined quantities by which the Clapeyron equation could be checked appeared to be the heat of vaporization of the boiling liquid, and the heat of fusion of the solid, which can be compared with the difference between the vaporization heats calculated for the solid and liquid at the triple point. Using

[1] Coolidge, THIS JOURNAL, 50, 2166 (1928).

the values of the vapor pressures from "International Critical Tables," it was found that in neither case did the calculated and observed values agree. It seemed worth while, therefore, to redetermine both vapor pressures and latent heats with the very pure formic acid available, in the hope of getting a thermodynamically consistent set of data.

Since the observed heat effects are to be compared with values computed by a process involving temperature differentiation of the observed pressures, it is clear that a higher order of accuracy is needed in measuring the latter than the former. Therefore, no attempt was made to surpass a precision of, say, 0.5% in the calorimetry, while no effort was spared to perfect the thermometry and manometry, and it is believed that the error does not exceed 0.1%.

Instability of Formic Acid

It was necessary to take constant precautions against errors arising from the spontaneous decomposition of the acid into water and carbon monoxide. This reaction appears to occur in the liquid at all temperatures, and to cease only when the acid is frozen. However, at room temperature the evolution of permanent gas is very slow, and does not interfere with the measurements provided the sample is one which has been pumped free from gas while frozen, and has been melted just before the experiment. At temperatures approaching 100° decomposition is more rapid, and cannot be ignored. In one experiment, a quantity of liquid, carefully freed from gas, was confined by a column of mercury of about 30-cm. height in addition to the atmospheric pressure, and was then raised to 100°. Within five minutes bubbles begain to escape through the mercury, Since the pure acid boils at 100.5°, the bubbles must have contained considerable permanent gas. Again, it was observed that when the pure acid was gently boiled under a reflux condenser, protected from atmospheric moisture, the boiling point rose a degree in ten hours, due presumably to dilution of the acid by the water resulting from its decomposition. The heat of combustion[2] of the acid is 62,800 calories per formula weight; that of carbon monoxide is 68,100 calories; the decomposition is, therefore, endothermic,a bsorbing 5300 calories per formula weight.

Vapor Pressure Measurenients

For temperatures up to 80° a static method was used to determine the vapor pressures. The acid was placed in a bulb communicating with a manometer on which pressures could be read to 0.01 mm. as high as 100 mm. For higher pressures, this instrument was used to determine the difference in pressure between the bulb and the rest of the system, in which a pressure of air nearly equal to that in the bulb was established, and could be read off another manometer by means of a cathetometer.

The bulb was maintained at the desired temperature, while the connections and

---

[2] "International Critical Tables," Vol. V, p. 165.

manometer must, of course, be kept slightly warmer to prevent distillation. A temperature of about −5° was obtained with a sodium chromate eutectic. The salt, a c. P. product, was not further purified, and the exact temperature obtained was not always the same; in any one experiment, however, the temperature, as shown by two thermometers in different positions, was uniform and constant to 0.01". Other temperatures up to 20° were secured with ice- and water-baths. From 30 to 80° an oil-bath was used. It was contained in a Dewar vessel which, together with the manometer and connecting tubing, was mounted in an air-bath with a plate-glass front. The air was maintained a degree or two hotter than the oil, which was prevented from overheating by a very slow stream of water through a coil. The temperature of mercury in manometer and exposed thread of thermometer was thus controlled, and suitable reductions applied.

The main supply of acid used had been purified in the manner described in the previous paper until it had the same vapor pressure at 0°, and was, therefore, probably 99.99% pure. It was kept continuously frozen to prevent deterioration. Samples for the measurements were distilled into the bulb, and before each reading were gently pumped to remove possible traces of permanent gas. At 70 and 80" constant readings were not obtained, the pressure rising steadily after each pumping, without approaching any limit. This situation was met by increasing the size of the dead space so as to dilute the evolved gas, and by making readings at definite time intervals after each pumping. By extrapolating back to zero time, satisfactory values could be obtained.

To extend the range upward, boiling points were taken at atmospheric pressure, and also at about 1000 mm. In this method no error can be produced by accumulation of carbon monoxide, since this gas is swept away by the stream of fresh vapor rising from the liquid. In order to minimize the error due to dilution with water, the boiling was reduced to the shortest possible time, and the acid was once repurified between readings. Nevertheless, it is possible that the values found may be a few hundredths of a degree too high.

Temperatures of 20° and higher were read on a thermometer certified by the Bureau of Standards. Particular care was taken with the temperatures below 20°, on which the calculation of the heat of fusion depends. The thermometer had been certified at ten degree intervals, but the correction at 10° was so different from that at either 0 or 20° that interpolation seemed uncertain. Therefore, the scale used below 20° was the mean of five good thermometers, including that certified by the Bureau of Standards and one certified by the Reichsanstalt, which were all carefully compared between −5 and 20". It is unlikely that the error exceeds 0.02°.

The triple point of formic acid is 8.25°, but the liquid can be cooled to −5° without immediate solidification; attempts to go below −5° always froze the acid. In attempting to measure the sublimation pressure, it was found that when a sample of acid having the correct vapor pressure as liquid at 0° was simply frozen and gently pumped, a pressure of about 8.7 mm. was obtained at 0°. The value given in the first paper was 8.67 mm. However, on exhaustive pumping, accompanied by occasional fusion and resolidification, the pressure dropped to 8.22 mm., below which it failed to go even when almost all of the sample had been pumped away. Evidently traces of volatile matter which remain in solution in the liquid without perceptible effect upon the vapor pressure, are set free on crystallization, and can be removed only with difficulty. The vapor pressure of the solid thus prepared was also determined at −5°. The pressure was also determined over a mixture of solid and liquid, at a temperature of 8.28" (8.26° was given in the first paper). Attempts were made to detect changes in the triple point due to variations in the conditions under which the crystals were formed, or their age, but no variation was found.

TABLE I

VAPOR PRESSURE MEASUREMENTS (MILLIMETERS OF MERCURY)

Liquid		Liquid		Solid	
T	*P*	*T*	*P*	*T*	*P*
−5.23°	8.12	49.93	130.1	−5.07°	4.98
0.00	11.16	59.98	192.7	0.00	8.22
8.25	17.94	70.04	280.6	8.25	17.94
12.57	22.72	79.93	395.6		
20.00	33.55	100.68	762.5		
29.96	54.36	110.62	1017.6		
39.89	85.18				

Table I gives the experimental values for the vapor pressure of solid and liquid, including the boiling points. Each entry is the mean of three closely concordant measurements, except those for the solid at −5° (two measurements) and for the liquid at 60, 80 and 110° (one measurement each).

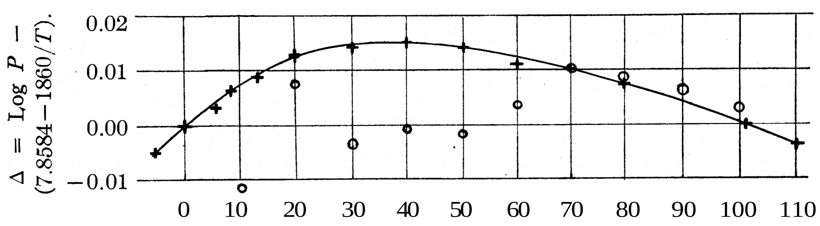

Fig. 1.—Vapor pressure of the liquid (deviation plot).

Adjustment and Comparison of Data

The three values for the vapor pressure of the solid are represented, to within 0.01 mm., by the equation

$$\text{Log P} = 12.486 - 3160/T \tag{1}$$

in which log P is the common logarithm of the pressure in mm., and T is the absolute temperature reckoned from −273.1°C. They may be compared with the values in "International Critical Tables."[3] These values are given only at temperatures from 1 to 8°, but may be easily extrapolated to 0 and 8.25°. The result is

Temperature	0°	8.25°
I. C. T.	8.0	18.0
A. S. C.	8.22	17.94

The experimental values for the vapor pressure of the liquid may be approximately represented by the equation

$$\text{Log P} = 7.8584 - 1860/T \tag{2}$$

but the deviations are systematic. Figure 1 shows the deviation plot, the quantity $\Delta = \log P - (7.8584 - 1860/T)$ being plotted against the

---

[3] "International Critical Tables," Vol. III, p. 209.

temperature. The present data are represented by crosses, those of the "International Critical Tables"[4] by circles. A smooth curve can be drawn through the crosses so that none of them, except the single determination at 60°, falls more than 0.0005 from the curve. This corresponds to a discrepancy of 0.12%. By taking A from this curve at round temperatures, values of the vapor pressure can be accurately interpolated. The results are given in Table II, which also shows the "International Critical Tables" values. The values at 0 and 20° are in excellent agreement with the corresponding values published in my first paper; that at 10° is a trifle lower (19.76 instead of 19.88) and is doubtless more reliable. The table also shows the apparent molecular weight of the saturated vapor, calculated as explained in the first paper.

Latent Heat Measurements

The latent heats directly measured were the heat of fusion at the triple point and the heat of vaporization of the liquid at temperatures from 0 to 100°.

For the former, a very simple calorimeter was used, consisting of a Dewar cylinder holding 200 cc. of water, provided with a stirrer, a Beckmann thermometer, and a heater of 44.5 ohms resistance, made of wire of negligible temperature resistance coefficient, and enclosed in a copper envelope. Current was supplied at 15 volts, being controlled by a sensitive voltmeter which could be read to 0.01 volt, and which was found actually correct to that degree by potentiometric comparison with a standard cell. The room temperature was constant within 0.5°, and it was found that

[4] "International Critical Tables," Vol. III, p. 215.

when the calorimeter was at room temperature, and evaporation stopped by a layer of kerosene, no detectable heat exchange occurred within twice the time required for a determination. During an experiment the calorimeter temperature fell for a few minutes to some 2° below that of the room. The rate of leak at that head was determined and the appropriate correction applied; it amounted to about 0.5% of the total heat measured.

The scheme of measurement consisted of introducing frozen acid into the calorimeter, and determining the time of current flow required to reestablish the original temperature. The acid (about 8 g.) was sealed into a vessel with five fingers, which it partially filled, thus offering a larger surface for heat transfer than a plain bulb. After freezing, it was left for some time in water at 7°, and was then quickly transferred, with a hasty wiping, to the calorimeter. The method seemed at first unpromisingly crude, but experiment showed that the errors due to the carrying over of cold water and to absorption of heat in transfer were surprisingly constant. At the same time the current was turned on and allowed to flow for a time which preliminary trial showed would nearly restore the original temperature. When equilibrium had been established, the temperature was found a few hundredths of a degree too low; the time of current flow which would have been needed to make good the deficiency was readily estimated. For example, in one experiment, the current flowed for 8.25 minutes, and the final temperature was 0.045' too low. If no thermal leak had occurred, it would have been 0.055° too low. Since 3.8 minutes of current were needed to raise the calorimeter 1° (when the acid was already at the calorimeter temperature) the extra current needed to restore exactly the original temperature would be 0.21 minutes, making the total time 8.46 minutes. Other determinations gave 8.40, 8.46 and 8.44 minutes, the average being 8.44. In some cases the acid was freshly frozen, in others it had been frozen for some hours.

What was actually measured was, of course, the heat of fusion at the triple point, plus the heat content of the solid from 7 to 8.25°, plus the heat content of the liquid from 8.25' to the calorimeter temperature, plus the heat content of the glass over the whole range, plus the errors of transfer. Exactly similar experiments were made (alternately with those described) in which the only difference was that the acid was not frozen. The results were 1.31, 1.34 and 1.31 minutes, average 1.32. The sum of heat quantities measured is evidently the same as before, except that the heat of fusion is absent, and the liquid, instead of the solid, has been heated from 7 to 8.25°. The difference between the two results, 7.12 minutes, evidently represents the heat of fusion at 7°. Similar determinations in which the original temperature was 0° gave 6.94 minutes, corresponding to the heat of fusion at 0°. The extrapolated value at 8.25° is 7.15 minutes, with a probable error of 0.03.

These values are given first in minutes, rather than in joules per gram, because an unfortunate accident prevented the exact determination of the quantity of acid used, and no more pure acid was available for a repetition. The vessel and contained acid were weighed, but when the vessel was opened to remove the acid, the liquid was thrown forcibly back by the inrush of air, and one of the fingers was broken. Almost all of the fragments were recovered and weighed, and by piecing them together it was estimated that not over 0.05 g. of glass was lost. On this basis, the acid weighed 7.85 grams. If, in reality, more glass was lost, the true weight of the acid was less, the true heat of fusion higher than that calculated, namely 268 joules per gram at 0°, 275 joules at 7° and 276 joules at 8.25°. The value given in "International Critical Tables"[5] is 246.5 joules.

The temperature coefficient indicates that the liquid has, as usual, a higher specific heat than the solid. Indeed, this difference can be taken directly from the experimental data, and amounts to 1 joule per degree per gram; this figure, involving differences between four larger quantities, is subject to a large uncertainty, estimated at ±0.2. According to "International Critical Tables" the specific heat of the liquid is 1.83 joules[6] and that of the solid 1.80 joules.[7] The latter datum, as well as those in Landolt–Börnstein,[8] is based on a paper by Massol and Faucon,[9] an inspection of which reveals that it was lauric acid, and not formic acid, with which they were obtained. There appears to be no reliable determination of the heat capacity of crystalline formic acid. Massol and Guillot[10] state that they found the specific heat of the solid to exceed that of the liquid, but as they make the same statement about acetic acid, which is certainly wrong, their figures must be considered worthless.

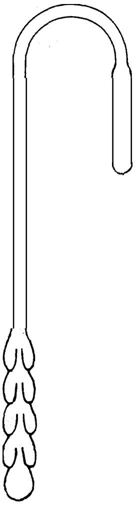

Fig. 2.—Device for ice calorimetry of heat of vaporization.

The heat of evaporation of the liquid at 0° was obtained by allowing a known quantity to evaporate slowly out of an ice calorimeter. The acid was sealed into a device illustrated in Fig. 2. The technique used in measuring and transferring the acid to this device was the same as that which had been used in filling the globes in which the vapor density had

been determined. The lower bulb contained a series of traps designed to hold the acid in several pools, in order to distribute the absorption of heat along the length of the calorimeter tube. In use, the acid was all collected in the lower tube, which was then inserted in the calorimeter. When equilibrium was established, the upper tube was cooled to about $-3°$, causing the acid to distil over in from one to two hours. Trials with water had showed that this procedure gave values correct within 1 In order to avoid errors in measurement and transfer, two samples of acid were used.

In determining the heats of vaporization at higher temperatures, it seemed important to use a condensation method, instead of the usual scheme in which the energy required to boil away a certain quantity of liquid is determined. For in the usual method decomposition is to be feared, especially if the boiling is produced by a hot platinum wire, and the heat absorbed by decomposition will be added to the true heat of vaporization, producing a positive error. A method was, therefore, devised in which a known amount of cold mercury was introduced into a bulb which was bathed in the saturated vapor, and the quantity of condensed liquid measured by volume. Figure 3 is a sketch of the apparatus. The vapor rises from liquid acid boiling in the bulb B, and is condensed by a reflux condenser attached at C. The pear P is heated by the vapor to the boiling point, and the condensate drips off into the calibrated tube T, where its level is read by a cathetometer. The pear is shielded from liquid running down from the condenser by the umbrella U. The rod R serves to carry the condenser liquid to the stem of the umbrella without splashing; it then runs over the surface and down the rods attached to the pointed tips, finally dropping off from the goose-neck bends just below the opening of T. It was found that when the pear had once been brought to the boiling point, no change in level in T occurred, showing that the shielding was adequate. The apparatus was constructed with a ground joint at G, but this joint was never opened in use, but was kept sealed with mercury. The acid was introduced or withdrawn by distillation through the top of the condenser, which was sealed to the main purifying and storage apparatus. Provision was made for admitting dry air at atmospheric pressure, or at a pressure controlled by a manostat.

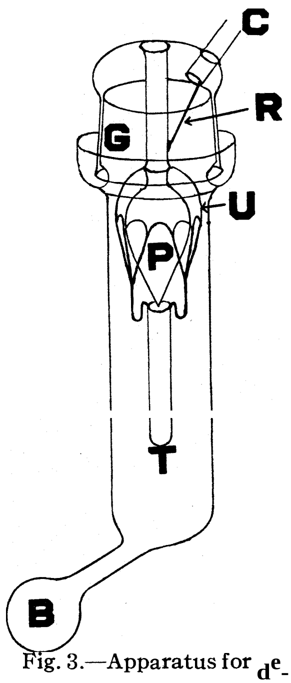

Fig. 3.—Apparatus for determining heat of vaporization.

Mercury from a water-jacketed pipet was then suddenly injected into P. The pipet was provided with *a* nozzle through which the mercury was forced by compressed air, the stream being so directed as not to touch the walls of the stem. As the nozzle was bathed in the water of the jacket, the only opportunity for the mercury to absorb heat prematurely was from the warm air in the stem, and the quantity so absorbed during the five or six seconds required to empty the pipet must have been very small. An obvious improvement would have been to evacuate the pear and its stem. When the level of liquid in T had again become constant, it was read, and the exact temperature of the mercury in P taken by introducing a thermometer. The weight of acid was calculated from the known volume of the tube, with the aid of the expansion formulas of Pierre and of Zander,[11] which agree sufficiently for the purpose.

A specimen calculation is as follows

Weight of mercury	268 g.
Original temperature	10 4°
Final (boiling) temp.	42.2"
Heat absorbed by mercury	282.8 cal.
Original height in T	830.6 mm.
Final height	859 8 mm.
Corresponding volume	2 23 cc.
Density of acid at 42.2°	1.195
Weight condensed	2.666 g.
Heat of evap. per gram	106.0 cal.

In working at atmospheric pressure, a serious difficulty arose. The liquid collected in the tube T, being maintained at about 100°, began to decompose spontaneously, with escape of bubbles. This interfered with reading the level of the liquid, not only because of uncertainty as to the volume occupied by the bubbles, but because they carried away considerable acid, causing the level to fall rather rapidly. (It was at first thought that this phenomenon was caused by insufficient purification of the acid, causing a fractionation to occur, in which the more volatile fraction collected in the tube, and was actually boiled away by immersion in the hotter vapor from the less volatile residue, but repeated purification caused no diminution in the rate at which the bubbles evolved. The experiment with acid confined under mercury was then carried out in order to prove actual decomposition.) No way was found to avoid this difficulty, and the readings made at this temperature had to be corrected by admittedly uncertain estimates. They are, therefore, not as reliable as the others.

Table III contains the results of the directly determined heats of vaporization, together with the value given in "International Critical Tables."[12]

Application of the Clapeyron Equation

The heat of vaporization per gram, λ, should be given by the equation

$$\lambda = T\Delta v(\mathrm{d}P/\mathrm{d}T) \qquad (3)$$

Here Av is essentially the volume of one gram of saturated vapor, hence we may write

$$\Delta v = (1 - \eta)RT/MP \qquad (4)$$

where M is the apparent molecular weight at the particular pressure and temperature considered, and η is the ratio of the vapor density to that of the liquid, and constitutes a correction term which is negligible except at pressures approaching the atmospheric. The Clapeyron equation, therefore, takes the form

$$\lambda = -\frac{R\,\mathrm{d}\ln P}{M\,\mathrm{d}(1/T)}(1 - \eta) = -19.146\,\frac{\mathrm{d}\log P}{M\,\mathrm{d}(1/T)}(1 - \eta) \text{ joules per gram} \qquad (5)$$

It follows from Equation 1 that the value of d log $P/\mathrm{d}(1/T)$ for the solid is —3160. At the triple point M has the value 84.57 and η is negligible. The calculated heat of sublimation is, therefore, 716 joules per gram.

For the liquid, we have evidently

$$\mathrm{d}\log P/\mathrm{d}(1/T) = -1860 - T^2\,\mathrm{d}\Delta/\mathrm{d}T \qquad (6)$$

A being the deviation function plotted in Fig. 1. The coefficient can be read off the smooth curve. For the four temperatures at which direct measurements were made, the calculated heats of vaporization are as shown in Table IV.

TABLE IV

APPLICATION OF CLAPEYRON EQUATION

Temp., °C	0°	42.2°	64.5°	100.5'
$\mathrm{d}\Delta/\mathrm{d}T \times 10^4$.	9	−1	−2	−3.5
d log $P/\mathrm{d}(1/T)$	−1927	−1850	−1837	−1811
M..	85.51	80.28	77.30	72.55
$\eta \times 10^4$	....	....	7	20
λ, calcd.	432	441	455	477
λ, obs..............	430	445	458	483

The calculated heat of vaporization of the liquid at the triple point is 434 joules, that of the solid 716 joules, and therefore, by subtraction, the calculated heat of fusion is 282 joules; the observed value was 276, or perhaps a trifle higher. We may also calculate the heat of fusion at 0°, but the method is less simple, because in this case the vapor produced by the liquid is at a different pressure from that produced by the solid, and the joule heat has to be considered. Let H_s be the heat content of one gram of solid, and H_8 that of its saturated vapor, while H_f and H_{11} are the corresponding quantities for the liquid and its vapor. Then we wish to calculate $H_f - H_s$ (neglecting the fact that these quantities refer to slightly different pressures). We have calculated that $H_{11} - H_f$ is 432 joules at 0°, and $H_8 - H_s$ comes out 717 joules. We need to know

$$H_{11} - H_8 = \int_{8.22}^{11.16} \left(\frac{\partial H}{\partial P}\right)_T \mathrm{d}P \tag{7}$$

Now

$$(\partial H/\partial P)_T = v - T(\partial v/\partial T)_P = \left(\frac{\partial(v/T)}{\partial(1/T)}\right)_P = \frac{R}{P}\left(\frac{\partial(1/M)}{\partial(1/T)}\right)_P \tag{8}$$

and the last differential coefficient can be evaluated from the dissociation equations for the vapor, namely

$$\frac{P \times (92 - M)^2}{46(M - 46)} = K \tag{9}$$

$$\text{Log } K = 10.758 - 3092/T \tag{10}$$

(These equations are taken from the first paper. The constants of the second equation have been slightly altered in order that T may be calculated from an absolute zero of −273.1°C., instead of −273°, the round number having been used in the first paper. Through an error, the value of K at 70° is there given as 56.60; it should be 55.72.) Logarithmic differentiation of (9) gives

$$\frac{M^3}{(92 - M)(M - 46)} \times \left(\frac{\partial(1/M)}{\partial(1/T)}\right)_P = \frac{\mathrm{d}\ln K}{\mathrm{d}(1/T)} = -7120 \tag{11}$$

The average value of M at 0° between 8 and 11-mm. may be taken approximately as 85, and, therefore, over a small range in that vicinity, we may take $\partial(1/M)/\partial(1/T)$ as constant and equal to —3.2. Substituting in (8) and then in (7)

$$H_{11} - H_8 = -23.R \int_{8.22}^{11.16} \mathrm{d}\ln P = -8.1 \text{ joules per gram} \tag{12}$$

The calculated heat of fusion at 0° is, therefore, 717—432—8 = 277 joules, 5 joules less than at the triple point. This makes the specific heat of the liquid greater than that of the solid by 0.6 joule, a figure considerably lower than the 1 ± 0.2 given by direct measurement. .

Criticism and Discussion

It will be seen that the present data are thermodynamically consistent to as good an approximation as is ordinarily obtainable in such calculations. The vapor density data were found by Ramsperger and Porter[13] to be in complete agreement with their own. The vapor pressure data, while

---

[13] Ramsperger and Porter, THIS JOURNAL, 50, 3036 (1928).

more regular than those of the "International Critical Tables," are not greatly different, but the directly determined heats of fusion and vaporization, if correct, require a considerable revision of the accepted values. In their favor stands the fact that they are thermodynamically consistent with the vapor density and pressure data, while the values in "International Critical Tables" are not. It is to be noted that the "International Critical Tables" value for the heat of vaporization is based upon the work of three authors, of whom one[14] worked long ago, while the other two[15] used a platinum wire to boil the acid, which may have caused error through decomposition. Neither author mentions any special precautions observed with the acid, which was merely one of several substances investigated. As for the heat of fusion, Pettersson[16] worked at a low temperature, and by a method which is stated by "International Critical Tables" to give low results. The paper of Guillot[17] is not available, but in view of his statement about the specific heat of crystalline acetic acid,[10] it seems more than likely that his results were vitiated by premelting, causing the specific heat of the solid to appear too great and the heat of fusion too low. The present evaluation of the difference in the specific heats of the solid and liquid must be regarded as giving an orientating value only, but leaves little doubt that it is of the ordinary sign and magnitude.

Interpretation

In the case of a solid or liquid emitting a vapor of constant molecular weight, a plot of log P as ordinate against $1/T$ as abscissa yields a curve whose slope is at every point proportional to the heat of vaporization. The temperature coefficient of the latter depends on the difference between the coefficients $\partial H/\partial T$ for the two phases, evaluated under the restriction that the pressure shall be maintained equal to the saturation pressure. For substances which may be regarded as perfect gases or incompressible dense phases, these coefficients are equal to the specific heats at constant pressure. For solids, C_p is nearly equal to C_p of the vapor, so that the temperature coefficient is small and the vapor pressure curve is approximately straight. Liquids have higher C_p, causing their heat of evaporation to decrease with rising temperature, and the vapor pressure curves to be concave downward. The heat of vaporization of liquid formic acid has been shown to rise rapidly with the temperature, and this is due to the very high value of $\partial H/\partial T$ for the vapor. There is no simple exact interpretation of $\partial H/\partial T$, but its largest term is the heat absorbed when the temperature of the vapor is raised under the prescribed conditions; and this is abnormally great with formic acid be-

cause the heating produces dissociation of double into single molecules with great absorption of energy.

A simple calculation will show to what extent the abnormal temperature coefficient may be accounted for by this interpretation. We may conceive of evaporation as a stepwise process, in which double molecules of vapor are first produced by evaporation, after which a certain fraction of them dissociate, absorbing heat at the rate of 14,125 calories per mole (value given in first paper) or 645 joules per gram. The whole process is conceived as isopiestic. Now, at 0°, only 7.6% of the saturated vapor is dissociated, so that, when 1 gram evaporates, 49 joules can be referred to dissociation. At 100° the figures are 30% and 194 joules, so that we might expect the heat of vaporization to be 145 joules higher at 100° than at 0°. Actually, it is only about 50 joules greater, because, superposed on the increase caused by dissociation in the vapor, we have also the normal decrease characteristic of all liquids. By adding to the actual heats of vaporization the calculated heats required to complete the dissociation of the vapor into single molecules, we may determine the heat of evaporation of single molecules from the actual liquid. The same result may be obtained by calculating the partial pressure of single molecules in the saturated vapor at various temperatures and applying the Clapeyron equation. Expressing the result in joules per mole (46 g.), we obtain 47,200 at 0° and 42,800 at 100°, a decrease of 4400. It is interesting to compare these figures with those for water, which in the liquid state is in many ways similar to formic acid, but which produces a monomolecular vapor on evaporation. For water, the heat of vaporization is 44,900 joules per mole at 0° and 40,700 at 100°, a decrease of 4200. The similarity in the figures is striking, and shows clearly how the actual temperature coefficient for formic acid is compounded of a positive term due to molecular association in the vapor, and the normal negative term. The latter may be interpreted as due to the excess of C_p for the liquid over the C_p which the vapor would possess if the equilibrium were frozen.

Although the latent heat increases with temperature, the vapor pressure curve is markedly concave downward. This is, of course, due to the variability of M in the Clapeyron equation. An inspection of Equation 5 together with Table IV shows that in determining the value of $d \ln P/d(1/T)$ at increasing temperatures, the decrease in M outweighs the increase in λ.

The vapor pressure curve of the solid presents an interesting case. Let us write Equation 9 in the form

$$P \times \varphi(M) = K$$

where $\varphi(M)$ is a function of M alone. Now, taking the value of K from Equation 10 and that of P from Equation 1, we see that they have nearly the same temperature coefficient, so that M is nearly independent of temperature. As a result the curve will be of the same type obtained with other solids, and will be almost straight. The specific heat of the saturated vapor will contain only a small term due to association. This small term is of opposite sign to that which occurs in the case of the liquid, for the saturated vapor of the solid undergoes a slight increase in association when heated, due to the very rapid rise in pressure. Assuming C_p for the solid equal to C_p for the vapor with frozen equilibrium, we shall have a slight fall in the heat of sublimation with rising temperature.

While the heat of sublimation probably falls, and the heat of evaporation rises with the temperature, the heat of fusion rises, instead of falling, as it must do if it were, as in the ordinary case, the difference between the other two. We have seen already that this is due to the presence of a term $H_{11} - H_8$, which is usually zero. This term may also be interpreted as due to variation in the degree of dissociation. Thus, at 0° the liquid produces a vapor 7.6% dissociated; the vapor from the solid is 9.1%, and conversion of one into the other involves some 9 joules of dissociation heat. (The thermodynamic evaluation gave 8 joules.)

Summary

The vapor pressure of pure formic acid, both solid and liquid, has been carefully determined between -5 and 110°.

The heat of vaporization of the liquid, and the heat of fusion of the solid, have been determined with moderate accuracy at several temperatures.

The values so found are thermodynamically consistent among themselves, but differ, sometimes considerably, from previously accepted values.

It is shown that the differences in thermal behavior between formic acid and substances producing normal vapors, especially water, are just those to be expected when account is taken of the heat absorbed or supplied by shifting of the dissociative equilibrium in the vapor.

THE DETERMINATION OF CALCIUM BY IGNITION OF CALCIUM OXALATE TO CARBONATE IN AIR

BY H. H. WILLARD AND A. W. BOLDYREFF

RECEIVED FEBRUARY 10, 1930 PUBLISHED MAY 8, 1930

Introduction

Because of its practical importance the quantitative determination of calcium has received a great deal of attention, and the various methods described in the literature have been made the subject of exhaustive critical study. Winkler[1] has tested and reviewed a number of methods, recommending, as the most reliable, precipitation as oxalate followed by ignition to oxide. Szebelledy,[2] continuing Winkler's work, recommends drying the precipitated oxalate to $CaC_2O_4 \cdot H_2O$. Ewe[3] compared experimentally ten standard methods, and determined their relative merits.

It is obvious that by using the proper temperature precipitated calcium oxalate, theoretically at least, can be changed quantitatively into any of the following forms: $CaC_2O_4 \cdot H_2O$, CaC_2O_4, $CaCO_3$ or CaO.

Weighing as $CaC_2O_4 \cdot H_2O$ always involves the danger of a slight variation in the water content; weighing as CaC_2O_4 is objectionable because of its hygroscopicity, and the errors in weighing CaO are too well known to need mentioning.

In spite of its advantages, the ignition of calcium oxalate to carbonate in air has never been satisfactorily studied. The proper temperature range has never been accurately determined, and the conditions given are usually such that the precipitate is partly converted to oxide, which must then be changed to carbonate by treating it with ammonium carbonate and igniting gently. This method was originally proposed by Fresenius[4] and studied by Irby,[5] Fram,[6] Brunck[7] and Canals,[8] the latter four authors contributing but little to the procedure of Fresenius.

In view of the fact that no thoroughly reliable procedure has yet been described, it is not surprising to find in standard books on analysis such obviously incorrect statements as "At 500°, the oxalate begins to decompose, free carbon is liberated and calcium carbonate begins to form,"[9]

while some authorities[10] are inclined to believe that while in careful hands the method will give accurate results, it requires much more careful attention than the oxide method, and hence will not commend itself widely.

Recent investigators, Foote and Bradley[11] and de Groot,[12] apparently believed that the only safe procedure was ignition in an atmosphere of carbon dioxide in a Rose crucible.

From Johnston's[13] measurements of equilibrium pressures of the thermal dissociation of calcium carbonate and from the partial pressure of carbon dioxide in air,[14] it can be shown that calcium carbonate is stable in air up to about 520". Likewise, the oxalate can be completely changed into carbonate by a prolonged ignition at a temperature as low as 430° as was shown by Irby.[5] It is to be expected, therefore, that conditions can be found under which ignition in air will result in complete and rapid conversion of calcium oxalate into carbonate, without any danger of decomposition of the latter into oxide. The purpose of this work was to investigate these conditions and the errors involved because, from the authors' experience, the precipitate is best weighed in this form.

Experimental

As a standard in this work, Kahlbaum's "Iceland Spar," consisting of **99.95%** calcium carbonate with magnesium and ferrous carbonate as main impurities, was used. The composition was checked by ignition of oxalate to oxide and by titration of oxalate with ceric sulfate.[15]

Samples ranging in weight from **0.2** to **0.9** g. were dissolved in **25** cc. of **1**:4 hydrochloric acid and the solution was diluted to **200** cc. Calcium oxalate was precipitated from the hot solution by adding to it slowly and with constant stirring twice the theoretical amount of pure ammonium oxalate, dissolved in **25** to **50** cc. of water, after which the solution was made just alkaline to methyl red by adding slowly with constant stirring a freshly filtered solution of **1:5** ammonium hydroxide. The solution was kept hot for two hours, filtered through **a** porcelaia filtering crucible (Type A2),[16] and the precipitate washed, either with hot 0.5% ammonium oxalate solution, or with cold water. The crucible containing the precipitate was dried at **110°**, and then ignited.

The ignitions were carried out in a Simon–Miiller crucible furnace[17] the temperature of which could be kept constant within less than 5° by maintaining a constant current through the heating coil with an accurate ammeter and a variable resistance in the circuit. This furnace was carefully calibrated in terms of current by means of a calibrated platinum–platinum-rhodium thermocouple, and the temperature–current calibra-

tion curve was repeatedly rechecked during the process of this investigation. A number of ignitions were also carried out in a large electric muffle, calibrated in a similar way.

Ignitions were carried out at 350, 400, 450, 500, 550 and 600°, using two different samples at each temperature. In this series the crucible with the precipitate was ignited for one hour, cooled in a desiccator and weighed inside a closed weighing bottle, using a similar weighing bottle for counterpoise. It was then ignited for one hour longer, cooled, weighed and the process repeated once more. The results are given in Table I.

TABLE I

IGNITION OF CALCIUM OXALATE BETWEEN 350 AND 600°

No.	Iceland spar, g.	Temp. of ignition, °C.	Time of ignition, hours	Precipitate, g.	Wt. $CaCO_3$ (theory), g.	Error, mg.
1	0.6174	350	1	0.7594	0.6171	+142.3
			2	.7374		+120.3

			3	.7160		− 65.6
2	.8432		1	.8153	.8428	− 27.5
			2	.7929		− 49.9
			3	.7783		− 64.5

Even at as low a temperature as 400°, a three-hour ignition gives practically quantitative results, if the sample is not too large. At 450 and 500°, respectively, one-hour ignition suffices for quantitative conversion into carbonate, but at 550° and above the results are low due to formation of oxide.

Calcium oxalate ignited in this way gives a product which is perfectly white in color. When, however, the precipitate is filtered through filter paper, which can be completely burned off in a muffle at 500° in thirty minutes, and then ignited for from one to twenty-four hours, the precipitate is gray, and the results are *2* to **3** mg. high, depending on the size of the sample. Ignition of C. P. calcium oxalate as purchased likewise results in the formation of a product which is gray in color.

The formation of this impurity has hitherto been explained on the assumption that the decomposition of oxalate results in the formation of a small amount of carbon.[9]

Since in our procedure no formation of this product took place, no attempt was made to determine its nature. It seems doubtful, however, that this product, so resistant to heating in air, is carbon, and it is suggested that it might be a stable polymer of carbon suboxide formed in decomposition of the oxalate.[18]

The influence of time of ignition at 500° is shown in Table II, which is self-explanatory.

TABLE II

IGNITION OF CALCIUM OXALATE AT 500°

No.	Iceland spar, g.	Time of ignition	Precipitate, g.	$CaCO_3$ (theory), g.	Error mg.
1	0.2194	30 min.	0.2192	0.2193	−0.1

The recommended procedure for the determination of calcium (in solutions of its pure salts) is as follows. Precipitate the oxalate by adding to the hot acid solution twice the theoretical amount of ammonium oxalate (or oxalic acid), and slowly neutralize with 1:5 ammonium hydroxide, using methyl red as indicator. Let the solution stand on the hot-plate

---

[18] Cf. Mellor, "A Comprehensive Treatise on Inorganic and Theoretical Chemistry," Longmans, Green and Co., London, 1924, Vol. V, pp. 904–907.

for two hours, filter through a filtering crucible (or a Gooch), dry at 110° for thirty minutes and ignite in an electric muffle for one hour at a temperature between 475 and 500°. For the separation of calcium from other elements the usual methods are applicable, followed by ignition to carbonate as above.

This method has been used in this Laboratory for the last three years, both in research work and by the students in quantitative analysis, and has given very satisfactory results.

When an accurate thermocouple is not available, the furnace can be adjusted to the right temperature in the following simple way. Silver chloride melts at 455° and lead chloride at 501°; thus the correct temperature can be easily obtained by adjusting the oven to such a temperature that silver chloride will melt, but not lead chloride. The melting point can be detected with the following device. In a small pyrex tube sealed at one end place some anhydrous silver chloride powder (or lead chloride); insert into the tube two electrodes, made by sealing into pyrex tubes short pieces of platinum wire with copper wire leads, so that the ends of the electrodes reach the bottom of the tube containing the powder, but do not touch each other. The electrodes can be kept in place by putting between them and wrapping around them a piece of asbestos paper, so that the whole fits tightly into the glass tube. The "melting point detector" so prepared (see Fig. 1) is placed inside the oven, with the leads going outside and connected in series with two dry cells and a small flash-light bulb. At the melting point the molten mass establishes an electrical connection between the electrodes and the light glows. A fresh detector has to be used each time, since the anode is strongly attacked by chlorine.

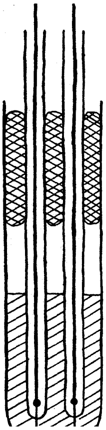

Fig. 1.—Melting point detector.

By the proper choice of material this simple method could be used to adjust the furnace to any desired temperature. It was tested in connection with this work and found to give very satisfactory results.

Summary

1. Ignition of calcium oxalate in air was studied at 350, 400, 450, 500, 550 and 600°.

2. Between 450 and 500° the oxalate is quantitatively converted into carbonate in one to two hours. This is made the basis of an accurate method for the gravimetric determination of calcium.

3. A simple method is described for adjusting a furnace to a desired temperature by utilizing the melting points of suitable salts.

THE MICRO DETERMINATION OF HALOGENS AND METALS IN ORGANIC COMPOUNDS

BY H. H. WILLARD AND J. J. THOMPSON

RECEIVED FEBRUARY 15, 1930 PUBLISHED MAY 8, 1930

Hitherto, the Carius method has been the only accurate one available for the determination of halogens in all types of solid and liquid organic compounds. The method recently described by Thompson and Oakdale[1] has proved so accurate and satisfactory, even in the case of volatile liquids, that it seemed desirable to apply it to the micro determination of halogens. For the micro procedure we have devised a much more compact apparatus and as a result the method has become simpler and more rapid. A complete analysis, from the time of weighing the sample until the weight of silver halide is obtained, requires only forty-five to sixty minutes.

The principle involved is, as stated previously,[1] the use of fuming sulfuric acid as oxidizing agent, to which in certain instances persulfate is added. Any halide formed is then oxidized by permanganate or hydrogen peroxide to free halogen, which is absorbed in alkaline arsenite and subsequently precipitated as silver halide.

The micro determination is so simple, rapid and accurate that it seems likely to replace the classical Carius method.

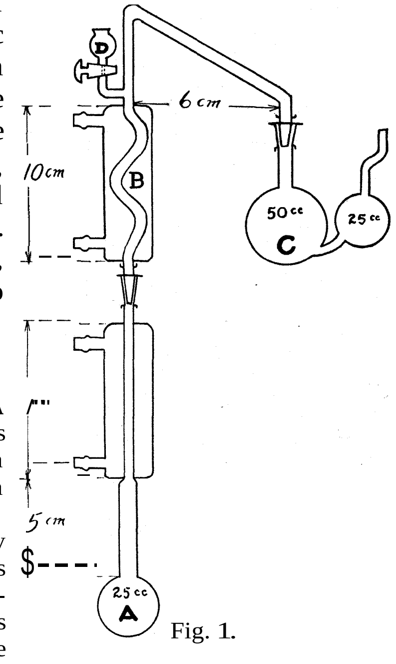

Fig. 1.

Experimental

The samples used weighed 15–25 mg. A micro balance was not required and weighings accurate to 0.01 mg. were quickly made on a Bunge air damped balance, type 4 DM, with a capacity of 200 g.

The apparatus used, which is made entirely of pyrex glass, is shown in Fig. 1. It consists of a 25-cc. flask provided with two small condensers and connected to two absorption bulbs by means of ground-glass joints, 7 mm. inside diameter. A small dropping funnel is fused to the top of the condenser.[1a] For much smaller samples the size of the apparatus can be reduced.

The Determining of Chlorine and Bromine.—If the compound is a solid, a sample of approximately 20 mg. or less is weighed into a micro beaker, about 6 X 7 mm., made from pyrex glass tubing. The sample and beaker are transferred to the decomposition flask

---

[1] Thompson and Oakdale, THIS JOURNAL, 52, 1195 (1930).

[1a] This apparatus can be purchased from the Arthur H. Thomas Co., Philadelphia.

(A), Fig. 1. Five-tenths g. of potassium persulfate is then added[2] together with a few glass beads and a little copper sulfate. Section (B) is connected, and water passed through the condensers.[3] The absorption flask (C) contains 0.1 g. of arsenic trioxide to reduce halogen to halide,[4] 1 g. of chlorine-free sodium hydroxide and 15 cc. of water. Through the dropping funnel (D) 4 cc. of fuming sulfuric acid containing 20% SO_3 is added and the mixture is allowed to digest for fifteen minutes, keeping the sulfuric acid boiling gently. Then 5 cc. of concd. sulfuric acid (sp. gr. 1.84) is added. After the acid has become colorless and while it is boiling gently, an excess of a saturated solution of permanganate is added (2 cc. is usually sufficient), then 5 cc. of water. At this stage the condensers are emptied and the solution boiled until sulfur trioxide fumes appear. The apparatus is disconnected immediately, to prevent the joints from freezing, the contents of the absorption flask are transferred to a 100-cc. beaker and neutralized with dilute nitric acid (sp. gr. 1.10), using methyl orange as indicator. An excess of silver nitrate is added, then concd. nitric acid (sp. gr. 1.42) until there is an excess of 2 cc. The solution is boiled to coagulate the silver halide and filtered through a filtering crucible with a porous porcelain bottom,[5] washed with 1% nitric acid, then with acetone, dried at 135° and weighed.

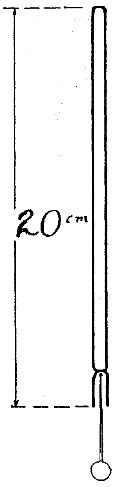

Fig. 2.

When liquid halogen compounds are to be analyzed, thin-walled bulbs are prepared. A bulb is filled by placing it and the liquid in a special apparatus.[1] The apparatus is evacuated through a side arm and then upon allowing the air to enter the apparatus the bulb is filled. Since the latter is too light to break by falling, it must be crushed somehow. A pyrex glass tube sealed off at both ends but having a pocket on one end to hold the stem of the bulb is used for this purpose (see Fig. 2). The bulb stem is placed in the pocket and then inserted into the flask which already contains the sulfuric acid, etc., and which is held horizontally. Care must be taken that the bulb does not fall out of the pocket. Both tube and crushed bulb are left in the apparatus until the determination is completed.

When chloroform or carbon tetrachloride is analyzed by this process, gaseous halogen compounds escape before complete reaction with sulfur trioxide occurs. This difficulty is surmounted by placing a narrow-bore quartz tube, about 20 cm. long, between the condenser and decomposition flask. Connection is made by heavy black rubber tubing. Heating the central portion of the tube to a red heat decomposes any organic halide gas and the halogen is completely absorbed.

The results of analyses of chlorine and bromine compounds are shown in Tables I and II. All the compounds used in this work were specially purified.

Determination of Iodine.—The procedure is identical with that for chlorine and bromine, except that no persulfate is added and an excess

---

[2] Since the persulfate is usually contaminated with perchlorate, some of it being quite unfit for use, a blank determination is made, using a halogen-free organic compound, such as starch.

[3] All joints are well lubricated with a viscous paste, made by mixing phosphorus pentoxide with warm, sirupy phosphoric acid. See also Stephens, THIS JOURNAL, 52, 635 (1930). Rubber bands are used on the glass hooks.

[4] Honigschmid and Zintl, *Ann.*, 433, 201 (1923).

[5] These crucibles (type A1 is densest) are manufactured by the Staatliche Porzellan Manufaktur, Berlin. They were cut down to a height of approximately one centimeter and then weighed about 3 g.

of halogen-free 10% hydrogen peroxide is used instead of permanganate. If persulfate is used, oxidation to non-volatile iodic acid occurs. The oxygen liberated from the peroxide expels the iodine from the apparatus and the hydriodic acid usually present is oxidized to free iodine. When a substance containing a very high percentage of iodine, such as iodoform, is analyzed in this way, some iodic acid is formed, due to insufficient organic reducing material. This may be remedied in either of two ways: first, by preventing the formation of iodic acid by adding 0.05 g. of starch to the iodine compound before decomposition begins; or, second, if iodic acid is formed, it is reduced, after all the iodine has been expelled from the apparatus, by adding a solution of hydrazine sulfate, followed by an excess of peroxide. For iodine determinations the dropping funnel (D) is conveniently sealed at the top of condenser (A) instead of (B).

TABLE III

RESULTS OF ANALYSES

Micro Determination of Metals in Metallic Organic Halides.—If metals are to be determined the procedure is the same except that copper sulfate need not be added. Arsenic was determined in diphenylarsyl iodide in the following manner. The residual liquid in flask (A) after removal of halogen was transferred to a 150-cc. conical flask, the arsenic pentoxide was reduced to the trivalent state with sulfur dioxide, the solution diluted to 75 cc., boiled to remove the excess, 10 cc. of concd. hydrochloric acid was added and the arsenic trioxide titrated at 80° with $N/100$ potassium bromate, using methyl orange as indicator.[6]

If only arsenic is to be determined it is best to decompose the compound and reduce the arsenic entirely in the original flask (A). The iodine is expelled with 30% hydrogen peroxide and the arsenic pentoxide is reduced by adding an excess of solid hydrazine sulfate,[7] which in turn is destroyed by heating the solution to 250° for ten minutes. Antimony in diphenylstibyl iodide is determined in the same manner as the arsenic. The results are shown in Table IV.

TABLE IV

$C_{12}H_{10}SbI$	20.32	30.23 Sb	29.98
$C_{12}H_{10}AsI$	19.59	21.05 As	21.25
$C_{12}H_{10}AsI$	34.03	21.05 As	20.96
Selenium and $CHBr_3$	26.42	97.87 Se	97.72

It seemed desirable to apply this method to the determination of selenium in organic compounds containing halogens. Because no organic compound containing selenium was available, pure selenium powder was mixed with bromoform and the mixture decomposed by heating with 2 cc. of fuming and 3 cc. of concd. sulfuric acid. The bromine was liberated by permanganate and absorbed as usual. The selenic acid remaining in the flask was determined by reduction to metallic selenium[8] with an excess of hydroxylamine hydrochloride and determined gravimetrically. No volatilization of selenium occurred in the presence of bromine. Results are shown in Table IV.

Summary

1. A micro method has been described for the determination of halogens in solid or liquid organic compounds, based upon oxidation of the sample with fuming sulfuric acid. The halogen is distilled into alkaline arsenite and then precipitated as silver halide.

AN APPLICATION OF MOVING BOUNDARIES TO A STUDY OF AQUEOUS MIXTURES OF HYDROGEN CHLORIDE AND POTASSIUM CHLORIDE

BY L. G. LONGSWORTH[1]

RECEIVED FEBRUARY 18, 1930 PUBLISHED MAY 8, 1930

Introduction

The purpose of this research was the measurement of the mobilities of the various ion constituents in aqueous mixtures of hydrogen and potassium chlorides. Since the conductances of such solutions do not follow the law of mixtures, it appeared of interest to determine which ion constituents were responsible for these deviations. The moving boundary method was employed in these determinations, boundaries of the rising type being used exclusively. The results, as will be shown below, are also of interest in connection with the recent work on the separation of the rare earth elements by the ionic migration method.[2]

Theoretical

The electrolysis of a mixture of hydrogen and potassium chlorides, using, for instance, a cadmium anode as the source of indicating cations, may be represented diagrammatically as follows. The use of the metallic anode in this manner is the method of Cady and Longsworth,[3] though the source of indicating ions may also be a solution of an appropriate electrolyte. Both methods were employed in these experiments. The tube is initially filled throughout with the mixture of uniform composition as shown in Fig. 1. After current has passed for a time, the hydrogen-ion constituent originally in the lower part of the tube will, due to its high mobility, have forged ahead of a portion of the potassium-ion constituent, and there should be the two boundaries, A and B, as shown in Pig. 2. These two boundaries have been observed and their separate progress has been followed quantitatively.

The boundary A divides the mixture originally placed in the tube from a region of pure potassium chloride. This boundary travels with a velocity determined by the mobility of the hydrogen-ion constituent and the potential gradient in the mixture.

The slower boundary B is the usual boundary between the indicating electrolyte formed by the electrochemical oxidation of the cadmium anode and a pure potassium chloride solution. The boundary B travels with a velocity determined by the mobility of the potassium-ion constituent and the potential gradient prevailing at the "adjusted" concentration C'_{K} of the region between the two boundaries. This adjusted concentration can be computed from the expression

$$\frac{C'_{\mathrm{K}}}{T'_{\mathrm{K}}} = \frac{C_{\mathrm{H}}}{R_{\mathrm{H}}} + \frac{C_{\mathrm{K}}}{R_{\mathrm{K}}}$$

in which C denotes concentration, T the transference number and R is a function of the ion mobilities. A derivation of this expression follows.

Throughout this treatment the velocity of an ion constituent will be used. This velocity is a measurable quantity. The velocity of an individual ion cannot, at present, be determined experimentally. If the electrolyte is completely dissociated, the velocity of an ion constituent is identical with the individual ion velocity. If incompletely dissociated, the two velocities differ by a factor equal to the degree of dissociation

Let V_{H} represent the observed velocity of the hydrogen-ion constituent and U_{H} the mobility of this ion constituent, then

$$V_{\mathrm{H}} = U_{\mathrm{H}}\frac{\mathrm{d}E}{\mathrm{d}x}, \textit{ and } A_H = FU_{\mathrm{H}}$$

where Λ_{H} is the conductance of 1 g. equivalent of hydrogen ion. F is the faraday in coulombs if U_{H} is expressed in practical units. The total hydrogen-ion concentration in gram equivalents per milliliter of solution is denoted by C_{H} and the same symbols with appropriate subscripts refer to corresponding quantities for the potassium- and chloride-ion constituents. If A is the (uniform) cross-sectional area in square centimeters of the tube in which electrolysis is taking place, the current flowing in the tube is

$$I = FA(C_{\mathrm{H}}V_{\mathrm{H}} + C_{\mathrm{K}}V_{\mathrm{K}} + C_{\mathrm{Cl}}V_{\mathrm{Cl}}) \tag{1}$$

The electro-neutrality of the solution is expressed by

$$C_{\mathrm{H}} + C_{\mathrm{K}} = C_{\mathrm{Cl}} \tag{2}$$

If x denotes distance along the tube, the quantity of hydrogen ion, Q_{H}, passing through a given cross section at x in At seconds is

$$Q_H = (AC_{\mathrm{H}}V_{\mathrm{H}})\Delta t \tag{3}$$

and at x + Ax

$$Q_{\mathrm{H}} + \Delta Q_{\mathrm{H}} = \left[(AC_{\mathrm{H}}V_{\mathrm{H}}) + \frac{\partial}{\partial x}(AC_{\mathrm{H}}V_{\mathrm{H}})\,Ax\right]\Delta t \tag{4}$$

The change in hydrogen-ion content within the region between x and x + Ax is given by the difference between (3) and (4)

$$\Delta Q_{\mathrm{H}} = -\frac{\partial}{\partial x}(AC_{\mathrm{H}}V_{\mathrm{H}})\Delta x\Delta t$$

Since the corresponding concentration change, ΔC_{H}, is equal to ΔQ_{H} divided by the volume, $A\Delta x$, in which the change occurs

$$\Delta Q_{\mathrm{H}} = A\Delta x\Delta C_{\mathrm{H}} = -\frac{\partial}{\partial x}(AC_{\mathrm{H}}V_{\mathrm{H}})\Delta x\Delta t \tag{5}$$

In the limit, Equation 5 becomes

$$A\frac{\partial C_{\mathrm{H}}}{\partial t} + \frac{\partial}{\partial x}(AC_{\mathrm{H}}V_{\mathrm{H}}) = 0 \tag{6}$$

and similarly for the potassium-ion constituent

$$A\frac{\partial C_{\mathrm{K}}}{at} + \frac{a}{at}(AC_{\mathrm{K}}V_{\mathrm{K}}) = 0 \tag{7}$$

Multiply (6) by $F(V_{\mathrm{H}} + V_{\mathrm{Cl}})/V_{\mathrm{H}}$ and (7) by $F(V_{\mathrm{K}} + V_{\mathrm{Cl}})/V_{\mathrm{K}}$, assuming the ratios $(V_{\mathrm{H}} + V_{\mathrm{Cl}})/V_{\mathrm{H}}$ and $(V_{\mathrm{K}} + V_{\mathrm{Cl}})/V_{\mathrm{K}}$ to be independent of the concentration, and add the resulting equations

$$AF\frac{V_{\mathrm{H}} + V_{\mathrm{Cl}}}{V_{\mathrm{H}}}\frac{\partial C_{\mathrm{H}}}{\partial t} + AF\frac{V_{\mathrm{K}} + V_{\mathrm{Cl}}}{V_{\mathrm{K}}}\frac{\partial C_{\mathrm{K}}}{\partial t} + \frac{\partial}{\partial x}[FAC_{\mathrm{H}}(V_{\mathrm{H}} + V_{\mathrm{Cl}})] + \frac{\partial}{\partial x}[FAC_{\mathrm{K}}(V_{\mathrm{K}} + V_{\mathrm{Cl}})] = 0$$

Collecting terms and setting $1/R_{\mathrm{H}} = (V_{\mathrm{H}} + V_{\mathrm{Cl}})/V_{\mathrm{H}}$ and $1/R_{\mathrm{K}} = (V_{\mathrm{K}} + V_{\mathrm{Cl}})/V_{\mathrm{K}}$,[4]

$$\frac{AF}{R_{\mathrm{H}}}\frac{\partial C_{\mathrm{H}}}{\partial t} + \frac{AF}{R_{\mathrm{K}}}\frac{\partial C_{\mathrm{K}}}{\partial t} + \frac{\partial}{\partial x}[FA(C_{\mathrm{H}}V_{\mathrm{H}} + C_{\mathrm{K}}V_{\mathrm{K}} + C_{\mathrm{H}}V_{\mathrm{Cl}} + C_{\mathrm{K}}V_{\mathrm{Cl}})] = 0 \tag{8}$$

From *(1)* and (2) it is seen that the bracketed expression in (8) is the current **I**, and since this is uniform throughout the tube

$$\frac{\partial I}{\partial x} = 0$$

The resulting differential equation can then be integrated to give

$$\frac{C_{\mathrm{H}}}{R_{\mathrm{H}}} + \frac{C_{\mathrm{K}}}{R_{\mathrm{K}}} = \text{constant} + f(x) \tag{9}$$

This corresponds to, but is not identical with, the "beharrlichen" function of Kohlrausch.[5] For any given value of x it retains its initial value (neglecting diffusion and convection) throughout electrolysis. If the composition of the solution originally present in the tube is uniform, $f(x)$ also becomes constant. Application of this function, which will henceforth be termed the "regulating" function, to the experiments described here yields the relation

$$\frac{C_{\mathrm{H}}}{R_{\mathrm{H}}} + \frac{C_{\mathrm{K}}}{R_{\mathrm{K}}} = \frac{C'_{\mathrm{K}}}{T'_{\mathrm{K}}} = \text{constant} \tag{10}$$

---

[4] The symbol R is identical with the transference number for a simple binary electrolyte but is not the transference number of an ion constituent in a mixture. In the latter case the transference number is given by a more complicated expression; see D. A. MacInnes, THIS JOURNAL, 47, 1922 (1925).

[5] Kohlrausch, Ann. *Physik,* 62, 209 (1897).

The primed quantities in (10) refer to the region of pure potassium chloride solution between the two boundaries, A and B, Fig. 2.

In connection with this regulating function it should be pointed out that the derivations given by Kohlrausch[5] and von Laue[6] are based on the Arrhenius theory of solutions of electrolytes with the attendant assumption of constant ion mobility. Experimentally, the mobility of an ion constituent varies more rapidly with the concentration than does a ratio of these mobilities. Consequently the assumption of R independent of concentration is a more limited assumption than the constancy of the individual mobilities. Otherwise the treatment given here is similar to that of von Laue and the generalized Equation 5, page **332,** in his development is identical in form with Equation 9.

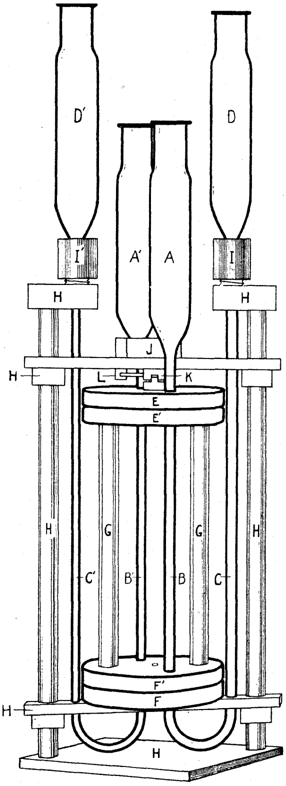

Fig. 3.

The Moving Boundary Apparatus

The cell used for these measurements in which the source of indicator ion is a solution is shown in Fig. **3.** The shearing mechanism of MacInnes and Brighton[7] was utilized for forming the boundary. The plate glass disks EE' and FF' are etched in the manner described by these authors and the electrode chambers AA'D and D' are designed according to their recommendations. Tubes B and B' are graduated[8] and calibrated tubes in which the motion of the boundary is observed. The system ABCD is quite independent of the system A'B'C'D', the tube B having an average cross-sectional area about twice that of B'. Only one of these tube systems is used in a determination. The glass disks E' and F', together with the brass supporting rods GG and the tubes BB', constitute an independent unit of the cell and may be removed for cleaning. By clamping this central unit to the lower disk F and turning E over E', boundaries may be formed which can reach the graduations by descending. On the other hand, clamping the central unit to the upper disk E and turning F' over F gives rise to boundaries that can be observed if they ascend the tube. The cell may thus be adapted for the study of either rising or falling boundaries, though all observations made in this paper were on the first mentioned type.

The parts H are of brass and constitute the supporting framework for the glass parts of the cell which are traced in heavier lines. I and I' are threaded bakelite couplings to permit removal of the electrode chambers D and D' for cleaning.

The manipulation using the tube system ABCD and observing a rising boundary is as follows. The plates E and E' are lubricated and clamped together with the tube B

[8] MacInnes, Cowperthwaite and Huang, *ibid.*, 49, 1710 (1927).

and chamber **A** in alignment. This unit is then filled with the solution whose transference number is to be determined. The tube C and chamber D are filled with solution of indicator electrolyte. Silver-silver chloride electrodes are introduced into the electrode chambers and, if necessary, a few milliliters of a more concentrated solution introduced around these electrodes. The disks F and F′ are then lubricated and pressed together with the protruding drops of solution from B and C in their respective recesses in the opposite disk, as described by MacInnes and Brighton.[7] The cell is then placed in a vibration-free thermostat and allowed to come to thermal equilibrium. Potential is then applied and the circuit tested to see that no current is flowing. The boundary is next formed in the following manner.

A coil spring **J** of phosphor bronze furnishes power for shearing the plate glass disks in initially forming the boundary. The brass coupling K transmits this power to the disk, also permitting the removal of the disk, E, together with the electrode chambers **AA'** which are sealed into it, for cleaning. **A** release mechanism L is operated by a flexible camera shutter cable (not shown in the diagram). This arrangement permits the turning of the plates and the formation of the boundary without starting vibration. The desirability of such an arrangement has been discussed by MacInnes, Cowperthwaite and Shedlovsky.[9] Upon the release of the spring tension, due to the viscosity of the lubricant between the plates, the plate F′, together with the cell units rigidly connected to it, smoothly turns about its center until tube B is exactly over tube C. The boundary is thus formed and starts to rise immediately, since the electrical circuit is now complete.

For rising boundaries where, according to the method described by Cady and Longsworth,[3] a metallic anode is used as the source of indicator ions, a similar cell was employed. It differs from the one just described in that a cylindrical recess was ground in the lower plate glass disk in which a small disk of anode metal was placed, and also in that no shearing mechanism is necessary.

The current through the cell was maintained constant throughout a determination by means of an improved constant current regulator.[10] This regulator is a modification of the apparatus used by MacInnes, Cowperthwaite and Blanchard,[11] modified so as to give a constant current in a circuit in which both increases and decreases of resistance may occur.

Materials and Purification.—The potassium chloride was recrystallized twice from conductivity water and fused in a platinum crucible. The hydrochloric acid was a pure product, diluted to constant boiling strength and distilled, the end fractions being rejected as recommended by Foulk and Hollingsworth.[12] The concentration of this constant boiling acid was interpolated from the data of these authors.

The materials used as indicators were treated as follows. The potassium iodate was recrystallized from water and dried over phosphorus pentoxide in *vacuo.* The sodium salt of iodeosin (tetra-iodofluorescein) was especially prepared by the makers and was further purified by four recrystallizations from water in this Laboratory. The cadmium metal and iodic acid were of a good grade and were not further purified.

Conductivity Measurements.—The conductances of the solutions were measured on the shielded bridge developed by Dr. Theodore Shedlovsky of these Laboratories Since this bridge has been described in a separate communication,[13] the following brief notes will suffice here. Pipet cells of the Washburn type were calibrated with 0.1 demal potassium chloride solution according to the recommendations of Parker and

Parker.[14] An audion oscillator operating at a frequency of 2000 cycles supplied the bridge current, which was amplified by two stages of audio frequency amplification before passing to the telephones. The bridge was of the direct reading type with equal ratio arms. The thermostat in which the conductivity cells were immersed was filled with oil. The temperature was maintained constant at 25 ± 0.002°. The temperature was determined by means of a carefully calibrated platinum resistance thermometer.

Rising Boundaries.—Since MacInnes, Cowperthwaite and Huang,[8] working with rising boundaries, observed convection currents due to heating, it seemed necessary to investigate this effect in detail. Their experiment with a rising boundary between potassium chloride and potassium permanganate, used as indicator electrolyte, was repeated and the same phenomena were observed. These were a diffuse color margin, and a "chimney" tinged with the purple color of the permanganate ion in the potassium chloride solution above the boundary. However, I have found that when the much heavier and less mobile iodeosin ion is substituted for the permanganate ion, an extremely sharp margin results with no trace of the intense red color of this ion in the colorless solution in advance of the boundary. The iodeosin ion has been used as an indicator by Franklin and Cady.[15]

If the mobilities of the chloride- and permanganate-ion constituents, and also the densities of the two solutions under the conditions of the experiment, are compared, it appears quite likely that the differences in these properties are not great enough to permit the development of an effective margin. An effective moving boundary results when the restoring effect due to the potential gradient change at the boundary is strong enough to overcome the disturbing effects of convection, diffusion and, possibly, electro-osmosis. The restoring effect has been described in a paper by MacInnes and Cowperthwaite.[16]

---

[14] Parker and Parker, THIS JOURNAL, 46, 312 (1924).

[15] Franklin and Cady, *ibid.*, 26, 499 (1904).

[16] MacInnes and Cowperthwaite, *Proc. Nat. Acad. Sci.*, 15, 18 (1929). These authors find experimentally that upon interruption of the current the two solutions forming the boundary begin to diffuse into each other. However, though the current may be interrupted for as much as thirty minutes, upon closing the circuit again the boundary reforms and soon recovers its original sharpness. After reformation and during the period between the reclosing of the circuit and the return to its original sharpness, the boundary moves at the correct velocity. The authors explain this restoring effect of the current as due to the change of potential gradient occurring at the boundary. The lower specific conductance of the indicator solution means a steeper potential gradient in this region. If a more mobile ion in front of the boundary diffuses into the indicator region, it will be subject to a steeper potential slope and will forge ahead of the surrounding less mobile indicator ions until it has regained the boundary. Conversely, if an indicator ion diffuses across the boundary into the region of lower potential slope prevailing in the solution under observation, it will, of necessity, lag behind until it has fallen back into the indicator region. This restoring mechanism of the potential gradient change at the boundary tends to keep the two ion constituents separated and the boundary sharp.

With rising boundaries mixing due to convection will be greater than with falling boundaries because with the former the hotter solution is underneath, an arrangement which tends to produce circulation in the cooler solution. Due to this greater tendency to mix, the restoring effect must, therefore, be greater in rising boundaries. However, mixing of the two solutions at the boundary will be decreased if there is a large difference in the density of those solutions. The choice of the proper indicator will, therefore, be a matter of experiment. For the determination of the anion mobilities in the solutions studied in this investigation, iodic acid and potassium iodate were used as the indicating electrolytes. The low mobility of the iodate-ion constituent and the high density of the solutions of its salts apparently eliminated the troubles, mentioned above, due to heating and convection.

One important advantage of rising boundaries over the descending type is the wider concentration range throughout which there is automatic concentration adjustment of the indicator solution. It is, therefore, not so necessary to make determinations at a series of indicator electrolyte concentrations as when working with falling boundaries. The data of Table I show the effect of indicator-ion concentration upon the observed anion transference number of potassium chloride at 0.1 normal or 0.1 g. equivalent per liter of solution. This unit of concentration differs from the one defined in the theoretical part by a constant factor of 10^{-3}, that is, for 0.1 normal potassium chloride, $C_{KCl} = 10^{-4}$. From Table I the transference number is seen to be independent of the concentration of the indicator solution of potassium iodate if the latter is between about 0.06 and 0.15 normal. A normality of about 0.06 is the value required by the "regulating" function applied to this simple boundary. To understand why concentration adjustment over such a wide range is not attained in the case of falling boundaries, let us consider the following comparison of the two methods.

TABLE I

THE EFFECT OF THE INDICATOR CONCENTRATION ON THE OBSERVED TRANSFERENCE NUMBER OF POTASSIUM CHLORIDE

Normality		dE/dx	
KCl	KIO_3	volts/cm.	T_a
0.1	0.05	3.086	[a]
.1	.066	3.692	0.5100
.1	.075	3.995	.5103
.1	.1	3.086	.5100
.1	.1	4.298	.5101
.1	.15	4.298	.5106
.1	.2	4.298	.5120

[a] Margin quite distorted and computed value of T_a changed from 0.532 at beginning of run to 0.513 at the close.

If a margin is formed between 0.1 normal potassium iodate and 0.1 normal potassium chloride, Fig. 4 represents the initial condition. On passage of a current the boundary will rise and after some time Fig. 5 will represent the new conditions in the tube. That is, a concentration gradient between 0.1 normal and 0.06 normal potassium iodate will remain at C. Since the relation of the densities d are $d_{0.1\,N\,\mathrm{KCl}} < d_{0.06\,N\,\mathrm{KIO_3}} < d_{0.1\,N\,\mathrm{KIO_3}}$, the lighter solution is on top and this distribution will not be disturbed by gravity. On the other hand, consider an analogous case for falling boundaries where the boundary is initially formed between 0.1 normal potassium chloride and 0.1 normal lithium chloride, Fig. 6. After the boundary has fallen some distance, Fig. 7 would represent conditions were it not for the fact that a denser solution of lithium chloride would' thus be left on top. These two solutions of lithium chloride would consequently tend to mix and destroy the concentration adjustment as fast as it was made. Both rising and falling boundaries are found, however, to give erroneous results when the indicator-ion concentration is initially too low.

Fig. 4.

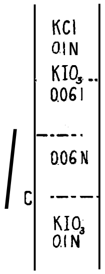

Fig. 5.

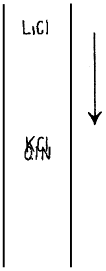

Fig. 6.

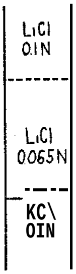

Fig. 7.

Experimental Results

Table II contains the results of transference measurements on the anion constituents. The chloride-ion concentration in all mixtures was maintained at 0.1 normal. The composition of the mixtures will be indicated by the ratio y of hydrogen-ion content to the chloride-ion content, that is, $y = C_{\mathrm{H}}/C_{\mathrm{Cl}}$ and $(1 - y) = C_{\mathrm{K}}/C_{\mathrm{Cl}}$. The indicator solutions for the anion constituents of the mixtures were made up to a total iodate-ion concentration of 0.1 normal, the ratio of hydrogen to potassium-ion content in these solutions being the same as that of the solution for which they were to serve as indicators.

TABLE II

CHLORIDE-ION CONDUCTANCE IN MIXTURES OF HYDROCHLORIC ACID AND POTASSIUM CHLORIDE AT A TOTAL CONCENTRATION OF 0.1 N AND 25°

Solution $C_{\mathrm{H}}/C_{\mathrm{Cl}}$	T_{Cl}	Λ	Λ_{Cl}	Λ_{Cl} (calcd.)
1.00	0.1693	391.28	66.32*	...
0.75	.2041	324.31	66.19	66.18
.50	.2560	258.07	66.07	66.03
.25	.3414	192.83	65.83	65.89
.00	.5101	128.89	65.75	...

The value of Λ_{Cl} marked with an asterisk is computed from the value of $T_{\mathrm{H}} = 0.8305$ recorded in Table III. This value is given preference since it is the mean of a larger number of determinations. Comparison of the results for the solutions of pure hydrogen chloride and pure potassium chloride as given in Tables 11, III and V shows that $T_c + T_a = 0.9998$ for the former and 0.9999 for the latter. The deviation from the theoretical value of unity is within the experimental error.

From Table II it is seen that Λ_{Cl} from 0.1 normal hydrogen chloride is slightly higher than from 0.1 normal potassium chloride. This is at variance with the constant value of Λ_{Cl} from these two salts found by MacInnes and Smith.[17] The author, however, has determined the chloride-ion conductance from a series of uni-univalent chlorides over the concentration range from 0.1 to 0.02 normal. The results deviate by a few tenths of one per cent. from the constancy found by MacInnes and coworkers at the higher concentration. These deviations from constancy tend to disappear, however, as the concentration is reduced. The chloride-ion conductance from these uni-univalent chlorides seems to be a function of the conductance of the co-ion.

The values of Λ_{Cl} quoted in the last column of Table II were computed on the basis of linear variation between the chloride-ion conductances in pure hydrogen chloride and pure potassium chloride solutions. The conductance of the chloride-ion constituent in the mixtures is thus seen to vary linearly between its values in the pure solutions. This is in complete agreement with the findings of MacInnes, Cowperthwaite and Shedlovsky[S] on mixtures of sodium chloride and potassium chloride. These authors find that though the conductances of the mixtures deviate from additivity, the conductance of the chloride ion remains constant. In other words, the mobility of the common ion constituent is not the cause for the deviation from additivity of the conductances of mixtures of this valence type.

Table III contains the results of observations on the leading boundary A of Fig. 2. As explained in a preceding section, this boundary is that which arises between the mixture of acid and salt and the region of pure potassium chloride. This boundary was visible as a refraction margin in only one of the mixtures (y = 0.75), where it was faint but sharp. In the other two mixtures the progress of this boundary was ascertained by

.00	63.14	.4898	314.0*	63.14	65.75

The values marked with an asterisk are extrapolated, assuming linear variation with the concentration of that constituent. They represent, respectively, the equivalent conductance of vanishingly small quantities of hydrogen ion in 0.1 normal potassium chloride and of potassium ion in 0.1 normal hydrochloric acid.

As the experimental work here presented was being completed, Bennewitz, Wagner and Kuchler[18] reported an extension of the Onsager[19] equations for the conductance of strong binary electrolytes to the case of a ternary ion mixture in which one ion constituent is present in very small quantities. The theory, as developed, is valid only at high dilutions where the equivalent conductance varies as the square root of the concentration. To extrapolate from this region of validity to 0.1 normal solutions can yield predictions of only a qualitative nature. In any event, their theory predicts that the equivalent conductance of vanishingly small quantities of hydrogen ion in 0.1 normal potassium chloride will be

---

[18] Bennewitz, Wagner and Kuchler, *Physik. Z.*, 30, **623 (1929).**

[19] Onsager, *ibid.*, **27,** 388 **(1926); 28, 277 (1927).**

less than in 0.1 normal hydrogen chloride, while the conductance of the potassium ion will be slightly increased in going from 0.1 normal potassium chloride to 0.1 normal hydrogen chloride. Reference to Table V shows that the extrapolated ion conductances are in qualitative agreement with their theory.

Concentration Changes and Test of the Regulating Function

Referring once more to Fig. 2, if the theoretical treatment leading to Equation 10

$$\frac{C_H}{R_H} + \frac{C_K}{R_K} = \frac{C'_K}{T'_K}$$

is valid, this equation provides a means for computing the "adjusted" concentration C'_K from the ionic mobility relationships across the boundary A and the known concentrations above this leading boundary. Since the leading solution of boundary B is the indicator solution of boundary A, this adjusted concentration C'_K can also be computed independently from observations on the motion of boundary B. If the results of the two methods agree, this is evidence for the correctness of Equation 10, which is an expression of the "regulating" function.

For a boundary between two simple solutions such as those meeting at the boundary B, there is the relation

$$T = \frac{VCF}{It} \tag{11}$$

In this equation, T is the transference number, V the volume swept through by the boundary in t seconds and the other terms represent, as before, the concentration, the faraday and the current. It is evident, therefore, that if T is known, the concentration C may be found. From the observed velocity of the boundary B and the independently determined transference number of potassium chloride over the range of concentrations involved, C'_K has been computed by means of Equation **11.** If the transference number changed very rapidly with the concentration, such a computation would require a series of approximations. For potassium chloride solutions, however, the transference number varies so slightly with concentration that one approximation is sufficient. The concentrations thus obtained are given in Col. 4 of Table VI, which also includes the data necessary for these computations. These data are the

TABLE VI

DETERMINATION OF THE "ADJUSTED" CONCENTRATION OF THE REGION OF PURE POTASSIUM CHLORIDE SOLUTION FORMED ON ELECTROLYSIS OF MIXTURES OF HYDROCHLORIC ACID AND POTASSIUM CHLORIDE

Solution C_H/C_{Cl}	VF/It	T'_K	$C'_K \times 10^6$
0.75	7065	0.4897	69.31
.50	6154	.4898	79.59
.25	5452	.4899	89.86

values of VF/It determined experimentally from the velocity of B, and the independently determined values of T'_K for pure potassium chloride solutions.

For comparison the values of C'_K (2) calculated by means of Equation 10 are recorded in Col. 7 of Table VII. The values of R_H and R_K used in this calculation and recorded in Cols. 2 and 4 are computed from the data of Table V. Reference to the values of the ion conductances given in Table V indicates, however, that the velocity ratio, $V_K(V_K + V_{Cl}) = \Lambda_K/(\Lambda_K + \Lambda_{Cl})$, is slightly different on the two sides of the boundary A. Thus the assumption as to the constancy of this ratio is only an approximation, but a rather close one in this case. The values of C'_K **(3)** recorded in the last column of Table VII are computed assuming the ratio R_K to remain constant on the two sides of the boundary A and equal to T'_K, the ratio or cation transference number in pure potassium chloride at the "adjusted" concentration C'_K. The independently computed values *(1)* are copied from Table VI to facilitate comparison.

TABLE VII

TEST OF THE REGULATING FUNCTION FOR MIXTURES OF HYDROCHLORIC ACID AND POTASSIUM CHLORIDE

$C_H \times 10^6$	R_H	$C_K \times 10^6$	R_K	T_K'	$C'_K \times 10^6$ (1)	$C'_K \times 10^6$ (2)	$C'_K \times 10^6$ (3)
75	0.8296	25	0.4962	0.4897	69.31	68.93	69.27
50	.8288	50	.4923	.4898	79.59	79.29	79.55
25	.8281	75	.4919	.4899	89.86	89.49	89.79

In Table VII the agreement between the independently computed values for the adjusted concentration of the region of pure potassium chloride solution between the two boundaries is quantitative evidence for the validity of the regulating function (Equation *10)* under the conditions of the experiments. Furthermore, in this region between the two boundaries a portion of the potassium-ion constituent has been concentrated free from the more mobile hydrogen ion present in the original mixture. Though the differences in the mobilities of the two cation constituents of these mixtures are very large, it is probable that the same regulating mechanism is operating in cases where the ion constituents have more nearly the same mobilities, as in mixtures of the rare earths.

Discussion of Results

All experimental values quoted in this paper are the mean of several closely agreeing determinations. The boundary velocities have been corrected for the volume changes as described by Lewis.[20] The apparent equivalent volume was used in making these corrections, this being assumed additive for the mixtures.

Bennewitz, Wagner and Kuchler[18] report measurements by the Hittorf

---

[20] Lewis, THIS JOURNAL, 32, 862 (1910).

method on several mixtures at a total concentration of 0.1 normal and at 18°. The only solution where comparison is possible, however, is that which is 0.05 normal to both hydrogen and potassium chlorides. For this solution at 18°, they obtain $T_H = 0.622$, $T_K = 0.124$ and $T_{Cl} = 0.254$. At 25°, the values recorded by the author are $T_H = 0.6198$, $T_K = 0.1242$ and $T_{Cl} = 0.2560$.

With regard to solutions of the pure electrolytes, reference has already been made to the work of MacInnes and co-workers. Denison and Steele,[21] using lithium chloride and potassium acetate as indicators, obtained 0.492 as the cation transference number of 0.1 normal potassium chloride at 18°. Using potassium chloride and iodic acid as indicators for the ions of hydrogen chloride, they obtained a cation transference number of 0.835 for this electrolyte at 0.1 normal and 18°. A comparison of the published values by the moving boundary method is given in Table VIII. The agreement is only fair. The data of this paper fulfil the following conditions, however. (1) They are independent of the potential gradient within wide limits. (2) They are independent of the nature and concentration of the indicator ion within certain limits. (3) They are very reproducible. (4) The sum of the anion and cation transference numbers is very nearly unity.

TABLE VIII

COMPARISON OF THE TRANSFERENCE NUMBERS OF THE SOLUTIONS OF THE PURE SALTS AS OBTAINED BY DIFFERENT INVESTIGATORS

Solution	Dennison and Steele, 18°	MacInnes, et *al.*, 25°	This paper, 25°
0.1 N HCl	0.835	0.8320	0.8305
0.1 N KCl	.492	.4920	.4899

The author wishes to express appreciation to Dr. D. A. MacInnes of these laboratories for the inspiring supervision of this work, to Dr. Theodore Shedlovsky for his cooperation in the determination of the conductivities of the solutions, and to Professor H. P. Cady of the University of Kansas for many helpful suggestions.

Summary

Ion mobility relations and concentration changes on electrolysis in mixtures of hydrogen and potassium chlorides at a total chloride-ion concentration of 0.1 normal have been studied by means of the moving boundary method, using rising boundaries.

Two cation boundaries are formed simultaneously and proceed at different rates. The velocity of the leading boundary yields the mobility of the hydrogen-ion constituent in the mixture. A portion of the less mobile potassium-ion constituent lags behind the hydrogen-ion constituent

---

and gives rise to a second boundary whose velocity yields information as to the concentration adjustment occurring in the region of the solution which contains pure potassium chloride between the two boundaries. From data on both boundaries it is shown that within this latter region the hydrogen ion has been quantitatively separated from the potassium ion and that the concentration of the potassium chloride residue is accurately determined by the "regulating" function of Kohlrausch,[5] a derivation of which is given.

It is shown experimentally that the mobility of the chloride-ion constituent varies linearly between its slightly different values in 0.1 normal hydrogen chloride and 0.1 normal potassium chloride.

SURFACE REACTIONS OF ATOMS AND RADICALS. I. A NEW APPROACH TO THE PROBLEM OF SPECIFIC SURFACE ACTION

BY HUGH S. TAYLOR AND GEORGE I. LAVIN

RECEIVED FEBRUARY 24, 1930 PUBLISHED MAY 8, 1930

The problem of specificity in the action of surfaces is still the outstanding problem of chemical reactivity at solid surfaces. The solution of the problem will contribute materially to the explanation of the varied phenomena grouped under the title of contact catalytic action. Hitherto, discussion of this problem has been confined mainly to the reactions which molecules undergo at various surfaces. Little attention has been paid to the influence of surfaces on reactions of atoms and of radicals. Frequently it has been implicitly assumed that, for reactions between atoms and radicals, a surface only was necessary; little regard has been paid to the influence of the nature of the surface. It is the purpose of the present communication to demonstrate that the surface is of importance in atom–radical reactions as in molecular reactions; that great differences in velocity of such reactions at different surfaces occur, though the actual time of reaction is many orders less than with molecules; that the available data, together with other experimental data presented herewith, indicate a connection between the activity of surfaces in atomic reactions and corresponding processes involving molecules. The evidence already in the literature is diffuse and only assumes important proportions when coordinated. It suggests, however, an extended experimental program of which the first results will be here detailed.

The Recombination of Halogen Atoms at Surfaces.—The specific influence of surface in the rate of recombination of halogen atoms is well illustrated by a recent publication of Senftleben and Germer.[1] In this

---

[1] Senftleben and Germer, *Ann. Physik*, **2**, 847 (1929).

work, atomic halogens were produced by illumination with light of wave length within the region of continuous absorption and the existence of atoms was demonstrated by measuring the increase in thermal conductivity of the vapor under illumination. This involved the use of a heated platinum wire which decreased in temperature and resistance when dissociation of the halogen occurred. The platinum wire showed a marked tendency to produce recombination of chlorine atoms; the efficiency of the surface in this respect could be materially diminished by glowing the wire in chlorine, a treatment which undoubtedly covered the surface in part with the metal chloride. In this manner the efficiency of the wire in causing recombination was so far diminished that the effect of illumination in producing dissociation was successfully demonstrated. With bromine the success was less great, it being found difficult to poison the wire so as to prevent recombination of bromine atoms. With iodine a new surface factor became of importance. The glass surface of the containing vessel caused rapid recombination of iodine atoms. To reduce this effect quartz was substituted for glass and proved to have a lower order of efficiency in this respect.

These direct observations may now be supplemented by others, somewhat less direct, involving additional types of surface. The low quantum yields in the photochemical hydrogen–chlorine combination found by Marshall[2] at pressures below 60 mm. could be explained by the influence of the walls on the recombination of atoms taking part in the chain reaction of the secondary processes succeeding the absorption process. This conclusion was more directly confirmed by the work of Trifonoff[3] using vessels of various sizes at low pressures, and by Chapman and Grigg[4] using capillary tubes at normal pressures. This effect of capillaries on atom recombination accounts for the failure of Bodenstein and Taylor[5] and later of Marshall[6] to obtain reaction by illuminating the chlorine alone and passing it directly (but, owing to experimental requirements, through capillaries) to unilluminated hydrogen. No reaction was observed even when the time interval between illumination of the chlorine and admixture with hydrogen was 10^{-4} seconds.

A varying influence of surfaces in this same reaction was demonstrated by Polanyi and Bogdandy[7] who found that when the hydrogen–chlorine combination was initiated by the reaction of chlorine with sodium vapor, $Na + Cl_2 = NaCl + Cl$, the chain length of the hydrogen–chlorine combination was short when a clean glass surface was present, but increased

30-fold after the glass surface became covered with sodium chloride. The operating pressure was below 10 mm. of mercury with hydrogen in large excess. In the corresponding experiments with potassium in place of sodium the chain length was shorter, pointing to an increased efficiency of potassium chloride over sodium chloride in the breaking of chains.[8] That the effect of the surface was on the recombination of chlorine atoms was indicated by the authors by reason of experience with the effect of surface on chemiluminescences produced by interaction of sodium and chlorine. Polanyi and Schay[9] found that in the interaction of sodium vapor and chlorine, the chemiluminescent flame was at first short and of weak intensity, gradually becoming stronger and longer as the surface of the vessel became coated with sodium chloride. Since the light-producing reactions are initiated by chlorine atoms, by the reaction sequence (1) $Na + Cl_2 = NaCl + Cl$; (2) $Cl + Na_2 = NaCl' + Na$; (3) $NaCl' + Na = NaCl + Na'$; (4) $Na' = Na + h\nu$, it follows that sodium chloride surfaces are less efficient than glass in terminating the activity of chlorine or sodium atoms. Since chlorine atoms are common to this reaction and the preceding, it indicates that it is the recombination of chlorine atoms which is involved at the two surfaces. This conclusion will be strengthened by our own results on the low efficiency of halide surfaces in the recombination of hydrogen atoms. Polanyi and Bogdandy also indicate that a glass surface which has been browned with sodium vapor is more efficient than clean glass surfaces for these atom recombinations.

The efficiency of glass surfaces in the recombination of chlorine atoms is apparent also in the kinetic analysis of the photochemical formation of phosgene[10] and of the photosensitized oxidation of carbon monoxide in presence of chlorine.[11] These studies show that a change from higher pressures to low pressures causes a change in the reaction kinetics directly associable with the changing influence of the wall in the recombination of chlorine atoms. In ordinary reaction vessels in the photochemical formation of phosgene the change manifests itself below 10 mm. of mercury working pressure. If the glass surface of the reaction vessel per unit volume be greatly increased, the change in kinetics is already revealed at 150-mm. mercury pressure. This points indubitably to the action of the glass wall on the reaction $2Cl = Cl_2$. From the cases cited in the

---

[8] There is, however, an untested possibility that the difference in chain length between a potassium chloride and a sodium chloride surface was due to impurities in the gases used. This does not apply to the glass–sodium chloride comparison since this was achieved with a given filling. It is evident that there is nothing improbable in the indicated difference in efficiencies of potassium chloride and sodium chloride for atom recombinations.

preceding paragraphs it is evident that the kinetics of these photo-reactions would be modified in entirely different pressure intervals were the walls of the reaction vessels coated with alkali halides. This could readily be made the subject of experimental test.

The Recombination of Hydrogen Atoms at Surfaces.—Wood,[12] in his initial work on the production of hydrogen atoms in discharge tubes, drew attention to the desirability of adding water vapor to the hydrogen used, in order to increase the concentration of hydrogen atoms obtained. Langmuir suggested, as a reason for this, the poisoning action of adsorbed water vapor on the surface activity of the glass walls for recombination. This procedure has since been followed and ice has been employed as the containing surface.[13] Recently von Wartenburg and Schultze[14] have further improved the protection of the glass by coating it with hygroscopic materials. Strong solutions of potassium hydroxide and water glass were useful but sirupy phosphoric acid was very efficient. These authors imply that the efficiency may be due to the film of water which such materials hold on the surface. There may be, however, a specific effect of the materials used.

Bonhoeffer[15] demonstrated a varying capacity of surfaces to effect recombination of hydrogen atoms. Metals were especially efficient and the order of efficiency was that of the metals in respect to activity as hydrogenating catalysts. Bonhoeffer states that, besides metals, many salts and especially oxides also catalyze the recombination. Concerning one oxide, Al_2O_3, cited by Bonhoeffer, we shall give experimental data of our own which are in conflict with this view.

Surface Effects in Explosion and Flame Reactions.—Reactions leading to the development of explosions and flames are now known in many cases to be of the chain reaction type.[16] Whether the chains are atom or radical chains or energy chains is not yet known in individual cases with certainty. In many of these reactions, however, the specific effects of surface are well known. The action of metal-organic compounds as "antiknock" agents in gasoline explosions has been attributed to the effect of the metal particles, produced by thermal dissociation of the compounds, on a chain mechanism produced in the process of gasoline combustion. Egerton[17] seems to favor energy chains but Berl and Winnacker,[18] reasoning from the efficiency of colloidal lead and iron as inhibitors and the

lack of activity of the corresponding dispersed oxides, reject the concept of energy chains and favor some specific chemical reaction (e. g., destruction of peroxide) as the mechanism of inhibition.

Metallic potassium vapor has a marked efficiency as inhibitor in automobile engine combustions and this is to be remembered in conjunction with the well-known use of potassium salts for the prevention of flame at the mouth of cannons firing high explosives.[19] Muraour cites other similar uses of potassium salts.

These latter observations link up with the recent studies of Hinshelwood[20] and of Pease[21] on the influence of surface on the slow combustion of hydrogen and oxygen and hydrocarbons and oxygen. Of especial interest is the observation of Pease that coating the glass surface of the reaction vessel with potassium chloride slows down the rate of reaction approximately 1000-fold. This is not due exclusively to the poisoning of the glass surface for a heterogeneous reaction of combination since an increase of surface by filling with coarse glass powder, either with or without a coating of potassium chloride, slowed down the reaction rate. It is evident that, in the oxidation of hydrogen and hydrocarbons, a surface of potassium chloride is more *efficient* in breaking chains than is a clean glass surface. The contrast between this conclusion and the opposite one reached in the case of chlorine atom recombination is compelling evidence of specificity of surface in chain reactions.

In the hydrogen–oxygen reaction the system is sufficiently simple that experimental evidence may be sought to permit a decision as to the nature of the influence of specific surfaces. Hydrogen atoms, oxygen atoms and hydroxyl radicals are the only atoms or radicals that might be involved if the chain is one involving such species. Spectral evidence indicates that hydrogen and hydroxyl are involved.[22] The behavior of these at surfaces may be studied since, in the hydrogen discharge tube, we have a source of atomic hydrogen and, in the corresponding tube, using water vapor, there is now evidence for the production, together with atomic hydrogen, of hydroxyl (with possibly free oxygen atoms).[23]

Experimental

The method employed consisted in an adaptation of that employed by Bonhoeffer in his study of atomic hydrogen. Thermometers whose bulbs were coated with the material to be studied were inserted in positions B, C and D of the exit tube from a dis-

charge tube operating either with water vapor or hydrogen (Fig. **1).** Since atomic hydrogen was known by spectroscopic observation to persist for longer intervals of time than hydroxyl, positions C and D were ordinarily used for detecting, by temperature rise on the thermometer, any atomic hydrogen recombination. The recombination of hydrogen with hydroxyl was studied at B, position **A** being used, with a clean glass thermometer **bulb,** to determine rise in temperature due to the discharge and also the effect of a clean glass surface on the recombination process. As an index of the active material reaching D, the thermometer bulb in this position was normally coated with metallic silver obtained by atomic hydrogen reduction of silver nitrate, since such a surface was shown by Bonhoeffer to act efficiently as a recombination agent for atomic hydrogen. In order to eliminate differences due to the varying efficiency of the discharge tube, the activities at B and C of the surfaces studied were always compared either with clean glass at **A** or with the silvered surface at D. The results of our experiments are recorded in the accompanying Table **I.** The data given represent a typical selection from a large number of experiments.

[a] The bulb of a 360° thermometer with opalescent back and etched scale constituted the glass surface. It was carefully washed in distilled water and dried with a soft cloth.

[b] KOH covered thermometer allowed to stand for one day in air and then again tried in Expt. 8.

[c] Two-minute interval.

Discussion of Experimental Data

It is apparent from Expts. 1, 2, 5 and 6 that neither a clean glass surface nor a potassium chloride surface has any marked efficiency in the recombination of hydrogen atoms either from water vapor at position C or from moist hydrogen at positions A or B. In marked contrast to this is the efficiency of potassium chloride as a reaction surface at position B when water vapor is passed through the discharge tube (Expts. 3 and 4). In this it is markedly superior to a clean glass surface at A (Expt. 4). We associate this efficiency with a recombination of hydrogen and hydroxyl since spectroscopic evidence shows marked concentrations of the latter at B and also for reasons indicated in the subsequent discussion of alumina.

Potassium hydroxide shows a more pronounced efficiency for atomic hydrogen recombination than does the chloride (Expts. 7 and 8 compared with Expt. 2). On standing in the air the potassium hydroxide appeared to improve in efficiency (Expt. 8). We, therefore, were led to try potassium carbonate and thus found it also to have good efficiency in the combination of atomic hydrogen (Expt. 9). When a surface shows marked activity in atomic hydrogen recombination at C, its test at B for the H–OH combination is useless since the present method of test does not distinguish between the two reactions, and at B there is always a higher concentration of hydrogen atoms than at C under given discharge tube conditions.

The specific action of surfaces, thus found for the two reactions, suggested a correlation with the specific behavior of surfaces in similar reactions involving molecules. Thus, the combination of atomic hydrogen and hydroxyl is analogous to the removal of water from organic molecules by means of dehydration catalysts. The recombination of atomic hydrogen is analogous to the removal of hydrogen from organic compounds by dehydrogenation catalysts. It seemed probable, therefore, that a purely dehydration catalyst might promote H–OH recombination without affecting the H–H reaction, while a purely dehydrogenation catalyst might secure the H–H recombination. To test this, we chose alumina as a dehydration catalyst and the now well-known mixture of zinc and chromium oxides (used in methanol synthesis) as a typical oxide dehydrogenation catalyst. The correlation of hydrogen atom recombination on metals with the catalytic activity of the latter has already been indicated by Bonhoeffer.[15] Our expectations were completely realized. It is evident that alumina has high efficiency in position B and low efficiency at position C (cf. Expts. 11, 12 and 13). Experiment 13 was especially conclusive since it immediately succeeded Expt. 12 in which the high activity at B was realized. Nevertheless, in Expt. 13 at C, only the activity associated with a small amount of residual water vapor is to be noted. Its inertness toward atomic hydrogen is also manifest in Expt. 18, where a zinc–chromium oxide surface immediately beyond it revealed a high residual concentration of atomic hydrogen.

We wish also to record one other observation with alumina which bears upon the problem of its surface activity. The oxide was prepared from the precipitated hydroxide which was dried after it had been placed on the thermometer bulb. The product displayed no activity at all in either position B or C until it had been dehydrated by heating in an electric furnace to 300°. A treatment of this kind at 250° was insufficient to activate the surface. This points to a poisoning of the oxide surface by adsorbed water.

It appeared necessary, in view of the observation already recorded by Bonhoeffer as to the efficiency of alumina in atomic hydrogen recombination, to ascertain to what factor Bonhoeffer's observation was due. We accordingly tested alumina at position B, the discharge tube operating with a stream of hydrogen which had been bubbled through water maintained at various temperatures. A perusal of the selection of our results given (Expts. 14–17) will indicate that the temperature rise obtained is dependent on the concentration of water vapor in the gas stream. We suggest, therefore, that Bonhoeffer's results with alumina were due to the hydroxyl content of his atomic hydrogen.

The efficiency of zinc–chromium oxide for the atomic hydrogen recombination in comparison even with silver is shown in Expt. 10 as well as in the Expt. 18 already quoted.

We wish also to record the observation that the active combination of the atoms and radicals in question is associated in many instances with the production of distinctive chemiluminescences at the reaction surfaces. With potassium chloride and water vapor in the discharge, the glow was purple; with potassium hydroxide and potassium carbonate a blue-green. With alumina one obtains also a purple glow. With zinc–chromium oxide and on the silvered thermometer there was no observable light production. We propose to investigate these phenomena in detail later.

Our experiments have demonstrated that the specificity of behavior of dehydration and dehydrogenation catalysts is associable with their activity in producing the recombination of H–OH and H–H, respectively. We plan a further series of investigations to ascertain the factors controlling the activity of surfaces in these simple reaction processes and hope thence to derive the explanation of specific surface action in these molecular processes.[24]

Summary

1. It has been demonstrated that the nature of the surface is of fundamental importance in determining the velocity of atom–radical reactions.
2. Potassium chloride is more efficient than clean glass in H–OH recombination. It is less efficient than clean glass in Cl–Cl recombination. Alumina is very efficient in the H–OH reaction.
3. Potassium chloride and alumina are inefficient in H–H recombination. Potassium hydroxide and carbonate, and especially zinc–chromium oxide, are efficient agents for this reaction as are also metal surfaces.
4. Active recombination of atoms and radicals is associated with the production of distinctive chemiluminescences at several of the surfaces.
5. A correlation of the activity of surfaces in atomic reactions with similar processes involving molecules has been given and the importance of this in the problem of specific surface activity has been indicated.

PRINCETON, NEW JERSEY

---

[24] It is evident that analogous to this specificity of surface in atom–radical reactions, there should exist specific third-body action in homogeneous systems. Such specificity is fundamental in the kinetics of such reactions, has not been emphasized and yet apparently exists in reactions already studied.

THE DIPOLE MOMENTS OF THE DISUBSTITUTED BENZENES

BY HUGH M. SMALLWOOD AND K. F. HERZFELD

RECEIVED MARCH 6, 1930 PUBLISHED MAY 8, 1930

Recent measurements of the dipole moments of organic molecules[1] have shown that the symmetrical hydrocarbons have no electric moment and that their mono-derivatives possess moments varying with the nature of the substituent group. It has further been shown, in accordance with a prediction of J. J. Thomson,[2] that the moment of a disubstituted hydrocarbon may be calculated, in certain cases, from the assumption that it is the vector sum of individual moments characteristic of the substituent groups and that these group moments are directed along the conventional valence bonds joining the substituents to the hydrocarbon residue. Thus, for example, if it be supposed that the carbon atoms of the benzene nucleus are situated at the corners of a regular hexagon, the moment of a disubstituted benzene may be calculated from the law of cosines

$$M = \sqrt{m_1^2 + m_2^2 + 2\, m_1 m_2 \cos \beta} \tag{1}$$

where M is the resultant moment of the molecule, m_1 and m_2 are the individual group moments, and β is the angle between m_1 and m_2. If the substituent groups are in the ortho position, @ = 60°; if in the meta position, $\beta = 120°$; and if in the para position, $\beta = 180°$. It has been found that the groups —Cl, —Br, —I, —CH_3 and —NO_2 follow this rule approximately, but that the experimental data for compounds containing —OH, —NH_2 and —O— do not obey it even qualitatively. The discrepancies shown by the last named groups have been explained by the postulate that the resultant group moment does not lie along the valence bond of the usual structural formula. This seems quite probable since analysis of the infra-red spectra of H_2O and of NH_3 indicates a triangular model for the former and a pyramidal model for the latter. If this structure is preserved in the —OH and —NH_2 groups, it follows that these groups are unsymmetrical about the line joining the centers of the carbon and oxygen or carbon and nitrogen atoms. They may, therefore, be expected to exhibit a moment in some direction other than that of the line of centers. On the other hand, the groups which do follow the rule of vector additivity are symmetrical about the line of centers.

The moments calculated for those compounds which do obey the rule, however, show systematic variations from the experimental values. Thus

the calculated moments of compounds of the type *o*-$C_6H_4X_2$ are from 10 to 30% higher than the experimental values. Höjendahl[3] has explained this by pointing out that the simple theory takes no account of interaction between the two dipoles. Such interaction might consist of either or both of two effects. In the first place there is a repulsive force between two dipoles in the ortho position which tends to force the dipoles apart, that is, to increase β of Equation 1. It is therefore possible to use β as an adjustable constant in order to bring the calculated value of M into agreement with the observed. In the second place, the dipoles may affect each other by induction. Since these molecules are not rigid and since each group is subjected to an electric force exerted by the other, dipole moments will be induced in each group in such a direction as to lessen the resultant moment. It is the purpose of the present paper to calculate the resultant moments of the disubstituted benzenes from the individual moments of the substituent groups, assuming that the group moments are directed along the valence bonds but taking into account the moments due to induction.

The dipole moment induced in any substituent as a result of an electric intensity E is given by the expression[4,5]

$$\mathbf{m}_i = \alpha\mathbf{E} \tag{2}$$

where α is the deformability of the substituent group. In the present case E is the force exerted by the dipole of the other constituent. If the dipole m exerting the force E is situated at the origin of a set of plane polar coordinates, the horizontal and vertical components of $\mathbf{E}$(E_x and E_y) at the point (r), are given by the equations.[6]

Equations 3 then follow since

$$E_x = -\frac{\partial\varphi}{\partial x} \text{ and } E_y = -\frac{\partial\varphi}{\partial y}$$

$$\left.\begin{aligned} E_x &= \frac{\xi}{r^3}\,(3\cos^2 6 - 1) + \frac{3\eta}{r}\sin 6 \cos 6 \\ E_y &= \frac{3\xi}{r^3}\sin 6\cos 6 + \frac{\eta}{r^3}\,(3\sin^2 6 - 1) \end{aligned}\right\} \qquad (3$$

where ξ and η are the horizontal and vertical components of m.

In order to calculate the resultant moment, M, of the molecule, it is

[4] P. Debye, "Polar Molecules," The Chemical Catalog Co., Inc., New York, **1929.**

[5] Throughout this article vector quantities will be indicated by bold face type.

[6] Cf. Jeans, "Electricity and Magnetism," Cambridge, **1925**, p. 50. The potential, φ, at a point (x, y) due to charges + e at (a, b) and $-e$ at $(-a, -b)$ is

$$\varphi = \frac{e}{\{(x-a)^2 + (y-b)^2\}^{1/2}} - \frac{e}{\{(x+a)^2 + (y+b)^2\}^{1/2}}$$

Upon expanding this expression and neglecting squared and higher terms, it is found that

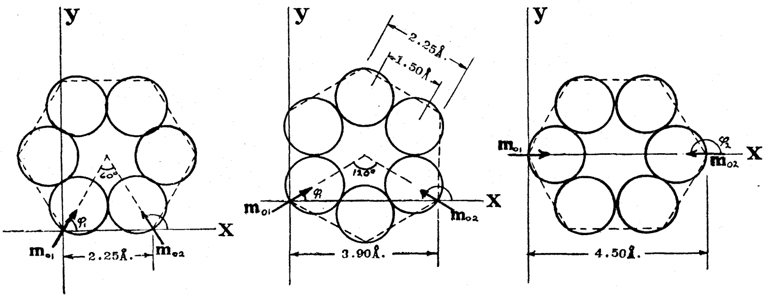
$$\varphi = \frac{2e(ax+by)}{(x^2+y^2)^{3/2}} = \frac{\xi x + \eta y}{(x^2+y^2)^{3/2}}$$

necessary to take into account the moments induced in the four unsubstituted —CH groups. These moments may be represented by the symbol $\mathbf{m}_i'$. $\mathbf{M}$ is then given by the expression

$$\mathbf{M} = \mathbf{m}_{o1} + \mathbf{m}_{i1} + \mathbf{m}_{o2} + \mathbf{m}_{i2} + \mathbf{m}_i' \tag{4}$$

where $\mathbf{m}_{o1}$ and $\mathbf{m}_{o2}$ are the original moments of groups 1 and 2, $\mathbf{m}_{i1}$ and $\mathbf{m}_{i2}$ the corresponding induced moments and $\mathbf{m}_i'$ the resultant moment induced in the —CH groups.

In order to apply these equations it is necessary to know the dimensions of the molecules involved. Although x-ray diffraction data on crystals indicate a tilted model for the benzene nucleus,[7] chemical evidence together with the small electric moment of symmetrical tri-derivatives of benzene may be cited in favor of a plane model for the benzene ring in substituted compounds.[8] The question cannot be regarded as settled at present.



Ortho Meta Para

Fig. 1.—Benzene nuclei and positions of dipoles of substituent groups in *ortho,* meta and para compounds.

Since, however, the differences in the dimensions of the two models are too slight to affect the present calculations, the plane model has been chosen for the sake of simplicity. The radius of the carbon atom has been taken equal to 0.75 Å.,[7] the value obtained from crystal structure data. The centers of the six carbon atoms are therefore assumed to lie on the corners of a regular hexagon of side equal to 1.50 Å.

In order to locate the position of the dipoles associated with the substituent groups, they are assumed to be situated at the circumference of the carbon atoms to which the particular groups are attached, and to be directed along a diagonal of the hexagon. Thus in all the compounds the group moments are assumed to be situated at the corners of a regular hexagon of side equal to 2.25 Å. (Fig. 1). Using this model it follows that the distance between the dipoles of the two substituents is 2.25,

3.90 or 4.50 Å., according to whether the substituents are in the ortho, meta or para position.

It is next necessary to obtain numerical values for ***a***. This quantity is related to the atomic refraction ***R*** by the equation

$$\alpha = 3R/4\pi N_A \tag{5}$$

where N_A is the Avogadro number per mole. Since ***R*** varies with the wave length of the light used in its determination, the values must be extrapolated to infinite wave length. This has been done, using the assumption that the curve of R against A becomes parallel to the λ axis in the region of the far infra-red. The values so obtained are tabulated in the first column of Table I. The quantity under consideration, however, is more a property of the bond between two atoms than of a single atom. It has, therefore, seemed advisable to use the octet refractions of the various groups in the calculations of ***a***. The octet refraction was introduced by Smyth[9] and defined by him as

$$R_{oct} = R_{at} + {}^1/_4 R_c \tag{6}$$

Here R_{at} is the usual atomic refraction and R_c the atomic refraction of carbon. The values of R_{oct} are tabulated in the second column of Table I and those of a in the third column. This use of R_{oct} instead of R_{at} involves such a slight change in α that the final results are not appreciably affected.

TABLE I

Group	R_{at}[a]	R_{oct}	$\alpha \times 10^{24}$	$m_c \times 10^{18}$		
—H	1.065	1 661[b]	0.654	0

[a] Data from Landolt-Börnstein, "Physikalisch-Chemischen Tabellen," 5th **ed.**, Berlin, 1923, p. *985*, extrapolated to infinite wave length. [b] This is a "bond refraction" rather than an octet refraction. [c] C. P. Smyth, S. O. Morgan and J. C. Boyce, THIS JOURNAL, *50, 1536 (1928).* [d] J. W. Williams and E. F. Ogg, *ibid., 50, 94 (1928).* [e] K. Höjendahl, Ref. 3. [f] J. W. Williams, *Physik. Z.*, 29, *174, 204, 271, 683 (1928);* THIS JOURNAL, *50, 2350 (1928).* [g] P. Walden and O. Werner, *Z. physik. Chem., 2B, 10 (1929).* [h] C. P. Smyth and S. O. Morgan, THIS JOURNAL, *49,1030 (1927).*

The experimental values of the moments of the monosubstituted compounds cannot be identified with the $\mathbf{m}_o$'s of Equation 4 since the former are the resultants of the latter and the moments induced in the five unsubstituted —CH groups. In order to calculate the actual group moment, m,, from the experimental value m, consider a set of axes oriented with respect to the benzene ring as in Fig. 2. Since the molecule is symmetrical about the x-axis,

$$\Sigma\eta_i = 0$$

---

[9] Smyth, *Phil.* Mag., *50,361 (1925); cf* also Fajans and Knorr, ***Ber.***, *59,249 (1926).*

Then

$$m_e = m_o + \Sigma\xi_i$$
$$= m_o + 2\xi_{i2} + 2\xi_{i3} + \xi_{i4}$$

where ξ_{i2}, etc., are the x-components of the moments induced in the second —CH group and so on. Substituting from Equations 3 it follows that

$$\mathbf{m}_e = 1.013\mathbf{m}_o \qquad (7)$$

if it be assumed that the fields of the induced moments are too small to produce an appreciable effect upon $\mathbf{m}_o$.

The foregoing assumption is valid only because the induced moments are small as a result of the small deformability of the —CH group. In calculating the moments induced in the substituent groups themselves, in the case of the disubstituted compounds, it is necessary to take into account the fields of the induced moments as well as those of the original moments. This can be done by substituting in the equations

$$\xi = {}_{40} + \xi_i \qquad (8)$$
$$\eta = \eta_o + \eta_i$$

where ξ_o, η_o are the components of the original group moment and ξ_i, η_i the components of the moment induced in that group by the second dipole.

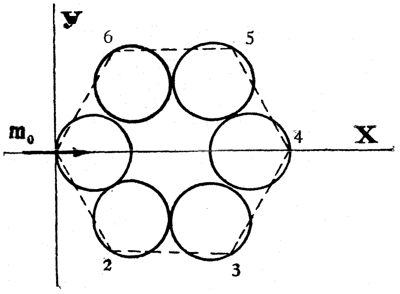

Fig. 2. .

Finally, it is necessary to calculate $\mathbf{m}_i'$, the moments induced in the unsubstituted —CH groups. This calculation is quite analogous to that leading to Equation 7. In this case, however, as well as in the final calculation, it is advantageous to choose the coördinate axes so that the substituent groups both lie on the x-axis (Fig. 1). Assuming, as before, that the moments induced in the —CH groups are too small to affect each other or the inducing groups, the total components of the former are found to be

$$\xi_i' = A'(\xi_1 + \xi_2) + A''(\eta_1 - \eta_2)$$
$$\eta_i' = B'(\xi_1 - \xi_2) + B''(\eta_1 + \eta_2) \qquad (9)$$

Here the subscripts 1,2 refer to groups 1,2. The ξ, η are the components of the total moments of the substituent groups. The *A's* and *B's* are numerical coefficients depending on the deformability of the —CH group and on the dimensions of the molecule. Their values are

	Ortho	Meta	Para
A'	−0.01339	+0.0206	+0.001083
A''	− .0511	− .0511	0
B'	− .0511	− .0511	0
B''	+ .1001	+ .1125	0

The resultant moment of the molecule may now be obtained by substituting Equations 2, 3, 8 and 9 in Equation 4. The result is

$$M^2 = \left[(1 + A')\left(\frac{(1 + 2a_2)\xi_{o1} + (1 + 2a_1)\xi_{o2}}{1 - 4a_1a_2}\right) + A''\left(\frac{(1 + a_2)\eta_{o1} - (1 + a_1)\eta_{o2}}{1 - a_1a_2}\right)\right]^2 +$$

$$\left[(1 + B'')\left(\frac{(1 - a_2)\eta_{o1} + (1 - a_1)\eta_{o2}}{1 - a_1a_2}\right) + B'\left(\frac{(1 - 2a_2)\xi_{o1} - (1 - 2a_1)\xi_{o2}}{1 - 4a_1a_2}\right)\right]^2 \qquad (10)$$

where a_1 and a_2 are equal to α_1/r^3 and α_2/r^3, respectively. ξ_{o1} and η_{o1} are obtained from Fig. *1* and Equation *7*.

$$\xi_{o1} = \frac{\cos \varphi_1}{1.013}\, m_{e1} \qquad \eta_{o1} = \frac{\sin \varphi_1}{1.013}\, m_{e1} \qquad (11)$$

Similar equations give ξ_{o2} and η_{o2}. It should be noted that Equation *10* contains no adjustable constants.

Upon selecting values of m_e with which to test Equation *10* it becomes apparent that the accuracy of the data given in the literature leaves much to be desired. Since the experimental data vary with the method and apparatus used, the relative agreement is better than the absolute. It has therefore seemed advisable, wherever possible, to use in the calculation of M that value of m_e determined by the same experimenter who measured M. Although in general better than the absolute, the relative agreement is not good in all cases. For example, the values obtained by Williams and by Hojendahl for the moment of *o*-dinitrobenzene, *6.05* $\times 10^{-18}$ and *6.00* $\times 10^{-18}$, respectively, are in good agreement, but their results for nitrobenzene, *3.90* $\times 10^{-18}$ and *3.75* $\times 10^{-18}$ show greater divergence.

The values of m_e used in the calculation are tabulated in the last column of Table I. The plus and minus signs indicate that some of the dipoles point toward and others away from the center of the ring. The assignment of sign to any one group is quite arbitrary. Once it is fixed, however, the signs of the other groups are definitely established.

The results of the calculations are summarized in Table II. Here the names of the compounds are given in the first column, the experimental

values of M in the second and, in the third, the values of M calculated from the approximate equation (1). In the fourth column are listed the differences between the observed values of M and the approximate calculated values (Δ_1). The values of M calculated from Equation 10 are given in the fifth column. In the sixth are listed the differences between the observed values and those calculated taking into account the effect of induction (Δ_2). The figures listed under the headings M' and Δ_3 will be discussed below. In the last column, headed "Remarks," are tabulated the values of m_e used in the calculations.

Inspection of Table II shows that all the values calculated from the assumption of interaction by induction, except for two groups of compounds, are nearer to the observed values than are those calculated from the approximate equation (1). For most compounds the agreement is within the experimental error. The cases in which the agreement is not good will be referred to later.

The Referee to whom this paper was referred, in order to pass upon its suitability for publication, criticized the method of calculation on the grounds that changes in the moments of the —C—C— bonds of the benzene nucleus should have been taken into account, since the changes in the —CH bonds are considered. We wish to express our indebtedness to him for raising this point. The omission was due to the fact that the effect of the —CH bonds is altered by the entrance of the second substituent group since in the disubstituted compound there is one less —CH bond than in the monosubstituted. The number of —C—C— bonds is the same in both types of compounds. Hence it seemed permissible to neglect the latter. For the sake of completeness, however, the calculations have been repeated taking into account the changes in the moments of the —C—C— bonds. This extension of the calculation merely involves using different values for the proportionality constant of Equation 7 and for the constants A', A'', B' and B'' of Equations 9. To arrive at numerical values for these constants it was assumed that the induced moments in question are located at the "points of contact" of the carbon atoms. α_{cc} was taken equal to 0.984×10^{-24} since

$$R_{cc} = \frac{1}{6}\left(R_{C_6H_6} - 6R_{CH}\right)$$

The constant of Equation 7 then turns out to be 2.38 instead of 1.013 and the others are

	Ortho	Meta	Para
A'	0.1159	0.939	1.348
A''	.712	.712	0
B'	.712	.712	0
B''	.939	.1159	0

The results obtained with the use of these values are listed in Table II under the headings M' and Δ_3. In most cases the values of M' do not differ essentially from those for $M_{\text{calcd.}}$ previously obtained, as is to be expected. In general the agreement between calculated and observed is slightly better than before. The improvement is greatest for the chlorotoluenes and o-nitrotoluene, but for these compounds the agreement still is not as good as might be desired. Moreover, consideration of the —C—C—

bonds makes the agreement in the cases of o-dinitrobenzene definitely worse. It is difficult to explain these discrepancies. The inconsistency of the experimental data for nitrobenzene has already been pointed out. Perhaps in the chlorotoluenes and o-nitrotoluene there is some other type of interaction between the substituent groups. It is unfortunate that there are available no other measurements upon compounds of this type, namely, compounds in which one dipole is directed toward and the other away from the center of the ring.

One further point must be considered in connection with calculations of this type. This is that, under sufficiently great electric intensity, Equation 2 is no longer valid since α must eventually decrease as E increases. The reality of this effect may be observed in Debye's[10] calculation of the moment of HCl. Furthermore, we have attempted to apply the methods of this paper to the derivatives of methane. In this case the correction term is again much too large, indicating that the region of validity of Equation 2 has been exceeded. Apparently the present methods cannot be employed when the distance from the inducing dipole is much less than 2 . On taking into account the —C—C— bonds in the above calculations, however, it is necessary to consider distances considerably smaller than this. That the results are satisfactory is only due to the fact, previously pointed out, that the effect of the —C—C— bonds very nearly cancels out of the resultant moment.

The determining factor in the correction for induction is the distance between the dipoles, since this enters to the third power. The results show that a correction of this type leads to concordant results only when the dipoles are assumed to be situated at the circumference of the carbon atoms. If the dipoles are assumed to be at the center of the substituent group, the effect considered in this paper is negligible. If they are assumed to be at the centers of the carbon atoms, this correction is far too large.

Summary

The calculated dipole moments of the disubstituted benzenes have been corrected for the effect of the mutual induction of the dipoles. The results show that, in order that a correction of this kind be successful, the dipoles must be assumed to be located on the circumferences of the carbon atoms, that is, at the conventional valence bond.

AZIDO-DITHIOCARBONIC ACID. V. ALKYL AND ACYL DERIVATIVES[1,2,3]

BY L. F. AUDRIETH, JOHN R. JOHNSON AND A. W. BROWNE

WITH MICROSCOPICAL STUDIES BY C. W. MASON

RECEIVED APRIL 21, 1930 PUBLISHED MAY 8, 1930

The marked photosensitivity of certain compounds of azido-dithiocarbonic acid with strongly electropositive elements or radicals, particularly the cesium, rubidium and tetramethylammonium salts, has been attributed[1c,1d] to a tendency on the part of these substances to undergo a reversible, superficial photolysis which results in the liberation, in situ, of certain metallic atoms or radicals in the crystal lattice. The hypothesis thus formulated serves also to explain the action of light in accelerating the decomposition of the solid inorganic azido-dithiocarbonates thus far studied. Discharge of the anions yields free azido-carbondisulfide, $SCSN_3$, which is known[2g] to undergo spontaneous thermal decomposition at ordinary temperatures into thiocyanogen, sulfur and nitrogen.

Photolytic action of the type thus assumed to take place during the illumination of the inorganic salts already investigated, all of which are believed to crystallize in the form of ionized lattices, could scarcely be expected to occur in the case of organic derivatives of azido-dithiocarbonic acid, which would, in all probability, in the solid state, take the form of molecular lattices. An important incentive to the preparation and study of these derivatives, none of which has yet been described, is therefore furnished by the possibility of investigating compounds of this type from the viewpoint of the hypothesis under consideration.

A second incentive is afforded by the desire to investigate the influence of various substituents for hydrogen upon the velocity of thermal decomposition of azido-dithiocarbonic acid,[2a] and upon the nature of the products of such decomposition. It is by no means a foregone conclusion

[3] This paper was presented at the St. Louis Meeting of the American Chemical Society in April, 1928. Manuscript received April 9, 1929, but withheld from publication by the author.

that organic derivatives of various types should decompose in a manner strictly analogous to that characteristic of the inorganic salts. It is entirely possible, for example, that in certain cases normal thiocyanates, and in others isothiocyanates, might be obtained as products of thermal decomposition.

In the present article are described the methyl, benzyl, benzohydryl, triphenylmethyl, benzoyl and *p*-bromobenzoyl derivatives of azido-dithiocarbonic acid.

Preparation.—Attempts to obtain alkyl and aryl azido-dithiocarbonates by direct condensation of the organic azides with carbon disulfide by a method analogous to that used in preparing the inorganic derivatives[2] did not prove successful. Formation of the azido-dithiocarbonates evidently involves the transfer of electrons from the azide ion to a molecule of carbon disulfide, or, more specifically, to one of the sulfur atoms of the disulfide, with consequent condensation of the two radicals: $N_3^- + CS_2 = SCSN_3^-$. Since the organic azides are not dissociated to an appreciable degree, the electronic transfer does not take place.

The general method finally adopted for the preparation of the compounds to be described involves the interaction, in acetone, of the alkyl or acyl halide and sodium azido-dithiocarbonate, in accordance with the equation:

$$RCl + NaSCSN_3 = NaCl + RSCSN_3$$

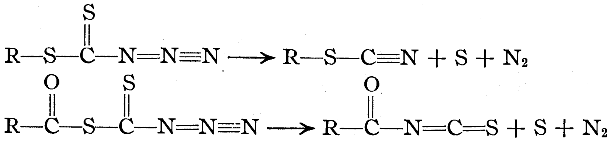
With the bromides, with triphenylmethyl chloride and with the acyl chlorides the reaction proceeds rather rapidly at room temperature. In the case of less reactive chlorides, the use of higher temperatures is precluded by the instability of the products. The precipitated metallic halide is removed by filtration, and if the product is but slightly soluble in acetone, the precipitate is treated with chloroform to extract the azido-dithiocarbonate.

General Properties.—All of the organic azido-dithiocarbonates studied were obtained as white, crystalline compounds which undergo at room temperature a slow spontaneous decomposition, with ultimate quantitative formation of the corresponding thiocyanate or isothiocyanate,[4] sulfur and nitrogen:

---

[4] The *normal* thiocyanates were invariably obtained as decomposition products of the alkyl azido-dithiocarbonates. In view of the circumstance that no normal acyl thiocyanate has as yet been isolated, it is not surprising that isothiocyanates, only, have been obtained by decomposition of the acyl derivatives. It is entirely possible, however, that the normal thiocyanate is in each case formed at first, as an intermediate product, but that, as suggested by Wheeler and Merriam[5] for the case of esters in which "the group R is strongly negative the product immediately undergoes a molecular rearrangement into the form RNCS (when R is the group C_6H_5CO-, etc.)."

[5] Wheeler and Merriam, THIS JOURNAL, **23**, 285 (1901).



$$R—S—\overset{\overset{S}{\|}}{C}—N=N\equiv N \longrightarrow R—S—C\equiv N + S + N_2$$

$$R—\overset{\overset{O}{\|}}{C}—S—\overset{\overset{S}{\|}}{C}—N=N\equiv N \longrightarrow R—\overset{\overset{O}{\|}}{C}—N=C=S + S + N_2$$

The velocity of this decomposition is sufficiently retarded at low temperatures to permit the storage of samples of the products at 0° for several weeks without appreciable deterioration.

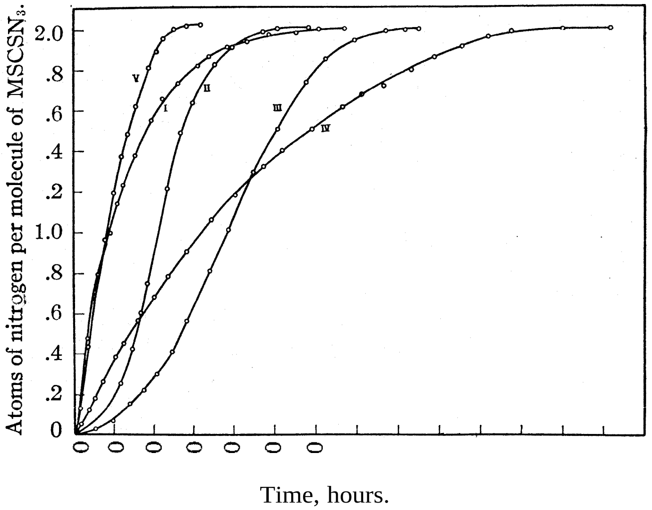


Fig. 1.—Nitrometric decomposition of derivatives of azido-dithiocarbonic acid at 40°. I, CH_3SCSN_3; II, $(C_6H_5)_2CHSCSN_3$; III, $C_6H_5CH_2SCSN_3$; IV, $(C_6H_5)_3CSCSN_3$; V, $C_6H_5COSCSN_3$.

The course of the isothermal decomposition of five compounds has been investigated nitrometrically at 40°. The data obtained are recorded graphically in Fig. 1. From these data the compounds may be listed in the approximate order of increasing stability as follows: $C_6H_5CO– < (C_6H_5)_2CH– < CH_3– < C_6H_5CH_2– < (C_6H_5)_3C–$. The benzyl and benzohydryl derivatives obviously undergo autocatalytic decomposition. The methyl- and phenyl-substituted methylazido-dithiocarbonates manifest a relative degree of stability reminiscent of the behavior of the substituted ammonium salts, of which the disubstituted derivative invariably differs from the mono-, tri- and tetra-substituted compounds in various physical properties, such as electrical conductivity.

Melting-point determinations were made with the aid of the Maquenne block,[6] an apparatus designed especially for use with substances which, like those under investigation, "melt with decomposition." Comparison

[6] Houben-Weyl, "Die Methoden der organischen Chemie," Georg Thieme, Leipzig, 1921, Vol. I, 2d ed., p. 734.

of the results obtained by this procedure with the melting points determined by the usual method, using a capillary tube (in an electrically heated Thiele apparatus), shows that the latter are usually lower in the case of compounds that undergo appreciable decomposition during fusion (see Table I).

Unlike the inorganic salts of the azido acid, the organic derivatives are not particularly explosive. They "puff" mildly when held in the flame, or when heated rapidly on a metal plate. Furthermore, on exposure to illumination they show no photosensitivity and undergo no coloration. This affords support to the photolytic theory mentioned in an earlier paragraph.

The results of qualitative determinations of the solubility of the compounds at room temperature in various non-aqueous solvents are presented in Table I. All of the organic derivatives studied were found to be insoluble in water and to be very soluble in chloroform.

TABLE I

MELTING POINTS AND SOLUBILITIES OF ORGANIC AZIDO-DITHIOCARBONATES

V = very soluble; M = moderately soluble; S = slightly soluble

R—SCSN$_3$ R =	Melting points, °C. Maquenne-block method	Melting points, °C. Capillary-tube method	Acetone	EtOAc	EtOH	MeOH	Ether	C_6H_6	CS_2	$CHCl_3$	CCl_4

p-BrC_6H_4CO—	127 (dec.)	99–101 (dec.)	S	S	S	S	S	S	M	V	M

Analysis.—The amount of nitrogen evolved during thermal decomposition of the compounds was determined in each case by slowly heating the sample, mixed with sand to minimize the danger of explosion, in a bulb attached to a nitrometer. The results obtained were invariably somewhat high, as it was not feasible to introduce a correction for the vapor tension of the thiocyanate formed as a product of the reaction. The sulfur was determined as barium sulfate after conversion to a soluble sulfate by ignition with sodium peroxide in a Parr bomb.

Methyl Azido-dithiocarbonate, CH_3SCSN_3.—The product, which was obtained by the interaction of methyl bromide and sodium azido-dithiocarbonate in acetone, was purified by recrystallization from chloroform. It is slowly attacked by concentrated aqueous alkalies.

Anal. (a) Subs., 0.1855, 0.2498: $BaSO_4$, 0.6485, 0.8759. Calcd. for $C_2H_3N_3S_2$: S, 48.14. Found: S, 48.02, 48.16. (b) Subs., 0.4148, 0.2623: N_2 (corr.), 71.4, 44.7 cc. Calcd. for CH_3SCSN_3: N_2, 1 mole. Found: N_2, 1.023, 1.013.

Under the microscope the crystals appear to consist of thick, four-sided prisms which are rhomb-shaped in cross section. The acute angle of the rhomb is about 75°. The terminal pinacoid is perpendicular to the prism faces. All prism views exhibit parallel extinction; end views of the prisms reveal a very small extinction angle, about 1–2°. The angle of the acute bisectrix parallel to the elongation with 2V is about 65°. The crystals are optically negative and exhibit strong double refraction. They are probably of monoclinic symmetry.

Benzyl Azido-dithiocarbonate, $C_6H_5CH_2SCSN_3$.—The interaction of benzyl chloride and sodium azido-dithiocarbonate in acetone at room temperature required for its completion approximately twenty-four hours. The precipitated sodium chloride was filtered off and a small amount of water was added to the filtrate. The crude benzyl derivative which separated on cooling with ice and salt was purified by recrystallization from chloroform.

Most reagents cause primary decomposition of the azido-dithiocarbonate to form the thiocyanate, which then exhibits its own characteristic reactions. Thus, boiling with nitric acid brings about oxidation to benzaldehyde; the prolonged action of aqueous alcohol causes hydrolysis. Benzyl thiocyanate was obtained readily by heating the azido-dithiocarbonate in a suitable organic solvent (absolute alcohol) and removing the precipitated sulfur. The solution after concentration deposited crystals of benzyl thiocyanate, m. p. 41°.

Anal. (a) Subs., 0.1705, 0.1640: $BaSO_4$, 0.3768, 0.3675. Calcd. for $C_8H_7N_3S_2$: S, 30.64. Found: S, 30.35, 30.78. (b) Subs., 0.2021, 0.4856: N_2 (corr.), 21.62, 52.47 cc. Calcd. for $C_7H_7SCSN_3$: N_2, 1 mole. Found: N_2, 1.000, 1.010. (c) Dumas total nitrogen determination. Subs., 0.2611: N_2 (corr.), 42.5 cc. Calcd. for $C_8H_7N_3S_2$: N, 20.1. Found: N, 20.4.

Benzyl azido-dithiocarbonate crystallizes in prisms of monoclinic symmetry, showing the forms 1 0 0, 1 1 0, 0 1 1 and 1 0 1. Extinction is parallel to the plane of symmetry, and oblique in this plane at an angle of 7°: The crystals are biaxial, positive, 2V about 80°, $v < r$. The axial plane is transverse of the prisms. Double refraction is moderately strong.

Benzohydryl Azido-dithiocarbonate, $(C_6H_5)_2CHSCSN_3$.—The interaction of benzohydryl bromide[7] and sodium azido-dithiocarbonate in acetone was complete after about half an hour. After filtering to remove the precipitated sodium bromide, addition of water caused a yellow liquid to separate. This was dissolved in a mixture of petroleum ether and benzene and the solution was dried over anhydrous sodium sulfate. Upon cooling with ice and salt, benzohydryl azido-dithiocarbonate separated in small colorless crystals.

Anal. (a) Subs., 0.1113, 0.1340: $BaSO_4$, 0.1877, 0.2201. Calcd. for $C_{14}H_{11}N_3S_2$: S, 22.47. Found: S, 22.55, 22.56. (b) Subs., 0.4212, 0.5428: N_2 (corr.), 34.42, 42.68 cc. Calcd. for $C_{13}H_{11}SCSN_3$: Nz, 1 mole. Found: N_2, 1.017, 1.025.

The substance, recrystallized from xylene, forms prisms and elongated tablets, the opposite edges of which are beveled, and the ends obtusely pointed (120"). These tablets are frequently shortened to thick rhomb-shaped plates, the four vertices of which are beveled. Prism views exhibit parallel extinction; the rhombs, symmetrical extinction. End views show oblique extinction, about 45°.

Good biaxial interference figures are obtainable, which indicate that the acute bisectrix is inclined to the pinacoid of the tablets. The axial plane is parallel to the acute diagonal of the rhombs. Double refraction is strong, positive, with 2V about 60°,

---

[7] The chloride reacted much more slowly, and for this reason was not as satisfactory as the bromide in this preparation.

and $r < v$ marked (or else inclined dispersion). Refractive indices were not determined on account of solubility in the standard immersion liquids. The oblique extinction of the end views of the prisms and tablets, and tilted position of the optic axes indicate that the plane symmetry of the crystals lies crosswise of them (parallel to the acute diagonal of the rhombs), and that they belong to the monoclinic system.

Triphenylmethyl Azido-dithiocarbonate, $(C_6H_5)_3C\text{-}SCSN_3$.—When triphenylmethyl chloride and sodium azido-dithiocarbonate were brought together in acetone, the ester was precipitated rapidly, together with sodium chloride. This precipitate was air-dried, and was extracted with chloroform, in which the triphenylmethyl ester is soluble. After concentrating and cooling, the solution deposited colorless crystals of triphenylmethyl azido-dithiocarbonate.

Anal. (a) Subs., 0.2743, 0.2348: $BaSO_4$, 0.3483, 0.3004. Calcd. for $C_{20}H_{15}N_3S_2$: S, 17.74. Found: S, 17.44, 17.57. (b) Subs., 0.3868, 0.3746: N_2 (corr.), 24.16, 23.37 cc. Calcd. for $C_{19}H_{15}SCSN_3$: N_2, 1 mole. Found: N_2, 1.008, 1.006.

The substance crystallizes in bipyramids and tablets of orthorhombic symmetry. The tablets possess end angles of about 120°. All views exhibit symmetrical extinction. The axial plane is parallel to the base of the pyramidal forms; 2V is large ($> 70°$). The crystals are optically positive.

Allyl Azido-dithiocarbonate, $C_3H_5SCSN_3$.—This substance was obtained by interaction of allyl bromide and sodium azido-dithiocarbonate in acetone. Because of the Instability and the difficulty of purification of the resulting product, no attempt was made to study it carefully. It apparently undergoes fairly rapid decomposition, since the characteristic odor of allyl isothiocyanate was very marked in all of the samples that were prepared.

Benzoyl Azido-dithiocarbonate, $C_6H_5COSCSN_3$.—This acyl derivative was prepared by the interaction of benzoyl chloride and sodium azido-dithiocarbonate, either in aqueous solution or in acetone. The latter medium is preferable, since the reaction is practically instantaneous in this solvent. The product was purified by recrystallization from chloroform.

Anal. (a) Subs., 0.1845, 0.2115: $BaSO_4$, 0.3810, 0.4348. Calcd. for $C_8H_5ON_3S_2$: S, 28.72. Found: S, 28.36, 28.24. (b) Subs., 0.2997, 0.2212: N_2 (corr.), 30.11, 22.33 cc. Calcd. for $C_7H_5OSCSN_3$: N_2, 1 mole. Found: N_2, 1.002, 1.006.

Benzoyl azido-dithiocarbonate is hydrolyzed by hot aqueous potassium hydroxide solution with the formation of potassium benzoate and potassium azido-dithiocarbonate. The formation of benzoyl isothiocyanate by the thermal decomposition of the benzoyl derivative is shown by the fact that the purified decomposition residue combines with alcohol to form ethyl benzoylthiocarbamate, $C_6H_5CO—NH—CS—OC_2H_5$, and with aniline to form α-phenyl-β-benzoylthiourea, $C_6H_5CO—NH—CS—NHC_6H_5$.[8] Apparently the strongly negative character of the benzoyl group causes the normal thiocyanate first formed to undergo immediately an intramolecular rearrangement to the isothiocyanate.

Benzoyl azido-dithiocarbonate crystallizes in the form of thin, oblique-ended plates, belonging to the monoclinic system; acute angles, 63°; obtuse angles, rarely truncated. When precipitated directly under the microscope, crystals are obtained in which the axial plane is inclined 21° to the longer edges of the plates, in the direction of the diagonal connecting their obtuse angles. Recrystallization from xylene alters the habitus so that the other two edges of the plates are longer, resulting in an apparent extinction angle of 6° instead of 21°. Seen edgewise the plates exhibit parallel extinction. They are optically negative, with 2V about 75–80°. The refractive index for vibrations in the

---

[8] Miquel, *Ann. chim. phys.*, [5] 11, 321, 334 (1877).

axial plane is about 1.50; for vibrations transverse to this the refractive index is estimated to be about 1.75.

p-Bromobenzoyl Azido-dithiocarbonate, $BrC_6H_4COSCSN_3$.—This compound was precipitated, together with sodium chloride, by the interaction of p-bromobenzoyl chloride[9] and sodium azido-dithiocarbonate in acetone. The product was purified by recrystallization from chloroform.

p-Bromobenzoyl azido-dithiocarbonate crystallizes from chloroform or xylene in tiny rhomb-shaped plates or oblique-ended prisms. These exhibit oblique extinction. dispersed, at an angle of about 7–8°; some views show parallel extinction. It probably crystallizes in the monoclinic system.

Anal. (a) Subs., 0.2280, 0.1870: $BaSO_4$, 0.3503, 0.2857. Calcd. for $C_8H_4ON_3$-BrS_2: S, 21.22. Found: S, 21.10, 20.98. (b) Subs., 0.2580, 0.3497: N_2 (corr.), 19.44, 25.95 cc. Calcd. for C_7H_4OBr—$SCSN_3$: N_2, 1 mole. Found: N_2, 1.016, 1.001.

The reactions of the p-bromobenzoyl derivative are strictly analogous to those of the benzoyl compound. Boiling with aqueous potassium hydroxide solution hydrolyzes the substance to form potassium *p*-bromobenzoate and potassium azido-dithiocarbonate; thermal decomposition yields nitrogen, sulfur and p-bromobenzoyl isothiocyanate, which was identified by its melting point and by the preparation of its condensation product with alcohol and with aniline. Since p-bromobenzoyl isothiocyanate had not previously been prepared and described in the literature, it was necessary, for purposes of identification, to synthesize not only the isothiocyanate but also its condensation product with alcohol and with aniline. These are briefly described below.

_p_-Bromobenzoyl Isothiocyanate, BrC_6H_4CONCS.—This substance was readily obtained by the interaction of p-bromobenzoyl chloride and sodium thiocyanate in acetone. Recrystallization of the crude product from chloroform gave a colorless crystalline solid, m. p. 55°.

Anal. Subs., 0.2395, 0.2453: $BaSO_4$, 0.2242, 0.2323. Calcd. for C_8H_4ONBrS: S, 13.2. Found: S, 12.9, 13.0.

Ethyl **_p_-Bromobenzoylthiocarbamate,** BrC_6H_4CO-NH-CS-OC_2H_5.—This derivative was prepared by direct combination of ethyl alcohol with p-bromobenzoyl isothiocyanate. It crystallizes from aqueous alcohol in fine, colorless needles, m. p. 99°.

Anal. Subs., 0.2097, 0.2119: $BaSO_4$, 0.1675, 0.1690. Calcd. for $C_{10}H_{10}O_2NBrS$: S, 11.1. Found: S, 11.0, 11.0.

α-Phenyl-β-(_p_-bromobenzoyl)-thiourea, BrC_6H_4CO-NH-CS-NHC_6H_5.—This compound was produced by direct combination of aniline and p-bromobenzoyl isothiocyanate. Recrystallization from aqueous alcohol yielded a colorless crystalline solid, m. p. 151°. It is very soluble in chloroform, toluene and aniline; it crystallizes from the latter in the form of fine, elongated prisms.

Anal. Subs., 0.2648, 0.1810: $BaSO_4$, 0.1827, 0.1245. Calcd. for $C_{14}H_{11}ON_2BrS$: S, 9.6. Found: S, 9.5, 9.5.

Summary

The methyl, benzyl, benzohydryl, triphenylmethyl, benzoyl and p-bromobenzoyl azido-dithiocarbonates have been prepared and described.

---

[9] p-Bromobenzoyl chloride may be prepared in good yield by the long continued action of an excess of thionyl chloride upon *p*-bromobenzoic acid, although the reaction is unusually slow. When 25 g. of thionyl chloride (0.21 mole) and 16 g. of the acid (0.08 mole) were refluxed for 120 hours, the yield of purified p-bromobenzoyl chloride, after one crystallization from petroleum ether, was 15 g. (85% of the calculated amount).

These compounds, the first organic derivatives of azido-dithiocarbonic acid to be isolated, were formed by interaction of the alkyl or acyl halide and sodium azido-dithiocarbonate in acetone. They are white, crystalline compounds, stable at 0°, but decomposing more or less rapidly at higher temperatures into thiocyanates or isothiocyanates, sulfur and nitrogen. The crystallographic properties, melting points and solubilities of the compounds have been determined. Unlike certain of the inorganic azido-dithiocarbonates, the organic compounds show no photosensitivity, presumably because of the molecular character of their lattices.

The preparation of *p*-bromobenzoyl isothiocyanate and its condensation products with alcohol and aniline is described.

ITHACA, NEW YORK

NOTES

The Rate of Rearrangement of Pinene to Dipentene.—The rate of disappearance of the optical activity of d-pinene upon heating has been measured by Smith.[1] His experimental results were treated by supposing that the reaction which occurred was a simple racemization, a view for which he presented some evidence. Recently it has been shown rather convincingly by Conant and Carlson[2] that the reaction Smith measured was the isomerization to dipentene. This substance is optically inactive and if the reaction went to completion the final rotation would be zero, just as in the supposed formation of the racemic mixture. The rate of the reaction, as calculated from the observed rotations, will not be the same in the two cases, and it is the purpose of this communication to point out how Smith's constants must be modified, if the reaction is actually an isomerization.

The equation appropriate to Smith's interpretation of the reaction was

$$\ln \alpha_1/\alpha_2 = 2k_1(t_2 - t_1) \qquad (1)$$

where α is a measured angle of rotation; but with the revised interpretation the rotation measures directly the amount of pinene remaining and we have

$$\ln \alpha_1/\alpha_2 = k_2(t_2 - t_1) \qquad (2)$$

This equation is of the same form as (1), and since Smith found that the values k_1 were constant, the values of k_2 will be constant also; clearly $k_2 = 2k_1$. That is, the correct first-order constants for the rearrangement are just twice the values reported by Smith.

It is still reasonable to suppose that this reaction occurs by a homogeneous unimolecular mechanism. Although it has lost some of its theoretical simplicity, since it can no longer be supposed that the heat of reaction is zero, it remains the only known example of a presumably unimolecular

---

A Capillary Gas Valve.—Having had occasion to withdraw many small samples of extremely pure chlorine from a large storage bulb without contaminating the main supply, the scheme in Fig. 1 was adopted. The outer tube D is of thin-walled 12-mm. tubing, 30-cm. long; the capillary E is less than 1-mm. bore, with thin walls. When a sample is to be collected in the reaction vessel which, together with tube D, has been evacuated, liquid air is applied at G. From this point on, H serves as a chlorine block, cotton wrapping around H being continually soaked with liquid air throughout all subsequent operations. The Dewar flask is then removed, and the chlorine in capillary G begins to melt. Current sent through an electromagnet held at point A, Fig. 1, causes the iron-cored glass capsule C to jump up and break the capillary at point A, and chlorine in G begins to distil over into the reaction vessel. C is then pulled out of the way, as in Fig. 2. When sufficient chlorine has been collected, F is shut, and a small flame applied momentarily at B. Since the pressure in D is less than one atmosphere, the thin tube immediately collapses as represented by the dotted curve in Fig. 2. The flame is now directed at A, and the capillary quickly sealed off as shown in Fig. 3. The blob of glass may be pulled off subsequently to give the appearance of Fig. 1 again. The capillary always breaks at point A-B where the strain of being sealed to D lies. Any gases given off from the momentary heating at B can be pumped out of D before opening F to the reaction vessel again; and none of these gases can pass into the storage bulb against the stream of chlorine which continually evaporates from G and flows into D through

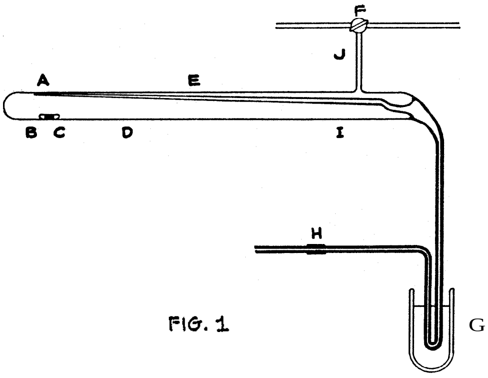

FIG. 1

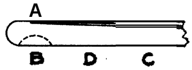

FIG. 2

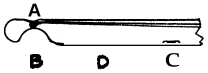

FIG. 3

---

[3] National Research Fellow in Chemistry.

capillary E. The latter is sufficiently long to permit the withdrawal of about thirty samples, after which a new tube can be sealed on at I, and thirty more samples withdrawn. Stopcock F, treated with a special chlorine-resisting lubricant,[1] can be dispensed with, if necessary, by a slight modification of the scheme in Fig. 1, such as by sealing off the reaction vessel each time at a constriction at J.

This scheme is, of course, applicable to gases other than chlorine to replace other more complicated and less satisfactory devices. It has the advantage of repeated use without replacement. In other cases the liquid air trap may or may not have application, according to circumstances, and may be omitted at will.

A New Line in the Absorption Spectrum of Samarium.—During the course of work on the concentration of illinium it was noticed that an extremely faint line appeared at 5960 Å. in the absorption spectrum of supposedly pure samarium. No line at 5960 Å. has been reported for this element. As the material had been prepared by fractional crystallization of the double magnesium nitrates, the line could be attributed only to neodymium, europium, illinium or to samarium itself.

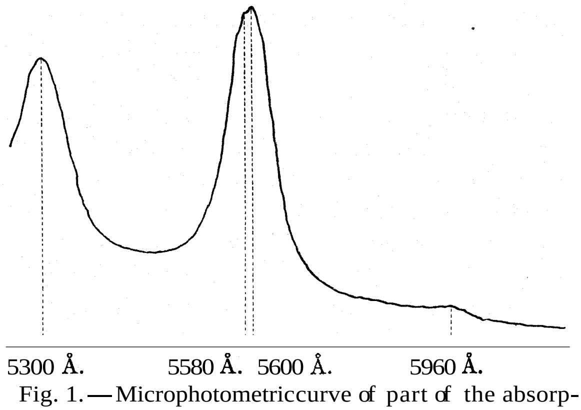

Fig. 1.—Microphotometric curve of part of the absorption spectrum of samarium nitrate, showing a new line at 5960 Å.

About two kilograms of rare earth oxide showing the line was, therefore, fractionally crystallized five hundred times as the double magnesium nitrate, and then one hundred times as the simple nitrate. During all this

[2] National Research Fellow.

time the line at 5960 Å. remained at the same relative intensity to the other lines of samarium throughout the series. The only impurity eliminated was a faint trace of neodymium, the absorption bands of which appeared quite distinct from the line in question. It was, therefore, concluded that the line at 5960 Å. belonged to samarium and had escaped observation before owing to its extreme faintness.

The figure shows a microphotometric curve taken from part of the absorption spectrum of samarium nitrate photographed on a Hilger E1 quartz spectrograph as described elsewhere.[1] The solution, which was 6.0 N in samarium nitrate, was in a 15-cm. absorption cell. The temperature was 80°, as the line is more intense when the solution is hot. Some idea of the relative intensities of the new line and the one at 5600 Å. may be gained from the figure.

The Standardization of Weights.—The accuracy of the Richards method[1] for the standardization of weights by substitution can be doubled by using the method of weighing by transposition. This latter method makes the use of a set of tare weights unnecessary, and involves no more time or difficulty than the Richards method. In fact, this is one operation to which the little-used transposition weighing seems peculiarly suited.

If the weights W_1 and W_2 are to be compared, W_1 is placed on the left pan and W_2 on the right and the zero point noted. The weights are then reversed and the difference, d, necessary to bring the pointer to the same zero point is noted. It can be shown readily that $W_2 - W_1 = d(l_2) \div (l_1 + l_2)$ where l_1 and l_2 are, respectively, the lengths of the beam to the left and to the right of the central knife edge. Since d is very small, any error introduced by assuming that $l_1 = l_2$ is entirely negligible, so $W_2 - W_1 = d/2$, where d may, of course, be either a positive or negative quantity. The method of calculating the corrections remains the same.

Variations in the relative lengths of the balance arms are not likely to occur during any one comparison, and variations between comparisons could not affect the value of $W_2 - W_1$ appreciably.

A STUDY OF MOLECULAR ORGANIC COMPOUNDS. II. THE MOLECULAR ORGANIC COMPOUNDS OF 2,4-DINITROANILINE, 2,4-DINITROCHLOROBENZENE AND 2,4-DINITROBROMOBENZENE[1]

BY C. A. BUEHLER, ALAN HISEY AND JESSE H. WOOD

RECEIVED AUGUST 24, 1929 PUBLISHED MAY 8, 1930

This paper is a continuation of the study[2] of the molecular organic compounds of m-dinitrobenzene and some monosubstituted *m*-dinitrobenzenes. In the present investigation the effect upon molecular compound formation of introducing amino, chloro and bromo groups into m-dinitrobenzene has been determined. Quite a few compounds were isolated, some of their properties were determined, and the substitution compounds, into which some were easily converted, were identified.

Experimental Part

The molecular compounds were prepared for the most part as described previously. In a few cases it was not possible to purify by recrystallization due to decomposition. In two cases—the naphthols with 2,4-dinitrobromobenzene—carbon tetrachloride was found to be the best solvent for purification by crystallization. Substitution compounds were frequently obtained with the dinitrohalogenobenzenes. These were easily recognized by their color, solubility and melting points.

The analyses for halogens were carried out by Pringsheim's method.[3] The amount of silver halide was determined in some cases gravimetrically and in others volumetrically. The melting points were taken by Mulliken's[4] capillary tube method with a thermometer calibrated by the Bureau of Standards.

No molecular compounds of 2,4-dinitro-aniline were isolated.

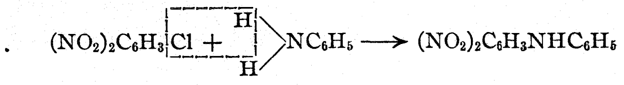
Substitution Compounds of 2,4-Dinitrochloro- and 2,4-Dinitrobromobenzenes.—Second components containing amino groups did not readily form molecular compounds with the 2,4-dinitrohalogenobenzenes. Instead, substitution compounds were usually formed with the elimination of the hydrogen halide according to the scheme



$$(NO_2)_2C_6H_3Cl + \begin{matrix}H\\ \\H\end{matrix}\!\!>NC_6H_5 \longrightarrow (NO_2)_2C_6H_3NHC_6H_5$$

Aniline,[5] methylaniline,[6] diethylamine,[7] *p*-toluidine,[8,5] *o*-toluidine,[5] *p*-aminophenol,[9] *o*-,[10] *m*-[6] and *p*-phenylenediamines[11] reacted in this manner. Dimethylaniline reacted with the elimination of the methyl halide to form a substitution compound identical with that formed with methylaniline.[12] Benzidine[5,8] gave a few crystals of the molecular compound with the chloro compound, but substituted completely with the bromo compound. The a- and β-naphthylamines[13] formed fairly pure molecular compounds but these were readily converted into the corresponding substitution compounds by simply refluxing them for several hours in alcoholic solution. Of the two, the a-molecular compound was the more resistant to decomposition.

Discussion

Molecular Compounds are Intermediates in the Formation of Substitution Compounds.—The idea that reactions between organic compounds are due to an attraction between molecules resulting in an initial combination is not new.[14] Cases similar to those mentioned in this investigation are those of the addition compounds of picryl chloride with the a- and β-naphthylamines,[15] which readily lost hydrochloric acid to

[11] Nietzki and Ernst, Ber., 23, 1852 (1890), gave the melting point of 2,4-dinitrophenyl-*p*-phenylenediamine as 177°; Morgan and Micklethwait, *J. Chem. Soc.*, 93, 610 (1908), stated that the compound melted at 190". Our result (177.8°) obtained repeatedly agreed more closely with the former. In addition the monoacetyl derivative, melting at 238°, checked the former's value.

[12] Leyman, Ref. 6, made this observation previously in the case of 2,4-dinitrochlorobenzene.

form the corresponding substitution products. Amines were particularly susceptible to molecular compound formation, but in most cases in this investigation substitution compounds were obtained. The α- and β-naphthylamines and benzidine were the sole amines which formed molecular compounds capable of being isolated. Since these were disrupted by moderate heat treatment in alcoholic solution, it seems reasonable to assume that molecular compounds were formed as intermediates in all cases of substitution.

Influence of the Substituent in a Dinitrobenzene on the Formation of Molecular Compounds.—Of the six dinitrobenzenes studied[16] each formed a different number of molecular compounds, a fact which shows that the substituent is an influencing factor. The groups arranged in the order of decreasing ability toward molecular compound formation are: $Cl > Br^{17} > OH > H > CH_3 > NH_2$. This order is the same as the electronegative character of these groups.[18]

Kendall[19] stated, from the results of a series of experiments, that addition compounds will be formed between two components if there is sufficient difference in acidic strength. Increasing the electronegative character of any substituent in a benzene ring should increase the acidic strength of the compound and, therefore, increase the number of possible molecular compounds. The results of this investigation with the amine molecular compounds bear out this relation. In the case of the hydrocarbon and phenol molecular compounds the number obtained was so small that no conclusions can be drawn in regard to this relation.

The Structure of Molecular Organic Compounds.—The electronic conception of valency as introduced by Lewis[20] has been very helpful in that it does account for the differences between inorganic (polar) and organic (non-polar) compounds. Quite recently Sidgwick[21] has applied it to the Werner complexes, solvation and various other chemical phenomena. His success in this work has raised the question: Can molecular compound formation be explained using the electronic interpretation of valency?

Bennett and Willis[22] have proposed formulas for the compounds formed between nitro compounds and amines and hydrocarbons. These investigators assumed that the union takes place by means of co-valent linkages

---

[16] Three were reported previously, Buehler and Heap. Ref. 2.

[17] Chlorine and bromine have been placed before the hydroxyl group since it has been assumed that the great number of substitution compounds of the former two implies the previous existence of molecular compounds.

[18] Crocker, *ibid.*, 44, 1618 (1922).

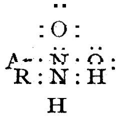
[19] Kendall, *ibid.*, *36*, 1722 (1914).

[20] Lewis, This Journal, 38,762 (1916).

[21] Sidgwick, "The Electronic Theory of Valency," Oxford University Press.

[22] Bennett and Willis, J. *Chem. Soc.*, 256 (1929).

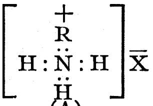
and that the nitro group is the point of attachment[23] in the nitro compound. Their representation of an amine nitro compound would be as indicated. Here the amine is the donor and the nitro compound the acceptor.



$$\begin{array}{ccccc} & & \overset{..}{:O:} & & \\ A\leftarrow & : & \ddot{N} & : & \ddot{O}: \\ R & : & N & : & H \\ & & H & & \end{array}$$

There is considerable evidence supporting this coordinate co-valent type of union in molecular compounds. In the first place mention may be made of the low melting points[24] of these compounds—all of them melted lower than the higher-melting component with the exception of the *α*-naphthol molecular compound. Again, the fact that the great majority of these consist of two molecules in a one-to-one ratio can best be explained upon the basis of a union of a co-valent type between atoms. The color which some of these show may also be interpreted in terms of this type of combination.[22]

Assuming a coordinate co-valent type of union, how can the molecular compounds formed in this investigation be best represented? In the case of the amine molecular compounds, the amine is undoubtedly the donor compound. It reacts with acids to form compounds of the type shown (A).[25] In this investigation the dinitrobenzenes were the acids and as such they may be considered as reacting to form ortho or para quinoid inner salts corresponding to the salts which trinitrobenzene forms with potassium methylate.[26]



$$\left[\begin{array}{c} + \\ R \\ H:\ddot{N}:H \\ \ddot{H} \end{array}\right]\bar{X}$$
(A)

The highly colored compounds resulting from their union with amines may then be represented as shown in diagram (B),[27] where X = Cl, Br, OH,[28] H or CH_3. In cases where X = Cl or Br, this complex was not stable with the more basic amines due to the fact that the halogen was eliminated with one of the hydrogens of the amino group, with the result that the arylimido group occupied the position (1) alone. With pyridine (when X = Cl) this complex seemed to have only a temporary existence.[29] Here, there were no hydrogen atoms attached to the nitrogen atom of the pyridine ring. For that reason the halogen was not eliminated as the halogen hydride but it ionized, resulting in the formation by rearrangement of the complex salt (C). This repre-

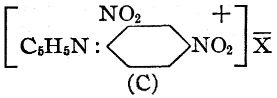
[28] The lack of color in some of the amine-2,4-dinitrophenol compounds seems to indicate that the attachment occurs between the lone pair of the amine and the hydrogen atom of the phenolic group. Additional support to this structure is furnished by the numerous amine–phenol compounds that are known.

[29] The compound, at first violet, showed signs of melting below 100"; the red droplets which appeared soon disappeared and the compound turned white and melted as reported above.

sentation explains very well the properties of the pyridine compounds with 2,4-dinitrochloro- and 2,4-dinitrobromobenzenes.



(C)

They are white or almost so, are soluble in water, have a high melting point and in aqueous solution they precipitate their halide atoms quantitatively with silver nitrate. In other words they are salts and therefore polar compounds.

The authors are greatly indebted to the Department of Chemistry, The Ohio State University, for the use of their library facilities.

Summary

1. New molecular organic compounds of 2,4-dinitrochlorobenzene and 2,4-dinitrobromobenzene have been isolated; no similar compounds with 2,4-dinitro-aniline could be isolated.

2. It has been shown in some cases that substitution products resulted through the intermediate formation of molecular compounds.

3. The influence of the substituent in the dinitrobenzenes upon molecular compound formation is discussed.

4. An electronic formula is proposed for the amine molecular compounds.

PHENOLIC DECOMPOSITION' OF CERTAIN MIXED ETHERS. THE VELOCITY CONSTANT

BY D. M. BIROSEL[1]

RECEIVED NOVEMBER 19, 1929 PUBLISHED MAY 8, 1930

Introduction

It is well known that mixed ethers, *e.* g., *p*-nitrophenyl methyl ether will give the corresponding phenol as one of the products of reaction according to the scheme

when they are acted upon by hydrogen bromide. Graebe and Martz[2] and also Raiford and Colbert[3] digested certain mixed ethers with 48% hydrobromic acid alone on the steam-bath for two hours and obtained varying degrees of decomposition depending upon the kind and number of substituents actually present in the phenyl residue. Stoermer[4] carried out

the decomposition with acetic acid as reaction medium and reported varying extents of decomposition depending upon whether the substituent occupied the ortho or para position in the benzene nucleus. The kinetics of this reaction does not seem to have been investigated and it seemed interesting to study the factors influencing the phenolic decomposition of mixed ethers.

Experimental Part

A. Preparation of Materials

2,4-Dibromophenyl Methyl Ether.—Twenty grams of unsubstituted anisole dissolved in 20 cc. of chloroform was treated according to the procedure of Raiford and Birosel,[5] with 59.14 g. of bromine dissolved in 20 cc. of the same solvent. The mixture was allowed to stand at room temperature for four days, after which it was freed from the unused bromine by washing with a dilute solution of sodium hydroxide, then with distilled water, and dehydrated with anhydrous sodium sulfate. The solvent was evaporated and the residue consisted of solid and liquid derivatives. The solid was separated and crystallized from alcohol, giving shiny scale crystals melting sharply at 63°.[6]

***p*-Bromophenyl** Methyl Ether.—The liquid obtained above was found to distil mostly at 223°. It was redistilled and the portion going over at 223°[7] was reserved.

o-Bromophenyl Methyl Ether.—Ten grams of unsubstituted anisole was treated as above with the required amount of bromine for a monomolecular proportion. A liquid was obtained which distilled at 210–213°. It was redistilled and the fraction going over at 210°[8] was reserved for use.

2,4,6-Tribromophenyl Methyl Ether.—This compound was prepared as above by treating 10 g. of 2,4-dibromophenyl methyl ether with the required amount of bromine for a monomolecular proportion. After four days the solvent and unused bromine were removed. Two distinct crystal forms were obtained when the residue was crystallized from alcohol. The needle crystal material was separated from the shiny scale crystals of dibromo-anisole and recrystallized from alcohol, giving a product which melted sharply at 87°.[9]

---

[5] Raiford and Birosel, This Journal, 51, 1652 (1929).

[6] Cahours, Ann., 52,331 (1884), obtained a liquid monobromo derivative of which he did not mention any characteristic and 2,4-dibromo-anisole, which gave shiny scale crystals, m. p. 54°, from alcohol, when he brominated anisole. Korner, *ibid.*, 137, 206 (1866), prepared 2,4-dibromophenyl methyl ether from 2,4-dibromophenol, sodium methoxide and methyl iodide and obtained shiny scale crystals, m. p. 59°. Kohn and Pfeifer, Monatsh., 48, 211 (1927), prepared 2,4-dibromophenyl methyl ether from 2,4-dibromophenol obtained by the reduction of *sym.*-tribromophenol, with potassium hydroxide and dimethyl sulfate. Crystallizing from alcohol they obtained shiny scale crystals which they reported as melting from 62 to 64°.

[7] Henry, *Ber.*, 2,711 (1869), prepared p-homo-anisole by treating anisole with one molecular proportion of phosphorus pentabromide. He obtained a liquid which distilled at 220° (uncorrected). Autenrieth and Mullinghaus, *Ber.*, 39, 4098 (1906), prepared this compound in the same way as Henry and obtained a liquid boiling between 213 and 216°.

[8] Michaelis and Geisler, *ibid.*, 27, 256 (1894), prepared o-bromo-anisole according to the directions of Mulhauser, Ann., 207,239 (1881), from *o*-anisidine, $CH_3OC_6H_4NH_2$. They obtained a liquid boiling at 210°.

[9] Kohn and Fink, Monatsh., 44, 18 (1923), prepared *sym.*-tribromo-anisole from 2,4,6-tribromophenol (1 mole), potassium hydroxide (10% solution) and dimethyl sulfate

B. Procedure of Decomposition

The velocity and extent of the phenolic decomposition of mixed ethers were determined at the temperature of the steam-bath. A weighed amount of the ether was digested with 30 cc. of constant boiling hydrobromic acid in glacial acetic acid solution made by adding 150 cc. of 48% hydrobromic acid to 300 cc. of acetic acid, for the desired period of time. The mixture was cooled and sodium hydroxide solution (1:4) was gradually added until the solution became slightly alkaline. The undecomposed ether was recovered by three ether extractions, washing each extraction with distilled water and adding the washings to the alkaline solution. Dilute sulfuric acid was added to the alkaline solution until slightly acidic and the phenol was extracted three times with ether. The solvent was evaporated, the residue heated on the steam-bath until the odor of acetic acid was no longer noticeable and then dehydrated in a desiccator.

The results obtained from experiments are given in the tables.

TABLE I

EXTENT OF DECOMPOSITION OF CERTAIN MIXED ETHERS

Compound	Time, hours	Ether used, g.	HBr used, cc.	AcH used, cc.	Acid soln. used, cc.	Phenol obtained, g.	Decomposition, %
o-Bromo-anisole	2	1.6835	10'	20	30	0.4135	26.57[a]
	4	1.0840	10	15	25	.8755	87.28
p-Bromo-anisole	2	2.1500	15	25	40	1.5437	77.60[a]
2,4-Dibromo-anisole	2	1.0000	10	10	20	0.2035	21.48
	2	1.0000	10	20	30	.1710	18.05
2,4,6-Tribromo-anisole	2	0.5000	10	20	30	.1885	39.40

[a] Stoermer, Ref. 4, obtained 67.8% decomposition of o-bromo-anisole for four hours of digestion and 75% decomposition of *p*-bromo-anisole for two hours of digestion. He did not give data from which his figures can be recalculated.

TABLE II

THE RATE OF DECOMPOSITION OF 2,4-DIBROMOPHENYL METHYL ETHER IN GLACIAL ACETIC ACID AS MENSTRUM

Expt.	Time, minutes	Ether used, *g.*	Acid soln. used, cc.	Dibromophenol obtained, *g.*	Calcd. decomposed ether, *g.*	Decomposition, %	k
1	60	1	30	0.0965	0.1025	10.19	0.00180

[a] Crystallization from alcohol gave fine needle crystals, m. p. 92°; the melting point recorded in the literature for *sym.*-tribromophenol is 92–95°.

C. Discussion

In Table I are given the detailed results of the extent of decomposition of four bromo derivatives of anisole. Comparison of the decomposition for an interval of two hours shows that 2,4-dibromophenyl methyl ether is the least decomposed, that 2,4,6-tribromophenyl methyl ether appears to give higher phenolic decomposition than the dibromo derivative, and that o-bromo-anisole is more resistant to phenolic decomposition than the *p*-bromo derivative.

In Table II are shown the results of a typical experiment on the velocity of the phenolic decomposition of mixed ethers at the temperature of the steam-bath. The rate constants, k, are those calculated from the integrated form of the differential equation for first-order reactions, using logarithms to the base e. It will be noted that the constancy of k is quite satisfactory. The calculated amount of decomposed ether was obtained by multiplying the amount of dibromophenol obtained directly from experiment by the factor 1.06.

Table III shows the effect of changing the amount of hydrobromic acid in glacial acetic acid solution upon the phenolic decomposition of 2,4-dibromophenyl methyl ether. The greater the amount of halogen acid used, the greater the degree of decomposition and the higher the rate constant becomes. This does not mean that decomposition is greater when the halogen acid is used alone. Digesting a weighed amount of the ether for several hours on the steam-bath with hydrobromic acid alone did not give appreciable decomposition, which experience led to the employment of glacial acetic acid as menstrum. The solvent, though not entering into the reaction, seems to play an important role. In Table IV are expressed the results obtained from experiments when formic acid was used in place of glacial acetic acid. The extent of decomposition and the rate constant calculated in the same manner as the velocity constant in Table III are very much lower.

In Table V are given the detailed results of the experiments on the decomposition of 2,4,6-tribromophenyl methyl ether. The rate constants are those calculated from the integrated forms of the differential equation for first-order reactions, using logarithms to the base e. It will be noted that the constancy of k is quite satisfactory. The calculated amount of decomposed ether was obtained by multiplying the amount of tribromophenol obtained directly from experiments by the factor 1.04.

Summary

1. The kinetics of the phenolic decomposition of mixed ethers has been studied in the case of 2,4-dibromophenyl methyl ether and with 2,4,6-tribromophenyl methyl ether. Experiments were made in glacial acetic acid and formic acid as menstrums.

2. The velocity constants of the decomposition of 2,4-dibromophenyl methyl ether and 2,4,6-tribromophenyl methyl ether were calculated from the experimental results and their constancy is quite satisfactory. The phenolic decomposition of mixed ethers appears to be a first-order reaction.

3. The extent of decomposition is proportional to the amount of halogen acid used and seems to be influenced by the reaction medium. Decomposition is greater in glacial acetic acid than in formic acid as menstrum.

4. The degree of decomposition is also influenced by the number of substituents actually present and the position occupied in the phenyl residue.

The kinetics of the decomposition of other mixed ethers is being studied.

QUALITATIVE ESTIMATION OF THE COMPOSITION OF BUTENE MIXTURES BY DISTILLATION METHODS[1]

BY HOWARD J. LUCAS,[2] ROBERT T. DILLON[3] AND WILLIAM G. YOUNG[3]

RECEIVED NOVEMBER 26, 1929 PUBLISHED MAY 8, 1930

Introduction

This paper describes some of the preliminary work done in studying methods for the analysis of the normal butenes, as follows: separation of dibromobutanes by fractional distillation at 50 mm.; separation of butenes by fractional distillation at atmospheric pressure; the reaction of 1-butene with hydrogen bromide.

Preparation of Dibromobutanes

Materials.—Eastman's 1-butanol No. 50, b. p. 116–118°, was slowly distilled through a 75 × 3 cm. fractionating column of cut-glass rings. The reflux ratio was ten to one. The fraction between 117.2 and 117.4° at 746.6 mm., which constituted about 85% of the whole, was collected. The 2-butanol[4] was similarly distilled and the fraction distilling at 98.8–99.0° at 745.3 mm was used. This had a refractive index n_4^{20} 1.3976, in satisfactory agreement with 1.397.[5] Merck's bromine was shaken with a solution of potassium bromide and distilled from concentrated sulfuric acid.

The aluminum oxide catalyst was prepared by precipitating aluminum hydroxide from a 5% solution of aluminum nitrate by the addition of dilute ammonium hydroxide. The precipitate was filtered off with suction, the solid was thoroughly agitated with a volume of water half that of the original solution and filtered again. The process was repeated. The final product was dried at 110–115° and broken into small pieces, the maximum dimensions being about 5 mm. This material was placed in the reaction tube and heated to 320–360° for four hours while air was drawn through. Some water was given off. The catalyst was now ready for use.

Decomposition of the Alcohols.—The alcohols were decomposed in the apparatus shown in Fig. 1. The alcohol, as it dropped from the graduated container into the heated tube, was volatilized and passed into a pyrex tube, 2.5 X 80 cm. The first half served as a preheater and the second half contained the aluminum oxide catalyst packed for a length of 25 cm. As the gas entered the reaction zone from the preheater the temperature was 205° for the 1-butanol and 250° for the 2-butanol, while the catalyst was maintained at 330–340° for the first, and 310–320° for the second alcohol. The average rates

[4] We have been aided in this research by the Stanco Distributors, Inc., New York, who through the courtesy of Mr. C. L. Bowman have kindly supplied us with pure 2-butanol.

[5] "International Critical Tables," McGraw-Hill Book Co., Inc., New York, 1926, Vol. I.

of flow were 35 g. and 25 g. per hour, respectively. The butene was cooled first in the condenser, then in the ice trap in order to condense water and unchanged alcohol, and then, after bubbling through 23% perchloric acid and drying with calcium chloride, passed into the all-glass reaction flask maintained at −15 to −20° and so arranged that it could be easily shaken. Except at the beginning and at the very end of the experiment butene was always in excess, the bromine being added slowly and at intervals. The possibility of substitution taking place with the production of tribromobutanes and monobromobutane was small. The resulting dibromobutane was shaken once each with cold water and dilute sodium sulfite solution, then twice with water and dried over calcium chloride. The yield was 85% on the alcohol reacted (corrected for that recovered) and 99% on the bromine.

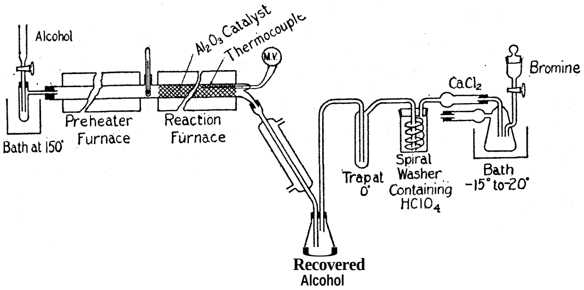

Fig. 1.—Apparatus used in the decomposition of the butanols over aluminum oxide.

Fractional Distillation of the **Dibromobutanes.**—The dibromobutane mixtures were fractionally distilled at 50-mm. pressure in the apparatus shown in Fig. 2. The material was placed in the flask B and when heated by the electric heater A boiled in a satisfactory manner without much bumping. (Pieces of scrap platinum or of anhydrous calcium chloride were found to be an aid.) The flask was attached by means of a ground-glass joint to the fractionating tube, 2 × 95 cm., containing a 70-cm. column of cut-glass rings and provided with a reflux condenser at the top. In lieu of a vacuum jacket, the tube was surrounded for a length of 70 cm. with a 5-cm. layer of mineral wool[6] packed in

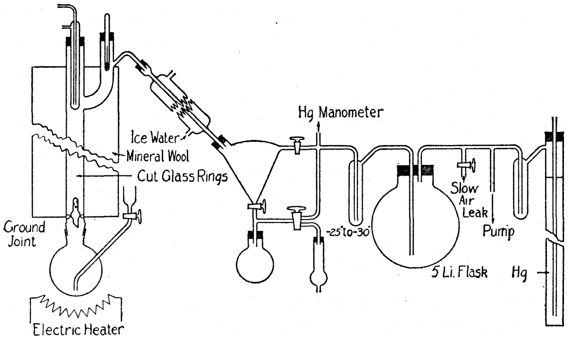

Fig. 2.—Apparatus used for fractionally distilling dibromobutanes at 50 mm. pressure.

---

[6] Supplied by the Mineral Wool Products Co., Torrance, Calif. This material has a lower heat conductivity than 85% magnesia, ground cork or pure wool, and gave satisfactory insulation.

a stove pipe. The cuts were made in the usual manner and the fractions were introduced into the distilling flask at the proper time through the side arm. The pressure was maintained at 50 mm. by a regulating device similar to that used by Schofield,[7] except that the greater part of the entering air came through a slowly leaking stopcock instead of through the mercury regulator. This gave a more uniform pressure. Fifty mm. was selected as the working pressure in order to have a satisfactory distilling temperature and one where decomposition and isomeric change would be negligible, since in the distillation at atmospheric pressure, hydrogen bromide is often evolved while on heating to higher temperatures isomeric change has been noted.[8]

Of the dibromides, 400 g. from 1-butanol and 480 g. from 2-butanol were systematically fractionated by six distillations. A comparison of the properties of the fractions with those of the pure dibromides, which were distilled in the same apparatus, and a consideration of the distribution of material in the various fractions shows that the separation was not complete. The densities, d_4^{20}, of the 80.5–81.0° fraction in the first experiment and of the 79.0–80.2° fraction in the second were both 1.7938, whereas that of pure 1,2-dibromobutane, b. p. 80.5–80.7° at 50.0 mm., is 1.7951. The incompleteness of the separation was also proved by the analysis of the largest (5th) fraction in the second experiment by the method subsequently developed,[9] which instead of pure higher boiling 2,3-dibromobutane showed 2.0% of 1,2-dibromobutane, 74.7% of higher boiling and 23.2% of lower boiling 2,3-dibromobutane. The separation, however, appears to be as good as or better than that obtained by Lépingle after ten distillations of a similar product.[10] These materials were used for preliminary work on reaction rates.

Butene from 2-Bromobutane

Preparation.—Butene was obtained in 85% yield from the action of 400 g. of potassium hydroxide in 600 g. of 95% ethanol upon 305 g. (2.23 moles) of 2-bromobutane, b. p., 89.8–89.9°, prepared from 2-butanol and 48% hydrobromic acid. The butene was generated in a suitable flask heated in an oil-bath at 128°, washed with 30% methanol and pure water in two scrubbing towers, passed through one tower of soda lime and three towers of anhydrous calcium chloride and collected in tubes immersed in ice–hydrochloric acid mixture. The tubes were sealed off.

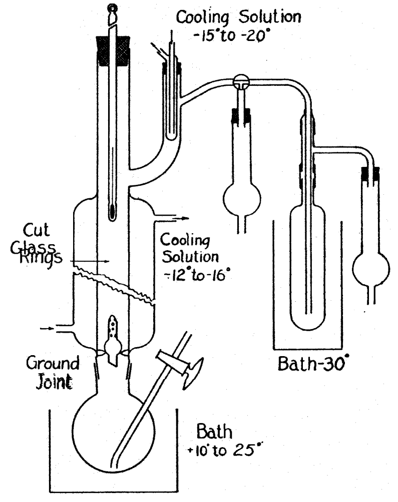

Fig. 3.—Apparatus used for fractionally distilling butenes at atmospheric pressure.

Distillation of the Butene Mixture.—The mixed butenes resulting from the decomposition were fractionally distilled through a 60-cm. column of cut-glass rings kept cold by the circulation of ice-hydrochloric mixture at –10 to –15° through an outer jacket and provided at the top with a reflux condenser cooled with brine at –14 to –18° for the purpose of insuring a rapid run-back of liquid, Fig. 3. This is the same

apparatus as that used in the final distillation of the isomeric 2-butenes.[11] Cuts were made at intervals of 0.5 and 1.0°, the latter where the temperature increased the more rapidly, for example between -5.5 and $+0.5°$. The butene was sealed off in the tubes in which it was collected and when needed was transferred to the distilling flask through the side arm, usually without material loss. Occasionally a part or all of the butene was lost. After four distillations the 1-butene, b. p. -6.7 to $-6.5°$, was fairly well separated, and apparently constituted 15 to 20% of the total. However, there was very little separation of the isomeric 2-butenes, b. p. 0.3 and 3.0°, respectively, the temperature rising gradually from 0 to 2°. The separation of any considerable quantity of a pure 2-butene from its stereoisomer by fractional distillation would appear to be impractical. Coffin and Maass[12] collected a fraction of 2-butene, free from 1-butene, over the temperature range of 1.5–1.7° for their physical measurement work. It is evident that their product was a mixture of the stereoisomeric forms.

Hydrogen Bromide and 1-Butene

Materials.—The 1-butene was synthesized from allyl bromide and methyl magnesium iodide,[13] the fraction used distilling at -6.6 to $-6.4°$ in the apparatus described above (yield was 68%). The 1-bromobutane and 2-bromobutane, on which densities and refractive indices were taken, were prepared in amounts of 215 g. and 180 g. by the action of 48% hydrobromic acid upon pure specimens of the respective alcohols. After careful washing and drying, the bromides on distillation gave fractions of i7C g. and 160 g., respectively, at constant temperatures of 101.5 and 89.8°.

Procedure.—22.4 g. (0.40 mole) of 1-butene was distilled into a solution of 41.0 g. (0.51 mole) of hydrogen bromide in 50 g. of glacial acetic acid at -18 to $-20°$. The tube containing the mixture was sealed off and left in the ice box at 5° for three days. The tube was opened, the contents poured into ice water, the bromide layer separated and washed in succession with dilute sodium bisulfite, water, cold concentrated sulfuric acid, water, dilute sodium bicarbonate and water. The yield was 63%. The product, after drying over anhydrous potassium carbonate, was distilled, 80% coming over at 90.0–90.2' and 95% up to 90.4'. By taking refractive indices on different fractions it was shown that the 3% fraction, 90.4–91.0°, was practically identical with the rest. A comparison of the refractive indices and densities of pure 1-bromobutane, pure 2-bromobutane and of the reaction product, Table I, shows the latter to be 2-bromobutane containing not more than 3% of 1-bromobutane. The reaction of 1-butene with hydrogen bromide is therefore of no use as a means of analyzing a mixture of 1- and 2-butene since they both yield the same product.

Summary

The dehydration of 1-butanol and 2-butanol over aluminum oxide at 300–350° gave butenes which were converted to the bromides. By means of fractional distillation at 50 mm. the three component dibromobutanes were separated from one another but not in a pure state. The approximate compositions of the butene mixtures were 68% 1-butene, 12% 2-butene, b. p. 0.3' and 20% 2-butene, b. p. 3.0° from 1-butanol and 26, 26 and 48%, respectively, from 2-butanol.

The butene mixture obtained from 2-bromobutane was partially separated by fractional distillation. It contained 15–20% of 1-butene, the balance consisting of a mixture of the isomeric 2-butenes.

When hydrogen bromide in glacial acetic acid reacted with 1-butene, the product was practically pure 2-bromobutane.

THE REACTION RATES OF POTASSIUM IODIDE WITH 1,2- AND 2,3-DIBROMOBUTANE. THE ANALYSIS OF MIXTURES OF THE NORMAL BUTENES[1]

BY ROBERT T. DILLON,[2] WILLIAM G. YOUNG[2] AND HOWARD J. LUCAS[3]

RECEIVED NOVEMBER 26, 1929 PUBLISHED MAY 8, 1930

The butenes are the simplest unsaturated hydrocarbons which exist in isomeric as well as stereoisomeric forms, *viz.*, 1-butene, cis-2-butene, *trans*-2-butene and isobutene. The variety of isomeric changes which they might conceivably undergo in passing from one form to another would include: (1) stereoisomeric change, for example, cis- to trans-2-butene, or vice versa; (2) shifting of the double bond, 1-butene or 2-butene, or vice versa; and (3) shifting of a methyl group, isobutene to 1- or 2-butene, or vice versa. A study of the transformations of these comparatively simple olefins would presumably be of value in the study of the higher olefins.

Before undertaking an investigation on the effect of subjecting the isomeric butenes to different treatments, it was first necessary to develop a satisfactory method of analyzing mixtures containing any combination of these four hydrocarbons. For this purpose the analysis of mixtures of the three normal butenes, *viz.*, 1-butene, cis-2-butene and trans-2-butene

---

[1] This paper contains results obtained in an investigation listed as Project 14 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund of the American Petroleum Institute donated by Mr. John D. Rockefeller. This fund is being administered by the Institute with the cooperation of the Central Petroleum Committee of the National Research Council.

[3] Director, Project 14, American Petroleum Institute.

would serve the purpose since isobutene can apparently be removed by absorption methods.[4] Moreover, the dibromide of this hydrocarbon has a boiling point some 10° lower than any of the others and in the proposed method it could be separated out by fractional distillation. Fortunately this hydrocarbon would not be present in many of the mixtures, especially those being studied at first, and for that reason also the analysis of the normal butenes serves our purpose.

Besides the fractional distillation of the corresponding dibromides, no method for analyzing mixtures of the three normal butenes has appeared in the literature.

The Analytical Method

The method herein developed depends upon the fact that each of the three normal butenes is quantitatively converted into a pure dibromide on treatment with bromine, and each of these dibromides has a different second-order reaction rate with potassium iodide in methanol at 75° to form potassium bromide, free iodine and an unsaturated hydrocarbon, thus: $C_4H_8Br_2 + 2KI \longrightarrow C_4H_8 + 2KBr + I_2$. Since these rates are not symbatic with the boiling points of the dibromides, while the physical properties of density and refractive index are, a combination of rate with one of these properties suffices for the analysis of any mixture of these three dibromides, and therefore of the three normal butenes. For this purpose the densities proved to be more useful than the refractive indices, since they differ by larger amounts.

In Table I are shown the boiling points of the three normal butenes[5] and the boiling points, densities, refractive indices and reaction rate constants of the corresponding dibromides. The rates with which these dibromides react with potassium iodide are proportional to the first power of both the dibromide and potassium iodide concentrations and are therefore second-

order. The discussion of the order of the reaction is taken up later on in this paper.

The rate with which iodine is formed when a mixture of the three dibromobutanes reacts with potassium iodide is given by Equation 1

$$\frac{dc}{dt} = k_{2a}(C_a)(C_{KI}) + k_{2b}(C_b)(C_{KI}) + k_{2c}(C_c)(C_{KI}) \tag{1}$$

in which C_a, C_b and C_c are the molal concentrations of the three dibromobutanes, A, B, C and k_{2a}, k_{2b}, k_{2c} are the respective second-order reaction constants of the pure components with potassium iodide. This expression is the summation of the three individual rates typified by Equation 2

$$\frac{dc}{dt} = k_{2a}(C_a)(C_{KI}) \tag{2}$$

and is true if the reaction rates are additive. Integration of (1) would give an expression by means of which the progress of the reaction could be followed for any mixture at any time, t, by a determination of the amount of iodine formed. However, the awkwardness of this integration makes it desirable to use instead a simpler expression by means of which an approximation to the real rate can be obtained. Equation 1 may be written in another form (Equation 3)

$$\frac{dc}{dt} = (k_{2a}x + k_{2b}y + k_{2c}z)C_{KI}\ C \tag{3}$$

where x, y and z are the respective molal fractions of A, B and C and ΣC is the total concentration of the dibromides. Setting

$$K_2 = k_{2a}x + k_{2b}y + k_{2c}z \tag{4}$$

Equation (3) becomes

$$\frac{dc}{dt} = K_2C_{KI}\ \Sigma C \tag{5}$$

In Equation 5 K_2 occupies formally the position of a second-order reaction rate constant; it is, however, not constant, because each dibromide disappears at a different rate due to the fact that k„ k_{2b} and k„ have different values, with the consequence that the molal fractions change with time. The rate of change of the molal fractions will depend upon the individual constants k_{2a}, k_{2b} and k_{2c} and will be small when these are of the same order of magnitude. Since this is true in the present case, the mole fractions and hence the value of K_2 will not undergo much change during a not too great interval of time. Accordingly, for experiments in which the reaction is not allowed to proceed too far, Equation 5 may be integrated under the assumption of constancy of K_2, and the value of K_2 taken as that corresponding to the initial molal fractions. K_2 is designated as a "pseudo" second-order reaction rate constant since it is not a true constant.

Assuming that the density of a mixture of the three dibromides may be obtained additively, their relationship may be expressed by Equation 6

$$D = d_ax + d_by + d_cz \tag{6}$$

in which D is the density of the mixture, while d_a, d_b and d_c are the densities of the respective components, A, B and C. Combining 4 and 6 with the additional Equation 7

$$x + y + z = 1 \tag{7}$$

the following solutions for the unknowns are obtained by means of determinants

$$x = \frac{-k_{2b}(d_c - D) + k_{2c}(d_b - D) - K_2(d_b - d_c)}{\Delta} \tag{8}$$

$$y = \frac{k_{2a}(d_c - D) - k_{2c}(d_a - D) + K_2(d_a - d_c)}{\Delta} \tag{9}$$

$$z = \frac{-k_{2a}(d_b - D) + k_{2b}(d_a - D) - K_2(d_a - d_b)}{\Delta} \tag{10}$$

where A $= k_{2b}(d_a - d_c) - k_{2c}(d_a - d_b) - k_{2a}(d_b - d_c) = 0.0005004$.

The assumption that the density of the mixture is an additive function of the individual densities, d_a, d_b and d_c, and that its specific reaction rate constant, K_2, is also an additive function of the individual constants k_{2a}, k_{2b} and k_{2c} would appear to be warranted in view of the fact that halogen compounds of this type are non-polar, non-associated liquids, mixtures of which would presumably deviate but little from ideal solutions.[6]

This method of calculating compositions, besides involving the above assumptions, requires that Equations 4, 6 and 7 should be independent of one another or, in other words, the proportionality constants should not be related in the following way

$$k_{2a} : k_{2b} : k_{2c} = d_a : d_b : d_c$$

Moreover, greater accuracy is realized by the fact that these constants are not symbatically related, that is, the higher-boiling 2,3-dibromide has a higher density but a lower reaction rate than the lower-boiling 2,3-isomer, while the 1,2-dibromide has the highest boiling point, density and reaction rate.

The deviations of approximately 1% in the rate constants of the pure compounds and the error involved in the calculations of the pseudo constant, K_2, determine the maximum error, which appears to be approximately 4% (see Tables VII and IX).

The Reaction Rates

Of the many compounds with which the dibromides react, for example, potassium iodide, sodium thiosulfate, sodium phenolate, potassium cyanide, silver nitrate, ammonia and substituted ammonias, the reactions with the first two only were studied. In all cases except with potassium iodide the amount of material reacted would be obtained from the difference between two much larger quantities while in this case the extent of the reaction can be determined directly and with less error from the amount of iodine formed.

---

[6] A mixture of ethylene bromide and propylene bromide is an ideal solution. **Zawidzki**, *Z. physik. Chem.*, *35*, 129 (1900).

The reaction with sodium thiosulfate was carried out in sealed tubes at 100°, preliminary experiments having shown that the rate was too slow at lower temperatures.[7] The reaction as carried out under these conditions is subject to two sources of error: the final titration of the excess of unused thiosulfate varies on the one hand with the gaseous volume above the reacting solution in the sealed tubes and on the other hand with the length of time the unopened reaction tubes stand after removal from the thermostat. Perhaps these errors are not significant at lower temperatures and therefore need not be considered, but they are interfering factors when the reaction is carried out at a temperature of 100°. A fairly satisfactory second-order constant was obtained in the reaction of thiosulfate with pure 1,2- and a mixed 2,3-dibromobutane, but because of the difficulty involved this method was not as suitable as the reaction with potassium iodide.

The reaction rates of alkyl chlorides with potassium iodide in absolute acetone have been studied by Conant and Kirner[8] and Conant and Hussey,[9] who found that the reactivities of the alkyl chlorides decrease in the order, primary, secondary and tertiary. The reaction rates of many dibromo-substituted compounds with potassium iodide have been investigated by Biilmann[10] and by van Duin.[11] Biilmann worked in dilute sulfuric acid solution and van Duin in both 70% ethanol and 70% ethanol acidified with hydrochloric acid. The reaction proceeds differently with the two classes of compounds, an alkyl chloride forming an alkyl iodide and potassium chloride, a dibromide forming an unsaturated compound, iodine and potassium bromide. Van Duin[11b] observed a difference in the reactivities of stereoisomeric dibromides, mesodibromosuccinic acid having a much higher rate than the racemic form. The three dibromobutanes (Table I) would thus be expected to differ in their rates, since the 1,2-dibromide contains a primary bromine atom, more reactive than a secondary, and the isomeric 2,3-dibromides exist as meso and racemic forms.

There are several mechanisms by which the reaction of potassium iodide with these dibromides may proceed, as shown by Equations 11 to 13 inclusive.

$$C_4H_8Br_2 + KI \longrightarrow C_4H_8BrI + KBr \tag{11a}$$

$$C_4H_8BrI + KI \longrightarrow C_4H_8I_2 + KBr \tag{11b}$$

$$C_4H_8I_2 \longrightarrow C_4H_8 + I_2 \tag{11c}$$

$$C_4H_8Br_2 + KI = C_4H_8BrI + KBr \tag{12a}$$

$$C_4H_8BrI + KI = C_4H_8 + I_2 + KBr \tag{12b}$$

---

[7] Slator [*J. Chem. Soc.*, *85, 1286 (1904); 87, 481* (1905)] studied the reaction of sodium thiosulfate with ethylene halides at temperatures ranging from *25* to 60°.

[8] Conant and Kirner, THIS JOURNAL, *46,232 (1924).*

[9] Conant and Hussey, *ibid., 47,476 (1925).*

[10] Biilmann, *Rec. trav. chim., 36, 319 (1916).*

[11] *(a)*Van Duin, *ibid., 43,341 (1924)*; *(b)* van Duin, *ibid., 45,345 (1926)*; (c) Kruyt and van Duin, *ibid., 40,258 (1921).*

$$C_4H_8Br_2 + 2KI = C_4H_8I_2 + KBr \tag{13a}$$
$$C_4H_8I_2 = C_4H_8 + I_2 \tag{13b}$$

In addition to the steps enumerated above, each process may, and probably does, involve to some extent the reaction of iodine with potassium iodide as given in Equation 14

$$I_2 + KI = KI_3 \tag{14}$$

In general, the rate will be second order if expressed by (11) and (12), and third order if by (13), provided the reactions of the different steps proceed with markedly different rates. In (11) and (12) the slow reaction may be either (a) or (b), and in (13) it must be (a), since Slator[12] found that diiodides and iodobromides in the presence of iodide ion dissociate quite rapidly even at temperatures of 25 and 35°. It is not possible to establish the extent to which iodine and potassium iodide react according to Equation (14) since in methanol part of the iodine is probably combined with the solvent. Moreover, even though KI_3 is formed, its effect upon the reaction rate can be made negligible by keeping the ratio of potassium iodide to iodine large.

In the experimental work the concentrations of both the reactants were varied. The rate was found to be second order, and to be proportional to the first power of the concentration of both the potassium iodide and dibromobutane. The reaction may then be represented by (11) or (12), but not by (13). This is in accordance with the observations of Biilmann, who studied the behavior of dibromopropionic acid with potassium iodide, but is not in agreement with those of van Duin, who concluded that this reaction and other similar ones were third order, according to Equation 13.

The specific second-order rate constant of a pure dibromide, k_2 (Equation 15), is derived from the differential form (Equation 16).

$$k_2 = \frac{2.303}{t(a - 2b)} \log_{10}\left(\frac{b(a/b - 2\phi)}{a(1 - \phi)}\right) \tag{15}$$
$$dc/dt = k_2(C_{KI})(C_{C_4H_8Br_2}) \tag{16}$$

The third-order constant, k_3 (Equation 17), given for comparison in Tables II, III and IV, is derived from the differential form (Equation 18).

$$k_3 = \frac{1}{t(a - 2b)^2}\left[2.303 \log_{10}\left(\frac{b(a/b - 2\phi)}{a(1 - \phi)} - \frac{2\phi(a - 2b)}{a(a/b - 2\phi)}\right)\right] \tag{17}$$
$$dc/dt = k_3(C_{KI})^2(C_4H_8Br_2) \tag{18}$$

In these equations t is time in hours, a is initial concentration of potassium iodide in moles per liter at 20°, b is initial concentration of dibromobutane in moles per liter at 20° and ϕ is fraction of the total dibromobutane which had reacted at the time, t. The values of k_2 and k_3 are thus expressed in hours and moles per liter at 20°, rather than in hours and moles per liter at 75°. This is done because the solutions are made up at 20° and the concentrations (a) and (b) would each differ at the two temperatures by a factor which is proportional to approximately the cubical coefficient of ex-

---

[12] Slator, *J. Chem. Soc.*, **85, 1697 (1904).**

pansion of methanol. Since the ratio of two concentrations occurs in each of the variable terms involving ϕ, the values of k_2 in moles per liter at 20° and of k_2 in moles per liter at 75° are each constant in themselves and differ from each other by this factor. Likewise the values of k_3 at the two temperatures are each constant in themselves but differ from each other by the square of this factor.

The pseudo second-order reaction constant, K_2, of mixtures is also calculated according to Equation 15.

Description of the Method

Materials.—The potassium iodide, "P. W. R. Analytical," was ground in an agate mortar to a powder, dried at 100° for twenty-four hours and kept in a desiccator until used. The sodium thiosulfate solution, 0.02 *N*, was made by dissolving "P. W. R. Analytical" material in distilled water and was allowed to stand some time before use. It was stored in the dark and standardized at frequent intervals against standard potassium dichromate.

The three dibromobutanes used for the reaction rate measurements were those prepared from pure 1-butene,[5a] cis-2-butene and *trans*-2-butene.[5b] The dibromides were fractionally distilled at 50 mm., the products boiling completely within a temperature range of 0.2" (Table I), indicating that each was a pure substance and not a mixture of isomers.

The synthetic methanol used as the solvent was purified by refluxing with sodium hydroxide and distilling from the solid. Water was subsequently added in order to bring the strength to 99.00%. It was not considered feasible to work with absolute methanol since the specific reaction rates are markedly affected by the addition of water to methanol, being much greater at a dilution of 75% than at 99%. Thus the accidental addition of traces of water to absolute methanol might produce greater effects than a slight variation in the composition at 99.00%.

The methanol as prepared usually contained a slight amount of impurity which reacted slowly with iodine at 75°. It was therefore necessary to determine the correction for this impurity by adding to the solvent definite amounts of iodine and potassium iodide equivalent to those encountered in the actual rate measurements and measuring the iodine decrease against time. These corrections, which for three different samples of methanol amounted to 0.00, 1.10 and 1.27 ml. of 0.02 *N* sodium thiosulfate per 20 ml. of solvent, were added to the titration values as determined in the different rate measurements.

Apparatus.—The reaction tubes were made by drawing out very thin glass test-tubes, previously cleaned and dried, to form a constriction near the end. They had capacities slightly greater than 20 ml. A thermostat suitable for carrying on reactions in the dark was maintained at 74.93 ± 0.03".

Procedure.—Each solution containing the reactants was made up to exactly 250 ml. at 20.0°, thoroughly mixed and pipetted into 8 or 10 reaction tubes with a 20-ml. pipet (exact volume, 19.94 ml.). Great care was exercised in keeping the solutions at exactly 20° while being made to volume and while being pipetted, since methanol has a large coefficient of expansion. The tubes were then sealed and placed in the thermostat, care being taken to avoid a large temperature drop by increasing the voltage of the continuous heater just before inserting the tubes. Tubes which were allowed to stand at room temperature for several hours showed no signs of reaction. The time could be considered from the time of immersion. At various intervals tubes were removed from the thermostat, quickly cooled in ice water and broken into a 600-ml. beaker containing 75 ml. of distilled water, 2 g. of potassium iodide and about three-fourths of the amount of sodium thiosulfate solution required for the titration. Thiosulfate was then added until the end-point as indicated with starch was reached. Reaction rate constants were then calculated from the titration values and are shown in the tables.

The densities of the dibromobutanes were determined with a 10-ml. pycnometer. The values have been calculated to vacuum[13] by applying the equation: $d_4^t = \frac{w_l}{w_w}(d_w - \sigma_2) + \sigma_3$. Here $\sigma_2 = \sigma_3 = 0.0012$ and the temperature of w_l and w_w are the same. Densities of the pure compounds are shown in Table I and of mixtures in Table VIII.

Results

In the tables which list the reaction rates, the following notations are used: KI is initial concentration of potassium iodide in moles/liter at 20° (given by "a" in the rate expressions, Equations 15 and 17), $C_4H_8Br_2$ is initial concentration of dibromobutane in moles/liter at 20° (given by "b" in the rate expressions), t is time in hours, ϕ is fraction of dibromide used up at time t, and k_2 and k_3 are second-order and third-order specific reaction constants.

In the experiments represented by Tables II, III and IV, essentially the same dibromide concentration was used throughout and essentially two different concentrations of potassium iodide, the ratio between these last two being approximately 1.5 to 1. In each table the second-order constants calculated for the two potassium iodide concentrations are in satisfactory agreement, whereas the third-order constants are not. This shows that the rates are proportional to the first power and not the second power of the potassium iodide concentration. Since ,previous work on other dibromides by investigators[10,11] had shown the rate to be proportional to the first power of the dibromide concentrations, and since preliminary work on the three dibromobutanes confirmed this observation, as was to be expected, evidence for this conclusion is not given here.

Percentage variation from the mean: $k_2 = 0.1\%$, $k_3 = 20.2\%$.

In determining the dependence of the specific reaction constant on the concentration of potassium iodide it was necessary to decrease this concentration to somewhat lower values than those ordinarily employed in the rate measurements. Thus under these conditions the ratio of the concentration of potassium iodide to dibromide was small compared to the usual values. With a ratio above 6.0, the values of the specific reaction constants were independent of this ratio in so far as investigated (that is, up to 12.0), but below 6.0 the specific reaction constants were found to increase slightly. This effect although quite small is very definite since it invariably occurred when the ratio was low; for example, the values for a given sample of dibromide were 0.0364 and 0.0365 when the ratios were 9.44 and 8.32, respectively, but 0.0381 when the ratio was 4.29.

Table V shows the iodine correction for one sample of methanol. Because of the low rate it was not possible to apply this correction before twenty hours; consequently in the rate determinations of the dibromides, readings taken under twenty hours are in error. Table VI shows that this iodine correction does not affect the second order rate constant.

The two samples, a and b, were prepared from different samples of 1-butene.

The satisfactory agreement in the case of the two samples of the 1,2-dibromide shows that the experimental conditions can be duplicated. This is likewise demonstrated by' the fact that two of the authors (R. T. Dillon and W. G. Young) obtained for each of the three compounds constants which are essentially identical.

When the method was applied to different mixtures of the dibromobutanes satisfactory pseudo second-order constants were obtained as shown in Table VIII.

The compositions of these mixtures are given in Table IX. Duplicate runs were made on Mixtures B and D, the less satisfactory result in each case being shown in Table VIII.

In Table IX these observed values of the pseudo constant K_2 are compared with the values calculated from the known constants of the com-

2,3-racemic	.00462	.0297	28,100	3.46	3.34

Summary

The specific reaction rates of 1,2-dibromobutane and of racemic and meso-2,3-dibromobutane with potassium iodide in methanol have been measured at 60 and at 75°. They are second-order reactions. The heats of activation and temperature coefficients have been calculated.

The reaction rates of mixtures of these dibromides have likewise been measured at 75°. Calculation of the composition of binary mixtures from the reaction rates and of a ternary mixture from the reaction rate and density gave results in satisfactory agreement with the known compositions. The maximum deviation was 4%.

Mixtures of the three normal butenes may be analyzed by first converting them to the corresponding dibromides and determining for these the reaction rates and densities.

THE COMPOSITION OF BUTENE MIXTURES RESULTING FROM THE CATALYTIC DECOMPOSITION OF THE NORMAL BUTYL ALCOHOLS

BY WILLIAM G. YOUNG* AND HOWARD J. LUCAS

RECEIVED NOVEMBER 26, 1929 PUBLISHED MAY 8, 1930

Introduction

Within recent years considerable interest has been attached to the decomposition of the normal butyl alcohols, partly because of its importance as a source of butenes and partly because of its bearing upon the theory of catalysis. These decompositions would be of particular value if they should yield, under the proper conditions, pure butenes, rather than mixtures of these hydrocarbons.

The catalytic decomposition of 1-butanol was first accomplished by Le

---

[1] Du Pont Fellow in Chemistry, 1928–1929.

Bel and Green,[2] who dropped the alcohol upon hot zinc chloride. The alcohol has also been dehydrated by passing the vapor over a variety of catalysts at elevated temperatures.[3] The catalytic dehydration of 2-butanol has likewise been accomplished in different ways.[3n,o,4]

The composition of the butene mixtures obtained in the decompositions of these alcohols depends to a considerable extent upon the catalyst used and in most cases has been reported as being 1-butene, 2-butene, or a mixture of these. The isobutene present in some of these mixtures, as reported by a few investigators,[3a,c,e,4a] probably arose from isobutanol in the alcohol used, as was actually demonstrated in one case.[4a] The methods which have been used for analyzing mixtures of 1- and 2-butene, except those which depend upon a separation of the corresponding dibromobutanes[2,3f,l,o] in general rely upon a difference in the reactivity of 1-butene and 2-butene. Since, however, there are two isomeric 2-butenes, it is evident that any method developed on the assumption that a mixture of the 2-butenes behaves as a pure compound lacks accuracy and consequently the results obtained by it are in error.[3n,5] This criticism, however, does not apply to the ozonide method,[4b,c] which distinguishes between 1-butene and the mixed 2-butenes.

TABLE I

THE CATALYTIC DECOMPOSITION OF THE NORMAL BUTYL ALCOHOLS

No.	Alcohol	Catalyst	Temp., °C.	Duration of run min.	Alcohol Used, *g.*	Recovered, *g.*
1	1-Butanol	H_2SO_4 60%	140–160	...	74	..
2	2-Butanol	H_2SO_4 60%	115–140	...	74	..

The method for analyzing mixtures of 1-butene, cis-2-butene and *trans*-2-butene by means of the densities and the reaction rates of the corresponding dibromides[6] has been applied to the mixtures resulting from the decomposition of 1-butanol and 2-butanol with different dehydrating agents. The results are given in Table I.

Experimental

Materials.—The 1-butanol and 2-butanol were purified as described for other decompositions.[3c,7]

Merck's bromine was shaken with a solution of potassium iodide and distilled from concentrated sulfuric acid.

Columbian spirits, free from acetone, was refluxed with sirupy phosphoric acid for three hours in order to remove traces of amines, and slowly distilled through the column used for purifying the butanols, the first and last portions being discarded. The main portion of the methanol was then refluxed for three hours with flake caustic soda, slowly distilled and the part distilling at 64.2–64.6° (745 mm.) was diluted with water to a density, d_4^{20}, of 0.7945, the density of 99.0% methanol.

The potassium iodide, P. W. R. analytical, was heated to 120° for four hours and placed in a desiccator until used.

The dehydrating agents for the alcohol decompositions were aluminum oxide,[3c] Baker's C. P. aluminum phosphate previously heated to 400°, Merck's phosphorus pentoxide, P. W. R. "highest purity" 85% phosphoric acid, 60% sulfuric acid, made by diluting Baker's C. P. acid, and pumice impregnated with phosphoric acid.

Apparatus.—The decompositions of 1-butanol and 2-butanol with phosphorus pentoxide, phosphoric acid and sulfuric acid were accomplished in a three-necked three-liter flask. The resulting butene was passed in succession through a reflux condenser, a trap at 0°, a 24% solution of perchloric acid contained in a spiral wash bottle, a calcium chloride drying tube and finally into the brominating flask at −15° provided with an outlet attached to calcium chloride and soda lime tubes. The apparatus used for effecting the decompositions over aluminum oxide, aluminum phosphate and pumice

[7] The 2-butanol was kindly supplied by the Stanco Distributors, N. Y., through the courtesy of Mr. C. L. Bowman.

impregnated with phosphoric acid and also the set-up employed in the distillation of the dibromides at 50 mm. were the same as those used for other decompositions.[3o]

Decomposition of the Alcohols.—The rate of decomposition of the alcohols was determined as rapidly as consistent with effective handling of the butene by the purifying train. The procedures used varied with the dehydrating agents. In the case of 60% sulfuric acid and 85% phosphoric acid, the alcohols and acid were heated together in the generating flask in the following proportions: 220 g. of 60% sulfuric acid with 74 g. (1.0 mole) of alcohol, 475 g. of 85% phosphoric acid with 148 g. (2 moles) of alcohol.[3n] The decomposition of 2-butanol proceeds the more readily. In the case of phosphoric acid no butene could be obtained from 1-butanol, even with the addition of diatomaceous earth.

The alcohols were dropped onto the phosphorus pentoxide in the following proportions: 74 g. (1.0 mole) of 1-butanol or 118 g. (1.6 moles) of 2-butanol[4b] upon 100 g. of phosphorus pentoxide.

In the case of aluminum oxide, aluminum phosphate and phosphoric acid on pumice the decompositions were effected in the usual manner.[3o] Of the last three catalysts, aluminum oxide was the most effective and the aluminum phosphate was decidedly inferior to the other two. Here also the 2-butanol was the more easily decomposed. The yield was calculated from the amount of alcohol decomposed, obtained by subtracting the amount recovered from that put through the furnace.

Purification of the Dibromobutanes.—The crude dibromides contained small amounts of lower-boiling impurities but no higher-boiling ones, such as tribromobutane. In every case the low-boiling impurity was removed by conducting the first part of the distillation at a very slow rate and removing in the first fraction about 10% of the total weight of the dibromides. The range of this fraction was usually three or four degrees and of this material about 90% came over at the top of its boiling range. The necessity of removing this first fraction was indicated by the analysis of the binary mixture of isomeric 2-butenes obtained in the decomposition of 2-butanol with phosphoric acid. A marked discrepancy was found between the reaction rate and the density of the resulting 2,3-dibromobutanes following one distillation at 50 mm. without fractionation. The separation effected by a subsequent fractional distillation was indicated by the refractive indices of successive cuts, the values being 1.5097, 1.5128, 1.5129, 1.5130 and 1.5132. After discarding the first fraction, the remaining fractions were combined and density and reaction rate measurements were taken. These values were 1.7775 and 0.0435, respectively, whereas the corresponding values for the material before fractionation were 1.7759 and 0.0435. From these figures it is evident that the impurity was material of low density and not isobutene dibromide, the density of which lies close to that of the 2,3-dibromobutanes. The ratio of the dibromides had not been materially altered by the removal of this first fraction since (1) the reaction rate was not affected, (2) the refractive indices of the other four fractions were about the same and (3) previous attempts at fractional distillation of dibromobutanes had not effected a complete separation even after six fractionations.[3o]

Analysis of the Dibromobutane Mixtures.—From the densities and the reaction rate measurements of the dibromobutane mixtures with potassium iodide in methanol, the percentage of 1-butene, cis-2-butene, b. p. 3.0°, and trans-2-butene, b. p. 0.3°, in the original butene mixture can be calculated according to the respective equations

$$X = \frac{-K_{2b}(d_c - D) + k_{2c}(d_b - D) - K_2(d_b - d_c)}{\Delta}$$

$$Y = \frac{k_{2a}(d_c - D) - k_{2c}(d_a - D) + K_2(d_a - d_c)}{\Delta}$$

$$Z = \frac{-k_{2a}(d_b - D) + k_{2b}(d_a - D) - K_2(d_a - d_b)}{\Delta}$$

in which k_{2a}, k_{2b} and k_{2c} are the specific second-order constants of the corresponding pure dibromobutanes, d_a, d_b, d_c are their densities, K_2 and D are the observed reaction rate and density of the dibromide mixture and $\Delta = k_{2a}(d_a - d_c) - k_{2c}(d_a - d_b) - k_{2a}(d_b - d_c) = 0.0005004$.

Since the results on known mixtures showed an error of 2 to 4%, it seems reasonable to assume that the maximum error in this method is not greater than 5%.[6] When analysis indicated that the decomposition product was a binary mixture, calculation from the density alone gave results in agreement within the limits specified, as shown in the table.

It should be pointed out that in using this method for the analysis of butene mixtures the purity of the solvent must be checked by running a reaction rate with pure 1,2- or 2,3-dibromobutane.

Discussion

Perhaps the most striking features of the decompositions are the presence of the 2-butenes in all of the reaction products and the absence of 1-butene in the reaction product from both 1-butanol and 2-butanol when phosphorus pentoxide, phosphoric acid or sulfuric acid is used at temperatures below 160°. In all these cases the lower-boiling 2-butene is in excess and its amount is largest from 1-butanol. The behavior of 2-butanol with the pentoxide is in agreement with the results of Harries and Evers,[4c] who found that no 1-butene was present although they made no distinction between the isomeric 2-butenes. The decomposition of 2-butanol with phosphoric acid has been carried out by Davis,[3a] who analyzed the butene fraction distilling at 1.5–1.7° by the bromine absorption method and found 84% to be rapidly brominated, therefore 2-butene, and 16% to be slowly brominated, therefore presumably 1-butene. He has misinterpreted his results, having failed to appreciate that the isomeric 2-butenes might absorb bromine at different rates. From our analysis and his bromination experiments it is evident that the lower-boiling (0.3°) isomer has the faster reaction rate with bromine. It is interesting to note that the dibromide of this isomer also has the higher reaction rate with potassium iodide. It is not likely that the composition of the distillate studied by Davis was materially different from that of his original butene mixture since the fraction at 1.5–1.7° is midway between the pure hydrocarbons.[8]

No appreciable quantity of butene was formed when 1-butanol was refluxed with 85% phosphoric acid. The composition of the butene mixtures resulting from the decomposition with 60% sulfuric acid has not been reported previously.

[8] Young, Dillon and Lucas, THIS JOURNAL, 51, 2528 (1929).

Of the higher temperature decompositions in the gas phase, 1-butene was in excess in only two cases, the largest amount coming from 1-butanol over aluminum oxide. Approximately the same quantity of 1-butene was obtained from 2-butanol irrespective of the catalyst. The higher-boiling 2-butene (cis) was in excess over the other two products in only one case, *viz.*, 2-butanol over aluminum oxide; and it was only with this catalyst that the amount of the cis-isomer exceeded that of the trans.

The decomposition of 1-butanol over phosphoric acid on pumice has been reported previously by King[3f] and by Coffin and Maass.[3m] The former found no isobutene and obtained nearly pure 2,3-dibromobutanes on fractionation of the mixed dibromides. The latter, by distillation of both the olefin and its dibromide, obtained 10–15% of 1-butene, the balance being 2-butene. Their result for 1-butene, although somewhat lower than ours, is in substantial agreement. The fraction distilling at 1.0° and believed by them to be pure 2-butene was undoubtedly a mixture.

The composition of the mixture from the decomposition of 1-butanol over aluminum oxide first reported by Ipatiew[3a] has been studied recently by Davis,[3n] Lépingle,[3l] and by Lucas, Dillon and Young.[3o] Davis claimed 65% 1-butene and 35% 2-butene by his bromine absorption method. His result for 1-butene would agree better with ours if correction could be made for the difference in reactivity of the isomeric 2-butenes. The results obtained by Lépingle for 1-butanol and by Lucas, Dillon and Young for 1- and 2-butanol over aluminum oxide agree fairly well with the analyses given in the table, considering the limitations of the distillation method. Lépingle obtained 78% 1-butene and 22% 2-butene for 1-butanol while Lucas, Dillon and Young report 68% 1-butene, 20% higher- and 12% lower-boiling 2-butene. The latter obtained from 2-butanol 26%, 48% and 26%, respectively.

The decomposition of 1-butanol over aluminum phosphate has been reported by Senderens,[3c] who obtained a mixture of 73% 1-butene and 27% isobutene, Since no evidence has been found for the presence of isobutene in any of the decompositions described in this paper, it seems likely that the presence of isobutene in the product reported by Senderens was due to isobutanol in the alcohol used by him.

From the results listed in the table it is evident that neutral dehydrating agents favor 1-butene, whereas the acidic ones favor 2-butene, the order for both alcohols being aluminum oxide, aluminum phosphate, phosphoric acid on pumice and finally the three acidic reagents, phosphorus pentoxide, phosphoric acid and sulfuric acid. The last three likewise favor the lower-boiling 2-butene.

Removal of Bromine from Dibromobutane.—Since bromine adds across the bond, and not on the same side,[9] a study was made of the re-

---

[9] Michael, *J. prakt.* Chem., 52,344 (1893); Chavanne, Revue *Générale des Sciences,*

moval of bromine from 2,3-dibromobutane to determine whether the original or the isomeric 2-butene was produced. It was found that the hydrocarbon formed by the removal of bromine from a mixed 2,3-dibromobutane gave, with bromine, a dibromide identical with the original. The removal of bromine therefore appears to be a trans elimination similar to other reactions in which halogens or halogen halides are eliminated.

135.5 *g.* of 2,3-dibromobutane, obtained from the butene resulting from the decomposition of 2-butanol with phosphorus pentoxide and having a second order reaction rate with potassium iodide, K_2, of 0.0430, was allowed to drop upon 77 g. of 10-mesh granulated zinc, P. W. R. C. P. under 110 ml. of ethanol at 80–95°. The evolved butene, after passage through a reflux condenser, was purified as usual and allowed to react with bromine. The purified dibromide, 122.3 g. (90% yield), gave for K_2 the value of 0.0231. It was thus identical, within experimental error, with the original dibromide.

Summary

Decompositions of 1-butanol and 2-butanol have been effected by dropping the alcohols upon phosphorus pentoxide, by heating the alcohols with 85% phosphoric acid and with 60% sulfuric acid and by passing the vapor of the alcohols at high temperatures over aluminum oxide, over aluminum phosphate and over pumice impregnated with phosphoric acid. The butene mixtures were analyzed by converting them to the dibromides and determining for the latter the densities and the reaction rates with potassium iodide in methanol. Both 1-butanol and 2-butanol gave a mixed 2-butene free from 1-butene when the dehydrating agent was phosphorus pentoxide, phosphoric acid or sulfuric acid and the decomposition was carried out below 160°, except, however, that 1-butanol was not decomposed by phosphoric acid. 2-Butanol with phosphoric acid on pumice, with aluminum phosphate, or with aluminum oxide gave largely 2-butene, the amount of 1-butene increasing slightly in the order named. With 1-butanol the amount of 1-butene obtained when these three catalysts were used increased rapidly in the order named, being 73% with aluminum oxide. In general, the more acidic reagents favor trans-2-butene and the less acidic favor I-butene and cis-2-butene.

The removal of bromine with zinc from a mixed 2,3-dibromobutane produced a mixed 2-butene identical in composition with the butene from which the dibromide was prepared.

PASADENA, CALIFORNIA

35, 229 (1924). The cis addition observed by Terry and Eichelberger, THIS JOURNAL, 47, 1067 (1925), was effected in aqueous solution in the presence of bromide ions.

STRUCTURE OF THE SALTS OF AROMATIC NITRILES

BY FRED W. UPSON, ROBERT T. MAXWELL AND HOWARD M. PARMELEE[1]

RECEIVED DECEMBER 3, 1929 PUBLISHED MAY 8, 1930

In the course of work reported in 1922 from this Laboratory,[2] the impure sodium salt of phenylacetonitrile was isolated. Because of certain properties the authors suggested the nitride structure $(C_6H_5)H{-}C{=}C{=}N{-}Na$ for this substance. It was also suggested that an imide form of the parent nitrile $(C_6H_5)H{-}C{=}C{=}N{-}H$ is an intermediate substance in certain condensation reactions undergoing rearrangement to the nitrile form $((C_6H_5)H{-}\underset{|}{C}{-}C{\equiv}N)H$.

In two papers published recently by Rising and co-workers[3] similar ideas are expressed and the theory concerning tautomerism of the nitriles is more fully developed than in the paper of Upson and Thompson.

Several reactions carried out in this Laboratory favor the nitride structure of the sodium salt.

(I) Decomposition at high temperatures yields stilbene and sodium cyanide.

$$(C_6H_5)H{-}C{=}C{=}N{-}Na \longrightarrow (C_6H_5)H{-}C{=} + NaNC$$
$$2C_6H_5H{-}C{=} \longrightarrow (C_6H_5)H{-}C{=}C{-}H(C_6H_5)$$

(II) An impure silver salt of phenylacetonitrile possessing in all probability the nitride structure was prepared from the sodium salt by interaction with silver nitrate in alcoholic solution. The silver salt on interaction with butyl iodide gave an alkyl derivative of nitride structure, since after decomposition there was isolated butylamine in the form of its hydrochloride.

$$(C_6H_5)H{-}C{=}C{=}N{-}Ag + C_4H_9I \longrightarrow (C_6H_5)H{-}C{=}C{=}N{-}C_4H_9 + AgI$$
$$(C_6H_5)H{-}C{=}C{-}N{-}C_4{-}H_9 \longrightarrow (C_6H_5)H{-}C{=} + C_4H_9{-}N{=}C$$
$$C_4H_9{-}N{=}C + H_2O + HCl \longrightarrow C_4H_9NH_3Cl + HCOOH$$

(III) Spontaneous oxidation of sodium phenylactonitrile in the air leads to the formation of benzoic acid and sodium cyanide

$$(C_6H_5)H{-}C{=}C{=}N{-}Na + O_2 \longrightarrow C_6H_5COOH + NaNC$$

(IV) Toluene and sodium cyanide are formed during the preparation of the salt.

$$2C_6H_5H{-}C{=}C{=}N{-}H + 2Na \longrightarrow 2(C_6H_5)H{-}C{=}C{=}N{-}Na + 2H$$

---

[1] Based in part upon theses presented by Robert W. Maxwell and Howard M. Parmelee for the Master of Science degree, University of Nebraska. Presented before the Organic Division of the American Chemical Society at the Minneapolis Meeting, September, 1929.

[2] Upson and Thompson, THIS JOURNAL, 44,181 (1922).

[3] Rising and Zee, *ibid.*, 50, 1699 (1928); Rising, Muskat and Lowe, *ibid.*, 51, 262 (1929).

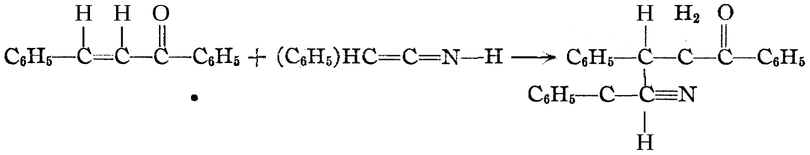
A part of the salt is reduced to toluene and sodium cyanide by the hydrogen liberated in the above reaction.*

$$(C_6H_5)H-C=C=N-Na + H_2 \longrightarrow C_6H_5CH_3 + NaNC$$

This reduction which always accompanies the formation of the sodium salt of phenylacetonitrile explains the difficulty experienced by us and by Rising and co-workers in preparing the pure salt.[5] Unless the sodium cyanide is removed it contaminates the salt of the nitrile. Details of the preparation of the salt in pure form will be found in the experimental part.

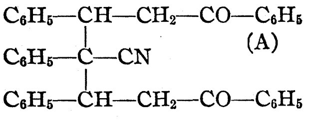
(V) Condensation reactions of the type studied by Avery[6] can be produced by the use of sodium phenylacetonitrile, as well as by the use of sodium methylate and benzyl cyanide.

The work of Avery involves condensation of benzyl cyanide with unsaturated esters and ketones using sodium methylate as the condensing agent. Benzalacetophenone condenses with the sodium phenylacetonitrile in methyl alcohol solution to give a 97% yield of 1,5-dibenzoyl-2,3,4-triphenyl-3-cyanopentane. The same compound is obtained by the use of sodium methylate and phenylacetonitrile



$$C_6H_5-\overset{H}{\overset{|}{C}}=\overset{H}{\overset{|}{C}}-\overset{O}{\overset{\|}{C}}-C_6H_5 + (C_6H_5)HC=C=N-H \longrightarrow C_6H_5-\overset{H}{\overset{|}{\underset{\underset{C_6H_5-C-\underset{\underset{H}{|}}{C}\equiv N}{|}}{C}}}-\overset{H_2}{C}-\overset{O}{\overset{\|}{C}}-C_6H_5$$

This latter through its imide form gives, with a second molecule of benzalacetophenone, the condensation product 'obtained by Avery (A). This result constitutes evidence that phenylacetonitrile is tautomerized by sodium methylate as well as by metallic sodium since the two methods give theidentical product.



(A)

$$\begin{array}{l} C_6H_5-CH-CH_2-CO-C_6H_5 \\ \qquad | \\ C_6H_5-C-CN \\ \qquad | \\ C_6H_5-CH-CH_2-CO-C_6H_5 \end{array}$$

Rising, Muskat and Lowe[7] have suggested that sodium phenylacetonitrile exists in two forms designated as "carbide" and "nitride." They explain "the behavior of this salt and of its homolog, sodium α-phenylbutyronitrile, in the reactions studied, upon the assumption of nitride–carbide tautomerism, obviously an extension of the Nef theory with regard to the tautomerism of hydrocyanic acid."

According to our interpretation of the behavior of these salt, there exists only the one form, the "nitride." We would explain condensation reac-

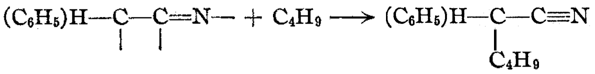
tions of these salts at the carbon atom as involving rearrangement of the anion during the reaction, and condensation at the nitrogen atom as direct replacement of the sodium without rearrangement. Thus just as silver cyanide gives alkyl isocyanides with alkyl halides, so we found that the silver salt of phenylacetonitrile gives a nitrogen derivative on reaction with butyl iodide

$$(C_6H_5)H{-}C{=}C{=}N{-}Ag + C_4H_9I \longrightarrow (C_6H_5)H{-}C{=}C{=}N{-}C_4H_9 + AgI$$

Rising, Muskat and Lowe found that the sodium salt condenses with butyl iodide to give α-phenylbutyronitrile. This we believe involves rearrangement of the anion.

$$(C_6H_5)H{-}C{=}C{=}N{-}Na \longrightarrow (C_6H_5)H{-}C{=}C{=}N{-} + Na^+$$

$$C_4H_9I + Na^+ \longrightarrow C_4H_9{-} + NaI$$



$$(C_6H_5)H{-}\underset{|}{C}{-}\underset{|}{C}{=}N{-} + C_4H_9 \longrightarrow (C_6H_5)H{-}\underset{\underset{C_4H_9}{|}}{C}{-}C{\equiv}N$$

Experimental Part

Preparation of Sodium **Phenylacetonitrile.**—In a 500-cc. flask were placed 4.4 g. of sodium in the form of fine shot and 220 cc. of ether which had been specially dried. The flask, connected to a reflux condenser, was warmed on a hot-plate just sufficiently to cause the ether to boil. Dry phenylacetonitrile (23 g.) was added drop by drop, over a period of one hour and thirty minutes. At the end of this time the contents of the flask consisted of a white solid suspended in a yellow solution. The heating was continued for six hours, at the end of which time the sodium had disappeared. All apparatus was specially dried and the reaction mixture was protected from moisture, oxygen and carbon dioxide during the course of the reaction.

The contents of the flask after cooling to 20° deposited a small quantity of white solid. This was removed by filtration under vacuum in an apparatus designed to exclude air and moisture. The solid weighed 1.2 g. and proved to be sodium cyanide. It gave the usual qualitative tests for the cyanide ion and on analysis was found to contain 47.44% Na; calculated for NaCN, 46.93%.

The sodium phenylacetonitrile precipitated from the ethereal filtrate after standing for several days, in the form of frost-like crystals. The salt was removed by filtration in an atmosphere of dry nitrogen and freed from ether in a vacuum desiccator over phosphorus pentoxide. The salt was light pink in color at first and of a yellow color after twenty-four hours. It was distinctly crystalline in character. A yield of 20 g. was obtained.

Anal. Calcd. for C_8H_6NNa: Na, 16.55. Found: Na, 16.57.

The sodium salt is very soluble in the parent nitrile, somewhat soluble in benzene, toluene and xylene and slightly soluble in ether. The reaction mixture contains ether, toluene and unchanged nitrile. The salt is thus quite soluble in the reaction mixture and separates slowly and incompletely. A large excess of ether is desirable since it dilutes the unchanged nitrile and toluene. Cooling increases the rate of precipitation. A second precipitation of the salt usually occurs on long standing of the filtrate.

Identification of Toluene in the Reaction Mixture.—The combined filtrates from five reaction runs, involving a total of 200 cc. of phenylacetonitrile and 1400 cc. of ether, were filtered from precipitated salt and subjected to fractional distillation; 1200 cc. of ether was recovered in the first fraction. The remainder was distilled with an efficient fractionating column. The fraction 110–115°, 54 cc., was again refractionated, yielding

47 cc. boiling at 110–111°, from which there was finally isolated 43 cc. of pure toluene with a boiling point of 110° (corr.). The toluene was further identified by conversion to 2,4-dinitrotoluene; m. p. 70° (corr.).

The higher-boiling fraction yielded a small amount of liquid (unidentified) distilling between 120 and 190°. Between 190 and 240° there was obtained a fraction of 20 cc. consisting chiefly of unchanged phenylacetonitrile. Between 240 and 260° a heavy oil of a red-green color distilled. A small amount of crystalline solid collected in the condenser. These latter were not identified.

Effect of Heat on the Sodium Salt.—The sodium salt obtained from 120 g. of phenylacetonitrile was subjected to rapid heating in a pyrex flask. A small amount of low-boiling liquid was obtained, after which the temperature rose rapidly to 200°. A distillate was obtained of oily appearance and of a green color by reflected light and red by transmitted light. The distillate smelled strongly of ammonia. A considerable amount of crystalline material collected in the condenser tube. This, on recrystallization from alcohol, gave crystals of a wax-like appearance and melting point 123–124°, which is the melting point of stilbene.

Anal. Calcd. for $C_{14}H_{12}$: C, 93.28; H, 6.72. Found: C, 93.41; H, 6.7.

The distillate was treated with an excess of bromine in carbon tetrachloride solution. There appeared almost at once a considerable quantity of fine needle-like crystals. The crystals were removed by filtration and washed well with alcohol. The yield was 4.6 g. The product on recrystallization from hot toluene gave white feathery needles, m. p. 237° (corr.), which is the melting point of stilbene dibromide.

Anal. Calcd. for $C_{14}H_{12}Br_2$: Br, 47.01. Found: Br, 47.11.

The dibromide was converted into tolane by heating with alcoholic alkali. The tolane was precipitated on addition of water, collected and recrystallized from alcohol as white leaflets, m. p. 50–60°. This is the melting point recorded for tolane. These results without doubt identify stilbene as a product of the decomposition of the sodium salt of phenylacetonitrile.

Reactions of the Silver Salt of Phenylacetonitrile.—The silver salt was prepared in an impure form through interaction of the sodium salt and silver nitrate in absolute alcohol solution. There was obtained a white insoluble compound which rapidly became dark in color. This substance decomposes with explosive violence on heating. The silver salt, freshly prepared was mixed with butyl iodide and allowed to stand for twelve hours, after which time a complete reaction had occurred. The mixture possessed a strong odor of isocyanide.

The solution obtained from the reaction mixture of silver salt and butyl iodide was filtered and distilled. The distillate was treated with hydrochloric acid and evaporated to dryness, giving a considerable quantity of white crystalline material. This was purified by recrystallization first from absolute alcohol and then an alcohol–benzene mixture. The substance was butylammonium chloride.

Anal. Calcd. for $C_4H_{12}NCl$: Cl, 32.36. Found: Cl, 32.47.

Condensation of the Sodium Salt of Phenylacetonitrile with Benzalacetophenone.—This condensation was carried out in order to prove that sodium phenylacetonitrile gives the same product that is obtained from phenylacetonitrile using sodium methylate as the condensing agent.

The sodium salt obtained from 2.2 g. of sodium was cooled to the temperature of ice water in a three-necked flask fitted with a stirring device. To this was added 25 cc. of absolute methyl alcohol and then 20 g. of solid benzalacetophenone. The contents of the flask were stirred constantly for three hours, keeping the temperature at 0°. After standing for thirty-six hours there had formed a dense crust of white crystals on the walls of the flask. This was removed, powdered in a mortar and washed with dilute hydrochloric acid to remove sodium compounds, and then with alcohol. There was obtained 24 g. or 93.7% of the theoretical yield of 1,5-dibenzoyl-2,3,4-triphenyl-3-cyanopentane. After recrystallization from chloroform and benzene there was obtained 9.9 g. of pure substance, m. p. 264.5–265.5° (corr.). The substance agrees in every respect with that obtained by Avery.[8]

Anal. Calcd. for $C_{38}H_{31}O_2N$: C, 85.6; H, 6.1; N, 2.6. Found: C, 85.6; H, 5.9; N, 2.5.

This compound has been prepared by Kohler and Allen,[9] who suggest the same structure but who found a melting point of 257". Avery has shown that this melting point is probably low, due to impurities, and that the corrected melting point is 264.5–265.5°.

Summary

1. A method for the preparation of pure sodium phenylacetonitrile is described.
2. New evidence for the existence of tautomeric forms of the nitrile and for the imide structure of the salt is presented.
3. It has been shown that the sodium salt enters into condensation reactions of the type produced by sodium methylate and phenylacetonitrile.

THE PREPARATION OF DIETHYL LEAD DICHLORIDE AND TRIETHYL LEAD CHLORIDE

BY HENRY GILMAN AND JACK D. ROBINSON

RECEIVED DECEMBER 9, 1929 PUBLISHED MAY 8, 1930

Introduction

Convenient methods have been determined for the ready preparation of diethyl lead dichloride and of triethyl lead chloride in essentially quantitative yields by means of the following reactions carried out in toluene and ether, respectively

$$(C_2H_5)_4Pb + 2HCl \longrightarrow (C_2H_5)_2PbCl_2 \qquad \text{(I)}$$
$$(C_2H_5)_4Pb + HCl \longrightarrow (C_2H_5)_3PbCl \qquad \text{(II)}$$

The most generally used method for the synthesis of diethyl lead dihalides is that elaborated by Grüttner and Krause,[1] and involves the direct action of halogens on tetraethyl lead at low temperatures. In that method they recommend that the triethyl lead halide be first prepared at −60° and then converted to the dihalide as the solution warms

---

[8] S. Avery, results soon to be published.

[9] Kohler and Allen, THIS JOURNAL, 46, 1522 (1924).

[1] (a) Grüttner and Krause, ***Ber.***, 49, 1415 (1916). (b) Other methods, not of preparative value, for the synthesis of diethyl lead dichloride may be found in the following references: Grüttner, ibid., 47, 3257 (1914); Moller and Pfeiffer, ibid., 49, 2441 (1916); Goddard and Goddard, J. Chem. *Soc.*, 121,256,482 (1922).

up to −20°. When the reaction with halogens is effected at −20° in large-sized runs, without the preliminary formation of triethyl lead halide, they caution against a vigorous reaction which may be of explosive violence. Incidentally, we have shown in this study that it is possible to prepare diethyl lead dichloride in a 98.6% yield by the direct action of chlorine on 0.05 mole of tetraethyl lead in ether cooled to −10°.

The same authors[1"] object to any method for the preparation of triethyl lead chloride which involves the use of hydrogen chloride or hydrochloric acid, basing such objection on the ground that the yield is lowered when large quantities of materials are used. This objection is not valid at least in a preparation starting with 113 g. (0.35 mole) of tetraethyl lead, inasmuch as our yield by Reaction II of triethyl lead chloride is 96%. Triethyl lead chloride has been prepared by Buckton[2] and Cahours[3] by warming tetraethyl lead with concd. hydrochloric acid, and by Buckton[4] from hydrogen chloride and tetraethyl lead. More recently, Browne and Reid[5] have given splendid directions for the preparation of triethyl lead chloride in 86% yields from tetraethyl lead and concd. hydrochloric acid with a trace of silica gel as a catalyst.

The greater stability of the diethyl and triethyl lead chlorides over the corresponding bromides and iodides, as well as their lesser expensiveness, makes them the most desirable halides. This is particularly the case in our studies of their reactions with other organometallic compounds, in which studies they have been shown to have a very high order of reactivity. When, however, it is desired to use the bromide or iodide, then two general methods are available for the conversion of the chloride to the other halides. One involves the hydrolysis to the corresponding hydroxide and subsequent treatment with the appropriate halogen acid.[6] The other method is based on a double decomposition reaction between an alkyl lead halide and the appropriate halide of sodium or potassium.[7] Both of these methods are applicable to the dialkyl lead dihalides as well as to the trialkyl lead halides.

Although we have not tried our method with halogen acids other than hydrochloric acid, it is probable that they can be extended to some of the other halogen acids. Also, it is altogether reasonable to believe that our methods for the synthesis of diethyl lead dichloride and triethyl lead

chloride are applicable to tetra-alkyl lead compounds other than tetraethyl lead.

Experimental Part

Diethyl Lead Dichloride, $(C_2H_5)_2PbCl_2$.—After dissolving 107.5 g. (0.3 mole) of tetraethyl lead in 500 cc. of toluene in an open[8] Erlenmeyer flask, and heating the solution to 90°,[9] dry hydrogen chloride is passed into the solution at a moderate rate. Inasmuch as the triethyl lead chloride which first forms is soluble in toluene, no precipitate appears before one-half of the hydrogen chloride has been absorbed. The approximate end of the reaction may be determined by adding hydrogen chloride at the same rate for twice the time necessary to cause the first precipitate of diethyl lead dichloride to form. At this stage the precipitate is removed by filtration and hydrogen chloride is again added in order to precipitate any unreacted triethyl lead chloride. If no precipitate forms on this subsequent addition of hydrogen chloride, the reaction is ended. The yield of 107 g. or 97.5% has been checked many times. The product is free of lead chloride, and if there were any significant quantity of triethyl lead chloride it would probably not contaminate the diethyl lead dichloride because of its high solubility in hot toluene.[10]

In another connection, chlorine was bubbled slowly into a well-stirred solution of 16.5 g. (0.05 mole) of tetraethyl lead dissolved in 150 cc. of dry ether and cooled to −10°. A smooth reaction occurred, and when the chlorine colored the solution, the reaction was considered to be complete. The diethyl lead dichloride was filtered off, and its weight was 16.6 g. which is equivalent to a 98.6% yield. This describes the only experiment we carried out between tetraethyl lead and chlorine.

Triethyl Lead Chloride, $(C_2H_5)_3PbCl$.—Forty-eight and one-half grams (0.15 mole) of tetraethyl lead is dissolved in 400 cc. of absolute ether and saturated with hydrogen chloride at room temperature. This requires about thirty minutes or more. depending on the rate of flow of gas. The rate at which the hydrogen chloride is absorbed appears to reach a maximum and the evolution of ethane is rather constant. Perhaps the best way to determine when the reaction is at an end is to remove the needles of triethyl lead chloride by filtration when the ethane is only slowly evolved, and then to saturate the filtrate again with hydrogen chloride. If no more needles form, the reaction is complete. The yield is 48.6 g. or 98.2%.[11]

In this preparation it is necessary that all moisture be rigorously excluded from the flask and reagents. Triethyl lead chloride is soluble in moist ether but quite insoluble in dry ether which contains moderate amounts of hydrogen chloride. However, triethyl lead chloride appears to be appreciably soluble in dry ether which contains a *large* quantity of hydrogen chloride. This finds support in two observations. First, it has been found that on boiling a solution to remove excess hydrogen chloride, another

---

[8] All operations are carried out, of course, with due care because of the toxicity of tetraethyl lead. This involves, primarily, working in a well-ventilated hood. Care should be exercised about long exposure to triethyl lead chloride. The observation of Krause and Pohland, *Ber.*, 55, 1282 (1922), that compounds of this type cause severe headaches has been confirmed.

[9] The temperature of the solution should be maintained at 90° by the application of heat, although there appears to be no harm with a temperature variation of 10°.

[10] The diethyl lead dichloride is in the reactive form and requires no further treatment prior to use. See Griittner and Krause, *Ber.*, **49**, 1546 (1916).

[11] The yields may vary between 92 and 98.2% depending on the careful conversion of the last small quantities of tetraethyl lead. The smoothness of these reactions has recommended them for other studies concerned with the lability or polarity of radicals.

crop of crystals frequently appears. Second, the saturation of a suspension of triethyl lead chloride in ether with hydrogen chloride induces some of the triethyl lead chloride to dissolve. This latter phenomenon appears to be unusual with organolead halides.

Summary

Diethyl lead dichloride and triethyl lead chloride can be very conveniently prepared in essentially quantitative yields by the reaction between tetraethyl lead and hydrogen chloride.

SOME PHYSICAL CONSTANTS OF MONACETIN, MONOPROPIN AND MONO-NORMAL-BUTYRIN[1]

BY H. A. SCHUETTE AND JOHN T. HALE

RECEIVED DECEMBER 12, 1929 PUBLISHED MAY 8, 1930

The discovery of the nature of fatty oils by Chevreul over a century ago gave a marked impetus to the synthesis of simple and mixed glycerides. The monoglyceryl esters of the acids of low molecular weight have not, however, shared the same degree of interest. Published information thereon is apparently non-existent for one of the esters pertinent to this communication; the reported physical constants of another are obviously in need of correction; and such data as are available have been determined at temperatures for which there is no uniformity.

In view of this situation there is an evident need for new data and for a revision of some of that now extant. These ends have been accomplished by the synthesis of the glycerides in question and the determination of their vapor pressures, densities, refractive indices and surface tensions. The method of preparation which was followed led to the formation of racemic compounds which probably possess, as might be expected, different constants than the corresponding naturally occurring glycerides, none of which, however, seems to have been isolated.

Monacetin has been made by Berthelot,[2] who heated a mixture of glycerol and acetic acid under pressure; by Geitel,[3] who isolated it from the reaction product resulting from heating a mixture of glycerol and acetic acid at atmbspheric pressure; by Averill, Roche and King,[4] who synthesized a-monoglycerin by a method developed by Fischer[5] and his

---

[5] Fischer, Bergwin and Barwind, *Ber.*, 53, 1589 (1920).

collaborators; and by one of us,[6] who improved upon Geitel's technique by introducing a suitable catalyst into the reaction mixture. Butyrin was made by Berthelot by a method already indicated;[2] by Guth[7] from sodium butyrate and α-monochlorohydrin; and by Hanriot, it is reported,[8] who used a biological method of synthesis in that he caused lipase to act upon a mixture of glycerol and butyric acid.

Experimental

A uniform method of procedure was followed in the synthesis of the monoglycerides pertinent to this communication. Its salient features consist of the use of phosphoric acid as catalyst; an esterification temperature whose order of magnitude is lower than that of the boiling point of the acid in question; and the removal of by-product water as fast as it is formed. The last two conditions were met by dispersing the reactants in carbon tetrachloride and carrying out the operation with the aid of a continuous separator.[9]

Because of the similarity in method the synthesis of but one glyceride is described as illustrative of a typical case. In each instance equivalent quantities of glycerol and fatty acid necessary to produce the monoglyceride in question were taken.

That a monoglyceride had actually been synthesized was deduced from the satisfactory degree of agreement between the molecular refractivity (Gladstone and Dale formula) and the sum of the atomic refractivities of the compound in question. Although it is true that no claim for great delicacy can be made for this method of identification, yet it would seem that, in this instance, the assumption is valid in view of the close concordance between observed and theoretical saponification equivalents.

Monopropin.—A mixture consisting of 150 g. of glycerol (1 mol), 118 g. of propionic acid (1 mol) (b. p. 140–141°), 10 g. of phosphoric acid (85%) and 200 cc. of carbon tetrachloride was heated under a reflux for approximately four hours, during which time an amount of water was recovered which was slightly in excess of the theoretical. Ten g. of sodium propionate was then added to the reaction mixture, and the whole concentrated by distillation at a temperature below 130°. The insoluble phosphate was then removed by filtration, whereupon the filtrate was distilled at a pressure of 3 mm., the fraction boiling between 132–134°, indicative of a 58% yield, being saved for further purification.

The following constants were noted: d_4^{20} 1.1537, n_{20} 1.4503; saponification equivalent, 148.2, calcd. for monopropin, 148.1; molecular refraction, 57.81, calcd. for monopropin, 57.18; γ_{20} 40.3 dynes/cm.

Monacetin.—The fraction boiling between 129–131° (3 mm.) on purification yielded the following constants: d_4^{20}, 1.2060; n_{20} 1.4517; saponification equivalent, 134.1,

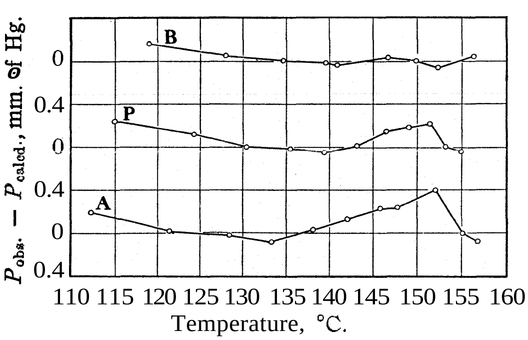
calcd. for monacetin, 134.2; molecular refraction, 50.21, calcd. for monacetin, 49.53; γ_{20} 47.1 dynes/cm.; yield of crude ester, 70%.

Mono-*n*-butyrin.—The fraction boiling between 139–140° (4 mm.) on purification yielded the following constants: d_4^{20} 1.1344; n_{20} 1.4531; saponification equivalent, 162.1, calcd. for monobutyrin, 162.1; molecular refraction, 64.75, calcd. for monobutyrin 64.83; γ_{20}, 37.6 dynes/cm.; yield of crude ester, 78%.

Vapor Pressure Measurements

Measurements of the vapor pressure of the three glycerides were made by the method of Ramsay and Young[10] over a temperature range of approximately 120°, minimum and maximum being 112 and 238°, respectively. Inasmuch as decomposition probably occurred in the upper zones, the values there observed have not been recorded. Temperatures were read with a thermometer graduated to 0.2°. They were corrected for stem exposure. Pressures were read to 0.1 mm. on an ascending and a descending temperature scale. When these data were subsequently plotted it was found that the observed points fell on one curve.

The curve for the vapor pressure of monacetin may be expressed by the empirical equation log P = 10.10518 − 3864.8/T. It holds for temperatures up to approximately 185°, and is reliable down to 112°. Similarly the equation for monopropin was found to be 10.29682 − 3961.3/T, an expression which is valid between the temperatures 115 and 183°. For mono-n-butyrin the curve for the vapor pressure corresponds to the equation log P = 10.78092 − 4200.8/T. It holds between the limits 119 and 176".



A, monacetin; P, monopropin; B, mono-n-butyrin.

Fig. 1.—Deviation plot.

Though due recognition is made of the fact that equations of this character are at best but approximate, yet the fact remains that the experimental points were found to lie on straight lines within the limits of accuracy of the experimental data. The least accurate factor probably lies in whatever limitations are inherent in the method which was employed for determining the vapor pressures.

That the differences between the experimentally determined and calculated vapor pressures might be graphically shown, there is reproduced a deviation plot (Fig. 1) for each of the glycerides pertinent to this study. Maximum and mean differences were found to be 0.40 and 0.12 mm.

---

[10] Ramsay and Young, J. Chem. *Soc.*, **47,** 42 (1885).

for monacetin. Similarly for monopropin and mono-n-butyrin these differences are 0.24 and 0.09, and 0.16 and 0.04, respectively.

Conclusions

The foregoing expressions of the vapor pressure–temperature relationships which obtain among the monoglycerides of low molecular weight make possible a critical inspection of such boiling points of these compounds as have found their way into some of the well-known texts and reference books. When viewed in the light of the data as herein recorded, it appears that the previously reported boiling points of monacetin of 189–191 (60 mm.)[6] and 130–132° (2–3 mm.)[8] are in substantial agreement with our observations. On the other hand, the statement[11] that monacetin boils at 158° (165 mm.) is rather difficult to explain except perhaps on the grounds of a typographical error in recording the pressure.

That monobutyrin boils at 269–271°[8] or at 271°[11] under atmospheric pressure appears to be an absurd statement because of the generally accepted view that the glycerides cannot be distilled under ordinary conditions without decomposition, and the fact that the calculated boiling point of this glyceride is approximately 535°. The assigned boiling point of 160–163° (16 mm.)[8] is in better agreement with fact.

The heat of vaporization per gram of ester when calculated with the aid of the Clausius–Clapeyron equation is for monacetin 132.4 cal., for monopropin 122.5 cal. and for mono-n-butyrin 118.75 cal.

Summary

The monoglycerides of acetic, propionic and n-butyric acids have been synthesized and their simpler physical constants determined at a uniform temperature. Of these data those for monopropin are new.

The vapor pressures of these glycerides have been determined over the temperature range in which they are stable.

The heats of vaporization have been calculated.

AN INVESTIGATION OF A SERIES OF DERIVATIVES OF NORMAL HEPTANE. I. PREPARATION, IDENTIFICATION AND PHYSICAL CONSTANTS

BY MARY L. SHERRILL[1]

RECEIVED DECEMBER 14, 1929 PUBLISHED MAY 8, 1930

In connection with further investigation of isomeric hydrocarbons similar to those obtained in the case of 2-pentene[2] it was found necessary to prepare and identify certain derivatives of normal heptane. The preparation, purification and identification of these products and the physical constants measured furnish the basis for the present paper. The measurement of the dielectric constants and the determination of the dipole moments of these compounds are given in the following paper. The work involved a study of the four straight-chain alcohols, heptanol-1, heptanol-2, heptanol-3, heptanol-4, the corresponding chloro and bromo derivatives, two of the iodo derivatives, and the aldehyde and the ketones obtained from these alcohols.

Experimental

Determination of Physical Properties

Boiling Point.—All distillations were made at diminished pressure except in a few specified cases. A fractionating column (a modified Vigreux type) 50 cm. in length, was used for these distillations. The receiver was so arranged that fractions could be removed and new receivers put on (evacuated by an auxiliary pump) so that the distillation could be continuous. In the case of distillations at atmospheric pressure the fractionating column was 50 cm. long, of the Crismer type, consisting of a glass spiral fitting closely around an inner tube, the tube and spiral fitting snugly into the column. The thermometers used were of the Anschiitz type, calibrated by the Physikalisch-Technische Reichsanstalt, and were placed in the side neck so that the mercury was completely immersed in vapor.

Freezing Point.—The freezing point determinations were made by Professor Jean Timmermans.[3] Approximately 5-cc. samples, in 15–18-cm.

---

[3] The author takes this opportunity of expressing appreciation of Professor Timmermans' interest and cooperation.

test-tubes, were cooled in liquid air and the temperature of the freezing point measured by Professor Timmermans' specially calibrated thermometers.

Density.—The density determinations were made in a 14-cc. Sprengel pycnometer and at least three checking determinations were made at each temperature. The measurements at 0° were made by surrounding the pycnometer with finely crushed ice, those at 15° were made in a Dewar flask in which the temperature remained constant within less than 0.1° over several hours, those made at 20° were made in a thermostat regulated constant to at least 0.01°. The weights were reduced to a vacuum basis.

Index of Refraction.—The refractive indices for the three helium lines, at 15 and 20° or at 17.5 and 20° were measured with a Pulfrich refractometer, supplied with a calibrated thermometer graduated in tenths of degrees. The water current through the refractometer came from an accurately regulated thermostat. The temperatures were accurate within 0.05'. Duplicate observations checked closely. The refractive indices for the sodium D line were made with an Abbé refractometer. The water current through the refractometer came from a thermostat.

Following each table of physical data there is a summary of literature data, complete in the case of the halogen derivatives, representative in the case of the other compounds.

Purification of **Heptanols.**—Three of the heptanols which were the source materials for the work were prepared especially for this problem by R. E. Marker by means of the Grignard synthesis from the corresponding alkyl bromide and alkyl aldehyde. These alcohols were methyl-*n*-amyl carbinol, ethyl-n-butyl carbinol and dipropyl carbinol. The fourth alcohol, n-heptanol, was obtained from Schering-Kahlbaum. In each case the alcohols were carefully dried and fractionated in *vacuo* in order to diminish any possibility of dehydration which might give a mixture of hydrocarbon and alcohol. Three distillations were made although the alcohols boiled very constantly in the second distillation. The boiling points and indices of the distillates in the second and third distillations were the same. The identity of the alcohols was proved by the oxidation of each and the preparation of the corresponding semicarbazone. In each

Halogen Derivatives—Each of the four chlorides and four bromides was prepared; the 3-iodoheptane was prepared; and the 1-iodoheptane (Schering–Kahlbaum) was purified. Especial care was taken in the preparation to prevent a shift of the position of the entering halogen and for the same reason the distillation was carried out under diminished pressure. The products were of very constant boiling point, showing no change on second distillation, and in each case, except for very small cuts at the beginning and the end, the distillate boiled completely within one-tenth of a degree.

The chloro derivatives were prepared by the action of concentrated hydrochloric acid and zinc chloride on the heptanols according to an adaptation of the method of Norris and Taylor.[19] One mole of the heptanol was added to two moles of ice-cold concentrated hydrochloric acid containing two moles of anhydrous zinc chloride. The product was kept in an ice-bath for several hours and vigorously stirred. Then the mixture was gradually allowed to come to room temperature. In the case of 1-chloroheptane the reaction mixture was refluxed gently for one hour and then the oil was slowly distilled off. With the 2-, 3- and 4-chloro derivatives the method was varied as suggested by Lucas,[20] the reaction being carried out at a lower temperature in order to avoid as much as possible any shift of position in the chain. The mixture of heptanol, hydrochloric acid and zinc chloride was kept ice cold for six to eight hours; then it was allowed to come to room temperature. After the mixture had stood from twelve to twenty-four hours, the oil layer was removed and the process repeated. The oil was added to fresh portions of ice-cold concentrated hydrochloric acid (two moles) and zinc chloride (two moles). This was repeated at the end of a second twenty-four hour period. Finally the oil and acid mixture was vigorously shaken.

For purification the chloride layer was separated from the water–acid layer, was washed three times with fresh portions of concentrated hydrochloric acid, four times with ice-cold water, once with 10% sodium hydroxide (ice cold) and twice with cold 15% sodium chloride. The crude oils, very pale yellow in color, were dried over calcium chloride and distilled twice *in vacuo* over phosphorus pentoxide. The crude yields were 77–80% of the theoretical and the yields of constant boiling products were from 60–64% of the theoretical yields. The purified chloro derivatives were perfectly colorless and have remained so for six months.

[20] Lucas, *ibid.*, 51, 249 (1929).

The 1-bromo derivative was prepared according to methods used for similar bromides by Kamm and Marvel,[21] Norris, Watt and Thomas[21] and Simon.[22] Eighty-eight grams of 1-heptanol was refluxed for two and one-half hours with 360 g. of 48% hydrobromic acid to which 92 g. of concentrated sulfuric acid had been added. The oil was separated and washed with water but proved to be lighter than water, so the procedure was repeated and the material was refluxed for three hours. The oil, when separated and washed with concentrated sulfuric acid, with water and with sodium carbonate, was so dark in color that it was distilled from four times its volume of 48% hydrobromic acid, which gave a practically colorless product.

The 2-, 3- and 4-bromo derivatives were prepared by slow saturation of the alcohols with hydrogen bromide.[2] The heptanol was kept at a temperature of about −10° by an ice and salt bath and a slow stream of hydrogen bromide was passed into the alcohol during a period of six to eight hours. The flask was then closed with a capillary tube or a tube carrying a rubber balloon and the mixture was allowed to come to room temperature and left overnight. The process was repeated each day for twelve days.

The bromides were purified as in the case of the chlorides by washing with 48% hydrobromic acid, water and sodium hydroxide and were dried over anhydrous calcium chloride. Then each was distilled twice in *vacuo* over phosphorus pentoxide. The crude yields of bromide were 70% of the theoretical in the case of 1-bromo-, and 85–90% in the case of the other three derivatives. The yields of constant boiling products were from 65–75% of the theoretical. The bromoheptanes so obtained showed no trace of color and have remained colorless for six months.

The 1-iodoheptane was obtained from Schering–Kahlbaum. It was shaken with mercury to remove excess iodine, filtered and distilled in *vacuo.* Eighty per cent. of the distillate was a constant boiling product and the iodoheptane so obtained has remained almost colorless for six months.

The 3-iodoheptane was prepared by a method analogous to that used for the preparation of the chloro derivatives. One hundred and thirty grams of 3-heptanol was treated with 750 g. of hydriodic acid in three separate portions and the mixture left for sixty hours, being agitated frequently. At the end of that time the oily layer was washed and found to be lighter than water so it was put back with the hydriodic acid and zinc iodide and refluxed for two hours at 60–70°. The reaction was still incomplete so gaseous hydrogen iodide was passed into the oily mixture of 3-iodoheptane and 3-heptanol for about five hours. At the end of this time

[21] **Kamm** and Marvel, "Organic Syntheses," John Wiley and Sons, Inc., New York, **1921,** Vol. I, p. 7; Norris, Watt and Thomas, THIS JOURNAL, 38, 1075 (1916).

[22] Simon, Bull. *soc. chim. Belg.*, 38, 48 (1929).

100 g. of the hydriodic acid (sp. gr. 1.5) and 100 g. of zinc iodide were added and the mixture left for twenty-four hours. The oil was then separated, purified as in the case of the chloro and bromo derivatives and distilled in *vacuo*. The distillation showed that the reaction was not complete, for there were two distinct distillates, one boiling fairly constantly at 75.2–75.6' at 30 mm. for more than an hour; then there was an interval (twenty-five minutes) when there was practically no distillate. Then the temperature rose rapidly to 88.8' at 30 mm. and a second constant boiling product distilled. This product was about 50% of the distillate.

Proof of Position of **the** Halogen.—In order to test the position of the substituting halogen each of the chloro derivatives was treated in the following manner. Approximately 10 g. of the chloro derivative was refluxed for seven hours with 15 g. of anhydrous potassium acetate and 10 g. of glacial acetic acid. The product was diluted with water and the ester extracted with ether. The ether was then removed by distillation and the ester was hydrolyzed by refluxing for six hours with 50 cc. of alcoholic potash (20% solution). The larger part of the ethyl alcohol was removed by distilling up to 85° (some of the heptanol distilled also, as was evidenced by the odor). Water was then added to the residue and an ether extraction was made. The ether was distilled off and the distillation continued up to 90° to remove all traces of ethyl alcohol. The residue of heptanol (approximately 3 g.) was oxidized by acidified bichromate. A solution of bichromate (2.7 g. in 35 cc. of water) was divided into two portions. Half was added to the heptanol; to the other half, 2.2 cc. of concd. sulfuric acid was added and this acid mixture was poured, drop by drop, into the well cooled mixture of heptanol and bichromate. The entire mixture was refluxed at 70–80° for one hour and a quarter. About 100 cc. of water was then added and the mixture distilled as long as oil distilled over. The ketone (or aldehyde) was separated from the water layer and washed several times with sodium carbonate solution. The ketone (approximately 2 g.) was then transformed into the semicarbazone by treatment with semicarbazide hydrochloride and sodium acetate. The semicarbazones formed were in each case similar in crystal form to those obtained from the original alcohols and they gave, without purification, the same melting points. The semicarbazone from 4-chloroheptane melted slightly lower, 129–130° and less sharply than the one obtained from the original, 132°. Mixed melting points with the original semicarbazones showed no change.

The 2-, 3- and 4-bromo derivatives were esterified, hydrolyzed and oxidized as in the case of the chloro derivatives, and the semicarbazones formed from the ketones were identical with those from the corresponding alcohols, except in the case of the 3-bromo, the semicarbazone from which melted at 96–97'. The amount of ketone obtained was small and the semicarbazone was filtered after standing for several days. The amount obtained was too small for purification. A mixed melting point of equal portions of this semicarbazone and of the pure semicarbazone, m. p. 88–89', melted at 90–91°, which indicated that it was the semicarbazone of 3-heptanone with some impurity. There are two points of interest to be noted in connection with this: first that Pickard and Kenyon[14] and Michael[23] give values 99–100° and 103° for the melting point of this substance, Mathus and Gibon[4] giving the lower value 89°. Second, in the preparation of the semicarbazone from 3-heptanol a large yield (12 g.) crystallized out instantly and melted at 88–89' sharply. A second precipitate (less than 2 g.) which came out after several days of standing melted at 97–98'. This material mixed with the 88–89' product melted at 90–91°. This seems to indicate that on oxidation of 3-heptanol, in addition to the 3-heptanone, there is a small amount of another ketone or other impurity which on long standing gives a semicarbazone.

1-Iodoheptane.—B. p. (754.8 mm.) 201°, d^{16} 1.346;[24] b. p. (16.5 mm.) 91°;[31] b. p. (20 mm.) 93–95°;[32] 203.8°, ordinary pressure, d_0^0 1.4008.[33]

3-Iodoheptane.—B. p. (8.5 mm.) 64.5°.[15]

Aldehyde and Ketone Derivatives.—The *n*-heptaldehyde, obtained from Schering–Kahlbauin, was distilled in *vacuo;* 82% of the total distillate boiled at a constant temperature. . The semicarbazone derivative of the aldehyde was prepared by treating 2 g. of the aldehyde with a water solution of 2 g. of semicarbazide hydrochloride and 2 g. of sodium acetate. Sufficient ethyl alcohol was then added to dissolve the aldehyde and the semicarbazone crystallized out in lustrous plate-like crystals which melted sharply at 109°.

The heptanones (methyl n-amyl ketone, ethyl n-butyl ketone, di-propyl ketone) were prepared by oxidation of the corresponding heptanols. To one mole of the alcohol, well cooled, was added one-sixth of a mole of potassium bichromate (8% solution). Then to the well-cooled mixture, a sixth of a mole of bichromate solution (8%) containing 1.5 moles of concentrated sulfuric acid was added dropwise. The reaction mixture was refluxed for one hour and a quarter at 70–80°. Water was added and the mixture distilled until all of the oil had distilled over. The oil was separated, washed three times with sodium carbonate and dried over calcium chloride. The crude yields were 85–90% of the theoretical.

The 2-heptanone was purified by making the sodium bisulfite addition product. The ketone was freed from the bisulfite compound by sodium carbonate and then distilled. Neither the 3-heptanone nor 4-heptanone formed sodium bisulfite addition products. The dried ketones were fractionated at atmospheric pressure and 60 to 70% of the products was constant boiling within *0.05'.

The semicarbazone of 2-heptanone was prepared and crystallized in fine lustrous crystals which, without purification, melted sharply at 123°. The semicarbazone from 3-heptanone crystallized in fine crystals somewhat granular in appearance. The semicarbazone, without purification, melted sharply at 89°. A second small fraction which crystallized out on long standing melted at 97–98'.

The semicarbazone from 4-heptanone crystallized in fine crystals, very similar in appearance to those obtained from 2-heptanone but very much less lustrous. These crystals, without purification, melted sharply at 132°.

Because of insufficient 4-heptanol the amount of 4-heptanone obtained was too small for the complete physical measurements. Dipropyl ketone

(purchased from Poulenc Frères) was dried and distilled. The total product boiled within less than one and one-half degrees and 70% was constant boiling within one-tenth of a degree. The boiling point of this compound and the melting point of its semicarbazone were identical with those obtained from the oxidation product of 4-heptanol. The physical constants of this product were measured.

Summary

The four heptanols (1-, 2-, 3- and 4-), the four corresponding chlorides and four bromides, two of the iodides (1- and 3-), the n-heptaldehyde and the three ketones (keto-2, -3 and -4) have been investigated and some of the physical constants determined.

AN INVESTIGATION OF A SERIES OF DERIVATIVES OF NORMAL HEPTANE. II. DIPOLE MOMENTS AND MOLECULAR CONSTITUTION[1]

BY JACQUES ERRERA AND MARY L. SHERRILL

RECEIVED DECEMBER 14, 1929 PUBLISHED MAY 8, 1930

The dipole moments of various aliphatic compounds containing one or more polar groups have been determined,[2] but it seemed advisable to study the effect on the moment of the position of the polar group in an aliphatic compound.

In order to have several different positions available a study of a series of derivatives of the straight chain heptane was begun, for in normal heptane it is possible to have a single substituent in four different positions in the molecule. The dipole moments of the four alcohols, heptanol-1 (n-heptyl alcohol), heptanol-2 (methyl-n-amyl carbinol), heptanol-3 (ethyl-n-butyl carbinol), heptanol-4 (dipropyl carbinol) have been measured. The three ketones, 2-heptanone (methyl-n-amyl ketone), 3-heptanone (ethyl-n-butyl ketone) and 4-heptanone (dipropyl ketone) have been prepared and purified and the moments of these and of the n-heptaldehyde have been determined. The chloro and the bromo derivatives corresponding to each of the heptanols have been synthesized and two of the iodo derivatives, 1-iodoheptane and 3-iodoheptane, have also been studied. Great care was taken in the preparation of these compounds to avoid any shift of position in the chain. The preparation of these derivatives and the proof of the position of the groups has been given by one of the authors.[3] The dipole moment of each of the compounds has been calculated from measurements of the dielectric constants of dilute solutions of the compound in a non-polar solvent, benzene, according to the well-known method

---

shown by Debye.[4] The resonance method was used and the wave length was 100 meters. The capacity measurements were of a precision of 1 part in 500.

The total polarization of a pure substance is regarded as made up of three parts, the polarization P_E caused by electronic shifts induced in the molecule, the polarization P_A attributed to atomic shifts and P_P, the polarization due to orientation of the permanent dipoles in the molecule.[5] The total polarization is determined according to the equation $P = \epsilon - 1/\epsilon + 2 \cdot M/d$, in which ϵ is the dielectric constant, M is the molecular weight and d is the density of the compound. P_∞ is the total polarization of the unassociated molecule obtained by extrapolation of $P_{1,2}$ and P_2 from the data of the dilute benzene solutions, in which $P_{1,2} = \epsilon - 1/\epsilon + 2 \cdot C_1M_1 + C_2M_2/d$ and $P_2 = P_{1,2} - C_1P_1/C_2$. Since it was not possible, at this time, to measure the refractive indices in the long waved infra-red, instead of measuring $P_E + P_A$, P_E was determined from the refractive index of the compounds obtained by measuring the helium yellow line at 20°. P_E is considered equal to the molecular refractivity RM as defined by the Lorenz-Lorentz law, $P_E = n^2 - 1/n^2 + 2 \cdot M/d$, in which n is the refractive index, M the molecular weight and d the density. The dipole moment μ is calculated according to Debye,[6] $\mu = 0.0127 \times 10^{-18} \sqrt{(P_\infty - P_E)T}$.

According to one of the authors,[7] the molecular association in a liquid may be considered as the result of two factors. The first is the dipolar molecular association which may be attributed to the electrostatic forces of the permanent dipoles in the molecule, these forces being determined by the size and position of the dipoles in the molecule and the form of the molecule itself. The second is the molecular association of the molecules which are not dipoles, which may be the result of intermolecular attraction as indicated by van der Waals. The total association, the sum of these two factors, must be determined by measurements such as vapor pressure, viscosity and surface tension. Polarization measurements, which give the electric moment in unit volume, are able only to give some insight into the first factor of this association corresponding to the association of the dipoles. In fact, in the consideration of the total polarization, $P = P_E + P_A + P_P$, Debye has shown that $P_E + P_A$ corresponds to the polari-

zation of those constituents whose field is determined by the van der Waals molecular attraction. For a substance whose molecules are not dipoles and whose total polarization is limited to $P_E + P_A$ it is not possible to determine the association through polarization measurements. Where, however, there are dipole molecules present, the association of the permanent dipoles affects greatly the P_P factor. It is then possible to determine the dipolar association, y, of the permanent dipoles present by the ratio of the total polarization at infinite dilution of the permanent dipoles, $P_{P\infty}(P_{P\infty} = P_, - P_E)$, to the total polarization of the permanent dipoles in pure state, P_P $(P_P = P - P_E)$, or $P_{P\infty}/P_P = y$. In the data for the various series of compounds tabulated below, P_E is a first approximation in place of $P_E + P_A$. The probable error in the dielectric measurements is 0.5%.

TABLE I

CONSTANTS OF HEPTANE DERIVATIVES AT 22°

Derivative	d_4	ϵ	P	P_∞	P_E	$\mu \times 10^{18}$	y
Heptanol-1	0.8214	12.10	110.90	98.0	36.08	1.71	0.83
Heptanol-2	.8153	9.21	104.30	97.5	36.07	1.71	.90
Heptanol-3	.8194	6.86	93.69	97.5	35.98	1.71	1.07

Heptanone-2	.8006	9.77	106.20	176.0	35.21	2.59	1.98
Heptanone-3	.8167	12.88	111.60	197.0	34.49	2.78	2.11
Heptanone-4	.8160	12.43	110.80	190.0	34.39	2.72	2.04
1-Chloroheptane	.8702	5.48	92.65	111.4	39.50	1.85	1.34
2-Chloroheptane	.8651	6.52	100.60	126.3	39.50	2.03	1.42
3-Chloroheptane	.8674	6.70	101.40	127.0	39.47	2.04	1.41
4-Chloroheptane	.8694	6.54	100.20	127.2	39.40	2.04	1.44
1-Bromoheptane	1.1342	5.38	93.71	113.2	42.39	1.85	1.40
2-Bromoheptane	1.1255	6.46	102.70	131.8	42.50	2.06	1.48
3-Bromoheptane	1.1341	6.93	104.80	130.0	42.42	2.04	1.40
4-Bromoheptane	1.1330	6.81	104.10	130.3	42.40	2.04	1.42
1-Iodoheptane	1.3736	4.90	93.03	117.0	47.60	1.84	1.53
3-Iodoheptane	1.3656	6.39	106.40	126.3	47.99	1.93	1.34

The results show that in the case of the hydroxy group in straight-chain hydrocarbons, such as the heptanols, the dipole moment is independent of the position of the polar group in the chain. It is also to be noted that the association is greatest in the case of 4-heptanol and decreases in order to 1-heptanol, which is least associated, for the dipole moment of each of the four alcohols is the same and the density practically the same, yet the dielectric constant which should be the same varies from $\epsilon = 6.2$ in 4-heptanol to $\epsilon = 12.1$ in the case of 1-heptanol. In the carbonyl derivatives, one of which is an aldehyde, the other three being ketones, it is found that the dipole moment of the 1-derivative, n-heptaldehyde, is smaller than that of the 3- and 4-heptanones. The 2-heptanone instead of being like the 3- and 4-derivatives has a dipole moment more like that of *n*-heptaldehyde. This seems to correspond somewhat to the chemical reactivity, for of these compounds only the aldehyde and the 2-heptanone form bisulfite addition products. The dipole moments of a number of ketones have been determined by Wolf,[8] and dipropyl ketone is one of these for which he found a value of $\mu \times 10^{18}$ of 2.73, which checks the value obtained in this work.

In the case of the halogen derivatives it is seen that in the 2-, 3- and 4-positions the dipole moment is practically independent of the position in the chain. In 1-chloro-, 1-bromo- and 1-iodoheptane the dipole moment is smaller than that of the other halogen derivatives. The dipole moment of n-heptylbromide is given by Smyth[9] as 1.86, which compares favorably with the value found in this work. From the data obtained with these halogen compounds of heptane it is to be inferred that the dipole moment is the same for the chloro, bromo and iodo derivatives of the aliphatic compounds as Williams[10] has found for the chloro and bromo derivatives of aromatic compounds, the numerical value, however, being greater than for the aromatic derivatives. For the disubstituted chlorides and bromides of benzene and of ethylene one of the authors[11] has found that the moment of the chloro derivatives was larger than that of the bromo and of the bromo larger than the iodo derivatives. In these heptane derivatives the dipole moment of the halogen compounds has been found to be greater than that of the hydroxyl derivative, which is different from that found for aromatic compounds,[10] where the dipole moment of the hydroxy derivative is greater than that of the halogen derivative. The characteristic moment of the polar substituents in n-heptane are tabulated below. The values are approximate in the sense that P_A, which in certain cases has a value which cannot be neglected, has not been taken into consideration.

TABLE II

CHARACTERISTIC MOMENTS ($\mu \times 10^{18}$) OF POLAR SUBSTITUENTS IN *n*-HEPTANE

Group	OH	H—C=O	C=O	Cl	Br	I
First position	1.70	2.55	(2.58) (2-ketone)	1.85	1.85	1.80
Other position	1.70	..	2.75	2.00	2.00	1.90

In addition to the alcohol derivatives of heptane there were available three of the petanols (n-amyl alcohol,[12] methyl propyl carbinol and diethyl carbinol). The dielectric constants of these alcohols were measured and the dipole moments calculated as in the case of the heptane derivatives.

Here as in the heptanols it is evident that the moment is independent of

TABLE III

PENTANE DERIVATIVES AT 22°

Derivative	d_4	ϵ	P	P_∞	P_E	$\mu \times 10^{18}$	y
Pentanol-1	0.8134	14.37	88.53	84.0	26.80	1.65	0.93
Pentanol-2	.8100	13 82	88.43	86.0	26.88	1.66	.94
Pentanol-3	.8142	13.02	86.82	83.0	26.52	1.64	.94

the position of the substituent in the molecule; the numerical value of the moment, 1.65, is, however, slightly smaller than that obtained for the heptanols, 1.70. Representative data on electric moments of the straight-chain alcohols as given in the literature are as follows: methyl alcohol, 1.73 (gas),[2e] 1.64 (solution);[13] ethyl alcohol, 1.63,[10] 1.72,"' 1.64;[14] n-propyl alcohol 1.66,[14] 1.53;[2f] n-butyl alcohol 1.65,[2f] 1.75;[2j] octyl alcohol 1.71.[2j] A comparison of these values with the electric moments of the C_5 and C_7 alcohols obtained in this study shows fairly good agreement.

Summary

Dielectric constant data have been obtained for the following compounds, pure and in benzene solution: four straight-chain heptanols, the n-heptaldehyde, the three ketones, the four chloro and four bromo derivatives and 1-iodo and 3-iodoheptane. From these data the electric moments have been determined.

The position of the polar group in the chain in the case of the alcohols has been found to have no effect. In the case of the halogen derivatives, the moment is found to be the same for chloro, bromo and iodo compounds but a slightly smaller moment is obtained when the substituent is in the 1-position than when it is in either of the other positions.

The electric moment characteristic of each of the groups, hydroxyl carbonyl and halogen, as shown in aliphatic compounds has been tabulated.

STUDIES ON THE POLYMETHYLBENZENES. III. THE VAPOR PRESSURES OF THE TETRAMETHYLBENZENES, AND OF PENTA- AND HEXAMETHYLBENZENE

BY F. H. MACDOUGALL WITH LEE IRVIN SMITH

RECEIVED DECEMBER 16, 1929 PUBLISHED MAY 8, 1930

No data are recorded in the literature on the vapor pressures of any of the polymethylbenzenes containing four or more methyl groups, and the work reported in this paper deals with the determination of the vapor pressure curves of five polymethylbenzenes: the three tetramethylbenzenes, penta- and hexamethylbenzene. Only the vapor pressures of the liquid hydrocarbons have been measured: the lower limit is either around room temperature, or as close to the melting point of the hydrocarbon as could be obtained with the apparatus used.

The purification of all the materials is given in a previous paper.[1] In every case except one the purest materials at hand were used, judging by the freezing point curve. The one exception is in the case of prehnitene (1,2,3,4-tetramethylbenzene), the vapor pressure sample showing a freezing point of $-6.8°$ as compared with a later sample purified through the picrate, and which showed a freezing point of $-6.4°$. However, the boiling point of this very pure sample was determined at two or three pressures and the results were found to check within the experimental error the values given by the sample freezing at $-6.8°$, so that it was not felt necessary to re-check the whole curve.

Apparatus and Procedure.—The procedure followed was to determine the boiling point under various pressures in a modified Claisen flask, arranged so that the distillate was returned to the flask. Superheating was avoided by passing a very fine stream of air through the boiling liquid, and the temperature of the outside (Wood's metal) bath was carefully regulated so that a nice even distillation resulted. The neck of the flask was made long enough so that the thermometer was completely immersed in the vapor, and was wide enough so that the thermometer did not touch the flask at any point. The thermometers used were all standardized. The pressure was read on a closed tube manometer, internal diameter about 7.5 mm., which had a range up to atmospheric, and which had been carefully checked against an accurately calibrated manometer. The accuracy of reading the manometer scale was about 0.3 mm., but since two readings were necessary in order to determine the pressure, the error in any given reading was double this, or about 0.5 mm. The pressure was varied by inserting a long tapering capillary into the line and cutting off small lengths in passing from one determination to the next.

---

[1] Smith and MacDougall, THIS JOURNAL, 51, 3001 (1929).

With a good pump having high capacity, this method permits the pressure to be changed easily and very constant readings were obtained. In every case the readings were checked: first the pressure was read, then the temperature, and after half a minute these readings were repeated in the reverse order.

Results.—The results are given in the tables and curves. Figure 1 is taken from the observed data directly, plotting alternate readings in order to simplify drawing these curves. In addition, the curves for durene and isodurene are so close together that only one of them has been drawn,

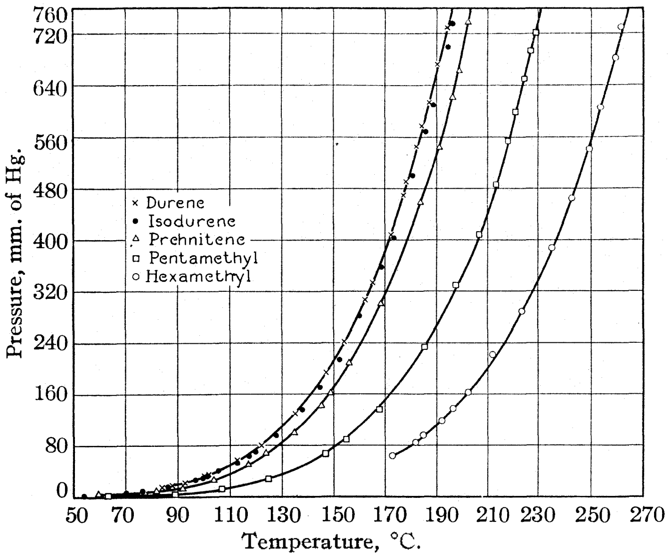

Fig. 1.—Vapor pressure curves of the polymethyl benzenes.

TABLE I

VAPOR PRESSURE EQUATIONS, $u = 1000/T$

Durene $\log_{10} P = 18.8224 - 3093/T - 3.499 \log_{10} T$

Isodurene $\log_{10} P = 5.9514 - 0.6033\, u - 0.3972\, u^2$

Prehnitene $\log_{10} P = 6.4470 - 1.0542\, u - 0.3099\, u^2$

Penta $\log_{10} P = 6.7125 - 1.323\, u - 0.309 u^2$

Hexa $\log_{10} P = 7.7760 - 2.4394\, u - 0.1009\, u^2$

TABLE II

CONSTANTS

Substance	T_{760}	L_{760}	$\frac{L_{760}}{T_{760}}$

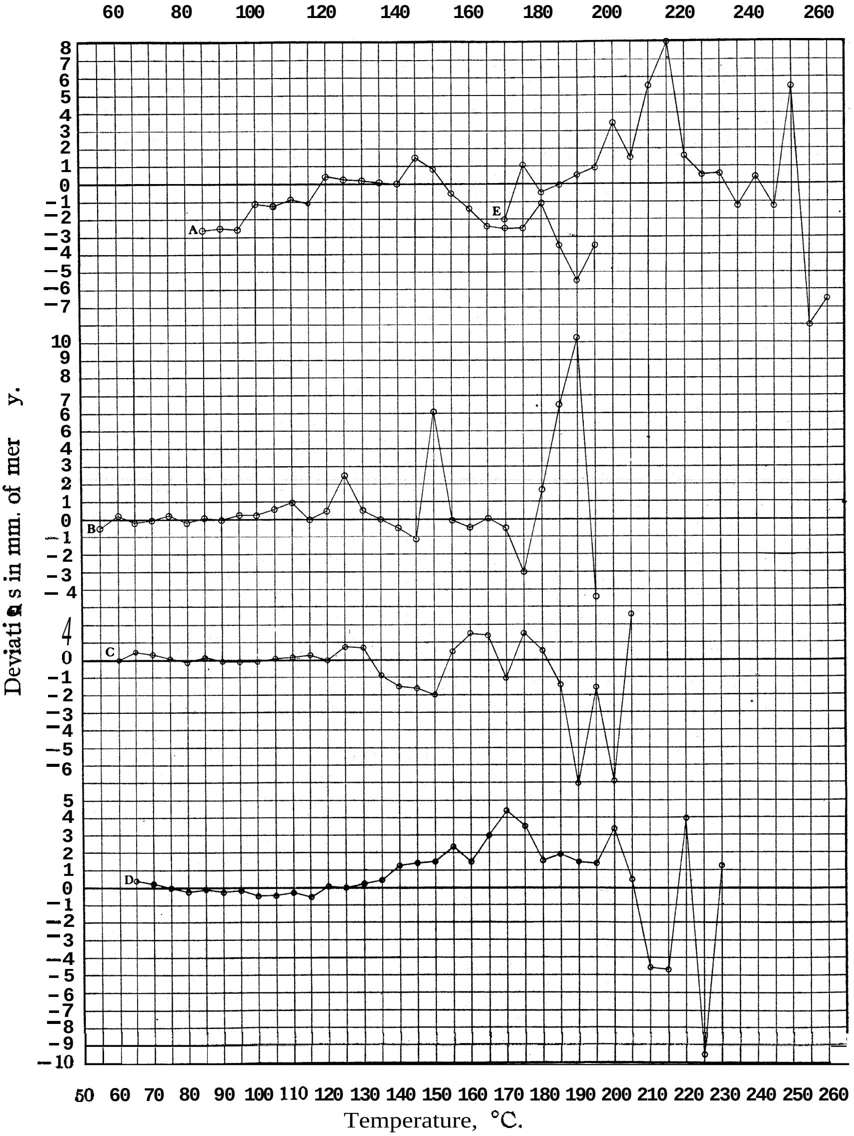
the points on the other merely being indicated. Table I gives the empirical equations for the vapor pressures. Figure 2 gives the deviations of the calculated pressures from the observed values. These deviations,



A, Durene; B, isodurene; C, prehnitene; D, pentamethylbenzene; E, hexamethylbenzene.

Fig. 2.—Deviation plots for the vapor pressures of the polymethylbenzenes. Positive deviations are to be added to the calculated to find the observed. Negative vapor pressures are to be added.

when positive, are to be added to the calculated pressures, and subtracted when negative. Table II gives the normal boiling point, the latent heats of vaporization, and L/T, or the "entropy of vaporization." All pressure readings are in mm. of mercury at 0°, and all temperatures are corrected.

Summary and Conclusions

1. The vapor pressures of all the polymethylbenzenes containing four or more methyl groups have been determined over a considerable range of temperatures, and the results are given in the form of tables and curves.
2. From these data, the latent heats of vaporization have been calculated.

RESEARCHES ON PYRIMIDINES. CXV. ALKYLATION ON NITROGEN OF THE PYRIMIDINE CYCLE BY APPLICATION OF A NEW TECHNIQUE INVOLVING MOLECULAR REARRANGEMENTS

BY GUIDO E. HILBERT[1] AND TREAT B. JOHNSON

RECEIVED DECEMBER 24, 1929 PUBLISHED MAY 8, 1930

That the *lactim* ethers I will undergo rearrangements to their isomeric and stable *lactam* configurations II has been known for a long time. These transformations are not reversible and are brought about by the application of heat or through the influence of special catalytic agents, and have been observed to take place in both the acyclic and cyclic series of organic compounds.[2]

$$N{=}C{-}OCH_3 \longrightarrow CH_3N{-}C{=}O$$

I II

The interesting data obtained by Knorr as a result of his study of molecular transformations in the pyrazolone and quinoline series suggested that corresponding changes might be brought about in pyrimidine combinations containing *lactim* ether groupings[3] Knorr showed that certain a- and γ-alkoxyquinolines interact with methyl iodide with formation of addition products IV which are unstable and break down on heating to form N-alkylquinolones V. The transformation of the ethoxyquinoline

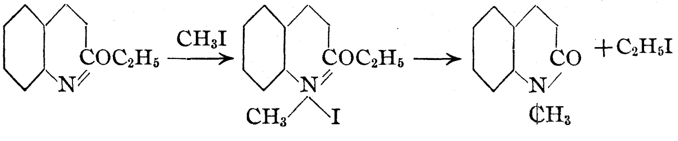
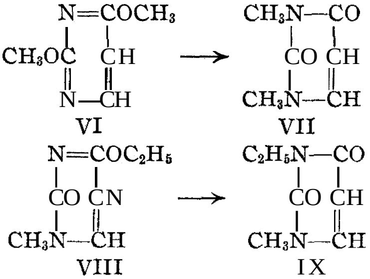
III into the corresponding N-methyl derivative (lactam construction) is expressed by the following formulas. Knorr also found that the *lactim*



III IV V

constructions 111 are rearranged by heating, forming the isomeric *lactams* in good yield.

Substituted pyrimidines of the type represented by the 2,6-dialkoxypyrimidines are analogous in constitution to the quinoline *lactim* compounds studied by Knorr. Several pyrimidine ether constructions of this type have been prepared,[4] but in no case has any tendency to undergo molecular rearrangements been observed, nor has the behavior of these compounds toward alkyl iodides been investigated. We have had occasion to investigate the properties of certain representatives of this series and we find that the 2,6-dialkoxypyrimidines and constructions like 2-oxy-3-alkyl-6-alkoxypyrimidines easily undergo rearrangement on heating to form the 1,3-dialkyluracils in excellent yields. The respective changes are expressed by the following formulas.



VI VII

VIII IX

These rearrangements open up a new technique for synthesizing N-alkylated uracils of known structure which hitherto have been very difficult to obtain in a pure condition. Thus far it has been impossible to produce a partial rearrangement by heating a 2,6-dialkoxypyrimidine leading to the formation of derivatives in which only one *lactim* grouping has been destroyed. 1,3-Dialkylpyrimidines are always the end-products of pyrolysis.

Pyrimidines representing the partially rearranged forms are obtained by the action of alkyl halides. The interaction of methyl iodide with 2,6-dimethoxypyrimidine VI at room temperature, for example, yields smoothly 2-oxy-3-methyl-6-methoxypyrimidine. In other words, the two

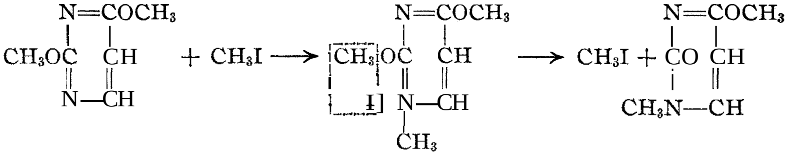
[4] Schlenker, Ber., 34, 2812 (1901); St. Augerstein, *ibid.*, 34, 3956 (1901); Buttner, *ibid.*, 36,2227 (1903); Gabriel and Colman, *ibid.*, 36, 3379 (1903); Johnson and Joyce, THIS JOURNAL, 37,215 (1915); Johnson and Moran, *ibid.*, 37,2591 (1915).

lactim configurations within the same pyrimidine molecule differ in their stability, and the nitrogen atom which is alkylated during the molecular changes is that one which is the most basic, or the nitrogen in position 3 of the pyrimidine ring. The mechanism of the reaction, which is practically quantitative, is easily explained by assuming the primary formation of an addition product with methyl iodide. This intermediate pentavalent nitrogen compound X being unstable, dissociates with the production of the 3-nitrogen derivative XI and a new alkyl halide by coupling of the *lactim* alkyl group with iodine. These changes are expressed by the formulas



VI X XI

That an intermediate addition product as expressed by formula X represents one stage of our reaction is supported by the behavior of 2,6-diethoxypyrimidine toward methyl iodide. In this case the product of the reaction was 2-oxy-3-methyl-6-ethoxypyrimidine, but we were unable to identify any substance corresponding to an addition compound. That such addition compounds, are exceedingly unstable was shown by the behavior of 2,6-dimethoxypyrimidine toward methyl iodide at ordinary temperature in quantities very much less than molecular proportions of the halide. Under these experimental conditions the dimethoxy compound was completely transformed into 2-oxy-3-methyl-6-methoxypyrimidine XI in a few days. This interesting result is direct evidence that the addition product is an unstable configuration, breaking down as soon as formed and continually regenerating the halide, thus allowing the reaction to go to completion.

In the above reactions methyl iodide was found to be much more reactive than ethyl iodide, and the use of benzene as a solvent decreased the rate of reactivity very appreciably, which is in accord with the recent work of Norris and Prentiss.[5] It is also a well-known fact that alkyl halides show a much greater tendency to add to basic nitrogen groupings than the corresponding alkyl bromides or chlorides. In the case of 2,6-diethoxypyrimidine, for every molecule of methyl iodide interacting with this compound, one molecule of ethyl iodide is liberated. However, since methyl iodide is in excess and is also the more reactive halide, the main product formed is 2-oxy-3-methyl-6-ethoxypyrimidine with the practical exclusion of 2-oxy-3-ethyl-6-ethoxypyrimidine.

The 2-oxy-3-alkyl-6-alkoxypyrimidines very easily undergo hydrolysis

---

[5] Norris and Prentiss, THIS JOURNAL, **50**, 3042 (1928).

by treatment with hydrochloric acid, yielding mono alkylated uracils quantitatively. This new reaction, which makes possible the application of a new technique for the preparation of 2,6-dioxypyrimidine compounds alkylated in position **3,** promises to assume an important biochemical significance. By application of this new procedure it should be possible to synthesize sugar derivatives of pyrimidines related structurally to the nucleosides found in nucleic acids. In fact, we have already found that the hexose derivative—bromotetra-acetylglucose—interacts smoothly with 2,6-dimethoxypyrimidine giving a crystalline compound exhibiting the properties of a true nucleoside derivative.[6] This special reaction is now under investigation and the results of our research will be reported in a future paper from this Laboratory.

Experimental Part

The Preparation of 2,6-Dialkoxypyrimidines.—The chlorine atoms occupying the 2- and 6-positions in the pyrimidine ring are very reactive and interact practically instantaneously with sodium alcoholates to give the corresponding 2,6-dialkoxypyrimidines in excellent yields.

2,6-Dimethoxypyrimidine, $\overline{\mathrm{N{=}C(OCH_3)N{=}C(OCH_3)CH{=}C}}\mathrm{H}$.—This compound has been described previously by Gabriel and Colman,[7] who prepared it by reduction of 2,6-dimethoxy-4-chloropyrimidine. They report a boiling point of 204.5–205° and a melting point at about 10°. Their method, however, is an impractical one for quantity production and we recommend the following. Forty grams of 2,6-dichloropyrimidine[8] are dissolved in 200 cc. of absolute methyl alcohol[9] and added slowly to a solution of 12.5 g. of sodium in 200 cc. of dry methyl alcohol. A vigorous reaction immediately takes place, sodium chloride precipitating and the mixture generating sufficient heat to raise the temperature of the solution to its boiling point. The reaction is complete within a few minutes. After filtering off the sodium chloride, the excess of alcohol is then expelled by distillation under reduced pressure and the residual oil treated with 100 cc. of 30% sodium hydroxide solution. The dimethoxypyrimidine separates as the upper layer and is extracted by ether, dried over sodium sulfate and finally purified by distillation. Our product distilled as a colorless oil boiling at 202°, and solidified on cooling. The compound melts at 17.5° and the yield is 35 g. or 93% of the theoretical.

Anal. Calcd. for $C_6H_8O_2N_2$: N, 20.00. Found: N, 19.72, 19.85.

2,6,-Diethoxypyrimidine, $\overline{\mathrm{N{=}C(OC_2H_5)N{=}C(OC_2H_5)CH{=}C}}\mathrm{H}$.—The procedure for obtaining this pyrimidine was similar to that described above. It was produced as a colorless oil boiling at 224–225° and melting at 19–20'. The yield was 85% of the theoretical.

Anal. Calcd. for $C_8H_{12}O_2N_2$: N, 16.67; H, 7.14; C, 57.14. Found: N, 16.27, 16.67; H, 7.21; C, 56.92.

---

[6] Johnson and Hilbert, *Science,* 69, 579 (1929).

[7] Gabriel and Colman, *Ber.,* 36, 3379 (1903).

[8] Hilbert and Johnson, THIS JOURNAL, 52,1152 (1930).

[9] On dissolving 2,6-dichloropyrimidine in methyl alcohol heat should not be applied as this initiates a reaction with replacement of halogen and formation of the dialkoxypyrimidine. The latter compound undergoes hydrolysis in the presence of the generated hydrochloric acid and is changed immediately into uracil.

Rearrangement of Alkoxypyrimidines

Rearrangement of **2,6-Dimethoxypyrimidine** to **1,3-Dimethyluracil.**—Four and one-half grams of the dimethoxypyrimidine is heated in an oil-bath at 220–240° for four hours. At first there is vigorous ebullition which gradually subsides and finally ceases as the proportion of rearranged compound increases. On cooling, the pale brown reaction product completely solidified. This was purified by dissolving in a mixture of alcohol and ether and allowing to cool after decolorization with norite. The yield of rearranged pyrimidine was 4 g. and it crystallized in colorless prisms melting at 123–124". A mixture of this substance with a sample of 1,3-dimethyluracil prepared by a known method[10] melted at the same temperature.

Rearrangement of 2-Oxy-3-methyl-6-methoxypyrimidine to **1,3-Dimethyluracil.**—This change is accomplished by heating under the same conditions that were employed for the molecular rearrangement of 2,6-dimethoxypyrimidine to dimethyluracil. The purified 1,3-dimethyluracil melted at 123–124° and the yield was excellent.

Rearrangement of 2-Oxy-3-methyl-6-ethoxypyrimidine to I-Ethyl-3-methyluracil, $CH_3N—CO—N(C_2H_5)COCH=CH$.—After heating 5 g. of the above ethoxypyrimidine in an oil-bath at 250" for eight hours, the resulting dark brown reaction product was extracted with ether, dried and purified by distillation under diminished pressure. The rearranged pyrimidine was obtained as a colorless oil boiling at 140–141° at 4 mm. which solidified on cooling. It melted at 60–61°. The yield was 4 g. This pyrimidine is very soluble in water, alcohol and ether and sparingly soluble in ligroin. It gives a negative Wheeler and Johnson color test.[11]

Anal. Calcd. for $C_7H_{10}O_2N_2$: N, 18.18; H, 6.49; C, 54.55. Found: N, 18.26, 18.43; H, 6.67; C, 54.64.

The Action of Alkyl Iodides on Alkoxypyrimidines from Uracil

2-Oxy-3-methyl-6-methoxypyrimidine, $CH_3NCON=C(OCH_3)CH=CH$.—Five grams of 2,6-dimethoxypyrimidine was mixed with 10 g. of freshly distilled methyl iodide and the solution allowed to stand at room temperature.[12] Within two to three hours large colorless crystals started to deposit in the solution, and in twelve hours the reaction was complete. The reaction product was separated by filtration and washed with ether. It was purified by recrystallization from warm alcohol and separated, on cooling, in the form of colorless prisms which melted at 149–150°. The yield of rearranged pyrimidine was quantitative. The compound is very soluble in alcohol and water and insoluble in benzene and ether.

Anal. Calcd. for $C_6H_8O_2N_2$: N, 20.00; H, 5.71; C, 51.43. Found: N, 19.98, 20.13; H, 5.82; C, 51.40.

The structure of this compound was established by its behavior on hydrolysis. When dissolved in dilute hydrochloric acid and the solution evaporated on a steam-bath it was converted quantitatively into 3-methyluracil melting at 237–238°.[13]

Anal. Calcd. for $C_5H_6O_2N_2$: N, 22.22. Found: N, 22.21, 22.19.

An experiment was carried out using the same quantities of 2,6-dimethoxypyrimidine and methyl iodide as given above. The solution, however, was diluted with

[11] Wheeler and Johnson, *J. Biol. Chem.*, 3,183 (1907).

[12] It is preferable to carry out this reaction in the dark and thereby reduce to a minimum the quantity of colored products formed during the reaction.

[13] Wheeler and Johnson, *Am.* Chem. J., 42, 30 (1909).

benzene. The effect of this was to decrease the rate of reaction enormously. as the rearrangement required several weeks to go to completion. The reaction was furthermore highly colored.

In a second experiment 5 g. of 2,6-dimethoxypyrimidine was mixed with two droplets of methyl iodide and the solution sealed in a tube. In two days the rearrangement was complete, giving a quantitative yield of 2-oxy-3-methyl-6-methoxypyrimidine. If two drops of ethyl iodide are substituted for the methyl iodide, similar results are obtained except that in this case the reaction requires several weeks for completion.

2-Oxy-3-Methyl-6-Ethoxypyrimidine, $CH_3\overline{NCON{=}C(OC_2H_5)CH{=}CH}$.—Five grams of 2,6-diethoxypyrimidine dissolved in 10 g. of methyl iodide was converted completely at room temperature and within ten hours into the above pyrimidine. It was purified by recrystallization from a mixture of alcohol and ether and separated as colorless plates melting at 136°. This pyrimidine is very soluble in alcohol and water and insoluble in ether. The yield was excellent and no trace of a pyrimidine containing an ethyl group substituted on nitrogen of the pyrimidine cycle was detected.

Anal. Calcd. for $C_7H_{10}O_2N_2$: N, 18.18; C, 54.5; H, 6.49. Found: N, 18.33, 18.20; C, 54.68; H, 6.33.

When this compound was warmed in hydrochloric acid solution it was converted quantitatively into 3-methyluracil.

1,3-Diethyluracil, $C_2H_5\overline{NCON(C_2H_5)COCH{=}CH}$.—This was formed by refluxing 2,6-diethoxypyrimidine (5 g) with ethyl iodide (10 g.) for one week. The excess of the iodide was then removed with a blast of air and the residue distilled under diminished pressure. It boiled at 135° at 4 mm. and the yield of pyrimidine was 4 g. 1,3-Diethyluracil is a colorless, odorless oil which solidifies on cooling and melts at 14–15°. It gives a negative Wheeler and Johnson color test.[11]

Anal. Calcd. for $C_8H_{12}O_2N_2$: N, 16.67; C, 57.14; H, 7.14. Found: N, 16.27, 16.67; C. 56.86; H, 7.48.

This rearrangement to diethyluracil is also brought about by heating the 2,6-diethoxypyrimidine in a bomb tube at 260" for twenty-four hours. The product of the reaction was a dark brown viscous oil. This was dissolved in ether, dried over sodium sulfate and purified by distillation. The yield was 4 g. of a colorless oil boiling at 290–295°.

Anal. Calcd. for $C_8H_{12}O_2N_2$: N, 16.67. Found: N, 16.55, 16.33.

1,3-Diethyluracil has not been described previously in the literature and as we wished to compare the properties of our new compound with a sample prepared by a different method, an alkaline solution of uracil was alkylated by interaction with diethyl sulfate according to the technique employed by Davidson and Baudisch[10] for the preparation of 1,3-dimethyluracil. Twenty grams of uracil and 17 g. of sodium hydroxide were dissolved in 100 cc. of water, warmed to 30° and 45 cc. of diethyl sulfate was added slowly with constant agitation. The reaction mixture, after standing for one hour, was finally heated to boiling and then cooled. This solution was then repeatedly extracted with chloroform to remove 1,3-diethyluracil. This was purified by distillation as described above and agreed in all its properties with the pyrimidine obtained by rearrangement of the 2,6-diethoxypyrimidine. The yield was 10 g.

1,3-Diethyl-5-bromo-uracil, $C_2H_5\overline{NCON(C_2H_5)COCBr{=}CH}$.—This is formed by dissolving the 1,3-diethyluracil in absolute alcohol and then adding to the solution the required amount of bromine. The alcohol was evaporated on a steam-bath and the bromopyrimidine left behind purified by crystallization from water. It separated in prisms melting at 80–81°. Depending on the conditions of crystallization it sometimes separates as colorless needles and at other times as colorless rhombic blocks. In one experiment a modification was obtained which melted at 71°; after resolidifying the melting point rose to 80–81°.

Anal. Calcd. for $C_8H_{11}O_2N_2Br$: N, 11.34. Found: N, 11.45, 11.38.

Summary

1. 2,6-Dialkoxypyrimidines are formed smoothly by interaction of 2,6-dichloropyrimidine with sodium alcoholates.

2. The 2,6-dialkoxypyrimidines and the 2-oxy-3-alkyl-6-alkoxypyrimidines rearrange on heating to form 1,3-dialkyluracils. This method of operating makes possible the synthesis of uracil derivatives which hitherto have not been available for the development of pyrimidine chemistry.

3. A new method for the alkylation of pyrimidines of the uracil type in position **3** has been developed.

4. This new reaction will be applied for the synthesis of hexose and pentose derivatives of pyrimidines. It is possible that some of these sugar derivatives will be found to be identical with the naturally occurring nucleosides. This same technique will also be applied in the purine series.

PIPERIDINE DERIVATIVES. IX. METHYLPIPERIDINO-ALKYL CINNAMATES

BY C. F. BAILEY AND S. M. MCELVAIN

RECEIVED DECEMBER 26, 1929 PUBLISHED MAY 8, 1930

It has been pointed out in two previous communications[1] from this Laboratory, that those piperidino-alkyl benzoates containing a methyl group as a substituent in the piperidine nucleus were much more effective as local anesthetics than the corresponding compounds in which the piperidine nucleus was unsubstituted or was substituted by certain other aliphatic groups. In two very interesting papers concerned with the correlation of aromatic properties with physiological action, Gilman and co-workers[2] have shown that in the amino-alkyl ester type of anesthetic a distinct local anesthetic effect is found associated with those structures in which the carbonyl group of the ester is attached to an unsaturated carbon atom. Of all such types of compounds that have been investigated, the cinnamates are by far the most effective. Apothesine, γ-diethylaminopropyl cinnamate, is a well-known example of this type of ester.

Since the methylpiperidino-alkyl nucleus has been found to be so efficient

[1] McElvain, THIS JOURNAL, **49**, 2835 (1927); Bailey and McElvain, *ibid.*, **52**, 1633 (1930).

[2] Gilman and co-workers, *ibid.*, **47**, 245 (1925); *ibid.*, **50**, 437 (1928).

in the benzoate series, it seemed desirable to prepare and submit for pharmacological study an analogous series of cinnamates. This paper gives the preparation, properties and a brief statement of the pharmacological action of the following six compounds: 2-methyl-, 3-methyl- and 4-methylpiperidino-ethyl and propyl cinnamates.

These substances were prepared by the condensation of the methylpiperidines'with β-chloro-ethyl cinnamate and y-chloropropyl cinnamate. The tertiary amino esters so obtained were isolated and used in the form of their hydrochlorides.

Experimental

Methylpiperidines.—The 2-methyl-, 3-methyl- and 4-methylpiperidines that were used were obtained from ***a*-**, β- and γ-picolines, respectively, by methods previously described.'

β-Chloro-ethyl Cinnamate.—This ester has previously been prepared[3] by the action of ethylene chlorohydrin on cinnamic acid in the presence of sulfuric acid. This procedure was not tried in this work since the following method gave very satisfactory results. To 111 g. of cinnamic acid in a 1-liter flask fitted with a reflux condenser, 179 g. of thionyl chloride was slowly added from a dropping funnel. The evolution of sulfur dioxide and hydrogen chloride began almost immediately. After all of the thionyl chloride had been added the mixture was heated on a steam-bath for two hours. The excess thionyl chloride was then removed by distillation. To the remaining material 61 g. of ethylene chlorohydrin was slowly added and the resulting solution heated for two hours at 180° in an oil-bath. The reaction mixture was then allowed to cool, poured into water and the immisciblelayer taken up in ether. After drying over calcium chloride the ether was removed and the remaining ester distilled under diminished pressure. There was obtained 126 g. (80% of the theoretical) of β-chloro-ethyl cinnamate which boiled at 162–163° (3 mm.). On distillation the ester crystallized in the receiver. Its melting point was found to be 35–37°. (The literature reference to this compound states that the melting point is 31°.)

Anal. (Stepanoff). Calcd. for $C_{11}H_{11}O_2Cl$: Cl, 16.86. Found: 17.03, 17.12.

γ-Chloropropyl Cinnamate.—This ester does not appear to have been described in the literature. It was prepared according to the procedure described above for β-chloro-ethyl cinnamate except that an equivalent amount of trimethylene chlorohydrin was used instead of ethylene chlorohydrin. The yield was 75% of the theoretical. The γ-chloropropyl cinnamate boiled at 174–177° (3 mm.); d_{20}^{20} 1.1512; n_D^{25} 1.5677. This ester is a liquid at ordinary temperatures.

Anal. (Stepanoff). Calcd. for $C_{12}H_{13}O_2Cl$: Cl, 15.81. Found: Cl, 15.83, 15.82.

Methylpiperidino-alkyl **Cinnamates.**—These compounds were prepared by the general procedure that was used[1] for the corresponding benzoates. There was, however, a distinct difference between the chloro-alkyl cinnamates and the chloro-alkyl benzoates in the ease with which they condensed with 2-methylpiperidine. It had been noted that the benzoates did not condense with 2-methylpiperidine to any appreciable extent under the conditions (100° for one hour) which caused quite complete condensation with 3- and 4-methylpiperidine. In the case of the chloro-alkyl cinnamates a temperature of 100" for one hour caused quite complete condensation with each of the methylpiperidines. These cinnamates were isolated as the hydrochlorides and recrys-

[a] The melting point of a mixture of No. 2 and No. 6 was 168–172°.

Pharmacological Report

These compounds are being studied pharmacologically by Mr. Charles L. Rose of the Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana. A preliminary report of their pharmacological properties is given in Table II. The anesthetic effect was determined by an application of a 2% solution of the anesthetic to the rabbit's cornea and noting the duration of anesthesia. Toxicities were determined by subcutaneous injection into white mice and intravenous injection into white rats. The various compounds are designated in Table II by the numbers associated with them in Table I. The analogous values for the corresponding benzoates are given in parentheses along with the cinnamate values.

TABLE II

PHARMACOLOGICAL DATA

Compound	Av. duration of anesthesia, min.	Subcutaneous toxicity to white mice, mg./kg. M.T.D.	M.L.D.	No. of mice used	Intravenous toxicity to white rats, mg./kg. M.T.D.	M.L.D.	No. of rats used
1	11 (0)	1100 (1500)	1200 (2000)	14	25 (25)	30 (30)	9
2	14 (15)	200 (800)	250 (900)	10	4 (15)	5 (17.5)	15
3	10 (0)	1700 (3000)	1800 (3500)	30	35 (25)	40 (30)	11
4	11 (11)	500 (450)	600 (500)	13	35 (20)	40 (25)	8
5	13 (11)	.. (1300)	..[a] (1400)	..	20 (40)	25 (42.5)	8
6	21 (14)	500 (....)[a]	600 (....)[a]	..	12.5 (20)	15 (22.5)	8

[a] Not determined because of scarcity of material.

Discussion of the Pharmacological Data

It is seen from the above data that, in general, the methylpiperidino-alkyl cinnamates are more active physiologically than the corresponding benzoates. This greater activity is particularly noticeable in the case of the ethyl esters, for 1 and 3 show quite marked anesthetic effect on the rabbit's cornea while the corresponding benzoates are without any such effect. The 4-methylpiperidino derivatives seem appreciably more active than the isomeric 3-methyl- and 2-methylpiperidino derivatives. With the exception of γ-3-methylpiperidinopropyl cinnamate, the toxicities of the members of the cinnamate series are, in general, greater than those of the benzoates.

Summary

1. The methylpiperidino-ethyl and propyl cinnamates have been prepared and described.

2. A comparison of their pharmacological properties with those of the corresponding benzoates is given.

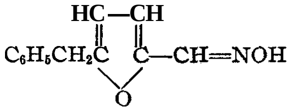
ATTEMPTED CORRELATIONS OF CONSTITUTION WITH SWEET TASTE IN THE FURAN SERIES. THE VERY HIGH SWEETENING POWER OF 5-BENZYL-2-FURFURALDOXIME

BY HENRY GILMAN AND J. B. DICKEY

RECEIVED DECEMBER 30, 1929 PUBLISHED MAY 8, 1930

Introduction

In extension of studies[1] concerned with some correlations of constitution with sweet taste in the furan series we have come upon a compound which is sweeter than saccharin. The compound is *syn*-5-benzyl-2-furfuraldoxime



and it was found to be 690 times sweeter than sugar. The anti-form of this oxime is about 100 times sweeter than sugar.

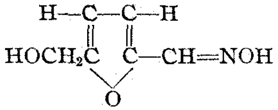
These two isomers were prepared earlier by Fenton and Robinson,[2] but apparently they overlooked the sweet taste of the compounds.

It is interesting to note that both the *syn*- and the anti-oximes of 5-hydroxymethyl-3-furfural

---

[1] (a) Gilman and Hewlett, *Iowa State Coll. J. of Sci.*, 3, 27 (1929). This article contains leading references to pertinent papers and standard texts. We omitted in that paper reference to (b) Asahina and Fujita, *J. Pharm. Soc. Japan*, 490, 1084 (1922); [*C. A.*, 17, 2578 (1923)].

[2] Fenton and Robinson, *J. Chem. Soc.*, 95, 1334 (1909).



are without sweet taste. This would hardly have been predicted. However, despite an increasing literature on taste and constitution, too little is known about the subject to warrant broad and inflexible generalizations. This is particularly true in connection with the interesting and important biological relationships of isomers, especially geometrical and optical isomers. For example, the anti-oxime of perilla aldehyde is the sweetest compound so far described, and its syn-form is without a sweet taste; the two oximes of furfural[1] appear to be equally sweet; the *syn*-oxime of furylacetaldehyde is one-half as sweet as its *anti*-isomer;[3] and our syn-oxime of 2-benzyl-furfural is about seven times sweeter than its anti-form. Of course, there is always the possibility that what is called the syn-form of some geometrical isomers may in reality be the trans form and vice *versa.*

Experimental Part

5-Chloromethyl-2-furfural, $ClCH_2(C_4H_2O)CHO$.—The 5-chloromethyl-2-furfural was prepared in accordance with the directions of Fischer and Neyman[4] from cane sugar and concd. hydrochloric acid. To prevent the emulsion described by them, the solution, after the addition of sodium carbonate, was filtered and the solid removed in this manner was washed with water to recover any chloromethyl furfural. The average yield of a number of preparations starting with 200 g. of sugar was 11.2%, and the maximum yield was 17%. The range of yield reported by Fischer and Neyman[4] was 22–25%, and the yield obtained by Middendorp[5] was 11% from one kilogram of sugar. All calculations are based on the weight of the sugar taken.

5-Hydroxymethyl-2-furfural, $HOCH_2(C_4H_2O)CHO$—Twenty-one grams (0.145 mole) of crude chloromethyl-furfural was poured into 750 cc. of boiling water and boiled for fifteen minutes. The yellowish solution containing some tar was cooled and then extracted 15 times with a total of one liter of ether until the solution was essentially colorless. The aqueous solution was salted out by saturating with hydrated sodium sulfate. The ether extract was then dried over anhydrous sodium sulfate. The yield was 45% in one experiment and 66.6% in another where the number of ether extractions was increased to 25.[6]

The two oximes of 5-hydroxymethyl-2-furfural were prepared in the manner described by Kiermayer.[7] A 62.5% yield of pure oxime was obtained from 10 g. of the crude aldehyde.

---

[3] Ref. 1b. It is interesting to know, apart from furan types, that Goldschmidt, Ber., 23, 2163 (1890), reported anti-anisaldoxime as being intensely sweet, whereas the syn-form is tasteless. There is a like difference with the *p*-nitrobenzaldoximes [see Cohn, "Die Organischen Geschmacksstoffe," Berlin, **1914**].

[4] Fischer and Neyman, Ber., 47, 974 (1914).

[5] Middendorp, *Rec.* trav. *chim.*, 38, 1 (1919).

[6] When the hydrolysis was effected in boiling water containing powdered barium carbonate [Cooper and Nuttall, J. Chem. *Soc.*, 99, 1193 (1911)] there appeared to be more decomposition and the yield was 30%.

[7] Kiermayer, *Chem.-Ztg.*, 19, 1003 (1895).

5-Benzyl-2-furfuraldoxime, $C_6H_5CH_2(C_4H_2O)CH{=}NOH$.—5-Benzyl-2-furfural was prepared by the reaction of chloromethyl-furfural, benzene and aluminum chloride.[2] In addition to the two oximes which were prepared by a standard procedure,[2] we also prepared the known phenylhydrazone[2] in order further to identify our aldehyde.

Relative Sweetening Powers.—The method of evaluating the sweetness of the several oximes was that described earlier by Gilman and Hewlett.[1] The tests were carried out by a number of people.[8] By a method of cross-checking used previously by Gilman and Hewlett,[1] the currently accepted values for saccharin[9] and dulcin were first checked within the experimental error for such studies. The solutions of the sparingly soluble syn- and anti-benzyl-furfuraldoximes were made up by dissolving 0.02 and 0.04 g., respectively, of each of the oximes in 819 cc. of distilled water. The standard sugar solution (of 1.8% concentration by weight) was prepared from 0.0892 g. of sugar in 5 g. of water. The saccharin and dulcin solutions were of the same concentration as the *syn*-benzyl-furfuraldoxime.

It was found that the syn-isomer is about 690 times sweeter than sugar, and the anti-isomer about 100 times sweeter than sugar. By direct comparison it was found that the syn-isomer is slightly sweeter than saccharin. Aqueous alcoholic solutions of the oximes are decidedly sweet.

It is interesting to note that with both isomers there is an apparent lag or induction period before the sweet taste becomes apparent. This time interval between no taste and a sweet taste is very short but distinct. Once the sweet taste becomes apparent it rapidly increases to a maximum. Later the sweet taste is replaced by a pungent taste. At their respective maxima the sweet taste of the anti-form is less pleasant than that of the syn-form.

Studies are in progress on the introduction of water solubilizing groups with the hope of retaining the sweetening characteristics of the benzyl-furfuraldoximes.

The 5-hydroxymethyl-2-furfuraldoximes were devoid of sweet taste.[10]

Summary

It has been found that syn-5-benzyl-2-furfuraldoxime is sweeter than saccharin and that it is also about seven times sweeter than its *anti*-

THE STEROLS OF ERGOT

BY MERRILL C. HART AND FREDERICK W. HEYL

RECEIVED DECEMBER 30, 1929 PUBLISHED MAY 8, 1930

In recent years considerable literature has developed about the chemistry of the ergosterol of yeast and its accompanying sterols, though but one paper[1] on the chemistry of the ergosterol of ergot since the original work by Tanret[2] has come to our attention. In this paper Rosenheim and Webster report on the irradiation of a "fungisterol" which, however, differs widely from that described by Tanret, and at the same time differs from any of the sterols accompanying the ergosterol of yeast as described by Wieland and Asano.[3]

Having at hand a considerable quantity of the ergosterol from ergot, it seemed desirable to us (1) to repeat and confirm if possible Tanret's isolation of fungisterol, and (2) to prepare a number of derivatives of our ergosterol, some previously described and some new, with a view to establishing more rigorously, or to disestablish, the complete chemical identity of the sterol from the two sources. That differences might be expected is indicated by the experience of Heilbron, Sexton and Spring,[4] who found two different specimens of ergosterol from yeast which behaved quite differently upon hydrogenation. In this paper we present our work on the fractionation of the ergot sterols; we hope in subsequent papers to report on a number of derivatives of the ergosterol of ergot.

Experimental

Preparation of **Ergosterol.**—Spanish ergot was exhaustively extracted with benzene and, after recovery of the solvent, the residue boiled with an excess of 20% alcoholic potassium hydroxide. The unsaponifiable fraction was removed in the usual way, and crude ergosterol precipitated by the addition of petroleum ether (b. p. 60–80°) to the concentrated ether extract. The yield of this crude averaged 0.13% of the ergot used. When twice crystallized from ethyl alcohol, plates melting at 152–157° were obtained. Filtration of a chloroform solution of this material removed a small amount of amorphous substance and subsequent crystallization of the soluble portion raised the melting point to 160–162°. Acetylation, crystallization of the acetate from acetic acid, ethyl and methyl alcohols, and subsequent hydrolysis, failed to raise this. $[\alpha]_D$ varied from -112.2 to $-100°$ in various runs, with the yield averaging about 60% of the crude.

---

[1] Rosenheim and Webster, *Biochem. J.*, 22, 1426 (1928).

[2] Tanret, *Compt. rend.*, **108**, 98 (1889); *ibid.*, **147**, 75 (1908).

[3] Wieland and Asano, *Ann.*, **473**, 300 (1929).

[4] Heilbron, Sexton and Spring, *J. Chem. Soc.*, 926 (1929).

Crystallization from the alcohol–benzene mixture of Bills and Honeywell[5] gave in poor yield a product melting at 163–164.5° and having $[\alpha]_D$ of −123°, which is the closest we have been able to approach Tanret's values (m. p. 165°, $[\alpha]_D$ −132") by these methods. Acetylation and hydrolysis of this preparation only served to lower the melting point to 160–162° and $[\alpha]_D$ to −112°.

Separation of Fungisterol.—The combined filtrates from the purification of about 250 g. of crude ergosterol were concentrated and fractionated from ethyl acetate. A large top fraction with $[\alpha]_D$ of −64° was discarded, and the rest refractionated twice with the results shown in Table I.

TABLE I

SEPARATION OF THE FUNGISTEROL FRACTION

Fraction no.	Weight, g.	$[\alpha]_D$	M. p., °C.
1	0.3	−20.8	130–140
2	.2	−19.1	130–135
3	.2	−20.8	125–130
4	.2	−20.8	130–132
5	.2	−2.6	116–120
6	..	....	Sirup

Each of the first four fractions when recrystallized from ethyl alcohol gave a small amount of fungisterol melting at 144–146°, which yielded an acetate melting at 156–157°. Tanret gives 144° for the sterol and 158.5" for the acetate. There was not enough material to establish the elementary analysis, but it probably contains at least two more hydrogen atoms than ergosterol, since it no longer gives the Rosenheim[6] color test with trichloro-acetic acid, which is regarded as specific for the $\Delta^{1,2}$ (or $\Delta^{1,13}$) linkage in sterols. The Liebermann–Burchard test was positive, showing that fungisterol is not completely saturated. The Salkowski reaction gave in the acid layer a yellow color which reddened with extreme slowness.

Isolation of a Third Sterol.—It was evident from Table I that there was also present a third compound of even lower rotatory power than fungisterol. Fraction 5 was acetylated, yielding an acetate melting at 121–124°. Several recrystallizations from acetic anhydride and from ethyl alcohol raised this to 122–125°.

Anal. Calcd. for $C_{27}H_{45}OCOCH_3$: CH_3CO, 10.0. Found: CH_3CO, 10.0.

The sterol recovered from this hydrolysis crystallized from alcohol in plates melting at 120–125°.

Anal. Calcd. for $C_{27}H_{46}O$: C, 83.85; H, 12.01. Found: C, 83.46; H, 11.55.

The Rosenheim color test was negative; the Liebermann–Burchard test positive; the Salkowski test gave a yellow color in the acid layer, which slowly changed to orange.

The petroleum ether filtrates from the separation of the crude ergosterol deposited on long standing considerable further crystalline material which is a mixture of the three ergot sterols. It is being worked up at present to prepare larger quantities of fungisterol and the third sterol.

Summary

1. The association of fungisterol (m. p. 144–146°, $[\alpha]_D$ −20°, acetate, m. p. 156–157°) with the ergosterol of ergot, as described by Tanret, is confirmed.

---

[5] Bills and Honeywell, *J. Biol. Chem.*, *80*, 15 (1928).

[6] Rosenheim, *Biochem. J.*, 23, 47 (1929).

2. The presence of a third sterol (m. p. 120–125°, $[\alpha]_D$ −2°, acetate, m. p. 121–124°) is established.

SOME NEW ESTERS OF ERGOSTEROL

BY HAROLD EMERSON AND FREDERICK W. HEYL

RECEIVED DECEMBER 30, 1929 PUBLISHED MAY 8, 1930

In continuation of our study of the sterols of ergot, we have prepared several new esters of ergosterol with acid derivatives which have frequently been used to characterize alcohols, namely, phthalic anhydride, phenyl isocyanate, and chloro-acetyl *o*- and *p*-nitrobenzoyl chlorides. Since it was found that the action of the acid chlorides in the absence of an agent to absorb the hydrogen chloride evolved yielded derivatives of isoergosterol, it was necessary to work in pyridine solution.

Experimental

Ergosteryl **Acid Phthalate.**—Ergosterol (2 g.) was refluxed with phthalic anhydride (3 g.) in 5 cc. of pyridine. The resulting product appeared in the form of prisms melting at 169° after several recrystallizations from alcohol; $[\alpha]_D$ was −51°.

Anal. Calcd. for $C_{35}H_{46}O_4$: C, 79.2; H, 8.7; mol. wt., 530. Found: C, 79.1; H, 8.9; mol. wt., 532 (by titration).

Upon hydrolysis with alcoholic potassium hydroxide, this gave ergosterol identical with the starting material.

The silver salt was made by adding a slight excess of an alcoholic solution of silver nitrate to the portion neutralized in titrating for the molecular weight. It separated as white crystals melting with decomposition at 170–180°, and blackening upon standing.

Anal. Calcd. for $C_{35}H_{45}O_4Ag$: Ag, 16.9. Found: Ag, 17.1.

The copper salt was prepared from cupric acetate in an analogous manner and separated as a green amorphous precipitate.

Anal. Calcd for $(C_{35}H_{45}O_4)_2Cu$: Cu, 7.06. Found: Cu, 7.17.

Ergosteryl **Phenylurethan.**—Ergosterol (1.6 g.) was refluxed with 5 cc. of phenylisocyanate and 25 cc. of benzene for three hours. The solvent and excess reagent were removed by distillation at 15 mm. and the residue was recrystallized by dissolving in hot benzene and adding alcohol to incipient precipitation. It crystallizes in short hard needles melting at 236.5–238° (corr.).

Ergosteryl m-Nitrobenzoate was prepared by refluxing 1 g. of ergosterol with 0.6 g. of *m*-nitrobenzoyl chloride in 5 cc. of pyridine for one hour. The reaction mixture was poured into hot alcohol and allowed to crystallize. It was purified by recrystallization from alcohol, forming tiny plates melting at 151°; $[\alpha]_D$ was −71°.

Ergosteryl **_p_-Nitrobenzoate** was made in a similar manner. It formed clusters of plates melting at 182°; $[\alpha]_D$ was −49.5°. Both this and the meta compound yielded ergosterol upon hydrolysis.

The m- and *p*-nitrobenzoates of isoergosterol were formed by melting together ergosterol and the corresponding acid chloride either in toluene or without a solvent. Upon crystallization from alcohol they melted at 172° (m-) and 189° (*p*-), respectively, and were both optically inactive.

Anal. Calcd. for $C_{34}H_{45}O_4N$: C, **76.8;** H, **8.5.** Found: (meta) C, **76.6;** H, **8.9;** (para) C, **76.5;** H, 8.9.

When hydrolyzed, both yielded isoergosterol, as plates melting at 137° with $[\alpha]_D$ of -32.6". Bills and Cox[1] give m. p. 140°, $[\alpha]_D$ $(= [\alpha]_{5461} \div 1.27) = -31.2°$ for isoergosterol made by treatment with cinnamoyl chloride.

Chloro-acetyl Derivatives.—An attempt was made to prepare ergosteryl chloro-acetate by warming ergosterol with the acid chloride in pyridine, but this resulted in a halogen-free compound, due to a further condensing effect of the pyridine. The nature of this reaction will be reported in a later paper.

Isoergosteryl chloro-acetate was readily obtained by warming **1.7** g. of ergosterol with **2** cc. of chloro-acetyl chloride on a steam-bath for three minutes. Crystallized from acetic acid and from ether it gave **1.2** g. of plates melting at 190°; $[\alpha]_D$ was $-45°$.

Anal. Calcd. for $C_{29}H_{43}O_2Cl$: Cl, **7.7.** Found: Cl, **8.0.**

Hydrolysis gave the same isoergosterol described above

Summary

Ergosteryl acid phthalate and its silver and copper salts, ergosteryl phenylurethan and *m*- and *p*-nitrobenzoates have been prepared from the ergosterol of ergot, as well as the *m*- and *p*-nitrobenzoates and chloro-acetate of isoergosterol.

ALPHA-ERGOSTENOL AND ITS ISOMERIZATION TO BETA-ERGOSTENOL

BY MERRILL C. HART, JOHN H. SPEER AND FREDERICK W. HEYL

RECEIVED DECEMBER 30, 1929 PUBLISHED MAY 8, 1930

Since ergosterol itself and its esters, containing as they do three double bonds, are decidedly unstable and acquire a distinct yellow color on standing even in a black vacuum desiccator, we decided to continue our investigation of the ergosterol from ergot by studying its very stable tetrahydro derivatives, a- and β-ergostenol. α-Ergostenol was first prepared by Reindel and co-workers[1] from yeast ergosterol by catalytically reducing the acetate and hydrolyzing the product obtained thereby. The same compound has later been prepared by other authors with variations of the catalyst and solvents used. α-Ergostenol as we have prepared it from ergot ergosterol differs slightly in physical constants from Reindel's values, and did not react at all to his method of isomerization to the β-form (passing dry hydrogen chloride gas into a chloroform solution of a-ergostenol acetate). The statement of Reindel, Walter and Rauch that "the chloro-acetyl derivative of a-ergostenol cannot be made by chloro-acetyl chloride, since thereby isomerization to β-ergostenol chloro-acetate takes place"

[1] Bills and Cox, J. *Biol. Chem.*, **84,455 (1929).**

[1] Reindel, Walter and Rauch, ***Ann.*, 452, 34 (1927);** Reindel and Walter, *ibid.*, **460, 212 (1928).**

led us to attempt the preparation of β-ergostenol acetate by esterification with acetyl chloride, instead of the anhydride which is normally used to form acetates without danger of isomerization. The fact that this yielded an acetate identical in every respect with genuine α-ergostenol acetate made it seem of interest to investigate the effect of a number of acid chlorides in causing this isomerization.

Experimental

Preparation of α-Ergostenol.—Three grams of ergosterol acetate (m. p. 170–172°, $[\alpha]_D$ −74.5°) was shaken with 0.3 g. of Adams[2] platinum oxide catalyst and 300 cc. of glacial acetic acid with 2 atmospheres of hydrogen at room temperature. The acetate rapidly dissolved, and the absorption of two mols of hydrogen was complete in about fifteen minutes Continued shaking and fresh catalyst did not cause any further absorption. After filtration from the catalyst and concentration of the solution, α-ergostenol acetate separated as plates melting at 110–111^e which were optically inactive. Reindel and co-workers give $[\alpha]_D$ +5.18°; yield, almost quantitative.

Sixty grams of this material was systematically fractionally crystallized from acetic acid five times, with the results shown in Table I.

TABLE I

FRACTIONATION OF α-ERGOSTENOL ACETATE

Fraction no.	Weight, g.	M. p., °C.	$[\alpha]_D$
1	11.83	110–111	0
2	8.00	110–111	0
3	14.08	109–110	0
4	11.10	109–110	0
6	5 24	107–108	0
6	2.07	103–106	0

Fractions 1–4 gave on hydrolysis a-ergostenol melting sharply at 133° and having $[\alpha]_D$ +10.5°. Reindel and co-workers give m. p. 130–131"; $[\alpha]_D$ +17.86°. This discrepancy is most simply explained by the difference in source of the ergosterol.

α-Ergostenol was quantitatively precipitated by digitonin, and was recovered unchanged by decomposing the digitoinide with boiling xylene.

Treated in chloroform solution with dry hydrogen chloride gas according to Reindel's directions, a-ergostenol acetate was consistently recovered unchanged in better than 80% yields, although Reindel reports yields of 95% of β-ergostenol acetate. As noted in the introduction, an attempt to prepare p-ergostenol acetate by the action of acetyl chloride on a-ergostenol also failed. We could without difficulty, however, prepare the p-ergostenol chloro-acetate, m. p. 166–167° reported by Reindel, by the action of chloro-acetyl chloride on or-ergostenol. We also confirmed their observation of a "back-isomerization" upon hydrolysis, since we obtained not pure β-ergostenol but a mixture containing some α-ergostenol, from which it was impossible to separate the pure β-form by fractional crystallization.

In order to determine if possible the conditions for isomerization, we prepared *a* series of esters as shown in Table II by warming 0.5 g. of α-ergostenol with 0.5 g. of acid halide and recrystallizing from alcohol. Hydrolysis with alcoholic potassium hydroxide gave either the characteristic low melting mixture of a- and p-ergostenol, or the homo-

geneous sharp melting needles of α-ergostenol, according as isomerization had or had not taken place. As a control experiment, esterification was also carried out in pyridine solution,[3] resulting in every case in an a-ergostenol derivative as shown in Table III. (Compounds which were identical with those in Table II are omitted from Table III.)

TABLE II

ESTERIFICATION OP α-ERGOSTENOL WITHOUT SOLVENT

[a] Reindel, Walter and Rauch give 118° for α-ergostenol benzoate.

TABLE III

ESTERIFICATION OR α-ERGOSTENOL WITH PYRIDINE AS SOLVENT

Ester	M. p., °C.	M. p. of hydrolysate, °C.
Monochloro-acetate	[a]	130–131
Trichloro-acetate	133.5	129–131
Propionate	90	129–130
a-Bromopropionate		130–131
Butyrate	67–68	130–131

[a] These two compounds were not true esters of α-ergostenol, a further reaction due to the condensing effect of the pyridine having taken place. Their true nature is being investigated.

It is difficult to understand why some acid halides should cause isomerization while others do not. It cannot be explained on the basis of the "strength" of the acid involved, for acetic acid stands intermediate between butyric and the chloro-acetic acids, and dichloro-acetic acid between monochloro- and trichloro-acetic acids in strength. Likewise, the presence or absence of halogen in the acid chain cannot be made to account for the results. In every case a copious evolution of hydrogen chloride was observed, so the presence of dry hydrogen chloride alone is not sufficient to effect isomerization. We are forced to the conclusion that the reaction is one the course of which cannot be predicted with our present knowledge.

Summary

1. a-Ergostenol prepared from ergot ergosterol was found to differ slightly in physical properties, and radically in ability to isomerize, from

---

[3] Houben, "Die Methoden der organischen Chemie," Georg Thieme, Leipzig, 1925, Vol. II, 3d ed., p. 667.

the a-ergostenol from yeast ergosterol as described by Reindel, Walter and Rauch.

2. The effect of a number of acid halides in causing isomerization of a-ergostenol to β-ergostenol has been investigated; no single factor could be made to account for isomerization in some cases and not in others.

3. A number of new esters of α- and of β-ergostenol are described.

AROMATIC AMIDES OF N-ARYLGLYCINE ARSONIC ACIDS

BY GEORGE W. RAIZISS AND LE ROY W. CLEMENCE

RECEIVED JANUARY 2, 1930 PUBLISHED MAY 8, 1930

In the search for therapeutic arsenical compounds, used in the treatment of syphilis, Jacobs and Heidelberger[1] deviated from the usual experimental lines, which involved changes in the aromatic nucleus containing arsenic. These older researches had involved changes in the structure of salvarsan base (diamino-di-hydroxy-arsenobenzene) and this field of study has been fairly well exhausted.

The above authors synthesized a new series of compounds utilizing the reaction between chloro-acetyl-alkyl or chloro-acetyl-aryl amines and arsanilic acid (*p*-aminophenylarsonic acid). The aromatic series furnished a new field for work inasmuch as the non-arsenical benzene nucleus could be still further substituted, giving rise to compounds of substituted chloro-acetyl-aryl amines and arsanilic acid. A large number of such compounds were prepared.

It is our purpose to add further to this series and in doing so we have used the chloro-acetyl derivatives of amines which in themselves are therapeutic to some degree. We have also obtained some compounds involving 3-methylarsanilic acid (*m*-methyl-*p*-amino-arsonic acid) which correspond to the known derivatives of arsanilic acid.

The intermediate compounds used by us in the preparation of the arsonic acids are chloro-acetyl derivatives of amines. In most of the experiments these were prepared by methods employed by Jacobs and Heidelberger;[2] the few exceptions will be described later.

Jacobs and Heidelberger in their experiments[3] employed arsanilic acid, and its corresponding derivatives, in the form of its sodium salt (*i. e.*, in alkaline solution). For several of our experiments this was not practicable inasmuch as the chloro-acetyl compounds were oxidizable in alka-

[3] Jacobs and Heidelberger, THIS JOURNAL, 41, 1587 (1919).

line mediums and gave very dark colored products, this being especially the case with 5-chloro-acetylaminosalicylic acid.

In such cases we employed the free arsanilic acid (or derivative) in aqueous medium. This required more time for the reaction and in a few instances reduced the yield; nevertheless the product was purer in composition and much lighter in color. Then, again, according to Jacobs and Heidelberger,[4] the reaction between arsanilic acid and chloro-acetylanthranilic acid did not go in the desired sense entirely, due to the high reactivity of the chlorine atom in the chloro-acetyl compound, resulting in side reactions and an impure product. We considered that this was perhaps due to the presence of sodium hydroxide, so we employed only a water medium. The product we obtained showed by analysis that it was not exactly pure, but still it was practically so, and on further purification would finally have yielded an absolutely pure product.

All of the arsonic acids we prepared are crystalline products with the possible exception of the N-(phenyl-4-arsonic acid)-glycyl-acriflavine, which is a very fine amorphous powder.

The subsequently mentioned compounds were elaborated with a view to possible application in the treatment of syphilis. The major requirements for qualification of a chemical substance as a therapeutic agent are therapeutic efficiency and relatively low toxicity, allowing a large margin of safety between the therapeutic and the toxic doses. From the point of view of toxicity some of our preparations showed remarkably high qualities. When injected into rabbits they proved to be of much lower toxicity than other pentavalent arsenicals, including tryparsamide and stovarsol (acetarsone), both accepted antisyphilitic drugs and generally considered of low toxicity.

TOXICITY OF VARIOUS ORGANIC COMPOUNDS OF ARSENIC WHEN ADMINISTERED INTRAVENOUSLY TO RABBITS

Compound	Max. tolerated dose calcd. per kg. of body weight, g.	Lethal dose, g.
Arsanilic acid	0.08	0.1
Tryparsamide (sodium N-phenylglycine-amide-p-arsonic acid)	1	1.25
Stovarsol (3-acetyl-amino-4-hydroxyphenylarsonic acid)	0.1	0.12
Sodium salt of stovarsol	0.5	0.6
Arsonodiacetyl-(diacetyl-3,5-diamino-4-hydroxy-phenyl-arsonic acid)	0.8	1
N-(phenyl-4-arsonic acid)-glycyl-5'-amino-salicylic acid	0.9	1
N-(phenyl-4-arsonic acid)-glycyl-5'-amino-salicylic acid (sodium salt)	1.75	2
N-(phenyl-2-methyl-4-arsonic acid)-glycyl-5'-amino-salicylic acid	0.9	1

---

[4] Jacobs and Heidelberger, THIS JOURNAL, 41, 1627 (1919).

Thus, N-(phenyl-4-arsonic acid)-glycyl-5′-aminosalicylic acid (sodium salt) is considerably less toxic for rabbits than tryparsamide and the sodium salt of stovarsol. The results of the spirocheticidal tests of this compound, however, were not very encouraging.

RESULTS OF INTRAVENOUS INJECTIONS OF N-(PHENYL-4-ARSONIC ACID)-GLYCYL-5′-AMINO-SALICYLIC ACID INTO RABBITS INOCULATED WITH TREPONEMA PALLIDUM

Dose per kilo of body weight, g.	Dark field negative for spirochetes after	Testicles normal after	Testicles remained normal (last examination)	Results of lymph node transplantation into control animals
0.15	14 days	Animal died after 3 days		
0.15	26 days	61 days	116 days	Negative
0.3	9 days	48 days	70 days	Negative

While this compound, as seen from the above table, is capable of destroying spirochetes in the animal body, it is evident that a dose had to be employed which was quite near to the maximum tolerated, in order to obtain early negative results in the dark field examination. It took nine days to make spirochetes disappear from lesions when the dose of 0.3 g. was used, *i. e.*, one-third of the maximum tolerated dose. For comparison, it was found by us that only 0.015 g. (about one-eighth of the maximum tolerated dose) of arsphenamine was required to obtain the same result in one day.

The same compound did not prove to be of therapeutic value in experimental trypanosomiasis in albino rats when injected intravenously in the dose of 1.1 g. per kilo (rats tolerated it in as high a dose as 4.5 g.).

Experimental Part

Preparation of **Chloro-acetyl Amines.**—The general method for chloro-acetylation is as follows: 1 mole of the amino compound or hydrochloride is dissolved or suspended in 1 liter of ice and water and cooled in a bath of ice water. Then with good stirring 1.5–2 moles of chloro-acetyl chloride is slowly added. The chloro-acetyl compound separates and is filtered. It is then washed with water or 2% hydrochloric acid, except in the cases of chloro-acetylamino-antipyrine and chloro-acetylacriflavine, which are both somewhat soluble in water. With the exception of these two compounds, all can be recrystallized from water.

TABLE I

CHLORO-ACETYL COMPOUNDS

( )-Chloro-acetyl	Formula	M. p., °C.	Nitrogen, % Calcd.	Found
4-( )-aminobenzoic acid	*p*-$(CH_2ClCO)NHC_6H_4COOH$	248	6.56	6.55

5-( )-aminosalicylic acid	$ClCH_2CONHC_6H_3(OH)COOH$-(*p,o*)	242–244	6.10	6.19
( )-amino-antipyrine	$ClCH_2CONHC_{11}H_{11}N_2O$	187	Cl, 12.66	12.87
( )-acriflavine	$ClCH_2CONHC_{14}H_{12}N_2Cl$	215–220, d.	......	...
4-( )-aminoguaiacol	$ClCH_2CONHC_6H_3(OCH_3)OH$-(*m,p*)	117	6.48	6.29

Preparation of Arsonic Acid **Amides** in Alkaline Medium.—The method used was that of Jacobs and Heidelberger in which the arsonic acid is dissolved in alkali to give the sodium salt in solution, except that we used 2 moles of the arsonic acid instead of 1 mole.

Two moles of arsanilic acid (or 3-methylarsanilic acid) was dissolved in a volume of normal sodium hydroxide solution (2 moles) and to this was added 1 mole of the chloro-acetyl amine. The mixture was then heated under a reflux condenserfor a time, varying with each reaction. Usually after refluxing for one to two hours the solid matter goes into solution, and on further heating precipitates again. In some cases the solid matter never goes into solution. The reaction is usually finished when a test portion of the mixture is completely soluble in alkali. The mixture is then made acid to congo red with hydrochloric acid and filtered off. The crude arsonic acid amide is insoluble. This can be purified by washing well with dilute hydrochloric acid and water, then dissolving in dilute sodium hydroxide, treating with "nuchar" and reprecipitating with hydrochloric acid while hot. The purified amides are insoluble in hot or cold water, insoluble in organic solvents, insoluble in dilute acids but soluble in dilute alkali. The following amides were prepared in this manner.

TABLE II

ARSONIC ACID AMIDES FROM ALKALINE MEDIUM

Compound	M. p., °C.	Time of reaction, hours
N-(Phenyl-4-arsonic acid)-glycyl-4'-aminobenzoic acid	Darkens at 230, melts at 260–265 (dec.)	3
N-(Phenyl-2-methyl-4-arsonic acid)-glycine-2'-toluidide	246 (dec.)	5
N-(Phenyl-4-arsonic acid)-glycine-(4'-nitro)-o-toluidide	115–120 (dec.)	6
N-(Phenyl-4-arsonic acid)-glycyl-amino-antipyrine	270 (dec.)	6
N-(Phenyl-4-arsonic acid)-glycyl-4'-aminoguaiacol	215–217	5

Formula	Nitrogen, %		Arsenic, %

p-$H_2O_3AsC_6H_4NHCH_2CONHC_6H_3(OCH_3)OH$-*m,p*	7.07	6.82	18.93	19.19

Preparation of **Arsonic** Acid **Amides** in Aqueous Medium.—This method is practically the same as the previous one with the omission of the alkali. The reactions require longer heating but the yields are approximately equal to those in reactions employing sodium hydroxide. The yields in both cases range from 25–40% based on the chloro-acetyl compound.

TABLE III

Two moles of arsanilic acid (or 3-methylarsanilic acid) is suspended in one liter of water and 1 mole of chloro-acetylamino compound added. The mixture is then heated until a test portion shows complete solubility in alkali. In some of the reactions the insoluble matter does not go completely into solution and the reaction is very slow, requiring long heating, as is particularly the case with *p*-chloro-acetylamino-acetanilide, which is heated for forty hours. After acidification with hydrochloric acid, the product is filtered and washed. It is purified by using "nuchar" and reprecipitating from alkaline solution. The amides obtained by this method are also insoluble in all solvents except dilute alkali.

Summary

1. Some new arsonic acids have been prepared following the work of Jacobs and Heidelberger.

2. The preparation of intermediate chloro-acetyl compounds has been described.

3. Some of the preparations described proved to be valuable, being of low toxicity. Their therapeutic effect, however, was found to be low.

CONDENSATION PRODUCTS OF AROMATIC ALDEHYDES WITH A,-ANGELICA LACTONE[1]

BY W. F. VON OETTINGEN

RECEIVED JANUARY 3, 1930 PUBLISHED MAY 8, 1930

J. Thiele, R. Tischbein and E. Lossow[2] described the condensation of anisaldehyde and Δ_2-angelica lactone with the formation of a-anisal-Δ_2-angelica lactone. In a study on the relation between chemical constitution and pharmacological action concerning the anthelmintic properties of some aliphatic lactones,[3] it was found that both the Δ_2- and Δ_1-angelica lactone produce a very marked depression of the musculature and to a smaller extent also of the nervous system, but these compounds could not be utilized as anthelmintics on account of their chemical instability and general toxicity. Eugenol is also a muscular depressant and is used as an anthelmintic; its action is said to depend upon the position of the OH and OCH_3 of the ring. Therefore, it appeared to be feasible to combine both the eugenol and the angelica lactone by condensing vanillin with Δ_2-angelica lactone by the method used by Thiele and his co-workers. Because this condensation was successful, a series of similar compounds was synthesized, in order to study the relation between chemical constitution and pharmacological action of these compounds.

It would have been logical to start with the a-benzal-Δ_2-angelica lactone, *i.* e., the angelica lactone in which the Hz group is substituted by a benzyl ring, but Thiele had already found that the compound is very unstable, the lactone ring being split with the formation of benzal-levulinic acid. In the present study it was also found impossible to obtain a pure product. The same holds true for the a-phenol acetal, the a-cinnamal- and the α-hydrocinnamal-Δ_2-angelica lactones.

On the other hand, it was found possible to prepare and to isolate the corresponding derivatives of the salicyl- and resorcylaldehyde in crystalline form.

Because it is known that closure of the phenol group reduces the pharmacological action of phenols, three further compounds were prepared, in which one or two hydroxy groups were masked by methyl groups. The compounds are a-anisal-, a-vanillal- and α-piperonal-Δ_2-angelica lactone.

The Δ_2-angelica lactone was prepared according to the directions of R. Gilmour,[4] which gave very satisfactory results.

---

[1] This investigation has been made with the assistance of a grant from the Committee on Therapeutic Research, Council on Pharmacy and Chemistry, American Medical Association.

[2] J. Thiele, R. Tischbein and E. Lossow, ***Ann.,*** 319, 180 (1901).

[4] R. Gilmour, *J. Chem. Soc.,* **105,** 75 (1914).

The condensation of the aromatic aldehydes with the Δ_2-angelica lactone was accomplished by heating small quantities of the angelica lactone, usually 2 *g.*, with little more than the equimolecular quantity of the aldehyde on the water-bath for a half to one hour with the occasional addition of a few drops of diethylamine. The condensation product was then shaken with sodium bisulfite solution (20 cc. of 15% solution), in order to remove the excess aldehyde; the resulting resinous mass was then dissolved in methyl alcohol, crystallized and recrystallized. Elementary analyses of the compound were made by Professor N. A. Lange of Case School of Applied Science. A study of the pharmacological action of these compounds will appear at another place; Table I gives the properties of the compounds thus obtained.

Summary

A series of aromatic aliphatic lactones has been synthesized, namely, a-salicylal-Δ_2-angelica lactone, α-resorcylal-Δ_2-angelica lactone, α-anisal-Δ_2-angelica lactone, a-vanillal-Δ_2-angelica lactone and a-piperonal-Δ_2-angelica lactone. The chemical properties are described.

[Contribution from the Chemical Laboratory of the University of Colorado]

THE ACTION OF GUANIDINE CARBONATE AND OF BENZAMIDINE HYDROCHLORIDE UPON GLYOXAL SODIUM BISULFITE

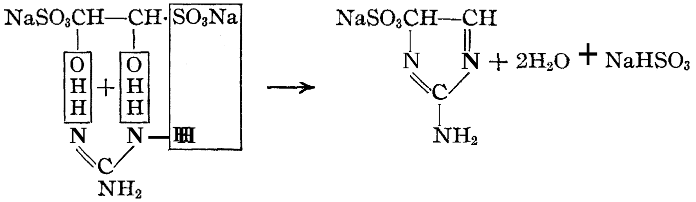
By John B. Ekeley and Jervis M. Fulmer

Received January 7, 1930 Published May 8, 1930

Very little has been published upon the reaction of guanidine or of benzamidine salts upon dialdehydes and diketones and, so far as we know, nothing upon their reactions with glyoxal sodium bisulfite. Wense[1] obtained mono- and diguanylbenzil and diguanylphenanthrenequinone from guanidine carbonate with benzil and phenanthrenequinone, respectively. By the action of benzamidine hydrochloride upon diacetyl, Diels and Schleich[2] obtained a very interesting addition product which, from its properties, seems to be a dihydroglyoxaline derivative.

This paper will describe compounds obtained by condensing guanidine carbonate and benzamidine hydrochloride, respectively, with glyoxal sodium bisulfite.

Guanidine carbonate reacts with glyoxal sodium bisulfite yielding the sodium salt of an aminosulfonic acid of a tautomeric form of glyoxaline, according to the following reaction



That the compound has the structure assigned to it is shown by the analysis, by the absence of a NH group (Liebermann's reaction), and by the fact that the NH_2 group may be replaced by OH by treatment with nitrous acid, yielding the corresponding hydroxy acid. Acidifying the salt or carrying out the reaction in acid solution would be expected to give the free acid. This, however, is not the case, since, as fast as the acid group is liberated, it reacts with the amino group, yielding the inner salt A, as is shown by the fact that the resulting compound is neutral. Boiling this compound with sodium hydroxide yields the original sodium salt. Nitrous acid reacts with the inner ammonium salt giving the corresponding hydroxy acid, B.

Benzamidine hydrochloride reacts in a similar manner with glyoxal sodium bisulfite, in this case forming the sulfonic acid of a tautomeric form of phenylglyoxaline, C.

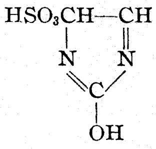
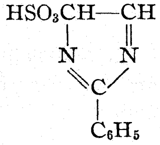
A



B



C

At 100° the compound, if slightly impure, loses sulfur dioxide and water, changing to a dark red resinous solid. Even at 80° the decomposition takes place slowly and at the end of a week the sample lost 26.3% of its weight. After raising the temperature to 100°, it lost 33.8%. The theoretical loss for sulfur dioxide in the above compound is 26.45% and for sulfur dioxide and water is 33.9%. If the compound is pure, it is stable, the crystals remaining unchanged apparently indefinitely.

Experimental

Sodium Salt of 2,4-Aminoglyoxalinesulfonic Acid.—Guanidine carbonate and glyoxal sodium bisulfite were brought together in water solution and boiled. Carbon dioxide was given off and, on evaporating the solution, colorless crystals were obtained. There was some decomposition during the concentration, the solution becoming light brown. The crystals were recrystallized from hot water, yielding colorless transparent prisms, which on drying became opaque. The sample for analysis was dried at 100° and melted at 260–263°.

Anal. Calcd. for $C_3H_4N_3NaSO_3$: C, 19.44; H, 2.18; N, 22.70; S, 17.32; Na, 12.42. Found: C, 19.22; H, 2.20; N, 22.41; S, 17.68; Na, 12.51.

The mother liquor was evaporated and allowed to cool, whereupon crystals of acid sodium sulfite separated out.

Inner Ammonium Salt of Aminoglyoxalinesulfonic Acid.—This compound is formed when the above sodium salt is acidified with hydrochloric acid or when water solutions of equimolecular proportions of guanidine carbonate and glyoxal sodium bisulfite are mixed, acidified with hydrochloric acid, concentrated and allowed to crystallize, whereupon colorless crystals of the inner salt are obtained. Recrystallized from hot water, they melt at 172–174°.

Anal. Calcd. for $C_3H_4N_3SO_3H$: C, 23.36; H, 2.61; N, 27.27; S, 20.80. Found: C, 23.33; H, 3.01; N, 27.02; S, 21.11.

2-Hydroxy-4-glyoxalinesulfonic Acid.—To an ice-cold water solution of the inner ammonium salt, acid with hydrochloric acid, cold sodium nitrite solution was added and allowed to stand. On concentrating the solution, colorless crystals were obtained which, recrystallized from hot water, melted at 225°.

Anal. Calcd. for $C_3H_3N_2SO_4H$: N, 17.07. Found: N, 17.10.

2-Phenyl-4-glyoxalinesulfonic Acid.—Molecular quantities of benzamidine hydrochloride and glyoxal sodium bisulfite were dissolved in warm water, mixed and concentrated on the water-bath. On cooling, a colorless crystalline compound was obtained which, recrystallized from hot water, melted at 109°. When impure, the crystals gradually decompose, but the pure compound is stable.

Anal. Calcd. for $C_9H_7N_2SO_3H$: C, 44.62; H, 4.13; N, 11.57; S, 13.22. Found: C, 44.74; H, 4.06; N, 11.53; S, 13.08.

Summary

1. The inner ammonium salt of 2-amino-4-glyoxalinesulfonic acid has been prepared. On boiling with sodium hydroxide, the sodium salt of the acid is obtained.
2. 2-Hydroxy-4-glyoxalinesulfonic acid has been prepared.
3. 2-Phenyl-4-glyoxalinesulfonic acid has been prepared.

NORMAL VALEROLACTONE. II. ITS VAPOR PRESSURE

BY H. A. SCHUETTE AND RALPH W. THOMAS

RECEIVED JANUARY 10, 1930 PUBLISHED MAY 8, 1930

During the course of a study of the chemical and physical properties of n-valerolactone under way in this Laboratory, it became desirable to verify the statement that this compound distils without decomposition[1] at 206–207°. A determination of its vapor pressure, which hitherto has not been reported, seemed to afford the most direct method of approach in the attack on this problem.

Experimental Procedure

The n-valerolactone used in this study was prepared by the reduction of levulinic acid as described by one of us.[2] That which was used for experimentation was dried over anhydrous sodium sulfate and redistilled, the fraction boiling at 125.3 ± 0.2° (68 mm.) serving for the vapor pressure measurements.

Vapor pressure measurements were made over the temperature range 69 to 203.4° by the dynamic method of Ramsay and Young[3] and the static method described by Smith and Menzies.[4] In both methods pressures were read directly from a manometer with the aid of lenses. They are accurate to ±0.2 mm. The necessity of making stem corrections was avoided in the dynamic method[3] by suspending the thermometer in the vapor pressure flask. All observed thermometer readings in the static method[4] were corrected for stem exposure. Two series of measurements were made by each method.

It was found that the vapor pressure curve as plotted in the usual manner from the data obtained by the dynamic method[3] of measurement can be expressed by the empirical equation $\log P = -2540.44/T + 8.2059$. Similarly, the corresponding expression for the data obtained by the static

[4] Smith and Menzies, THIS JOURNAL, 32, 1412 (1910).

method[4] of measurement is $\log P = -2558.42/T + 8.2544$. Furthermore, it was observed that if a composite curve be drawn of the 59 pairs of readings obtained by the two methods of vapor pressure measurement, and an equation fitted to it, there is presented a picture of the relative sensitiveness of these procedures to any decomposition of the lactone that might take place. The deviation plot (Fig. 1) illustrates this situation by showing the differences under the above condition between the observed and calculated pressures at any given temperature. For reasons which will become apparent later, the data obtained by the static method together with the pertinent equation are deemed to be less accurate than the former.

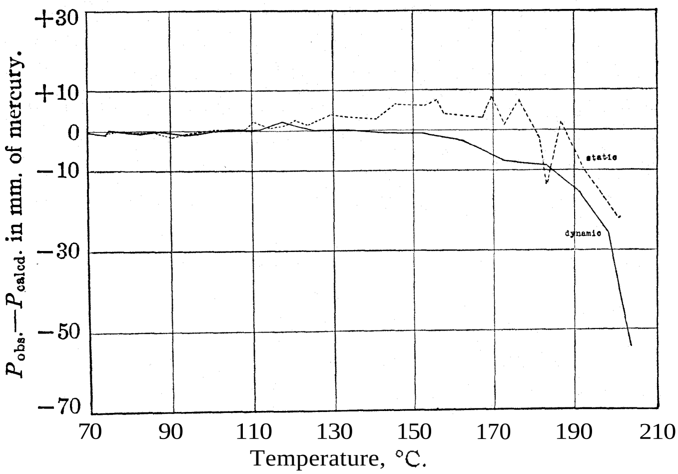

Fig. 1.—Deviation between observed and calculated pressures by two methods of measurement.

Discussion

At the completion of the determination by the Ramsay and Young method, a slight carbonaceous residue was noted in the apparatus where an occasional drop of the lactone had fallen from the thermometer bulb to the hot surface of the flask. The observed pressures for this method agree very well with the calculated up to about 160°, but beyond this temperature there is considerable disagreement, which increases with rising temperature (Fig. 1). Since both of the above facts point to decomposition, it was decided to check these data by using a different method[4] for determining the vapor pressure. Since in this, the isoteniscopic or static, method the material under examination is constantly exposed to view, decomposition becomes visual, if not real, by a change in color of the liquid in question. In this particular instance the lactone showed the first signs of discoloration at about 170°, the color gradually increasing until at the completion of the run it was a dark brown. The observed and calculated values for the vapor pressure again were found to agree very well at low temperatures and to vary considerably at higher temperatures (Fig. 1).

These data bring out the following points: (1) at low temperatures the values for the two methods agree very well; (2) as the temperature increases the pressures recorded by the static method are higher than those by the dynamic; and, (3) in both cases, the observed values are less than the calculated at the higher temperatures.

Conclusion

In the light of the information obtained in this study it appears that n-valerolactone does undergo some decomposition as it approaches its boiling point at atmospheric pressure. This statement is further verified by the darkening of the compound. The isoteniscopic method of determining vapor pressure is in this instance more sensitive to this decomposition. This is due to the fact that the resulting decomposition products are confined to the small space between the liquid in the bulb and in the U-tube rather than being swept out of the apparatus as is the case in the Ramsay and Young apparatus, hence affecting the observed pressure much more. That the values obtained by this latter method actually were lower bears out this conclusion. At first thought it might be expected that if decomposition takes place the observed values would be higher than those calculated. However, this is not necessarily the case since the values log $P/(l/T)$ give a straight line only when the heat of vaporization is a constant with change of temperature. There is no necessity for deeming the heat of vaporization of valerolactone to be a constant; in fact it is very probable that the calculated values would be still lower were it not for the compensating effect of decomposition.

The method most sensitive to decomposition, *i. e.*, the isoteniscopic,[4] does give a better agreement with the calculated pressures at higher temperatures, which justifies the above reasoning.

Summary

1. The vapor pressure of n-valerolactone has been determined and may be expressed by the equation log $P = (-2540.44/T) + 8.2059$, which holds for temperatures up to 160°.

2. It was found that decomposition takes place as n-valerolactone approaches its boiling point at atmospheric pressure.

A STUDY OF THE BENZOIN CONDENSATION[1]

BY AVERY A. MORTON AND JOSEPH R. STEVENS

RECEIVED JANUARY 14, 1930 PUBLISHED MAY 8, 1930

Introduction

In the condensation of benzaldehyde to benzoin under the influence of an alkali cyanide, the specific action of the catalyst has been ascribed, in general, to its ion or to its hydrolysis product. There is a large amount of experimental work which supports this but nearly all has been done in an ionizing solvent which contains water. No systematic attempt has ever been made to observe the reaction under conditions where no ionization nor hydrolysis can occur. In this paper we shall report experiments which show that the reaction will take place in anhydrous petroleum ether, and that an addition compound consisting of one molecule of benzaldehyde and one of sodium cyanide can be obtained, which in the dry state, slowly changes to benzoin. These facts cannot be explained by the common mechanisms. We have, therefore, suggested two possible ways in which the catalyst may function. The results also raise the question as to whether the mechanism in ionizing solvents has been correctly represented in the past.

Experiments

The general experimental method was as follows. Two grams of benzaldehyde (Eastman Kodak Co. technical grade) and one gram of potassium cyanide were put into an 8-inch test-tube with a given amount of the solvent. The test-tube was tightly stoppered and shaken overnight. The contents were then poured into an Erlenmeyer flask, dilute acetic acid added to stop the reaction and the mixture boiled for a short time to volatilize the organic solvent. Any high boiling amines used with the solvent were soluble in the acid solution. The insoluble benzoin was filtered, dried and weighed. A number of these test-tube runs were made at one time. A blank experiment, identical in all respects except that the solvent was 95% alcohol alone, was made with each series. The results are referred to this blank on a basis of 100. Values recorded as (s) slight and (vs) very slight indicate yields of benzoin too small to be measured by our method.

Effect of Solvent

Series 1.—The solvent was 12 cc. of 95% alcohol with 12 cc. of another liquid. The yield in the blank was 1.44 g. of benzoin. Comparative yields were in alcohol with carbon disulfide vs, ethyl bromide vs, ether vs, acetone s, carbon tetrachloride 14, chlorobenzene 31, petroleum ether 120. These results show the marked effect of petroleum ether as compared with carbon disulfide, ether, acetone and certain chlorides.

Series 2.—Twenty-five cc. of a single solvent was used. No effort was made to dry the solvent; in fact, at this stage of the work a trace of moisture was supposed to be favorable in order to hydrolyze the cyanide, Comparative yields were in acetic acid 0,

---

[1] From the thesis of Joseph R. Stevens presented in partial fulfilment of the requirements for the degree of Bachelor of Science, 1929.

iso-amyl alcohol vs, tertiary butyl alcohol 6, benzene 47,[2] toluene 52. xylene 55, water 83, methyl alcohol 95.

Series 3.—The comparative yield in a solvent consisting of 20 cc. of 95% alcohol with one gram of phenol was 0, with phthalic anyhdride vs, formaldehyde vs, ethyl acetate vs, isopropyl alcohol 2, aniline 2, hexamethylene tetramine 46, triethylamine hydrochloride 62, benzyl chloride 67, benzal chloride 68, diphenylamine 68, dimethyl aniline 89, hydroquinone 95, pyridine 94, urea 101, acetamide 102, butyl isocyanide 106. The series shows the inhibitory effect of many carbonyl and amine compounds.

The Inhibitory Effect of Ethyl Acetate.--These experiments were made to study the effect of one of the compounds in Series 3 when used in several different concentrations. The solvent was 10 cc. of petroleum ether with 2 cc. of 95% alcohol, this ratio having been found to be very suitable in a number of preliminary tests. Table I gives the results.

TABLE I

RESULTS

KCN, moles	0.02	0.02	0.02	0.03	0.04
Ethyl acetate, moles	.00	.01	.02	.01	.02
Yield of benzoin, g.	.810	.375	.228	.400	.195

Comparison of Sodium Cyanide with Potassium Cyanide. Yield vs. Time.—The solvent was 5 cc. of petroleum ether with 1 cc. of 95% alcohol. An excess of the cyanide (2 g.) was added, which was sufficient to keep the solution saturated at all times with the catalyst and to combine with the product.

The quantities of benzoin formed with potassium cyanide as a catalyst were so very small that only one point could be determined. The results are plotted in Fig. 1. The fact that the values fall on a straight line suggests that the main factor in this solvent is that of the solubility of the catalyst. The solubilities were determined by shaking an excess of the cyanide with the solvent for one hour at room temperature, filtering, evaporating to dryness, and heating in a vacuum oven at 110° to constant weight. The solubility of sodium cyanide was found to be 0.067 mole; that of potassium cyanide 0.0063 mole per liter of solution. The sodium cyanide is therefore 10.6 times more soluble than the potassium cyanide; its reaction velocity is only 6.8 times greater. Since only one point was obtained with potassium cyanide, we are unable to say that this difference is beyond the error of the experiment.

The product from potassium cyanide was white; that from sodium cyanide was yellow. Franzen[3] has prepared the addition compound between calcium cyanide and benzaldehyde and found it to be bright orange-yellow in color. When our sodium cyanide was recrystallized the yellow color largely disappeared. Since sodium cyanide is made from the calcium salt, it is very probable that the orange-yellow color is due to some calcium cyanide present.

Comparison of the Reaction in Alcohol and in Petroleum Ether–Alcohol.—In this series each test-tube contained 6 cc. of 95% alcohol, 2 cc. of benzaldehyde and 2 g. of sodium cyanide. The procedure was identical with that of the experiment just above and the results are plotted in the same figure.

---

[2] Conclusions from these series must not be too hastily drawn. The solubility of the cyanide is of very great importance and, as will be shown later, the sodium is much more soluble than the potassium salt. Had sodium cyanide been used in this series instead of potassium cyanide the results for benzene, toluene and xylene might have been very good. The experiments were made to locate any pronounced effect of a solvent and not to assign an absolute value to each.

[3] Franzen, *Ber.*, 42, 3293 (1909).

A constant calculated for this reaction (see Table II) shows that for the first five hours at least the formation of benzoin is in agreement with that expected from the equation for a bimolecular irreversible reaction in which the initial concentration of benzaldehyde is taken as 2 g. The sodium cyanide concentration is assumed to be constant and does not enter into the equation.

TABLE II

RESULTS OF EXPERIMENTS

Time, hours	1.5	2.5	3.5	4.5	5.5
Benzoin, g.	0.52	0.81	0.95	1.05	1.13
K	.12	.14	.13	0.12	0.12

The solubility of sodium cyanide in 95% alcohol was determined in the same manner as in the petroleum ether–alcohol mixture and found to be 0.405 mole per liter. This is six times the solubility of sodium cyanide in the 5:1 mixture. The values as plotted in Fig. 1 show, however, that at no time did the amount of benzoin formed in alcohol even at the very start of the reaction exceed by three times that in the mixed solvent. Per sodium cyanide dissolved, therefore, the reaction is faster in the solvent containing petroleum ether[4] than in alcohol alone. The type of velocity curve is also different with the two solvents. In alcohol the sodium cyanide is so soluble that the formation of benzoin can proceed according to the mass action principle and the customary curves will be obtained; in the petroleum ether–alcohol mixture the sodium cyanide is so slightly soluble and is so continually removed by the precipitation of the addition compound that the rate is governed almost entirely by the rate of solution of the sodium cyanide.

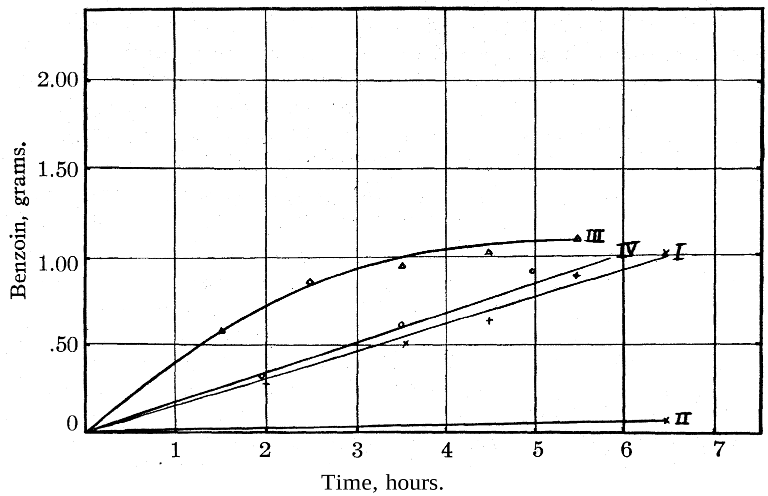

Fig. 1.—I, NaCN in 5:1 mixture of petroleum ether and ethyl alcohol; II, KCN in 5:1 mixture of petroleum ether and ethyl alcohol; III, NaCN in ethyl alcohol; IV, same as I but with purified benzaldehyde.

---

[4] The reason for this may be the chemical inertness of petroleum ether. The polar groups present in other solvents would form complexes with the sodium cyanide, thus competing with the benzaldehyde.

Comparison of Technical with Purified Benzaldehyde.—Benzaldehyde was purified by shaking the technical grade with a dilute solution of sodium carbonate, drying over anhydrous potassium carbonate, filtering and distilling. The first 25 cc. out of the 100 cc. was rejected and 2 cc. from the next fraction collected and used at once. This run was made to compare with the results given in Fig. 1, Curve I, for sodium cyanide and the experimental conditions were, therefore, identical in all respects except in regard to the purity of the benzaldehyde. The results are plotted in Fig. 1, Curve IV. The agreement is within 8%, which is as close a check as the experimental conditions would allow.

Isolation of the Addition Compound.—In all of the reactions run in a solvent containing petroleum ether, an addition compound was precipitated. This compound was isolated and analyzed as follows. In a 250-cc. Erlenmeyer flask 3 to 5 g. of sodium cyanide lumps about the size of small peas were placed. A solution of 5 cc. of benzaldehyde in about 30 cc. of the 5:1 petroleum ether–alcohol mixture was added. The mixture was allowed to stand for one-half hour, after which it was shaken and 20 cc. of benzaldehyde added. A large precipitate formed; 100 cc. of petroleum ether was then added and the solution filtered. The large particles of sodium cyanide either settled out before filtration or were mechanically separated from the dried flocculent compound on the paper. The addition product was washed with petroleum ether to free it from benzaldehyde and dried in a vacuum desiccator. Two analyses gave 14.8 and 13.9% of sodium; the calculated value for a product consisting of one molecule of benzaldehyde to one of sodium cyanide is 14.8%. When decomposed with water immediately after removing from the filter paper and drying, benzaldehyde and sodium cyanide were recovered. When allowed to stand in the desiccator over calcium chloride it very slowly changed to benzoin.

Reaction in Anhydrous Medium

Experiment A.—A dry glass tube was sealed off at one end and in it was placed 4–5 g. of sodium cyanide which had been dried in a vacuum oven at 110° for two hours. From 100 cc. of technical benzaldehyde from a freshly opened bottle the first 40 cc. was distilled in a current of dry hydrogen and rejected; 5 cc. of the middle fraction was then distilled directly into the tube aod sealed in an atmosphere of hydrogen. No solvent was used. After two days a precipitate was formed which steadily increased in amount. When decomposed with water this proved to be benzoin.

Experiment B.—A 16-mm. glass tube was heated nearly to its softening point in a current of dry air until no cloud of moisture appeared on the surface of the glass when it was allowed to cool and then reheated. Ten cc. of petroleum ether dried for twenty-four hours over sodium wire, and 3 4 g. of sodium cyanide prepared from commercial sodium cyanide by recrystallizing once from water and drying in a vacuum oven at 110° for four hours, were put into this tube. Ten cc. of benzaldehyde, treated as in Experiment A (except that nitrogen purified by passing through pyrogallol solution and drying with concentrated sulfuric acid was used instead of hydrogen) was distilled directly into the reaction vessel. The tube was then filled with dried nitrogen, sealed off and allowed to stand. A white addition compound formed on the surface of the cyanide; in four days the appearance of benzoin in fair quantity was observed and in ten days a large precipitate had formed.

These experiments do not exclude the possibility of catalysis by an extremely minute quantity of water, but they do show that when the reactants are dried in a manner fully equivalent to that used in reactions where water must be excluded, such as the preparation of the Grignard reagent, the benzoin condensation will still occur. It is necessary only to dissolve the catalyst and to exclude oxygen which would form benzoic acid with the benzaldehyde.

Other Addition Compounds.—Cinnamic aldehyde does not undergo the benzoin condensation. Hence when finely powdered sodium cyanide was added to a solution of an excess of the aldehyde in alcohol, the addition compound was precipitated from the solution and later recrystallized from alcohol. This compound has already been observed but not analyzed by Zincke and v. Hagen.[5] We found 11.1 and 13.0% of sodium as compared with a calculated value of 12.7 for the addition compound, $NaCN{\cdot}C_9H_8O$.

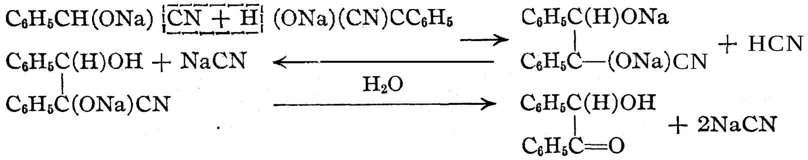
Other addition compounds which were observed but not analyzed were those of sodium cyanide with ethyl benzoate and benzoyl cyanide. Ethyl acetate and benzamide apparently formed no solid addition compound under the conditions of the experiment.

Reaction at Higher Temperature.—Cinnamyl aldehyde[6] will not undergo the benzoin condensation nor will ethyl benzoate condense with benzaldehyde. Since addition compounds are formed in these cases which by their stability might hinder the reaction, higher temperatures were tried. When heated to 150° no condensation occurred in either case. Benzamide and benzaldehyde melted together with sodium cyanide gave off ammonia but nothing was isolated except benzoic acid.

Catalysts Other than Potassium or Sodium Cyanide.—The effect of other compounds as catalysts in this reaction was tried in 10 cc. of the 5:1 petroleum ether–alcohol mixture. About 5 cc. of benzaldehyde and 1 g. of the cyanide compound were used in each experiment. No effect was observed with mercuric, cuprous, thallous, triphenylmethyl, and tertiary butyl cyanides. Barium cyanide had a slight effect. Because sodium cyanide is more soluble[7] than potassium cyanide, it was thought that lithium cyanide would be even more soluble in an organic solvent and therefore a better catalyst. The single attempt to prepare lithium cyanide failed.

Mechanism of the Reaction.—Since the reaction goes in an anhydrous non-ionizing medium it is absolutely impossible to apply the ordinary interpretation to our experiments. It is necessary to consider instead the role of the non-ionized portion. This may be done in two ways. (1) Sodium cyanide may add across the double bond of the carbonyl group. The equations for this would be

$$2C_6H_5CHO + 2NaCN \longrightarrow 2C_6H_5CH(ONa)CN$$



$$C_6H_5CH(ONa)\boxed{CN + H}(ONa)(CN)CC_6H_5 \longrightarrow \begin{matrix}C_6H_5C(H)ONa\\|\\C_6H_5C{-}(ONa)CN\end{matrix} + HCN$$

$$\begin{matrix}C_6H_5C(H)OH\\|\\C_6H_5C(ONa)CN\end{matrix} + NaCN \longleftarrow$$

$$\xrightarrow{H_2O} \begin{matrix}C_6H_5C(H)OH\\|\\C_6H_5C{=}O\end{matrix} + 2NaCN$$

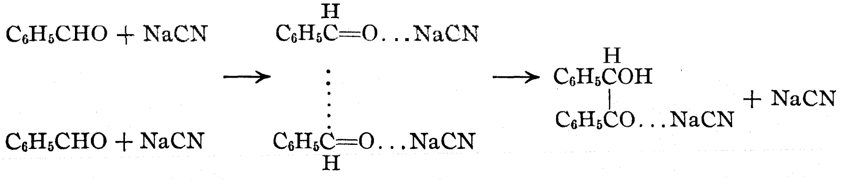
---

[5] Zincke and v. Hagen, *Ber.*, 17, 1814 (1884).

[6] Cinnamicaldehyde, ethyl acetate, ethyl benzoate and benzamide may not undergo the benzoin condensation because they contain other polar groups in the molecule which combine with the cyanide salt and therefore hinder the reaction in the same manner that ethers, chlorides, alcohols or esters used as solvents block the catalytic influence of the condensing agent. One exception to this is here noted. Smith, *Proc. Chem. Soc.*, *29*, *266* (1913), has reported that benzoyl chloride condenses with *o*-nitrobenzaldehyde in the same manner that benzaldehyde condenses with itself. The product is benzoyl-*o*-nitromandelonitrile, the chlorine atom being replaced by the cyano group.

[7] Tripropylamine cyanide should be a very good catalyst since its organic nature would make it soluble in petroleum ether and Lapworth, *J. Chem. Soc.*, *83*, 1004 (1903), has shown that tripropylamine, mandelonitrile and benzaldehyde form benzoin when allowed to stand together.

This is the nearest approach possible to the common interpretation of the reaction. Its weakness lies in the fact that free hydrogen cyanide instead of a salt must split out to cause the condensation. (2) A molecular addition compound may form which then adds to another molecule of the same kind. The reaction is completed by the wandering of a hydrogen atom in the complex. In the formation of the first intermediate compound the sodium cyanide absorbs some of the valence energy of the oxygen atom in the benzaldehyde. This will cause a certain amount of energy to become available on the carbon atom of the benzaldehyde, *i. e.*, it will possess a certain amount of unsaturation. When two of these addition compounds come close to each other, a valence is realized between the unsaturated carbon atoms with the simultaneous wandering of a hydrogen atom. The steps are graphically represented in the equations



$$\begin{array}{lclcll} C_6H_5CHO + NaCN & & \overset{H}{C_6H_5C}{=}O\ldots NaCN & & & \\ & \longrightarrow & \vdots & \longrightarrow & \begin{array}{l} \overset{H}{C_6H_5COH} \\ \quad | \\ C_6H_5CO\ldots NaCN \end{array} & + NaCN \\ C_6H_5CHO + NaCN & & \underset{H}{C_6H_5C}{=}O\ldots NaCN & & & \end{array}$$

This formulation[S] of the role of an addition compound as an intermediate has been developed by Pfeiffer,[9] who states that the catalytic action of metal salts and acids, which in many cases is dependent upon the formation of addition compounds,[10] can be ascribed to the formation of a single unsaturated active carbon atom. He gives as examples of this the catalytic saponification of esters by hydrochloric acid, the formation of ketones in the Priedel–Crafts reaction, and the polymerization of unsaturated compounds by means of sulfuric acid. This picture gives us a very simple explanation for the occurrence of a side reaction, namely, the formation of benzyl benzoate. If instead of the reaction above pictured the single unsaturated carbon atom in the molecular addition compound should unite with the oxygen of another molecule of benzaldehyde, the product upon the wandering of a hydrogen atom will be benzyl benzoate. The possibilities in the reaction of benzaldehyde with itself in the presence

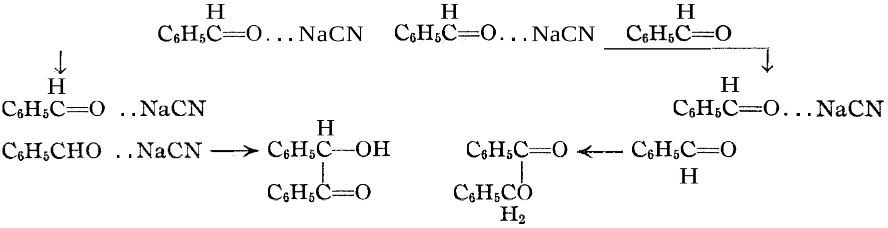
---

[8] The sodium cyanide might be attached through its unsaturated carbon atom to the benzaldehyde. On this point we have no evidence. We have preferred the formula as above written because metallic sodium alone will cause the condensation and because certain analogies might be drawn with alkaline condensing agents in general and with pinacone formation.

[9] Pfeiffer, *Ann.*, **383,** 93 (1911).

[10] *Sammlung Chemischer und chemisch-technischer Vortrage,* **30,** 136 (1928). Muller expresses Pfeiffer's views by saying that the positive metal ion strongly pulls the electron of the carbon atom. The bonding electrons between the carbon and oxygen atoms then move far toward the oxygen side. The carbon atom which now possesses only a small part of the binding electron will then possess a secondary valence.

of a catalyst such as sodium cyanide are illustrated in the following diagram.



Lachman[11] has shown that benzyl benzoate is formed to some extent in the synthesis of benzoin. In the case of alkali hydroxide or alcoholate addition compounds the formation of benzyl benzoate may be assumed to predominate to the entire exclusion of the formation of benzoin.

This conception[12] also eliminates the peculiar role of the cyanide salts as the only catalysts which can bring about the reaction. Lachman[13] mentions that benzoin is sometimes formed by metallic sodium and Blicke[14] in the same year published a study of the action of sodium on benzaldehyde in which he discovered benzoin among the products.

Summary

A preliminary study of the effect of various solvents upon the benzoin condensation has been made. The reaction has been found to proceed in the absence of water and in a non-ionizing medium.

An addition compound has been isolated which consists of one molecule of benzaldehyde and of sodium cyanide. This solid addition compound changes to benzoin upon standing.

Previous mechanisms which involve ionized or hydrolyzed sodium cyanide are not applicable to our work. Two mechanisms have been suggested which accord with the facts observed. One of these mechanisms is based upon Pfeiffer's view of the role of addition compounds as catalysts.

CAMBRIDGE, MASSACHUSETTS

---

[11] Lachman, THIS JOURNAL, **46, 712 (1924).**

[12] **A** similar mechanism might possibly apply to other reactions catalyzed by sodium cyanide. Thus Chalanay and Knoevenagel *[Ber.,* **25,291** (1892)] found that the benzoin condensation took place in the case of certain chlorides and nitriles. Smith *[Ber.,* **26, 60 (1893)]** condensed benzaldehyde with acetophenone, benzoin with acetophenone, and benzoin with mesityl oxide in the presence of potassium cyanide. Strain has shown that benzylidene-aniline and benzylidene-p-toluidine [THIS JOURNAL, 50, **2219** (1928)] undergo the benzoin condensation. In case the mechanism is applicable in ionizing solvents, it might be possible to interpret the action of alkalies in certain condensations such as the Schotten–Baumann reaction on this same basis.

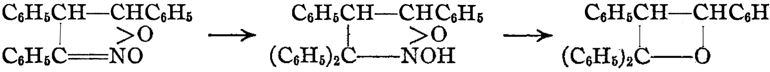
ISOXAZOLINE OXIDES. IX. THE REACTION BETWEEN TRIPHENYL ISOXAZOLINE OXIDE AND ORGANIC MAGNESIUM COMPOUNDS

BY E. P. KOHLER AND N. K. RICHTMYER

RECEIVED JANUARY 16, 1930 PUBLISHED MAY 8, 1930

Inasmuch as the mode of addition of organic magnesium compounds to cyclic nitrones has been definitely established,[1] it is possible, now, to interpret with more confidence the results of an investigation of the reaction between organic magnesium compounds and isoxazoline oxides that was completed several years ago. The investigation is one of a series that deals with the mode of addition to substances containing the unsaturated system $>C{=}\overset{|}{N}O$. Triphenyl isoxazoline oxide was one of the compounds selected for study because it contains a highly phenylated ring and therefore might be expected to offer but one point of attack to the reagent. The reaction was tried with methyl, ethyl, benzyl and phenyl magnesium halides, but the outcome was not so favorable as had been anticipated because it was rarely possible to arrest the action at the first stage.

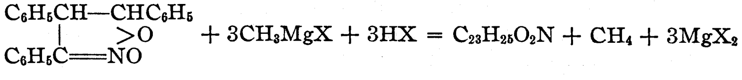
Of all the reagents tried, phenyl magnesium bromide alone gave a product that was formed by the addition of but one molecule of reagent to one of the oxide. The mode of addition appears to be the same as that to the cyclic nitrone, but the product is extremely unstable, decomposing spontaneously both in solution and in solid form. In glacial acetic acid it loses both nitrogen and oxygen and passes into one of the few known derivatives of propylene oxide



$$\begin{array}{l} C_6H_5CH-CHC_6H_5 \\ \quad | \qquad >O \\ C_6H_5C{=}NO \end{array} \longrightarrow \begin{array}{l} C_6H_5CH-CHC_6H_5 \\ \qquad | \qquad >O \\ (C_6H_5)_2C-NOH \end{array} \longrightarrow \begin{array}{l} C_6H_5CH-CHC_6H_5 \\ \qquad | \qquad\quad | \\ (C_6H_5)_2C-O \end{array}$$

I II III

In the reaction with methyl magnesium iodide gas was evolved in the cold. A quantitative determination showed that one molecule of the oxide reacts with three molecules of the reagent and liberates one molecule of methane. The composition of the product confirms this relation, the reaction being represented by the equation



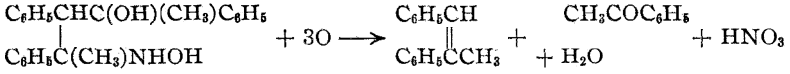
$$\begin{array}{l} C_6H_5CH-CHC_6H_5 \\ \quad | \qquad >O \\ C_6H_5C{=}NO \end{array} + 3CH_3MgX + 3HX = C_{23}H_{25}O_2N + CH_4 + 3MgX_2$$

The product of the reaction is a base. It reacts with methyl magnesium iodide, liberating two molecules of methane and forming a magnesium derivative from which it is regenerated by acids; and when it is acetylated it forms, in succession, a mono- and a diacetyl derivative. It, there-

---

Kohler and Addinall, THIS JOURNAL, 52, 1590 (1930).

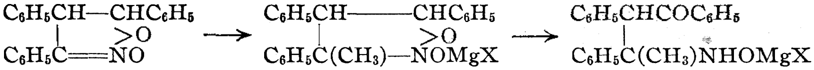
fore, contains two active hydrogen atoms and its two oxygen atoms are presumably present as hydroxyl. In acetone the Grignard product reduces permanganate in the cold, being oxidized to water, nitric acid, acetophenone, and methyl stilbene—all primary oxidation products because permanganate does not oxidize methyl stilbene under these conditions. By combining these facts with the formula of the oxide, we arrive at formula IV for the product, the oxidation proceeding in accordance with the scheme



$$\begin{array}{l} C_6H_5CHC(OH)(CH_3)C_6H_5 \\ \quad | \\ C_6H_5C(CH_3)NHOH \end{array} + 3O \longrightarrow \begin{array}{l} C_6H_5CH \\ \quad \| \\ C_6H_5CCH_3 \end{array} + \begin{array}{l} CH_3COC_6H_5 \\ \\ + H_2O \end{array} + HNO_3$$

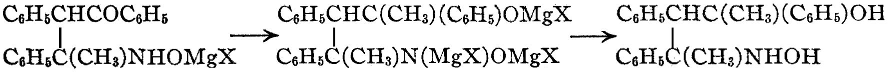
IV

The formation of the hydroxylamine derivative is most easily accounted for by assuming that, in this case also, the reaction begins with addition to the unsaturated system, and that the primary product—an isoxazolidine derivative—immediately undergoes a well-known rearrangement



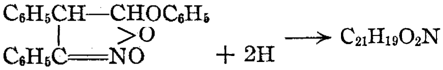
$$\begin{array}{l} C_6H_5CH\text{—}CHC_6H_5 \\ \quad | \qquad >O \\ C_6H_5C\text{=}NO \end{array} \longrightarrow \begin{array}{l} C_6H_5CH\text{———}CHC_6H_5 \\ \quad | \qquad\qquad >O \\ C_6H_5C(CH_3)\text{—}NOMgX \end{array} \longrightarrow \begin{array}{l} C_6H_5CHCOC_6H_5 \\ \quad | \\ C_6H_5C(CH_3)NHOMgX \end{array}$$

The resulting open-chained compound then reacts with two more molecules of the reagent



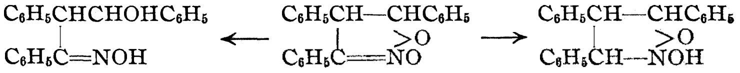
$$\begin{array}{l} C_6H_5CHCOC_6H_5 \\ \quad | \\ C_6H_5C(CH_3)NHOMgX \end{array} \longrightarrow \begin{array}{l} C_6H_5CHC(CH_3)(C_6H_5)OMgX \\ \quad | \\ C_6H_5C(CH_3)N(MgX)OMgX \end{array} \longrightarrow \begin{array}{l} C_6H_5CHC(CH_3)(C_6H_5)OH \\ \quad | \\ C_6H_5C(CH_3)NHOH \end{array}$$

In the case of ethyl magnesium bromide the quantitative picture[2] is far less definite. At the ordinary temperature the reaction consumes 2.8 moles of reagent and liberates 0.6 mole of gas. The gas is not homogeneous, being composed of ethane and ethylene in the proportion of fom to one. The formation of ethane implies a reaction similar to that with methyl magnesium iodide, and the formation of ethylene indicates reduction. No substance corresponding to that obtained with methyl magnesium iodide was isolated. A very small quantity of a substance that appears to be an addition product was obtained, but most of the solid material was a reduction product that is formed in accordance with the equation



$$\begin{array}{l} C_6H_5CH\text{—}CHOC_6H_5 \\ \quad | \qquad >O \\ C_6H_5C\text{=}NO \end{array} + 2H \longrightarrow C_{21}H_{19}O_2N$$

This same reduction product had been obtained previously[3] by reducing the oxide with zinc and acetic acid, and two formulas for it were considered at the time



$$\begin{array}{l} C_6H_5CHCHOHC_6H_5 \\ \quad | \\ C_6H_5C\text{=}NOH \end{array} \longleftarrow \begin{array}{l} C_6H_5CH\text{—}CHC_6H_5 \\ \quad | \qquad >O \\ C_6H_5C\text{=}NO \end{array} \longrightarrow \begin{array}{l} C_6H_5CH\text{—}CHC_6H_5 \\ \quad | \qquad >O \\ C_6H_5CH\text{—}NOH \end{array}$$

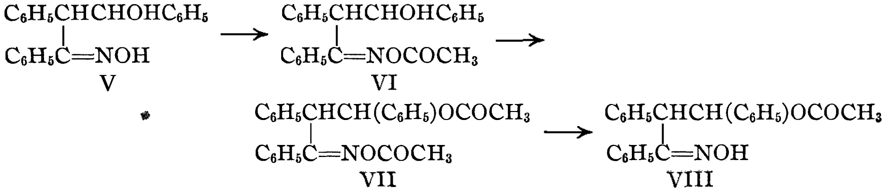
V I B

---

[2] Kohler and Barrett, THIS JOURNAL, 46, 2112 (1924).

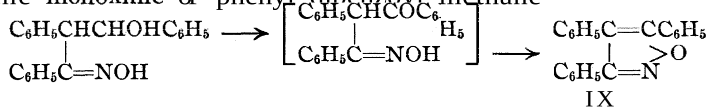
[3] Ref. 2, p. 2110.

The cyclic formula B was preferred to the open-chained formula V largely because the substance is capable of forming a copper derivative. We have now succeeded in getting this copper derivative in a crystalline form, and we have found that it contains one atom of copper to the molecule. It therefore cannot be a derivative of the cyclic form. Moreover, we have found that when the substance is acetylated exhaustively, it forms not only the mono-acetate previously described, but also a di-acetate which on partial hydrolysis passes into a mono-acetate that is isomeric with that obtained by partial acetylation. These facts cannot be reconciled with the cyclic formula. They show that the Grignard product must be the open-chained oxime and that β- as well as α-hydroxy oximes[4] can form copper derivatives when their ethereal solutions are shaken with copper acetate



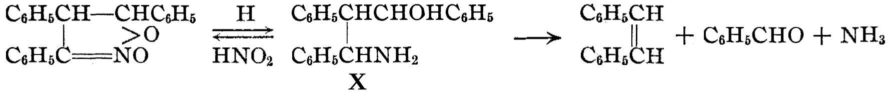
$$\begin{array}{c} C_6H_5CHCHOHC_6H_5 \\ | \\ C_6H_5C{=}NOH \\ \text{V} \end{array} \longrightarrow \begin{array}{c} C_6H_5CHCHOHC_6H_5 \\ | \\ C_6H_5C{=}NOCOCH_3 \\ \text{VI} \end{array} \longrightarrow \begin{array}{c} C_6H_5CHCH(C_6H_5)OCOCH_3 \\ | \\ C_6H_5C{=}NOCOCH_3 \\ \text{VII} \end{array} \longrightarrow \begin{array}{c} C_6H_5CHCH(C_6H_5)OCOCH_3 \\ | \\ C_6H_5C{=}NOH \\ \text{VIII} \end{array}$$

The behavior of the reduction product on oxidation and on further reduction likewise shows that it must be the open-chained oxime. It does not reduce permanganate but it is easily oxidized by chromic acid. The product is triphenyl isoxazole, which, as is known, is readily formed from the monoxime of phenyl dibenzoyl methane[5]



$$\begin{array}{c} C_6H_5CHCHOHC_6H_5 \\ | \\ C_6H_5C{=}NOH \end{array} \longrightarrow \left[\begin{array}{c} C_6H_5CHCOC_6H_5 \\ | \\ C_6H_5C{=}NOH \end{array}\right] \longrightarrow \begin{array}{c} C_6H_5C{=}CC_6H_5 \\ |\quad\;\; >O \\ C_6H_5C{=}N \\ \text{IX} \end{array}$$

On further reduction, which can be accomplished by prolonged heating with zinc and acetic acid, both the Grignard product and the parent isoxazoline oxide are converted into the corresponding amine—a strong base which forms a hydrochloride that is not hydrolyzed by water. Like the oxime, the amine liberates two molecules of methane from methyl magnesium iodide and forms a magnesium derivative from which it is regenerated by acids. When it is heated it decomposes into ammonia, benzaldehyde and stilbene. Its behavior toward nitrous acid is surprising; instead of forming the corresponding di-hydroxyl compound it reverts to the isoxazoline oxide



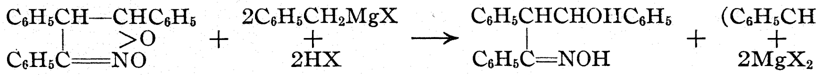
$$\begin{array}{c} C_6H_5CH{-}CHC_6H_5 \\ |\quad\;\; >O \\ C_6H_5C{=}NO \end{array} \underset{HNO_2}{\overset{H}{\rightleftharpoons}} \begin{array}{c} C_6H_5CHCHOHC_6H_5 \\ | \\ C_6H_5CHNH_2 \\ \text{X} \end{array} \longrightarrow \begin{array}{c} C_6H_5CH \\ \| \\ C_6H_5CH \end{array} + C_6H_5CHO + NH_3$$

---

[4] Feigl, Sicher and Singer, *Ber.*, 58, 2294 (1925).

[5] Marshall, *J. Chem. Soc.*, 107, 521 (1915).

The reaction between the oxide and benzyl magnesium chloride is relatively free from complications. Reduction predominates and the principal products are dibenzyl and the same open-chained oxime that is formed, in small quantities, in the reaction with ethyl magnesium bromide



$$\begin{array}{l}C_6H_5CH{-}CHC_6H_5\\ \quad |\qquad >O\\ C_6H_5C{=}NO\end{array} + \begin{array}{c}2C_6H_5CH_2MgX\\ +\\ 2HX\end{array} \longrightarrow \begin{array}{l}C_6H_5CHCHOHC_6H_5\\ \qquad |\\ C_6H_5C{=}NOH\end{array} + \begin{array}{c}(C_6H_5CH_2)_2\\ +\\ 2MgX_2\end{array}$$

Experimental Part

Preparation of Triphenyl Isoxazoline Oxide, I.—Since the oxide prepared according to previous directions[6] often contained triphenyl isoxazole, from which it could not be completely freed by crystallization, it was found necessary to modify the procedure so that no isoxazole would be formed. The operations are as follows: to 9 g. of nitro stilbene and 6 g. of phenyl nitromethane in 100 cc. of gently boiling dry methyl alcohol is added a solution of 0.9 g. of sodium in 50 cc of dry methyl alcohol in the course of three minutes; the solution is allowed to boil for one minute more, then cooled for two minutes by shaking it in a freezing mixture; the mixture of oxide and nitrite is filtered by suction, washed three times with water, then three times with 15-cc. portions of methyl alcohol. The yield is 8.5 g. of oxide melting at 156–159°. Once recrystallized from acetone it melts at 160–162°.

Reaction with Phenylmagnesium Bromide

A Grignard reagent made from 7.5 g. of magnesium and 52 g. of bromobenzene in ether is chilled in ice; to it is added 15.7 g. of solid oxide in the course of two minutes. The mixture is stirred for fifteen minutes, then removed from the ice-bath and stirred for fifteen minutes more. Prolonged stirring is disadvantageous and may result in failure to isolate any solid product.

Decomposition of the reaction mixture is effected by pouring it on ice; crystals appear in the ether layer when the sides are rubbed with a glass rod. A 1:1 mixture of ice and concentrated hydrochloric acid is added to dissolve the basic magnesium salts and then petroleum ether to decrease the solubility of the crystalline product. The mixture is kept cold and stirred for fifteen minutes before filtering. The solid is washed on the filter with water, a little ether, and then thoroughly with petroleum ether.

The Grignard product crystallizes in small colorless needles melting at about 105°, with decomposition. The low melting point implies solvent of crystallization and the analytical results indicate that the crystal solvent is benzene, but since the substance cannot be recrystallized, the significance of the result is doubtful. The substance cannot be benzoylated by the Schotten–Baumann method and an attempt to benzoylate it in pyridine gave but a very small quantity of solid.

2,2,3,4-Tetraphenyl Trimethylene Oxide, III.—When the Grignard product is shaken for an hour with enough glacial acid to cover it, it disappears and the solution gradually deposits the oxide. After washing with ether, the oxide was recrystallized from acetone and methyl alcohol. It separated in diamond-shaped plates melting at 162°.

Anal. Calcd. for $C_{27}H_{22}O$: C, 89.5; H, 6.1; mol. wt., 362. Found: C, 89.1; H, 6.0; mol. wt., 340.

Structure and Cleavage.—The structural formula assigned to the oxide is based upon its behavior toward methyl magnesium iodide and upon its cleavage. When it was treated with methyl magnesium iodide in an apparatus with which it is possible to determine both the amount of reagent consumed and the volume of the gas evolved,

---

[6] Ref. 2, p. 2109.

it was found that it consumed one mole of reagent and evolved only a negligible volume of gas. The oxide underwent no change when heated to 220° in a vacuum but it was readily cleaved in the following manner.

A solution of one g. of the oxide in 40 cc. of absolute methyl alcohol containing 5 drops of acetyl chloride was heated on a steam-bath for twenty-five minutes. The alcohol was evaporated nearly to dryness, cooled and inoculated; it deposited 0.56 g. of very pure triphenyl ethylene. The filtrate from the unsaturated hydrocarbon was diluted with water and then shaken with ether. From the ethereal solution sodium bisulfite extracted benzaldehyde, which was liberated with sodium carbonate and turned into its phenyl hydrazone for comparison with a known sample.

Dibenzophenone Peroxide, $(C_6H_5)_2CO_2O_2C(C_6H_5)_2$.—Before triphenyl ethylene was available for comparison, a sample of the cleavage product was ozonized in the following manner. A current of ozonized oxygen containing about 5% of ozone was passed through a solution of 4 g. of the hydrocarbon in 30 cc. of dry chloroform. At first, feathery needles appeared on the surface of the vessel; this was, doubtless, the ozonide because it became pasty when rubbed on a drying plate. Later, sharply defined crystals appeared in the liquid. These were separated by evaporating the solvent under diminished pressure, diluting the viscous residue with a little ether and filtering. The crude peroxide was recrystallized from ether.

Anal. Calcd. for $C_{26}H_{20}O_4$: C, 78.8; H, 5.0; mol. wt., 396. Found: C, 78.6; H, 5.1; mol. wt. (in freezing naphthalene), 350.

The peroxide dissolves slowly in most organic solvents. It crystallizes from ether in flattened prisms and melts between 200–220°, depending upon the rate at which the temperature is raised. When it is heated with phosphorus pentachloride it liberates chlorine and when it is heated by itself it passes quantitatively into benzophenone and free oxygen.[7]

Reaction between the Oxide and Methyl Magnesium Iodide

The reaction between the oxide and methyl magnesium iodide, when carried out in the "machine"[8] was found to consume 2.92 moles of reagent and liberate 1.11 moles of gas. The evolved gas was collected and analyzed; it was pure methane. For the purpose of isolating the product the oxide was added to a large excess (6 moles) of methyl magnesium iodide at the ordinary temperature. The mixture was left to itself overnight, then decomposed with ice and cautiously treated with acid. At times this treatment left a sparingly soluble iodide, which separated in colorless needles melting at about 100°, and from which the product was liberated with sodium carbonate. Generally the product remained in solution, from which it was isolated by evaporation.

α,γ-Dimethyl-α,β,γ-triphenyl-γ-hydroxy Propylhydroxylamine, IV.—The hydroxyamine was purified by recrystallization from ether–petroleum ether or from dilute alcohol from which it separated in stout needles melting at 180–195°, depending upon the rate of heating.

Anal. Calcd. for $C_{23}H_{25}O_2N$: C, 79.5; H, 7.2. Found: C, 79.1; H, 7.3.

The Monoacetate,  $C_6H_5C(CH_3)NHOCOCH_3$ with $C_6H_5CHC(CH_3)(C_6H_5)OH$ above the C .—The oxime dissolves in cold acetic

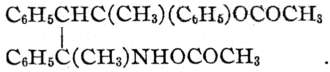
---

[7] By the action of ozone on a tetraphenyl butene, Lebedev, Andreevski, and Matiushkina [*Ber.*, 56, 2349 (1923)] obtained *a* benzophenone peroxide which began to melt at 170° and which they represent as the monomolecular peroxide  $(C_6H_5)_2C{<}O_2$.

[8] Kohler, Stone and Fuson, THIS JOURNAL, 49, 3181 (1927).

anhydride to form the monoacetate, which was isolated by decomposing the excess of reagent with water and extracting with ether. The substance crystallizes from a mixture of ether and petroleum ether in small prisms; it melts to a colorless liquid which turns yellow and then red between 135–155°.

Anal. Calcd. for $C_{25}H_{27}O_3N$: C, 77.1; H, 6.9. Found: C, 77.7; H, 7.1.



The Diacetate, $\begin{array}{l}C_6H_5CHC(CH_3)(C_6H_5)OCOCH_3\\ \qquad\quad | \\ C_6H_5C(CH_3)NHOCOCH_3\end{array}$.—The diacetate was obtained by warming a solution of the oxime in acetic anhydride for an hour on the steam-bath and then allowing it to evaporate slowly over solid potassium hydroxide in a vacuum desiccator. It was purified by recrystallization from a mixture of ether and petroleum ether; it separated in small needles that melt with decomposition at about 172°. In the machine it liberated only a negligible volume of gas.

Anal. Calcd. for $C_{27}H_{29}O_4N$: C, 75.2; H, 6.7. Found: C, 75.0; H, 6.8.

Oxidation.—The hydroxylamine derivative instantly decolorizes a cold solution of permanganate in acetone. A solution of 3.6 g. of the compound (1 mole) reduced 3.2 g. of permanganate instead of 3.4 g. (2 moles) calculated. The manganese was removed by filtration and the filtrate evaporated to small volume; it deposited potassium nitrate. The acetone solution was then diluted with water and extracted with ether. The ethereal solution on evaporation left an oil. This oily residue was distilled with steam. The first 500 cc. of distillate contained acetophenone, which was recognized by its odor and completely identified by condensing it with meta nitro benzaldehyde.

The remainder of the steam distillate yielded a light-colored oil that solidified when rubbed. This was identified as methyl stilbene by comparison with a sample made by Ley's modification[9] of the method devised by Klages.[10] Methyl stilbene did not reduce permanganate in acetone at the ordinary temperature.

Reaction with Benzyl Magnesium Chloride

To a chilled Grignard reagent made from 7.2 g. of magnesium and 42 g. of benzyl chloride was added 18.9 g. of the oxide. The mixture was left to itself overnight, then decomposed with ice and hydrochloric acid. The ethereal solution yielded 12.3 g. of solid product (V) and the residue that was left after the solid had been removed, on distillation gave 9.7 g. of dibenzyl. The solid crystallized from ether in needles melting between 180–200°, depending on the rate of heating. A comparison of the substance itself and of its monobenzoate with two substances described by Kohler and Barrett[3] proved their identity. In the machine one mole of the substance liberated 2.06 moles of methane and formed a magnesium derivative from which it was regenerated by acids. It therefore cannot have the formula previously ascribed to it.

The Copper Derivative.—An ethereal solution of the hydroxy oxime when shaken with aqueous copper acetate precipitates a very finely divided copper derivative that coagulates as the ether evaporates during persistent filtration under suction. Thus obtained, the copper compound is a dull greenish-brown powder that can be purified by extraction with alcohol and with boiling ether. Upon treatment with 1:1 hydrochloric acid it regenerates the hydroxy oxime.

Anal. Calcd. for $C_{21}H_{17}O_2NCu$: C, 66.6; H, 4.5; Cu, 16.8. Found: C, 65.9; H, 4.8; Cu, 16 5.

The Mono-acetate, VI.—The monoacetate was made by Kohler and Barrett and described as the acetate of the hydroxy isoxazolidine B. It crystallizes with water and melts with decomposition at 100–110°.

---

[9] Ley, *Ber.*, 50, 249 (1917).

[10] Klages, *ibid.*, 35, 2648 (1902).

The Di-acetate, **VII.**—The di-acetate was obtained by heating the hydroxy oxime with acetic anhydride on a steam-bath for thirty minutes and then allowing the excess of anhydride to evaporate slowly over solid potassium hydroxide in a vacuum desiccator. The thick oil that remained crystallized readily when moistened with methyl alcohol. The solid crystallized from a mixture of ether and petroleum ether in clusters of large needles melting at 131–132°.

Anal. Calcd. for $C_{25}H_{23}O_4N$: C, 74.8; H, 5.7. Found: C, 74.8; H, 5.8.

The Isomeric Mono-acetate, **VIII.**—A second mono-acetate was obtained by shaking an ethereal solution of the di-acetate for twenty hours with a concentrated solution of ammonia. The ethereal layer deposited small prisms which after recrystallization from a mixture of ether and petroleum ether melted, with decomposition, at 170–176°.

Anal. Calcd. for $C_{23}H_{21}O_3N$: C, 76.9; H, 5.8. Found: C, 76.9; H, 5.9.

Oxidation with Chromic Acid.—A solution of the hydroxy oxime in glacial acetic acid was warmed for five minutes on a steam-bath with an excess of chromic acid. The solution was poured into a large volume of water, and the suspension extracted with ether. The ethereal solution was freed from acetic acid, dried and evaporated. It deposited fine needles of the triphenyl isoxazole (IX)—identified by comparison with a sample on hand.

A small quantity of the oxime of phenyl dibenzoyl methane,[5] which is, doubtless, the intermediate in this reaction, was dissolved in hot glacial acetic acid. The solution began to deposit the isoxazole derivative within thirty seconds.

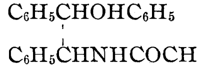
Reduction of Hydroxy **Oxime. α-Hydroxy- γ-amino-α,β,γ-triphenyl** Propane, X—Two g. of zinc dust was added to a solution of the hydroxy oxime in glacial acetic acid diluted with 10% of water. The suspension was warmed on a steam-bath for an hour, then greatly diluted with water and extracted with ether, which removed a small quantity of unchanged oxime. The acid solution, upon neutralization with ammonia, precipitated a white solid which was extracted with ether. The ethereal solution, dried and concentrated, deposited the amine in a yield of 70%.

The same amine was obtained directly from triphenyl isoxazoline oxide by boiling the oxide for six hours with zinc and acetic acid. The yield was 30%

The amine crystallizes from a mixture of ether and petroleum ether in two forms: long glistening needles melting at 123°, and shorter, stouter prisms melting at 128–129°. The melting point of a mixture of the two forms shows no depression, and if the lower melting amine is kept at 120° for ten minutes its melting point becomes 128–129°. Either the needles or the prisms can be obtained at will from an ether–petroleum ether solution by inoculation with the desired form.

Anal. Calcd. for $C_{21}H_{21}ON$: C, 83.2; H, 6.9. Found: (123°) C, 83.2; H, 7.1; (128°) C, 82.6; H, 7.0.

The Hydrochloride.—A benzene solution of the amine was saturated with dry hydrogen chloride and set aside overnight. Since no solid separated from the solution, it was evaporated. The residue was an oil which solidified when ether was added. The solid melted at 232°, dissolved in water without undergoing hydrolysis and regenerated the amine when it was treated with ammonia.

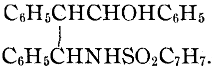


$$\begin{array}{l}C_6H_5CHOHC_6H_5\\ \quad\ |\\ C_6H_5CHNHCOCH_3\end{array}$$

The **Acetyl Derivative,** $C_6H_5CHNHCOCH_3$.—Both forms of the amines are readily acetylated by cold acetic anhydride and they give the same mono-acetyl derivative. This mono-acetyl derivative was also obtained when a solution of the amine in acetic anhydride was warmed for half an hour on a steam-bath, and then allowed to evaporate slowly over potassium hydroxide in a vacuum desiccator. From a mixture of ether and petroleum ether the acetyl derivative crystallized in flattened needles which apparently contain ether of crystallization, because when they are heated rapidly in a capillary tube (plunge method) immediately after crystallization they melt with decomposition at about 135°, while they melt at 142° when heated slowly. After drying overnight at 105°, the melting point is 142° regardless of the rate of heating.

Anal. Calcd. for $C_{23}H_{23}O_2N$: C, 80.0; H, 6.7. Found: C, 79.6; H, 6.8.

In the machine the acetyl derivative consumed 1.9 moles of reagent and liberated 1.9 moles of gas, and it was regenerated when the resulting magnesium compound was treated with acid. It was slowly hydrolyzed to the amine and acetic acid when it was boiled with hydrochloric acid; but it was recovered unchanged after treatment with sodium nitrite in glacial acetic acid. It is, therefore, not the isomeric amino acetate which would be obtained by replacing the hydrogen of the hydroxyl group with an acetyl group.



$$\begin{array}{l} C_6H_5CHCHOHC_6H_5 \\ \qquad\quad | \\ C_6H_5CHNHSO_2C_7H_7 \end{array}$$

The *p*-**Toluene** Sulfonamide, $C_6H_5CHNHSO_2C_7H_7$.—A solution of *0.6* g. of the amine and 4 g. of *p*-toluene sulfone chloride in 10 g. of pyridine was heated for ten minutes, then poured on ice. The resulting suspension was extracted with ether, freed from pyridine, dried and evaporated. It left 0.65 g. of the sulfonamide which, by recrystallization from ether-petroleum ether, was obtained in small prisms melting at 146–148°. It is insoluble in aqueous alkalies and it is precipitated from its solution in methyl alcoholic potash by addition of water.

Anal. Calcd. for $C_{28}H_{27}O_3NS$: C, 73 5; H, 5.9. Found: C, 73.4; H, 6.2.

Action of Nitrous Acid on the **Amine.**—To a solution of 1 g. of the amine in glacial acetic acid was added 0.7 g. of solid sodium nitrite When the formation of gas bubbles had ceased, the solution was poured into water and extracted with ether. The ethereal solution was freed from acetic acid, dried over calcium chloride and evaporated. Addition of petroleum ether to the concentrated solution resulted in the separation of 0.4 g. of triphenyl isoxazoline oxide melting at 155–157°. After one recrystallization from dilute acetone, it melted at 159–161°, and the addition of pure oxide produced no depression in the melting point. A small portion was converted into triphenyl isoxazole to complete the identification.

Thermal Decomposition.—The amine was heated in a small distilling flask until the temperature of the metal-bath reached 330°. Ammonia and benzaldehyde were recognized by their odors and the residue in the flask—which solidified on cooling—was identified as stilbene by comparison with a sample on hand.

Reaction between the Oxide and Ethyl Magnesium Bromide

The reaction with ethyl magnesium bromide has been briefly described by Kohler and Barrett,[2] who obtained a moderate yield of the same reduction product that is formed in the reaction with benzyl magnesium chloride. Since the mechanism by which the oxide is reduced must be very different in the two cases, we have repeated the experiments mainly for the purpose of determining the quantitative relationships. To this end we prepared a solution of ethyl magnesium bromide in iso-amyl ether and with this solution determined the amount of reagent consumed, the volume of the gas evolved and the composition of the gas. We found that 2.8 moles of reagent disappears and that 0.6 mole of gas was liberated. By a suitable contrivance a quantity of the gas was collected over mercury and analyzed. It contained only ethane and ethylene and these were present in the ratio of four to one.

We also repeated the experiment with a reagent made in ethyl ether, but added the oxide to the chilled reagent and decomposed the product an hour later. Under these conditions the amount of reduction produced was much less than that reported by

Kohler and Barrett and in addition to the reduction produced we isolated a small quantity of another solid product. By recrystallization from 50% methyl alcohol this new product was obtained in colorless plates melting at 126°.

Anal. Calcd. for $C_{23}H_{23}O_2N$: C, 80.0; H, 6.7. Found: C, 80.0; H, 6.6.

The composition indicates the addition of C_2H_6 to the oxide, but the substance was obtained in an amount too small for further investigation.

Summary

There are two types of reaction between isoxazoline oxides and organic magnesium compounds.

In one type of reaction the organic magnesium combines at the ends of the unsaturated system $C{=}NO$. The extremely unstable products of this system usually undergo rearrangement to open-chained compounds which react with two more molecules of the reagent.

In another type of reaction the magnesium compounds act as reducing agents. The product of this reaction is an open-chained hydroxy oxime formed by adding two atoms of hydrogen to the oxide.

CONVERSE MEMORIAL LABORATORY
CAMBRIDGE, MASSACHUSETTS

STUDIES IN THE DIPHENYL SERIES. II. SOME ANTIMONY DERIVATIVES OF DIPHENYL

BY DAVID E. WORRALL

RECEIVED JANUARY 16, 1930 PUBLISHED MAY 8, 1930

The physiological activity of certain organo-metallic compounds has revived interest and attention to this great class of compounds in the past two or three decades. This has been particularly true of arsenic and in a previous communication[1] some arsenic derivatives of diphenyl were described. While the antimonials have not been as thoroughly studied, it has been found that in certain diseases of protozoan origin they are even more efficacious than arsenicals, a fact that naturally has stimulated work in this field. No work, however, has been done previously in the diphenyl series; therefore some of the more accessible antimonials containing diphenyl have been prepared in this Laboratory and their properties studied.

Tri-biphenylstibine was obtained, using the method of Michaelis and Reese,[2] by the action of an excess of sodium on 4-chlorodiphenyl and antimony chloride dissolved in benzene. The yield was excellent. As in similar condensations with arsenic chloride, diphenyl was formed as a by-prod-

$$3C_6H_5C_6H_4Cl + SbCl_3 + 6Na = (C_6H_5C_6H_4)_3Sb + 6NaCl$$

---

[1] Worrall, THIS JOURNAL, **52**, 664 (1930).

[2] Michaelis and Reese, ***Ber.***, **15**, 2877 (1882).

uct. Tri-biphenylstibine instantly decolorized bromine or permanganate solutions because of the ease with which it formed pentavalent antimony derivatives. It did not react with methyl iodide, in this respect differing from tri-biphenylarsine. The halogen addition products, tri-biphenylarsine dichloride, for example, were found to be less sensitive to water than the corresponding arsenic derivatives. In other respects the two series of compounds have similar properties, separating from chloroform solution with a molecule of chloroform, decomposing at the melting point, etc.

The mono- and diarylated derivatives were obtained together by long heating of antimony chloride with tri-biphenylstibine. According to Morgan and Micklethwait[3] two reactions take place with triphenylstibine, the second of which is reversible. The changes would be represented as follows with tri-biphenylstibine

$$2(C_6H_5C_6H_4)_3Sb + SbCl_3 = 3(C_6H_5C_6H_4)_2SbCl$$
$$(C_6H_5C_6H_4)_2SbCl + SbCl_3 \rightleftharpoons 2C_6H_5C_6H_4SbCl_2$$

A fairly good yield of the mixture was obtained, but in the separation by fractional crystallization much material was lost and the amounts of pure substances obtained were much less than the theoretical. Vacuum distillation could not be used, as the substances decomposed. The amount of di-biphenylstibine chloride isolated was about one-fourth of that of mono-diphenylstibine chloride. A certain amount of hydrolysis of tri-biphenylstibine, apparently due to wet material, took place when it was heated with antimony chloride for antimonous oxide and diphenyl were isolated from the products of the reaction and identified.

$$2(C_6H_5C_6H_4)_3Sb + 3H_2O = 6C_6H_5C_6H_5 + Sb_2O_3$$

The low yield of the di-phenylstibine chloride led to a study of the effect of heat on tri-biphenylstibine dichloride in the hope that it might give the desired substance by the reaction

$$(C_6H_5C_6H_4)_3SbCl_2 = (C_6H_5C_6H_4)_2SbCl + C_6H_5C_6H_4Cl$$

Such a decomposition actually took place but additional changes followed, for the quantity of desired product isolated was negligible. Considerable chlorodiphenyl was isolated.

Both mono-diphenylstibine dichloride and di-biphenylstibine chloride when hot gave off irritating vapors, but decomposed when the boiling point was attained. They are readily hydrolyzed and can be changed to stibinic acids by treating with chlorine before hydrolysis.

$$C_6H_5C_6H_4SbCl_2 + Cl_2 + 3H_2O = (C_6H_5C_6H_4)SbO_3H_2 + 4HCl$$

The intermediate tetrachloride may be isolated if desired by working with dry reagents. The stibine acids were air dried at 100° before analysis.

---

[3] Morgan and Micklethwait, *J. Chem. Soc.*, **99**,**2286** (1911).

Most of these diphenyl antimony derivatives, as was true of the corresponding arsenicals, decompose when heated; consequently, the melting points vary if the rate of heating changes and are not always easy to reproduce.

Experimental

Tri-biphenylstibine.—To a solution of 100 g. of 4-chlorodiphenyl and 40 g. of freshly distilled antimony chloride in 500 cc. of dry benzene was added an excess (50 g.) of granulated sodium. The mixture was heated under a reflux condenser until boiling started. The reaction subsequently became so vigorous that it was moderated by immersion of the container in ice water. This spontaneous action slackened in about half an hour and heat was again applied for several hours. The product was filtered while hot, the black residue twice extracted with 250 cc. of hot benzene and the combined filtrates concentrated to approximately 250 cc. On addition of an equal volume of warm alcohol the entire mass quickly became semi-solid due to the separation of a bulky crystalline precipitate. It was filtered with difficulty by suction, washed thoroughly with cold alcohol and dried at 100°; yield, 89 g.

Anal. Calcd. for $C_{36}H_{27}Sb$: Sb, 21.0. Found: Sb, 21.2.

The last filtrate was evaporated to dryness and steam distilled. The distillate contaiped diphenyl, identified by its odor and properties, contaminated with some 4-chlorodiphenyl. The residue was not further examined.

Tri-biphenylstibine is easily dissolved by chloroform, methyl iodide or benzene, separating from the latter in microscopic hair-like crystals. It melts at 176.5–177.5" with preliminary softening. Decomposition takes place at the boiling point with the formation of diphenyl and antimony among other things.

Tri-biphenylstibine dichloride, dibromide and di-iodide were obtained by dissolving 5 g. of tri-biphenylstibine in 20 cc. of pure dry chloroform, adding slightly less than the theoretical amount of the corresponding halogen in chloroform and filtering the resulting precipitate. This procedure gave a pure white product, not otherwise obtained With the chloride this precaution was not necessary. The halogen in all cases was instantly absorbed plus considerable heat evolution. The products contained chloroform of crystallization and melted with preliminary softening and decomposition.

	Crystal form	M. p., °C.	Yield. g.	Analysis,[4] %	Calcd.	Found
Dichloride	Small prisms	273–274	5.4	Cl,	9.0	8.9
Dibromide	Narrow plates	259–260	5.6	Br,	18.6	38.4
Di-iodide	Small plates	176–178	6.0	I,	26.6	26.8

Tri-biphenylstibine Hydroxide.—The above halogen derivatives did not react with water, hot or cold, and only slowly with warm 95% ethyl alcohol. Boiling for an hour with alcohol containing ammonia, however, converted them quantitatively into tri-biphenylstibine hydroxide.

Anal. Calcd. for $C_{36}H_{27}Sb(OH)_2$: Sb, 19.8. Found: Sb, 19.6

It is sparingly soluble in hot alcohol, crystallizing out in small flat needles. It begins to sinter at 205° and melts with foaming at 210–211°. The substance is almost insoluble in benzene.

---

[4] A weighed amount of the substance after heating for an hour with alcoholic ammonia was evaporated to dryness, extracted with water, and the filtered solution treated in the usual way with silver nitrate. The chloroform of crystallization escaped intact into the air.

Tri-biphenylstibine **sulfide.**[5]—Microscopic needles from the action of hydrogen sulfide on an alcohol solution of the hydroxide.

Anal. Calcd. for $C_{36}H_{27}SbS$: S, 5.2. Found: S, 5.3.

It softens above 168°, melting with foaming at 173°.

Action of Antimony **Trichloride.**—A mixture of 10 g. of tri-biphenylstibine and 8 g. of antimony in 25 cc. of xylene was heated to 220–240° in a sealed tube for 100 hours. The paste-like product was filtered by suction and washed with cold benzene; yield, 9.6 g. The black filtrate on examination was found to contain an appreciable amount of diphenyl.

The solid product proved to he a mixture of two substances difficult to separate and purify. It was dissolved in hot benzene and the resulting cloudy discolored solution filtered while warm. The filtrate on standing deposited crystals which were removed and the new filtrate further concentrated until a new crop of crystals formed. Each lot was dissolved in warm benzene and the process repeated a number of times. Eventually the mixture was separated into two portions, the less soluble consisting of needle-like crystals and the main part of lustrous plates. Slightly more than half a gram of di-biphenylstibine chloride together with two grams of biphenylstibine dichloride was isolated. The final substances probably contained traces of impurities due to hydrolysis, as a slightly cloudy solution formed when benzene was used as a solvent. This cloudiness could be cleared up with hydrogen chloride gas, in harmony with the fact that the chlorides are much more soluble in benzene than the corresponding oxygen derivatives.

Mono-biphenylstibine Dichloride.—Lustrous white plates from benzene melting with preliminary softening at 132–133°.

Anal. Calcd. for $C_{12}H_9SbCl_2$: Cl, 20.5. Found: Cl, 20.4.

The vapors from the hot substance are irritating to the throat, while the skin of the face is slightly sensitive to the solid itself.

Mono-biphenylstibine Oxide.—Obtained as a white powder from the dichloride by the action of alcoholic ammonia. It softens above 155°, melting slowly at 159–160°.

Anal. Calcd. for $C_{12}H_9SbO$: Sb, 41.9. Found: Sb, 42.2.

Mono-biphenylstibinic Acid.—Biphenylstibine tetrachloride was prepared from the dichloride as a thick sirup which partially crystallized on rubbing with a glass rod, by the action of chlorine in chloroform solution and subsequent evaporation of the solvent. It was converted directly by stirring with water into the stibinic acid, a white powder decomposing above 300°.

Anal. Calcd. for $C_{12}H_{11}SbO_3$: Sb, 37.5. Found: Sb, 37.9.

Di-biphenylstibine Chloride.—Obtained by the action of antimony chloride on tri-biphenylstibine.

Anal. Calcd. for $C_{24}H_{18}SbCl$: Cl, 7.6. Found: Cl, 7.8.

It is less soluble than phenylstibine dichloride, separating from benzene in aggregates of small needles. It softens gradually above 150°, melting at 187–188°.

This substance was also obtained by heating tri-biphenylstibine dichloride above its melting point. Foaming occurred and a perceptible odor of chloroform became evident. On further heating the vapors contained chlorodiphenyl and a substance very irritating to the nose. A good yield of 4-chlorodiphenyl was obtained, but the first-formed di-biphenylstibine chloride obviously underwent decomposition, as only traces of it were isolated.

---

[5] Sulfur was determined by the method of Carius. The organic matter was not completely destroyed, but the residue after dilution with water was removed and found to be sulfur free.

Di-biphenylstibinic Oxide.—Crystalline powder, melting at 120–121" with preliminary softening, obtained from the preceding chloride by the action of alcoholic ammonia.

Anal. Calcd. for $C_{48}H_{36}Sb_2O$: Sb, 27.9. Found: Sb, 28.1.

Di-biphenylstibinic Trichloride.—Pale yellow flat needles from the action of chlorine on di-biphenylstibine chloride dissolved in chloroform. It softens above 200°, melting at 210°.

Anal. Calcd. for $C_{24}H_{18}SbCl_3$: Cl, 19.9. Found: Cl, 20.0.

Di-biphenylstibinic Acid.—White amorphous powder from the trichloride and alcoholic ammonia. It softens above 201° and melts with decomposition at 204–205°.

Anal. Calcd. for $C_{24}H_{19}SbO_2$: Sb, 26.5. Found: Sb, 26.5.

Summary

Tri-biphenylstibine has been obtained by the interaction in benzene solution of chlorodiphenyl, antimony chloride and sodium.

It is converted into a mixture of mono- and di-biphenylstibine chloride by long heating with antimony chloride. Various tri- and pentavalent antimony derivatives of these substances have been prepared.

RESEARCHES ON CKLORIMINES. I. ORTHO-CHLOROBENZALCHLORIMINE AND ANISALCHLORIMINE

BY C. R. HAUSER AND M. L. HAUSER

RECEIVED JANUARY 18, 1930 PUBLISHED MAY 8, 1930

There is evidence[1] that benzalchlorimine has been prepared, but due to its instability it has not been isolated and analyzed. I,uxmoore[2] apparently obtained benzalchlorimine from benz-anti-aldoxime and phosphorus trichloride but the compound decomposed into hydrogen chloride and benzonitrile even below 0°. Later workers[3] apparently obtained impure benzalchlorimine from monochloramine and benzaldehyde but the chlorimine could not be purified as it readily decomposed into hydrogen chloride and benzonitrile.

The decomposition of benzalchlorimine may be represented by the equation, $C_6H_5CH{=}NCl \longrightarrow C_6H_5CN + HCl$. It seemed possible that by substituting electronegative groups in the phenyl radical a more stable chlorimine might result. As a first step in testing this idea, *o*-chlorobenzalchlorimine and anisalchlorimine have been prepared from the corresponding aldehyde and monochlorimine in alkaline solution. Both of these chlorimines are apparently more stable than benzalchlo-

---

rimine. Furthermore, o-chlorobenzalchlorimine is much more stable than anisalchloriminc. This might be explained by assuming an anti configuration[4] for the former chlorimine and a syn configuration for the latter. However, there seems to be evidence that they are both anti compounds. The analogous oximes have anti configurations[5] when prepared from the corresponding aldehydes and hydroxylamine in alkaline solution, and as the chlorimines were prepared by a similar method, possibly they also have anti configurations. Luxmoore's work[2] indicates that *syn*-benzalchlorimine is so unstable as to be incapable of existence. He found that benz-anti-aldoxime with phosphorus trichloride presumably yielded the anti chlorimine, while benz-syn-aldoxime was instantly converted by the same reagent into benzonitrile, which is the decomposition product of the chlorimine. Of course there is a possibility that the latter reaction was simply a dehydration. It would be interesting to repeat Luxmoore's work with syn and anti aldoximes having electronegative groups in the benzene ring.

o-Chlorobenzchlorimine and anisalchlorimine liberate hydrogen chloride slowly at room temperature and more rapidly as the temperature is raised. If anti configurations for these chlorimines are assumed, then either the elements of hydrogen chloride split off directly from the anti compounds or the anti modifications are first transformed into the syn isomers, which then decompose. A trace of hydrogen chloride might favor such a transformation.[6] The isolation of a second isomer should help to decide this.

Since o-chlorobenzalchlorimine is more stable than anisalchlorimine, chlorine in the ortho position appears to have a greater influence on the stability of the chlorimine than has the methoxy group in the para position. A further study of the stabilizing influences of these and other substituent groups is now in progress.

Experimental

o-Chlorobenzalchlorimine[7] and anisalchlorimine, prepared by the condensation of the corresponding aldehyde with monochloramine[1] in cold aqueous solution, were filtered and washed with cold water. Since crude o-chlorobenzalchlorimine melts around 20°, it is best to use a cooled funnel if the temperature of the room is above 20°. How-

---

[4] By analogy with oximes and similar compounds stereoisomeric ald-chlorimines are possible. For stereoisomeric keto-chlorimines, see, Stieglitz and Peterson, *Ber.*, 43, 782 **(1910).**

[5] In this discussion the generally accepted ideas of syn and anti representation are used. Brady and Bishop, however, have presented some evidence that these should be reversed. Brady and Bishop, J. Chem. *Soc.*, **127, 1357 (1925).**

[6] It is interesting to note that although keto-chlorimines could not be induced to change from one isomer to the other by artificial means, the change was effected once when one isomer was allowed to stand for some time. Peterson, *Am. Chem.* **J.,** 46, **325 (1911).**

[7] This chlorimine was previously obtained in an impure condition (see ref. 1).

ever, this precaution is unnecessary in the case of anisalchlorimine as its melting point is higher. A yield of approximately 85% of crude chlorimine was obtained in each case. The chlorimines were recrystallized by dissolving them in 95% alcohol at room temperature, adding just enough water so that the precipitate which formed redissolved on shaking and allowing the solution to stand in an ice-bath or cool place. Since the chlorimines slowly decompose in alcohol as described below, the crystals were filtered shortly after they were formed, pressed on a porous plate until dry and analyzed. Nitrogen was determined by the Kjeldahl method. Active chlorine was determined by treating an alcoholic solution of the chlorimine with potassium iodide solution and concentrated hydrochloric acid and immediately titrating with sodium thiosulfate.

Anal. Calcd. for $ClC_6H_4CH{=}NCl$: N, 8.05; Cl, 20.38. Found: N, 8.07, 8.13; Cl, 20.33, 20.26.

Anal. Calcd. for $CH_3OC_6H_4CH{=}NCl$: N, 8.20; Cl, 20.92. Found: N, 8.19, 8.42; Cl, 20.73, 20.84.

Slightly low results for nitrogen were obtained when anisalchlorimine, either free or in alcoholic solution, was allowed to stand for some time in concentrated hydrochloric acid and then neutralized and distilled into standard acid. Results are liable to be low for active chlorine unless the determination is carried out rapidly using well cooled solutions.

o-Chlorobenzalchlorimine, $ClC_6H_4CH{=}NCl$.—This substance was obtained as small white crystals and melted at 27–29°. By recrystallizing very slowly, small needles were obtained which melted at 28–29°. When the chlorimine was heated above its melting point, a temperature was reached at which it suddenly decomposed rather violently. This decomposition temperature ranged from 120–160°, depending upon the rate of elevation of temperature and possibly upon other factors. About 0.5 g. of one preparation in a small test-tube was immersed in a bath at 146° and the temperature gradually raised to 155°, when the chlorimine suddenly decomposed rather violently, evolving fumes of hydrogen chloride and leaving a residue from which o-chlorobenzonitrile was isolated. The nitrile was identified by the mixed melting point method and by hydrolysis to the corresponding acid.

o-Chlorobenzalchlorimine kept in a desiccator over solid sodium hydroxide for several hours at room temperature was shown by analysis for active chlorine to be practically unchanged. Even after five days an analysis showed that about 90% of the chlorimine remained unchanged.

The chlorimine is also quite stable in benzene solution. A benzene solution of the chlorimine was allowed to stand at room temperatures (18–24°) for fifteen days. When the benzene was allowed to evaporate, an oil was obtained which was identified as slightly impure o-chlorobenzalchlorimine. Recrystallization from alcohol yielded the pure chlorimine.

The chlorimine slowly decomposed in alcoholic solution yielding principally o-chlorobenzaldehyde. The phenylhydrazone of this aldehyde was prepared and identified by the mixed melting point method. Since alcohol was used as the crystallizing solvent, the following preliminary experiment was performed in order to determine whether the rate of decomposition of the chlorimine in alcoholic solution was appreciable. The decomposition of the chlorimine in 95% alcohol solution (approx. 0.2 M) at 12–18° was followed by titrating a 10-cc. portion of the solution with sodium thiosulfate immediately after the solution was prepared and then every twenty-four hours until the decomposition was complete. At the end of the first twenty-four hours the amount of thiosulfate required was practically the same as the amount required for the initial titration. At the end of forty-eight hours a slightly smaller amount of thiosulfate was required. The decomposition then proceeded more rapidly until it was practically complete after five or six days. The acidity of the solution increased as the decomposition proceeded. The increased acidity, due perhaps to the decomposition of some chlorimine or possibly some ethyl hypochlorite, apparently accelerated the rate of hydrolysis of the chlorine. A more detailed study of this will be made.

Anisalchlorimine, $CH_3OC_6H_4CH{=}NCl$.—This substance, obtained as well-formed white crystals from alcohol, melted at 43–44" when it was immersed in a bath at 40° and then heated gradually. Due perhaps to slight decomposition the chlorimine began to soften at a lower temperature when the melting point was determined in the usual way. Similarly to o-chlorobenzalchlorimine, when antsalchlorimine was heated above its melting point, a temperature was reached at which the substance decomposed rather violently into hydrogen chloride and the nitrile. This decomposition temperature varied from **60** to 85°. Doubtless some decomposition occurred at lower temperatures but due to the greatly increased rate of decomposition at higher temperatures the chlorimine appeared to decompose all at once. Sometimes this reaction was almost explosive in nature. When the chlorimine in a melting point tube was immersed in a bath at 69–70° over two minutes elapsed before sudden decomposition occurred. However, at 81–82" violent decomposition took place after several seconds. When a small amount of one preparation was kept at 65° for several minutes the inside of the tube became coated with a white solid. However, when a larger quantity, about 0.5 g., was immersed in a bath at 65" for several seconds, it decomposed violently, evolving hydrogen chloride and leaving a residue from which the nitrile and imine hydrochloride were isolated. Evidently the heat of decomposition of some of the chlorimine raised the temperature of the rest so that the decomposition became violent. The nitrile was identified by the mixed melting point method and by hydrolysis to the corresponding acid. The imine hydrochloride was hydrolyzed to anisaldehyde, which was identified by the preparation of the phenylhydrazone.

Anisalchlorimine decomposes at room temperature more rapidly than o-chlorobenzalchlorimine. After standing in a desiccator over solid sodium hydroxide for twenty-four hours, an analysis for active chlorine indicated that only 8% of the chlorimine remained unchanged. After five days the material had a mouldy appearance and an analysis showed that only a trace of active chlorine was left. When 0 873 g. of this material was warmed with several small portions of anhydrous ether and filtered, **0.346** g. remained as the insoluble portion; calculated by difference, 0.527 g. of the material was dissolved by the ether. When the ether was evaporated about 0.4 g. of residue was obtained, which after recrystallizing from ligroin was identified as anisic nitrile by the mixed melting point method and by hydrolysis to the corresponding acid. The fraction of material insoluble in ether was shown to consist almost entirely of the imine hydrochloride The latter compound was hydrolyzed to ammonium chloride and anisaldehyde and the phenylhydrazone of the aldehyde was prepared. The decomposition of the chlorimine may therefore be represented by the equations

$$2CH_3OC_6H_4CH{=}NCl \longrightarrow 2CH_3OC_6H_4CN + 2HCl$$
$$CH_3OC_6H_4CH{=}NCl + 2HCl \longrightarrow CH_3OC_6H_4CH{=}NH\cdot HCl + Cl_2$$

A crude portion of the chlorimine after standing for several hours in a desiccator spontaneously decomposed rather violently, evolving fumes of hydrogen chloride and leaving a brown residue from which the nitrile was isolated.

Apparently anisalchlorimine also decomposed in benzene solution according to the above equations. After a benzene solution had stood at room temperatures (18–24°) for several days, chlorine was detected above the solution by means of starch–potassium iodide paper. After fifteen days the benzene was allowed to evaporate, and the residue obtained was shown to consist principally of the imine hydrochloride and the nitrile.

Since anisalchlorimine in alcoholic solution yielded principally anisaldehyde, apparently an hydrolysis similar to that described for o-chlorobenzalchlorimine occurred.

Reduction of Anisalchlorimine to *o*-Methoxybenzylamine.—Two grams of the chlorimine in alcoholic solution was reduced with sodium amalgam at about 30° by the method described in a recent paper.[1] A 64% yield of white crystals of amine hydrochloride was obtained.

Anal. Calcd. for $C_8H_{11}ON \cdot HCl$: N, 8.05. Found: N, 8.04.

Summary

o-Chlorobenzalchlorimine and anisalchlorimine were prepared from the corresponding aldehyde and monochloramine. Since the former chlorimine is more stable than the latter, chlorine in the ortho position apparently has a greater influence on the stability of the chlorimine than has the methoxy group in the para position.

The chlorimines decompose slowly at room temperatures and more rapidly as the temperature is raised into hydrogen chloride and the corresponding nitrile.

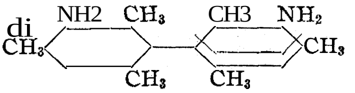
STEREOCHEMISTRY OF DIPHENYL COMPOUNDS. V. PREPARATION AND RESOLUTION OF 2,4,6,2',4',6'-HEXANITRO-3,3'-DICARBOXYDIPHENYL[1]

By L. H. Bock, W. W. Moyer[2] and Roger Adams

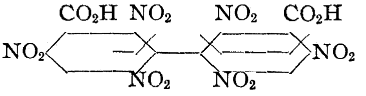
Received January 20, 1930 Published May 8, 1930

The resolution of 2,4,6,2',4',6'-hexamethyl-3,3'-diaminodiphenyl (I)[1b] (diaminodimesityl) demonstrated that the groups in the 2,6,2',6'-positions in diphenyl could all be methyl and still render the molecule capable of existing in optically active forms. The conclusion from this research was that probably any group in place of the methyl would be equally satisfactory for producing similar results providing it is sufficiently large.

In this investigation the preparation of a compound containing four nitro groups in the 2,2',6,6'-positions was undertaken and the specific compound studied was 2,4,6,2',4',6'-hexanitro-3,3'-dicarboxydiphenyl (II).



I



II

This substance is of particular interest as compared to diaminodimesityl because of the entirely different electrochemical character of the nitro

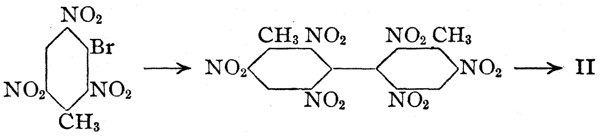
[2] This communication is an abstract of portions of theses submitted by W. W. Moyer and L. H. Bock in partial fulfilment of the requirements for the Degree of Doctor of Philosophy in Chemistry at the University of Illinois.

and methyl groups, due chiefly to the extra unshared electrons in the former. It was found that this compound could be readily resolved through the strychnine salt.

The optically active isomers were resistant to racemization. Ten hours of refluxing in glacial acetic acid or twelve hours of heating at 90–95° in 5% ammonium carbonate solution resulted in essentially no change in rotation. A cold 5% solution of sodium bicarbonate had no effect and heating in the same solution for one and one-half hours at 100° changed the rotation only about 4%. Since this latter treatment caused a coloring of the solution, it is likely that decomposition may have accounted for the slight change. The x-ray data presented in the previous paper would lead to the expectation that the optically active 2,2′,6,6′-tetranitro-3,3′-dicarboxydiphenyl would have no tendency to racemize.

The 2,4,6,2′,4′,6′-hexanitro-3,3′-dicarboxydiphenyl was prepared by nitration of 3-bromotoluene to the trisubstituted derivative (III), condensation of this to 2,4,6,2′,4′,6′-hexanitro-3,3′-dimethyldiphenyl (IV) and oxidation of the methyl groups to the dibasic acid (II).



III IV

The condensation of trinitrobromotoluene to the diphenyl derivative by means of copper was accomplished only after very carefully regulated conditions were discovered. Successful results were obtained with nitrobenzene as a solvent and a temperature about 10° below the point where trinitrobromotoluene and copper give a vigorous exothermic reaction. The oxidation of the condensation product took place readily with a mixture of sodium dichromate, sulfuric acid and fuming nitric acid. The final acid showed no signs of resolution with brucine or quinine but readily separated into two salts with strychnine. Hexanitrodicarboxydiphenyl did not lose carbon dioxide readily, as after heating in various solvents there were no signs of decomposition.

A few words concerning the unsuccessful experiments to obtain 2,4,6,2′,4′,6′-hexanitro-3,3′-dimethyldiphenyl and other compounds with the 2,6,2′,6′-position filled with nitro groups should be included. (1) 3,3′-Dimethyldiphenyl, which was readily prepared by the action of 3-tolylmagnesium bromide with cupric chloride could, in spite of many experiments, be nitrated only to the tetranitro compound with only two of the nitro groups undoubtedly in the desired positions. (2) From tolidine by tetrazotization and treatment with cuprous cyanide, 3,3′-dimethyl-4,4′-dicyanodiphenyl was obtained which was then hydrolyzed to 3,3′-dimethyl-4,4′-dicarboxydiphenyl. Nitration gave what at first appeared to be the desired 2,6,2′,6′-tetranitro compound. A few attempts at resolution failed but no exhaustive study was made owing to the uncertainty of the constitution of the product. (3) Through the 4-chloro derivative of *o*-acetoluidide by hydrolysis, diazotization, introduction of the cyano group and hydrolysis, 4-chloro-2-methylbenzoic acid was obtained. Contrary to the reports in the literature, no dinitro compound could be obtained which it was hoped might be esterified and condensed with copper to the diphenyl derivative, 2,6,2′,6′-tetranitro-4,4′-dicarboxy-3,3′-dimethyldiphenyl.

Experimental

2,4,6-Trinitro-3-bromotoluene.—The preparation was carried out in two steps Dinitro-3-bromotoluene was prepared first as suggested by Grete[3] by the nitration of 3-bromotoluene and then further nitrated to the trinitro compound by the method of Bentley and Warren.[4]

2,4,6,2′,4′,6′-Hexanitro-3,3′-dimethyldiphenyl.—In a 500-cc. three-necked flask fitted with a thermometer and a mechanical stirrer was placed a solution of 110 g. of trinitrobromotoluene in 320 cc. of nitrobenzene. The flask was heated on an oil-bath to 160°, at which point about 5 g. of copper powder (Kahlbaum's Naturkupfer C) was added and the temperature slowly raised to 175° with constant stirring. At this temperature the reaction begins to take place as evidenced by the loss of metallic luster of the copper and a rise in temperature. The flame under the oil-bath was turned low and the temperature was maintained at 175–183° by adding copper powder slowly until 110 g. in all had been used. A higher temperature than 183° must be avoided since this results in a tarry product difficuit to purify. The mixture was stirred for one-half hour at 175–180° after all the copper powder was added. The flask was then allowed to cool and the copper residue was filtered off and washed with acetone. The filtrate and washings were combined and subjected to steam distillation to remove all the nitrobenzene. The product was filtered from the water in the flask, dissolved in about one liter of acetone and refluxed for an hour with 25 g. of norite. The norite was filtered off and the acetone was removed by distillation until the volume was about 100 cc. When allowed to stand for several hours the hexanitromethyldiphenyl crystallized in yellow granular crystals. The product was recrystallized from glacial acetic acid. Fifty-seven grams (70%) of a light yellow product melting at 240–241° was obtained. Hexanitrodimethyl diphenyl is practically insoluble in alcohol and ether but very soluble in acetone. It dissolves in warm benzene, toluene and acetic acid.

Anal. Calcd. for $C_{14}H_8O_{12}N_6$: H, 1.78; C, 37.16. Found: H, 1.87, 1.90; C, 36.72, 37.1.

2,4,6,2′,4′,6′-Hexanitro-3,3′-dicarboxydiphenyl.—A solution was made of 33 g. of hexanitrodimethyldiphenyl in a mixture of 330 cc. of fuming nitric acid (1.52 sp. gr.; moreover, the acid must be of superior grade to give good results) and 115 cc. of 20% fuming sulfuric acid. The solution was placed in a one-liter three-necked flask equipped with a thermometer and a mechanical stirrer. The mixture was cooled to 20° with stirring and 120 g. of sodium dichromate was added slowly over a period of one-half hour. The temperature was maintained below 30°. The temperature rises very slowly and the reaction requires attention for two hours or more in order to maintain the

---

[3] Grete, Ann., 177, 258 (1875).

[4] Bentley and Warren, Am. *Chem.* J., 12, 4 (1800).

proper temperature. The mixture was stirred for twenty hours at room temperature and poured into one kilo of cracked ice. A white powdery precipitate was formed which was filtered off and washed with 20% hydrochloric acid. The solid was dissolved in 250 cc. of cold alcohol and filtered to remove any insoluble unreacted material. The filtrate was treated with concentrated hydrochloric acid to reprecipitate the hexanitrodicarboxydiphenyl. This was filtered and recrystallized from one liter of benzene. A yield of 27 g. (72%) of pure acid was obtained, melting at 292–293°. Hexanitrodicarboxydiphenyl is colorless when pure but rapidly turns yellow when allowed to stand in the air. For this reason it was always dried in a vacuum desiccator. It is very soluble in acetone, alcohol and ether, and warm water. It dissolves slowly in boiling benzene and separates as long colorless needles on cooling.

Anal. Calcd. for $C_{14}H_4O_{16}N_6$: N, 16 41. Found: N, 16 14, 16.57.

Resolution of **2,4,6,2′,4′,6′-Hexanitro-3,3′-dicarboxydiphenyl.**—A solution of 10 g. of hexanitrodicarboxydiphenyl was dissolved in 500 cc. of methyl alcohol and added to 13.5 g. of strychnine dissolved in 3 liters of methyl alcohol. The solution was allowed to stand for several hours and the salt was filtered off. Concentration of the mother liquor showed that practically all of the salt had separated. The salt was dissolved in a mixture of one-third pyridine and two-thirds water by volume and crystallized slowly. The first fractions were recrystallized three times from the same solvent to obtain the maximum levo rotation. The soluble fraction separated as a gum on concentrating the mother liquors. By adding acetone to these mother liquors, the gum crystallized. Two recrystallizations yielded a salt of constant dextro rotation. The yields obtained were about 6 g. of 1-salt and 4 g. of d-salt.

I-Salt. 0.1080 made up to 15 cc. with pyridine at 20° gave a, − 0.54; $l = 1$, $[\alpha]^{20}_{\text{D}}$ −74.7°.

d-Salt. 0.1171 made up to 15 cc. with pyridine at 20° gave a, 0.47, $l = 1$, $[\alpha]^{20}_{\text{D}}$ +60.0°.

No sharp melting point could be obtained for either salt as they decomposed above 250°, the 1-salt decomposing at a slightly higher temperature.

Anal. Calcd. for $C_{56}H_{48}O_{20}N_{10}$: H, 4.1, C, 56.93. Found: *l*-salt—H, 4.0; C, 57.4. *d*-salt—H, 4.2; C, 58.04.

It was found impossible to resolve this compound either by means of brucine or quinine. Attempts to resolve by adding portions of strychnine to the acid and fractionally precipitating salt in this way gave variable results due, probably, to the separation of both normal and acid salt in the fractions.

d- and **l-2,4,6,2′,4′,6′-Hexanitro-3,3′-dicarboxydiphenyls.**—The active acids were liberated from the active salts by treating with hydrochloric acid in alcohol. To a mixture of 150 cc. of 95% alcohol and 40 cc. of concentrated hydrochloric acid was added 4.5 g. of 1-salt. The mixture was placed in a 500-cc. round-bottomed flask and stirred at 60° for two hours. The mixture was then cooled and 50 cc. of concentrated hydrochloric acid was added to insure the complete precipitation of the free acid. The mixture was then cooled to 0° and filtered. The solid obtained was redissolved in 95% alcohol, filtered to remove any undecomposed salt and again precipitated with hydrochloric acid. A yield of 2 g. of acid was obtained. The acid was recrystallized by dissolving in acetone and concentrating until crystals started to separate. An equal volume of benzene was then added and the solution allowed to stand until the acid had all crystallized. A pure acid was then readily obtained but the recovery was very poor. The product melts with decomposition at about 230–240°.

1-acid: 0.1143 g. made up to 15 cc. with acetone at 20° gave α_{D} −0.17°, 1 = 1, $[\alpha]^{20}_{\text{D}}$ −21.84'. 0.2230 g. made up to 25 cc. with acetic acid at 20° gave a, −0.24°, $l = 1$, $[\alpha]^{20}_{\text{D}}$ −27.22'. 0.1034 g. made up to 15 cc. with 5% $NaHCO_3$ solution at 20°

gave α_D −0.55°, 1 = 1, $[\alpha]_D^{20}$ −80.5". 0.1377 g. made up to 25 cc. with 5% $(NH_4)_2CO_3$ solution at 20° gave α_D −0.37°, l = i, $[\alpha]_D^{20}$ −66.74".

The d-acid was obtained from the d-salt by similar treatment. To a mixture of 15 cc. of 95% alcohol and 5 cc. of concentrated hydrochloric acid was added 0.6 g. of d-salt, On stirring, the salt completely dissolved, showing that it decomposed readily in the cold. An additional 5 cc. of concentrated hydrochloric acid was added to precipitate the free acid, and it was purified by the same method as used with the I-acid. About 0.2 g. of d-acid was obtained.

d-Acid. 0.0555 g. made up to 15 cc. with 5% $NaHCO_3$ solution at 20° gave a, +0.29°, 1 = 1, $[\alpha]_D^{20}$ +79.67°.

Racemization Experiments on Active Acids

1. A solution of 0.223 g. of 1-acid in 25 cc. of glacial acetic acid was prepared and the initial specific rotation was [or]? −27.22°. The solution was heated for four hours at 100" in a flask connected with a reflux condenser by a ground-glass connection. The solution showed no change in rotation. The solution was then refluxed for ten hours, when it showed a slightly increased rotation which was probably caused by the concentration of the acetic acid through loss from the top of the condenser. The acid was precipitated by adding an equal volume of concentrated hydrochloric acid. The acid so precipitated was filtered and dried in a vacuum desiccator and the rotation determined.

0.0528 g. made up to 15 cc. with 5% $NaHCO_3$ solution at 20° gave α_D − 0.26°, 1 = 1, $[\alpha]_D^{20}$ −73.89".

2. A 5% sodium bicarbonate solution was made and rotations were read at intervals for three days during which time the solution was stored in a dark place at room temperature.

Initial Rotation.—0.1034 g. made up to 15 cc. with 5% $NaHCO_3$ solution at 20° gave α_D −0.55°, l = 1, $[\alpha]_D^{20}$ −80.5°. Rotation after eighty *hours*.—α_D −0.53°, l = 1. $[\alpha]_D^{20}$ −76.5°.

3. A sodium bicarbonate solution was heated on a steam-bath for one and one-half hours. At the end of this time it was becoming colored so the heating was not continued. The solution was not made up to standard volume but the rotation changed from an initial reading of α_D −0.28" to a final reading of α_D −0.26". The changing of color may have affected the rotation here as in the experiment described above. Sodium carbonate solution could not be used as it became deep red on short standing.

4. A sample of 1-acid was heated in a 5% ammonium carbonate solution for twelve hours on a water-bath at 85–95° The solution did not become colored.

Initial rotation.—0.1377 g. made up to 25 cc. with 5% $(NH_4)_2CO_3$ solution at 25° gave α_D −0.37°, l = 1, $[\alpha]_D^{20}$ −66.74°. Rotation after twelve hours of heating.—a, −0.35"; l = 1, $[\alpha]_D^{20}$ −62.96°.

3,3'-Dimethyldiphenyl.—A Grignard solution was prepared from 342 g. of pure 3-bromotoluene and 49 g. of magnesium turnings in 750 cc. of dry ether and a few crystals of iodine. A suspension of 300 g. of finely powdered anhydrous cupric chloride in 600 g. of ether was added with stirring while the flask was cooled with ice. The mixture was refluxed overnight. Decomposition by pouring on ice and hydrochloric acid yielded 3,3'-dimethyldiphenyl, which distilled at 138–139° at 5 mm. The yield was 118 g. (64%).

Tetranitro-3,3'-dimethyldiphenyl.—To 50 g. of fuming nitric acid cooled to −5° was added slowly, with vigorous stirring, 10 g. of 3,3'-dimethyldiphenyl. The temperature was not allowed to rise above 0° during the whole addition. Then, with stirring, 50 g. of concentrated sulfuric acid was added and the temperature allowed to go up to 60–70°. The mixture was stirred for two hours and then poured on cracked ice. The white product was filtered, washed, dried and recrystallized from 250 cc, of glacial acetic acid until pure. Nine g. of light-yellow crystals of a constant melting point at 234" (corr.) was obtained.

Anal. Calcd. for $C_{14}H_{10}O_8N_4$: C, 46.40; H, 2.78. Found: C, 46.78; H, 2.87.

The acetic acid filtrate from the first recrystallization, upon dilution with water, gave a gummy material, which was recrystallized many times from alcohol. Finally, a substance melting over the range 102–110° was obtained which was not identified.

All attempts at further nitration by heating with fuming nitric and fuming sulfuric acids under varying conditions were unsuccessful.

3,3′-Dimethyl-4,4′-dicarboxydiphenyl.—A solution of 210 g. of concentrated sulfuric acid and 140 g. of water was heated to 160° in a 2-liter, three-necked flask fitted with stirrer, thermometer and reflux condenser. 3,3′-Dimethyl-4,4′-dicyanodiphenyl[5] was added, with vigorous stirring, in small amounts to the hot acid solution. A deep purple color at first appeared, but faded with the separation of a grayish solid. Hydrolysis was continued for five hours at 150–160°, with constant stirring. The reaction mixture was poured into ice water and filtered. The acidic product was dissolved in dilute alkali solution and decolorized with norite. By the addition of hydrochloric acid, the product came down as a gelatinous mass that could not be filtered dry by suction. The wet acid was dried in a vacuum oven at 120°. The weight of crude acid was 71 g., the extra weight over the calcd. 64 g. being due to the inorganic salt occluded in the gelatinous mass. The compound was not further purified, but pulverized, and used in the nitration as such.

Nitration of 3,3′-Dimethyl-4,4′-dicarboxydiphenyl.—In a 1-liter, three-necked flask fitted with a thermometer and mechanical stirrer, was placed 300 g. of fuming nitric acid. The flask was surrounded by an ice-salt freezing mixture and the nitric acid cooled to −5°. Then, with stirring, the 71 g. of crude 3,3′-dimethyl-4,4′-dicarboxydiphenyl described in the last preparation was added in small amounts, while the temperature was kept at 0° or below. Then, through a separatory funnel was added 700 g. of 15% fuming sulfuric acid. The temperature rose to 65°, at which point a solid began to separate from the solution, with foaming. The mixture was stirred for an hour at 65° and then heated to 90° for one-half hour. The cool nitration mixture was poured on cracked ice and the product filtered. The crude product was dissolved in dilute ammonium hydroxide solution and reprecipitated with hydrochloric acid. After filtering and washing the weight was 78 g.

The nitro compound was then decolorized by boiling with norite in 600 cc. of alcohol. The alcohol filtrate from the norite was heated to boiling and hot water was added until turbidity was noticed. On cooling, 40 g. of yellowish-white crystals, powder-like in fineness, were obtained. The melting point was 320–350° with decomposition.

Anal. Neut. equiv. Subs., 0.2070 g. required 12.0 cc. of 0.0733 *N* alkali. Calcd. mol. wt.: 225. Found: 235.

After four crystallizations from dilute alcohol, a product with a neutral equivalent of 227 was obtained. The melting point range was 330–350° due to decomposition dependent upon the rate of heating.

Anal. Calcd. for $C_{16}H_{10}O_{12}N_4$: C, 42.66; H, 2.24. Found: C, 42.66; H, 2.29

Summary

1. 2,4,6,2′,4′,6′-Hexanitro-3,3′-dicarboxydiphenyl has been prepared by condensing 2,4,6-trinitro-3-bromotoluene with copper and oxidizing the resulting 2,4,6,2′,4′,6′-hexanitro-3,3′-dimethyldiphenyl with a mixture of fuming nitric acid, sulfuric acid and sodium dichromate.

---

[5] Löwenherz, *Ber.*, 25,1036 (1892).

2. The compound was readily resolved through the strychnine salt.

3. The active forms did not racemize under the ordinary conditions which might be expected to effect racemization.

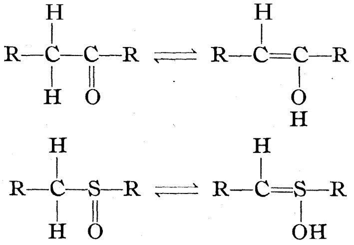
THE PREPARATION AND PROPERTIES OF CERTAIN SULFOXIDES AND SULFONES

BY R. L. SHRINER, H. C. STRUCK AND W. J. JORISON

RECEIVED JANUARY 20, 1930 PUBLISHED MAY 8, 1930

Although the enolization of a methylene group adjacent to a carbonyl group has been thoroughly studied, not much information is available on the behavior of compounds containing other linkages adjacent to a methylene group. The purpose of the present investigation was to study the influence exerted on a methylene group by the sulfoxide and sulfone linkages.

Using the customary notation, a comparison of the following formulas would indicate a similarity in chemical behavior; *i. e.*, under the proper conditions the sulfoxide might be expected to tautomerize in the same manner as the ketone



$$R-\underset{\substack{|\\H}}{\overset{\substack{H\\|}}{C}}-\underset{\substack{\|\\O}}{C}-R \rightleftharpoons R-\overset{\substack{H\\|}}{C}=\underset{\substack{|\\O\\H}}{C}-R$$

$$R-\underset{\substack{|\\H}}{\overset{\substack{H\\|}}{C}}-\underset{\substack{\|\\O}}{S}-R \rightleftharpoons R-\overset{\substack{H\\|}}{C}=\underset{\substack{|\\OH}}{S}-R$$

However, it has been known for some time that the chemical behavior of the sulfoxide linkage does not parallel that of the carbonyl.[1] Moreover, the electronic structures of sulfur–oxygen compounds, as formulated on the Lewis–Langmuir octet theory of valence, do not parallel exactly the electronic structure for carbon–oxygen.[2] The recent work of Sugden, who has found a considerable difference in the parachors of the carbonyl and the sulfoxide[3] groups, and the resolution by Phillips[4] of the sulfinic esters and sulfoxides, have furnished good evidence of the dis-

---

[1] For example, the Grignard reagent does not add to the sulfoxide linkage as it does to the carbonyl linkage. Courtot, "Le Magnesium en Chimie organique," Rigot and Co., **1926**, pp. 125,225, ff.

similarity between these two groupings. The behavior of compounds containing the sulfone group adjacent to a methylene group has been studied in two instances. Michael and Comey[5] and Tröger and Lux[6] have prepared and studied benzene sulfonyl acetic ester, and Schroeder and Herzberg[7] have alkylated the esters of methionic acid. Although many of the simple sulfones of the type RSO_2R are described in the literature, practically no data are available on their properties and especially on the behavior of sulfones with different radicals.

Accordingly, a series of sulfoxides and sulfones was prepared, and their behavior toward reagents which would indicate the influence exerted by these groupings on the adjacent methylene groups studied. The compounds prepared are listed in Table I. They were made by modifications of general methods given in the literature which resulted in increased yields, and hence made larger quantities available for their study. The details of their preparation are given in the experimental part. Table I also lists the effect of various reagents on these sulfoxides and sulfones and summarizes the data obtained.

TABLE I

PROPERTIES OF SULFOXIDES AND SULFONES

Compound	Solubility in 10% NaOH	Solubility in 10% Na_2CO_3	Color with $FeCl_3$	Reaction metallic Na	Salt formation with sodium ethylate	Alkylation with MeI and NaOEt

Theoretical Discussion

The Sulfoxides.—It will be noted that none of the methylene hydrogens in any of the sulfoxides (2, 3, 4) was activated. Diphenyl sulfoxide (1) was prepared and used as a control in order to guard against addition compounds. In each case the result was negative, even compound (4), which possessed a methylene group between two sulfoxide linkages, showed no tendency to alkylate and was recovered unchanged from the attempted alkylations. All of these compounds were insoluble in aqueous sodium and potassium hydroxides, and their benzene solutions did not

---

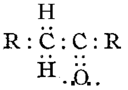
[5] Michael and Comey, *Am. Chem. J.*, 5, 116 (1883).

[6] Tröger and Lux, *Arch. Pharm.*, 247, 618 (1909).

[7] Schroeder and Herzberg, *Ber.*, 38, 3391 (1905).

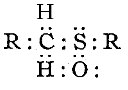
react with metallic sodium. Alcoholic solutions of these sulfoxides did not give any color with ferric chloride. The behavior of these sulfoxides is in sharp contrast to that of the corresponding ketones.

These results furnish further evidence that the nature of the sulfoxide linkage differs from that of the carbonyl. It is of interest in this connection to consider the following electronic formulas



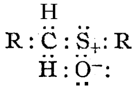
$$\begin{array}{cccc} & H & & \\ R: & \ddot{C} & :C: & R \\ & \ddot{H} & \cdot\ddot{O}\cdot & \end{array}$$

I



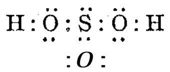
$$\begin{array}{cccc} & H & & \\ R: & \ddot{C} & :\ddot{S}: & R \\ & \ddot{H} & :\ddot{O}: & \end{array}$$

II



$$\begin{array}{cccc} & H & & \\ R: & \ddot{C} & :\ddot{S}_{+}: & R \\ & \ddot{H} & :\ddot{O}^{-}: & \end{array}$$

III



$$\begin{array}{c} H:\ddot{O}:\ddot{S}:\ddot{O}:H \\ :O: \end{array}$$

IV

Formulas II and III are the only ones possible which are consistent with the postulates of the octet theory[2] and Phillips'[4] resolution of the sulfoxides. Formula II is analogous to that given to sulfurous acid (IV) by Latimer and Rodebush[8] and used by them to explain the weakly acidic nature of sulfurous acid. Formula III is given by Sugden,[3] in which the sulfur–oxygen linkage is classed as a semi-polar linkage, *i.* e., a pair of electrons and an electrostatic charge.[9] Formulas II and III are essentially the same, the chief difference being one of notation. Latimer and Rodebush consider that the disproportionation of the electrostatic charges (caused by the fact that the oxygen is held to the sulfur atom by sharing only one pair of electrons, neither of which came from the oxygen atom) is understood as the natural result of writing Formula II. Sugden indicates this electrostatic effect at the sulfur-oxygen linkage in giving Formula[10] III.

In either case both Formulas II and III indicate a different condition of the oxygen atom from (I). It seems probable that it is the unshared pair of electrons on the sulfur atom which prevents the hydrogen atoms from ionizing. Latimer and Rodebush[8] explain the weakly acidic properties of sulfurous acid (IV) as due to the presence of an unshared pair of electrons on the sulfur atom. This mobile pair of electrons prevents the pulling in of the electrons shared between the oxygen and hydrogen in

---

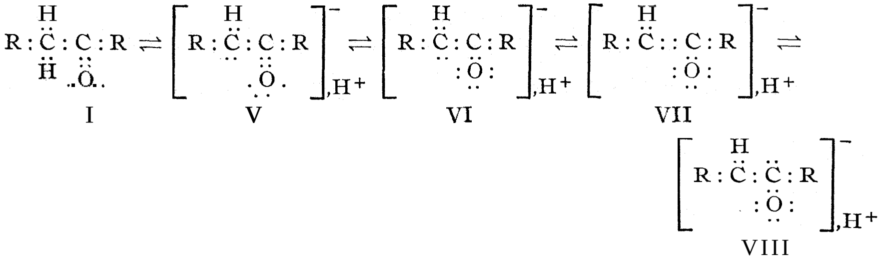
[8] Latimer and Rodebush, THIS JOURNAL, 42,1425 (1920).

[9] The disproportionation of the electrostatic charges can be shown by making use of the formula for the calculation of residual atomic charge. [See Langmuir, *Science*, 54, 59 (1921); Carothers, THIS JOURNAL, 46, 2228 (1924)]. Residual charge $= e - (S - V_e)$ where e is electrons in shell of the atom in free state; S is electrons in shell of the atom in the compound and V_e is valence. For the sulfur in a sulfoxide we obtain: Res. charge $= 6 - (8 - 3) = +1$. For the oxygen, Res. charge $= 6 - (8 - 1) = -1$. This, of course, is the fundamental basis for Sugden's formula.

[10] It is to be emphasized that Sugden's method of indicating the semi-polar double bond is a separate and distinct notation. The presence of the plus and minus signs does *not* indicate unit charges as in the case with H^+, Cl^- where there is the complete transference of an electron. It also has nothing in common with the use of plus and minus signs used by Fry, Lowry, Ingold and others to denote an alternating polarity.

the case of sulfurous acid and it seems probable that the same explanation will hold for the sulfoxide (II or III) where the unshared pair prevents the pulling in of the electrons between carbon and hydrogen.

Further support for this explanation may be obtained by considering the process of enolization of a ketone. In terms of the electron theory enolization may be regarded as a change from the non-polar form of (I) to the polar forms of (V, VI, VII, VIII), this transformation being due to the pull exerted by the oxygen atom on the electrons. These stages in the enolization of a carbonyl compound may be indicated as follows



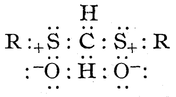
All four of the above polar forms are undoubtedly in equilibrium with each other and the electrostatic charges change from carbon to oxygen according to solvents and reagents.

Now it is well known that only one of the hydrogens is tautomeric at a time; *i.* e., only one can be replaced by sodium and the second one does not ionize off or does so only to a very, very slight extent. The anions (V, VI, VII and VIII) would have to dissociate again and they exhibit no such tendency. Now these anions resemble, in one respect at least, the normal structure for the sulfoxides; i. e., there is present in (V, VI and VIII) an unshared pair of mobile electrons which act to prevent any further ionization of the second hydrogen atom of the adjacent carbon. Hence, in the sulfoxides which also possess an unshared pair of electrons (Formulas II, 111), the ionizing tendency should resemble the secondary ionization of (V, VI, VII, VIII); *i.* e., they should not undergo enolization. This is in agreement with the experimental data. It also receives confirmation from the data obtained on the corresponding sulfones.

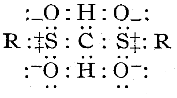
The Sulfones.—By reference to Table I it will be noted that the methylene hydrogens of the sulfones were activated in each case, the greatest activity being exhibited by Compound 7, which was readily soluble in sodium hydroxide and easily alkylated. The behavior of the sulfones is in sharp contrast to the behavior of the sulfoxides, which exhibited no such tendency. Dibenzoylmethane, which is the carbonyl compound analogous to methylene diphenyldisulfone, undergoes enolization[11] and may be alkylated but it is not soluble in aqueous alkalies. This behavior

[11] Claisen, *Ann.*, **277,** 184 (1893); **291,** 25 (1896).

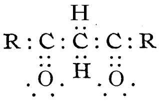
constitutes still further evidence of the difference between the carbon–oxygen linkage and the sulfur–oxygen linkage. It is of interest to compare in this connection the electronic formulas for the sulfoxides, sulfones and carbonyl compounds



IX



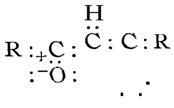
X



XI

The first two formulas make use of the semi-polar linkage developed by Sugden as the result of the calculation of the parachors for sulfoxides and sulfones.[3] It has already been pointed out that the failure of the hydrogen of the methylene group in the sulfoxide (IX) to ionize was probably due to the presence of the unshared pair of electrons on the sulfur atom. The sulfone (X) contains no unshared pairs of electrons on its sulfur atoms. Each sulfur atom in the above sulfone has two semi-polar linkages, which results in the sulfur being doubly positive.[12] This resultant residual positive charge on the sulfur atom causes a distortion or pull on the electrons in the octet about the carbon of the methylene group which pulls in one pair of electrons and thus renders one of the hydrogens active. Since (X) has two sulfone groups, one on each side of the methylene group, the hydrogens in the latter group should be activated very readily. Compound 5 having only one sulfone group and a phenyl group about the methylene group should give rise to active hydrogens less readily and in dibenzyl sulfone (6) the distorting effect caused by the sulfonyl group is distributed among two methylene groups and hence this compound is the least active of the three.

The diketone (XI) contains a non-polar double bond on each of the carbons of the carbonyl group. The enolization of this substance is due to its transformation under the influence of reagents into one of the active forms of the double bond between carbon and oxygen.[13] If we suppose this conversion to result in the momentary production of the form shown, then it is evident that one carbonyl carbon carries a residual atomic charge of plus one and hence exerts a pull on the electrons of the octet about the methylene carbon atom with resultant activation of the hydrogen. Since the carbon in the above diketone carries a residual charge of only plus one, while the sulfur atoms in the disulfone (X) have a residual charge of plus two, it is now clear that the methylene hydrogens in (X) should be more active than those in (XI). This is in agreement with the experimental facts.

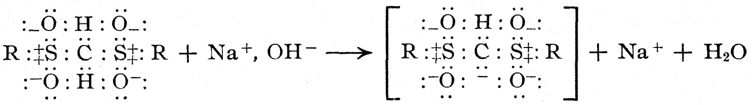


---

[12] *Cf.* Ref 9. The approximate residual charge calculated from the formula $e - (S - V_e)$, for the sulfur atom is $6 - (8 - 4) = +2$. This does not mean that there are two ***unit*** charges on the sulfur atom. See Ref. 10.

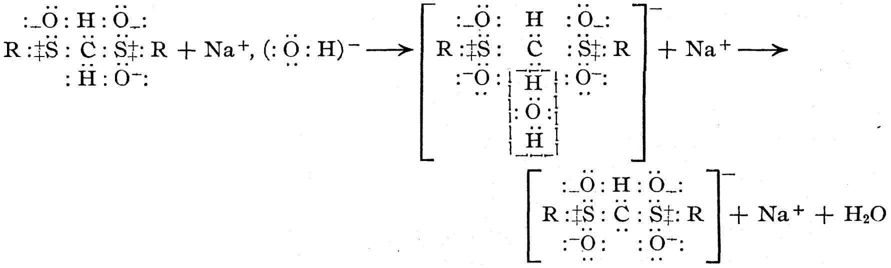
[13] Carothers, THIS JOURNAL, 46, 2229 (1924).

The conversion of the sulfone (X) into a salt under the influence of alkalies is of considerable theoretical interest since it is the first case in which the position of one of the residual negative charges is unquestionably on the methylene carbon atom.



It is obviously impossible to write any other electronic formula without violating the postulates of the octet theory. This, of course, does not mean that the sodium is attached to the carbon atom. This compound is an excellent example of the redistribution of electrostatic charges about the molecule in accordance with the reagents acting upon it. The second point of theoretical interest is that in the case of this sulfone the sodium salt is *not* formed as the result of a primary transformation to a true *enol* form,[14] with ionization of the enolic form, and finally combination of the hydrogen ion with the hydroxyl ion.

Since no true enol form exists, the formation of the sodium salt probably takes place by a combination of the sulfone with hydroxyl ion by means of a "bivalent" hydrogen[15] of the methylene group and subsequent elimination of a molecule of water. The following equation represents this type of transformation

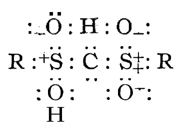


Experimental

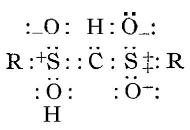
Preparation of Diphenyl Sulfoxide.—One hundred grams of benzene and 33 g. (0.28 mole) of thionyl chloride were placed in a 500-cc. round-bottomed flask. The

---

[14] The possibility of an enol form of either of the following forms is extremely improbable



A



B

Form (A) leaves an unshared pair of electrons on the central carbon and (B) puts ten electrons in the valence shell of sulfur.

[15] Lewis, "Valence arid the Structure of Atoms and Molecules," The Chemical Catalog Company, New York, 1923, p. 109.

mixture was immersed in an ice-salt bath and 60 g. of anhydrous aluminum chloride added in 0.5-g. portions over a period of two hours. Then 40 g. of benzene was added and the solution refluxed on a steam cone until no further hydrochloric acid gas was evolved.

After about one hour the contents were poured slowly on 600 g. of cracked ice which had been slightly acidified with dilute hydrochloric acid. A vigorous reaction took place and the yellow oil which separated was removed and washed four times with 50-cc. portions of distilled water. The excess benzene was driven off by distillation and the reddish-brown oil that remained solidified upon cooling. The diphenyl sulfoxide was extracted with (70-90") petroleum ether. Ten to fifteen extractions were necessary to completely remove the sulfoxide. It was a white crystalline substance, m. p. 70–71°, which agreed with the value given by previous investigators;[16] yield, 28.9 g. or 51%.

Anal. (Parr Bomb) Subs., 0.5158: $BaSO_4$, 0.5912. Calcd. for $C_{12}H_{10}SO$: S, 15.84. Found: S, 15.72.

Preparation of Dibenzyl Sulfide.[17]—One hundred and sixteen g. (0.56 mole) of benzyl chloride was dissolved in 300 cc. of 95% alcohol. The solution was then heated on the steam cone and 35 g. of sodium sulfide, which had been dissolved in 100 to 125 cc. of distilled water, was added. The mixture was stirred continuously and heated on the steam-bath for three days. The greater portion of the alcohol was distilled and the contents were then poured on 700 g. of cracked ice. The yellowish-brown oil which separated was removed and vacuum distilled to remove water and excess benzyl chloride. The distillation was accomplished by heating until the temperature of the vapors reached 134°, or until the distillate in the receiving flask began to solidify. The residual oil was then placed in the ice box until it solidified and was recrystallized from 70% alcohol; m. p. 49°; yield, 48 g. or 83%.

Preparation of Dibenzyl Sulfoxide.—Thirty grams of dibenzyl sulfide was dissolved in 250 cc. of acetone. The solution was filtered to remove undissolved substances. Then 15 g. of 30% hydrogen peroxide was added, the solution thoroughly shaken and allowed to stand at room temperature for forty-eight hours. The acetone was distilled and the oily residue cooled. It solidified to a white crystalline solid which was purified by recrystallization from petroleum ether;[18] m. p. 132–133°; yield, 22 g. or 75%.

Anal. Subs., 0.5463: $BaSO_4$, 0.5519. Calcd. for $C_{14}H_{14}SO$: S, 13.91. Found: S, 13.93.

Preparation of Benzyl Phenyl Sulfide.—Twelve grams (0.52 mole) of metallic sodium was dissolved in 300 cc. of absolute alcohol in a 1-liter three-necked flask fitted with a reflux condenser and a mechanical stirrer. Then 57 g. of thiophenol was added in a slow but steady stream. Next 68.8 g. of benzyl chloride was added drop by drop over a period of one and one-half hours and the mixture refluxed on a steam-bath for two hours. The alcohol was practically all distilled and while the solution was still hot it was poured on 400 g. of cracked ice. The impure sulfide was filtered and washed twice with 50-cc. portions of distilled water to remove any traces of sodium chloride. The sulfide was a white, crystalline compound;[19] m. p. 40–41°; yield, 61 g. or 60%.

Preparation of Benzyl Phenyl Sulfoxide.—Fifty-two grams of the sulfide was dissolved in 250 cc. of acetone. The solution was filtered to remove any undissolved substances. Then 40 g. of 30% hydrogen peroxide was added, the mixture thoroughly

shaken and allowed to stand at room temperature for seventy-two hours. The acetone was evaporated and the oil which remained solidified immediately upon slight cooling. The sulfoxide was recrystallized from 60% alcohol; m. p. 122–123°; yield, 40 g.

Anal. Subs., 0.4709: $BaSO_4$, 0.5105. Calcd. for $C_{13}H_{12}SO$: S, 14.81. Pound: S, 14.86.

Preparation of Methylene Diphenyl **Disulfide.**—This intermediate was prepared by modifying methods previously given by Otto and Tröger,[20] Baumann[21] and Fromm.[22] Twenty-three grams (1 mole) of metallic sodium was dissolved in 400 cc. of absolute alcohol. The mechanical stirrer was started and 110 g. (1 mole) of thiophenol was added in a slow but steady stream. Then 86.9 g. (0.5 mole) of methylene bromide was run in drop by drop. The addition of the methylene bromide took one hour. The mixture was refluxed, with stirring, on a steam-bath for two and one-half hours. The hot contents were immediately poured on 1000 g. of cracked ice. The solid product 'which separated was filtered and recrystallized from 95% alcohol. It was a white, crystalline powder; m. p. 35–36°; yield, 112 g. or 96.5%.

Anal. Subs., 0.3144: $BaSO_4$, 0.6294. Calcd. for $C_{13}H_{12}S_2$: S, 27.54. Found: S, 27.48.

Preparation of Methylene Diphenyl **Disulfoxide.**—Fifty grams of methylene diphenyl disulfide was dissolved in 400 cc. of acetone and filtered to remove any undissolved substances. Then 58 g. of 30% hydrogen peroxide was added. The mixture was allowed to stand at room temperature for forty-eight hours and heated for six hours at 37.5°. The acetone was distilled and the oil which remained behind was placed in the ice box overnight. The water was decanted and the solid disulfoxide was recrystallized five times from alcohol; m. p. 188–189°; yield, 30 g. or 52%.

Anal. Subs., 0.5004: $BaSO_4$, 0.8836. Calcd. for $C_{13}H_{12}S_2O_2$: S, 24.25. Found: S, 24.21.

Preparation of Phenyl Benzyl **Sulfone.**—Phenyl benzyl sulfone was prepared by the method given by Otto.[23] A mixture of 178 g. (1 mole) of sodium benzene sulfinate and 127 g. (1 mole) of benzyl chloride in 500 cc. of absolute alcohol was refluxed for seven to eight hours. The sulfinate did not dissolve completely, but this did not interfere with the reaction. The hot reaction mixture was poured into 1000 cc. of ice water. The crude product was filtered and dried. It was recrystallized from alcohol; m. p. 146–146.5°; yield, 120 g. (52%).

Anal. Subs., 0.5330: $BaSO_4$, 0.5363. Calcd. for $C_{13}H_{12}O_2S$: S, 13.78. Found: S, 13.80.

Preparation sf **Dibenzyl Sulfone.**—Twenty-five grams (0.11 mole) of dibenzyl sulfide was dissolved in 130 cc. of glacial acetic acid, and 32 g. of CrO_3 added over the period of an hour. The reaction was started by the application of heat, but, once started, it proceeded smoothly. After the CrO_3 was added, the mixture was refluxed gently for fifteen minutes. The hot solution was poured directly on 500 g. of crushed ice. The precipitate was filtered and washed with ice water. Recrystallization three times from 95% alcohol gave white needles; m. p. 149.5–150". This melting point agrees with that of Vogt and Henniger,[24] who prepared it by the action of benzyl chloride on potassium sulfite; yield, 7 g. or 23.7%.

Preparation of Methylene Diphenyl Disulfone.—A modification of the methods of Otto and Tröger[20] and Fromm[22] was used; 18 g. (0.077 mole) of crude methylene diphenyl disulfide was dissolved in 80–100 cc. of glacial acetic acid and 42 g. of CrO_3 was added slowly over a period of one and one-half hours. The flask was warmed at first, but later the reaction proceeded smoothly without further heating. After the reaction had stopped, the hot mixture was poured on 1000 g. of crushed ice. The crude methylene diphenyl disulfone was filtered by suction and washed with ice water. Recrystallization twice from water gave white needles; yield, 4.2 g. (18% of the theoretical); m. p. 118–119°.

Anal. Subs., 0.4888: $BaSO_4$, 0.7640. Calcd. for $C_{13}H_{12}O_4S_2$: S, 21.62. Found: S. 21.48.

Properties of Sulfoxides

I. Solubility in Alkali.—The solubilities of the above four sulfoxides in 5 and 10% sodium and potassium hydroxides were tested. None of the compounds dissolved.

II. Metallic Sodium.—A solution of 0.5 g. of each of the above sulfoxides in dry benzene was treated with 0.1 g. of sliced sodium. No reaction took place in the cold.

III. Ferric Chloride.—Addition of ferric chloride to alcohol solutions of these sulfoxides caused no deepening of the yellow color as compared with a blank alcohol solution.

IV. Attempted Alkylations.—All three of the above sulfoxides were treated with sodium ethylate in absolute alcohol and methyl iodide added. A typical experiment is as follows.

Attempt to Alkylate Methylene Diphenyl Disulfoxide.—Eighty-seven hundredths gram of metallic sodium was dissolved in 100 cc. of absolute alcohol and 10 g. of methylene diphenyl disulfoxide was added. The solution was heated to dissolve the disulfoxide and 17 g. of methyl iodide was added slowly over a period of fifteen minutes with vigorous shaking. The mixture was then refluxed on a steam-bath for three hours and the hot contents poured on 200 g. of cracked ice. The reddish-brown solid upon recrystallization was found to be the original compound; m. p. 188–189°.

Properties of Sulfones

I. Solubility in Dilute Alkalies.—The solubilities of the three sulfones in 10% sodium and potassium hydroxides were tested. It was found that methylene diphenyl disulfone dissolved readily, phenyl benzyl sulfone only partially and dibenzyl sulfone not at all. All of the sulfones were completely insoluble in 6 N hydrochloric acid and this reagent was used to precipitate the first two compounds above from their alkaline solutions. All of the sulfones were insoluble in 5 and 10% sodium carbonate solution.

II. Metallic Sodium.—A solution of 0.5 g. of each of the above sulfones in dry benzene was treated with 0.1 g. of sliced sodium. Hydrogen was liberated very slowly and the sodium became coated with the salt after about half an hour.

III. Ferric Chloride.—Addition of dilute ferric chloride to alcohol solutions of these sulfones caused no deepening of the yellow color as compared with a blank alcohol solution.

IV. Alkylations.—The alkylation of phenyl benzyl sulfone and dibenzyl sulfone was attempted using the same procedure outlined above. Both compounds failed to alkylate and were recovered almost quantitatively from the reaction mixture unchanged.

Alkylation of Methylene Diphenyl Disulfone

(a) With One Equivalent of Methyl Iodide.—To a solution of 0.23 g. (0.01 mole) of sodium in 300 cc. of absolute alcohol was added 3 g. (0.01 mole) of methylene diphenyl disulfone. Next, 1 cc. (slight excess) of methyl iodide was added and the mixture refluxed for two and one-half hours; 150–200 cc. of alcohol was distilled from the mixture and the residue poured on crushed ice. The precipitate was filtered by suction and washed with ice water. Four recrystallizations from alcohol gave white needles: yield, 1 g. (47.6%); m. p. 100–101"; mixed melting point with original disulfone (m. p. 118–119°), 80–86°; mixed melting point with disubstitution product (m. p. 181–182°), 94–98°.

Anal Subs., 0.2821: $BaSO_4$, 0.4151. Calcd. for $C_{14}H_{14}O_4S_2$: S, 20.64. Found: S, 20.22.

(b) With Two Equivalents of Methyl **Iodide.**—To a solution of 0.46 g. (0.02 mole) of sodium in 300 cc. of absolute alcohol was added **3** g. (0.01 mole) of methylene diphenyl disulfone. Next, ***2.5*** cc. (slight excess) of methyl iodide was added and the mixture refluxed for two and one-quarter hours; 150 cc. of alcohol was distilled from the flask and the residue poured on crushed ice. The product was filtered bv suction and washed with ice water. Three recrystallizations from alcohol gave white needles: m. p. 181–182°; mixed melting point with original disulfone (m. p. 118–119°), 101–105°.

Anal. Subs., 0.4672: $BaSO_4$, 0.6723. Calcd for $C_{15}H_{16}O_4S_2$: S, 19.75. Found: S, 19.76.

Summary

1. The preparation and enolization tendency of certain sulfoxides have been studied. It was found that the sulfoxides do not tautomerize into enolic forms under the conditions used.
2. Phenyl benzyl sulfone, dibenzyl sulfone and methylene diphenyl disulfone were prepared and their properties studied.
3. The hydrogen of the methylene group in methylene diphenyl disulfone was most active and the hydrogen in dibenzyl sulfone least active.
4. In each case the sulfone group activated the hydrogens to a much greater extent than the sulfoxide group.
5. Some of the theoretical aspects of the behavior of these compounds are discussed.

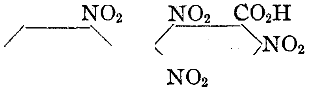
STEREOCHEMISTRY OF DIPHENYL COMPOUNDS. VI. PREPARATION AND RESOLUTION OF 2,4,6,2′,4′-PENTANITRO-3-CARBOXYDIPHENYL[1]

BY H. A. STEARNS[2] AND ROGER ADAMS

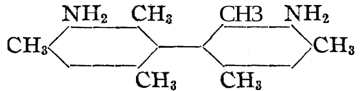
RECEIVED JANUARY 21, 1930 PUBLISHED MAY 8, 1930

Only two 2,2′,6-trisubstituted derivatives of diphenyl have as yet been prepared and resolved. Both of these compounds were readily racemized in alkaline solution. Pertinent information concerning the phenomenon of optical activity in the diphenyl series should be obtained more readily by a study of 2,2′,6-trisubstituted compounds than from the 2,2′,6,6′-tetrasubstituted compounds.

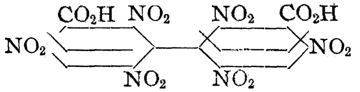
In this communication is given the description of 2,4,6,2′,4′-pentanitro-3-carboxydiphenyl (I), the first trisubstituted derivative prepared with the 2,2′,6-positions filled with the same groups and with each of the rings unsymmetrical in itself. As might be anticipated after the preparation and resolution of 2,2′,6,6′-tetramethyl-3,3′-diaminodiphenyl (II) and 2,4,6,2′,4′,6′-hexanitro-3,3′-dicarboxydiphenyl (111), this trisubstituted compound was readily resolved. Further evidence is thus submitted that the mechanical interference of the groups is preventing free rotation of the rings.



I



II



III

The active forms of 2,4,6,2′,4′-pentanitro-3-carboxydiphenyl are stable to racemization. Eight hours of boiling in ammonium carbonate solution or six hours of boiling in glacial acetic acid, or several days' standing in cold sodium carbonate solution failed to change the rotation, and eight hours of boiling in 95% acetic acid saturated with hydrogen chloride failed to change the rotation more than slightly. Hot sodium carbonate solution caused a deep reddening of the solution so that possible racemization could not be determined.

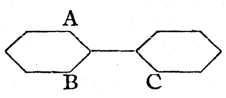
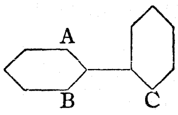
[2] This communication is a portion of an abstract of a thesis submitted by H. A. Stearns in partial fulfilment of the requirement for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

The probable effects within these trisubstituted molecules should be considered. If it is assumed that the two rings remain symmetrically placed toward each other when they arrive in or approach the same plane, then all that should be required for a substance to be capable of resolution is to have in the general formula (IV), group C large enough to interfere materially with B and with A.



IV



V

If the interference at either or both points is small, the compound should racemize more or less readily. If, however, the two rings may be assumed to bend toward each other when the same plane for both rings is approached closely (in the manner represented in V), it is conceivable that non-resolution of certain compounds which should otherwise be capable of resolution might be expected. Though during the process of resolution much distortion of this kind seems unlikely, it might well occur under the conditions used in racemization experiments and consequently racemization of certain compounds might readily take place.

A 2,2′,6-trinitro compound from this standpoint would give the following results. Using the values[1d] $\mathrm{C{-}NO_2}$, 1.92 Å; C–H, 0.92 Å.; C–C (2,2′), 2.90 Å, the interference of two nitro groups will be as follows: 1.92 Å. + 1.92 Å. = 3.84 Å. − 2.90 Å. ⟶ + 0.94 Å., a large difference compared to what was found necessary for interference in the tetrasubstituted compounds. At the same time on the other side of the molecule the nitro and the hydrogen would not collide at all; 1.92 Å. + 0.92 Å. = 2.84 Å. − 2.90 Å. ⟶ −0.06 Å. If the molecules were distorted so that the nitro and the hydrogen pulled toward each other more than 0.06 Å., collisions would occur on both sides of the molecule simultaneously, without reducing to any great extent the interference between the two nitro groups. In such a molecule racemization would not be expected and does not occur.

On the other hand, such a compound as 2,6-diamino-2′-methyldiphenyl presents other possibilities. Using the values, $\mathrm{C{-}NH_2}$, 1.56 Å.; $\mathrm{C{-}CH_3}$, 1.73 Å.; C–H, 0.92 Å., on the side of the molecule holding the amino and methyl groups the interference would be as follows: 1.73 Å. + 1.56 Å. = 3.29 Å. − 2.90 Å. ⟶ +0.39 Å. On the other side of the molecule 1.56 Å. + 0.92 Å. = 2.48 Å. − 2.90 Å. ⟶ −0.42 Å. Upon the assumption of a symmetrical position for the two rings at all times, resolution of the compound should take place readily and the active compounds should not racemize at all or at least not readily. On the other hand, if the amino and the hydrogen are pulled toward each other to the extent of 0.39 Å., then the groups could pass by each other without collisions on either side of the molecule. Although it is improbable that such a distorted position would exist so as to prevent resolution, it is likely that under certain conditions it might be approached to an extent which would allow easy racemization of the active compounds. The extent to which the possible distortion might occur in various molecules will, of course, depend upon the character of the groups present. It is of little value to speculate further with the x-ray data until more facts are available.

In connection with the assumptions just made, it is necessary to consider the 2,4′-dinitro-6,6′-dicarboxydiphenyl[3] and the 2,4,4′-trinitro-6,6′-dicarboxydiphenyl,[4] both of which have two carboxyls and one nitro group in the critical positions. Using the values given previously and in addition C–COOH, 1.56 Å., the side with two carboxyls would give the following results: 1.56 Å. + 1.56 Å. = 3.12 Å. − 2.90 Å. ⟶ +0.22 Å. On the other side, 1.92 Å. + 0.92 Å. = 2.84 Å. − 2.90 Å. ⟶ −0.06 Å. It is obvious, then, that not much distortion would be necessary in such a molecule to reduce the interference to the point where racemization would take place. These substances do racemize slowly by heating at 100° with sulfuric acid. On the other hand, if the size of the carboxyl groups is decreased, as happens when ionized, racemization should be comparatively rapid. Results have shown these compounds to racemize readily in alkaline solution.

The 2,4,6,2′,4′-pentanitro-3-carboxydiphenyl was prepared by condensing, under carefully specified conditions, 2,4,6-trinitro-3-bromotoluene and 2,4-dinitrochlorobenzene by means of copper. The resulting compound, 2,4,6,2′,4′-pentanitro-3-methyldiphenyl was oxidized with a mixture of fuming nitric acid, fuming sulfuric acid and sodium dichromate to the corresponding carboxylic acid. This latter compound was resolved readily through the strychnine salt.

Experimental

2,4,6,2′,4′-Pentanitro-3-methyldiphenyl.—In a 1-liter flask equipped with a mechanical stirrer were placed 133 g. of 2,4-dinitrochlorobenzene, 100 g. of 2,4,6-trinitro-3-bromotoluene,[5] 240 cc. of nitrobenzene and 3 g. of copper bronze. The mixture was stirred and heated on an oil-bath until the contents of the flask had reached a temperature of 160°, at which temperature brown copper halides began to form. The oil-bath was then removed, and 230 g. of copper bronze was added at such a rate that the reaction mixture remained at a temperature of 160–165° during the addition. Exterior heating was then continued so that the mixture remained within this temperature range for a total period of one hour.

The hot reaction mixture was filtered, the copper residues extracted with acetone and the extract added to the filtrate. Acetone and nitrobenzene were then removed from the products by means of a steam distillation. The product was next washed with

[4] Kuhn and Albrecht, *Ann.*, 455, 272 (1927); 458, 221 (1927).

[5] Bentley and Warren, *Am. Chem. J.*, **12**, 4 (1890).

alcohol to remove traces of nitrobenzene, dissolved in acetone and this solution refluxed with norite for one-half hour. After filtration, the acetone was evaporated off and the residue washed twice with alcohol, then recrystallized from glacial acetic acid until a melting point of 200–201° was reached. Finally, the product was dissolved in a minimum of boiling acetone, and thrown out of solution as a fine, white, granular powder by the addition of a large excess of alcohol; melting point, 200–201°. The yield was about 52 g. (40%).

Anal. Calcd. for $C_{13}H_7O_{10}N_5$: C, 39.69; H, 1.80. Found: C, 39.74; H, 2.08.

2,4,6,2′,4′-Pentanitro-3-carboxydiphenyl.—In a 1-liter flask provided with a mechanical stirrer and cooled by means of a salt–ice-bath was placed 20 g. of pure 2,4,6,2′,4′-pentanitro-3-methyldiphenyl dissolved in 220 cc. of fuming nitric acid[6] (sp. gr. 1.52). Eighty cubic centimeters of fuming sulfuric acid (20%) was added to the stirred mixture at such a rate that the temperature did not rise above 20° during the addition. To the stirred and cooled solution, 40.4 g. of powdered potassium dichromate was added at such a rate that the temperature of the solution did not rise above 10° during the addition (about three-quarters of an hour). Stirring was continued for twenty-four hours, and the bath was permitted to rise slowly to room temperature during this period. The reaction mixture was then poured into a large excess of ice and the free acid obtained by filtration. The acid was purified by recrystallization from benzene and formed a fine, white, crystalline powder of m. p. 205–206°. The yield was 7 g. (32.5%).

The yield from this reaction varied from 30 to 50% for successive runs, apparently because of a difference in purity of the crude acid obtained. The crude acid varies considerably in purity depending upon conditions which have not been defined. If, upon one crystallization from benzene, the melting point of the crude acid rises, further recrystallization will readily purify it; on the other hand, if the melting point lowers or if, for any other reason, the acid acts peculiarly, it is advisable to purify through the pyridine salt. This was precipitated from a saturated alcoholic solution of the acid by the slow addition of its chemical equivalent of pyridine. The salt was extracted twice with small amounts of boiling benzene, then dissolved in a minimum of acetone, and the free acid obtained by the addition of excess concentrated hydrochloric acid to this solution. The acetone solution was cooled and stirred during the hydrochloric acid addition, and the acid so obtained was recrystallized from benzene.

Anal. Calcd. for $C_{13}H_5O_{12}N_5$: C, 36.88; H, 1.19; N, 16.55. Found: C, 36.98; H, 1.83; N, 16.88.

Resolution of 2,4,6,2′,4′-Pentanitro-3-carboxydiphenyl.—To a solution of 10.2 g. of 2,4,6,2′,4′-pentanitro-3-carboxydiphenyl in 700 cc. of methyl alcohol was added slowly and with stirring 800 cc. of a solution of 8.08 g. of strychnine in 2 liters of methyl alcohol. The solution was cooled to 0° and allowed to stand for one hour. A crop (7.5 g.) of pale yellow, needle-like crystals (A) was obtained. To the mother liquor from (A) was added an additional 300-cc. portion of the strychnine–methyl alcohol solution. The resulting mixture was evaporated to about 700 cc. under diminished pressure and a second crop (3 g.) of yellow crystals (B) was filtered off. To the mother liquor from (B) was added the remainder of the strychnine solution. This mixture was evaporated to a volume of about 300 cc., cooled overnight at 0°, and a third crop (7.8 g.) of orange-colored, granular crystals (C) obtained.

Crystals (A) were purified by dissolving them in a minimum of warm acetone and adding to this stirred solution petroleum ether until the solution was slightly opaque. Upon standing overnight at 0°, the salt separated as fine, pale yellow needles. The

---

[6] A good grade of fuming nitric acid is important. Inferior grades give much poorer results.

purified salt turns red at 265° and melts with decomposition at some point between 270 and 280°. Two successive recrystallizations of salt **(A)** sufficed to bring the salt to a constant rotation.

Rotation. 0.1373 g. of salt made up to 15 cc. with pyridine at 20° gave om $-1.13°$; $l = 1$, $[\alpha]^{20}_{D}$ $-123.5°$.

Anal. Calcd. for $C_{34}H_{27}O_{14}N_7$: C, 53.88; H, 3.59. Found: C, 53.75; H, 4.06.

Strychnine salt (C) was purified by dissolving it in boiling alcohol, evaporating this solution down to such a volume that crystals started to appear in the hot solution, then allowing the solution to stand at 0° overnight. Crystals of (C) were obtained as a light orange colored powder. This material turns red at 203–205° and apparently melts at 222–226°. Two successive recrystallizations brought the rotation to a constant value.

Rotation. 0.1319 g. made up to 15 cc. in pyridine at 20° gave α_D $+0.74°$, $l = 1$, $[\alpha]^{20}_{D}$ $+84.4°$.

Anal. Calcd. for $C_{34}H_{27}O_{14}N_7$: C, 53.88; H, 3.59. Found: C, 53.52; H, 4.35.

l-2,4,6,2′,4′-Pentanitro-3-carboxydiphenyl.—To 2.19 g. of the pure strychnine salt **(A)** was added 20 cc. of acetone. Solution was not complete. The beaker was cooled with an ice-bath, and 50 cc. of concentrated hydrochloric acid added with stirring, at such a rate that the temperature of the mixture was always kept below 20°. The cooled mixture was permitted to stand for fifteen minutes so as to assure complete crystallization of the free acid, then filtered. The acid was completely redissolved in 10 cc. of acetone and again thrown out of solution by the addition of 50 cc. of concentrated hydrochloric acid in the manner just described. The acid was dried *in vacuo* at room temperature and then purified further by recrystallizing twice from benzene to a constant rotation and melting point. The pure acid was obtained as white, granular crystals of melting point 233". The yield was 0.87 g. (71.3%).

Rotation. 0.1165 g. of acid made up to 15 cc. in acetone at 20° gave α_D $-0.82°$, $l = 1$, $[\alpha]^{20}_{D}$ $-105.3'$.

d-2,4,6,2′,4′-Pentanitro-3-carboxydiphenyl.—To 1.19 g. of the strychnine salt (C) dissolved in 5 cc. of acetone and cooled with an ice-bath, slowly and with stirring was added 50 cc. of concentrated hydrochloric acid. The cooled mixture was permitted to stand for one-half hour so as to assure complete crystallization of the liberated acid, then filtered. The acid was redissolved in 9 cc. of acetone and reprecipitated by the addition of another 50-cc. portion of concentrated hydrochloric acid in the manner just described. It was recrystallized twice from benzene and formed a white, granular powder of melting point 229–231°. It gave a negative strychnine test when dissolved in sulfuric acid and treated with manganese dioxide. The yield of recrystallized acid was 0.4 g.

Rotation. 0.1116 g. of acid made up to 15 cc. in acetone at 20° gave α_D $+0.73$, $l = 1$, $[\alpha]^{20}_{D}$ $+98.8°$.

Racemization Experiments

(a) **A** 0.1357-g. sample of d-2,4,6,2′,4′-pentanitro-3-carboxydiphenyl was made up to 25 cc. in glacial acetic acid at 20° and the following rotation found for the solution: α_D $+0.53$, 1 = 1, $[\alpha]^{20}_{D}$ $+98.3°$. The entire solution was transferred to a ***50-cc.*** flask equipped with a glass-fitted reflux condenser and refluxed for one and one-half hours. The solution was then evaporated to a volume of about 10 cc., transferred to a volumetric flask, and its volume again made up to 25 cc. with glacial acetic acid at 20°. The rotation of the solution was then α_D $+0.53°$; *1* = 1, $[\alpha]^{20}_{D}$ $+98.3'$. The solution was refluxed for an additional two and one-half hours and its rotation again taken: cuD $+0.52°$, $l = 1$, $[\alpha]^{20}_{D}$ $+95.8°$.

(b) **A** 0.1268-g. sample of l-2,4,6,2′,4′-pentanitro-3-carboxydiphenyl, $[\alpha]^{20}_{D}$ -105.3" in acetone, was refluxed with 20 cc. of 5% ammonium carbonate solution for a period of eight hours. The solution was then cooled with an ice-bath and 30 cc. of concentrated hydrochloric acid added slowly and with stirring. The precipitated acid was filtered from this mixture, dried *in vacuo* at room temperature, and its rotation taken as follows: 0.1073 g. of acid made up to 15 cc. in acetone at 20° gave α_D $-0.76°$, $l = 1$, $[\alpha]^{20}_D$ $-105.8°$.

(c) A 0.1236-g. sample of the *l*-acid, $[\alpha]^{20}_D$ $-105.3°$ in acetone, was dissolved in 20 cc. of a solution that had been prepared by saturating an acetic acid solution, which contained 5% of water, with hydrogen chloride. The resulting solution was refluxed for eight hours, then cooled in an ice-bath and 50 cc. of concentrated hydrochloric acid added. After permitting the cooled mixture to stand for one-half hour. the precipitated acid was filtered from it, dried *in vacuo* at room temperature, and its rotation taken as follows: 0.0967 g. of acid made up to 15 cc. in acetone at 20° gave α_D $-0.54°$, $l = 1$, $[\alpha]^{20}_D$ $-83.4°$.

(d) A 0.1535-g. sample of the *l*-acid was made up to 15 cc. in a 5% sodium carbonate solution at 20° and its rotation taken: α_D $-2.13°$, $l = 1$, $[\alpha]^{20}_D$ $-208.0°$. This pale yellow solution was permitted to stand in a sealed tube at room temperature for seven days, during which period it developed an amber color. Its rotation was then taken and found to be: α_D $-2.11°$, $l = 1$, $[\alpha]^{20}_D$ $-206.3°$.

An attempt was made to heat the solution in a sealed tube to a temperature of 50–60°, but after eight hours of this treatment the solution had developed such a deep red color that its rotation could not be taken.

Summary

1. The compound 2,4,6,2′,4′-pentanitro-3-carboxydiphenyl has been prepared and resolved. This is the first diphenyl derivative with three of the same groups in the 2,2′,6-positions which has been resolved.

2. The active forms could not be racemized in acid, neutral or alkaline solution.

3. Discussion is given of what properties may be anticipated of various 2,2′,6-trisubstituted diphenyls.

NATURAL AND SYNTHETIC RUBBER. IV. 4-METHYL-4-OCTENE BY ISOPRENE ETHYLATION

BY THOMAS MIDGLEY, JR., AND ALBERT L. HENNE

RECEIVED JANUARY 22, 1930 PUBLISHED MAY 8, 1930

In preceding papers[1] it has been shown that when isoprene accepts hydrogen, or when two molecules of isoprene link together, the reaction affects only the 1- and 4-positions. This behavior has been regarded as a general property, and it has been used to explain the polymerization of isoprene to synthetic rubber.

The present paper offers one more evidence of the 1,4-addition. Two ethyl groups have been attached to an isoprene molecule

$$H_2C{=}C(CH_3)CH{=}CH_2 + 2C_2H_5Br \xrightarrow{Na} CH_3CH_2CH_2C(CH_3){=}CHCH_2CH_2CH_3$$

---

[1] Midgley and Henne, THIS JOURNAL, 51, 1215, 1293, 1294 (1929).

The experimental conditions were precisely those which are required for the formation of synthetic rubber: the reaction took place at room temperature in the presence of an alkaline metal and, in each case, a certain amount of synthetic rubber was formed. This favors the view that the ethylation of isoprene is a process very analogous to its polymerization.

As was expected, the ethyl groups linked exclusively to the first and the fourth carbon atoms; a hydrocarbon was thus obtained which on examination proved to be 4-methyl-4-octene. The criteria used for its identification were a combustion, a molecular weight determination by freezing point depression in benzene, a double bond determination by hydrogenation and by bromination, a computation of the molecular refraction and finally an oxidation with ozone.

Since the experimental results support the postulation that isoprene accepts radicals *exclusively* on its 1- and 4-carbon atoms (under the conditions required for synthetic rubber formation), they also fortify the hypothesis that the chain formula of natural rubber proposed by Staudinger[2] and his associates is much more acceptable than any formula involving the formation of a ring.

Experimental

Two-gram molecules of metallic potassium are covered with one gram molecule of isoprene, which has been sufficiently purified to be capable of rapid polymerization. Two-gram molecules of ethyl bromide (or one gram molecule of ethyl sulfate) is dissolved in a like volume of dry ether, and added gradually to the isoprene. A gentle shaking is maintained, and heat is applied sufficiently to maintain a moderate ebullition. Much gas is evolved; the decomposition of the ethylation agent is the predominant reaction. After twenty-four hours, the residual metal is eliminated by the cautious addition of alcohol, and the ethylate is then decomposed with water. The mixture is washed with dilute hydrochloric acid and water, decanted, dried and fractionated. About 4% of the theoretical amount of C_9H_{18} is obtained. This compound shows the following physical constants: b. p. 136–144° (chiefly 139°), d_{20}^{20} 0.7495, n_D^{20} 1.4225, A = 1.0 per C_9H_{18}. The molecular weight determined by freezing point depression in benzene was found to be 122: theory requires 126, but the discrepancy is within the permissible experimental error of 3%. A combustion checked the formula already evident. The molecular refraction computed from the density and the refractive index by means of the Lorentz–Lorenz formula was found to be 42.8. This value compares favorably with the theoretical value 43.3.

To prove that isoprene had accepted the ethyl groups exclusively on the 1- and 4-carbon atoms, it was necessary to locate the double bond in the resulting nonene, and this was done by ozone oxidation in a glacial acetic acid solution. The ozonization procedure has been previously recommended.[3] After decomposition of the ozonide with a dilute potassium dichromate solution, two compounds were isolated and characterized: methyl butyl ketone, and butyric acid. No trace of any other compound was detected. The results of the ozonization were in complete agreement with the formula postulated for the nonene.

[3] Henne, THIS JOURNAL, 51, 2676 (1929).

Summary

Isoprene has been ethylated; 4-methyl-4-octene was formed exclusively. The structure of this nonene is in agreement with the usual behavior of a conjugated double bond system. This type of addition is further evidence in favor of the hypothesis which regards the polymerization of isoprene to synthetic rubber as the formation of long chains of isoprene units linked together by ordinary valences in the 1,4-position.

NATURAL AND SYNTHETIC RUBBER. V. TETRAMETHYLOCTADIENE

BY THOMAS MIDGLEY, JR., AND ALBERT L. HENNE

RECEIVED JANUARY 22, 1930 PUBLISHED MAY 8, 1930

The third paper of this series[1] has shown how the polymerization of isoprene to synthetic rubber could be stopped at the dimeric stage by addition of an atom of hydrogen to each terminal carbon of the transitory dimer.

A similar experiment can be carried out with dimethylbutadiene substituted for isoprene. Although details differ, the general trend of the reaction remains the same, the reaction products are comparable and the conclusions are similar.

If the views presented before are correct, the linkage of two molecules of dimethylbutadiene, during polymerization to methyl-rubber, should form the transitory compound

$$—H_2CC(CH_3)=C(CH_3)CH_2CH_2C(CH_3)=C(CH_3)CH_2—$$

Should polymerization be allowed to proceed further, the unstable molecules would link together by their terminal free valences and form a long chain; methyl-rubber would be the final product. This agrees with Kondakow's ideas.[2] On the other hand, should polymerization be stopped by addition of an atom of hydrogen on each end of the unstable dimeric derivative, a duodecadienic hydrocarbon should result. This hydrocarbon has been isolated and analyzed. As expected, it was 2,3,6,7-tetramethyl-2,6-octadiene.

The polymerization of dimethylbutadiene can never be entirely stopped at the dimeric stage; an appreciable amount of a rubber-like material is always formed. The amount of this compound varies with the experimental conditions. This can be used as an evidence that the formation of tetramethyloctadiene and that of methyl-rubber are simultaneous and

---

[1] Midgley and Henne, THIS JOURNAL, 51, 1294 (1929).

[2] I. L. Kondakow, "Scientific Memoirs of the Imperial Yuriev University for the year 1901."

analogous processes. Consequently, the structure of the tetramethyloctadiene will have a very close relation to the structure of methyl-rubber. Moreover, since isoprene and dimethylbutadiene behave in a similar way, the structure of ordinary synthetic rubber may be postulated by analogy with that of methyl-rubber.

Experimental

The apparatus, procedure and proportions of reagents have been described previously. Runs were made at 0, 25 and 70°. In each case, 200 g. of dimethylbutadiene has been used. The best yield was obtained by running at 70°; 65 g. of $C_{12}H_{22}$ was collected and 45 g. of C_6H_{10} recovered, the balance being polymerized to methyl-rubber (15 g.) or carried out with the escaping hydrogen. The tetramethyloctadiene, purified by fractionation under reduced pressure, exhibited the following constants: b. p. (18 mm.) 87.5–88.5°, d_4^{25} 0.7971, n_D^{25} 1.45963. Molecular refraction found, 57.0; calcd., 56.7. The determination of the number of double bonds was made by bromination with a KBr–$KBrO_3$ mixture, and by hydrogenation in the presence of platinum oxide; in each case 4 atoms were accepted per molecule of hydrocarbon. To complete the analysis, a combustion, a molecular weight determination by freezing point lowering in benzene and an oxidation with ozone were performed. The ozonization was carried out in glacial acetic acid, as reported previously.[3] Two compounds were obtained and characterized: acetone and acetonylacetone. Not a trace of any other derivative could be detected. The result of the examination thus proves that the formula of the tetramethyloctadiene is $(CH_3)_2C{=}C(CH_3)CH_2CH_2(CH_3){=}C(CH_3)_2$.

The physical constants of the compound obtained by hydrogenation have been measured. They are: b. p. (20–22 mm.) 92°, d_4^{25} 0.7593, n_D^{25} 1.42527; mol. refr, found, 57.2; calcd., 57.6. A combustion and a molecular weight determination agree with the expected values. From its method of formation this compound should be 2,3,6,7-tetramethyloctane.

It is to be noted that when the polymerization is carried out at a low temperature the sample of tetramethyloctadiene obtained is considerably less pure; its boiling point is not constant, it can be fractioned into portions whose densities and refractive indexes vary between d_4^{25} 0.7980 and 0.8003 and n_D^{25} 1.45952 and 1.46111. The odor of the compound strongly resembles that of turpentine. Particularly, the addition of bromine or hydrogen to the double bonds is strongly hampered. This gave the impression that only one double bond was present and led to the erroneous belief that a ring compound had been formed. A better interpretation would be to consider that tetramethyloctadiene formed at low temperature is contaminated by a small quantity of cyclic or even dicyclic compound, which would account for the odor, the higher density and the high refractive index.

Summary

Dimethylbutadiene treated with potassium and alcohol gives 2,3,6,7-tetramethyl-2,6-octadiene and methyl-rubber. The structure of the first hydrocarbon has been established, and is used as an evidence that the methyl-rubber formula must be a long, open chain. This is also regarded as an evidence in favor of the chain formula of natural rubber.

THE PREPARATION AND PROPERTIES OF SOME NEW FURAN DERIVATIVES[1]

BY FREDUS N. PETERS, JR., AND RICHARD FISCHER

RECEIVED JANUARY 23, 1930 PUBLISHED MAY 8, 1930

Forty-six years ago Pawlinoff and Wagner[2] prepared ethyl furyl carbinol, the first known alkyl furyl carbinol, from furfural and zinc diethyl. In 1901, Grignard[3] obtained iso-amyl furyl carbinol by the use of furfural and iso-amylmagnesium halide. During the same year Hale, McNally and Pater[4] reported negative results in their attempt to obtain phenyl furyl carbinol from the reaction between furfural and phenylmagnesium halide and a similar failure has been reported by Mahood and Jordan.[5] While the manuscript from which this paper is abstracted was being prepared, Pierce and Adams[6] reported the preparation of crude phenyl furyl carbinol and of n-butyl furyl carbinol and ethyl furyl carbinol, the latter compound having previously been prepared by Douris.[7] Jolkver[8] and Jaworsky[9] prepared n-propyl and allyl furyl carbinol, respectively.

This paper describes the preparation and properties of several heretofore unreported alkyl furyl carbinols, impure phenyl furyl carbinol, several esters of these substances and a few unidentified oxidation and chlorination products.

The organomagnesium furyl complexes obtained in the preparation of these carbinols by the Grignard reaction are pale to orange-yellow in color and, with one exception, insoluble in ether. The exception is the n-butyl derivative, which in this respect is similar to titanium n-butoxide, which is also an ether-soluble substance, while the lower aliphatic titanium alkoxides are ether insoluble. Isobutylfurylmagnesium bromide was obtained more nearly white than any of the other insoluble magnesium furyl complexes.

All of the carbinols are colorless liquids when pure. They are slightly soluble in water, the solubility and density decreasing with increasing molecular weight. They are all completely miscible with alcohol, nitro-

benzene, benzene, chloroform and ether. Phosphorus pentachloride, acetyl chloride, benzoyl chloride and concentrated hydrochloric acid resinify the carbinols, the first two reagents acting with almost explosive violence. Light and air change the carbinols more or less rapidly to reddish brown, viscous liquids which solidify upon standing for some time. Treatment with metallic sodium liberates hydrogen and produces a dark brown mass, soluble in alcohol or ether. The methyl and phenyl furyl carbinols are the most unstable toward acids, whereas the isopropyl furyl carbinol is practically unchanged within two hours by 10% hydrochloric acid and when the pure substance is sealed in a glass tube it remains colorless for several months. Methyl furyl carbinol in a sealed tube in an atmosphere of hydrogen was only slightly colored within one year and after four years it has changed very little more. The other alcohols which were less carefully protected became dark brown liquids in this time. The alkyl furyl carbinols have very little odor and none that can be ascribed as distinctly due to the furan nucleus, the odor being dependent more on the nature of the radical attached to the secondary carbon atom.

The preparation of the esters was not attempted in every case but where tried the only successful method was the treatment of an ethereal solution of the carbinol with acetic anhydride using anhydrous sodium acetate as a catalyst. This method did not give results with the methyl and phenyl derivatives, these being resinified by even small quantities of acetic acid. Treatment of the magnesium complex of furfural and ethyl bromide with acetyl chloride or with benzoyl chloride resulted in resinification of the substance within one hour. The magnesium complex was also treated with ethyl acetate according to the method of Stadnikoff.[10] However, nothing but ethyl acetate and the unchanged carbinol were isolated at the close of the experiment. The use of pyridine according to the method of Einhorn also failed to produce an ester of methyl furyl carbinol. Attempts to prepare an ester of ethyl furyl carbinol by the Schotten–Baumann or Einhorn methods failed. Pawlinoff reported failure in attempts to prepare this ester.

Molecular refractions were calculated using the values for atomic refractions given by Roth and Eisenlohr[11] and in every case checked very well with the values obtained from the Lorentz–Lorenz formula. Molecular weights were determined cryoscopically using benzene as a solvent.

It was impossible to prepare phenyl furyl carbinol in a pure state, the product always being contaminated with diphenyl and some unidentified products. Attempts to oxidize n-butyl furyl carbinol with potassium permanganate in acid solution gave a colorless liquid, b. p. 90–95° (3 mm.),

---

[10] Stadnikoff, *Ber.*, 57, 1 (1924).

insoluble in **10%** hydrochloric acid or sodium hydroxide. This product was slightly acidic and slowly decolorized bromine water; it gave no phenyl hydrazone, semicarbazide or sodium bisulfite addition products. This material resinified to a yellow, viscous gel within one week.

Treatment of ethyl furyl carbinol with diethyl sulfate and potassium hydroxide gave no appreciable yield of the expected ether. The product obtained by treating ethyl furyl carbinol with metallic sodium was refluxed with ethyl bromide and a small quantity of material of aromatic odor was isolated but the amount was too small for characterization. Dry hydrochloric acid gas diluted with carbon dioxide was passed through an ethereal solution of n-butyl furyl carbinol. A liquid, b. p. 90–95° (5 mm.), containing chlorine was isolated. This chloride upon refluxing with sodium ethoxide precipitated sodium chloride and a small quantity of liquid with a pronounced terpene-like odor was obtained.

Experimental

Reagents.—The furfural used in this work was obtained through the courtesy of The Miner Laboratories of Chicago, to whom the authors are deeply grateful. The magnesium employed was in the form of turnings furnished for this purpose. The ether and organic halides were dried and purified by conventional methods.

Procedure.—In the early work a special apparatus was used in which the organomagnesium halide was formed in a dry, carbon dioxide–oxygen-free atmosphere and then was forced through a glass wool filter into the furfural. The majority of experiments, however, were carried out by forming the Grignard reagent in the usual manner and adding the furfural to the cool and well-stirred solution. Approximately one gram mole of the Grignard reagent was used in each run. Hydrolysis was carried out by pouring the mixture over ice and this was followed by steam distillation without the use of ammonium chloride or other reagent generally added to aid hydrolysis. The distillate was treated with solid potassium carbonate and the organic layer was shaken with freshly prepared bisulfite solution to remove any unreacted furfural. This was followed by treatment with sodium carbonate to neutralize any free acid and then by vacuum distillation.

Tables I and II give the compounds isolated and some of their physical constants.

Summary

1. Methyl, ethyl, propyl, isopropyl, butyl, isobutyl and phenyl furyl carbinols have been described and some of their physical and chemical properties reported.
2. The acetic acid esters of ethyl furyl, isopropyl furyl and isobutyl furyl carbinols have been prepared and some of their physical properties determined.
3. A chloride, which is probably *α-n*-butyl furfuryl chloride and two substances which are very likely the ethyl ethers of ethyl and n-butyl furyl carbinols, respectively, were isolated.
4. An unidentified product was isolated from the acid permanganate oxidation of n-butyl furyl carbinol.

THE SIMPLE HALOGEN DERIVATIVES OF FURAN

BY A. F. SHEPARD, N. R. WINSLOW AND JOHN R. JOHNSON

RECEIVED JANUARY 25, 1930 PUBLISHED MAY 8, 1930

Syntheses in the furan series are limited by the lack of direct methods for introducing organic radicals into the furan ring. For this reason the furan derivatives which have been most widely studied are largely those with substituent organic groups in the 2-position, for which furfural serves as a suitable starting material. A certain number of furan derivatives with organic substituents in the 2- and 5-positions are available from 5-methylfurfural and its derivatives,[1] and a few others may be obtained through various types of ring formation that lead to furan derivatives.[2]

3-Methylfuran[3] and 3-furoic acid[4] have been obtained from natural sources but the structure of these compounds has not been confirmed by synthesis. In fact, a review of the literature showed that no furan derivative with a single organic substituent in the 3-position has ever been synthesized. Although halogen, nitro and sulfonic acid groups may be introduced directly into the furan ring, the resulting compounds have not been studied further with the idea of introducing organic substituents by indirect methods. With the object of extending the methods of synthesis in the furan series through the use of these groups, a series of investigations was undertaken. The present paper deals with the preparation and properties of the simpler halogen derivatives of furan.

Although a number of halogenated furans containing two or more halogen atoms are known,[5] only one of the monohalogenated furans, 3-bromofuran,[6]

---

[1] The synthesis of furan derivatives with a methyl group in the 5-position and substituent groups in the 2-position has been facilitated by the recent observation that certain replacement reactions of α-furfuryl chloride involve rearrangement of the α-furfuryl group into the 5-methyl-2-furyl group [Runde, Scott and Johnson, THIS JOURNAL, 52, 1284 (1930); Reichstein, Ber., **63**, 749 (1930)].

[2] An excellent review of this subject is given by Marquis, *Ann. chim. phys.*, [8] *4*, 200–208 (1905); see also Benary, *Ber.*, 44, 493 (1911).

[3] Asahina and Tanaka [*Acta Phytochim.*, 2, 1 (1924); C. A., 19, 1139 (1925)] prepared 3-methylfuran by decarboxylation of 3-methyl-2-furoic acid, which had been obtained from the naturally occurring ketone, elscholtzione.

[4] Rogerson, *J. Chem. Soc.*, 101, 1044 (1912); Power and Salway, *Pharm. J.*, 90, 550 (1913); C. A., 7, 2659 (1913).

[5] These include 2,5- and 3,4-dibromofuran, 2,5-di-iodofuran, 2,3,4-tribromofuran, 2,3,4-tribromo-5-chlorofuran, tetrabromofuran and tetra-iodofuran.

[6] Canzoneri and Oliveri, *Gazz. chim. ital*, 17, 43 (1887). These authors obtained a small amount of 3-bromofuran in an attempt to prepare 3-hydroxyfuran or 3-hydroxyfuroic acid by heating 3-bromofuroic acid with excess calcium hydroxide. Although they stated an intention of preparing an hydroxyfuran from this compound and of preparing the isomeric 2-bromofuran, we were unable to find any further published results on this subject.

has been obtained in a state of purity. Several investigators have noted the formation of these compounds in small amounts but have not purified or characterized them.[7]

For the purpose of preparing the simple halogenated furans it appeared that the corresponding furoic acids would be the most satisfactory materials. Various chlorofuroic and bromofuroic acids have been prepared in a pure state by Hill and his collaborators,[8] and the positions of the halogens have been established with reasonable certainty. By decarboxylation of these acids, the corresponding halogenated furans of known constitution could be obtained. After a preliminary study it was found that this method was quite satisfactory and the chlorofurans and bromofurans could be obtained in excellent yields.

Decarboxylation of 3-broniofuroic acid, 5-bromofuroic acid, 3,4-dichlorofuroic acid and 3,4,5-trichlorofuroic acid was effected simply by heating the substances at temperatures between 210 and 300°. 3-Chlorofuroic acid and 5-chlorofuroic acid proved to be more stable and could not be decarboxylated in this way. It was found that copper bronze or finely divided nickel, prepared by reducing the oxide at 300–400°, effectively catalyzed the decarboxylation[9] and in the presence of these catalysts 3-chlorofuroic acid and 5-chlorofuroic acid could be decarboxylated. The results of typical decarboxylation experiments are given in Table I.

It seemed likely that the pyrolysis of the halogenated furoic acids under the above conditions gave rise through secondary reactions to the formation of some free halogen acid, toward which the simpler furan derivatives are relatively sensitive. In order to avoid decomposition of the resulting halogenated furans, it appeared advisable to effect the decarboxylation in the presence of a base, which would combine with any free halogen acid formed during the pyrolysis. Quinoline was selected as a suitable base and proved to be quite satisfactory. The addition of quinoline made possible the isolation of 2-bromofuran, which we had not been able to accomplish in earlier experiments, and effected a marked improvement in the yields in other cases. The results of a series of semi-quantitative

---

[7] (a) Henninger [*Ann. chim. phys.*, [6] 7, 222 (1886)] states that the bromination of furan leads to a monobromofuran and a dibromofuran, but describes only the latter. (b) Hill and Jackson [*Proc. Am. Acad. Arts Sci.*, 24, 320 (1888)] state that a small amount of a colorless liquid separated upon adding water to the first portions of the distillate obtained upon distilling the alcoholic alkali used in saponifying ethyl 5-chlorofuroate. This liquid, which they did not investigate lurther, may have been a monochlorofuran or a dichlorofuran.

TABLE I

PYROLYSIS OF HALOGENATED FUROIC ACIDS

Substituted furoic acid	Decompn. temp. (approx.), °C.	Sample, g	Substituted furan	Product, g	Yield, %
3-Chloro-	260[a]	20	3-Chloro-	4.2	30
5-Chloro-	260[a]	20	2-Chloro-	6.7	47
3,4-Dichloro-	300	20	3,4-Dichloro-	9.6	63
3-Bromo-	260	20	3-Bromo-	7.4	48
5-Bromo-	210	20	2-Bromo-	0[b]	0

[a] One gram of copper bronze (Kahlbaum's "Naturkupfer C") was added in these experiments, since these acids did not decompose appreciably below 300° in the absence of catalysts.

[b] 5-Bromofuroic acid was readily decarboxylated but the resulting 2-bromofuran was converted into a black resin in the reaction tube. The resinification of the product was circumvented in later experiments (see Table II) and yields of 2-bromofuran as high as 90% of the theoretical were obtained.

experiments, in which the evolved carbon dioxide was measured, are shown in Table II.

TABLE II

PYROLYSIS OF HALOGENATED FUROIC ACIDS IN THE PRESENCE OF COPPER BRONZE AND QUINOLINE

Substituted furoic acid	Temp.,[a] °C.	Sample, g.	Carbon dioxide Found	Carbon dioxide Calcd.	Carbon dioxide Percentage of calcd.	Substituted furan	Percentage of theory[b]
3-Chloro-	250	5.00	1.45	1.50	96	3-Chloro-	79
5-Chloro-	240	10.00	3.19	3.01	106	2-Chloro-	91
3,4-Dichloro-	220	10.00	2.46	2.43	101	3,4-Dichloro-	97
5-Bromo-	220	15.00	3.38	3.45	98	2-Bromo-	75

[a] This column indicates the minimum temperature of the bath which was necessary to obtain vigorous decomposition. The acids decomposed slowly at somewhat lower temperatures.

[b] The yields given here are based upon the weights of the products after purification by two steam distillations.

The monohalogen derivatives of furan are colorless liquids with a pleasant sweet odor closely resembling that of chloroform and bromoform. With strong aqueous hydrochloric acid they produce at first a green coloration, and on longer standing change to resins. 3,4-Dichlorofuran does not give this coloration with hydrochloric acid, but forms a resin on standing in contact with this reagent. The halogen atoms in these compounds are surprisingly unreactive; all attempts to carry out metathetical reactions were entirely unsuccessful. Such reagents as aqueous sodium hydroxide and sodium cyanide solutions, metallic sodium, mercury dimethyl and zinc dimethyl were without action.[10] In one case, however, it was possible to obtain a Grignard reagent. 2-Bromofuran in ethereal solu-

---

[10] Several of the experiments mentioned here were carried out by Mr. E. B. Reinbold, who also found that the bromine atom of ethyl 5-bromofuroate was extremely unreactive.

tion, on treatment with a highly activated magnesium–copper alloy,[11] gave 2-furylmagnesium bromide. The latter was characterized by the formation of 2-furoic acid by the action of carbon dioxide, and of 2-furoic anilide by the action of phenyl isocyanate. The use of this Grignard reagent in synthesis should render available a number of furan derivatives that cannot be prepared by the usual methods, such as difurylcarbinol, trifurylcarbinol, and others.

Experimental Part

Preparation of Halogenated Furoic Acids.—The methods used for the preparation of the various halogenated acids were essentially those of Hill and his collaborators,[8] with slight modifications in a few details. The acids used in this work were free from isomeric acids according to the criteria of Hill, and their purity was checked by halogen determinations.

Substituted furoic acid	*M. p., °C. (corr.)*	*Percentage of halogen*[a]		
		Calcd.	*Found*	
3-Chloro-	148.5–149.5	Cl, 24.20	24.04	23.99
5-Chloro-	179–180	Cl, 24.20	24.29	23.90
3,4-Dichloro-	169.5–170.5	Cl, 39.19	39.00	38.33
3,4,5-Trichloro-	174.5–175.5	Cl, 49.39	48.97	48.73
3-Bromo-[c]	127–129	Br, 41.85	......[c]	
5-Bromo-	184–186	Br, 41.85	40.87[b]	

[a] Halogen determinations by the Parr peroxide bomb method.

[b] 5-Bromofuroic acid was purified conveniently as the ethyl ester, which was readily prepared through the acid chloride. The latter method was more satisfactory than direct esterification with ethyl alcohol and sulfuric acid. Forty-eight grams (0.25 mole) of 5-bromofuroic acid was heated for one and one-half hours with 57 g. (0.275 mole) of phosphorus pentachloride, and part of the resulting oxychloride was removed by distillation from an oil-bath at 125–130°. The residue was treated cautiously with 100 cc. of absolute alcohol and warmed for three or four hours. The crude ester was washed with a large volume of water, then sodium bicarbonate solution, dried and distilled. There was obtained 48 g. (87% yield) of ethyl 5-bromofuroate, b. p. 134–136° at 34 mm. (Br analysis, calcd., Br, 36.51. Found: Br, 36.62, 36.85). Similarly, 3,4-dichlorofuroic acid gave ethyl 3,4-dichlorofuroate in 90% yield.

[c] For our first experiments on the preparation of 3-bromofuran we used pure 3-bromofuroic acid, m. p. 127–129°, which was obtained according to Hill's procedure by the reduction of 3,5-dibromofuroic acid, prepared by the bromination of furoic acid. In later experiments in an attempt to improve the preparation of 3,5-dibromofuroic acid, we brominated furoyl chloride and obtained a dibromofuroic acid which was apparently not pure 3,5-dibromofuroic acid. The dibromofuroic acid from furoyl chloride gave on reduction a monobromofuroic acid or a mixture of monobromofuroic acids which melted indefinitely at 110–118° instead of 128–129°. Bromine determinations and neutralization values showed that the material in hand corresponded to a monobromofuroic acid or a mixture of monobromofuroic acids (Br: calcd., 41.25; found, 41.60; neutralization value: calcd., 190.9; found, 191.3, 192.9), and decarboxylation gave 3-bromofuran. It appears that bromination of furoyl chloride gives rise to a mixture of 3,5-dibromofuroic acid and 4,5-dibromofuroic acid. Reduction of

---

[11] Gilman, Peterson and Schulze, ***Rec. trav. chim.***, 47, 19 (1928).

these would produce 3-bromofuroic acid and 4-bromofuroic acid, both of which would yield 3-bromofuran on decarboxylation. Since Hill and his collaborators have not described 4-bromofuroic acid or 4,5-dibromofuroic acid, further work is being done to determine the nature of the products of bromination of furoyl chloride and of the monobromofuroic acid obtained therefrom.

Preparation of Halogenated **Furans.** General Procedure.—Decarboxylation of the halogenated furoic acids was carried out by heating the acids in a large pyrex tube, 25 × 200 mm., bearing a side tube which was provided with a small condenser and a receiver for the liquid distillate. The decomposition tube was closed with a cork holding a glass tube drawn out to a narrow tip reaching to within 60–80 mm. of the bottom of the tube. Dry nitrogen was passed through the small tube to provide an inert atmosphere and to remove the volatile products as rapidly as possible from the zone of high temperature. The decomposition tube was heated in a bath of Wood's metal at temperatures varying from 210–300° (see Tables I and II). It was found that better yields were obtained by decomposing the acids in small portions of about 5 g. each.

Five grams of the halogenated furoic acid, 10 g. of quinoline and 1 g. of copper bronze (Kahlbaum's "Naturkupfer C") were placed in the reaction tube, which was lowered into a previously heated bath of Wood's metal. The bath was maintained at such a temperature that a vigorous evolution of carbon dioxide took place. The decarboxylation proceeded smoothly and the halogenated furan distilled into the receiving flask. When the acid was completely decarboxylated, as shown by cessation of gas evolution, the tube was raised from the bath and allowed to cool. A second portion of 5 g. of the halogenated acid was added and the above process repeated. In this way 20–30 g. of the acid could be decarboxylated before dismantling the apparatus. In cases where the decomposition temperature of the halogenated furoic acid was relatively high, it proved advantageous to use a base of higher boiling point than quinoline (b. p. 238°) in order to avoid distilling traces of the base into the receiving flask. For this purpose a high-boiling fraction of crude coal tar bases, b. p. 285–310°, proved entirely satisfactory.[12] The halogenated furans were purified by two steam distillations and were dried over fresh calcium oxide. After trial experiments had shown that these substances did not react with metallic sodium, certain of them were dried by means of this metal, *e. g.*, 3-chlorofuran and 2-bromofuran. The yields of the halogenated furans varied from 75–95% of the calculated amounts

The halogenated furans are slightly soluble in water and soluble in organic solvents such as alcohol, ether and benzene; they have an odor very similar to that of chloroform or bromoform. The purified products were colorless liquids when freshly distilled but darkened on standing and eventually changed completely to insoluble resins.[13]

It was found that the products could be kept for months without appreciable decomposition by covering them with an alkaline solution of hydroquinone and storing in corked bottles. Determinations of physical constants were made on freshly distilled specimens of the pure liquids boiling over less than 0.5° temperature range, and samples for analysis were sealed in small bulbs within thirty minutes of the time of distillation. Halogen determinations were made by the Parr bomb method on samples sealed in thin-walled glass bulbs.[14] The physical constants and analyses of the halogenated furans are shown in Tables III and IV.

---

[12] The authors wish to express their thanks to Mr. W. R. Gerges of the Chemical Department of the Barrett Company, Philadelphia, for supplying a generous sample of this material.

[a] The combustion analyses of this compound were unsatisfactory, probably on account of the difficulty of achieving complete combustion and complete retention of the halogen.

[b] Analysis for bromine in this particular compound was effected by the method of Stepanow [*Ber.*, 39, 4056 (1906)] and the low results are probably due to loss of bromofuran by volatilization. The Stepanow method for halogen determinations was replaced by the Parr bomb method for all other compounds, but the analyses of 3-bromofuran were not repeated since this compound had previously been described and analyzed.

Oxidation of **3,4-Dichlorofuran.**—(a) Ten grams of pure 3,4-dichlorofuran was added slowly to 28 g. of nitric acid (sp. gr. 1.42) at room temperature. The oxidation proceeded slowly at first and then became extremely vigorous. On standing the solution deposited crystals, which were filtered and crystallized from hot water. After drying in a vacuum desiccator the product weighed 3 g.; m. p. 124–125° (corr.). The melting point and chlorine analysis indicate that this compound is mucochloric acid,  $\underbrace{HO—CH—CCl=CCl—CO}_{O}$, (α,β-dichloro-β-formylacrylic acid).

Anal. Subs., 0.1792, 0.2966: 20.60, 34.20 cc. of 0.1018 *N* $AgNO_3$. Calcd. for $C_4H_2O_3Cl_2$: Cl, 41.98. Found: Cl, 41.50, 41.62.

(b) Seven grams of pure 3,4-dichlorofuran was added slowly to 21 g. of fuming nitric acid (sp. gr. 1.49) at room temperature. A transient green coloration was developed and oxides of nitrogen were evolved in large quantity. After standing for two days the crystals that had separated were filtered, pressed on a porous plate and dried in a vacuum desiccator. The crude dichloromaleic anhydride weighed 5 g. and melted at 110–115°; it was identified by the procedure of Salmony and Simonis,[15] by heating with aniline. The resulting anil of anilidochloromaleic anhydride, after crystallization from alcohol, formed greenish-yellow crystals, which discolored on heating and melted to a brown liquid at 188.7–190.2° (corr.). Salmony and Simonis reported that the anil of anilidochloromaleic anhydride began to turn brown at 175° and melted to a brown liquid at 188°.

Attempt to Prepare **2-Iodofuran.**—A number of experiments were made in an effort to prepare a mono-mercurated furan, from which an iodofuran might be obtained by treatment with iodine in aqueous potassium iodide. Ciusa and Grillo[16] succeeded in obtaining tetrachloromercuri-furan and in converting it to tetra-iodofuran by this method. In one experiment they obtained a mono-mercurated furan but were unable to repeat this preparation, and were consequently unable to obtain a mono-iodofuran. In our experiments we used a mixture of mercuration products and attempted to separate the mixture of iodo derivatives obtained therefrom. The following experiment illustrates the methods used.

A solution of 318 g. of mercuric acetate in 1300 cc. of water was added slowly, while stirring vigorously, to a solution of 150 g. of furoic acid in 2 liters of water at 80°. Bubbles of carbon dioxide were evolved and a heavy precipitate was formed. After standing for twelve to twenty-four hours to complete the reaction, the precipitate was filtered with suction and washed thoroughly with water. To convert the mercuri-acetate to the corresponding mercuri-chloride, the moist precipitate was stirred with a solution of 75 g. of sodium chloride in 1 liter of water, and allowed to stand for thirty minutes. The resulting precipitate was filtered with suction, suspended in 4–5 liters of water, and treated dropwise with a solution of iodine in aqueous potassium iodide, until a faint color indicated the presence of an excess of iodine. The amount of iodine added corresponded to 0.80–0.85 mole for each mole of furoic acid used. The resulting suspension was extracted several times with ether and, after drying and distilling off the solvent, a semi-solid residue remained. In a preliminary experiment, when this material was distilled through a fractionating column, a small amount of liquid distilled at 120–125°; the temperature then rose sharply and the residue decomposed rapidly with the evolution of violet vapors. For this reason, in subsequent experiments the residual mixture of iodofurans was subjected to three or four steam distillations in order to effect a partial separation of the liquid products from the solids. In this way there was obtained 3 g. of a liquid fraction (sp. gr. > 1) which was dried over anhydrous sodium sulfate and distilled at atmospheric pressure. About 2 g. of an almost colorless liquid, with an odor resembling that of iodoform, distilled at 120–140°. Since the liquid acquired a green color very rapidly, samples were sealed at once for analysis. Within thirty minutes of the time of distillation both the sealed samples and the material that had been allowed to stand in the air had completely resinified. For this reason the halogen determinations were not satisfactory.

Anal. Subs., 0.2978, 0.2054: 15.70, 9.10 cc. of 0.1018 N $AgNO_3$. Calcd. for C_4H_3OI: I, 65.5. Found: I, 68.11, 57.37.

2-Furylmagnesium Bromide.—Preliminary experiments indicated that 2-bromofuran in ethereal solution did not react with ordinary magnesium nor with magnesium activated by heating with iodine. It was found, however, that 2-bromofuran would react with a magnesium–copper alloy[17] that had been activated by heating with half

---

[15] Salmony and Simonis, ***Ber.***, 38, 2588 (1905).

[16] Ciusa and Grillo, *Gazz. chim. ital.*, *57*, 323 (1927).

its weight of iodine. In solution in di-n-butyl ether[17] no reaction occurred with the activated magnesium-copper alloy, even on heating to 100°.

A solution of 8 g. of 2-bromofuran in 20 cc. of anhydrous ether was treated in small portions with 3 g. of magnesium-copper alloy that had been heated gently with 1.5 g. of iodine. The addition of each portion of the alloy was accompanied by a vigorous reaction but a considerable excess of magnesium remained undissolved when the reaction subsided. The ethereal solution of 2-furylmagnesium bromide which resulted was red-brown in color and gave a strong color test for R–MgX with Michler's ketone, by the procedure of Gilman and Schulze.[18]

2-Furoic **Anilide.**—The solution obtained above was decanted from the residual magnesium–copper alloy and an ethereal solution of 1.2 g. of phenyl isocyanate was added dropwise, with constant stirring. A vigorous reaction occurred and after thorough shaking the solution still gave a strong test for R–MgX. It is advisable to avoid an excess of phenyl isocyanate, since the diphenylurea formed upon subsequent hydrolysis is difficultly separated from the anilide. The reaction product was hydrolyzed in the usual way, and the crude 2-furoic anilide was crystallized twice from alcohol, with the addition of decolorizing charcoal, and finally from water; m. p. 121–122° (corr.). For comparison, a sample of 2-furoic anilide was prepared from furoyl chloride and aniline; m. p. 121–122° (corr.). A mixture of the two specimens melted at the same temperature, 121–122° (corr.). The melting point of this compound is reported by previous investigators as 123.5°.[19]

2-Furoic Acid.—A solution of 2-furylmagnesium bromide prepared as above from 5 g. of 2-bromofuran gave a curdy precipitate when treated with carbon dioxide. The reaction mixture was decomposed with dilute sulfuric acid and the ether layer extracted with sodium hydroxide solution. The alkaline extract was acidified and extracted repeatedly with ether. The ether extracts on evaporation left a residue of crystals mixed with a tarry impurity. Sublimation gave crystals of 2-furoic acid, which was identified by comparison with furoic acid obtained from furfural.

Summary

A satisfactory method has been devised for the preparation of the simple halogenated furans from the corresponding halogenated furoic acids. 2-Chloro-, 3-chloro-, 3,4-dichloro-, 2,3,4-trichloro- 2-bromo- and 3-bromofuran have been prepared in a state of purity and their properties described.

The halogen atoms in these compounds were found to be extremely unreactive. No metathetical reactions could be effected with a number of reagents either in aqueous or anhydrous media.

A Grignard reagent, 2-furylmagnesium bromide, was prepared from 2-bromofuran in ethereal solution. This substance reacts normally with carbon dioxide and with phenyl isocyanate to produce 2-furoic acid and 2-furoic anilide.

THE ELEMENTARY COMPOSITION OF THE PENTOSAN XYLAN[1,2]

BY KARL PAUL LINK

RECEIVED JANUARY 30, 1930 PUBLISHED MAY 8, 1930

Introduction

When it was demonstrated by Wheeler and Tollens[3] that xylose, the sugar which Koch[4] had originally described and isolated from the products of hydrolysis of wood gum, was a pentose sugar with the empirical composition $C_5H_{10}O_5$, it became very probable that the corresponding anhydride, xylan, had the composition $(C_5H_8O_4)_n$. Soon after the relationship of xylan to xylose was established, a controversy arose with respect to the elemental composition of xylan. In 1896 Johnson[6] reviewed the controversy initiated by the conflicting analyses of Thomsen, Koch, Schuppe, Wheeler and Tollens. The analyses reported, with the exception of those by Schuppe, agreed with the formula $(C_5H_{10}O_5)_n$. Schuppe's analyses for the most part gave higher figures for carbon and hydrogen. The analyses reported by Johnson were on a xylan preparation from corn (Zea Mays) cobs. He concluded that xylan has the empirical formula $(C_5H_8O_4)_n$ and that the discrepancies and disagreements reported by other investigators were mainly attributable to the fact that xylan is a very hygroscopic substance, difficult to maintain at a constant moisture content. Although the analyses reported by Johnson appear to have been conducted with the necessary precaution, the conclusion that he reached with respect to the empirical formula of the pentosans was apparently not accepted. The third edition of the late B. Tollens'[6] excellent treatise on the carbohydrates published in 1914 still gave the empirical formula

for xylan as $(C_{10}H_{18}O_9)_n$ or $(C_5H_9O_{4.5})_n$. In fact the old controversy on the question of the elemental constitution of the pentosans still persists at the present time.

The expression $(C_{10}H_{18}O_9)_n$ has again been advanced by Schorsch,[7] who formulates the expression $(C_{10}H_{18}O_9)_n$ for the formula of the pentosans on the evidence that: (1) a quantitative recovery of the corresponding pentose sugar is not attainable; (2) the purest preparations available when distilled with 12% hydrochloric acid by the Kröber–Tollens method never give an amount of furfural estimated as the phloroglucide compound corresponding to more than 92–96% pentosan; **(3)** no sugar other than a pentose has ever been isolated from a pentosan. According to Schorsch the formula $(2C_5H_{10}O_5 \cdot H_2O)_n$ equivalent to $(C_{10}H_{18}O_9)_n$ is in accord with the experimental results. However, it must be borne in mind that it is not possible to hydrolyze pentosans with weak acids without the formation of some decomposition products, and that attempts at a quantitative crystallization of the free pentose sugar are always accompanied by mechanical losses and some retention of sugar in the mother liquors. In addition, it is well known that the Kröber–Tollens method never gives quantitative results even with the free pentoses.

Heuser and Schorsch[8] have advanced evidence that under certain conditions xylan retains sodium hydroxide and appears to form the compound $((C_5H_8O_4)_2 \cdot NaOH)_n$ corresponding to the formula of the hydrate $((C_5H_8O_4)_2 - H_2O)_n$, the formula implicated in the expression $(C_{10}H_{19}O_9)_n$. It should be noted, however, that the union formed with xylan and alkali is an exceedingly labile one, since the sodium hydroxide can readily be eliminated. In addition, it is important to take cognizance of the fact that specimens of anhydrous xylan can be readily obtained by desiccation at 115° in a vacuum of 15 mm., or over phosphorous anhydride at a lower temperature.

In a recent paper from the laboratory of Professor Haworth in Birmingham, England, methylation studies have been extended to the pentose polysaccharides. In this research Haworth and co-workers[9] used a xylan preparation obtained from esparto cellulose. By the method of estimating separately the carbon and hydrogen, and then the moisture content of an air-dried xylan sample, they concluded that their work substantiated the empirical formula $(C_5H_8O_4)_n$. It is apparent that a definite empirical formula for the pentosans is essential for a critical consideration of the molecular constitution of the pentose polysaccharides. In 1926, while the writer was at the laboratory of Professor Fritz Pregl, Graz, Austria, engaged in elementary micro-organic analyses, it was possible to investigate

the problem of the empirical composition of xylan, by micro-combustion methods.

The results obtained from the analyses of 15 xylan specimens from various sources corroborate the contention of Johnson, Haworth and coworkers in formulating xylan as $(C_5H_8O_4)_n$ and the methylated xylan compounds as derivatives of this parent formula.

Experimentation

Five xylan preparations from corn *(Zea Mays)* seedlings isolated as described in this Journal,[10] four xylan specimens from corn cobs, two from corn stalks and one each from beech wood, cherry wood, rye straw, and esparto grass were subjected to the ultimate carbon and hydrogen analysis by the Pregl micro-combustion method.[11] With the exception of the xylan specimens prepared from the corn seedlings, which were isolated as stated above, the various specimens were prepared by the method of Wheeler and Tollens.[12] After the initial isolation the various specimens were subjected to a further purification using the method of Heuser.[13] The preparations were thrice precipitated from 5.0% sodium hydroxide solution (carbonate free) as the copper–xylan complex, from which the copper was eliminated as already described.[14] All of the freshly precipitated preparations were first dried through the use of organic solvents; the importance and significance of this procedure has already been mentioned.[15] When the moisture content of the various xylan preparations was reduced to less than 3% through the employment of the aforementioned technique, no difficulty was encountered in obtaining an absolutely anhydrous xylan by drying the specimens in the Pregl micro-desiccator block at 100° for eight to ten hours at 15 mm. pressure. While it may not be difficult to produce absolutely dry xylan specimens by drying in the Pregl micro-desicca-

tor block, it is necessary to employ the utmost care to prevent a re-absorption of water. This difficulty was circumvented by placing enough of the partially dried xylan specimens in a platinum combustion boat to insure a sample of from six to eight milligrams when completely dry. The boat was then quickly transferred to a micro-weighing bottle by holding the mouth of the bottle against the drying tube and tilting the latter to discharge the boat. After weighing the specimen the boat was expeditiously transferred to the combustion tube in the manner described above. Through the use of this technique the absorption of water from the atmosphere was practically nil, as indicated by control weighings made on samples in platinum boats that were transferred back and forth from the combustion tube to the weighing bottle. The carbon and hydrogen values obtained in the highly purified xylan specimens are given below, calculated on the moisture and ash-free basis. Calcd. for $(C_5H_8O_4)_n$: mol. wt., 132.06; C, 45.44; H, 6.11.

In conclusion the writer wishes to express his gratitude to Dr. Arnulf Soltys (Graz) for the generous assistance and helpful suggestions that he contributed to this work.

Summary

The analytical results obtained by subjecting fifteen highly purified xylan specimens from various sources to the ultimate carbon and hydrogen analyses by the Pregl micro-method, indicate that pure xylan has the empirical formula $(C_5H_8O_4)_n$. This is in agreement with the theoretical formula for xylan when formulated as the anhydride corresponding to xylose, $C_5H_{10}O_5$. Judging from the ultimate analyses of xylan preparations reported in the literature, pure xylan has in most cases either not been obtained, or the preparations were analyzed under conditions that did not exclude the absorption or loss of water in the course of the analytical procedure.

THE STRUCTURAL ISOMERS OF BROMOBENZOYLACRYLIC ACID

BY GRACE POTTER RICE

RECEIVED FEBRUARY 1, 1930 PUBLISHED MAY 8, 1930

In a recent paper published from this Laboratory[1] two pairs of unsaturated bromo-γ-ketonic esters and the pair of acids corresponding in configuration to them were described and shown to be geometrical isomers, but the position of the bromine atoms in these substances was not determined. In 1925 Bogert and Ritter[2] prepared an unsaturated bromo acid of benzoylacrylic acid and stated that the bromine atom in this substance was probably in the a-position because it gave acetophenone on

---

[1] Rice, THIS JOURNAL, 50, 1481 (1928).

[2] Bogert and Ritter, *ibid.*, 47, 526 (1925).

treatment with sodium hydroxide. This bromobenzoylacrylic acid was prepared by the elimination of hydrogen bromide from the two racemic dibromo acids $C_6H_5COCHBrCHBrCOOH$; the position of the bromine atom in the unsaturated acid is, therefore, determined by the comparative reactivities of the two hydrogen atoms in the dibromo acids. Since the mode of addition to benzoylacrylic ester and its substitution products, which have two conjugated systems of double linkages $C_6H_5\overset{1}{O}\overset{2}{C}\overset{3}{C}\underset{4}{H}{=}\overset{4}{C}\underset{3}{H}\underset{2}{C}\underset{1}{O}OR$, has been shown to be a result of 1,4-addition according to the scheme $C_6H_5\overset{1}{O}\overset{2}{C}\overset{3}{C}H{=}\overset{4}{C}HCOOR$,[3,4] it seemed probable that the hydrogen atom α to the C_6H_5CO group would be the reactive one and that the unsaturated acid would, therefore, hold its bromine atom in the β-position to the COOH group. This has been proved to be the case. The proof rests on the synthesis of the structural isomer of the acid of Bogert and Ritter from bromomaleic anhydride by the Friedel and Crafts reaction. This new acid gives phenylglyoxal on ozonization; it is the a-acid, $C_6H_5COCH{=}CBrCOOH$. The acid of Bogert and Ritter must, therefore, be the β-acid $C_6H_5COCBr{=}CHCOOH$.

Since the isomeric unsaturated bromo acids recently described were prepared by elimination of hydrogen bromide from dibromo acids which are substitution products of the dibromobenzoylpropionic acids, they too, undoubtedly, hold their bromine atoms in the β-position. They are, accordingly, $(CH_3O)_2C_6H_2BrCOCBr{=}CHCOOH$ and their esters $(CH_3O)_2C_6H_2BrCOCBr{=}CHCOOR$.

Experimental Part

Before the structure of the bromobenzoylacrylic acids was established, the Friedel and Crafts reaction with bromosuccinic anhydride and benzene was carried out with the idea that if the course of the reaction was such that either a- or β-bromobenzoylpropionic acid was formed exclusively, a clue would be given as to the position of the bromine atom in the bromobenzoylacrylic acid formed in the analogous reaction with bromomaleic anhydride and benzene. The evidence sought was not obtained because not one but two unsaturated bromo acids were isolated from bromomaleic anhydride.

A solution of 14.4 g. of bromosuccinic anhydride in 60 g. of benzene was stirred mechanically and warmed while it was treated gradually with 25 g. of aluminum chloride; the product, which was thrown to the sides of the flask as a solid, was decomposed cautiously with ice and hydrochloric acid and the solution extracted five times with benzene. The benzene deposited 3.7 g. of solid melting at 110–117° which was purified

by boiling it with carbon disulfide and crystallizing the residue from benzene; 2.5 g. of a-bromobenzoylpropionic acid, melting at 118° into a red liquid, was obtained.

Anal. Calcd. for $C_{10}H_9O_3Br$: C, 46.69; H, 3.50. Found: C, 47.09; H, 3.93. It is the acid prepared by Bougault[5] by addition of hydrogen bromide to benzoylacrylic acid. Evaporation of the benzene and carbon disulfide filtrates left a red oil from which boiling water extracted 1.6 g. of benzoylacrylic acid. This was formed from the maleic anhydride which separated during the distillation of bromosuccinic anhydride under diminished pressure. Extraction of the original aqueous solution with ether gave 9 g. of bromosuccinic acid; the yield of a-bromobenzoylpropionic acid calculated from the bromosuccinic anhydride which reacted was 30%. No β-bromobenzoylpropionic acid could be found though seed was available for inoculation. The behavior of bromosuccinic anhydride is thus different from that of methylsuccinic anhydride,[6] which gives both a- and β-substituted ketonic acids in the Friedel and Crafts reaction.

a-Bromobenzoylacrylic Acid, $C_6H_5COCH{=}CBrCOOH$.—The bromomaleic anhydride used for the preparation of this acid by the Friedel and Crafts reaction was made from both isodibromosuccinic acid[7] and from dibromosuccinic acid.[8] From dibromosuccinic acid an 81% yield of the unsaturated anhydride was obtained[9] by heating the acid with half its weight of phosphorus pentoxide at 200–210° until hydrogen bromide was no longer eliminated, distilling the product (b p. 215–216°) and redistilling it under reduced pressure with fresh phosphorus pentoxide—b. p. 110° at 18 mm.

A solution of 24.5 g. of freshly distilled bromomaleic anhydride in 80 g. of benzene was warmed and treated gradually with 38 g. of aluminum chloride with constant stirring. When the vigorous evolution of hydrogen chloride slackened, the product was heated for one hour, the viscous mass treated cautiously with ice and concd. hydrochloric acid and the brownish colored solid filtered off; 18 g. of crude acid melting at 110" into a cherry-red liquid was obtained. The acid was purified by recrystallization from benzene, from which it separates in fine needles; it can also be recrystallized from ether, chloroform, benzene and ligroin, chloroform and ligroin and boiling water. By using water it is possible to get rid of the trace of color which is carried down with other solvents. When impure the acid is extremely sensitive to heat; on evaporation of its solution the residue is a cherry-red oil. From 18 g. of crude product 11.1 g. of pure acid, melting at 129° into a red liquid, was separated.

Anal. Calcd. for $C_{10}H_7O_3Br$: C, 47.05; H, 2.74. Found: C, 47.00; H, 3.01.

The aqueous filtrate, after removal of the crude acid, was extracted four times with benzene; the first crop of crystals from the benzene was 1.5 g. of pure β-bromobenzoylacrylic acid (109°) identified by comparison with a specimen of this acid. The benzene filtrate deposited 2.2 g. of acid, melting at 85–110° into a red oil, from which 1.5 g. of p-bromo acid was separated. This acid gave a colorless melt which solidified on cooling. The residue from benzene as well as the residue left after purifying the a-bromo acid contained a mixture of the a- and β-bromo acids which was contaminated with oily decomposition products. The solid separated from these residues was a mixture of isomeric acids. A trace of the a-bromo acid in the β-bromo acid can invariably be detected because the melt shows the characteristic red color of the a-isomer. The mixture of the a- and β-bromo acids melts at 90–102°. It is an interesting fact that the α-bromo saturated acid and the a-bromo unsaturated acid form red oils on melting, whereas the β-bromo saturated acid and the β-bromo unsaturated acid melt into colorless liquids.

Ozonization of a-Bromobenzoylacrylic Acid.—Ozonized oxygen containing about 5% of ozone was passed for one and one-half hours through a solution of 1 g. of α-bromobenzoylacrylic acid in 25 cc. of glacial acetic acid at ordinary temperature. The ozone was then swept out with a current of nitrogen, the solution diluted with water. neutralized with sodium carbonate and extracted with ether. The ether was pumped off in the presence of water and the resulting water solution treated with a slightly acid solution of phenylhydrazine. This produced a yellow precipitate which was dried and recrystallized from low-boiling petroleum ether. It separated in the characteristic needles of the low-melting phenylhydrazone of phenylglyoxal, with which it was identified by a mixed melting point.

On boiling with water a-bromobenzoylacrylic acid gives acetophenone, which was identified by its semicarbazone. With warm sodium methylate the acid also gives acetophenone. In one case when steam was passed into the crude product from the Friedel and Crafts reaction in order to remove benzene, acetophenone was formed instantly and not a trace of the unsaturated bromo acids was found after steam distillation had been continued for fifteen minutes. The red oil, which separated from the aqueous layer, solidified in contact with ether into a brick red powder which held no bromine and did not melt below 250°. This behavior of a-bromobenzoylacrylic acid suggests the reactions of benzoylacrylic acid by which von Pechmann[10] prepared a red dye.

Before the structure of a-bromobenzoylacrylic acid was established by ozonization, this acid was treated with sodium hydrosulfite in the hope of reducing it to one of the known saturated bromobenzoylpropionic acids, but the reduction product was benzoylpropionic acid. This reaction is similar to that in which chlorodibenzoylethylene is changed into dibenzoylethane.[11]

Methyl **a-Chlorobenzoylacrylate,** $C_6H_5COCH{=}CClCOOCH_3$.—This unsaturated chloro ester was obtained by saturating a methyl alcohol solution of the a-bromo acid with hydrogen chloride and allowing it to stand. The crude product of reaction was used for analysis.

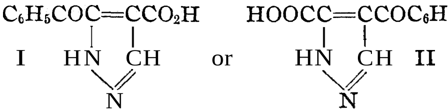
Anal. Calcd. for $C_{11}H_9O_3Cl$: C, 58.79; H, 4.00; Cl, 15.81. Found: C, 58.35; H, 4.17; Cl, 15.76.

The ester remains a yellow liquid after exposure to diffused daylight for a year; it is probably formed by addition of hydrogen chloride followed by elimination of hydrogen bromide.

Methyl a-Bromobenzoylacrylate, $C_6H_5COCH{=}CBrCOOCH_3$.—This ester was prepared by refluxing a methyl alcohol solution of the acid containing a trace of concd. sulfuric acid for three hours. The yellow liquid product is stable in the light but on distillation in a vacuum half of the material was left behind as a red oil; the ester which distilled at 198–200° at 25 mm. was amber colored.

Anal. Calcd. for $C_{11}H_9O_3Br$: C, 49.07; H, 3.34. Found: C, 49.64, 49.70; H, 3.77, 3.49.

5-Benzoylpyrazole-4-carboxylic Acid or 4-Benzoylpyrazole-5-carboxylic Acid,



I $C_6H_5COC{=}CCO_2H$ (HN–N=CH ring) or $HOOCC{=}CCOC_6H_5$ (HN–N=CH ring) II .—The reaction between α-bromobenzoylacrylic acid and diazomethane was carried out for the purpose of determining whether the yellow liquid ester corresponds in configuration to the acid. An absolute ether

---

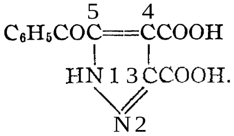
[10] Von Pechmann, Ber., 15, 885 (1882).

[11] Conant and Lutz, THIS JOURNAL, 47, 883 (1925).

solution of diazomethane was added to an absolute ether solution of the acid until evolution of nitrogen ceased; evaporation of the solvent left a yellow oil which gave on analysis a percentage of carbon 3.6% too high for the ester. This yellow oil, after standing for several hours, began to deposit a colorless solid and finally was almost completely changed into this solid. By extracting the mixture with ether the solid was separated from a small quantity of yellow liquid which contained bromine, was insoluble in sodium carbonate solution, was stable in the sunlight, gave acetophenone on warming with water and was probably the ester described above. The solid separated from methyl alcohol in rosets of fine, colorless needles melting at 218° with evolution of gas.

Anal. Calcd. for $C_{11}H_8O_3N_2$: C, 61.11; H, 3.70; N, 12.96. Found: C, 60.76, 61.00; H, 3.71, 4.02; N, 12.86.

The hydrogen bromide is undoubtedly eliminated after formation of the ring nitrogen compound. This reaction is like that of the ester of a-bromocinnamic acid with diazoacetic ester which gives an intermediate product containing bromine.[12] A pyrazole derivative melting at 220" with evolution of gas was made by Wolff,[13] and shown to be



$$\begin{array}{l} \overset{5}{C_6H_5COC}{=\!=}\overset{4}{C}COOH \\ \quad\;\; | \qquad\quad | \\ \quad HN\,1\;\;3\,CCOOH \\ \qquad\;\; \diagdown\!\!\diagup\!\!\diagup \\ \qquad\quad N\,2 \end{array}$$

Since the elimination of carbon dioxide from the COOH at 3 is known to take place more readily than from the COOH at 4, it might be possible to determine the structure of the pyrazole formed from the a-bromo acid by obtaining it or its isomer by removal of carbon dioxide[14,15] from the pyrazole of Wolff. The importance of deciding between the two possible structures for the pyrazole, however, did not seem to warrant the laborious synthesis of Wolff's substance. Since it is known that the carbon of the diazomethane molecule adds to the 8-carbon atom of an unsaturated substance,[16] it is probable that formula I represents the structure of the pyrazole.

In order to prepare the unsaturated bromo acid[2] now proved to be β-bromobenzoylacrylic acid, for purposes of comparing it with the α-bromo acid, it was necessary to brominate benzoylacrylic acid. Von Pechmann,[10] who recrystallized the dibromo acid prepared in chloroform solution from dilute alcohol, gives a melting point of 135° and Bougault,[5] who recrystallized it from carbon disulfide and benzene, gives 148" as its melting point. Bogert and Ritter[Z] report a yield approximately quantitative by bromination of benzoylacrylic acid in glacial acetic acid and give 147.5" as the melting point of the dibromo acid. They state that this is prepared by bromination in chloroform or glacial acetic acid and that search for the second racemic isomer was in vain. In this Laboratory a mixture of racemic isomers was invariably obtained on bromination in both chloroform and glacial acetic acid; this reaction was carried out five times and always a quantitative yield of solid was obtained melting at 110–125°. From this mixture one of the isomers can be separated by boiling the crude solid with benzene and filtering off the less soluble portion, boiling this again with benzene and finally recrystallizing the residue from the same solvent; from 22.6 g. of the mixture 10.1 g. of the dibromo acid which melted at 150° was thus isolated. The rest of the mixture resisted separation though ten different solvents were used. The isomeric dibromo acid can be

---

[12] Buchner and Fritsch, Ber., 26,256 (1893).

[13] Wolff, *Ann.*, 325, 187–189 (1902).

[14] Buchner and Dessauer, ***Ber.***, 26, 260 (1893).

[15] Koenigs and Koerner, ***ibid.***, 16, 2153 (1883).

separated, however, by starting with the product of bromination melting at 110–125" and boiling it in carbon disulfide, filtering off the less soluble portion, boiling the solid which crystallizes from the carbon disulfide again with this solvent, filtering off the less soluble portion and allowing the filtrate to crystallize. The first crop of crystals from this solution melted at 148°; the mixture of this acid and the solid melting at 150° melted at 110–132°.

This lower-melting isomer, described as a solid melting at 142°, has been prepared from isodibromosuccinic anhydride by the Friedel and Crafts reaction.[2] It readily can be obtained by bromination of benzoylacrylic acid in carbon disulfide solution; 2 g. of the acid was suspended in carbon disulfide and the calculated quantity of bromine added with vigorous stirring. Suddenly the bromine color disappeared and the solution at once deposited 2.8 g. of solid melting at 140–145°; including the residue which was a mixture of isomers, the yield was quantitative. The 2.8 g. of solid was recrystallized twice from chloroform, from which it separates in clusters of needles melting at 148°; 50% of the product was separated as this isomer. It crystallizes from benzene in clusters of fine needles while the isomer (150°) separates in long needles from this solvent. There is no depression in the melting point when the isomer (148°) from bromination in carbon disulfide is mixed with the isomer (148°) described above. A mixture of it and the acid (150°) melts at 110–132°. A mixture of the isomers was recrystallized from benzene; the crystals which separated looked like one substance but they melted at 110–143°.

Isomeric Methyl **Dibromobenzoylpropionates, $C_6H_5COCHBrCHBrCOOCH_3$.**—An absolute ether solution of the isomer (150") was treated with an absolute ether solution of diazomethane; evaporation of the solvent left a colorless solid in quantitative yield which melted at 58° after one recrystallization from methyl alcohol.

Anal. Calcd. for $C_{11}H_{10}O_3Br_2$: C, 37.71; H, 2.85. Found: C, 37.83; H, 3.08.

When the isomer (148") was likewise treated with diazomethane and the solid recrystallized from methyl alcohol, a quantitative yield of ester melting at 48° was obtained.

Anal. Calcd. for $C_{11}H_{10}O_3Br_2$: C, 37.71; H, 2.85. Found: C, 37.80, 37.70; H, 3.08, 3.11.

The mixture of the two esters is a liquid. These esters were prepared in order to confirm a statement made in an earlier paper[17] that bromination of methyl benzoylacrylate gives a product which fails to crystallize because it is a mixture of racemic isomers. The liquid product of bromination of this ester was seeded with the dibromo ester (58°); after standing for several days a crop of crystals which were the ester (58°) separated.

When β-bromobenzoylacrylic acid was prepared from dibromobenzoylpropionic acids,[2] 18% of the dibromo acids was recovered unchanged; it is necessary to heat a glacial acetic acid solution of the dibromo acids in a boiling water-bath for one hour with potassium acetate in order to complete the elimination of hydrogen bromide; the highest yield of unsaturated acid obtained in this work was 55%. β-Bromobenzoylacrylic acid separates from benzene in large, transparent crystals melting at 95–98'; on standing these crystals become opaque and give up their solvent gradually. . If the solid (95–98°) is boiled with carbon disulfide, it loses its benzene and shows the melting point reported, 109'.

β-Bromobenzoylacrylic acid does not give a trace of acetophenone on boiling for one hour with water but on heating it for two hours on a boiling water-bath with a 20% sodium carbonate solution, oxalic acid and acetophenone (identified by its semicarba-

---

[17] Rice, THIS JOURNAL, 45, 227 (1923).

zone) were formed. With potassium hydroxide solution (15g. in 25 cc. of water) the acid gives acetophenone even when the solution is kept cold with ice; after warming this solution for two minutes a 94% yield of benzoic acid was separated. The behavior of the ***a-*** and β-bromo acids on hydrolysis shows that treatment with alkaline reagents and even boiling with water can offer no clue as to the position of the bromine atom in the unsaturated bromo acids. That an acetylenic compound was formed[2] from dibromobenzoylpropionic acid in the presence of 3 M sodium hydroxide seems improbable in view of the ease of hydrolysis of the unsaturated p-bromo acid which would be the intermediate product formed on treatment with alkali. Further, the tendency which acetylenic compounds of the type $C_6H_5COC{\equiv}CCOC_6H_5$ show to form addition products in the presence of alkaline reagents[1,11] indicates that an acetylenic compound, if formed, would probably not escape reaction. Attempts have been made to prepare benzoylpropiolic acid but it has not yet been obtained in reactions analogous to those used by Lutz[18] for the preparation of dibenzoylacetylene from dibromodibenzoylethane. Further work on this reaction is in progress.

β-Bromobenzoylacrylic acid, like the a-bromo acid, gives benzoylpropionic acid on treatment with sodium hydrosulfite, so that again no conclusion as to structure can be drawn from the reduction reaction.

Methyl **β-Bromobenzoylacrylate,** $C_6H_5COCBr{=}CHCOOCH_3$.—A liquid mixture of isomers was obtained by bromination of 8.3 g. of methyl benzoylacrylate in carbon disulfide solution; this was dissolved in methyl alcohol, the solution heated for five minutes with 8 g. of potassium acetate and poured onto ice. The yellow liquid, obtained by extraction with ether, gave 10.5 g. of product distilling at 180–185° at 20 mm., a 90% yield. On standing, the yellow liquid deposited a colorless solid which melted at 86° after two recrystallizations from methyl alcohol. In the sunlight the yellow liquid is rapidly and completely transformed into the colorless solid. These esters, therefore, are geometrical isomers.

Anal. Calcd. for $C_{11}H_9O_3Br$: C, 49.07; H, 3.34. Found: I (86°) C, 49.24; H, 3.54. II (yellow liquid) C, 49.41; H, 3.63.

On treatment of β-bromobenzoylacrylic acid with diazomethane a quantitative yield of the ester (86") was obtained. This ester, then, corresponds in configuration to the known β-bromo acid (109°). These esters are not reduced even on warming with sodium hydrosulfite.

When the β-bromo esters are boiled with water the vapor at first carries a sharp, tear-producing substance which soon disappears and, after several hours of boiling, acetophenone is formed. On slight warming with potassium hydroxide solution both esters give acetophenone and benzoic acid.

In marked contrast to the behavior of a-bromobenzoylacrylic acid, the β-bromo acid gave a bromo ester when its methyl alcohol solution was saturated with hydrogen chloride. This ester (86°) on standing for two days in methyl alcohol saturated with hydrogen chloride was partially changed into a chloro ester. Micro Pregl determinations gave 20.85, 21.59% of halogen; calcd. for Br, 29.73; for Cl, 15.81.

Summary

a-Bromobenzoylacrylic acid has been prepared and its structure proved. A comparison of its reactions and those of the known bromobenzoylacrylic acid, now shown to be a β-substituted acid, has been made.

RELATIONS BETWEEN ROTATORY POWER AND STRUCTURE IN THE SUGAR GROUP. XXVII. SYNTHESIS OF A NEW DISACCHARIDE KETOSE (LACTULOSE) FROM LACTOSE[1]

BY EDNA M. MONTGOMERY AND C. S. HUDSON

RECEIVED FEBRUARY 3, 1930 PUBLISHED MAY 8, 1930

The comparison of the rotation of sorbose with that of methylsorboside,[2] which indicated that sorbose may possibly exist in solution in only one form, namely, as a-sorbose, opened a line of thought which has led us to undertake the preparation of new ketoses and ketose derivatives. If the fact that several of the known ketose sugars (sorbose, tagatose, mannoketoheptose and α-glucoheptulose)[3] do not show mutarotation is to be ascribed to the existence of these sugars in only one form in solution, one must inquire why these ketoses are unable to undergo the tautomeric balanced reactions which cause the mutarotation of aldoses. In sharp contrast to the behavior of these four ketoses stands the observation that fructose, turanose[4] (which is glucosido-fructose) and perseulose (which is very similar in configuration to fructose)[5] exhibit mutarotation. If the four non-mutarotating ketoses do not change partially in solution from alpha to beta forms of like ring structure, is the mutarotation of the other three due to such a change or may it not rather involve a shifting of the oxygen ring? The fact that fructose mutarotates but its tetra-acetate does not, whereas both glucose and glucose tetra-acetate mutarotate, is indeed evidence that the mutarotation of fructose is caused by ring-shifting; its tetra-acetate cannot shift the ring except by an improbable acetyl migration. With these questions and ideas in mind we have begun the collection of further experimental data on ketoses and their derivatives.

Few ketoses are known in comparison with the large number of aldoses that are recognized. The number may be increased either by the discovery of new naturally occurring ketoses or by way of laboratory synthesis. The discovery of mannoketoheptose in the avocado[5] and of sedoheptose in the stonecrop[6] indicates that a systematic search for other new ketoses in natural products might be well repaid, but for the present the

The synthesis of lactulose was reported by the authors at the April, 1929, meeting of the National Academy of Sciences [*Science,* 69, 556 (1929)]. The name lactoketose was then used for the sugar but it has been decided subsequently to name it lactulose.

path of synthesis appears to offer prospect of larger or at least more rapid returns.

The conversion of aldoses to ketoses is a rich and only slightly explored field. The first synthesis of this kind was performed by Emil Fischer[7] in the following two ways: (1) glucose → glucose osazone → isoglucosamine → fructose; *(2)* glucose → glucose osazone → glucosone → fructose. Although Fischer was hopeful that these reactions would prove of general application, such has not been the case and no other ketose has been synthesized by them. Philippe's[8] attempt to prepare a ketose from a-glucoheptose through Fischer's methods was unsuccessful. New methods of ketose synthesis, introduced by Bertrand and by Lobry de Bruyn, have led to the discovery of perseulose,[9] α-glucoheptulose,[3] tagatose and *d*-sorbose,[10] the antipode of natural *l*-sorbose. Bertrand has utilized the sorbose bacterium to oxidize alcohols of the sugar group to ketoses but the application of this biological method seems to be considerably restricted by the specificity of the bacterium. The Lobry de Bruyn rearrangement of aldoses and ketoses in alkaline solution appears at the present time to offer the best prospect for synthesizing new ketoses from the large number of known aldoses. The researches of Lobry de Bruyn, Van Ekenstein, and Nef[11] have shown that the important factors for the success of the synthesis are (1) the obtaining of conditions of alkaline concentration, time and temperature which give suitable rearrangement of the aldose with a minimum of side reactions and (2) a separation of the ketose from the mixture of sugars and decomposition products which results from the alkaline treatment of an aldose. The success which Wolfrom and Lewis[12] have reported in the rearrangement of tetramethylglucose and tetramethylmannose at 35° in saturated limewater has led us to select these conditions for the initial step in ketose synthesis. In carrying out the second step the procedure of Nef[11] in a modified form has been used and aldoses have been removed from ketoses by oxidizing them with bromine water under the mild conditions of acidity that result from the presence of a buffering salt such as barium benzoate, as recommended lately by Hudson and Isbell.[13] By applying these reactions to lactose it has been possible to transform it to a new crystalline disaccharide ketose, to which the name lactulose is given because of its origin, and in the following article there is described by our colleague, W. C. Austin, the preparation in similar manner of a new crystalline ketose from d-a-glucoheptose, to which he has given the name *d*-

glucoheptulose. These results indicate that the directions which we have worked out are probably of general applicability for synthesizing many new ketoses from the large number of aldoses that are known. Work in this field is being continued by the authors and at present the synthesis of d-mannoketoheptose is being attempted.

Behavior of Lactose in Weak Calcium Hydroxide Solution.—A solution of **180** g. of a-lactose monohydrate in one liter of clear limewater of **0.043** normality, which had been prepared by saturating distilled water with slaked lime at 35°, was kept at 35° until the change of rotation that results from the Lobry de Bruyn rearrangement was complete. The initial mutarotation of lactose in such an alkaline solution is very rapid and the first reading, which was made after the lapse of four minutes, showed the equilibrium rotation of lactose, $[\alpha]_D$ +52.5. The rearrangement became noticeable at the end of half an hour, when the rotation was **+50.7.** After twenty-four hours it was +37.7, after thirty-six hours +31.6 and after forty-eight hours +31.5. The time required for the equilibration of lactose, thirty-six hours, is much shorter than that observed by Wolfrom and Lewis for d-glucose under like conditions, which was ten days. The addition of more lime to samples of the equilibrated lactose solution caused no further change of rotation. When the equilibrated solution was analyzed for aldoses by alkaline hypoiodite, using the directions of Goebel,[14] a high result indicating the absorption of more iodine than could be accounted for by all the lactose originally present, was obtained. This result conforms with the observation of Wolfrom and Lewis in the case of the glucose rearrangement and is presumably due, as they have suggested, to the presence of an unsaturated enolic derivative of the aldose. The equilibrated lactose solution was acidified at 10° with sulfuric acid to a normality of **2.0** and kept at 35° for two hours, as recommended by Wolfrom and Lewis, to accomplish de-enolization. Its analysis then by iodine oxidation indicated a mixture of approximately 70% aldose and 30% ketose. Experience in preparing the crystalline ketose from a considerable number of equilibrated solutions indicates that the yield is somewhat increased by the introduction of the step of de-enolization but that the increase is hardly worth the extra labor involved.

Isolation of a New Ketose from the Equilibrated Solution.—If one employs a de-enolized solution, the sulfuric acid is neutralized with calcium carbonate without heating and the filtrate and washings are concentrated under reduced pressure to a sirup. When de-enolization is omitted, the equilibrated solution is reduced similarly to a sirup. In either case the sirup resulting from the treatment of **180** g. of lactose is dissolved in **500** cc. of **95%** alcohol. Lactose crystallizes abundantly (about **110–125** g.) and is filtered off after several days' standing at low temperature. The mother liquor and alcoholic washings are concentrated to a sirup which is then mixed with six volumes of 95% alcohol and the precipitated calcium salts are removed. The filtrate is concentrated again, the sirup obtained is dissolved in **50** cc. of absolute methyl alcohol and allowed to crystallize slowly in a desiccator, yielding a second crop of lactose; repetition of this treatment usually gives a third small crop of lactose, bringing the total recovery to about **120–135** g. Another repetition yields by a slow crystallization, which is much aided by seeding with crystals of lactulose, a crop of about 14 g. of impure ketose of $[\alpha]_D$ **−32** (final) when a de-enolized solution has been employed, or about **11** g. showing $[\alpha]_D$ **−23,** when de-enolization has been omitted. The impure sugar is a mixture of lactulose and presumably lactose; the pure ketose can be obtained from it through the process of oxidizing the aldose with bromine water in the presence of a buffering salt. The amount of aldose present, calculated as lactose, is first estimated

---

[14] Goebel, *J. Biol.* Chem., **72, 801** (1928).

by hypoiodite; it is usually about 15% of the total dry matter. Bromine to the extent of 1.1 moles (Br_2) for each mole of aldose present is added to a 10% aqueous solution of the impure ketose containing an excess of barium benzoate (1.25 mole) and the solution is kept at room temperature in the dark for two days. The excess bromine, the barium and the benzoic acid are then removed as described by Hudson and Isbell and the aldobionic acid is converted to a salt (calcium, barium or lead) without heating. The solution is concentrated to a sirup and the salts are precipitated by adding 6 volumes of 95% alcohol, filtering, reconcentrating the filtrate, dissolving it in 250 cc. of absolute alcohol, refiltering and reconcentrating. A solution of the last sirup in an equal volume of absolute methyl alcohol yields by a slow crystallization (seven days) about 65% of the ketose that was present in the impure product; its $[\alpha]_D^{22}$ value is −51.5 (final) and the rotation is not changed by recrystallization from 50% methyl alcohol. The yield of pure lactulose is about 6 to 7.5 g. from 180 g. of lactose or 10 to 15% of the lactose that underwent rearrangement. We have not investigated the other products that are apparently formed in considerable quantity. While the yield of lactulose leaves much to be desired, it is probable that the general application of the method will show better results with many other aldoses because lactulose is very difficult to crystallize; in support of this expectation it is mentioned that Austin (see next article) has obtained much higher yields of *d*-glucoheptulose from d-a-glucoheptose by the method.

Properties of **Lactulose.**—Lactulose crystallizes in hexagonal, colorless plates often grouped in clusters. It melts at 158°, gives the Seliwanoff test for ketoses, is not oxidized by hypoiodite, reduces Fehling's solution on heating and is sweeter than lactose but not as sweet as sucrose. It is an anhydrous sugar of the formula $C_{12}H_{22}O_{11}$. Its combustion shows C, 41.90% and H, 6.50%, whereas the calculated values from this formula are C, 42.09% and H, 6.43%; the freezing-point method indicates its mol. wt. to be 340–352, agreeing with the formula. It is very soluble in water. Lactulose exhibits rapid mutarotation. In aqueous solution at 22° its $[\alpha]_D$ value is −23.8 two minutes after solution and the final value is −51.5. The course of the mutarotation is shown in the table. It follows the unimolecular order and the extrapolated initial rotation is about $[\alpha]_D^{22}$ −5. Since the change is toward the negative and the mutarotating component (fructose, see later) is a d-sugar, the crystalline form of the disaccharide is to be designated a-lactulose. The rate of its mutarotation (0.114) at 22° is approximately the same as that of fructose[15] (0.082 at 20").

Preparation of **Lactone Osazone** and its Anhydride from **Lactulose.**—The phenylosazone of lactulose was not distinguishable from lactose osazone and it showed the unique characteristic of the latter in changing to a crystalline anhydride on heating its

---

[15] Hudson and Yanovsky, THIS JOURNAL, 39, 1013 (1917).

solution in dilute sulfuric acid.[16] This anhydride is particularly suitable for the characterization of lactose osazone because it shows a definite rotatory power and does not exhibit mutarotation. We find that lactose osazone, which exhibits mutarotation, shows varying final values and by successive recrystallizations it was not possible to obtain a substance of constant final rotation. The anhydro-osazone from lactose melted at 226° (uncorr.) with decomposition and showed $[\alpha]_D^{20}$ —174 in a mixture of four parts of pyridine and six parts of alcohol[17] (concentration, 2 g. of anhydro-osazone/100 cc.). The anhydro-osazone from lactulose melted at 226 with decomposition and showed $[\alpha]_D^{20}$ −174. A mixture of the two products melted at 225–226 with decomposition. The nitrogen content of the anhydro-osazone from lactulose by the Dumas method was 11.06%; theory requires 11.15%. Finally, the identity of the anhydro-osazones from the two sugars was conclusively established by solubility measurements of the two substances in acetone at 5°. The solubility of the anhydro-osazone from lactose was 0.1484 g./100 cc. from supersaturation and 0.1476 from undersaturation, and the corresponding values for the anhydro-osazone from lactulose were 0.1492 and 0.1480. The possibility that the anhydro-osazones might be different compounds of closely agreeing solubilities and other properties was tested by a measurement of the solubility of a mixture of equal quantities of the two anhydro-osazones, which gave the values 0.1484 and 0.1492 from under- and supersaturation; these data make it certain that the two products are the same chemical substance because if such were not the case the solubility of the mixture would be the sum of the individual solubilities, approximately 0.297 g. This method of testing the identity of pure substances is somewhat like the method of "mixed melting points" and may well be designated a "mixed solubility" method. It is very sensitive and is recommended in cases where the mixed melting-point method is of questionable significance because of decomposition of the substance.

Identification of the Component Hexoses of **Lactulose.**—A solution of 6 g. of lactulose in 120 cc. of 1% sulfuric acid was kept at 100" for eight hours to accomplish hydrolysis. Exact removal of the acid with barium hydroxide and concentration of the solution under reduced pressure to a thick sirup, which was taken up in very little methyl alcohol, yielded 1.5 g. of a crystalline sugar. After one recrystallization from this solvent, 1.0 g. of the sugar, dried at 50° for six hours, was obtained, showing $[\alpha]_D^{20}$ +81 (final) in aqueous solution; this value agrees with the known rotation of d-galactose. Fructose was isolated from the mother liquor in the form of its crystalline compound with calcium hydroxide, which was then decomposed with the exact equivalent of oxalic acid. Evaporation of the filtrate to a sirup, solution of this in alcohol and slow evaporation in a desiccator yielded 0.36 *g*. of crystalline sugar, of $[\alpha]_D^{20}$ —91.5 (final), which agrees with the known rotation of d-fructose.

The Structure of **Lactulose.**—Lactulose shows the composition and molecular weight of a disaccharide, $C_{12}H_{22}O_{11}$, as has been mentioned. Its reduction of Fehling's solution, the positive Seliwanoff test and the fact that it is not oxidized by bromine or by hypoiodite show that its molecule contains a ketose with a free reducing group. The fact that its anhydro-osazone is identical with lactose anhydro-osazonc shows that its structure is to be expressed as d-galactosido-4-d-fructose, because lactose is known to be d-galactosido-4-d-glucose~and lactose anhydro-osazone can result from no ketose of any other structure. Since lactulose crystallizes as an alpha form, as shown by the direction of its mutarotation, and since lactose is a beta galactosido disaccharide as shown from its hydrolysis by emulsin and from its rotation (see article XXVI[19] of this

---

[16] Fischer, **Ber., 20,** 821 (1887).

[19] Hudson, THIS JOURNAL, 52, 1707 (1930).

series), its structure may be further specified by the designation alpha 4-*β*-*d*-galactosido (1,4)-*α*-*d*-fructose, the 1,4-ring being assigned to the galactose portion because of the ring structure of lactose shown in article XXVI. The ring of the fructose component remains unknown, but it obviously cannot be of the 2,4-type. The isolation of *d*-galactose and d-fructose by the acid hydrolysis of lactulose agrees with the assigned composition.

Summary

As an experimental introduction to the extension of the Lobry de Bruyn rearrangement for the synthesis of new ketoses, conditions for the conversion of lactose to a disaccharide ketose have been studied and a new ketose named lactulose has been isolated in pure crystalline condition. Lactulose is shown to be 4-*β*-*d*-galactosido(1,4)-*d*-fructose and the crystalline sugar is an alpha form.

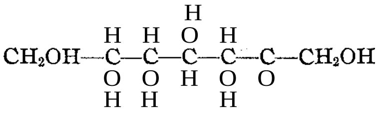
RELATIONS BETWEEN ROTATORY POWER AND STRUCTURE IN THE SUGAR GROUP. XXVIII. THE CONVERSION OF d-ALPHA-GLUCOHEPTOSE TO A NEW KETOSE, d-GLUCOHEPTULOSE[1]

BY W. C. AUSTIN

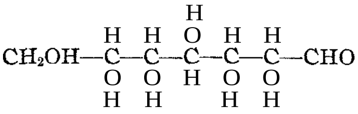
RECEIVED FEBRUARY 3, 1930 PUBLISHED MAY 8, 1930

It is to be expected on structural grounds that a new ketose of configuration **(A)** may be prepared in some suitable way from the known *d*-*α*-glucoheptose, of configuration[2] (B). The osazone of this hypothetical



$$\begin{array}{ccccccccccc} & & & & & H & & & & & \\ & H & & H & & O & & H & & & \\ CH_2OH- & C & - & C & - & C & - & C & - & C & -CH_2OH \\ & O & & O & & H & & O & & O & \\ & H & & H & & & & H & & & \end{array}$$

A



$$\begin{array}{ccccccccccc} & & & & & H & & & & & \\ & H & & H & & O & & H & & H & \\ CH_2OH- & C & - & C & - & C & - & C & - & C & -CHO \\ & O & & O & & H & & O & & O & \\ & H & & H & & & & H & & H & \end{array}$$

B

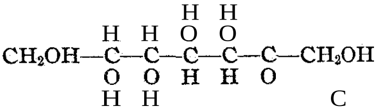
ketose should be identical with d-glucoheptose osazone, which has been prepared by Fischer[2] through the action of phenylhydrazine on either d-a-glucoheptose or *d*-*β*-glucoheptose. This ketose, to which the name d-*glucoheptulose* might well be given, should bear the same configurational relationship to the epimeric aldoses, d-a- and *d*-*β*-glucoheptose, as does *d*-fructose to d-glucose and d-mannose. The properties of d-glucoheptulose should apparently be of considerable interest because all the asymmetric

---

[1] Publication approved by the Director of the U. S. Bureau of Standards. The author was a National Research Fellow in Medicine, 1927–1928. He has arranged with Dr. C. S. Hudson, under whose direction the research was carried out, that it will be included as No. XXVIII in the series entitled "Relations between Rotatory Power and Structure in the Sugar Group." No. XXVII was published in THIS JOURNAL, 52,2101 (1930).

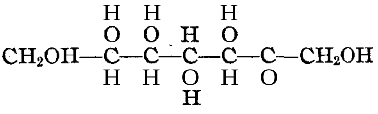
[2] Fischer, ***Ann.,*** 270, 64 (1892).

carbon atoms (Nos. **3,** 4, 5 and 6) of the sugar have precisely the configurations of the corresponding asymmetric carbon atoms (Nos. 2, 3, 4 and 5) of the d-glucose molecule. Also, since d-mannoketoheptose, of configuration[3] C shows no mutarotation, it may be expected that its epimeric[4] ketose,



$$\mathrm{CH_2OH{-}\underset{\substack{O\\H}}{\overset{H}{C}}{-}\underset{\substack{O\\H}}{\overset{H}{C}}{-}\underset{H}{\overset{\substack{H\\O}}{C}}{-}\underset{H}{\overset{\substack{H\\O}}{C}}{-}\underset{\substack{O\\C}}{C}{-}CH_2OH}$$

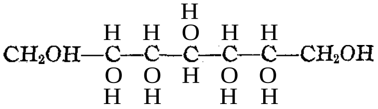
d-glucoheptulose, will not mutarotate. The value of the specific rotation of d-glucoheptulose may indeed be calculated in first approximation by adding the "epimeric difference of molecular rotation" (6700)[5] to the molecular rotation of d-mannoketoheptose ($[\alpha]_D + 29.2$) and dividing by the mol. wt. (210) of glucoheptulose, with the result that $[\alpha]_D = ((29.2)(210) + 6700)/210 = +61$. From these arguments it obviously follows that the antipodal sugar, *l*-glucoheptulose, of configuration



$$\mathrm{CH_2OH{-}\underset{H}{\overset{\substack{H\\O}}{C}}{-}\underset{H}{\overset{\substack{H\\O}}{C}}{-}\underset{\substack{O\\H}}{\overset{H}{C}}{-}\underset{H}{\overset{\substack{H\\O}}{C}}{-}\underset{O}{C}{-}CH_2OH}$$

may be expected to show $[\alpha]_D$ —61, approximately, with no mutarotation.

These deductions from structural theory and rotatory relations appear to have an important bearing upon the results of some recent synthetic work in the sugar group. Bertrand and Nitzberg[6] have obtained a pure crystalline ketose, to which they give the name a-glucoheptulose, by the action of the sorbose bacterium upon a solution containing a-glucoheptitol, of configuration



$$\mathrm{CH_2OH{-}\underset{\substack{O\\H}}{\overset{H}{C}}{-}\underset{\substack{O\\H}}{\overset{H}{C}}{-}\underset{H}{\overset{\substack{H\\O}}{C}}{-}\underset{\substack{O\\H}}{\overset{H}{C}}{-}\underset{\substack{O\\H}}{\overset{H}{C}}{-}CH_2OH}$$

Since Bertrand has shown during his extended researches with this bacterium that the ketose which it produces in a given case results from the oxidation of the secondary alcohol group on the carbon atom that is adjacent to a terminal primary alcoholic carbon atom, he and Nitzberg consider that the bacterium probably oxidizes a-glucoheptitol either at its Carbon 2 or 6 and that the configuration of a-glucoheptulose is thus probably either

---

[3] La Forge, *J. Biol. Chem.*, 28, 511 (1917).

[4] The concept of "epimeric" has been developed for aldoses (Votoček) but it is apparent that it can be extended to ketoses; see Hudson, THIS JOURNAL, 52, 1680 (1930). Epimeric aldoses (e. g., d-glucose and d-mannose) differ only in the configuration of their carbon atom 2; epimeric 2-ketoses (e. g., d-glucoheptulose and d-mannoketoheptose) differ only in the configuration of their carbon atom **3.**

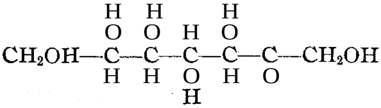
d-Glucoheptulose

or



$$\mathrm{CH_2OH{-}\underset{H}{\overset{OH}{C}}{-}\underset{H}{\overset{OH}{C}}{-}\underset{OH}{\overset{H}{C}}{-}\underset{H}{\overset{OH}{C}}{-}\underset{O}{C}{-}CH_2OH}$$

l-Glucoheptulose

These configurations represent antipodal forms of one sugar and the designations d and *l* are used in the sense of the dextro and levo series of Fischer, without regard to the actual directions of rotations of the two enantiomorph~. The researches of Bertrand and Nitzberg have not as yet given a decision between these configurations for their a-glucoheptulose and they use this designation of the ketose in the purely empiric sense that the sugar is derived from a-glucoheptitol. Bertrand and Nitzberg report that α-glucoheptulose shows no mutarotation and that it is levorotatory, $[\alpha]_D$ -67.1. From the agreement of these data with the present deductions from rotatory relations, it seems highly probable that their ketose is *l*-glucoheptulose.

The rotation which has been calculated for d-glucoheptulose (+61) is of interest also in another respect, since it has now become probable from the data of the preceding paragraph that these calculations are substantially correct. The known alpha form of d-mannose (mol. wt. 180) shows[7] $[\alpha]_D$ +30 and the 1,A = 1,4-ring has been assigned to it by Hudson? By use of the epimeric difference of rotation Hudson[S] calculated from this value the rotation of the epimeric alpha d-glucose, of 1,A = 1,4-ring structure, to be $[\alpha]_D = ((30)(180) + 6700)/180 = +67$. Neither of the two known crystalline forms of d-glucose (of $[\alpha]_D$ +113 and +19, respectively), can be this substance and Hudson concluded that the calculated value must refer to a form of d-glucose which has not yet been isolated. If it should now prove possible to isolate a crystalline form of d-glucoheptulose having an $[\alpha]_D$ value of approximately +61, strong evidence would be at hand for the belief that alpha d-glucose of 1,A = 1,4-ring structure rotates near +67, because the calculated rotation of d-glucoheptulose is obtained from that of d-mannoketoheptose by the same method that the rotation of α-*d*-glucose (1,A = 1,4) is obtained from that of a-d-mannose (1,A = 1,4). Moreover, the close agreement between the values of $[\alpha]_D$ for a-d-mannose (1,A = 1,4) (+30) and d-mannoketoheptose (+29.2) has its counterpart in the agreeing calculated rotations of α-*d*-glucose (1,A = 1,4) (+67) and d-glucoheptulose (+61), which may be correlated with the like configurations of the asymmetric carbon atoms in the members of each of these pairs, as has been indicated.

These various considerations and correlations, which were disclosed to me by Dr. Hudson shortly after the appearance of Bertrand and Nitzberg's

[9] Hudson, abid., 48, 1434 (1926).

first paper, made the synthesis of d-glucoheptulose from d-a-glucoheptose by some chemical method which would leave no uncertainty regarding the configuration of the resulting ketose appear very desirable and the work was accordingly undertaken. It was noticed that Philippe[10] had sought to accomplish this synthesis through the reactions d-a-glucoheptose ⟶ *d*-α-glucoheptose osazone ⟶ d-glucoheptulose, which would be analogous to the methods by which Fischer[11] converted d-glucose to d-fructose, but that he was unable to carry out the second stage. Repetition of Philippe's work by the writer led likewise to failure. Success came, however, through the use of Lobry de Bruyn's method of conversion of an aldose to a ketose in weakly alkaline solution. It has been possible in this way to synthesize d-glucoheptulose with a yield of about 30% by applying to *d*-α-glucoheptose the procedure through which Montgomery and Hudson[12] have recently synthesized lactulose from lactose in this Laboratory. Proof that the new heptose is a ketose was readily obtained from the observation that it is not oxidized by bromine water. Since its osazone proved to be identical with that of d-a-glucoheptose in analysis, melting point and mixed melting point, solubility and mixed solubility,[12] rotation and mutarotation, it seems certain that the ketose has the indicated configuration of *d*-glucoheptulose. The sugar crystallizes in prisms of m. p. 171–174°, shows no mutarotation and is dextrorotatory, $[\alpha]_D^{20}$ +67 in dilute aqueous solution. These results, which have been very carefully established, agree in every respect with the theoretical deductions from rotatory relations. They show that the a-glucoheptulose of Bertrand and Nitzberg is *l*-glucoheptulose (m. p. 173.5°, $[\alpha]_D$ -67), the optical antipode of the synthetic *d*-glucoheptulose. The existence of this d-glucoheptulose, of $[\alpha]_D$ $+67$, is strong experimental evidence that Hudson's calculation of 4-67 for the rotation of the now unknown a-d-glucose, of the 1,A = 1,4-ring structure, is substantially correct.

Preparation of *d*-Glucoheptulose.—Following the directions of Wolfrom and Lewis[13] for the enolization of aldoses in alkaline solution, a saturated solution of calcium hydroxide in water at 35° was prepared and some d-a-glucoheptose was dissolved in it to make a 10% solution. At 35° the $[\alpha]_D$ value changed from an initial rotation of about $-$**20,** the equilibrium rotation of d-a-glucoheptose, to $-$**17** after one hour, 0 after ten hours, +**30** after forty-six hours, and became constant after about seven days at +**40.** An iodine estimation of aldoses in this equilibrated solution showed about 40% aldose and 60% ketose. In a second experiment the end rotation was $[\alpha]_D$ +35. These two solutions, representing **55** g. of d-a-glucoheptose, were united and concentrated under reduced pressure to about **75** cc. and an equal volume of methyl alcohol was mixed with the sirup. A crop of **4.5** g. of crystalline d-a-glucoheptose separated from the solution when it was kept overnight in the ice box. A second crop of 5 g. of the original aldose

[13] Wolfrom and Lewis, *ibid.*, **50, 837 (1928).**

was obtained from the mother liquor by concentration and like treatment. The second mother liquor was concentrated to a thick sirup which was dissolved in about 600 cc. of methyl alcohol. An amorphous residue was filtered off, 200 cc. of absolute ether was added to the filtrate and more amorphous material was filtered off with the aid of decolorizing carbon. The clear and nearly colorless filtrate was concentrated to a sirup, taken up in about 45 cc. of alcohol and the solution was kept in a vacuum desiccator. After several days crystal foci appeared and on stirring with 80% ethyl alcohol the mass quickly solidified and yielded 27 g. of a new sugar, d-glucoheptulose, showing $[\alpha]_D$ +66, without mutarotation. The sugar was recrystallized several times, to constant rotation, by dissolving it in a small amount of water and adding alcohol or glacial acetic acid. It tastes quite sweet. It crystallizes very readily as well-formed prisms of m. p. 171–174°, after softening at 167°. It is anhydrous, does not lose weight on heating at 100° under reduced pressure in the presence of phosphorus pentoxide, and its analysis corresponds to the formula for a heptose, $C_7H_{14}O_7$. The combustion of 0.2-g. samples gave C, 39.81 and 39.72; H, 6.75 and 6.86; calcd.: C, 40.00; H, 6.67. The pure sugar showed $[\alpha]^{20}_D$ +67.46 in 2.5% aqueous solution and 67.66 in 10% solution; hence $[\alpha]^{20}_D = 67.4 + 0.027\ C$ (where C is concentration) in this range. Decrease of temperature increases the rotation and the formula $[\alpha]^t_D = +67.4 + 0.0278 - 0.027(t-20)$ applies over the range t = 15–30°. Since d-glucoheptulose and d-sorbose are similar in configuration for carbons 3, 4 and 5, it is interesting to note that they are much alike in the ease of crystallization, absence of mutarotation, and the influence of concentration and temperature on their rotations. The dextrorotation of d-sorbose ($[\alpha]_D$ +43) increases with concentration and decreases with rise of temperature.[14] For the mercury yellow line the $[\alpha]^{20}_{578}$ value of d-glucoheptulose is +70.28 in 2.5% solution and for the mercury green line $[\alpha]^{20}_{546.1}$ +79.5 and $[\alpha]^{29.3}_{546.1}$ +79.11 in 2.5% solution.

In the first experiment it was possible to obtain the ketose in pure form, unmixed with d-a-glucoheptose, but in subsequent preparations the two sugars were obtained as a crystalline mixture, due probably to the existence of crystal nuclei of the ketose in the laboratory. The separation of the ketose from this mixture is best accomplished by the oxidation of the aldose with bromine water containing barium benzoate,[15] which leaves the ketose largely unaffected. The precise directions may be omitted, as they have been published for the similar separation of lactose and lactulose by Montgomery and Hudson.[12] The yield of purified ketose when the bromine oxidation step was included in the procedure was about 30% of the weight of the original d-a-glucoheptose.

d-Glucoheptulose is not fermented by baker's yeast. It reduces Fehling's solution on heating and yields 87.6% of the weight of cuprous oxide that is produced by an equal quantity of anhydrous d-glucose. It is not oxidized by the hypoiodite reagent and is therefore a ketose. It gives a blue color in the orcin test, stronger than that produced by d-xylose and weaker than that shown by d-a-glucoheptose. With phloroglucin the same order of color development was found. The ketose also gives positive Seliwanoff and Pinoff tests, as does fructose, while the aldoses do not develop color in these tests; the intensity of the color was much greater for fructose than for *d*-α-glucoheptulose.

Identity of the Osazones of *d*-Glucoheptulose and *d*-α-Glucoheptose.—The osazone of the ketose was prepared by heating a solution of 5 g. of sugar, 15 cc. of phenylhydrazine, 10 cc. of glacial acetic acid and 50 cc. of water for five hours on the steam-bath. After twenty-four hours' standing in the ice box, a good crop of yellow needle crystals was

---

[14] Tollens and Smith, *Ber.*, 33, 1289 (1900). Their measurements were upon the levorotatory *l*-sorbose. Bertrand and Nitzberg (Ref. 6, first article) have called attention to the marked resemblance of their a-glucoheptulose (which may now be designated *l*-glucoheptulose) to *l*-sorbose.

[15] Hudson and Isbell, THIS JOURNAL, 51, 2225 (1929).

obtained, weighing 5.5 g. after washing with warm water, 95% alcohol and ether and drying. It was purified by dissolving it in 500 cc. of hot absolute alcohol, treating the solution with decolorizing carbon and keeping it in the ice chest for several days. Anal. combustions of samples weighing 0.2 to 0.3 g. showed C, 58.40 and 58.63; H, 6.32 and 6.36; N (Dumas), 14.43 and 14.25. Calcd. for $C_{19}H_{24}O_5N_4$: C, 58.76; H, 6.19; N, 14.43. The melting point was 194–195° with decomposition after darkening at 185–189°. A solution of 0.4 g. of osazone in 10 cc. of pyridine and 15 cc. of absolute alcohol showed $[\alpha]_D^{20}$ −5.3 two minutes after preparation, +9.6 after two and three-fourths hours and +35.0 final (ninety-six hours).

The osazone of d-a-glucoheptose was prepared similarly and recrystallized twice. Anal. N (Dumas), 14.64; calcd. 14.43. The melting point was 194–195° with decomposition after darkening at 189–190°. A solution of 0.4 g. of osazone in the usual pyridine–alcohol mixture showed $[\alpha]_D^{20}$ −1 two minutes after preparation, +9 after 2.9 hours and +35.6 final (ninety-six hours). A mixture of the two osazones melted at 194–195° with decomposition after darkening in the usual manner. These data show that the two osazones are the same chemical compound, namely, d-glucoheptose osazone, according to the usual tests that are applied to osazones.[16]

These tests have been supplemented by one which Montgomery and Hudson[12] have lately suggestedin connection with the proof of the identity of the anhydro-osazone from lactose and lactulose, namely, the thermodynamic criterion that the solubility of a mixture of two pure samples of the same chemical substance has the same value as the solubility of either sample alone. This test, which is analogous to the mixed melting point test of substances which do not decompose on melting, is rigorous for osazones because there is no decomposition at the temperature of the solubility measurement, whereas the decomposition that occurs on melting invalidates, from the standpoint of thermodynamic theory, tht strict applicability of the mixed melting point test for most osazones. The solubility of *d*-α-glucoheptose osazone in acetone at 20° from undersaturation was 0.0806 g. per 25 cc. of acetone, from supersaturation 0.0814 g.; that of *d*-glucoheptulose osazone was 0.0796 g. from undersaturation and 0.0793 g. from supersaturation, and the solubility of a mixture of the two osazones was 0.0794 g. from undersaturation and 0.0792 g. from supersaturation. Equilibrium was attained in twenty-four to forty-eight hours. This is decisive proof that the two osazones are identical because if such were not the case the mixed solubility would be of the order $0.081 + 0.079 = 0.160$ g. This method is highly recommended in the case of substances for which the mixed melting point test is not theoretically sound because of decomposition on melting or other complications.

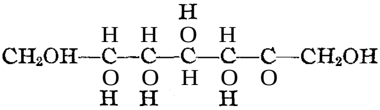
---

[16] Bertrand and Nitzberg (Ref. 6, first article) state that the osazone of their ketose is identical with *d*-α-glucoheptose osazone but they make no mention of the rotations of the two substances. It seems quite unlikely from the results of the present investigation that the two osazones can be identical. It is to be expected that they are enantiomorphous substances and that the osazone of Bertrand and Nitzberg's ketose, *l*-glucoheptulose, will show a rotation equal to that of d-glucoheptose osazone but of opposite sign.

The author wishes to thank the Medical Fellowship Board of the National Research Council for the award of a fellowship which made possible the carrying out of this research. He also expresses his deep indebtedness to Dr. C. S. Hudson for many valuable suggestions.

Summary

A new crystalline ketose, d-glucoheptulose, of configuration



$$CH_2OH-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-\underset{H}{\overset{HO}{C}}-\underset{OH}{\overset{H}{C}}-\underset{O}{C}-CH_2OH$$

has been synthesized from d-a-glucoheptose by use of the procedure which Montgomery and Hudson have recently developed for the synthesis of ketoses from aldoses through the Lobry de Bruyn rearrangement. It proves to be the optical enantiomorph of the ketose which Bertrand and Nitzberg recently made through the action of the sorbose bacterium upon a solution of a-glucoheptitol and their ketose is accordingly *l*-glucoheptulose. The rotation of d-glucoheptulose, which does not exhibit mutarotation, is near the value that was predicted by the rotatory relations developed by Hudson. The existence of this ketose, of the calculated rotation, is strong evidence that Hudson's calculation of +67 for the $[\alpha]_D$ value of an unknown a-d-glucose, of the 1,A = 1,4-ring type, is substantially correct.

ESTERS OF CYCLOHEXYLRESORCINOL AND PARA-CYCLOHEXYLPHENOL[1]

BY VIRGIL GREENE LILLY AND C. E. GARLAND

RECEIVED FEBRUARY 6, 1930 PUBLISHED MAY 8, 1930

In view of the excellent germicidal properties of some of the alkyl and aryl substituted hydroxy derivatives of benzene[2] and their general low toxicity, some esters, of the salol type, have been prepared using cyclohexylresorcinol[2,3] and *p*-cyclohexylphenol, with a hope that they may prove of therapeutic value.[4]

In general, esters of cyclohexylresorcinol are rather difficult to prepare, while those of p-cyclohexylphenol are less so. Cyclohexylresorcinol does

[4] Kursanoff, *Ann.*, 318, 309 (1901); Wuyts, Bull. *soc. chim. Belg.*, **26**, **304** (1912); Schrauth and Görig, *Ber.*, **56**, 1900 (1923); v. Braun, *Ann.*, **472**, 61 (1929).

not form a crystalline salt when treated with sodium hydroxide, or when cyclohexylresorcinol is dissolved in an indifferent solvent and treated with metallic sodium, but gives a red mass of horn-like consistency. In many of the esterification reactions attempted it appeared to undergo a kind of polymerization to give tar-like products which we were unable to purify. The sodium salt of *p*-cyclohexylphenol crystallizes easily from aqueous solution in thin plates. The potassium salt does not crystallize readily.

Three general methods were used to prepare the esters, as follows: the Schotten–Baumann reaction, the action of thionyl chloride or other condensing agents, and the action of acid chlorides upon the dry alkali phenolates.

The cyclohexylresorcinol and cyclohexylphenol used in preparing the following esters were supplied through the courtesy of Dr. R. R. Read, of Sharpe and Dohme, Baltimore, to whom the thanks of the authors are due.

Experimental Part

Cyclohexylresorcinol Dibenzoate, $(C_6H_3)(C_6H_{11})\cdot(C_7H_5O_2)_2(1,2,4)$.—To 100 cc. of 10% potassium hydroxide was added 10 g. of cyclohexylresorcinol, which dissolved to a red wine color. Fifteen and three-tenths grams of benzoyl chloride was added gradually, the reaction mixture being stirred vigorously during the course of the reaction, which was complete within twenty minutes. A heavy yellow oil formed which settled to the bottom. The supernatant liquid was decanted and the heavy oily product repeatedly washed with water. This oil did not deposit crystals, so it was dissolved in a small quantity of hot alcohol, from which the solid product readily separated on cooling. After two recrystallizations from alcohol the white plate crystals melted sharply at 88°. The crystals have a pleasant aromatic odor; yield, 60%.

Anal. Calcd. for $C_{26}H_{24}O_4$: C, 78.00; H, 6.00. Found: C, 77.81, 77.96; H, 5.51, 6.19.

p-Cyclohexylphenol Salicylate, $C_6H_4(C_6H_{11})\cdot(HOC_6H_4COO)(1,4)$. Method I.—Eight grams of well dried sodium *p*-cyclohexylphenolate and 12 g. of sodium salicylate together with 30 cc. of phosphorus oxychloride and 10 g. of finely powdered sodium chloride were heated in a balloon flask[6] on a sand-bath for an hour at 130°. The heat was then removed and the flask allowed to cool to room temperature. The reaction mixture was extracted with an equal mixture of ethyl and methyl alcohols. White crystals separated from the alcoholic solution, which melted at 103.5'. Results by this method are very uncertain and usually the yield is very small.

Method 11.—Twenty grams of cyclohexylphenol and the theoretical amount of salicylic acid were refluxed with an excess of thionyl chloride on a water-bath for two hours. The excess thionyl chloride was decomposed with cold water, the residue well washed and dissolved in alcohol. The crystalline product after further purification melted at 103.5°. A mixed melting point of the products from Methods I and II gave 103°; yield, 25%.

Anal. Calcd. for $C_{19}H_{20}O_3$: C, 77.03; H, 6.75. Found: C, 77.09, 76.94; H, 7.10, 6.91.

---

[5] U. S. Patent 1,606,171.

p-Cyclohexylphenol Hydrocinnamate, $C_6H_4(C_6H_{11})\cdot(C_6H_5CH_2CH_2COO)(1,4)$.—The acid chloride of hydrocinnamic acid was prepared by the method of McMaster and Ahmann.[6] Hydrocinnamic acid was refluxed with an excess of thionyl chloride for two hours, the excess thionyl chloride distilled off, and the acid chloride purified by vacuum distillation. (Other acid chlorides used in this investigation were prepared in a similar manner.)

Twenty grams of sodium cyclohexylphenolate and 17 g. of hydrocinnamoyl chloride were well stirred for ten minutes and at the same time gently warmed. The product was repeatedly washed with water and the residue dissolved in hot alcohol. On cooling, fine needle-like crystals rapidly separated out. On recrystallization the product melted at 74°; yield, 33%.

Anal. Calcd. for $C_{21}H_{24}O_2$: C, 81.82; H, 7.79. Found: C, 81.39, 81.57; H, 7.88, 7.84.

p-Cyclohexylphenol m-Nitrobenzoate, $C_6H_4(C_6H_{11})(O_2NC_6H_4COO)(1,4)$.—The acid chloride of *m*-nitrobenzoic acid and the calculated amount of well dried sodium cyclohexylphenolate were warmed together for ten minutes, the reaction mixture washed repeatedly with water and dissolved in hot alcohol. The crystals on further purification melted at 114°. Analysis was by the method of Knecht and Hibbert.[7]

Anal. Calcd. for $C_{19}H_{19}O_4N$: N, 4.31. Found: N, 4.50, 4.32.

p-Cyclohexylphenol p-Nitrobenzoate, $C_6H_4(C_6H_{11})(O_2NC_6H_4COO)1,4$.—Three grams of p-cyclohexylphenol and the calculated amount of *p*-nitrobenzoic acid were heated with 10 g. of thionyl chloride and 5 g. of phosphorus trichloride for an hour on a water-bath. The excess acid chlorides were decomposed with water and the residue was crystallized from alcohol. The first crop of crystals was rejected and the second portion after repeated recrystallizations melted at 137°; yield, 15%.

Anal. Calcd. for $C_{19}H_{19}O_4N$: N, 4.31. Found: 4.37, 4.41.

Summary

The following salol type esters of cyclohexylresorcinol and *p*-cyclohexylphenol have been prepared and described: (1) cyclohexylresorcinol dibenzoate, (2) p-cyclohexylphenol salicylate, (3) p-cyclohexylphenol hydrocinnamate, (4) p-cyclohexylphenol m-nitrobenzoate and (5) *p*-cyclohexylphenol *p*-nitrobenzoate.

LOCAL ANESTHETICS DERIVED FROM DIALKYLAMINOPROPANEDIOLS. I. PHENYLURETHANS

BY T. H. RIDER

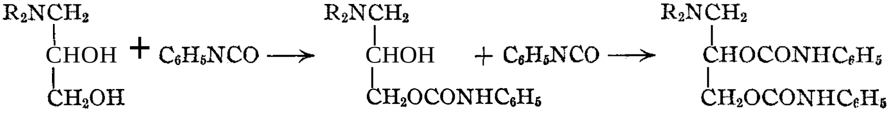
RECEIVED FEBRUARY 7, 1930 PUBLISHED MAY 8, 1930

A great majority of the more recently synthesized local anesthetics are *p*-aminobenzoates of suitable alcohols. In view of the structural similarity between phenylcarbamic acid esters (I) and *p*-aminobenzoic acid esters (II), it is surprising that the field of the phenylurethans

(I) $C_6H_5NHCOO—$ (II) $NH_2C_6H_4COO—$

has not been more generally investigated from the standpoint of the determination of their local anesthetic properties. This is perhaps due to the rather unsatisfactory properties of the urethans studied by Fromherz[1] and Bonar and Sollman.[2] The only other references to this type of compound are found in patents[3] which give no data on pharmacological properties.

In a previous communication,[4] a general preparation of dialkylaminopropanediols ($R_2NCH_2CHOHCH_2OH$) was described and attention was called at that time to their probable usefulness in the synthesis of certain types of local anesthetics. This paper, the first of a series devoted to the preparation of anesthetics derived from these intermediates, deals specifically with the mono- and diphenylurethans, prepared by the action of phenyl isocyanate on the dialkylaminopropanediols



$$\begin{array}{l}R_2NCH_2\\ \quad|\\ \quad CHOH\\ \quad|\\ \quad CH_2OH\end{array} + C_6H_5NCO \longrightarrow \begin{array}{l}R_2NCH_2\\ \quad|\\ \quad CHOH\\ \quad|\\ \quad CH_2OCONHC_6H_5\end{array} + C_6H_5NCO \longrightarrow \begin{array}{l}R_2NCH_2\\ \quad|\\ \quad CHOCONHC_6H_5\\ \quad|\\ \quad CH_2OCONHC_6H_5\end{array}$$

The di-urethans are formed with comparative ease when the alcohols are reacted with two molecular proportions of phenyl isocyanate, The mono-urethans, however, are more difficult to obtain, since there is a decided tendency of the β-hydroxyl group of the dialkylaminopropanediols to react, even in the presence of an excess of the alcohol, yielding the di-urethans where the mono-urethans might be expected. In isolating the product from the reaction mixture, the obvious procedure would be to extract with dilute acid and liberate the free base by the addition of alkali. While it is possible to isolate the di-urethans in this manner, the mono-urethans are decomposed by alkali before they can be isolated. These considerations without doubt explain the error in German Patent 272,529,

---

[1] Fromherz, *Arch. Exptl. Path. Pharmakol.*, *76*, **257 (1914).**

[2] Bonar and Sollman, J. *Pharmacol.*, 18, *467* **(1921).**

[3] German Patents **272,529** and 364,038.

[4] Rider with Hill, THIS JOURNAL, **52, 1528 (1930).**

purporting to cover the mono-phenylurethan of diethylaminopropanediol. The free base only was prepared, and the preparation of this compound is poorly described by the patent. The only property given is the melting point, 106.5°, which is identical with that of the true diurethan as isolated by the writer. It seems certain, therefore, that this compound was isolated, rather than the one claimed.

In the preparation of these compounds the author has prepared for the first time di-n-butylaminopropanediol according to the procedure outlined in a previous paper.[4] In most cases the hydrochlorides of the urethans were prepared without isolating the free bases, and little consideration has been given to improving the yields, which range from 25–60%. Only those compounds whose pharmacological properties are satisfactory merit a more detailed study.

Experimental

Di-*n*-butylaminopropanediol.—Equimolecular proportions of di-n-butylamine and glycidol were mixed and heated on a steam-bath for two hours. The reaction mixture was distilled under reduced pressure; di-n-butylaminopropanediol distils at 127" (3 mm.). The yield is 90% of the theoretical.

Anal. Calcd. for $C_{11}H_{25}O_2N$: N, 6.90. Found: N, 6.91, 6.93.

Hydrochlorides of Mono-phenylurethans of Dialkylaminopropanediols.—An ethereal solution of one mole of phenyl isocyanate is rapidly mixed with an ethereal solution of the dialkylaminopropanediol. The reaction mixture is refluxed until the characteristic odor of phenyl isocyanate disappears, this being taken as a criterion of the completion of the reaction. After cooling of the reaction mixture, the hydrochloride is precipitated, usually as an oil, by the addition of an ethereal solution of dry hydrogen chloride. The ether is decanted and the hydrochloride is recrystallized from acetone. The solubility of the urethans in acetone increases with the molecular weight, necessitating the use of a mixture of acetone and ethyl acetate for the recrystallization of the higher homologs. No difficulty is found in obtaining a crystalline solid when seed crystals are available, although the first isolation sometimes proves difficult. The urethan of the amyl homolog is exceedingly difficult to purify, since it must be thrown out of an ethyl acetate solution with ether, or recrystallized by evaporating a water solution. Either procedure gives a product of somewhat varying properties. The compounds prepared are as follows.

TABLE I

$C_6H_5NHCOOCH_2CHOHCH_2NR_2 \cdot HCl$ COMPOUNDS

R	Formula	Nitrogen, % Calcd.	Nitrogen, % Found		Chlorine, % Calcd.	Chlorine, % Found		M. p., °C.

Piperidino (NR_2)	$C_{15}H_{22}O_3N_2HCl$	8.90	...	...	11.3	11.3	11.8	176–177

Hydrochlorides of Diphenylurethans of Dialkylaminopropanediols.—The diphenylurethans are prepared in a manner entirely analogous to that of the mono-phenylurethans by using two molecular proportions of phenyl isocyanate. The di-urethans are more soluble in acetone than the corresponding mono-urethans but are crystallized in the same manner. The following hydrochlorides of the di-phenylurethans of dialkylaminopropanediols have been prepared.[5]

TABLE II

$C_6H_5NHCOOCH_2CH(OCONHC_6H_5)CH_2NR_2 \cdot HCl$

R	Formula	Nitrogen, % Calcd.	Nitrogen, % Found		Chlorine, % Calcd.	Chlorine, % Found		M. p., °C.

The Free Base of the Di-phenylurethan of Diethylaminopropanediol.—The hydrochloride, prepared as above described, was dissolved in water, an excess of alkali added, the product separated by means of ether extraction, the ethereal solution dried over anhydrous sodium sulfate, filtered and evaporated. The residue was recrystallized from high-boiling petroleum ether, yielding crystals of the di-phenylurethan of diethylaminopropanediol; melting point 106.5°.

Anal. Calcd. for $C_{21}H_{27}O_4N_3$: N, 10.9. Found: N, 10.7, 10.9.

Pharmacological Properties.—The following table will serve roughly to evaluate the strength of the two series of compounds as local anesthetics. The tests were made with a 1% solution of the hydrochloride in distilled water. The time in minutes required for the production of sensory and motor anesthesia in the exposed sciatic nerve of the frog is given in the second and third columns. The fourth column gives the duration of anes-

TABLE III

ANESTHETIC PROPERTIES

Compound	Time of onset of anesthesia, min. Sensory	Time of onset of anesthesia, min. Motor	Duration of anesthesia, min. Cornea
Cocaine	4	14	26
Mono-urethans			
R = methyl	30	52	Incomplete

---

[5] The methyl and amyl homologs were also prepared, but not purified, the methyl compound being hygroscopic and the weakest anesthetic of the series, while the hydrochloride of the amyl compound is practically insoluble in water.

thesia after a one-minute application of the solution to the cornea of the rabbit.

From the table it may be seen that the compounds are comparatively much more effective on the cornea than on the exposed nerves. The isobutyl homolog of the series of mono-urethans, which is approximately twice as effective on the cornea as cocaine, has a much lower apparent toxicity, the minimum fatal dose for white mice, injected subcutaneously, being 1500 mg. per kilo.

Both the study of the production of anesthesia and that of the toxicity are complicated, more especially in the di-urethan series, by the tendency of the higher homologs to precipitate proteins. A further study of this feature, together with a more complete pharmacological report, will be published elsewhere.

Since these urethans show such promising local anesthetic properties, the author proposes to extend this field through the preparation of other urethan combinations of the dialkylaminopropanediols and the urethans of other amino alcohols.

Summary

The mono- and di-phenylurethans of a number of dialkylaminopropanediols have been prepared and have been shown to have interesting local anesthetic properties.

Di-n-butylaminopropanediol has been prepared for the first time.

METHYL ISOPROPYL THIOINDIGOID DYES FROM PARA-CYMENE. I. DYES FROM AMINOCYMENE[1]

BY A. W. HIXSON AND W. J. CAUWENBERG

RECEIVED FEBRUARY 8, 1930 PUBLISHED MAY 8, 1930

Introduction

The number of known sulfur-containing indigoid dyes is very great[2] and their commercial importance is steadily increasing, as shown by the introduction of new colors of this series into the industry. These dyes are of particular interest due to the great effect of substitution on the color. Whereas the derivatives of indigo do not differ greatly in color, those of thioindigo cover almost the entire range of the spectrum. A survey of the literature showed that practically all of the simple benzene derivatives

---

[1] This communication is an abstract of a portion of a thesis submitted by W. J. Cauwenberg in partial fulfilment of the requirements for the Degree of Doctor of Philosophy, to the Faculty of Pure Science of Columbia University.

[2] Truttwin, "Enzyklopadie der Kupenfarbstoffe," Springer, Berlin, 1920.

have been converted into thioindigo dyes but that no derivative containing an isopropyl group has been used. It was thought that *p*-cymene, which is produced in large quantities as a by-product in the sulfite paper industry, could be used as a starting material for the production of methyl isopropyl thioindigo dyes.

The simplest thioindigo was first prepared by Friedländer[3] by the application of the Badische modification of the Heumann synthesis for indigo to thiosalicylic acid. Condensation with chloro-acetic acid gives the desired grouping, namely, a-carboxyphenylthioglycolic acid. In the preparation of highly substituted derivatives, anilines containing the desired groups are usually employed. The ortho sulfur atom is introduced through a sulfonic acid group or by the Hofmann reaction. The amino group is then converted to the carboxyl by the Sandmeyer reaction and hydrolysis.

A very important industrial method for the production of *o*-aminophenylthioglycolic acids has been introduced by Herz.[4] Aromatic amines with an unsubstituted ortho position are condensed with sulfur chloride and the condensation product is caused to react with chloro-acetic acid. The resulting product is the desired substituted o-aminophenylthioglycolic acid. The amine is converted by the Sandmeyer reaction to the nitrile, which is then hydrolyzed and condensed to the thionaphthene. These compounds are employed to prepare a large number of sulfur-containing indigoid dyes. They may be oxidized to give thioindigos or condensed with isatin through the alpha or beta oxygen to give Thioindigo Scarlet or Ciba Violet derivatives and with acenaphthenequinone to give substituted Ciba Scarlets.

This paper presents the preparation of methyl isopropyl thioindigoid dyes from aminocymene by the sulfur chloride condensation method. 4-Methyl-6-chloro-7-isopropyl-3-hydroxythionaphthene produced by this method was condensed with isatin and acenaphthenequinone. The relative fastness properties are reported using the commercial dye made from o-toluidine as a standard. Spectrum analyses are also reported and the effect of the isopropyl group is a shift of nine millimicrons in the direction of the longer wave lengths.

The method followed in the synthesis of these dyes may be represented as indicated in the Flow Sheet.

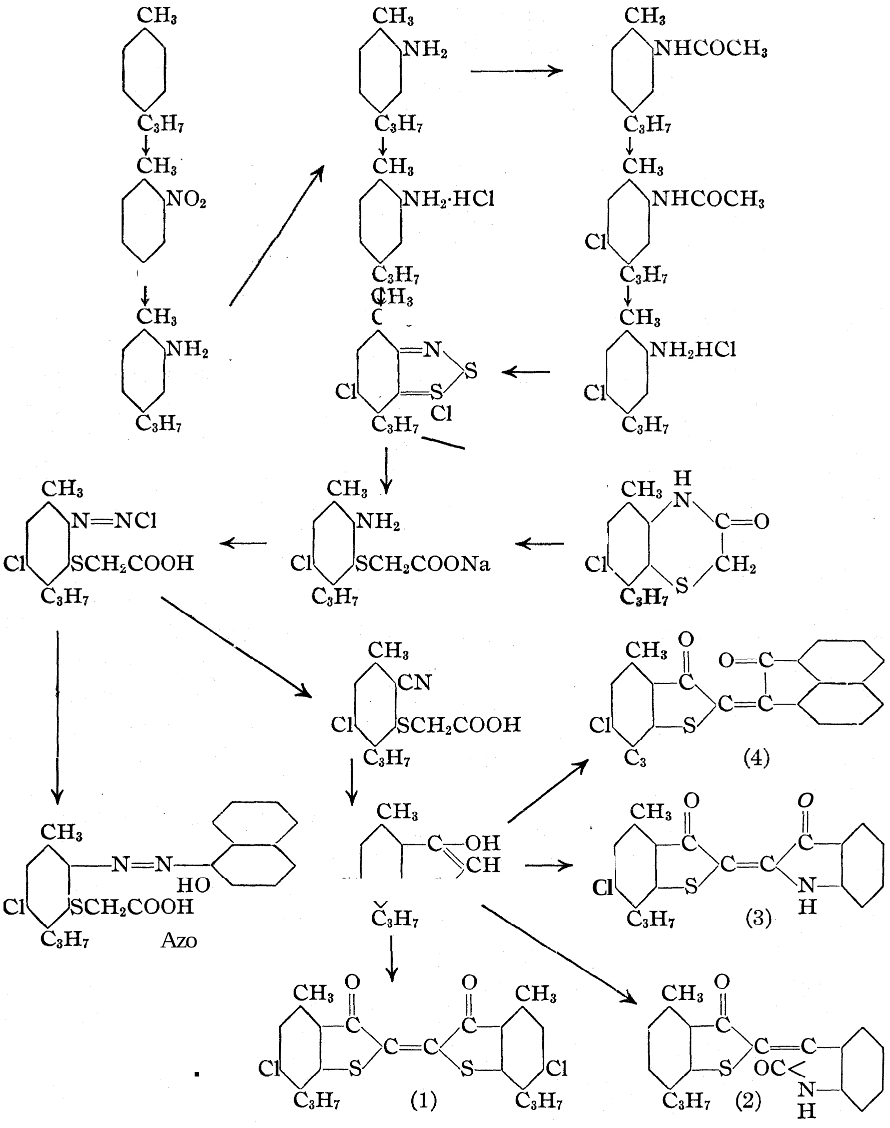
Experimental Part

Preparation of Materials.—The cymene used for this work was prepared by steam distillation of the spruce turpentine after two hours aeration at room temperature in the presence of aqueous caustic. At first the distillate was colorless and contained 37% of oil by volume. The distillation was continued until the oil had a slight yellow color and the rate had fallen to 17% oil. The average yield was 67.5%. A distillation test

---

[3] Friedländer, *Ber.*, **39,** 1060 (1906).

[4] Herz. German Patent 360.690.



FLOW SHEET

showed that 80% of the oil distilled between 173.8–177.5°. The oil was not further purified for nitration.

The nitration of cymene was carried out as outlined by Demonbreun and Kremers.[5] The crude nitrocymene was purified by distillation at 6 mm. and the fraction boiling between 105–127° was separated. The greater portion of this fraction boiled between 112–120°. The yield was 54.6%.

---

[5] Demonbreun and Kremers, *J. Am. Pharm. Assocn.*, *12,* 296 (1923).

Aminocymene was prepared by the standard iron reduction with a yield of 88.8%. Since the amine was wanted as the hydrochloride, it was dissolved in benzene and precipitated with hydrochloric acid gas.

Condensation Product of Aminocymene and Sulfur Chloride.—Sulfur chloride (210 g.) was placed in a one-liter flask equipped with an agitator, reflux condenser and gas outlet. After cooling to 20°, 30 g. of aminocymene hydrochloride was added as fast as it could be incorporated by the agitator. The mass was stirred for three hours under these conditions and allowed to stand overnight at room temperature. The next morning it was heated to 50° and held until the evolution of hydrochloric acid had ceased. An equal volume of benzene was added and cooled to 30°. The condensation product crystallized in orange-red plates. It was separated by filtration and washed free from sulfur chloride with dry benzene. The cake was dried *in vacuo* at 50° and the yield was 38 g. or 84% of the theoretical based on $C_{10}H_{11}NS_2Cl_2$.

Since the condensation mass became very thick during the heating period and required constant attention, the amount of sulfur chloride was increased to ten parts This increase gave a much smoother reaction but a smaller yield, 77.5%.

The compound is a bright orange-red powder which slowly changes to brown. It is hydrolyzed by water with the removal of one chlorine atom, and by alcohol, in which the hydrolysis product is soluble. It is soluble in benzene, toluene, acetic acid and other organic solvents with which it does not react. It was purified by dissolving in glacial acetic acid and precipitating with ether. The purified product gave the following analysis.

Anal. Calcd. for $C_{10}H_{11}NS_2Cl_2$: S, 22.82; Cl, 25.35; Cl/S, 1.11. Found: S, 22.08; Cl, 24.52; Cl/S, 1.11.

The material charred at 120° without melting.

The filtrate and benzene washings from the condensation was fractionated and 43% of the sulfur chloride was recovered. The total benzene recovery was 91%.

5-Chloro-2-aminocymene-3-thioglycolic Anhydride.—The sulfur chloride condensation product (16.8 g.) was added to 120 cc. of water at 10°. The suspension was well agitated for two hours, during which time the material turned to a gray precipitate with a colorless supernatant liquor. The hydrolysis product was separated by filtration and washed free of acid with cold water. The cake was suspended in 150 cc. of cold water and 25 cc. of a 40% caustic soda solution was added. A neutralized solution of 8.5 g. of chloro-acetic acid in 50 cc. of water was added and it was heated to 45°. After one-half hour at this temperature the yellow solution was filtered from solid impurities and acidified with sulfuric acid. The precipitated acid was converted to the anhydride by heating to 70°. It was filtered and washed first with water and then with dilute ammonia. The yield was 12.1 g. or 79% of the theoretical.

The material was purified by crystallization from benzene. The product was obtained as fine white crystals soluble in organic solvents, insoluble in water, dilute acids and alkalies. It melted at 159.0–159.8°.

Anal. Calcd. for $C_{12}H_{14}ONSCl$: Cl, 13.92; S, 12.57; N, 5.48. Found: Cl, 13.89; S, 12.33; N, 5.50.

The anhydride ring can be opened to the acid by heating with 40% caustic soda solution (containing an amount of caustic equal to the weight of anhydride) at 120°. The anhydride first melts and then solidifies as the sodium salt.

Allocation of the Chlorine Atom Introduced during the Sulfur Chloride Condensation.—Herz[4] states that if the amine contains an unsubstituted para position, a chlorine atom will be introduced during the sulfur chloride condensation. Analysis of the condensation product showed the presence of two chlorine atoms, one of which could not be removed by hydrolysis. The thioglycolic anhydride indicated chlorination either in the nucleus or the side chain. The anhydride ring was opened with caustic soda as previously described but the time was extended thirty minutes. The salt was dissolved in water, filtered from insoluble impurities and converted back to the anhydride. Chlorine analysis showed that the substitution was in the nucleus.

If the above substitution theory is correct, then p-chloro-aminocymene should give the same condensation product and anhydride. This procedure was thought to be the best method of attack for the solution of this problem. The *p*-chloro-aminocymene was prepared by the method reported by Wheeler and Giles[6] and converted to the thioglycolic anhydride. The anhydrides obtained from aminocymene and p-chloro-aminocymene were identical, as shown by analyses, melting point and mixed melting point. The position of the chlorine atom is therefore established, being assigned to the 5-position or para to the amino group.

TABLE I

SUMMARY OF THE ANALYSES OF THE ANHYDRIDES

	Cl	*S*	N	**M. p., °C.**
Calcd.	13.92	12.57	5.48	......
Aminocymene	13.89	12.33	5.50	159.0–159.8
Chloro-aminocymene	13.90	12.50	..	159.8
Mixed	...	...	..	159.8

Diazotization of 5-Chloro-2-aminocymene-3-thioglycolic Acid.—A solution of the sodium salt which was obtained from an experiment similar to the one described under the preparation of the anhydride was filtered and to the clear solution, which contained 0.045 mole, was added 3.45 g. of sodium nitrite dissolved in 20 cc. of water. This solution was added through a dropping funnel to 50 cc. of water, 50 g. of ice and 15 cc. of hydrochloric acid. The temperature was held at 10° by means of an external ice-bath. The diazo solution was filtered and diluted to 500 cc.

Efficiency.—A @-naphthol solution containing 0.00139 mole as the sodium salt was titrated with the above diazo solution. Twenty-one cubic centimeters of the diazo solution was required, which gives an efficiency of 73.4%.

Azo Dye.—Two hundred and fifty cubic centimeters of the diazo solution after neutralization was added to **a** cold solution of 2.5 g. of @-naphthol in 100 cc. of water plus enough caustic soda to give a clear solution. The dye formed immediately and was coagulated with acetic acid. It was separated by filtration, washed and dried. The yield was 7.0 g. or 99.4% of the theoretical. The crude dye was crystallized from acetic acid and the pure compound was obtained as long red needles with a metallic reflex.

Anal. Calcd. for $C_{22}H_{21}O_3N_2SCl$: Cl, 8.27; S, 7.48. Found: Cl, 8.28; S, 7.50.

Preparation of 2-Cyano-5-chlorocymene-3-thioglycolic Acid and **4-Methyl-6-chloro-7-isopropyl-3-hydroxythionaphthene.**—The conversion of the aminophenylthioglycolic acid to the cyano derivative may be applied to the sodium salt obtained either from the anhydride or from the chloro-acetic acid condensation. The reaction is very sensitive to sulfite, sulfide and hydroxyl ions. The sulfite and sulfide ions were

---

[6] Wheeler and Giles, THIS JOURNAL, 44, 2605 (1922).

removed by salting out the sodium salt with sodium chloride at 10° and washing the cake with cold saturated brine. The hydroxyl-ion concentration was adjusted by the addition of dilute acetic acid.

A solution (1.5 liters) containing 0.31 mole of the sodium salt prepared from 0.392 mole of the sulfur chloride condensation product was cooled to 10° and saturated with sodium chloride. The precipitated salt was filtered and washed with cold saturated brine. The washed product was dissolved in warm water and diluted to 765 g. Twenty-five grams of this solution was acidified and converted to the anhydride, which was weighed. It was 10% by weight. The remainder of the solution (740 g. or 0.29 mole) was diazotized by the method previously described. The neutral diazo solution was added to the cyanide and adjusted to PH 6.1 using chlor phenol red as indicator. The reaction mass was heated to 50° and held for thirty minutes. The stirring was stopped and the material allowed to stand overnight at room temperature. The clear supernatant liquor was acidified with hydrochloric acid. The cuprous cyanide and nitrile were separated and the nitrile was extracted with dilute sodium carbonate. The carefully neutralized solution was separated from the precipitated tar and after saturating with sodium chloride the sodium salt of the nitrile separated as long white needles. It was purified by recrystallization from water and converted to the free acid. The nitrile separated as a light tan-colored oil.

Anal. Calcd. for $C_{13}H_{14}O_2NSCl$: S, 11.30. Found: S, 11.76.

The tar which precipitated during the evolution of the nitrogen and contained the greatest portion of the nitrile was isomerized at 80° with dilute caustic soda and transferred to a mechanically agitated apparatus to which was connected a reflux condenser and oil separator. It was refluxed with a 25% sulfuric acid solution and the thionaphthene distilled as a colorless oil which assumed a red color due to atmospheric oxidation. The rate was about 5 g. in eight hours. The yield was 19.5 g. or 39.8% of the theoretical on the diazo salt.

The thionaphthene is a colorless oil heavier than water, in which it is insoluble. It is soluble in organic solvents and caustic soda, with which it forms a sodium salt. It cannot be distilled at atmospheric pressure without decomposition but distils readily at 10 mm. The fraction boiling between 191–193° at 10 mm. was separated for analysis.

Anal. Calcd. for $C_{12}H_{13}OSCl$: S, 13.30. Found: S, 13.31.

An interesting observation was made on this oil. When sealed in glass tubes at atmospheric and 10 mm. pressure and exposed to sunlight the red color of the oil at reduced pressure was discharged in five to seven minutes and after standing in the dark for twelve hours returned to its former intensity. The action of sunlight on vat dyes is generally considered to be a reduction of the dye to the leuco compound. In an atmosphere deficient in oxygen the color of this oil was discharged due to the reduction of the dissolved dye to the colorless leuco.

Dyes from 4-Methyl-6-chloro-7-isopropyl-3-hydroxythionaphthene

4,4-Dimethyl-6,6-dichloro-7,7-di-isopropyl-2,2-*bis*-thionaphthene Indigo. **1.**[7]—Thionaphthene was dissolved in ten parts of 5% caustic soda solution and heated to 60°.[8] One-half part of sulfur was added and the heating continued until the dye was completely precipitated. It was separated by filtration, washed and dried. The yield was quantitative.

The dye was purified for analysis by crystallization from xylene, from which it was obtained as fine red crystals. It is sparingly soluble in high-boiling organic solvents.

4-Methyl-6-chloro-7-isopropyl-2-thionaphthene-3-indol Indigo. 2.—Thionaphthene (1.76 g.) and isatin (1 g.) were dissolved in 30 cc. of acetic acid[0] and heated to 90°. The catalyst (two drops of hydrochloric acid) was added and held at 90° for thirty minutes. The dye, which separated in fine red crystals, was filtered and recrystallized from xylene. The yield was 1.7 g. or 63%.

Anal. Calcd. for $C_{20}H_{16}NO_2SCl$: S, 8.67; Cl, 9.61. Found: S, 8.65; Cl, 9.41.

4-Methyl-6-chloro-7-isopropyl-2-thionaphthene-2-indol Indigo. 3.—Isatin (1.36 g.) was dissolved in 50 cc. of benzene with 1.9 g. of phosphorus pentachloride to form isatin chloride,[10] which was added to 1.76 g. of thionaphthene dissolved in 200 cc. of benzene at 50°. The violet dye which formed immediately was separated and recrystallized from xylene. The yield was 2.4 g. or 89%.

Anal Calcd. for $C_{20}H_{16}NO_2SCl$: S, 8.67. Found: S, 8.52.

4-Methyl-6-chloro-7-isopropyl-2-thionaphthene-acenaphthene Indigo. 4.—Thionaphthene (0.95 g.) and acenaphthenequinone (0.7 g.) were dissolved in 30 cc. of acetic acid and heated to 90°.[11] Two drops of hydrochloric acid was added and the reaction held at 90" for thirty minutes. The dye was separated and crystallized from xylene with a yield of 1 g. or 64%.

Anal. Calcd. for $C_{24}H_{17}O_2SCl$: S, 7.92. Found: S, 7.82.

Properties of Dyes

Solubility.—These dyes are insoluble in water, dilute acids and alkalies and salts with the exception of alkaline hyposulfite, with which they form the vat.

Fastness.—The relative fastness to light was determined by exposing them for seventy-two hours to an ultraviolet lamp (used less than 200 hours) at a distance of eighteen inches.

The fastness to washing was determined by applying the standard test except that the time was increased from five to ninety minutes.

TABLE II

PROPERTIES OF DYES

No.	Color in H_2SO_4	Color of vat	Color in xylene[a]	Wash test	Fastness to light	Color of crystals
FF"	Green	Yellow	Pink y	Exc.[a]	Bxc.	Red

METHYL ISOPROPYL THIOINDIGOID DYES FROM PARA-CYMENE. II. DYES FROM SODIUM CYMENE SULFONATE[1]

BY A. W. HIXSON AND W. J. CAUWENBERG

RECEIVED FEBRUARY 8, 1930 PUBLISHED MAY 8, 1930

Introduction

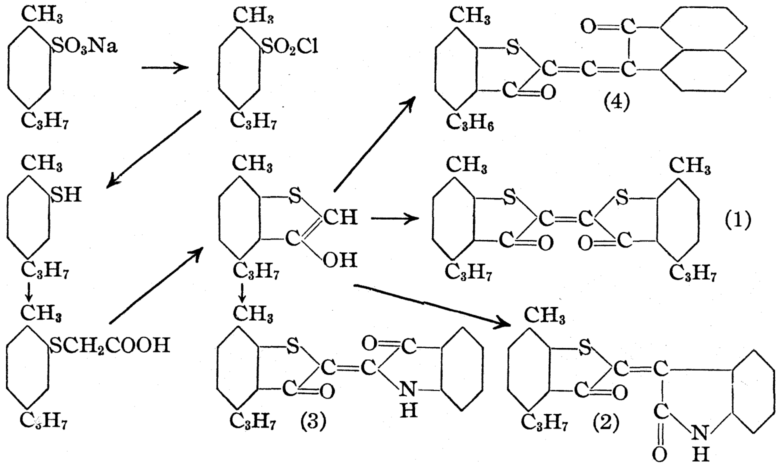
The original Heumann synthesis of indigo may be applied to thiophenols for the preparation of thioindigo dyes and this method is now employed in the industry on substituted thiophenols. These compounds are usually prepared by the reduction of the corresponding sulfonyl chlorides or by the action of potassium ethyl xanthate on diazotized amines. After condensing with chloro-acetic acid, the substituted phenylthioglycolic acids are internally dehydrated to the thionaphthene derivatives by chloro-sulfonic or sulfuric acids.

The application of this method to sodium cymene sulfonate would produce thioindigoid dyes which are isomeric with those prepared from amino-

---

[1] This communication is an abstract of a portion of a thesis submitted by W. J. Cauwenberg in partial fulfilment of the requirements for the Degree of Doctor of Philosophy, to the Faculty of Pure Science of Columbia University.

cymene by the sulfur chloride method.[2] This paper presents the preparation of methyl isopropyl indigoid dyes from sodium cymene sulfonate. 7-Methyl-4-isopropyl-3-hydroxythionaphthe prepared by this method was oxidized to the thioindigo and condensed with isatin and acenaphthenequinone. The relative fastness, properties and spectrum analyses are reported. The method followed in the synthesis of these dyes may be represented as shown in the Flow Sheet.



FLOW SHEET

Experimental Part

Reparation of Materials

The sodium cymene sulfonate prepared according to Hixson and McKee[3] was obtained from the Chemical Engineering Laboratory of Columbia University. It was recrystallized twice from alcohol and dried for eighteen hours at 140°.

Cymene-2-sulfonyl chloride was prepared as outlined by Phillips.[4]

Thiocarvacrol.—This compound was first prepared by Flesch[5] from camphor by the action of phosphorus pentasulfide. Roderburg[6] reported the preparation from the sulfonyl chloride. The method used in this work was an adaptation of the thiophenol process of Adams and Marvel.?

The wet sulfonyl chloride from 25 g. of sodium cymene sulfonate was added slowly to a mixture of 210 g. of ice and 71 g. of sulfuric acid at −5°. Thirty-six grams of zinc dust was introduced, keeping the temperature below 0°. After stirring the mixture for one and one-half hours at 0°, the ice–salt bath was removed and a reflux condenser connected to the Y-tube. The mass was heated to boiling (no vigorous reaction during the

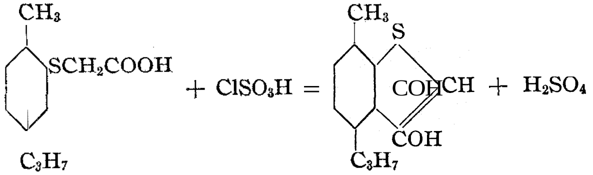
heating) and refluxed for seven hours. The thiocarvacrol was distilled from the reaction mixture with steam and dried over calcium chloride. It was purified by distillation and the fraction boiling at 235–237° was separated. The yield was 49% of the theoretical.

Anal. Calcd. for $C_{10}H_{14}S$: S, 19.27. Found: S, 19.19.

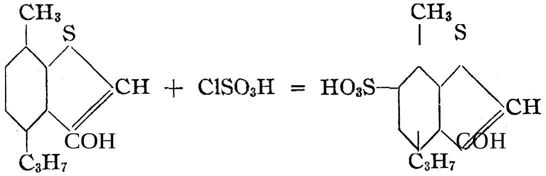
Cymene-2-thioglycolic Acid.—Thiocarvacrol (11 g.) was dissolved in 250 cc. of water containing 20 cc. of a 40% caustic soda solution. After adding a trace of sodium hyposulfite to prevent oxidation, 9 g. of chloro-acetic acid as the sodium salt in 50 cc. of water was added. The solution was heated to 70° and held for thirty minutes. The thioglycolic acid was precipitated by acidifying with hydrochloric acid at 20°. The acid was recrystallized from aqueous alcohol with a yield of 13 *g*. or 88% of the theoretical. It melted at 97°.

Anal. Calcd. for $C_{12}H_{14}OS$: S, 14.38. Found: S, 14.26.

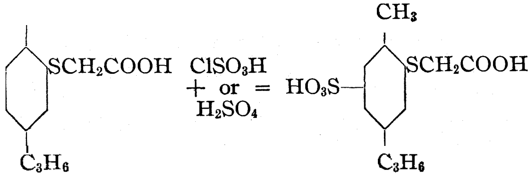
7-Methyl-4-isopropyl-3-hydroxythionaphthene—The action of chlorosulfonic acid on cymene-2-thioglycolic acid may be represented by the reactions



(1)



(2)



(3)

Reactions 1 and 3 may be considered as consecutive with respect to the liberated sulfuric acid or side by side with respect to the thioglycolic acid. Reaction 2, the sulfonation of the thionaphthene, is consecutive.

A series of experiments was run and the time and yields are given in Table I. The method employed was as follows. Three grams of thioglycolic acid was added in two minutes to 30 g. of chlorosulfonic acid at 0°. The reaction mass was stirred for the time given in the table and poured onto 200 g. of ice. The thionaphthene was obtained as pale yellow plates by steam distillation of the dilution mass. It was purified by redistillation with steam; melting point, 86°.

Anal. Calcd. for $C_{12}H_{14}OS$: S, 15.52. Found: S, 15.41.

Assuming that 72% of the thioglycolic acid is available for conversion to thionaphthene and that this conversion and subsequent sulfonation of the thionaphthene appear as first-order reactions due to the large excess of chlorosulfonic acid (10.3 moles per mole of thioglycolic acid), the velocity constants ratio

$$\frac{K_1}{K_2} = \frac{\text{Rate of formation of thionaphthene}}{\text{Rate of sulfonation of thionaphthene}} = 53.3$$

gave the following results when substituted in the general equation for two consecutive first-order reactions.

$$\text{Yield of thionaphthene at time } \Theta = \frac{C_0K_1}{K_1 - K_2}\, e^{-K_2\Theta}$$

where C_0 is 0.72, K_1 is 64, 8 is time in hours and K_2 is 1.2.

Experimental yield, g.	27.8	41.5	61.0
Calculated yield, g.	22.0	40.5	63.8

The time at which the yield of thionaphthene is a maximum is given by: $8 = I/(K_1 - K_2)$ In $(K_1/K_2) = 0.063$ or **3.8** minutes.

The maximum yield of thionaphthene is given by

$$\text{Thionaphthene}_{(\text{max.})} = C_0 \left[\frac{K_1}{K_2}\right]^{\frac{K_2}{K_2 - K_1}} = 0.667 \text{ or } 66.7\%$$

Dyes from 7-Methyl-4-isopropyl-3-hydroxythionaphthene

7,7-Dimethyl-4,4-di-isopropyl-2,2-bis-thionaphthene Indigo. **1.**—A solution of 5 g. of thionaphthene in 100 cc. of 5% caustic soda solution was heated to SO°; 2.5 g. of sulfur was added and the heating continued until the dye was completely precipitated. The product was separated by filtration and boiled with 5% caustic soda solution to remove any excess sulfur. The yield was quantitative. It was purified by recrystallization from xylene, from which it separated as fine, dark red crystals.

Anal. Calcd. for $C_{24}H_{24}O_2S_2$: S, 15.70. Found: S, 15.77.

7-Methyl-4-isopropyl-2-thionaphthene-3-idol Indigo. **2.**—Thionaphthene (1.5 g.) and isatin (1 g.) were dissolved in 30 cc. of acetic acid and heated to 90°. Two drops of hydrochloric acid was added and the reaction held at 90° for thirty minutes. The dye was filtered, washed with alcohol and recrystallized from xylene. The yield was 1.9 g. or 79% of the theoretical.

Anal. Calcd. for $C_{20}H_{17}NO_2S$: S, 9.55. Found: S, 9.62.

7-Methyl-4-isopropyl-2-thionaphthene-2-id Indigo. 3.—Isatin chloride formed by adding 1.9 g. of phosphorus pentachloride to 1.35 g. of isatin in 50 cc. of benzene was added to a solution of 1.5 g. of thionaphthene in 200 cc. of benzene at 50°. The benzene was removed with steam and the dye after drying was recrystallized from xylene. The yield was 1.7 g. or 71% of the theoretical.

Anal. Calcd. for $C_{20}H_{17}NO_2S$: S, 9.55. Found: S, 9.63.

7-Methyl-4-isopropyl-2-thionaphthene-acenaphthene Indigo. 4.—This dye was prepared from 0.8 g. of thionaphthene and 0.7 g. of acenaphthenequinone in acetic acid containing two drops of hydrochloric acid at 90°. The product was filtered, washed with alcohol and recrystallized from xylene. The yield was 1.2 *g.* or 86% of the theoretical.

Anal. Calcd. for $C_{24}H_{18}O_2S$: S, 8.91. Found: S, 8.79.

Thioindigo Dye from Crude Cymene Sulfonate

The production of a thioindigo dye from crude cymene sulfonate was investigated. The intermediates were not purified and the thionaphthene process was modified so as to obtain the maximum yield of dye and to eliminate unnecessary mechanical operations.

Thiocarvacrol was obtained with a yield of 50.8%, which gave a yield of 99.6% of crude thioglycolic acid.

Since the thionaphthene was precipitated by dilution of the reaction mass, it was thought advisable to separate it by filtration and to oxidize it directly. The temperature of the reaction was lowered to −10° and a series of runs was made varying the time.

TABLE II

VARIATION OF YIELD OF DYE WITH TIME

Time in minutes	15	7	4
Percentage yield	26.5	55.0	58 5

A semi-technical batch gave a yield of 51.2% in large-scale equipment.

Properties of Dyes

Solubility.—These dyes are insoluble in water, dilute acids and alkalies and salts with the exception of alkaline hyposulfite.

Fastness.—The relative fastness to light was determined by exposing them for seventy-two hours to an ultraviolet lamp (used less than 200 hours) at a distance of eighteen inches. The fastness to washing was determined by applying the standard test for ninety minutes.

TABLE III

PROPERTIES OF DYES

No. of dye[a]	Color in H_2SO_4	Color of vat	Color in xylene[b]	Wash test	Fastness to light	Color of crystals
FF	Green	Yellow	Pink y	Exc.	Exc.	Red
1	Green	Yellow	Red y	Fair	Exc.	Red
BB	Green	Pale pink	Red y	Fair	Fair	....
2	R violet	Yellow	Pink	Fair	Fair	Red
3	B green	Yellow	Violet	Good	Fair	B black
4	Green	Violet	Yellow y	Good	Fair	Orange

[a] F F is the commercial dye made from o-toluidine. BB is the semi-technical hatch.

[b] y after color in'xylene denotes yellow fluorescence; exc. for excellent.

Spectrum Analyses

The spectrum analyses were made with a Koenig–Martens spectrophotometer using xylene as the solvent.

TABLE IV

SPECTRUM ANALYSES OF DYES

No. of dye	1	BB	2			3		4		
Wave length, millimicrons	559	555	510	520	529	546	575	500	510	521

The authors acknowledge their indebtedness to Dr. B. Kurrelmeyer, Department of Physics, Columbia University, for his helpful suggestions during the spectrum analyses of these dyes.

Summary

1. 7-Methyl-4-isopropyl-3-hydroxythionaphthene was prepared from sodium cymene sulfonate.

2. Four new thioindigoid dyes containing an isopropyl group were prepared.

3. The production of a thioindigo dye from crude sodium cymene sulfonate on a semi-technical scale was made.

4. Fastness tests and spectrum analyses of the dyes were made.

THE ISOLATION AND IDENTIFICATION OF d-MANNURONIC ACID LACTONE FROM THE MACROCYSTIS PYRIFERA

BY WILLIAM L. NELSON AND LEONARD H. CRETCHER

RECEIVED FEBRUARY 10, 1930 PUBLISHED MAY 8, 1930

That alginic acid is a polymer of one or more aldehyde sugar acids was demonstrated by the authors in a previous communication.[1] It was shown at the same time that it is composed, at least in part, of *d*-mannuronic acid. The identity of this uronic acid was established on the basis of the fact that on oxidation it formed a dibasic acid whose diamide and diphenylhydrazide corresponded in properties to the analogous compounds prepared from pure d-mannosaccharic dilactone.

At the time of our earlier paper we had not succeeded in obtaining the aldehyde acid in crystalline condition and were consequently unable to publish any data on the physical properties of the new compound. The present paper describes experiments which led to the preparation of crystalline d-mannuronic lactone and the determination of its melting point and optical rotation.

The extraction of alginic acid from the fronds of the Macrocystis, as well as the method of hydrolysis and subsequent preparation of the barium and cinchonine salts of the hydrolysis product, has been previously described.[1] The yield of pure cinchonine salt was much less than the calculated amount based on the weight of the barium salt from which it was prepared. The mannosaccharic acid formed, in poor yield, after oxidation of the barium salt might, therefore, not have been an oxidation product of the acid whose cinchonine salt we had in hand. In other words, it remained to be proved that the cinchonine salt was that of d-mannuronic acid. This is shown to be the case in the present paper. The problem as to whether or not there are other uronic acids present in the algin remains for the future.

---

[1] Nelson and Cretcher, THIS JOURNAL, 51, 1914 (1929).

Experimental Part

Preparation **of** the Lactone.—Five grams of cinchonine salt was dissolved in 125 cc. of water. The cinchonine was precipitated by addition of the calculated amount of (thrice recrystallized) barium hydroxide solution. **A** drop of phenolphthalein was added to the filtered solution and the pink color discharged by a few drops of dilute sulfuric acid. The solution was filtered through "Nuchar" and evaporated under reduced pressure to a few cc. The barium salt was then precipitated by the addition of **95%** alcohol. The salt was dissolved in water, evaporated to a small volume and again precipitated with alcohol. Barium was removed with sulfuric acid. The solution, after filtering through "Nuchar," was again evaporated under reduced pressure to a thick sirup which was placed in a vacuum desiccator for nineteen days over phosphorus pentoxide. During the drying period the material slowly crystallized. It was extracted twice with 5-cc. portions of hot glacial acetic acid and filtered. There was a considerable residue insoluble in acetic acid which proved to be inorganic. Crystallization of the lactone occurred as soon as the solution was cool. After standing for several hours, the mother liquor was decanted and the crystals were washed twice with absolute alcohol and ether. The melting point was 136–138°. After twice recrystallizing from glacial acetic acid, the melting point was constant at **140–141°**. On further heating effervescence took place at 153–155°.

Anal. Calcd. for $C_6H_8O_6$: C, **40.90;** H, **4.58.** Found: C, **40.73, 41.04; H, 4.64,** 4.59 (micro). **5.109 mg.** required **2.35** cc. of **0.01263** *N* NaOH. Calcd. neutralization equivalent: **176.** Found: **172. 0.0551** g. in **3.017** cc. of aqueous solution gave α $+$**1.64**" in a I-dm. tube; $[\alpha]_D^{25}$ **+89** 8°. There was no mutarotation in forty-six hours. Uronic acid CO_2: **0.1829** g. of sample gave **0.0462** g. of CO_2. Calcd. for $C_6H_8O_6$: CO_2, **25.0.** Found: CO_2, **25.26.**

The lactone was titrated for aldehyde according to the method of Willstätter and Schudel.[2] **A** large excess of iodine over the amount theoretically required for an aldehyde of molecular weight **176** was required. Much of the iodine was consumed in the production of iodoform. This is in harmony with our observation that mannosaccharic acid was easily oxidized by cold alkaline iodine with formation of much iodoform. The study of this reaction and the identification of its products are now under way.

Identification **of** the **Lactone.**—0.250 g. of lactone and **0.924** g. of barium benzoate[3] were dissolved in **30** cc. of water; **0.1** cc. of bromine was added and the solution allowed to stand in the dark for forty-eight hours. The solution was filtered to remove the precipitated benzoic acid and the excess bromine was evaporated by passage of a stream of air. The solution was twice extracted with chloroform and heated for thirty minutes with an excess of barium carbonate. After filtering, the solution was evaporated to a few cc. under reduced pressure. **A** granular precipitate of the barium salt formed during evaporation. The precipitation was completed by the addition of several volumes of alcohol. The salt was dissolved in hot water and again evaporated and treated with alcohol. After filtering and washing with alcohol, the barium was removed with sulfuric acid, the solution filtered through decolorizing carbon and evaporated, in *vacuo,* to a sirup. Crystallization was induced by seeding with a crystal of mannosaccharic lactone. The partially crystalline sirup was dried for twenty-four hours in a vacuum desiccator over phosphorus pentoxide. The material was twice extracted with about 5-cc. portions of hot glacial acetic acid and filtered. On cooling the product separated in crystalline condition. Again filtered, washed with alcohol and ether and dried, the compound melted at 182–184° with decomposition.

---

[2] Willstatter and Schudel, *Ber.*, 51, 780 **(1918).**

[3] Hudson and Isbell, THIS JOURNAL, 51, **2225 (1929).**

A sample of pure mannosaccharic lactone melted at 182–183° when heated at the same rate and there was no change in the mixed melting point.

Optical rotation.—0.0360 g. in 3.017 cc. of aqueous solution rotated +2.38° in a 1-dm. tube: $[\alpha]_D^{20}$ +199.5°. The sample of d-mannosaccharic dilactone prepared in this Laboratory had $[\alpha]_D^{23}$ +199.8°. Titration with alkali: 0.0102 g. required 2.01 cc. of 0.0590 N NaOH. Neutralization equivalent, calcd.: 87. Found: 86.

The **Diamide.**—The solution which had been used for determination of the optical activity was evaporated to dryness under reduced pressure and several drops of concd. ammonium hydroxide was added. After several hours a white crystalline compound was deposited. It melted at 189° and after mixing with pure d-mannosaccharic diamide the melting point was unchanged.

Summary

A hitherto unknown aldehyde sugar acid—d-mannuronic—has been isolated, in the form of its lactone, from the hydrolysis product of the algin in the *Macrocystis pyrifera.*

THE NITRATION OF ABIETIC ACID AND THE STUDY OF SOME OF ITS NITROGEN DERIVATIVES[1]

BY L. A. GOLDBLATT WITH ALEXANDER LOWY AND W. B. BURNETT

RECEIVED FEBRUARY 14, 1930 PUBLISHED MAY 8, 1930

A number of investigators have studied the effect of nitric acid, nitrous acid and nitrogen oxides on more or less purified mixtures of rosin acids. Easterfield[2] reported that nitro derivatives are obtained when abietic acid is treated with nitric acid in glacial acetic acid solution, but gave no experimental data. Johansson[3] first reported a crystalline nitro derivative of abietic acid. This was obtained in 15% yield by the action of fuming nitric acid at a low temperature on an abietic acid of m. p. 155–168° and $[\alpha]_D$ −28.6°. This, a dinitro compound, $C_{20}H_{28}N_2O_6$, m. p. 178–184° and $[\alpha]_D$ +44.25°, was sensitive to light and was easily esterified. Aschan and Virtanen[4] duplicated the work of Johansson on pinabietic acid and obtained the same product. They concluded that Johansson's abietic acid was in reality pinabietic acid.

Dubourg[5] also attempted, unsuccessfully, to duplicate the work of Johansson on an abietic acid $[\alpha]_D$ −100°. Dubourg, however, succeeded

in isolating several white crystalline nitro derivatives of abietic acid. A dinitro derivative, $C_{19}H_{26}N_2O_6$, m. p. 162–165° and $[\alpha]_D$ $-115°$, was obtained by the action of concentrated nitric acid on a hot alcohol or acetic acid solution of abietic acid. The maximum yield was 33%. This compound was stable toward light and air, markedly levorotatory and could be esterified only with difficulty. It was, therefore, different from the dinitro compound of Johansson and Aschan and Virtanen. A trinitro compound, $C_{16}H_{17}N_3O_8$, m. p. 156–158° and $[\alpha]_D$ $-136.2°$, was prepared by the action of fuming nitric acid on the dinitro derivative. A different trinitro derivative, $C_{20}H_{23}N_3O_8$, m. p. 177–178° and $[\alpha]_D$ $-95°$, was prepared with a yield of **2–3%** by the action of concentrated nitric acid at room temperature on a solution of abietic acid in carbon tetrachloride.

Patents covering the products obtained by the action of nitric acid on rosin or rosin acids have been granted to Fry, Kesler and Arnot,[6] but these patents were entirely concerned with empirical processes.

There has been considerable controversy as to the products obtained by previous investigators from the nitration of abietic acid. Further, only low yields of products were reported and practically nothing was said as to the fate of the remainder of the abietic acid used. It was therefore deemed desirable to make a further study of the nitration of abietic acid. It was also the purpose of this investigation to study certain chemical properties of abietic acid and derivatives such as salts and esters with special reference to nitration and the reduction of nitro bodies produced.

Experimental Part

Nitration of Abietic Acid.—Twenty-four experiments were conducted to observe the effect of nitric acid on abietic acid or sodium tetra-abietate, prepared according to the method of Kesler,[7] dissolved in alcohol. The effects of concentration of abietic acid, concentration of nitric acid, stirring, temperature and time of reaction were studied. In general, two products were obtained, a white crystalline dinitro derivative and a yellow uncrystallizable nitrogen-containing product. The formation of the white dinitro compound was accompanied by a vigorous effervescence and frothing and, in general, was favored by a high temperature, a short time of reaction and an excess of nitric acid. A maximum yield of 40% of the white dinitro compound was obtained in this series of experiments. A yield of 50% was obtained in an experiment in which the combined mother liquor and wash alcohol from one nitration was used as the solvent for a second nitration.

A **Typical** Experiment.—One hundred grams of abietic acid, m. p. 166° and $[\alpha]_D^{20}$ $-67°$, and **200** cc. of 95% ethyl alcohol were placed in a 5-liter round-bottomed pyrex flask. The mixture was heated to boiling on a water-bath. When solution was effected,

[7] C. C. Kesler, Alexander Lowy and W. F. Faragher, THIS JOURNAL, 49, **2898** **(1927).**

fifteen 5-cc. portions of nitric acid (sp. gr. 1.42) were added at half-minute intervals. The last 5 cc. was added in 0.5-cc. portions at half-minute intervals, and was allowed to run down the side of the flask. This procedure is necessary in order to start a localized reaction. The solution was colored a deep brownish-black at this stage. A violent frothing accompanied by the evolution of a small amount of nitrogen oxides, carbon dioxide and acetaldehyde commenced when the last portion was added. The flask was quickly removed from the water-bath and the upper surface cooled by means of cold wet cloths to prevent expulsion of the liquid by the violent frothing. The reaction soon subsided and a clear orange colored liquid resulted.

On cooling, needle-like crystals gradually formed throughout the entire liquid. The crystals were filtered by suction and washed with 150 cc. of alcohol. They were recrystallized from alcohol and dried in vacuo over anhydrous calcium chloride. Twenty g. of a white crystalline material, discussed as the white dinitro compound, m. p. 170–171° and $[\alpha]_D^{20}$ −118°, was thus obtained. (All melting points have been corrected. The rate of heating for the last 20° was 2–3° per minute. The rotation in this case was measured on a 0.6% solution in 95% ethyl alcohol.) The combined filtrate and wash liquor was placed in an ice-box overnight. The additional crystalline deposit was filtered and treated like the above-described first crop. In this way an additional 10 g. of the white crystals was obtained. In order to get a second crop, this cooling should not be too intense as an orange oily product separates when this solution is cooled to −10°.

The orange colored filtrate was then poured with vigorous stirring into 3 liters of water acidulated with 100 cc. of concentrated hydrochloric acid. An orange-yellow amorphous precipitate was thus obtained; (when the water was not previously acidulated a gelatinous precipitate, difficult to filter, was formed). This product was filtered by suction and washed free of chlorides with about 10 liters of water. When dried in *vacuo* over calcium chloride, 75 g. of a yellow nitrogen-containing product (discussed as the yellow nitrogen-containing product) was obtained.

Neither the white dinitro compound nor the yellow product were obtained when an alcoholic solution of abietic acid was treated with ethyl nitrate, used alone or with a little nitric acid, as the nitrating agent.

Other Nitration Experiments.—Seventeen experiments were conducted to observe the effect of various amounts of nitric acid on abietic acid in acetic acid solution at temperatures ranging from 25–120°. Very little reaction took place at low temperatures and there was no frothing below 90°. Above 90° frothing occurred, the reaction mixture became orange-red in color and the yellow nitrogen-containing product was obtained. When acetic acid was used as a solvent, only a small quantity of the white crystalline dinitro acid was obtained. The maximum yield of this compound, 4%, was obtained in an experiment in which 4 cc. of concentrated nitric acid was added in 0.5-cc. portions at half-minute intervals to a solution of 10 g. of abietic acid in 25 cc. of acetic acid at a temperature of 90°.

Several experiments were carried out on the nitration of abietic acid dissolved in benzene, nitrobenzene, carbon tetrachloride and 1,4-dioxan. The white dinitro compound was not obtained in any of these experiments. The use of concentrated nitric acid and elevated temperature resulted in the formation of the yellow nitrogen-containing product.

A number of experiments were conducted in which abietic acid or sodium tetra-abietate was treated directly with nitric acid. Oxidation occurred and no crystalline nitro derivatives of abietic acid were isolated. The results obtained were invariably the yellow uncrystallizable nitrogen-containing material.

The White Dinitro Compound.—The rate of heating affects the melting point of this compound. After two recrystallizations from alcohol, the following melting points were observed. Rate of heating above 140°: 1° per minute, m. p. 163.8–164.2°; 1.5° per minute, m. p. 165.9–166.2°; 2 5° per minute, m. p. 171.2–171.4°. Successive recrystallizations from alcohol, ether, acetic acid and acetone did not appreciably alter the melting points taken at corresponding rates.

The analytical data presented by Dubourg[5a] are quite inconclusive. Since the melting point was higher and since Dubourg reported the loss of a methyl group, this compound was analyzed. Analysis substantiated the formula $C_{19}H_{26}N_2O_6$ proposed by Dubourg.

Anal. Calcd. for $C_{19}H_{26}N_2O_6$ (without CH_3): C, 60 28; H, 6 93; N, 7 41, neutral equivalent, 378.2. Calcd. for $C_{20}H_{28}N_2O_6$ (with CH_3): C, 61.19; H, 7.19; N, 7.16; neutral equivalent, 392.2. Found: C, 59.94, 59.45; H, 7 30, 7.21; N, 7.57, 7.69, 7.33, 7.63, 7.67; neutral equivalent, 374.5, 367.4, 373.7.

The sodium salt was precipitated by adding an excess of 30% aqueous sodium hydroxide to an alcoholic solution of the dinitro compound. After washing with alcohol and drying in vacuo over calcium chloride, it was analyzed as the sulfate.

Anal. Calcd. for $C_{19}H_{25}N_2O_6Na$ (without CH_3): Na, 5.75. Calcd. for $C_{20}H_{27}N_2O_6$-Na (with CH_3): Na, 5.56. Found: Na, 5.56, 5.78, 5.71.

The ethyl ester, m. p. 157.5–157.8°, was prepared by refluxing an alcoholic suspension of the sodium salt with diethyl sulfate. This compound was also prepared by the action of nitric acid on an alcoholic solution of ethyl abietate,[8] b. p. 195–ZOO° (4 mm.).

It is quite difficult to saponify this ester. Analysis indicated the formula $C_{21}H_{30}N_2O_6$ for this compound and thus further substantiated the formula $C_{19}H_{26}N_2O_6$ for the free acid.

Anal. Calcd. for $C_{21}H_{30}N_2O_6$ (without CH_3): C, 62.04; H, 7.44; N, 6.90. Calcd. for $C_{22}H_{32}N_2O_6$ (with CH_3): C, 62.82; H, 7.67; N, 6.65. Found: C, 61.74, 61.63; H, 7.52, 7.61; N, 7.21, 7.04, 7.17, 7.13, 7.12.

Molecular weight determinations of the white dinitro compound indicate slight association in ethyl acetate solution and considerable association in benzene solution. Calcd. for $C_{19}H_{26}N_2O_6$ (without CH_3): mol. wt., 378.2. Calcd. for $C_{20}H_{28}N_2O_6$ (with CH_3): mol. wt., 392.2. Found: mol. wt., 401.1 (in ethyl acetate); 571.2 (in benzene).

Saponification experiments indicated that the white dinitro compound is a nitro derivative of abietic acid and not a nitrate. It was reduced by means of zinc dust and acetic acid, zinc dust and hydrochloric acid in 50% ethyl alcohol and alkaline sodium "hydrosulfite," $Na_2S_2O_4$. It was also reduced catalytically in ethyl acetate solution with a platinum oxide catalyst, $PtO_2 \cdot H_2O$, prepared according to the method of Adams and Shriner.[9]

Nitrogen oxides were evolved during the reduction in acid solution. Ammonia was evolved during the reduction in alkaline solution. A white solid melting at 171.5–172" was precipitated in 80% yield from the ethyl acetate solution during the catalytic reduction. One mole of the white dinitro compound absorbed 1.74 moles of hydrogen during the reduction. The reduction product evolved ammonia when dissolved in hot alcohol or when treated with cold dilute aqueous alkali.

The Yellow Nitrogen-Containing Product.—The yellow nitrogen-containing product did not have a definite melting point but decomposed above 100°. A 0.5% solution in alcohol gave $[\alpha]^{20}_{D}$ −36°. This product was only slightly soluble in chloroform, carbon tetrachloride and petroleum ether. Attempts to separate components of this material

---

[8] Supplied by the Hercules Powder Company.

[9] Roger Adams and R. I,. Shriner, THIS JOURNAL, 45, 2171 (1923).

and to secure crystalline products by the use of a number of solvents, mixtures of solvents and partial precipitation of metallic salts were unsuccessful. This product dissolved in cold aqueous sodium hydroxide, potassium hydroxide and ammonium hydroxide, imparting a deep red color to the solution. Abietic acid dissolved in these reagents forming colorless solutions. The respective products were reprecipitated by bubbling carbon dioxide through the solution. The analytical data show this to be a nitrogen-containing hydroxylated acid.

Anal. Found: C, 63.76, 63.60, 63.27, H, 7.83; N, 6.74, 6.46, 6.70. Neutral equivalent, 365.5, 367.7. Acetyl chloride indicated the presence of 0.84 OH per neutral equivalent.

The red alkaline aqueous solution of this yellow nitrogen-containing product completely absorbed oxygen from air; 300 cc. of a 3% alkaline solution absorbed 20 cc of oxygen in fifteen minutes; 1.8 g. dissolved in 100 cc. of 1% aqueous sodium hydroxide absorbed 92 cc. of oxygen in the course of three days. The alkaline solution froths or lathers quite readily.

The yellow product was reduced in the same manner as the white dinitro compound. Nitrogen oxides were evolved during reduction in acid media and ammonia was evolved during reduction in alkaline media. The evolution of ammonia when the catalytic reduction product was made alkaline indicated the reduction of a nitro group. No crystalline reduction products of the yellow nitrogen-containing material could be obtained. Analysis of the brown solid obtained by pouring the zinc–acetic acid reduction product into water further indicated the loss of nitrogen from this product during the reduction.

Anal. Found: (before reduction): N, 6.74, 6.46; (after reduction): N, 3.54, 3.64.

A light yellow sodium salt was precipitated from acetone solution when aqueous sodium hydroxide was added drop by drop. Attempts at esterification of the sodium salt of the yellow product with dimethyl or diethyl sulfate resulted only in uncrystallizable tars.

Summary

1. A study of the conditions of nitration of abietic acid and some of its derivatives has been made.

2. Two main products were obtained: a white crystalline dinitro acid, $C_{19}H_{26}N_2O_6$ (substantiating Dubourg's results), m. p. 171.2–171.4° (Dubourg reported a m. p. of 162–165°) and a yellow amorphous nitrogen-containing product, decomposing above 100°. The latter is a hydroxylated nitro derivative of abietic acid while the former is not. The properties of these products have been studied.

3. The alkaline solution of the yellow nitrogen-containing product readily absorbs oxygen.

THE REACTION BETWEEN THIOCARBANILIDE AND MONOCHLORO-ACETIC ACID IN ALCOHOL AND IN ACETIC ACID SOLUTION[1,2]

BY KLARE S. MARKLEY AND E. EMMET REID

RECEIVED FEBRUARY 17, 1930 PUBLISHED MAY 8, 1930

Following the general directions of Lange[3] for the preparation of diphenylisothiohydantoin from thiocarbanilide and monochloro-acetic acid, in order to study its condensation with aldehydes, Hann and Markley[4] and later Kingsbury and Markley[5] observed that the reaction conditions markedly affected not only the yield but also the compound which was formed. No explanation of these observations could be obtained from the papers of Lange, Andreasch,[6] Liebermann and Lange,[7] and Liebermann,[8] who previously prepared diphenylisothiohydantoin for the purpose of studying its constitution, since these authors failed to mention either the yields obtained or the effect of variations in the experimental conditions on the reaction. A number of experiments were therefore undertaken to determine what influence the concentration of reactants, time of reflux, solvent and catalyst had on the course of the reaction.

Results and Discussions.—As a result of this investigation it has been determined that, irrespective of solvent, the primary reaction between thiocarbanilide and monochloro-acetic acid is the formation of diphenylisothiohydantoin (I). From the results recorded in Table I it is evident that with alcohol as solvent the best yields are obtained with a short period of reflux, a small ratio of solvent to reactants, a slight excess of monochloro-acetic acid and the addition of sufficient anhydrous sodium acetate to remove the hydrochloric acid from the reaction as rapidly as it is formed. A high yield of diphenylisothiohydantoin may likewise

[a] The actual yields are somewhat higher due to the slight solubility of the compound in 95% alcohol. [b] Theoretical nitrogen: 10.45%. [c] Reaction mixture treated with water to separate the CH_3COONa.

When these precautions are not observed a mixture of diphenylisothiohydantoin and 3-phenyl-2,4-thiazolidione[9] (II) is formed in alcohol solution, whereas with glacial acetic acid (in proper proportion)[10] as the solvent and provided the time of reflux is sufficiently prolonged (five hours or more), practically quantitative yields of the latter compound are obtained, as indicated in Table II. It is apparent that the cyclic diketone results from the secondary hydrolysis of the diphenylisothiohydantoin under the influence of the hydrochloric acid formed in the primary reaction, as was suggested by Lange.

The hydrolysis of diphenylisothiohydantoin to form 3-phenyl-2,4-thiazolidione, however, is not the only factor which lowers the yield of diphenylisothiohydantoin as prepared in alcoholic solution, since the mother liquors from these preparations were found to contain, in addition to 3-phenyl-2,4-thiazolidione, urea, phenyl mustard oil and phenylthiourethan. The addition of hydrochloric acid to the original reaction mixture (Expt.

---

[9] Liebermann and Völtzkow, *Ber.*, 13, 276 (1880), obtained the same compound by heating phenylthiourethan, monochloro-acetic acid and absolute alcohol under pressure; P. Meyer, *Ber.*, 14, 1659 (1881), by the hydrolysis of o-phenylthiohydantoic acid and o-phenylthiohydantoin; Evers, *ibid.*, 21, 962 (1888), by the reaction of ethyl-, propyl- and allylphenyldithiourethan and monochloro-aceticacid; Wheeler and Barnes, Am. *Chem. J.*, 24, 60 (1900), by melting together phenylthiourethan and monochloroacetic acid.

[10] If the volume of glacial acetic acid is too large, diphenylisothiohydantoin is not completely converted into the cyclic diketone; if too small, partial decomposition ensues with the formation of phenyl mustard oil.

$$C_6H_5NCS + C_2H_5OH \longrightarrow \begin{matrix} C_6H_5NH \\ C_2H_5O \end{matrix}\!\!>CS \qquad (IV)$$

Experimental

Diphenylisothiohydantoin.—The general method used in preparing the diphenylisothiohydantoin was briefly as follows: 25 to 100 g. of thiocarbanilide and slightly more than the corresponding molar quantity of $CH_2ClCOOH$ were dissolved in 300 to 500 cc. of alcohol and heated under a reflux condenser for one and one-fourth to five hours. As long as the solid phase of the compound was absent, no crystals separated although the solution was enormously supersaturated with respect to diphenylisothiohydantoin. At the expiration of the time of refluxing, the hot solution was filtered with the aid of a hot water funnel. The diphenylisothiohydantoin separated from the hot filtrate in beautifully iridescent, very thin plates. When the volume of alcohol was sufficiently large the compound was found to separate in a very pure form as was shown by nitrogen analysis and melting point. When the compound was recrystallized, 3 to 5 times the volume of boiling alcohol was necessary to redissolve it as compared with the original volume of solvent from which it was obtained. Upon pouring the hot alcoholic solution into cold water, pure diphenylisothiohydantoin separated as a white microcrystalline powder and not as an oil as was reported by Lange. It did, however, separate as a red oil from the crude reaction mixture when the latter was treated with water in a similar manner A solubility determination of diphenylisothiohydantoin in 95% alcohol at 27° gave a value of 0.35 g. per 100 g. of solvent, or 0.28 g. per 100 cc. The optical properties of diphenylisothiohydantoin as determined by Mr. G. L. Keenan of the Bureau of Chemistry and Soils were as follows. Recrystallized from 95% alcohol the compound consisted of thin, colorless, micaceous plates. The indices of refraction were found to be n_α 1.654, n_β 1.690, both ±0.003, $n_\gamma > 1.734$. In convergent polarized light, crossed nicols, biaxial interference figures were observed occasionally, particularly in plates perpendicular to an optic axis.

3-Phenyl-2,4-thiazolidione.—Since the condensation of diphenylisothiohydantoin with aromatic aldehydes is readily effected in glacial acetic acid, it was thought that this acid would prove to be an ideal solvent for its preparation. Nitrogen analysis, melting point and microscopic examination of the resulting product showed, however, that the compound formed was 3-phenyl-2,4-thiazolidione and not the expected diphenylisothiohydantoin. Almost quantitative yields were obtained when the following conditions were observed: 50 g. of $(C_6H_5NH)_2CS$, 25 g. of $CH_2ClCOOH$ and 60 cc. of glacial acetic acid were shaken together in a 300-cc. flask to form a paste. Partial solution occurred, accompanied by considerable cooling. The flask was connected with a reflux condenser and gentle heat applied to effect complete solution, after which vigorous boiling was maintained for five hours or more. On cooling, the contents of the flask solidified to a mass of star-shaped clusters of yellow needles quite unlike diphenylisothiohydantoin. Following the addition of water the mass was disintegrated by shaking, and the product washed first by decantation and then on a Büchner funnel. On recrystallization from alcohol it separated in the form of bushy rosets of long thin yellow needles.

Mother Liquors of Diphenylisothiohydantoin.—When the mother liquors from the alcohol series of preparations, which always possessed a typical phenyl mustard oil odor, were evaporated either by the aid of heat or spontaneously, crystallization continued with the separation of a compound which appeared to the casual view to be diphenylisothiohydantoin. When evaporation was continued to dryness it was observed that two different layers formed; an upper one which appeared like diphenylisothiohydantoin and a lower one composed of a dark red, oily material shot through with fine needle-like crystals. When heated to 100° or to an even lower temperature the whole mass melted to a clear red oil which solidified again on cooling. Examination of the mother liquors from Prepns. 3, 5, 7 and 8 (Table I) led to the isolation and identification of the following compounds: phenyl mustard oil, phenylthiourethan, diphenylisothiohydantoin, 3-phenyl-2,4-thiazolidione and diphenylthiourea. Although quantitative separations were impracticable, it appeared that phenyl mustard oil and phenylthiourethan comprised the bulk of the products contained in the mother liquors.

In addition to the experiments recorded in Tables I and II, two additional preparations were made by refluxing for two hours 25 g. of diphenylthiourea and 12 g. of $CH_2ClCOOH$ dissolved in 300 and 250 cc. of 95% alcohol, respectively. After separating the crystallized diphenylisothiohydantoin in the usual manner, the mother liquors and washings were evaporated until but 25 to 35 cc. of a red oil remained, which on cooling solidified to a light yellow crystalline mass. To the first residue there was added 5 g. of $CH_2ClCOOH$, 5 cc. of concd. hydrochloric acid and 60 cc. of acetic acid, and to the second 25 cc. of acetic acid only. Both mixtures were then refluxed for four hours. After cooling the reaction mixtures were poured into large volumes of cold water and allowed to stand for twenty-four hours to separate the crystalline material from the oil. The crude product which separated was then collected on a Buchner funnel, washed with water, dried and weighed. In the first case diphenylisothiohydantoin and 3-phenyl-2,4-thiazolidione equivalent to 49.4 and 17.5% and in the second case 42.5 and 26%, respectively, of the original thiocarbanilide were recovered.

Secondary Formation of **3-Phenyl-2,4-thiazolidione.**—Since hydrochloric acid separated in molar proportions in the course of the reaction, its effect on diphenylisothiohydantoin and the original reactants was studied in this concentration. Two samples of 10 g. each of pure diphenylisothiohydantoin were dissolved in 60 cc. of glacial acetic acid and 1.35 g. of hydrochloric acid added in the form of its concentrated aqueous solution. To the second sample was added 6 g. of anhydrous sodium acetate. Both samples were boiled under a reflux condenser for four hours. Upon cooling, the reaction mixtures were poured into large volumes of cold water, the precipitates collected on Büchner funnels and washed to remove the acetic acid, hydrochloric acid and sodium acetate. After drying at 105°, the product from the first reaction, amounting to 7.0 g. (calcd. 7.2 g.), was identified by microscopic examination and nitrogen analysis as 3-phenyl-2,4-thiazolidione. The diphenylisothiohydantoin was quantitatively recovered in the second case.

Summary

The reaction between thiocarbanilide and monochloro-acetic acid has been studied in alcohol and in acetic acid under different experimental conditions and the probable mechanism of the reaction established. With anhydrous solvent containing sufficient anhydrous sodium acetate to remove both the water and hydrogen ions from the sphere of action, the maximum yield of diphenylisothiohydantoin is obtained. With acetic acid as solvent and a period of refluxing exceeding five hours, almost quantitative yields of 3-phenyl-2,4-thiazolidione are obtained.

THE VESICANT ACTION OF CHLORO-ALKYL FURFURYL SULFIDES

BY HENRY GILMAN AND A. P. HEWLETT

RECEIVED FEBRUARY 19, 1930 PUBLISHED MAY 8, 1930

Introduction

In connection with studies concerned with furfural and its derivatives,[1] we have had occasion to synthesize β-chloro-ethyl furfuryl sulfide and γ-chloropropyl furfuryl sulfide. It was considered worth while to test these compounds for their vesicant action. This we have done. The β-chloro-ethyl sulfide has a marked vesicant action, which, however, is not so great as that of mustard gas ($(ClCH_2CH_2)_2S$). The γ-chloropropyl compound is without vesicant action. These results are in complete agreement with recent studies by Kirner.[2] He showed that in a

[2] Kirner, THIS JOURNAL, 50, 2446 (1928).

series of related chloro-alkyl sulfides only the β-chloro-ethyl (and not the α-chloro-methyl nor the γ-chloropropyl) sulfide had vesicant properties.

The following reactions were used for the preparation of our compounds in quite satisfactory yields.

The y-chloropropyl furfuryl sulfide when applied to the skin in undiluted form produces no skin irritation.

$$C_4H_3OCH_2SMgBr + 2ClCH_2CH_2OSO_2C_6H_4CH_3\ (p) \longrightarrow$$
$$C_4H_3OCH_2SCH_2CH_2Cl + ClCH_2CH_2Br + (p\text{-}CH_3C_6H_4SO_2O)_2Mg \qquad \text{(IV)}$$

Experimental Part

Furfuryl Disulfide (See Reaction I).—The disulfide was prepared after recent patent directions.[3] Dry hydrogen sulfide was added rapidly over a two-hour period to a mixture (cooled by ice and salt) made up of 288 g. (3.0 moles) of furfural in 1500 cc. of 95% alcohol and 250 g. (3.2 moles) of sodium sulfide. After permitting the mixture to stand at room temperature overnight, the liquid was separated from the undissolved sodium sulfide, refluxed for one hour and then distilled from a water-bath to remove one liter of the alcohol. The residue from the water-bath distillation was poured into four liters of water and extracted with two liters of ether. The ether layer was separated, dried over sodium sulfate, and then the ether was removed by distillation from a water-bath. The residue of disulfide was thereupon reduced without further purification. However, a small portion was found to distil with some decomposition and discoloration at 160–165° (5 mm.). The boiling point previously3 given is 112–115" (0.5 mm.), and the melting point 10–10.5°.

Furfuryl Mercaptan (See Reaction II).—To the crude disulfide dissolved in 500 cc. of alcohol and 25 cc. of acetic acid was added in small portions 130 *g*. (2 atoms) of powdered zinc. The time required for the addition of zinc was about one hour, during which period the mixture was refluxed on a water-bath and stirred vigorously. Subsequent to an additional two hours of refluxing, a saturated solution of oxalic acid containing 180 g. (1.43 moles) was added, and the whole subjected to steam distillation. The distillate was extracted with ether, dried over sodium sulfate and distilled. The yield of mercaptan distilling at 155' at atmospheric pressure was 250 g. or 73%. The boiling points reported previously are 45–47° (12 mm.)[3] and 84° (65 mm.).[4] The p-nitrobenzoate of the mercaptan was found to melt at 77°, which is in agreement with that reported elsewhere.' Furfural mercaptan is a colorless liquid, very stable and with an extremely disagreeable odor.

---

[3] Staudinger and Reichstein, Canadian Patent 283,765 (Oct. 2, 1928); *C.* **A.**, **22**, 4537 (1928); Internationale Nahrungs- und Genussmittel A.-G., Brit. Patent 286,152 (July 25, 1927); *C.* **A.**, **23**, 155 (1929).

[4] Kirner, THIS JOURNAL, 51, 3134 (1929), has just reported the preparation of furfuryl mercaptan in a 33% yield by hydrolysis, without isolation, of the product obtained by condensation of a-furfuryl chloride with thiourea.

β-Chloro-ethyl Furfuryl Sulfide (See Reactions III and IV).—The reactions used for the preparation of the chloro-alkyl furfuryl sulfides are applications of the alkylating action of alkyl sulfonates on organomagnesium halides reported previously from this Laboratory.[5]

An ethereal solution of ethylmagnesium bromide prepared from 24 g. (2.2 moles) of ethyl bromide in 250 cc. of ether was siphoned from unaltered magnesium into a one-liter, three-necked flask provided with a mercury-sealed mechanical stirrer, condenser and separatory funnel. To the Grignard solution, cooled by an ice–salt mixture, was added dropwise a solution of 22.8 g. (0.2 mole) of the furfuryl mercaptan dissolved in 250 cc. of ether. A vigorous reaction ensued, and because of the separation of the white heavy intermediate (see Reaction 111), 100 cc. of ether was added. After allowing the mixture to come to room temperature, it was refluxed for three hours on a water-bath.

To the mixture, which was then permitted to come to room temperature, was added dropwise and with vigorous stirring, a solution of 93.8 g. (0.4 mole) of β-chloro-ethyl *p*-toluenesulfonate in 150 cc. of ether. The resulting mixture, subsequent to a two-hour period of reflusing on a water-bath, was cooled and then hydrolyzed by 250 cc. of water containing 30 cc. of sulfuric acid. The hydrolysate was transferred to a separatory funnel and 500 cc. of water was added to dissolve the magnesium *p*-toluenesulfonate. The ether layer (after washing with water and drying with sodium sulfate) was distilled at atmospheric pressure to remove the ether and most of the ethylene chlorobromide. The β-chloro-ethyl furfuryl sulfide was obtained by vacuum distillation as a colorless liquid boiling at 128° (5 mm.). The yield was 32 g. or 90%. It distils at 5 mm. without decomposition, but begins to darken after standing for a few days and decomposes on long standing The chlorosulfidehas a pronounced odor which is very disagreeable at high concentration, but in dilute form it is pleasant and resembles somewhat a mustard odor. A saturated solution in water at 30° contains 0.123% of the sulfide; d_{30}^{30} 1.1914; n_{D}^{30} 1.5200.

Anal. Calcd. for C_7H_9OClS: S, 18.13; Cl, 20.11. Found: S, 17.41, 17.49; Cl, 20.26, 20.09.

γ-Chloropropyl Furfuryl Sulfide, $C_4H_3OCH_2S(CH_2)_3Cl$.—This chlorosulfide was prepared after the method just described for the synthesis of the p-chloro-ethyl homolog. From a 0.1-mole run using 3 g. of magnesium, 11 g. of ethyl bromide, 11.4 g. of furfuryl mercaptan and 49.6 g. of y-chloropropyl p-toluenesulfonate, the yield of γ-chloropropyl furfuryl sulfide distilling at 135° *(5 mm.)* was 15 g. or 79%. It is a colorless liqyid with an odor similar to that of p-chloro-ethyl sulfide, and although it darkens on standing it is more stable than the p-chloro-ethylsulfide; d_{30}^{30} 1.1687; n_{D}^{25} 1.4740.

Anal. Calcd. for $C_8H_{11}OClS$: S, 16.80; Cl, 18.63. Found: S, 16.38, 16.26; Cl, 18.59, 18.59.

Physiological **Tests**

The γ-chloropropyl furfuryl sulfide when applied to the skin in undiluted form produces no skin irritation.

Several preliminary qualitative tests were carried out with the β-chloro-ethyl furfuryl sulfide. When applied to the skin in undiluted form a red spot appeared in two to three hours, and with some men, large deep blisters developed in five to eight hours. Of the five who were tested in this Laboratory, three developed burns very like those of mustard gas, whereas

---

[5] The most recent reference is that of Gilman and Heck, ***Ber.,*** 62, 1379 (1929). From this all previous references may be traced.

the other two had deep red blotches which persisted for several months.[6]

In a more exact study, six men were selected for the test which was run with a 0.5% mustard gas control. The mustard gas caused a blister on all subjects, while our chlorosulfide was negative up to 2%. A 3% solution caused redness and slight itching. A 5% solution caused a blister which was equal in nearly every case to the blister caused by a 0.5% solution of mustard gas. It also caused itching comparable to mustard gas. Carbon tetrachloride was used as a solvent for both compounds. It is quite probable that the furfuryl sulfide is more effective than these results indicate, because the tests were carried out with a sample that had undergone partial decomposition. Because of this decomposition no toxicity tests were made.

The authors wish to thank the Miner Laboratories of Chicago for liberal supplies of furfural, and those who helped carry out the several tests.

Summary

Directions are given for the preparation of β-chloro-ethyl furfuryl sulfide and γ-chloropropyl furfuryl sulfide in good yields. The β-compound in agreement with other results has a pronounced vesicant action, whereas the γ-chlorosulfide is without vesicant action.

ALPHA-METHYL-GAMMA-TETRAHYDRO-2-FURYLPROPYLMAGNESIUM BROMIDE

BY HENRY GILMAN AND JOSEPH B. DICKEY

RECEIVED FEBRUARY 19, 1930 PUBLISHED MAY 8, 1930

Introduction

In extension of studies concerned with furan compounds, it was quite natural for us to turn to the preparation of organomagnesium halides synthesized from furan types, primarily with a view to an interpretation of other furan reactions. An astonishingly small number of such investigations has been made, undoubtedly because of the inaccessibility of halogen furan compounds and the relative inertness of the halogen in many of these compounds. Moureu, Dufraisse and Johnson[1] prepared furylacetenylmagnesium bromide $C_4H_3OC{\equiv}CMgBr$, by an indirect method in-

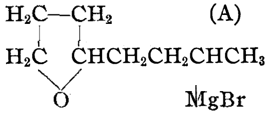
---

[6] Some tests were carried out with the assistance of Professor M. D. Helser (to whom grateful acknowledgments are made) on hogs, in connection with the possible utility of these and other compounds for the marking of hogs. When applied in undiluted form to the skin of hogs twelve hours before killing, intense red spots remained on the skin of the animals after removal from the depilatory bath. However, no blisters developed.

[1] Moureu, Dufraisse and Johnson, Ann. *chim.*, 7, **1 (1927).**

volving the reaction between ethylmagnesium bromide and furylacetylene, which is prepared with unusual difficulty and in depressingly low yields after a series of transformations. Allen and Rosener[2] were unsuccessful in their attempts to prepare a Grignard reagent from 2,3,5-triphenyl-4-bromofuran. This is understandable in view of the extreme inertness of the bromine even toward hot alcoholic potash. Fenton and Gostling[3] reported no appreciable reaction between 5-bromomethylfurfural and magnesium in benzene.

The organomagnesium halide which we have prepared is readily obtainable by standard reactions which start with furfural. This aldehyde is condensed to furfuralacetone,[4] which is then catalytically reduced by the method of Kaufmann and Adams[5] to a-methyl-y-tetrahydro-2-furylpropanol. There was no difficulty in converting this carbinol to the corresponding bromide, and the Grignard reagent is prepared from the bromide with great ease and in excellent yields (94%). The organomagnesium halide so prepared, a-methyl-y-tetrahydro-2-furylpropylmagnesium bromide (A) has been characterized by appropriate derivatives.



(A)

Experimental Part

The furfuralacetone, prepared after the directions of Leuck and Cejka,[4] was obtained in the yields described by them. However, we could not equal the yields described for the preparation of α-methyl-γ-tetrahydro-2-furylpropanol. Our yields varied from 15 to 25% when 55.0 g. (0.404 mole) of furfuralacetone in 150 cc. of 95% ethyl alcohol was catalytically reduced with 1.0 g. of the platinum catalyst. Several runs were made with varying small quantities of ferrous chloride as a promoter, but there was no essential alteration in yield. The promoter was tried in the hope that the catalytic reduction, which proceeds with ease, might be restricted, because it is possible to have a miscellany of reduction products with a compound like furfuralacetone. Possibly a part of our difficulty lies in incomplete fractionation. Whatever the cause, it is very gratifying to report that unpublished results on the catalytic reduction of furylacrolein by the method of Adams and Bray[6] have consistently given yields which are several per cent. in excess of those reported by them. In this latter reduction, absolute ethyl alcohol was used as the medium, and there is a possibility that such alcohol might improve the yield of α-methyl-γ-tetrahydro-2-furylpropanol. The ready accessibility of α-tetrahydro-2-furylpropanol, the high yields of chloride from this, and the high yields of Grignard reagent from the chloride make this a better organomagnesium halide for synthetic purposes.

Benzoate of a-Methyl-y-Tetrahydro-2-Furyl-Propanol, $C_4H_7OCH_2CH_2CH(CH_3)OCOC_6H_5$.—The butanol was characterized by the preparation of the benzoate. This ester was obtained in a 72% yield by refluxing the carbinol with benzoyl chloride in benzene. It is a colorless, stable liquid, with a sharp taste and with no appreciable odor. The boiling point is 164–166° (3 mm.).

Anal. Calcd. for $C_{15}H_{20}O_3$: C, 72.53; H, 8.12. Found: C, 72.20, 72.35; H, 8.05, 8.02,

a-Methyl-y-tetrahydro-2-furylpropyl Bromide, $C_4H_7OCH_2CH_2CH(CH_3)Br$.—This bromide was obtained in a 59.8% yield by saturating a solution of 20.4 g. (0.141 mole) of the carbinol in 20 cc. of anhydrous benzene with hydrogen bromide.[7] The bromide distils at 79.5–80° (4 mm.) as a clear, colorless liquid, of sweet odor and sharp taste. It is insoluble in water, but soluble in the more common organic solvents; d^{20}_{20} 1.2000; n^{20}_{D} 1.4719.

Anal. Calcd. for $C_8H_{15}OBr$: Br, 38.6. Found: Br, 38.03, 38.10.

a-Methyl-y-tetrahydro-2-furylpropylmag Bromide, $C_4H_7OCH_2CH_2CH(CH_3)MgBr$.—Following the directions of Gilman, Zoellner and Dickey,[8] the reaction was started by adding a few drops of the undiluted bromide and a crystal of iodine to 2.39 g. (0.0986 atom) of 30–80 mesh magnesium in 10 cc. of ether. Then the remainder of the bromide, totaling 18.5 g. (0.0896 mole) in 35 cc. of ether was added over a period of one and one-half hours. Subsequent to addition of the halide, the mixture was refluxed for one hour. Titration by the method of Gilman, Wilkinson, Fishel and Meyers[9] showed the yield to be 91.5%. In another experiment of 0.02 mole size, the yield was 94%.

The Grignard solution gave a beautiful blue color when a small aliquot was treated after the color test directions of Gilman, Schulze and Heck[10] for reactive organometallic compounds.

α-Methyl-γ-tetrahydro-2-furyl-butyro-α-Naphthalide, $C_4H_7OCH_2CH_2CH(CH_3)CONHC_{10}H_7$-$\alpha$.[11]—The a-naphthalide was prepared in accordance with the directions of Gilman and Furry[12] from the Grignard reagent and α-naphthylisocyanate. It melts[13] at 109.5–110°.

Anal. Calcd. for $C_{19}H_{23}O_2N$: C, 76.72; H, 7.77. Found: C, 76.06, 76.00; H, 8.29, 8.23.

a-Methyl-y-tetrahydro-2-furylbutyric Acid, $C_4H_7OCH_2CH_2CH(CH_3)CO_2H$.—The acid was prepared by the carbonation of the organomagnesium bromide, in accordance with the directions of Gilman and Parker.[14] The yield of pure acid, distilling at 104–106° (0.2–0.3 mm.), was 59% (calculated on the RMgBr compound). It is a water-

---

[7] No study was made of optimal conditions for the preparation of the bromide. Because our chief interest was to procure the bromide free of carbinol, this saturation was extended over several days. Unquestionably the time can be drastically reduced because the first saturation, in a cooling mixture, was accompanied by a somewhat vigorous reaction.

white, stable liquid of a sharp taste and disagreeable odor, and is slightly soluble in water; d_{20}^{20} 1.0401; n_{D}^{20} 1.4528.

Anal. Calcd. for $C_9H_{16}O_3$: C, 62.74; H, 9.37. Found: C, 62.50, 62.35; H, 9.50, 9.46.

Summary

α-Methyl-γ-tetrahydro-2-furylpropylmagnesium bromide is obtainable in excellent yields from the corresponding bromide which is accessible, in turn, from furfural. This organomagnesium halide is one of the unusually small number of the furan type so far reported, and probably the first to be obtained by a direct reaction. It has been characterized by appropriate derivatives.

CRYSTALLINE MONOMETHYLDIETHYLMERCAPTOGLUCOSE

BY PHILIPPOS E. PAPADAKIS

RECEIVED FEBRUARY 21, 1930 PUBLISHED MAY 8, 1930

The author has had occasion to prepare pentamethyldiethylmercaptoglucose using Fischer's[1] method for the formation of diethylmercaptoglucose and a combination of Haworth[2] and Freudenberg's methods for the methylation process as described by Levene and Meyer.[3]

In some experiments, instead of following Levene and Meyer's procedure, which favors the formation of the polymethylated product, the following method was adopted. The dimethyl sulfate, three times the required amount, was placed in a three-necked flask; the flask was provided with an efficient stirrer, a reflux condenser and a large separatory funnel; the diethylmercaptoglucose was suspended in the sodium hydroxide, which was placed in the separatory funnel, and thence was allowed to flow into the flask gradually. The temperature was kept at 67°.

The methylated product was extracted by ether. After the ether was evaporated the remaining brown sirup which was supposed to contain the polymethylated product was very little in quantity. From the brown sirup, however, a crystalline substance was obtained which was recrystallized from absolute alcohol and gave a melting point of 156°. These crystals were kept for future reference.

Besides these crystals it was observed that during the ether extraction *a* solid substance was going into suspension in the ether layer. From this solid substance some unmethylated mercaptoglucose was extracted by boiling ether. The residue had a melting point between 155 and 160°.

---

[1] E. Fischer, Ber., 27, 673 (1894).

[2] W. N. Haworth, J. Chem. *Soc.*, 107, 11 (1915).

[3] Levene and Meyer, J. Biol. Chem., 67, 176 (1926).

It had an appearance similar to the unmethylated product, but a different melting point. At this point it was decided to subject this substance to further methylation.

These crystals as well as more diethylmercaptoglucose were further subjected to methylation. This time the procedure described by Levene and Meyer was followed. The results with respect to the polymethylated diethylmercaptoglucose were more satisfactory, but the yield was smaller than that of Levene and Meyer. On account of this, the water layer after the ether extraction of the polymethylated product was placed aside for later investigation. After some days it was observed that a precipitate was formed which was not soluble in water. This substance was dissolved in chloroform and alcohol and left to stand overnight. In the alcohol layer were formed thin silky fibrous crystals which were recrystallized three times from absolute alcohol and gave a melting point of 156–157'. The results of micro analysis of this substance are given later.

The ether extract which contained the polymethylated diethylmercaptoglucose had dissolved some of the above substance. On evaporation of the ether and distillation of the polymethylated mercaptoglucose under reduced pressure, a substance remained in the distilling flask which always charred at higher temperature. This residue before charring was dissolved in chloroform and from the dark oily liquid after long standing crystals were obtained which were recrystallized from hot alcohol and gave a melting point of 152"; on further recrystallization they gave a melting point of 156–157'.

The analyses for carbon, hydrogen, sulfur, ethyl and methyl radicals were made according to F. Pregl's micro analytical methods at the Rockefeller Institute for Medical Research by Mr. D. Rigakos. The results are indicated in the following Table.

TABLE I

ANALYTICAL DATA FOR MONOMETHYLDIETHYLMERCAPTOGLUCOSE

Sample. mg.	Weighed, mg		Calculated for	%	Found. %
3.630	AgI	8.440	1 Me, 2 Et	24.35	24.13
3.350	$BaSO_4$	5.195	S	21.28	21.30
4.450	H_2O	3.30	H	8.05	8.28
	CO_2	7.185	C	43.97	44.03
4.930	H_2O	3.615	H	8.05	8.20
	CO_2	7.920	C	43.97	43.81

These results indicate that the partially methylated diethylmercaptoglucose is the monomethyl derivative.

The author wishes to express his thanks to Professor W. C. MacTavish of New York University at Washington Square College and to Professor John M. Nelson of Columbia University for their constant interest in his research. The author is indebted to Mr. Rigakos for the analytical part of this work.

Summary

Monomethyldiethylmercaptoglucose has been isolated as a by-product from the preparation of pentamethyldiethylglucose.

NEW YORK CITY

NOTE

The Use of Aryl Esters for the Preparation of **Amides** and Derivatives of Urea. - During my investigations with Professor W. A. Noyes concerning optically active diazo compounds, the preparation of N-substituted acid amides was frequently necessary in order to separate certain stereoisomeric amines. They were also required as intermediate products in obtaining the diazo compounds. These preparations have been accomplished, usually, by condensation of the ethyl esters of the organic acids concerned with the amine by means of refluxing for several hours. In this condensation it has been observed that in general the esters of phenol or substituted phenols react more rapidly and at lower temperatures than the corresponding ethyl esters. Occasionally a considerable development of heat was noticed. Isolated examples of this behavior may be found in the literature. Diphenyl carbonate hss been recommended as especially adapted for the preparation of urea, since it reacts very readily with ammonia even at water-bath temperature.[1] The corresponding ethyl ester reacts only by heating at 180° for a long time in a sealed tube.[2]

It has been recorded in the literature that guaiacol carbonate behaves with ammonia and amines in the same manner as diphenyl carbonate, forming urea or its N-substituted derivatives, instantly.[3] Dr. Noller, in this Laboratory, has recently prepared diphenylcarbazide $(C_6H_5NH\text{-}NH)_2$-CO, from phenylhydrazine and guaiacol carbonate.[4]

It has now been found that diphenyl carbonate reacts as readily with aniline, bornylamine and other amines as it does with ammonia. A mixture of bornylamine and diphenyl carbonate melts with an evolution of heat. By warming on the water-bath the reaction will be finished after five to ten minutes, with solidification. In the use of diethyl carbonate no action could be obtained even by heating to 180° in a sealed tube for four hours.

It has also been found that diphenyl oxalate shows a behavior very similar to the diphenyl and guaiacol carbonates, being much more reactive than the diethyl ester. Bornylamine and diphenyl oxalate react at 80° within a few minutes, forming dibornyloxamide, while the reaction with diethyloxalate requires refluxing for three to four hours. Also, the formation of

oxanilide and other derivatives proceeds more rapidly when using the phenyl ester.

By the use of the aryl esters a method of obtaining N-substituted amides is available which is much more suitable than the one employing ethyl esters, ordinarily used. The phenol formed by the reaction can be removed easily by the addition of aqueous sodium hydroxide and filtering off the amide from the soluble phenolate. In some cases steam distillation of the phenol is possible. Aryl esters are easily obtained by treating a mixture of the phenolic compound and the free acid with phosphorus oxychloride. Of course, for preparation of the carbonate, phosgene is used.

PHOTOSENSITIZATION BY AMMONIA

Sir:

A research by Parkas, Haber and Harteck[1] on the photosensitization of the oxidation of hydrogen and carbon monoxide by means of ammonia is so similar in concept to work at present in progress in this Laboratory that it seems desirable to record immediately our data already obtained.

The illumination of mixtures of ammonia and ethylene at room temperatures and 100° by a mercury arc produces a rapid reduction in pressure which does not obtain with ethylene alone or with ethylene–hydrogen mixtures. It is not, therefore, a mercury resonance-radiation effect but is determined by the ammonia. During the reaction an oil separates which, as it accumulates, slows down the reaction rate.

By analogy with our earlier work[2] with excited mercury one might attribute the pressure change to a polymerization of ethylene under the influence of atomic hydrogen liberated in the photodecomposition of ammonia. We have shown, however, that in the presence of ethylene the normal decomposition of ammonia is much retarded. In the presence of 15 cm. of ethylene the photodecomposition of 5 cm. of ammonia is reduced to 5% of the normal rate. A further distinction from the work with excited mercury is found when hydrogen is present in the reaction system. With hydrogen, ethylene and ammonia an equally rapid pressure decrease occurs on illumination but no hydrogen disappears. Hence, even in presence of hydrogen, the reaction is one of polymerization.

[1] Parkas, Haber and Hartcck, *Naturwissenschaften*, **18**, 266 (1930).

[2] Taylor and Hill, THIS JOURNAL, 51, 2922 (1929).

Over a wide concentration range the rate of reaction is independent of the ethylene concentration and increases with increasing ammonia concentration. The temperature coefficient is low and of the order of 1.03 per 10°. The quantum yield is of the order of unity if that for ammonia is taken as 0.2.

We are dealing, therefore, with a polymerization of ethylene photosensitized by ammonia. The retarded decomposition of the ammonia is of very great importance since it has been assumed of molecules showing predissociation spectra that absorption leads to decomposition without collision within $\sim 10^{-12}$ sec. In our pressure range (5–15 cm.) the collisions occur only after $\sim 10^{-9}$ sec. It is, therefore, difficult to account for the retarded ammonia decomposition on the present accepted ideas concerning predissociation. We are pursuing this work.

A CAPILLARY MERCURY-VAPOR LAMP

Sir:

A simple mercury-vapor lamp of high intensity has been developed in this Laboratory. It is cheap and easily constructed so that one can afford to operate it at a considerable overload for photochemical investigations. These lamps have been used in several different researches and they have been tested by friends in other laboratories.

The lamp is made from clear fused quartz tubing, 10 cm. long with an inside diameter of 1.5 mm. and an outside diameter of 4 mm. Three bulbs are blown, the first 15 mm. from the top, the second 20 mm. and the third 40 mm. from the top. The ends are constricted to enclose the tungsten electrodes, 0.75 mm. in diameter. The upper electrode is sealed in with fused silver chloride, the proper amount of pure mercury is introduced and the second electrode is sealed in with silver chloride. The electrodes are connected to copper wires and covered with de Khotinsky cement, which insulates the wires and makes the seals gas tight. The upper electrode is long enough to reach through the uppermost bulb and nearly to the second bulb. The mercury reaches to the bottom of the uppermost bulb and the remaining air space serves as an expansion chamber.

The lamp is held in a vertical position over a funnel and a water jet is mounted just above it. It is started by adjusting the resistance in series with the lamp, closing the circuit (500 or 110 volts d. c.), and separating the mercury thread between the second and third bulbs (20 mm. apart)

---

[3] Commonwealth Fund Fellow.

with a small Bunsen flame or an electric heating coil. As soon as the arc strikes, a stream of water is immediately run over the lamp. Soft water or distilled water should be used. The lamps operate satisfactorily on 3 to 5 amperes with a potential drop of 60 to 300 volts. The upper electrode is positive.

The intensity varies with the individual lamps but the intensities on the different lines have been found to be approximately ten times or more as great as those obtained with commercial lamps operating under normal conditions. Uranyl oxalate has been decomposed at the rate of 0.5 g. of oxalic acid per minute using a cylindrical cell around the lamp. Raman effects have been observed with shorter exposures than are required with other lamps.

Some lamps have given fifty hours of service but when operated at very high intensity they usually fail after ten hours. Many lamps have shown but little decrease in intensity over the first few hours.

The lamp described here is particularly useful for illuminating spectrometer slits or for irradiating small volumes of material. Experiments are being continued also with metals other than mercury.

NEW BOOKS

Einführung in die theoretische Wutschaftschemie. (Introduction to the Principles of Economic Chemistry.) By Dr. Phii. RUDOLF KOETSCHAU. Theodor Steinkopff, Residenzstrasse **32,** Dresden-Blasewitz, Germany, 1929. xii + **155** pp. 13 figs. 15.5 × 23.5 cm. Price, unbound, RM. 12; bound, RM. 13.50.

Scientists in the past, starting from the known or central truth of phenomena, have tended to explore outward almost exclusively along the straight line of their own discipline. Chemists stuck to chemistry, and biologists to biology.

In the last few decades, however, there has been a steady obliteration of boundary lines, and a continually increasing cooperation among specialists. Research in the no man's land between the natural sciences is bringing astounding results, now partly embodied in texts on physical chemistry, biochemistry, astrophysics and the like. The social scientists have likewise exchanged results among themselves. But the natural sciences and the social sciences have generally been thought in the main to lie in different strata.

Dr. Koetschau does not think so. In fact, he believes that a new science ought to be recognized: economic chemistry or chemical economics. It conceivably might be the forerunner of a host of hybrid sciences—economic botany, economic geology, etc. All such new sciences need analytical working tools, concepts unequivocally defined. Such Dr. Koetschau's book purports to give for economic chemistry.

It quite naturally divides itself into three main parts: an introductory essay on epistemology, a description of certain alleged economico-chemical concepts for which sundry symbols are coined, and a manifesto consisting of twenty theses or tentative generalizations, presented in the approved medieval manner for verification, modification or nullification.

The first part (pp. 1–29, 55–65) endeavors to prove that economics and chemistry as sciences lie on the same plane, that their concepts are germane, and that, therefore, cross-fertilization is possible. The familiar contentions of the Neo-Kantians, especially Windelband, Rickert, and Cassirer, are adduced. The natural sciences and the social sciences both use the quantitative-mathematical method of fixing the orbit of their concepts, and in so far as that is true, their concepts are not contradictory, but correlative. The arguments of Oppenheim in his "Natural Classification of Sciences" are also used. In short, no gulf exists between the natural and the social sciences. Their laws differ in degree, not in kind. In other words, it is possible for a science of theoretical economic chemistry to exist.

The second part (pp. 29–55, 65–86) describes four sets of concepts, supposedly coordinate, which lie in the domain of economic chemistry. The first consists of the totality of chemical and physico-chemical processes in so far as they have or can have economic significance. The symbol "ch" is used to designate all the laws of homogeneous and heterogeneous chemical equilibria for all states of aggregation—the law of mass action, the Le Chatelier principle, the phase rule, etc. The second set of concepts comprises (p. 45) the totality of changes of matter which are purposively manipulated to take place in definite amounts during a set period of time. Chemical processes can now be represented by vectors, which, when combined, show a definite quantum of salable product. All the principles which guide the chemical technologist, such as the tendency to substitute continuous for batch processes, are designated by the Greek letter χ. The third set of concepts, represented by the letter w, comprises the numerous laws (sic! p. 50) which economics has discovered; laws which have reference to demand, supply, value, credit, and so on; laws which, by assuming that business is run to maximize profits, formulate the interaction of the forces at work in a given system of interdependent economic equilibria, and evaluate their benefit or harm to society as a whole. A superficial attempt is made to utilize the results of statisticians and of mathematical economists such as Schumpeter and Pareto. The fourth set of concepts, designated by the Greek letter τ, logically it ought to come third, represents all those principles of procedure, both technological and commercial, which are commonly implied in the phrase, "the present state of the arts." τ stands for all those practices of sound business administration, plant location, process costing, etc., which Mr. Chaplin Tyler has so ably elucidated in his "Chemical Engineering Economics."

Thus the transition is made from pure chemistry via chemical technology and business technique to economics. A science is mapped out which is designed to coordinate the efforts of the chemist seeking the truth for its own sake, the endeavors of the chemical engineer interested primarily in the technological perfection and dovetailing of the productive processes, the energies of the business man worshiping profits, and the theoretical and practical programs of the political economist endeavoring to maximize social income and general prosperity.

The third part of Dr. Koetschau's book consists of twenty theses, which in part recapitulate, and in part trace interrelationships between, the four sets of concepts. The result, as one might expect, is meager. Chemists who go into business must keep in mind that chemical processes must be adjusted so as to earn maximum profits. Such are the platitudes to which the theses can be reduced, so that one has the distinct feeling of being all dressed up in formidable terminological clothes, with no place to go.

Finally, attention must be called to the extraordinary amount of reading which has been epitomized in the book. Over 210 authors are cited, twenty of them more than five times, in about 130 pages of text. The volume shows not only ingenuity in the coining and defining of terms, but also an heroic, even if to the skeptical reader an unsuccessful, attempt to found a new science.

THEODORE J. KREPS

The American Illustrated Medical Dictionary. A Complete Dictionary of the Terms used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, Nursing, Veterinary Science, Biology, Medical Biography, etc., with the Pronunciation, Derivation, and Definition. By W. A. NEWMAN DORLAND, A.M., M.D., F.A.C.S., Lieut. Colonel, M.R.C. U. S. Army, Member of the Committee on Nomenclature and Classification of Diseases of the American Medical Association; Editor of American Pocket Medical Dictionary. Fifteenth edition, revised and enlarged with the collaboration of E. C. L. MILLER, M.D., Professor of Bacteriology and Biochemistry, Medical College of Alabama. W. B. Saunders Company, Philadelphia, 1929. 1427 pp. 16 × **23** cm.

This fifteenth edition of a volume first issudd in 1900 has been amplified and brought up to date by the inclusion of many new terms, and is reset from new type. The reasons for its popularity may easily be understood. The typography and the arrangement of material are excellently chosen. making it convenient to consult and read. Some 70,000 of the terms of medicine and related arts and sciences are contained in it. The definitions are brief, encyclopedic discussions being happily absent. The many illustrations are for use rather than ornament; and the hundred or so tables are admirably selected, sufficiently complete and carefully arranged, whereby the user's time and effort are economized.

Many terms in the borderland subjects of medicine have been included, and here lies its value to chemists, for not only may the common terms of chemistry be found but also the words and phrases of modern biological science with which the chemist of today is increasingly concerned.

Although in the introduction it is stated that the nomenclature adopted by the American Chemical Society (among others) has been followed, this is not always true, nor is the chemistry invariably as modern as would appear desirable. Soda, for example, is defined as "a loose term which generally refers to sodium hydrate, (NaOH)"; and the spelling hydrochinone is preferred to the commonly accepted form hydroquinone. Nevertheless, for its borderline terms alone it is valuable and should be available to every student and worker in the biological sciences.

WILLIS A. BOUGHTON

Handbook of Chemical Microscopy. Vol. I. By ÉMILE MONNIN CHAMOT, B.S., Ph.D., Professor of Chemical Microscopy and Sanitary Chemistry, Cornell University, and CLYDE WALTER MASON, Assistant Professor of Chemical Microscopy, Cornell University. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, 1930. xiii + 474 pp. 162 figs. 15.5 × 23.5 cm. Price, $4.50.

"The present Handbook of Chemical Microscopy is an attempt to present in logical and concise form the principles and methods involved in practical microscopy. * * * Altho based on 'Elementary Chemical Microscopy,' the present book has been entirely rewritten, and expanded in all sections. * * * Much of the material here compiled and discussed for the first time in book form is of paramount importance to all microscopists * * *. Volume I has been confined to a discussion of optical principles of instruments, manipulative methods of general application and the observation of physical and physico-chemical phenomena." The purposes indicated in the preceding extracts from the preface have been well carried out. The first chapters discuss the microscope in general, and the microscope for chemical use in particular. More attention might well have been given to the petrographic microscope, since the more accurate measurement of properties, as opposed to merely qualitative observation, is becoming of increasing importance in general work. Subsequent chapters give adequate discussions of illumination methods, ultramicroscopy and photomicrography and much detailed information is given of special manipulative procedures. The determination of melting points with the aid of a hot stage surely is not inherently so inaccurate a procedure as is implied in the footnote to the table on page 211: "Melting points as observed under the microscope are apt to be several degrees lower than those recorded above." A great deal of attention is given to petrographic methods, including the study of crystals in both polarized and non-polarized light, and, on the whole, the discussion is unusually clear. The difficult subject of interference figures and their interpretation is well treated. The difference between the "Becke line" and the bright line obtained with axial illumination is not clearly brought out, and in subsequent discussion leads to some confusion. In practice the Becke test is used far less than the axial illumination method, and the remarks on page 374 concerning their relative accuracy apply equally well to anisotropic substances. In the footnote on page 376 mention should also be made of the publications of Winchell, "The Optic and Microscopic Characters of Artificial Minerals," University of Wisconsin Studies in Science No. 4, and Fry, "Tables for the Microscopic Identification of Inorganic Salts," Bull. No. 1108, U. S. Dept. of Agriculture. The sentence, middle of page 377, beginning, "If the material is uniaxial * *," is misleading; the index for the ordinary ray, ω, is determinable on every grain, but only when it is oriented properly with respect to the polarizer. A grain cannot lie in such a manner as to show β, and appear isotropic, as implied near the top of page 378. It does not necessarily follow from $(\gamma - \beta) > (\beta - \alpha)$ that the grain is positive, as stated on page 378; this is a first approximation that does not hold when the birefringence is large.

The increased scope of this book as compared with "Elementary Chemical Microscopy" will greatly add to its value both as a textbook and for general reference, and it is encouraging to think of a generation of chemists equipped to make use of the powerful aid of the microscope both to supplement and to replace chemical analysis. The illustrations are well done. The reviewer will look forward with great interest to the appearance of Vol. II.

GEORGE W. MOREY

Colloid Symposium Monograph. Vol. VI. Papers presented at the Sixth Symposium on Colloid Chemistry, University of Toronto, June, 1928. Edited by HARRY BOYBR WEISER, Professor of Chemistry, The Rice Institute. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York, 1928. 346 pp. Illustrated. 16 X 23.5 cm. Price, $6.50.

Colloid Symposium Annual. Vol. VII. Papers presented at the Seventh Symposium on Colloid Chemistry, Johns Hopkins University, June, 1929. Edited by HARRY BOYER WEISER, Professor of Chemistry, The Rice Institute. John Wiley and Sons, Inc., New York, 1930. viii + 300 pp. Illustrated. 15.5 × 23.5 cm. Price, $4.50.

The annual Colloid Symposia have been foci of research enthusiasm and the annual volumes containing the papers delivered at these Symposia have been and are important factors in the publication of American chemical research. The articles thus published are not only useful, but in marked contrast with much of our periodical literature in chemistry they are interesting. This is due in part to the great variety of subjects covered under the caption of Colloid Chemistry, but chiefly to the fact that these articles are often not merely the report of a single detached investigation but are a readable summary of all of the author's researches and those of others in the field.

The two most recent volumes (VI and VII), containing the papers presented at the annual Symposia on Colloid Chemistry in 1928 and 1929, are particularly varied and interesting in their contents. It is perhaps invidious to select particular articles for special mention, for such a selection is at once highly subjective and arbitrary. The reviewer cannot, however, refrain from calling attention to the brilliant, trenchant and interesting introductory address in the 1928 volume, entitled "Living Matter," by Sir William B. Hardy, and to the very instructive articles in the same volume, by Alfred J. Stamm on "The Structure of Softwoods" and by A. Baird Hastings on "The Rôle of Hemoglobin in the Blood."

Again in the 1929 volume, the paper by A. Frumkin, entitled "Significance of the Electrocapillary Curve," is an unusually careful and exhaustive study of this difficult subject. The article by Donald H. Andrews, entitled "Some Evidence on the Nature of Extra-Molecular Forces," appears to offer a promising and novel avenue of attack to this fundamental problem.

Attention should be called to the fact that the name of the publication has been changed in the 1929 volume from Colloid Symposium Monograph to Colloid Symposium Annual, and that the publishing firm has also been changed. The editor and publisher are to be congratulated on their success in reducing the price from $6.50 to $4.50 for practically the same sized volume without any sacrifice of appearance or quality.

ARTHUR B. LAMB

Organic Syntheses. An Annual Publication of Satisfactory Methods for the Preparation of Organic Chemicals. Vol. X. Edited by HANS T. CLARKE, with ROGER ADAMS, JAMES B. CONANT, HENRY GILMAN, C. S. MARVEL, C. R. NOLLER and FRANK C. WHITMORE. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, 1930. vii + 119 pp. 15.5 X 23.5 cm. Price, $1.75.

Inasmuch as the Editorial Board of Organic Syntheses is preparing a revised collection of the material presented in the first nine volumes, volume ten is treated as the first number in the second decade of the series and contains no index to preceding volumes. "Otherwise no departure has been made from the general plan adopted in recent numbers, beyond the inclusion of a rather greater proportion of organic preparations of a biochemical rather than a strictly synthetic character."

The list of preparations is as follows: acetol, n-amyl benzene, benzenesulfochloride, benzophenoneoxime, bromoacetone, a-bromonaphthalene, casein, *o*-chlorobenzoic acid, dimethylglyoxime, diphenylmethane imine hydrochloride, durene, duroquinone, erucic acid, ethyl fumarate, ethyl oxomalonate, glutaric acid, heptanol-2, lauryl alcohol, malononitrile, methyl oxalate, m-nitroacetophenone, oxalic acid (anhydrous), α-phenyl-β-benzoylpropionitrile, piperonylic acid, 1-propylene glycol, isopropyl lactate, pyromellitic acid, β-resorcylic acid, sodium 2-bromoethanesulfonate, taurine, *l*-tryptophane.

E. P. KOHLER

Der adsorbierende Bodenkomplex und die adsorbierten Bodenkationen als Grundlage der genetischen Bodenklassifikation. (The Adsorbing Soil Complex and the Adsorbed Cations of the Soil as a Basis for the Genetic Classification of Soils.) BY Professor K. K. GEDROIZ, Leningrad. Translated from the second edition of the original Russian by Dipl.-Ing. H. KURON, Assistant in the Agricultural Chemistry Institute of the University of Breslau. Foreword by Professor Dr. Paul Ehrenberg. Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1929. viii + 112 pp. 15.5 × 23.5 cm. Price, unbound, RM. 5.

The author discusses the problem of soil classification and genesis on the basis of the chemical and physical characteristics of the soil colloid. His general conclusion is that such knowledge of soil colloids as we now possess is adequate for a separation of the soils into broad fundamental groups but it is not adequate for a more detailed classification. The great soil groups which he discusses are the chernozem, the solonetz, the podsol and the laterite. If this conclusion were the net result of his discussion the book was perhaps not worth review, but such is not the case. He not only discusses the present state of our knowledge of the genesis of the soils and the composition of the colloids derived from widely varying kinds of soil but he presents a tactful and critical review of the recent literature on the subject, especially that from American and Russian sources.

He presents a coherent theory of the nature of the soil colloid and supports it with cogent theoretical and experimental evidence. His ideas are cautiously expressed and interspersed with regrets because of the frequent lacunae in our information and the paucity of experimental evidence, especially of the relationship of the bases in the soil colloid.

Because of his high position as a soil scientist his ideas are worthy of careful consideration and will be found stimulating even though, as he says himself, many of them are purely speculative and may not receive general acceptance. His consideration of alkali soils is especially important because he, if any one, is in a position to speak with a certain authority in that field.

The book is certainly to be commended to the attention of any one interested in soil research.

THE HEAT OF FORMATION OF ZINC OXIDE[1]

By Charles G. Maier[2]

Received July 25, 1929 Published June 6, 1930

In spite of the recent careful work of Parks, Hablutzel and Webster[3] on the heat of solution of zinc oxide in hydrochloric acid, the heat of formation of the oxide derivable therefrom by combination with the heat of solution of zinc and the heat of formation of water still remained uncertain by several hundred calories. Parks and co-workers used the results of Richards and Burgess[4] for the solution of zinc, but Richards and Thorvaldson[5] made later determinations in solutions of higher final zinc concentration which differed by 280 calories when brought to comparable conditions of dilution and temperature. This discrepancy is greater than the probable error of available free energy and entropy determinations on zinc oxide.[6,7]

The Pacific Experiment Station of the U. S. Bureau of Mines, in the course of its program of study of the thermodynamic properties of metallurgically important oxides, has carried out redeterminations of the heat of solution of zinc and zinc oxide, in order to arrive at finally acceptable figures. The results, aside from their practical interest with relationship to the metallurgy of zinc, are of some theoretical interest, because they furnish the last link in a comparison of heat of formation, free energy and entropy as derived from widely different experimental methods, and so constitute a direct and many-sided check on the third law of thermodynamics. Although few would now question the utility of this law, it has not as yet attained widespread application to metallurgical processes in this country. The use of the Nernst approximation formula is unsatis-

factory for the prediction of even moderately precise reduction equilibrium, and the precise methods of Lewis and Randall have been unavailable to discussions of oxides, because of dearth of data on these materials.

The experiments here described were performed in a calorimeter with some unusual features. Because of the wide variety of determinations included in the originally projected program, an instrument of considerable flexibility was desired. The apparatus was designed and constructed before the appearance of White's[8] catechistical treatise, and it was first proposed to render the calorimetric process both adiabatic and isothermal. Initial experiments showed, however, that Newton's law of cooling for the completed calorimeter was so accurately obeyed that the maintenance of neither of these conditions was essential for precise work when the duration of the experiments did not exceed a few hours.

The Calorimeter

The unusual features of this calorimeter are the use of a specially constructed and calibrated copper resistance thermometer for measurements of temperature; the equipment of the instrument with a special heating coil of manganin, and an ethyl bromide "boiler" for cooling; and the expedient use of tantalum and bakelite for those portions subject to corrosion. The resistance thermometer is described in detail elsewhere.[9] Details of the other arrangements will be evident from the diagram of Fig. 1.

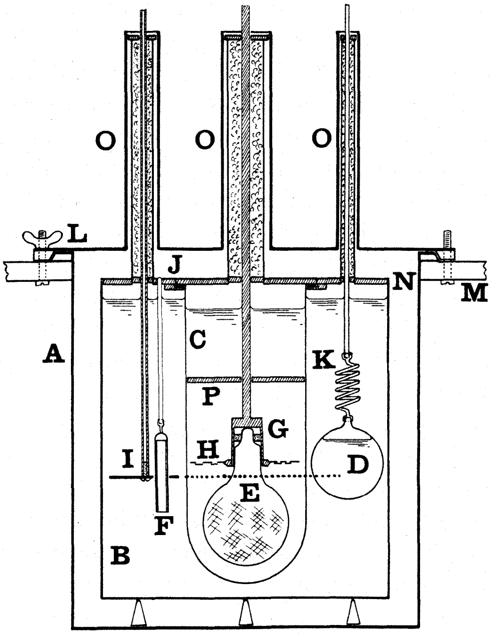

Fig. 1.—The calorimeter.

The outer cylindrical shell A is of heavy sheet copper, heavily gold plated and polished on the inner surface, and is 24 cm. diameter and 26 cm. high. A compression top of similar material has a ground seal at L, and is held in place by twelve screws and wing nuts. From the top extend five copper chimneys O–O–O (three only shown). The calorimeter jar, B, is of 22-gage copper, gold plated and polished externally. It is separated from the shell A by a 2-cm. air space and supported on the bottom by three bakelite cones. A tightly fitting top J is of $^3/_{16}$-inch bakelite, and carries bakelite tubing chimneys, which serve as packing glands. Kapok floss, lightly oiled, serves as a nearly frictionless, yet relatively impervious, packing material.

[9] Maier, "Resistance Thermometers for Chemists," submitted to J. *Phys.* Chem., but not yet published.

The mixing chamber, C, is of 10 mil thick tantalum, with roller welded seams, hemispherical bottom and flanged top. It is suspended from the top by a bakelite ring at J.

Reciprocating stirrers I and H are suspended from bakelite tubes or rods. Three such tubes support the copper ring I, which is slit to prevent inductive effects in the thermometer circuits because of its motion in the earth's magnetic field and to render the stirring more effective by lack of symmetry, and which has ports for passing the resistance thermometer F, the "boiler" D, and the manganin heater not shown, but similar in construction to F. The inner stirring head G is of bakelite, and carries the 25-mil. tantalum stirrer H. The three supporting tubes for I, and the single solid rod carrying G are attached to a specially designed "splashless" reciprocator (not shown), carried by *a* cross member of the supporting frame M. The actuating cam motion of the reciprocator is of such a type that the velocity at the top of the stroke is a minimum and a maximum at the bottom. The speed is adjustable to **6**-, **3**- or 2-second cycles, and the stroke is about **5** cm. A bakelite spider P serves as guide for the inner stirrer.

The sample flask E is blown with thin bulb walls, and fixed into the head G with a rubber washer. The attachment of the supporting rod to the reciprocator is a quick release mechanism, enabling the bulb E to be readily smashed against the bottom of the tantalum can while the stirring mechanism is in uninterrupted motion.

The boiler D is of thin-walled pyrex glass, connected by a soldered joint to the helical $^1/_8$-inch copper tube coil K. This coil serves to prevent entrainment of ethyl bromide, and make certain that the vapors issuing from D are at the temperature of the calorimeter. The extension of K through the chimney is of thin glass, with **a** soldered joint.

The frame M, carrying the reciprocator, is suspended above an oil thermostat by a rack and pinion operated through an irreversible worm drive. Under operating conditions the entire shell is submerged approximately to the **O–O–O** level.

The joint L is made oil tight with a thin coating of a heavy paste consisting of zinc oxide and glycerin. The top of the jar is sealed at N by winding several thicknesses of electrician's rubber tape about it with considerable tension. The joint at J is sealed by a coating of heavy stopcock grease.

The tantalum and bakelite construction of this calorimeter has proved highly satisfactory. As compared to a gold or platinum calorimeter, the tantalum shows a decided saving in first cost, and its hardness and toughness render it immune to damage by rough treatment. After breaking numerous flasks upon the bottom, the surface was unmarred, nor has there been the slightest trace of corrosion in 2.7 N hydrochloric acid after a total time of contact extending over several months. The bakelite, too, has proved to be practically unaffected by the solutions used. Because of plastic flow the bakelite top has become slightly concave, but this could have been avoided by better design, or perhaps a ribbed construction. The ease with which fairly good screw threads may be cut in bakelite, combined with its low thermal conductivity and ability to withstand acid corrosion, commends it highly for calorimetric construction where these properties are desired.

Operation of the Calorimeter

The thermostat in which the calorimeter is submerged is at 25 ± 0.005°. The zero of the resistance thermometer temperature scale is 25.006°, and within satisfactory limits of error the resistance thermometer reading gives the thermal head of heat exchange between calorimeter and surroundings. The total heat capacity of the calorimeter with **5** liters of water in the jar, and 0.6 to 0.8 liter of acid in the can, is between 5500 and

6000 calories per degree, and the Newton's law constant is 0.001° per degree per minute. The rate of heat exchange was a linear function of the thermal head to within 0.5%, so that the uncertainty of determination of heat exchange under unit thermal head for an experiment of 100 minutes' duration is about 0.005°, or 2.5 calories.

Because of the exactness with which the heat exchange rate depends upon the thermal head, the ethyl bromide boiler was used only for adjusting the temperature of the calorimeter in these experiments. The operation of the calorimeter, both adiabatically and isothermally, will be described at a later date. The sequence of operations in these experiments was as follows: (1) determination of initial heat capacity, (2) adjustment of temperature by evaporation of ethyl bromide in preparation for the determination of the heat of solution, (3) determination of heat of dissolution, (4) determination of final heat capacity.

The determination of initial and final heat capacities was accomplished electrically. The manganin heater, previously mentioned as similar in construction to the resistance thermometer, had an accurately determined resistance of 100.034 International ohms, as compared with a standard resistance calibrated by the Bureau of Standards. Energy was obtained from thermally insulated polarized alkaline storage batteries, and the current measured every five minutes by observing the drop across a standardized 0.4-ohm manganin resistance (0.399395 International ohms) (kept in the thermostat) with a White double potentiometer. The energy rate was 1 to 1.5 cal. per second. The heating periods of from one to one and a half hours were measured with a stop-watch which had been compared to an astronomically checked chronometer, and during this period the current variation was less than 1%. If I, is the current at any reading time $= I$, $+$ A„ where I_o is a selected approximately mean value, the average square of the current was taken as $I_o^2 + [\Sigma_o^n(2I_o\Delta_n)]/n$ neglecting the Δ_n^2 terms, and the total energy calculated as $I_{av.}^2$ Rt, using 4.184 for the conversion factor from International joules to 15° calories. During the experiments the temperature range was held within approximately one degree from the temperature of the surroundings.

After determination of the initial heat contents, the temperature was brought back to a suitable point in preparation for the dissolution experiment, by applying uniform suction to the outer end of K. With no appreciable difficulty the external pressure in the line to K was maintained constant, resulting in a uniform cooling rate variable from 0 to 1.5 cal. per second.

When the desired temperature (about 24°) had been reached by the contents of the calorimeter, no further evaporation of the bromide was permitted. Thermal equilibrium was attained in four to six minutes. After a preliminary rating period, flask E was smashed at a definite instant and the determination completed in a conventional manner. Points on the temperature curve were plotted on an adequately large scale and the corrected temperature rise was calculated by a graphical Regnault–Pfaundler method. Before the calorimeter was dismantled, the determination of final heat capacity was made. In the calculations correction for the heat content of ethyl bromide evaporated was made at a rate of 0.193, 15° calories per gram, a measured value from experiments to be described elsewhere.

The method of use described above has a number of advantages. Foremost of them is the possibility of direct determination of the temperature coefficient (ΔC_p) of the reaction, a matter of considerable importance in reactions such as the solution of metals or oxides in acid, where the coefficients may be as high as 100 or more calories per degree per formula weight. Moreover, the calibration of the resistance thermometer enters only for the determination of the corrections of heat to a definite temperature; the essential heat determination might be made with a purely arbitrary thermometer scale, that is to say, the direct determination of the electrical energy required to carry the calorimeter and contents through the same temperature rise as that produced by chemical heat. Since random errors in the heat contents determinations are largely magnified in the ΔC_p calculated by difference, the concordance of this quantity per formula weight in a number of duplicate determinations, especially where different quantities of reagents are used, serves as a useful criterion for the authentication of the experimental results. Thus any systematic errors will be ascribable, in a series of determinations showing good concordance in ΔC_p, only to systematic errors in the measurements of electrical energy. In these measurements, repeated checks of the resistances and standard cells used for the electrical measurements showed the uncertainty in energy determinations to be less than one-half per mille.

The Heat of Solution of Zinc Oxide

In the article by Parks and co-workers the statement is made: "Thus the resulting solutions in our experiments had the same concentration of hydrochloric acid and zinc chloride as those obtained by Richards and Burgess." Since water is formed by the action of zinc oxide and acid, but not by metal and acid, it is impossible to have identical initial and final concentrations in the dissolution of oxide and metal, and the authors of the quotation seem to have used identical initial, and not final concentrations. Richards and Burgess dissolved 7.3 g. of zinc in 941.4 g. of hydrochloric acid, $1HCl$ to $20H_2O$, and in these low concentrations the heat of dilution of the solutions, caused by the formation of water, is not great. Because of the large excess of acid used, the heats of dilution of the zinc-containing solutions will not be markedly different from that of pure hydrochloric acid, and may be estimated by the methods of Lewis and Randall[10] to be 27 calories per gram atom of zinc at these concentrations. In the higher concentrations of Richards and Thorvaldson the effect is much larger and cannot be satisfactorily estimated.

In the experiments here described, the "dry process" zinc oxide used had less than 0.05% of impurity, the chief impurity being traces of water-soluble sulfate. The samples were washed, dried and ignited at 600° to decompose traces' of carbonate. A blank heat of wetting determination was made on this material by breaking an evacuated sample bulb containing 41.13 g. of oxide under 850 g. of carbonate-free water in the calorimeter. There resulted a temperature rise of 0.0048°, corresponding to a heat effect of 53 calories per formula weight of ZnO. This heat represents the summation of the heat of wetting of the oxide, the heat to form a saturated solution of oxide in water, and the heat of solution of residual traces of soluble impurities such as sulfate.

No better accuracy than 50 calories per formula weight may, therefore, be claimed for experimental results in which the particle size of zinc oxide is not determined, and since it did not seem practical to separate the various items of heat involved, the following experiments could not be of greater accuracy than this.

TABLE I

SOLUTION OF ZINC OXIDE, RICHARDS AND BURGESS CONCENTRATIONS

[10] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co, New York, 1923, pp. 92, 96, 477.

In Table I are given the results of two dissolution tests using concentrations similar to those of Richards and Burgess. Through an error, the zinc weighed out in the first experiment was slightly less than should have been used to conform strictly to these concentrations. Because of the relatively low concentration of zinc in the final solution of these first tests, no appreciable error will be introduced because of this. The weights of zinc and acid are reduced to a vacuum basis.

The heat capacities of the calorimeter are 15" calories, and represent the thermal content per degree before the reaction. The heat of reaction calculated, therefore, represents the isothermal heat at the final temperature. Because the dissolution of 8 g. of oxide in 850 g. of acid does not produce a marked total change of heat capacity in this calorimeter, the temperature coefficient of the reaction was calculated rather than determined experimentally as in later experiments. Prom the data of Richards, Mair and Hall[11] the specific heat of the acid used was estimated to be 0.8528 at 25°, and from these data and those of Richards, Rowe and Burgess[12] that of the resulting zinc chloride solution, 0.8618. Then $\Delta C_p = 858.3 \times 0.8618 - (850 \times 0.8528 + 0.1013 \times 9.65) = 13.7$ calories per degree, or 135 calories per formula weight of ZnO. The figure 9.65 for the molal specific heat of zinc oxide is taken from the results of Millar.

In correcting the heat of solution of zinc given by Richards and Burgess as 30,190, 18° calories at 20 to 25°, the difference in heat capacities of final and initial solutions was taken from the work of Richards, Rowe and Burgess (page 1182) as 9 calories for 5 g. of zinc. When this is corrected for the specific heat of the zinc, $\Delta C_p = 8.5$ or 111 calories per formula weight of zinc.

The heat of formation of liquid water was taken as $\Delta H_{298} = -68{,}270$ from Lewis and Randall, with an additional 28 calories as correction for the relative partial molal heat content of the water in the acid solutions used.

The final result of the experiments for the heat formation of oxide, $\Delta H_{298} = -83{,}156$ calories, compared well with the result of Parks and co-workers, $-83{,}244$, although this latter figure would seem to require a correction of 27 calories for the heat of dilution of the solutions creditable to the water formed by the reaction, resulting in $-83{,}271$ calories. The agreement is well within the accuracy of 200 calories estimated by Parks. Because the author's results are somewhat lower than Parks', the discrepancy of 280 calories noted between Richards and Burgess' results, and the presumed more accurate results of Richards and Thorvaldson for zinc metal becomes enhanced in the heat of formation of the oxide, and the desirability of determining the heat of solution of the oxide in more concentrated solutions becomes apparent.

The first experiments at the higher concentrations were failures because

[12] *Richards,* Rowe and *Burgess, ibid.,* **32,** 1176 (1910).

of the formation of insoluble oxychlorides. In one case the oxide was stirred for two days in the acid without complete dissolution, and the final product was a rock-hard cake. Many expedients were tried, but the only one which proved effective was to wet the oxide with water before sealing into the bulb E; when this was done the dissolution could be completed in less than one hour. At these concentrations the thermal effect of water formed by the reaction was not calculable, and subsequent experiments were made with a weighed amount of water added to each sample. Since the heat effect of the reaction is independent of the path, the determination of the heat of dilution of a zinc chloride–hydrochloric acid solution, from the concentration used by Richards and Thorvaldson to the final strength obtained in these experiments, enables the effect not only of the added water, but also of the water formed during the reaction, to be determined.

In order to determine this heat of dilution, 663.59 g. of a solution identical in concentration with Richards and Thorvaldson's final was diluted in the calorimeter with 58.61 g. of water, the stoichiometric equivalent of the concentrations used later for the water added to and formed by the zinc oxide. The uncorrected temperature rise was 0.0355°, the corrected, 0.0337° and the final temperature 24.80°. The initial heat capacity of the calorimeter was 5582.2 calories, the final 5602.5, and ΔC_p per formula weight of zinc in solution 39.6 calories per degree. The heat of dilution is then $\Delta H_{298} = -359$ cal.

In Table II are recorded the results of three successful experiments on the dissolution of zinc oxide at the higher concentrations, the final result of which, $\Delta H_{298} = -17.280$ calories (corrected for dilution), is to be considered in connection with the data of Richards and Thorvaldson, who gave 32,795 calories at 20° for the reaction giving wet gas, or 33,017 for dry gas. Their temperature coefficient was 74 calories per degree for the wet gas reaction, which with appropriate correction becomes 72.6 calories per degree for the dry. Then the heat of dissolution of zinc at 25°, and at these concentrations, is 32,654, which upon conversion to 15° calories is 32,641. By combination with the author's figure at these concentrations corrected for dilution, and using the same heat of formation of liquid water as before, the heat of formation of zinc oxide at 25° from these data appears to be 83,659, as compared to 83,156 from the previous experiments. The discrepancy of 503 calories between the former figure and that calculated from the results of Richards and Burgess is not readily explainable on any basis except that the measurements of Richards and Thorvaldson were not, in fact, more precise than the earlier data, but rather less so. From the free energy determined by cell measurements, and the entropy from low temperature specific heats, Millar calculated by thermodynamic methods $\Delta H_{298} = -83{,}130 \pm 100$, thus confirming the earlier data, rather than the results obtained in concentrations similar to those of Richards and Thorvaldson.

Heat of Solution of Zinc

Through the courtesy of the New Jersey Zinc Company a sample of "spectroscopically pure" zinc, containing less than 0.001% impurity was obtained, and its heat of solution was measured at the same concentrations used by Richards and Thorvaldson. Because of the extreme purity of the metal, much difficulty was experienced in dissolving it in the calorimeter. Small amounts of platinic chloride added to the hydrochloric acid accelerated the reaction, but did not give acceptable speed. The metal was finally melted in silica, cast into rods, the oxide-containing skin removed on the lathe, and the inner part turned into a thin curl-like ribbon some 0.005″ thick. A sample of the material was weighed, submerged in a nearly neutral 0.3% platinic chloride solution for a few moments, quickly removed, rinsed and dried with absolute alcohol. From the weight after this treatment the residual mass of zinc was calculable, since the absence of hydrogen evolution indicates stoichiometric replacement. Such material was completely soluble in a half hour's time.

In order to insure saturation of the evolved hydrogen with water vapor and prevent entrainment of solution, bulb E was slightly modified. It was made cylindrical, and had a separate thin, slightly convex bottom attached by rubber tubing. Instead of sealing the top, a small rubber stopper carrying a downward extending glass rod was provided. This rod nearly touched the convex bottom, so that when the bottom was broken, the rod pushed out the stopper. The bakelite head G then served as a bubbler for the gas. The zinc was prevented from issuing from the cylindrical part of the container by means of rather coarse mesh screens of fine platinum wire, held in place by tantalum spring-rings.

Five determinations of the heat of solution of the pure zinc metal in acid concentrations similar to Richards and Thorvaldson's were made, of which the two reported in Table III were completely satisfactory. The first three were made upon unplated zinc, where the action of the acid on the zinc was enhanced in the first by mechanical contact with a platinum wire, and in the next two by the addition of small amounts of platinic chloride solution to the acid. In the first case complete solution required more than four hours' time, and in the following two cases three, and one and one-half hours, respectively-. The results obtained were identical with those shown in the table to within *125 calories, but are not reproduced in full because they were obviously not completely satisfactory. Large temperature corrections were involved in this time period, and the uncertainty involved in correcting for the platinic chloride added was considerable. The concordance of ΔC_p values in the two completely satisfactory determinations of Table III is taken to indicate that further experiments would not change the results for the materials used.

From data of the "International Critical Tables" the vapor pressure of water above these solutions at the average temperature of Expt. 6 (24.99°) is estimated to be 20.3 mm., the corrected atmospheric pressure being 760.0 mm., including a small hydrostatic pressure on the exit gas. Then 0.001219 mole of water vapor was carried off by the hydrogen; correcting the heat of vaporization of water, 10,450 calories, for the relative partial molal heat content of water in these solutions, 28 calories, the heat absorbed in vaporization is 127.7 calories, or 287 calories per gram atom of zinc. From this the dissolution of zinc to produce dry gas becomes $\Delta H_{298} = -32,190$, as compared to $-32,654$ calculated from Richards and Thorvaldson, and the heat of formation of zinc oxide from the author's results is then $\Delta H_{298} = -83,208$. This final figure differs by but 50 calories from the results obtained using Richards and Burgess' heat of solution of zinc, and it seems certain that Richards' earlier results were the more accurate. The difference between

TABLE III

SOLUTION OF ZINC METAL, RICHARDS AND THORVALDSON CONCENTRATIONS

	Expt. 6	Expt. 7
Weight of zinc, g.	29.0737	29.9701
Gram atoms of zinc	0.44476	0.45847
Weight of acid, $1HCl:20H_2O$, g	549.17	565.70
Initial heat capacity	5630.2	5658.7
Final heat capacity	5663.3	5692.8
ΔC_p for the reaction	33.1	34.1
ΔC_p per gram atom of zinc	74.4	74.5
Uncorrected temperature rise, °C	2.3971	2.5561
Corrected temperature rise	2.5127	2.5816
Final temperature, °C	26.19	25.63
Heat of the reaction	14147	14608
ΔH at final temperature	−31807	−31862
ΔH_{298} (moist gas)	−31896	−31909

the dissolution of wet and dry oxide as estimated from the blank experiment was shown to be 53 calories, and if this correction be applied to the results of Expts. 1 and 2, which were performed with dry oxide, the heat of formation of wet oxide from these experiments becomes $\Delta H_{298} = -83{,}212$.

The concordance is probably fortuitous, and no accuracy better than 50 calories is claimed.

In the above calculations, the heat of formation of liquid water has been taken from Lewis and Randall as $\Delta H_{298} = -68{,}270$, but Roth has given as a more probable figure $\Delta H_{298} = -68{,}330$.[13] If this latter figure is accepted, the heat of formation of zinc oxide becomes $\Delta H = -83{,}270 \pm 50$.

Conclusion

Except for the work of Parks discussed above, recent thermochemical determinations of the heat of formation of zinc oxide are limited to the experiments of Roth and Chall,[14] who worked at 50°, and obtained results varying from 82,825 to 82,905 calories per formula weight. W. Biltz and Wagner[15] and Biltz and Hohorst[16] determined the heat of solution of metallic zinc in hydrochloric acid, but their results cannot be regarded as significant for the determination of the heat of formation of oxide. By a curiously elliptic process of reasoning, these investigators first determined the water equivalent of their calorimeter by the use of Richards and Burgess' heat of solution of zinc, then gave the heat of solution of zinc obtained from slightly different quantities of metal, differing from Richards by more than 100 calories.

None of the previous investigators seem to have been much at pains to correct their results for the temperature coefficients of the reaction, with the exception of Richards and Burgess and Richards and Thorvaldson. These coefficients are seen from the data given above to be more than 100 calories per formula weight per degree for the solution of oxide, and may result in corrections of several hundred calories in actual cases. In the present work such corrections have been made, as well as those resulting from heats of dilution.

Summary

A calorimeter of some unusual features, including the use of tantalum, bakelite, cooling and heating devices, and a precision resistance thermometer, is described.

The heats of solution of zinc oxide and zinc metal have been redetermined, and the result agree with the earlier work of Richards and Burgess on the metal, rather than the later results of Richards and Thorvaldson.

The figure for zinc oxide $\Delta H_{298} = -83{,}270 \pm 50$ (15° calories) is proposed as most acceptable on the basis of experimental work now available. The probable uncertainty of about 50 calories is nearly the same as may be inherent in the heats of formation of water as used. The experimental results confirm estimates by thermodynamic methods.

THE ADSORPTION OF WATER AND BENZENE VAPORS BY MANGANESE DIOXIDE[1]

BY H. W. FOOTE AND J. K. DIXON

RECEIVED SEPTEMBER 10, 1929 PUBLISHED JUNE 6, 1930

Manganese dioxide is an active catalyst for the oxidation of carbon monoxide. Bray and his students[2] have made a very complete investigation of the properties of copper oxide–manganese dioxide catalysts. Bray and Draper[3] have determined water isotherms for these oxide mixtures at 25° and showed how these vapor isotherms could be used in determining the structure of the oxides. Whitesell and Frazer[4] have developed a method for preparing manganese dioxide, yielding a product which is a more active catalyst than the mixtures with other oxides. The present investigation deals with the adsorption of water and benzene by manganese dioxide prepared according to this method. The effects on the adsorption isotherms of temperature, temperature of outgassing, and the presence of permanent gases have been investigated and the results have been used to draw some conclusions with regard to the structure of the oxide and the mechanism of the adsorption process.

Materials

The manganese dioxide used in the adsorption isotherms was prepared by sifting finely powdered C. P. potassium permanganate into concentrated nitric acid, according to the method of Whitesell and Frazer.[4] The suspension was stirred by a motor at a temperature of 25–30°. After complete reaction, the oxide was allowed to settle, then filtered and washed until the filtrate showed no test for nitrates. The product was dried for seventy-two hours at 110–115°. The product was then further washed by decantation and on the filter for a week. Different lots of this material were heated

at the temperatures desired, and were then analyzed. The temperatures and composition of the oxide after heating are given in Table I.[5] Manganese was determined as the pyrophosphate, available oxygen by the oxalate method, water by the Penfield method, and impurities by difference.

[a] Oxide analyzed after use in a water isotherm

The benzene used had been washed five times with mercury, four times with sulfuric acid, and then recrystallized twice. It was dried over sodium and distilled from this metal directly into the adsorption apparatus. The boiling point of the benzene was 80.04° at 760 mm.[6]

Apparatus and Experimental Procedure

The adsorption isotherms were determined in an apparatus in which the amount of vapor adsorbed was determined by direct weighing It is similar in principle to the apparatus described by Zsigmondy, Bachmann and Stevenson.[7] A diagrammatic sketch is shown in Fig. 1. The apparatus was of pyrex glass and was evacuated by means of a mercury pump which was backed by an oil pump. Pressures above 2 mm were determined with an accuracy of ±0 05 mm by measuring the difference in height of the mercury column at N, by means of a cathetometer. Pressures from 0 001 mm. to 2 mm. were determined by means of a modified McLeod gage, L It consisted of a bulb, D, of known volume, to which was attached the glass tubing, EFGHI. The section of tubing, EF, was of 12 mm. bore, FG was of 6 mm , and GHI was large capillary tubing. The volumes of the tubing and bulb were determined by calibration with mercury and water, respectively. The calibration figures are given in Table II.

[5] The second long washing noted above was subsequently found to be unnecessary. Two adsorption isotherms carried out with material which had only been subjected to the first washing showed nearly identical but slightly greater adsorption than the more thoroughly washed material.

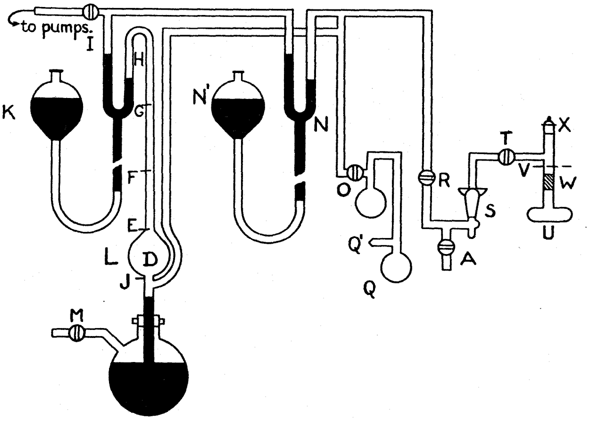
[6] We are indebted to Dr. R. P Smith of this Laboratory for this very pure product and for the boiling point determination

[7] Zsigmondy, Bachmann and Stevenson, *Z anorg* Chem , 75, 189 (1912); Anderson, *Z. physik. Chem.*, 88, 191 (1914)

pression and the final pressure were known, the pressure in the apparatus could be easily calculated. The pressures calculated checked the values found at N when they were of the order of 1–2 mm. and were accurate to 2%. Coolidge[8] has pointed out that such a gage may give erroneous results below 0.01 mm. Our experimental results below this pressure, however, show no peculiar or irregular behavior and indicate that the pressures are correct.

The vapor used in the adsorption isotherms was distilled into Q through Q' in a vacuum produced by opening stopcock O. Distillation between the two bulbs a number of times, with intermittent pumping, served to remove any permanent gases dissolved.

The bulb, U, which contained the manganese dioxide, had a volume of 14.4 cc. X is a ground-glass stopper which was sealed with wax; T, a stopcock; and S, a ground joint. By unseating the bulb at S, after closing T, it was possible to determine the weight of the adsorption bulb with its contents. Ramsay grease was used at S and removed with ether before each weighing of U. Any weighing could be checked within 0.2 mg. after greasing the joint S again and recleaning. A small plug of ignited asbestos at W, weighing less than 0.2 g., prevented the adsorbent from flying out of the bulb when it was heated and outgassed. A preliminary experiment had shown that the vapor adsorbed by the asbestos was negligible.



Pig. 1.

The procedure in determining an isotherm was as follows. The weight of the evacuated adsorption bulb was found and from 3 to 4 g. of manganese dioxide introduced. The asbestos was introduced, the stopper put in place and sealed with wax, and the weight of wax and asbestos determined. By proper manipulation of stopcocks T and R and the leveling bulb, N', the adsorbent was pumped free of gases. A small platinum-wound furnace was drawn up about U and the bulb containing adsorbent was heated at the desired temperature while being subjected to the full vacuum produced by the pumps. The temperature was indicated by a calibrated thermometer clamped against the bulb, U, and could be kept constant within ±3°. After outgassing in this manner, U was cooled and weighed. The actual weight of outgassed oxide could then be calculated.

The bulb, U, was now reseated at S and immersed in the thermostat, the tubing from R to T evacuated and a suitable amount of vapor admitted to the system through

---

[8] Coolidge, THIS JOURNAL, 46, 596 (1924).

O. The stopcock, T, was then opened, The oxide adsorbed the vapor until equilibrium was reached, which was shown by a constancy of pressure. The time to reach equilibrium was four hours or longer, depending largely on the temperature. The weight of vapor taken up was found by removing and weighing the bulb, U Each successive point in an adsorption isotherm was determined in a similar way, and it is apparent that either adsorption or desorption curves could be found. The weight of vapor adsorbed was corrected for the amount of vapor as such in the bulb.

Adsorption isotherms at 25 and 40° were obtained by immersing U in a well-stirred water thermostat up to the mark V. Isotherms at 0 and −17.46' were found by immersing the bulb in ice and water, and in the eutectic mixture of ice and sodium nitrate.[9]

Attempts were made to determine corresponding isotherms for carbon tetrachloride and certain alcohols, but they were unsuccessful, due to oxidation by the manganese dioxide.

The Adsorption Isotherms for Water and Benzene

The data for a typical adsorption and desorption isotherm are given in Table III. The first column, p, gives the observed vapor pressure in millimeters of mercury and the second column, p/p_0, is the ratio of the observed vapor pressures to that of pure water at the temperature of the experiment (25°). The third column, q, gives the weight of water adsorbed by one gram of the outgassed oxide.

TABLE III

ADSORPTION AND DESORPTION OF WATER BY MANGANESE DIOXIDE WHICH HAD BEEN OUTGASSED AT 190° (SEE TABLE I). $t = 25°$

p	p/p_0	q	p	p/p_0	q	p	p/p_0	q

The results are plotted in Fig. 2.[10] The broken lines between the two curves are taken from a subsequent experiment and illustrate the way transitions occur from desorption to adsorption curves, or the reverse. Hysteresis is present and, as so often in other cases, seems to be due to some property of the adsorbent. Lambert and Clark[11] observed hysteresis

---

[9] "International Critical Tables," Vol. IV, p. 259.

[10] The time allowed for the system to reach equilibrium extended overnight in some cases, but these points show no regular deviation from points determined in the usual way.

[11] Lambert and Clark, Proc Roy. *Soc.* (London), **117A,** 183 (1927); *ibid.*, **122A,** 497 (1929).

in the adsorption of benzene by ferric oxide; with the same apparatus and experimental procedure, they found none in the adsorption of benzene by silica gel. Since each isotherm exhibited hysteresis phenomena exactly similar to that shown in Fig. 2, only the adsorption curves will be considered in the subsequent curves and discussion.

Figure 3 shows the adsorption isotherms of water on the oxide (outgassed at 190°) at the temperatures —17.5, 0, 25 and 40°. Here log q is plotted against log *p*, q and *p* representing, as before, the weight of water adsorbed per gram of oxide, and the corresponding pressure. The isotherms at 25 and 40° are each plots of two separate series of determinations and show that, with a fixed method of treatment, the oxide gives reproducible adsorption curves. The two series at 25° were determined three months apart, showing that the oxide did not change during this time. Also, the water used in the later series had been standing in the apparatus for two months in the absence of air with occasional intermittent pumping, so that the presence of traces of gases from this source is excluded. The adsorption isotherms of benzene on the oxide (outgassed at 190°) were determined at 0 and 25° and the results are shown (together with two other isotherms mentioned later) in Fig. 4.

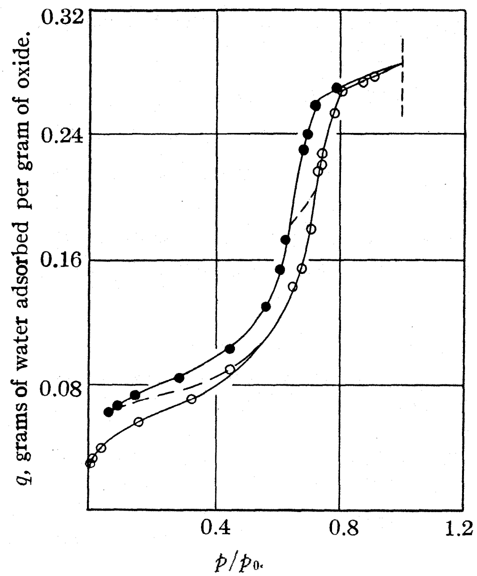

Fig. 2.—Adsorption isotherm for water on manganese dioxide at 25°: o, adsorption; ●, desorption.

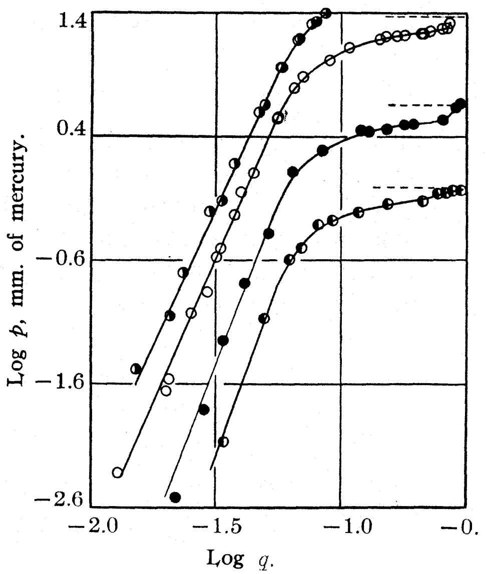

Fig. 3.—Adsorption isotherms for water on manganese dioxide: ◑, 40"; ○, 25°; ●, 0°; ◐, −17.5'.

The isotherms for water and benzene show that these vapors are adsorbed at lower pressures in the same way that permanent gases are adsorbed by charcoal, since the log p–log q curves are nearly straight. It is reasonable to assume that pure surface adsorption is taking place over this range of pressures. At a value of p/p_0 of about 0.5, the isotherms break rather sharply and the amount of vapor adsorbed increases rapidly with a small increase in pressure. If this great increase in the rate of adsorption is due to condensation in the capillary spaces of the oxide,[12] the radii of the capillary spaces can be calculated by means of Thomson's equation.[13] Such calculations for water and benzene at different temperatures give values which are in good agreement, the capillaries having radii extending from 10 to 40 Å. Shereshefsky[14] has shown that for very small capillaries, however, the surface tension of the condensing liquid is not normal, and Polanyi and Goldmann[15] have shown that the density of an adsorbed liquid is greater than that of the free liquid. For these reasons, it is doubtful if calculations by the Thomson equation have more than qualitative significance.

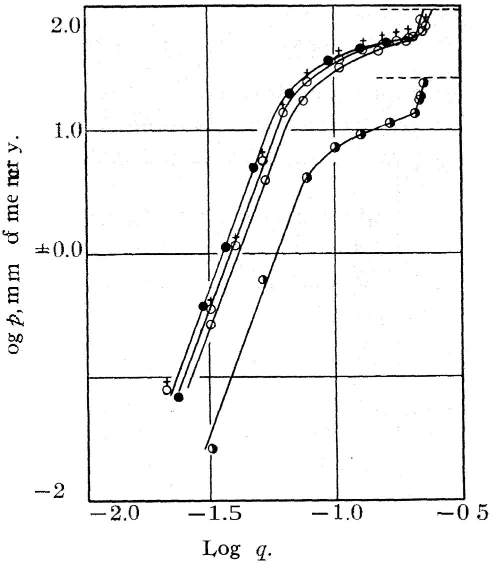

Fig. 4.—Curves showing the adsorption isotherms of benzene on MnO_2: ◑, 0°; ⊙, 25° (oxide outgassed at 190° in both isotherms); ȯ, 25°, oxide outgassed at 290°; ●, 25°, same as last with oxide outgassed two hours more at 190°.

Polanyi has developed[15,16] an expression for the so-called adsorption potential which, so far as it is applicable, can be used to calculate the adsorption isotherms for a given adsorbent and vapor at any temperature when one isotherm is known. Aq, the adsorption potential, is given by the equation: $Aq = RT \ln (p_0/p)$, in which R is the gas constant, T, the absolute temperature and p and p_0 have their usual significance. Plotting Aq against q, the curves should coincide at all temperatures, if correction is made for the change with temperature of the density of the adsorbed vapor. When their results were uncorrected for density changes, Polanyi and Goldmann[15] found experimentally that a lower temperature curve fell above a higher temperature curve in the cases of chloroform, carbon bisulfide, ether and pentane ad-

sorbed by charcoal. In Fig. 5 our data for water and benzene, uncorrected for density changes, have been plotted in the same way. The coincidence of the curves, on the whole, is surprisingly close. The curves for water are almost identical except at −17.5° for high values of p/p_0, where the difficulties of accurate determination are great. Polanyi's theory postulates surface adsorption and, subsequently, liquefaction of the adsorbed vapor, which is in accord with the theory of capillary condensation. The two theories differ in that they propose different causes of liquefaction. The theory of Polanyi has proved to be the more useful.

The Effect of the Temperature of Outgassing

Almquist and Bray[17] have shown that the catalytic activity of CuO–MnO_2 mixtures decreased as the temperature of dehydration was increased above 200°. Drucker and Hüttner[18] have shown that when manganese dioxide is heated, it loses oxygen somewhat irreversibly, forming a lower oxide on the outside of the particles. We have investigated the effects of the temperature of outgassing on the adsorption isotherms in order to show the surface and other structural changes taking place on heating.

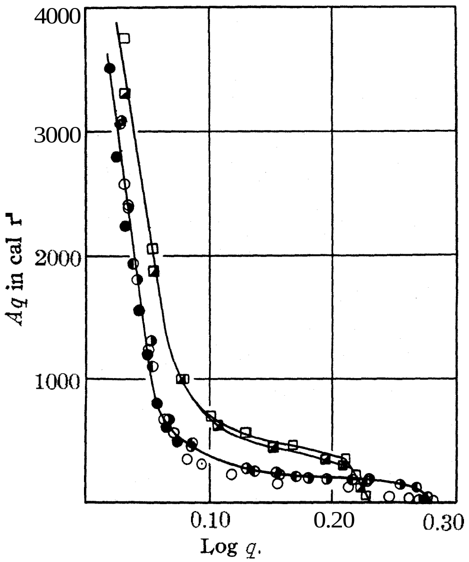

Fig. 5.—Adsorption potential curves for water and benzene on manganese dioxide. Water: o, −17.5"; @, 0°; @, 25°; @, 40°. Benzene: O, 0°; ▨, 25".

For this purpose a sample of manganese dioxide was heated in a vacuum for three hours at 290° and the benzene isotherm at 25° determined. The oxide was then outgassed for two hours more at 190° and the benzene isotherm at 25° again determined. The results are plotted in Fig. 4, together with two isotherms previously mentioned.

Water isotherms at 0° were determined (a) on a sample previously used for a 0° isotherm and which was then heated at 390° for three hours, and (b) on a sample heated at 475° for three hours. These two isotherms, together with one on material heated normally at 190°, are plotted in Fig. 6. The diagrams show that preliminary heating has a marked effect on the adsorption curves only when the temperature is so high (475°) that

---

[17] Almquist and Bray, This journal, 45, 2305 (1923).

[18] Drucker and Huttner, *Z. physik. Chem.*, 131, 237 (1928).

the composition of the oxide is materially changed, as shown by Table I. On this high-temperature oxide, both surface adsorption and that attributed to capillary condensation are markedly decreased, due to sintering or to the formation of an inactive lower oxide, or both. When capillary condensation begins on this oxide the capillaries have radii of 54 Å. (using the Thomson equation), which is three times the value found for the oxide outgassed at 190°. The accompanying decrease in surface area will not account for more than one-tenth of the decrease in surface adsorption at low pressures. Hence, the state of the surface as well as its area is important in the adsorption process. The surface adsorption of water vapor is a measure of the ability of the oxide to take up a gas by primary adsorption, and Benton[19] has pointed out that this adsorption is a measure of catalytic activity as far as the oxidation of carbon monoxide is concerned. It is probable that the parts of the vapor isotherms due to capillary condensation yield information only with regard to surface area and uniformity of the capillary spaces and are otherwise useless in predicting catalytic phenomena.

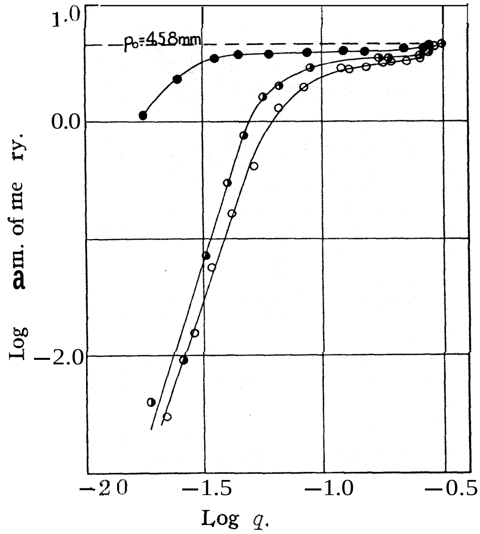

Fig. 6—Curves showing the effect of the temperature of outgassing on the water isotherms for MnO_2 at 0°. Temperature of outgassing: ○, 190°; ◐, 390°; ●, 475°.

The oxide outgassed at 475° corresponds closely to Mn_2O_3. Its water isotherm showed very little hysteresis, and for this reason it is probable that the manganese dioxide is the cause of any difference between the adsorption and desorption curves of an isotherm, rather than traces of any gas. If, for instance, adsorbed oxygen coats the oxide particles and causes hysteresis at lower outgassing temperatures, there appears to be no reason why it should not do so when the outgassing temperature is increased, with correspondingly increased oxygen pressure.

The Effect of the Presence of Permanent Gases

If a permanent gas is adsorbed on the surface of the manganese dioxide, it should cover the most active adsorbing patches and reduce the area available for the surface adsorption of a vapor. Capillary condensation (or condensation caused by forces acting between adsorbent and vapor)

---

[19] Benton, THIS JOURNAL, 45, 887, 900 (1923).

should be little affected by the presence of permanent gases. This was found to be the case experimentally. The effects of adsorbed carbon monoxide and carbon dioxide were entirely similar to each other, so the results for the former will be given as typical of both.

Experiment 1.—Carbon monoxide, which had been dried carefully by passing through sulfuric acid and phosphorus pentoxide, was admitted to a sample of manganese dioxide which had been outgassed as usual at 190° for three hours. The equilibrium pressure of the gas after adsorption was 29.6 mm. The gas was then removed by pumping for one hour and the water isotherm at 25° determined.

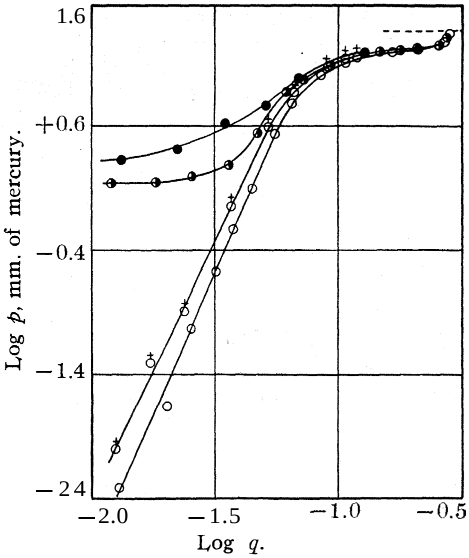

Fig. 7.—Curves showing the effect of the presence of carbon monoxide on the water isotherms for MnO_2 at 25°: o, carbon monoxide absent; @, carbon monoxide present; @, carbon monoxide present (greater amount); ♁, same, after outgassing at 190°.

Experiment 2.—Similar to Experiment 1; equilibrium pressure of carbon monoxide 88.5 mm. The gas was removed by pumping for one and one-half hours; pressure after standing for twelve hours, 0.215 mm. The gas was again pumped off for one hour, and the water isotherm determined as before. The oxide was then outgassed at 190° and the water isotherm redetermined. The results of the three isotherms are plotted in Fig. 7. It is evident that surface adsorption has been markedly reduced, the effect being greater at lower pressures. There is no effect on that portion of the water isotherm attributed to capillary condensation. Very possibly the water displaced some of the permanent gas from the surface, which would mean that the pressure of the water vapor was less than that measured, but this would merely decrease the difference between a treated and untreated oxide. This error would be negligible at pressures where condensation begins. The experiments with oxygen were carried out similarly.

Experiment 3.—(Run in duplicate.) After outgassing the oxide, dry oxygen was admitted at a pressure of 135 mm. There was no evidence of adsorption. After evacuating and allowing the apparatus to stand for twelve hours, the pressure was less than 10^{-4} mm. The water isotherm was then determined as before at 25°. This was identical, within the errors of the experiment, with an isotherm run on the outgassed oxide, which had not been treated with oxygen, and the hysteresis had not been changed.

These experiments with the three gases show rather definitely that the vapor isotherms run on the outgassed oxide have been measured on an oxide surface and not on a surface covered with oxygen. Carbon monoxide and carbon dioxide cover the active adsorption patches, reducing the surface adsorption of water, while oxygen has no effect. Condensation of water on the adsorbent (which occurs at the higher pressures) is not measurably affected by the permanent gases. Heating removes the permanent gas which is adsorbed, cleaning up the surface of the oxide, and restores the surface adsorption of water vapor to its normal value.

Summary

The adsorption isotherms of water on manganese dioxide have been determined at −17.3, 0, 25 and 40°, and corresponding isotherms for benzene at 0 and 25°. The isotherms consist of two parts due to surface adsorption and condensation of the vapor on the surface of the oxide. Polanyi's theory of adsorption is in agreement with the data.

When the temperature of outgassing is raised, the surface adsorption for water is greatly reduced, due to the destruction of active adsorption patches. The treatment of the oxide with a permanent gas which can be adsorbed reduces the surface adsorption of water vapor and leaves the part of the isotherm due to condensation unaltered. The use of vapor isotherms in predicting the catalytic behavior of an oxide has been discussed.

The isotherms exhibit hysteresis and the present experiments indicate that this phenomenon is not due to false equilibrium or the presence of permanent gases on the surface of the oxide.

MEASUREMENTS OF THE ELECTROMOTIVE FORCE OF THE CALOMEL ELECTRODE AGAINST THE HYDROGEN ELECTRODE AT LOW CONCENTRATIONS OF HYDROCHLORIC ACID

BY JNANDRANATH MUKHERJEE AND KALI KUMAR KUMAR

RECEIVED SEPTEMBER 19, 1929 PUBLISHED JUNE 6, 1930

Introduction

It is well known that the calomel electrode is not reliable at concentrations of hydrochloric acid below 0.03 N.[1] There is a difference of opinion as to the causes responsible for the unreliability of calomel electrodes.[2] Our observations generally corroborate previous authors and deal with the questions (a) how far the observed potential can be taken as a measure of the actual concentration of the hydrochloric acid in the cell, and (b) the nature of the chemical reactions responsible for the observed change in concentration.

Experimental

The chemicals used were Merck's "Reagent" or Kahlbaum's "pro analyse" quality purified as usual. The hydrogen was obtained from electrolysis of a strong solution of

---

[1] Ellis, THIS JOURNAL, 38, 737 (1916); Noyes and Ellis, ibid., 39, 2532 (1917).

[2] See Clark, "Determination of Hydrogen Ions," The Williams and Wilkins Co., Baltimore, 3rd ed., 1928, p. 309.

caustic potash. Dolezalek type hydrogen electrodes, prepared from borosilicate glass, having ground-glass joints were used. The type of calomel cell was a simplified form of that given by Clark.[3] Our measurements relate to the e. m. f. of the system $\mathrm{Hg}-\mathrm{HgCl}/\mathrm{HCl}(C_1)/\mathrm{HCl}(C_2)/\mathrm{HCl}(C_2)/(\mathrm{Pt})\mathrm{H}_2$. A set of three to four calomel electrodes was set up against a hydrogen electrode. A tall cylinder filled with acid of approximately the same concentration was interposed between the two electrode vessels. The side tubes of the electrodes dipping into the cylinder were kept plugged except when measurements were taken. The thermostat was kept at 35 * 0.1'. A Leeds and Northrup K type potentiometer (bridge wire calibrated in the laboratory) was used. The galvanometer used was very sensitive up to 0.01 *N* hydrochloric acid but not so with more dilute solutions. The hydrogen electrode vessels after cleansing with conductivity water were rinsed several times with the solution in which the electrode was completely immersed. Hydrogen was passed into the vessel for two hours, at first keeping it at room temperature. The electrode vessel was then removed to the thermostat and the stream of hydrogen was continued for about two hours more, though one hour was found to be sufficient for attainment of equilibrium.

Calomel Electrode.—The paste was prepared by gently shaking for half an hour the hydrochloric acid solution with about 1 cc. of mercury and 5 to 8 g. of calomel powder in a 100-cc. (wide mouth) stoppered bottle. The bottle was then kept in a thermostat for about two days. Jena glass vessels were used for dilute solutions less than 0.05 N. The supernatant solution was then removed and titrated against standard baryta with phenol red as indicator and the change in concentration was noted. The bottle was then refilled with acid solution previously saturated with calomel and the whole procedure repeated. Both the calomel electrode vessel and the cylinder interposed between it and the hydrogen electrode were kept in the thermostat for two days before the e. m. f. was measured.

A. The Observed E. m. f. and the Concentration of the Acid.—On passing hydrogen gas for a long time, the concentration of acid increased slightly and to avoid this the e. m. f. within an hour after attainment of a steady value was noted. An appreciable fall of the concentration of the acid in the calomel electrode vessel was observed even in 0.05 N solution. It will be seen from Table I that the concentration was found to correspond approximately to the observed e. m. f. In the case of the more dilute solutions the change in concentration was considerable and a correction (Nernst's formula has been used) for the liquid junction potential resulting therefrom was felt necessary. The activity coefficients as generally given in the literature refer either to the freezing point or to 25°. The present measurements were made at 35° at which temperature Ellis[1] gives a value of 81.4 for 0.1 N. The values given by Lewis and Randall[4] have been found to disagree with the results of very careful measurements of Randall and co-workers.[4,5] For a proper extrapolation it is necessary to know the heats of dilution at different temperatures. The heat capacities[6] have been given

[6] Lewis and Randall, Ref. 4, p. 279.

by Randall and Ramage,[7] but the recent determinations of these quantities by Randall and Rossini have not yet been published.[8] An examination of the activity coefficients given by Randall and Young[g] shows that at 0.1 N the activity coefficients at the freezing point and at 25° are, respectively, 80.22 and 79.56, a difference of 0.66. This difference will evidently be smaller at the lower concentrations. By extrapolation the value for the activity coefficient at 25° for 0.1055 N is found to be 79.26. We have taken the value 79.0 for 35°. The existence of the liquid junction potential makes such an approximation permissible and high accuracy is not claimed. In Table I are given C_1, the concentration of the acid in the calomel vessel (as determined after the measurement of the e. m. f.); C_2, the concentration in the hydrogen electrode; the observed e. m. f. ($E_{\text{obs.}}$); E_l, the liquid junction potential calculated as above; E_x, the magnitude only of the e. m. f. which corresponds to the difference in e. m. f. at either electrode if the concentration of the acid around it had the same value as that in the other electrode and assuming that the activity coefficient is the same for the concentrations in the two electrode vessels; E_{c_1}, the e. m. f. of the cell (Pt) $H_2/HCl(C_1)/HgCl–Hg$ is given by $E_{\text{obs.}} - E_l + E_x$; E_{c_2}, the e. m. f. of the cell (Pt) $H_2/HCl(C_2)/HgCl–Hg$ is given by $E_{\text{obs}} - E_l - E_x$; γ in Table II denotes the percentage activity coefficients of the acid calculated as above. The value of N,, the transport number of hydrogen ions at 35°, has been taken to be 0.815.[10]

TABLE I

Sometimes at the lower concentrations the titer of the acid in the electrode vessel was found to have decreased by as much as 20% after the e. m. f. measurement. At the last three concentrations, instead of calculating the liquid junction potential, a saturated solution of potassium chloride was inserted. The activity coefficients given in Table II show, in view of the uncertainty as to the liquid junction potential, that the change in the concentration of the acid is mostly responsible for the observed unreliability

of the calomel electrode, and that the slight trace of mercuric chloride which may be assumed to be present has little effect. The influence of such factors as grain size, surface structure, or incomplete equilibrium between the different regions of the system suggested by previous workers[2] is of minor importance. The procedure used had, however, the effect of minimizing their influence.

B. The Chemical Reactions Responsible for the Observed Change in Concentrations.—The progressive diminution of the concentration of the acid in a mixture containing calomel and mercury is illustrated in Table III. On introduction of electrolytic oxygen, the rate increases markedly, while on expulsion of the dissolved oxygen the reaction practically ceases, in conformity with the experience of others.

In a 500-cc. Jena glass-stoppered bottle about 300 cc. of 0.0108 N hydrochloric acid solution was taken and 13.5 g. of mercury and 5 g. of mercurous chloride were added. The bottle was made air-tight with a coating of paraffin, shaken for an hour and kept in the thermostat. A measured volume of the supernatant liquid was withdrawn at different intervals and titrated against a standard solution of baryta (0.0176 N). The bottle was made air-tight after each withdrawal of the liquid. The decrease in acid concentration has been given as percentage of the original.

TABLE III

DIMINUTION OF ACID CONCENTRATION

Days	1	2	3	4	5	8	9	12	26
Decrease, %	1.3	6.6	7 2	12.0	20.0	22.8	25.0	41 0	58.8

On the ninth day the solution (about 200 cc.) was saturated with electrolytic oxygen, shaken and kept in the thermostat.

The possible chemical reactions[11] are: (a) the oxidizing action of the dissolved oxygen and the action of the liberated chlorine (or of hypochlorous acid formed). No evidence could be obtained of this direct oxidation with starch iodide. (b) Interaction of acid and mercury in presence of oxygen. Calomel is known to be formed from mercury and a solution of potassium

[11] See Mellor, "A Comprehensive Treatise on Inorganic Chemistry," Vol. IV.

chloride in the presence of dissolved air. We have confirmed this and reaction (b). Using 50 cc. of 0.01 *N* potassium chloride and 13 g. of mercury in a Jena glass bottle, a PH of 7.4 developed in eight days and simultaneously a gray deposit of calomel became visible. With 50 cc. of 0.01 *N* hydrochloric acid, a 2% decrease was observed in ninety days, but no reaction for mercuric ions with hydrogen sulfide was obtained in this case or in that of the e. m. f. measurement. The above measurements were repeated at room temperature after driving off the oxygen by boiling, followed by passage of hydrogen at room temperature and then boiling once more. No sign of formation of calomel nor any change in concentration could be observed.

(c) Mercurous chloride may react directly with oxygen. Mercurous chloride, in contact with the acid and air for a week, shows no change in the concentration of the acid. Pure oxygen, however, reacts more quickly with calomel, and mercuric ions can be detected by hydrogen sulfide.

The main reaction thus appears to be (b) above. A mixture of calomel and mercury, however, reacts more rapidly than mercury alone, possibly owing to the formation of mercuric chloride (from the oxychloride in presence of the acid), which disappears as mercurous chloride. Mercurous chloride may also have a direct effect on the velocity of the reaction.

The following experiments (Table IV) show the erratic variations of the concentration when the supernatant solutions are replenished. Four bottles of ordinary glass, each containing 13 g. of mercury, 5 g. of calomel and 50 cc. of 0.024 N hydrochloric acid were kept as usual in the thermostat; 25 cc. of the acid required 25.8 cc. of standard baryta. In each case, after the supernatant liquid had been withdrawn for titration, as much of it as possible was decanted without disturbing the paste and 50 cc. of the original solution was again added. The days are counted since the acid was first added to the bottle.

TABLE IV

Summary

To summarize, we find (a) that although presence of oxygen and mercury are both essential, mercurous chloride plays an important part in the reaction leading to the formation of calomel and loss of hydrochloric acid and (b) that the observed e. m. f. corresponds within the limits of experimental error, to the actual concentration of the acid in the electrode vessel.

HYDROGEN DISULFIDE

BY K. H. BUTLER AND O. MAASS

RECEIVED OCTOBER 5, 1929 PUBLISHED JUNE 6, 1930

Although hydrogen persulfide was discovered in 1777 by Scheele,[1] it has not proved an attractive subject for investigation and advances in the knowledge of the substance have been made slowly. Sabatier[2] succeeded in distilling the liquid in vacuo. This line of attack was followed by Block and Höhn,[3] who showed that crude hydrogen persulfide gave on fractionation two compounds, H_2S_2 and H_2S_3. Walton and Parsons[4] repeated and extended this work, using quartz apparatus in part.

In the present work the optimum conditions for the preparation of hydrogen disulfide were investigated, a method of purification was developed and the physical properties of the pure substance were determined.

Preliminary Experiments.—Preliminary experiments, which followed closely the final procedure, dealt with the effect of varying composition of the sodium polysulfide on the yields of the products. The results are given in Table I.

TABLE I

EFFECT OF COMPOSITION OF REACTANTS ON YIELD OF PRODUCTS

Polysulfide	Dilution[a]	Crude oil, g. per 100 g. total S	H_2S_3 G. per 100 g. crude oil	H_2S_2
Na_2S_2	750	47	29.0	7.8
$Na_2S_{2.25}$	700	60	21.9	9.3
$Na_2S_{2.50}$	700	59	23.6	13.5
Na_2S_3	650	81	28.6	5.6
Na_2S_4	600	80	25.5	5.6

[a] Dilution indicates weight of solution per gram mole of sodium polysulfide.

The crude oils obtained from the different solutions varied considerably in appearance and properties. The crude persulfide from Na_2S_2 was a

[4] Walton and Parsons, THIS JOURNAL, 43, 2539 (1921).

rather mobile liquid, light yellow in color, and sensitive to impurities. It had *a* very sharp odor and the vapor was highly irritating to the nose and eyes. On fractionation it distilled very readily at 120°.

As the amount of sulfur in the sodium polysulfide solution increased, there was a gradual change in the properties of the resulting persulfide. That obtained from Na_2S_4 was a dark yellow viscous liquid with only a slight odor. It was comparatively stable. The oil distilled very slowly at 120°.

Preparation of Sodium Polysulfide.—These preliminary experiments showed that $Na_2S_{2.50}$ was the most satisfactory polysulfide. It was used in all later preparations of hydrogen disulfide. The solution used was made by heating on a water-bath a mixture containing 150 g. of flowers of sulfur, 725 g. of sodium sulfide crystals and 500 cc. of distilled water. A tared 2-liter flask was used and the mouth closed by a rubber stopper bearing a Bunsen valve. After solution of the solids was complete, distilled water was added to make the total weight of the solution 2650 g. and the flask was tightly stoppered.

Preparation of Crude Hydrogen Persulfide.—The preparation of hydrogen persulfide was carried out in a 3-liter pyrex beaker supported on rubber stoppers within an insulated battery jar used as a cooling bath. A suitable quantity of acetone was introduced into the battery jar and cooled to −40° by the addition of solid carbon dioxide. The pyrex beaker containing 1500 cc. of c. p. hydrochloric acid (sp. gr. 1.19) was put into position and stirring commenced. When the acid had cooled to −15° the sodium polysulfide solution was added from a dropping funnel, the tip of which was immersed in the acid to a depth of *2* cm. During the remainder of the operation the acetone bath was kept below −25° and the flow of the polysulfide solution regulated to keep the acid temperature between −10 and −15°.

After a liter of the solution had been added, the hydrogen persulfide began to rise to the surface as a scum and decompose with evolution of hydrogen sulfide. The addition of sodium polysulfide was then stopped, the beaker replaced by one containing a fresh portion of hydrochloric acid, and the operation completed with the remaining half of the polysulfide solution.

This preparation resulted in an emulsion of crude hydrogen persulfide with suspended sulfur, in an acid solution of sodium chloride. The mixture was allowed to stand for two to three hours with occasional stirring, the yellow crude oil settling mainly to the bottom of the beaker and the finely divided sulfur forming a thick layer just above this. The upper layer of liquid was decanted, the mixture diluted with cold water to one liter, transferred to a separating funnel and the persulfide layer drawn off into a tared Erlenmeyer flask. After the weight of the persulfide had been determined, a few grams of phosphorus pentoxide was added cautiously and the flask allowed to stand overnight. The phosphorus pentoxide was removed by filtering through asbestos and the filtered oil was fractionated. All apparatus used in this preparation was of pyrex and the surface was carefully acidified immediately before use by treatment with concentrated hydrochloric acid.

Fractionation of Hydrogen Persulfide.—The apparatus used in fractionation is shown in Fig. 1. It was built from pyrex glass: A, a 100-cc. flask; B, a special flask made from a 50-cc. distilling flask; C, made from a 100-cc. flask; G, a capillary contraction in the connecting tube. The inner tube of the condenser was constructed of tubing of 9 mm. outside diameter; all other tubing was 5 mm. outside diameter.

Before setting up, all parts of the apparatus were carefully cleaned and dried. The rubber stoppers were soaked in hot beeswax. After setting up, the apparatus was warmed in a current of dry air. Dry hydrogen chloride was then passed through for ten minutes, care being taken to fill the funnel F by displacement. The apparatus was then pumped out using an efficient water pump which reduced the pressure to 10 mm. or less. The flask B was immersed in a bath of glycoline held at 120°. The test-tube D was immersed in acetone at −40°.

To start the distillation, stopcock S was closed, S_2 being open, and the crude hydrogen persulfide was allowed to drop slowly from F. After twenty minutes the flow of persulfide was cut off, though the distillation was allowed to continue for five minutes. The flask B was then one-third filled with a dark reddish-yellow viscous fluid. This was removed by opening stopcock S_2 and closing S, thus drawing the residue into A, where it solidified to a lemon-yellow, semi-crystalline mass. The distillation was then continued as before.

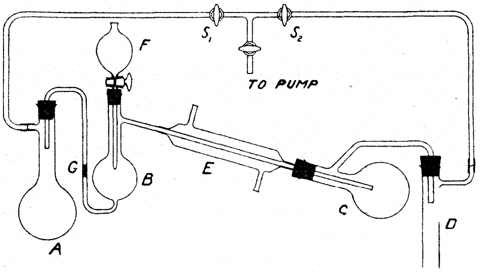

Fig. 1.

Two fractions were condensed. The first, collected in C, was approximately H_2S_3 by analysis and was considered to be hydrogen trisulfide. The second, condensed in D, was H_2S_2, hydrogen disulfide. The two liquids were removed, weighed and placed in quartz bulbs for storage at −78°.

Series of experiments were carried out to determine the effect of temperature and pressure of distillation on the yields of the two products. These results are shown in Table II.

TABLE II

EFFECT OF TEMPERATURE AND PRESSURE OF DISTILLATION ON YIELDS OF DISULFIDE

Sodium polysulfide	Press., mm.	Temp., °C.	G. per 100 g. of crude persulfide Trisulfide	Disulfide
Na_2S_2	10	102	30.2	10.3
Na_2S_2	10	118	29.0	7.8
$Na_2S_{2.50}$	10	112	26.6	15.2
$Na_2S_{2.50}$	10	122	36.5	11.2
$Na_2S_{2.50}$	10	135	14.6	8.3
$Na_2S_{2.50}$	30	120	9.5	10.4
$Na_2S_{2.50}$	18	120	30.3	12.5
$Na_2S_{2.50}$	10	120	36.5	11.3

It is evident that decrease in temperature of distillation leads to increased yields of hydrogen disulfide. The rate of distillation is, however, much slower. The most suitable temperature for the persulfide from $Na_2S_{2.50}$ is 122°. Increase in pressure leads to greatly decreased yields of hydrogen trisulfide.

Cracking of Trisulfide.—Observations were made by Block and Hohn and by Walton and Parsons to the effect that distillation of hydrogen trisulfide gave considerable amounts of hydrogen disulfide as a by-product. This appeared to offer a second method of obtaining the disulfide.

A 100-cc. flask was provided with a 50-cm. reflux condenser and two receivers in series, as in the fractionation apparatus. In one experiment 38 g. of trisulfide was placed in the flask, which was heated to 75° at the start and to 125° at the end. Seventeen g. of hydrogen disulfide was obtained.

Attempts to purify the trisulfide by distillation in vacuo met with slight success. The distillation must be carried out at very low pressures and below room temperature to avoid decomposition.

Purification of Disulfide.—The hydrogen disulfide prepared by the methods outlined above was purified by a distillation in *vacuo* from phosphorus pentoxide.

A pyrex still was used at first and the liquid was transferred by pouring. This type of still gave satisfactory results but the distilled liquid was hygroscopic and owing to moisture picked up in transfer it became turbid on cooling. Trouble was also caused by decomposition when the glass was not thoroughly acidified by the hydrogen chloride passed into the still.

A quartz still was developed in which the hydrogen disulfide was distilled directly into apparatus in which measurements were made and sealed off. This is shown in Fig. 2. A is a 100-cc. distilling flask; the neck and side arm were drawn down and 7-mm. tubing sealed on B is a receiver made from 16-mm. tubing The tube at E is joined to the vacuum line by a de Khotinsky joint. After setting up and drying, phosphorus pentoxide was distilled into A. The air was displaced by dry carbon dioxide and the impure hydrogen disulfide introduced. The tube D was sealed off; the atmosphere of carbon dioxide prevented ignition of the disulfide vapor even at the high temperature needed to work quartz.

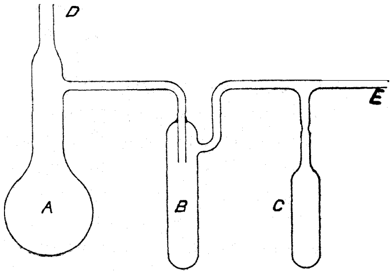

Fig. 2.

The distillation was carried out at 10 mm., A being at room temperature and B at −78°. When the receiver was filled, A was also cooled and the connecting tube sealed. The pressure was then reduced to less than 1 mm. by a Toepler pump and the stopcock to the vacuum line closed. The disulfide was distilled from B to the piece of apparatus attached at C. This was then sealed off.

Method of Analysis.—All analyses were made by the method of Walton and Parsons.[4] A sample of about 1 cc. was transferred to a quartz weighing tube and weighed. The sample was poured into a porcelain evaporating dish and the tube washed with 10 cc. of carbon disulfide. Ten cc. of acetone was added, causing a quiet decomposition of the hydrogen persulfide, The solvents were allowed to evaporate overnight and the sulfur was weighed.

Owing to the small quantities of material available, analyses were made only to check improvements in procedure. The mean results are

	H_2S, %
Crude persulfide from Na_2S_2	17.7
Disulfide from fractionation	47.0
Disulfide from cracking	48 0
Redistilled disulfide	51.3
Theoretical value for disulfide	51.2
Trisulfide from fractionation	32.4
Trisulfide from cracking	32.4
Theoretical value for trisulfide	34.7

Containers for Persulfides.—The problem of keeping hydrogen disulfide and trisulfide presented a number of difficulties. The products from the initial fractionation decomposed rapidly at room temperature, even in all-quartz containers. Long-necked quartz bulbs immersed in solid carbon dioxide were satisfactory for short periods. It was possible to keep the carefully purified disulfide in sealed bulbs for indefinite periods without decomposition.

Cleaning of Apparatus.—The necessity for most rigorous care in cleaning and acidification of all apparatus cannot be too greatly emphasized. Aqua regia proved very useful in cleaning, as an unusually rapid evolution of chlorine indicated the presence of surface impurities. Acidification of apparatus with dry hydrogen chloride was found to be necessary in all cases.

Melting Point.—Two determinations were made of the melting point of hydrogen disulfide. The sample was enclosed in a sealed tube which was immersed in an ether-bath cooled by liquid air.[5] The temperature was determined by a platinum resistance thermometer. The first sample had stood in pyrex glass for eight days at −78"; its melting point was −88.6°. The second sample was condensed in quartz; its melting point was −89.8'.

Freezing Point Curve **with Sulfur.**—The freezing points of solutions of sulfur in hydrogen disulfide were determined in the following way. A quantity of hydrogen disulfide was placed in a small quartz tube and weighed. A suitable quantity of sulfur was added and the tube immersed in a bath of ether cooled by liquid air. The bath temperature was lowered until a solid was precipitated from the solution on stirring vigorously. The temperature was measured by a thermometer in contact with the freezing point tube. This freezing point was then checked, the temperature being varied more slowly. The tube was then removed from the bath, another portion of sulfur added and the mixture stirred until solution was complete. The next point was then obtained. Solution of the solid, which appeared to be sulfur, was very slow unless

[5] Maass and McIntosh, THIS JOURNAL, 36, 738 (1914).

the tube was warmed nearly to room temperature. The results are tabulated and are shown in Fig. 3.

The results obtained by Walton and Whitford are also shown in the figure. These investigators determined the solubility of sulfur in the hydrogen persulfide. They added an excess of sulfur to a sample of the persulfide kept in a constant temperature bath. The mixture was stirred until the equilibrium was reached and a sample of the liquid phase analyzed. They claimed that the disulfide and the trisulfide gave solutions of the same composition when saturated at 0°. Hydrogen trisulfide was used for all points except that at −34.72°, where hydrogen disulfide was substituted. Their results were recalculated to the basis used in the present work.

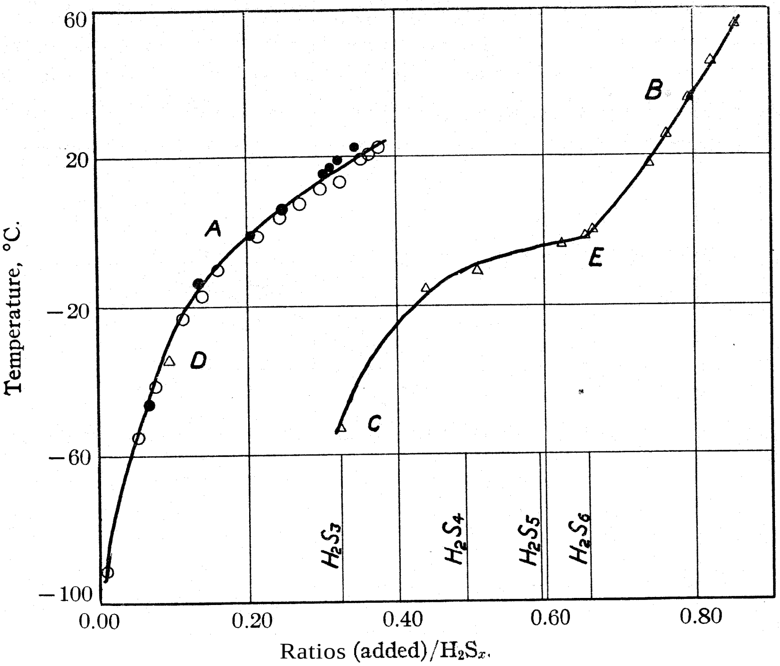

Fig. 3.

TABLE IV

RESULTS OF WALTON AND WHITFORD

Temp., °C.	Sulfur not evolved as H_2S, %	$\frac{(X - 2)S}{H_2S_x}$	Temp., °C.	Sulfur not evolved as H_2S, %	$\frac{(X - 2)S}{H_2S_x}$
−34.72	53.56	0.099	17.92	86.77	0.743
−15.42	71.18	.441	25.4	87.98	.767
−10.6	75.16	.511	35.4	89.46	.795
− 3.75	80.71	.626	45.15	91.00	.825
− 1.45	82.50	.660	55.3	92.49	.854
0.05	82.97	.669			

The ratios corresponding to the various possible persulfides are shown by vertical lines in the figure.

Point C is the freezing point of hydrogen trisulfide as given by Walton and Parsons and by Bloch and Hohn. Point D was obtained by Walton and Whitford using hydrogen disulfide.

Curve **A** represents the solubility of sulfur in hydrogen disulfide. There is no evidence for a break corresponding to the composition $H_2S_2 + S$, and the freezing point of such a solution is far above the recorded freezing point of H_2S_3. It may be stated, therefore, that hydrogen trisulfide is not a molecular compound of hydrogen disulfide with sulfur.

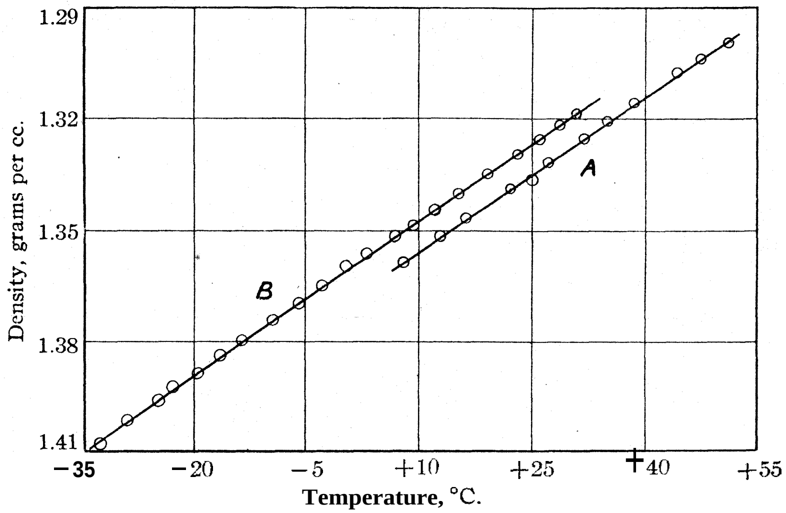

Fig. **4.**

It is obvious that Curve B must be drawn to represent the results of Walton and Whitford, and that Point D does not fall on this curve. This curve represents the solubility of sulfur in hydrogen trisulfide; it has a break at E corresponding to the molecular compound $H_2S_3 \cdot 3S$.

The evidence is strongly in favor of the existence of two chemical compounds H_2S_2 and H_2S_3 and a molecular compound $H_2S_3 \cdot 3S$.

Density.—Two determinations were made of the density and coefficient of expansion of hydrogen disulfide. The first dilatometer had a bulb of 2.73 cc. A scale from a Beckmann thermometer was attached to the stem. Calibration was carried out with water.

The dilatometer was filled with hydrogen disulfide by using a pyrex capillary funnel. The material had been redistilled, but not from phosphorus pentoxide, and was slightly turbid at 0°. The density was determined from S to 51°. The values are tabulated below and are shown in Fig. 4, Curve A.

In the second determination a quartz dilatometer similar to the first was used. The volume of the bulb was 2.08 cc. and of the stem 0.0446 cc. per cm. A reference mark was scratched on the stem about 15 mm. above the top of the bulb. Readings were made by placing the dilatometer so that the stem was in a vertical position and measuring the distance from the reference mark to the bottom of the meniscus with a cathetometer.

Hydrogen disulfide was distilled into the dilatometer from a pyrex still and the apparatus sealed off. A bath of ether stirred by a stream of air was used. Temperatures were measured with a mercury thermometer correct to one-tenth degree. The densities were corrected for the buoyancy of the air. The results are tabulated, and are given in Curve B of Fig. 4. This curve was used for calculating surface tension, since much greater weight must be given to this second determination. A few points lying close to the curves are omitted from the figure.

TABLE V

VARIATION OF DENSITY OF HYDROGEN DISULFIDE WITH TEMPERATURE

Run No. 1		Run No. 2		Run No. 2	
Temp., °C	Density	Temp., °C.	Density	Temp., °C.	Density
7.9	1.3583	−32.5	1.4074	−5.8	1.3697
9.6	1.3557	−31.4	1.4054	−3.9	1.3669
11.0	1.3535	−28.8	1.4012	−2.5	1.3649
12.5	1.3517	−26.9	1.3986	−1.1	1.3635
12.9	1.3515	−24.7	1.3959	0.6	1.3598
14.7	1.3490	−22.6	1.3921	1.7	1.3594
16.3	1.3467	−22.1	1.3918	3.5	1.3563
22.2	1.3386	−21.1	1.3906	5.6	1.3535
25.0	1.3360	−19.3	1.3883	7.2	1.3513
27.3	1.3314	−17.0	1.3853	8.0	1.3503
32.1	1.3250	−16.1	1.3836	9.7	1.3485
35.1	1.3203	−15.5	1.3826	10.8	1.3463
38.7	1.3152	−14.7	1.3816	12.4	1.3442
44.3	1.3072	−13.3	1.3797	14.0	1.3419
45.0	1.3065	−11.8	1.3776	15.4	1.3401
47.4	1.3037	−10.7	1.3761	19.5	1.3347
48.7	1.3015	−9.1	1.3741	23.4	1.3294
51.0	1.2992	−7.8	1.3726	26.3	1.3253
		−6.9	1.3711	29.0	1.3217
				31.2	1.3185

The two values for the density at 15° are 1.341 and 1.348 as compared with Bloch and Hohn's value of 1.376. The purer sample has the lower density and hence it is probable that the disulfide used by Bloch and Hohn contained an excess of sulfur. The density at 0° is 1.3615 and at 25°, 1.3270; the coefficient of expansion is 0.00104.

Vapor Pressures.—For measuring the vapor pressure of hydrogen disulfide a special type of apparatus was needed, since the vapor was decomposed by mercury and the liberated hydrogen sulfide attacked the mercury surface. The apparatus shown in Fig. 5 used a buffer column of air and a soda lime tube in series to protect the mercury surface. A is a 100-cc. flask; B, C and D are bulbs made from pyrex test-tubes. B is provided with a stirrer consisting of a piece of iron wire enclosed in pyrex tubing. C and D are designed so that any liquid distilling from B will collect in the bottom without blocking the connecting tube. E is a pyrex to soft glass ground joint. The manometer was constructed of tubing 1 cm. in diameter. One arm was open to the air. The paper scale was calibrated against a standard steel scale.

Two determinations were carried out with hydrogen disulfide. The disulfide was distilled from A over phosphorus pentoxide into B and a seal made at F. B, C and D were then immersed in a four-liter beaker of water; the stirrer was put in motion and the temperature brought to a suitable point.

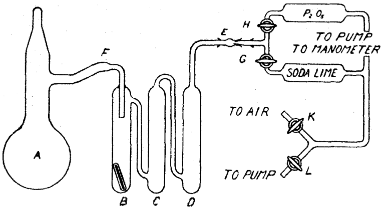

Fig. 5.—Vapor pressure apparatus.

A rough guess was made of the vapor pressure and the manometer set to this point by manipulation of the taps K and L. The apparatus was evacuated by opening H until practically all the air had been driven from C and D by the vapor from the boiling liquid. Tap H was closed and G opened, thus connecting the manometer to the system. Equilibrium was reached within a minute and readings were made of both sides of the manometer and the temperature of the bath. This procedure was repeated until several readings were obtained.

TABLE VI

VARIATION OF VAPOR PRESSURE OF HYDROGEN DISULFIDE WITH TEMPERATURE

First Series

Temperature °C.	Temperature °K.	Pressure, mm. of Hg at 0°	Log P	$1/T \times 10^4$
0.2	273.3	33.3	1.522	36.59
6 8	279.9	44.2	1.645	35.73
10.6	283.7	55.5	1.744	35.25
14.7	287.8	67.1	1.827	34.75
20.1	293.2	87.8	1.944	34.11
24.3	297.4	108.6	2.036	33.62
29.1	302.2	142	2.155	33.09
34.1	307.2	204	2.310	32.55
38 5	311.6	291	2.464	32.09
41 9	315.0	427	2.630	31.75

Second Series

Temperature °C.	Temperature °K.	Pressure, mm. of Hg at 0°	Log P	$1/T \times 10^4$
0.1	273.2	23.9	1.378	36.60
12.6	285.7	54.1	1.733	35.01
24.1	297.2	91.2	1.960	33.65
30.0	303.1	143.6	2.163	32.99
34.0	307.1	187	2.274	32.56
37.2	310.3	202	2.305	32.23
39.8	312.9	277	2.442	31.96
42.5	315.6	273	2.438	31.68
44.6	317.7	315	2.498	31.47

Greater weight was given to the first determination since the stirring was more efficient. Although the observations were carried up to 44°, those above 30° are of little value, due to decomposition of the material in B. When the bath was heated above room temperature, there was considerable difficulty in obtaining correct values, since the liquid distilled into the connecting tubing and decomposed.

The temperature of the bath was taken with a standard mercury thermometer. The readings of the manometer were corrected to 0°. The results are tabulated and shown in Fig. 6. The pressure–temperature curve is merely a smooth curve through the observed points. The log P–$1/T$ curve is a straight line drawn through the observed points. This line passes through the observed value for the boiling point.

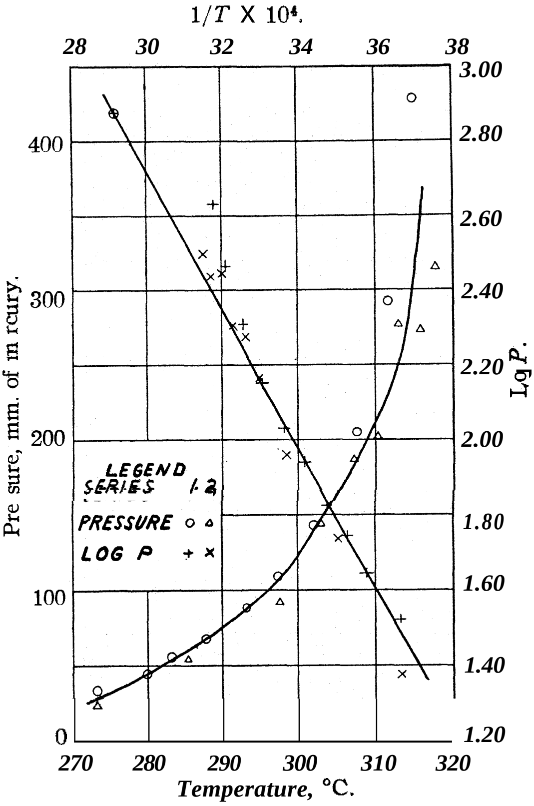

Fig. 6.

The value of the latent heat of evaporation is calculated from the slope of the vapor pressure curve by the formula

$$M\lambda = \frac{2.303 \log (P_1/P_2)}{1/T_1 - 1/T_2}$$

It is found that the molecular heat of evaporation, $M\lambda$, is 8544 cal. and the latent heat per gram, λ, is 129.2 cal.

Boiling Point.—The boiling point of hydrogen disulfide was determined by Bloch and Hohn, and by Walton and Parsons. Since their materials may have been impure and since the vapor came in contact with glass, their values were probably in error by several degrees. It was decided, therefore, to determine the boiling point in an apparatus so designed that the vapor could come in contact only with quartz. The platinum in quartz resistance thermometer (Heraeus type) was placed so that the rubber connection could not come in contact with the vapor.

A sample of hydrogen disulfide was prepared by distillation in a pyrex still from phosphorus pentoxide and transferred into the apparatus. The liquid was heated by a micro flame and boiled quietly for five minutes, the temperature remaining constant. Superheating was prevented by fragments of quartz tubing. Decomposition then started and was detected by a sudden drop in temperature and by a change in the size of bubbles within the liquid.

Owing to a hysteresis effect for the type of thermometer used, the calibration cannot be trusted above room temperature. The platinum thermometer was, therefore, transferred directly from the boiling liquid to a bath of water at approximately the same temperature and compared with a standard mercury thermometer.

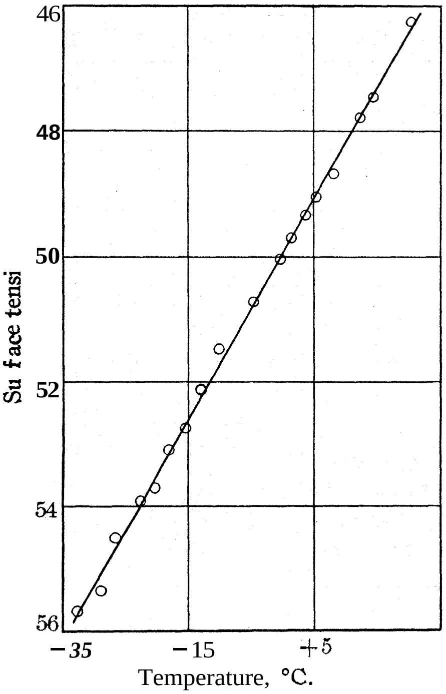

Fig. 7.

The value obtained for the boiling point was 69.9' at 749 mm. A second determination gave 70.6° at 748 mm. The boiling point at 760 mm. may be given as 70.7 ± 0.5°.

From the boiling point and the calculated value for the heat of evaporation the value 24.9 is obtained for Trouton's constant. This value indicates association of the liquid.

Surface Tension.—The surface tension of hydrogen disulfide was determined by measuring the rise in a capillary tube. The liquid was distilled directly into the capillarimeter from a pyrex still and sealed off in *vacuo*. The instrument, built entirely of quartz, is essentially that of Richards.[6] The capillary had an internal diameter of about 1.4 mm. and the wide tube about **13** mm. The constant for the instrument was obtained by a calibration with benzene over a range of temperature.

The capillarimeter was completely immersed in an ether-bath cooled by addition of solid carbon dioxide and stirred by a current of air. The difference in level of the menisci was measured by a cathetometer. Temperatures were measured by a mercury thermometer. The values of the surface tension are tabulated and are given in Fig. 7.

From the smooth curve for the surface tension one may obtain values for

Richards, THIS JOURNAL, 37, 1656 (1915).

TABLE VII

VARIATION OF SURFACE TENSION OF HYDROGEN DISULFIDE WITH TEMPERATURE

Temp., °C.	*Rise*, mm.	*d*	γ	Temp, °C.	*Rise*, mm.	*d*	γ
−32.7	1135	1.406	55.6	− 4 5	10.60	1.367	50.7
−29.0	11 30	1 401	55.3	--0.3	1050	1.361	50.0
−26.8	11.15	1.398	54 5	1 5	10.45	1.359	39.7
−22.8	11.10	1.392	53.9	3.8	10.40	1.355	49.3
−20.5	11.05	1.389	53.7	5.4	10.35	1.354	49.0
−18.2	10.95	1.386	53.1	8.3	10.30	1.350	48.7
−15.9	10.90	1.383	52.7	12.4	10.15	1.344	47.8
−12.9	10.80	1.379	52.1	14.6	10.10	1.341	47.4
−10.1	10.70	1.375	51.5	20.5	9.90	1.333	46.2

calculation of the molecular surface energy, the total surface energy and the Ramsay and Shields constant. The variation of molecular surface energy with temperature is shown in Table VIII.

TABLE VIII

VARIATION OF SURFACE ENERGY OP HYDROGEN DISULFIDE WITH TEMPERATURE

t	γ	*d*	$\gamma(M/d)^{2/3}$
−30	55 10	1 4028	719.1
−20	53.41	1.3890	701.7
−10	51.71	1.3752	683 9
0	50 02	1 3616	666.0
10	48.32	1,3477	647.7
20	46.63	1.3339	630.4

This gives for the Ramsay and Shields constant the value of —1.78. This is lower than the normal value, —2.12, indicating that the liquid is associated. $d\gamma/dt = -0.1695$ and hence the total surface energy, $\gamma + T(d\gamma/dT)$, is 96.3 ergs. The critical temperature may be calculated from the surface tension data; the value found is 278°, which is in good agreement with that calculated from the boiling point. These values cannot be considered as exact, since the liquid is associated.

Heat Capacity.—Measurements were made of the total heats of hydrogen disulfide from various initial temperatures to 25" in an adiabatic calorimeter.

TABLE IX

TOTAL HEATS OF HYDROGEN DISULFIDE BETWEEN 25° AND LOWER TEMPERATURE

Expt.	Initial *temp.*, °C.	*Heat capacity* to +25 00" (cal. *per g*)	Expt.	*Initial* temp., °C.	*Heat* capacity to +25 00° (cal. per g.)
1	0.0	7.62	8	−113.5	63.85
2	− 32.2	18.90	9	−113.5	68.91
3	− 34.2	19.11	10	−115.0	64.80
4	− 78.5	34.09	11	−115.0	69.49
5	− 78.5	34.59	12	−140.0	73.29
6	− 78.5	34.77	13	−184.8	79.71
7	−113.5	63.84	14	−186.8	79.66

A sample of hydrogen disulfide was purified by distillation from phosphorus pentoxide in a quartz still. This sample, contained in a quartz bulb, showed no evidence of decomposition over a period of ten weeks. The apparatus and method of procedure was similar to that of Maass and Barnes.[7] The variation in the temperature of the thermostat in which the disulfide was cooled was less than one degree. The total heat of the quartz bulb from the initial temperature to +25° was obtained from a mean specific heat curve given by Sosman.[8] The results of the determinations are tabulated and are shown in Fig. 8.

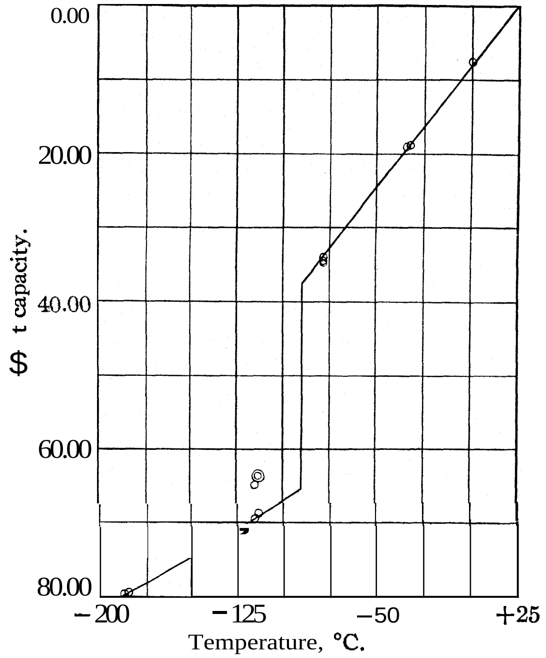

Fig. 8.

The deviation of Expts. 7, 8 and 10 is much too large to be caused by the container not reaching the temperature of the thermostat. It is practically certain that these anomalous results indicate the existence of a metastable crystalline form of hydrogen disulfide. It was impossible to freeze the liquid without supercooling to about −105° and owing to this supercooling the metastable form can exist.

These results permit calculation of the specific heats of the liquid and solid and of the latent heat of fusion.

Specific heat of liquid hydrogen disulfide	0.333
Specific heat of solid hydrogen disulfide	0.142
Latent heat of fusion of hydrogen disulfide	27.3 cal. per g.

Refractive Index.—The refractive index of hydrogen disulfide was measured by an Abbé refractometer. The prisms were carefully washed, using successively benzene, alcohol, hydrochloric acid, water, alcohol and ether. Observations were made over five minutes and the curve extrapolated to zero time. A typical series was

Molecular refractive power (calcd.)	9.89	17.58	3.725	5.250

The melting point of hydrogen disulfide is a little lower than that of hydrogen sulfide. The melting point of hydrogen peroxide is slightly lower than that of water. The boiling point of hydrogen disulfide is considerably higher than that of hydrogen sulfide; the boiling point of hydrogen peroxide is considerably higher than that of water. The general conclusion is that the change in physical property due to the added sulfur atom in the sulfur compounds is followed in an analogous manner by the change in physical property due to the addition of an oxygen atom in the oxygen compounds. Thus a striking similarity is brought out in the physical properties, as well as the chemical, of hydrogen disulfide and hydrogen peroxide.

Association of the liquids increases in the order H_2S, H_2S_2, H_2O, H_2O_2, the latter two being much more highly associated, as is shown by the Ramsay and Shields constant and the melting point. The agreement of the observed values of the parachor and molecular refractive power with those calculated for the formula H–S–S–H proves that hydrogen disulfide does not contain a double bond or a coordinate bond. The deviation between the observed and calculated values for hydrogen peroxide indicates a possible coordinate bond in this compound.

Acknowledgment is made of a studentship and a fellowship granted to one of us by the Research Council of Canada.

Summary

The preparation and purification of hydrogen disulfide have been described and the conditions investigated for obtaining large yields. It was shown that the higher persulfides are not formed by the solution of sulfur in hydrogen disulfide. The solubility of sulfur in the hydrogen disulfide was measured. The melting point, vapor pressures, density of the liquid, surface tension, refractive index, specific heat and latent heat of fusion of hydrogen disulfide were determined, and related constants were calculated. A comparison of the physical properties of hydrogen sulfide, hydrogen disulfide, water and hydrogen peroxide brings out the relations existing between these compounds.

THE NATURE OF THE SORPTION BY CHARCOAL OF GASES AND VAPORS UNDER GREAT PRESSURE

BY JAMES W. McBAIN AND GEORGE T. BRITTON

RECEIVED NOVEMBER 7, 1929 PUBLISHED JUNE 6, 1930

The McBain–Bakr sorption balance[1] has enabled regions of sorption previously inaccessible to be explored with comparative ease. Nearly all studies of sorption have been broken off below atmospheric pressure,[2]

---

[1] The microbalance described by McBain and Tanner [*Proc. Roy. Soc.* (London), **A125**, 579 (1929)] has many points of superiority over the McBain–Bakr balance. It is of the beam type, of extreme sensitivity, robust and compact enough to be placed within a glass tube and subjected to great extremes of temperature and pressure while in use.

[2] The chief investigations in which higher pressures have been used are: J. Hunter [*J. Chem Soc.*, 24, 76 (1871)], charcoal with ammonia and cyanogen to 3.5 atmospheres and carbon monoxide to 5.3 atmospheres in a Fontana experiment; E. W. R. Pfeiffer ["Dissertation," Erlangen, 1882, *cf. Beiblatter*, **8**, 630 (1884)], glass wool or charcoal with glass wool in Cailletet's compression apparatus with carbon dioxide or ammonia between 2 and 8 atmospheres, showing no saturation value; Sir James Dewar [*Proc. Roy. Inst.*, *18*, **437** (1906)], 1 g. of charcoal at $-185°$ sorbed 9.3 cc. of hydrogen at 1 atmosphere pressure; this was raised to 13 81, 156.7, 149.3, 145.5 and 138.1 cc. at 5, 10, 15, 20 and 25 atmospheres, respectively; Dewar regarded this as constancy. J. I. Graham [*The Colliery Guardian*, 122, **809** (1921)], carbon dioxide, methane and nitrogen by dry and moist coal up to about 30 atmospheres. The moist sorbed about one-third as much as the dry coal dust, I g. of which, together with a small amount of glass wool, at 30 atmospheres, sorbed about 10 cc. of nitrogen, the amount still apparently rising with increase in pressure. H. Briggs and W. Cooper [*Proc. Roy. Soc.* Edinburgh, 41, **119** (1921)] tested the capacity of steel cylinders partly filled with moist or dry charcoal or silica, using nitrogen, oxygen and hydrogen in some cases up to 100 atmospheres. They found agreement between their results and the Williams–Henry formula, but in some cases the term $k_2 \times x/m$ of that formula was negligible. F. A. Henglein and M. Grzen-

chiefly because of the rapidly growing inaccuracy and uncertainty of measurements where sorption is increasing only slowly with pressure, and the amount of gas or vapor in the poorly defined "dead space" within the apparatus is rapidly becoming the dominant quantity observed.

The present communication describes measurements of the sorption of nitrogen, nitrous oxide and ethylene at pressures up to 60 atmospheres, which were completed at Bristol University, England, early in 1927. The results are of especial interest in that, being carried out with a permanent gas and with vapors above and below critical temperatures and pressures, they enable a decision to be reached between rival views as to the nature of sorption by charcoal.

Experimental

Apart from minor modifications introduced to suit each gas studied, the apparatus consists essentially of the main experimental glass tube A which contains the vapor or gas to be studied and in the upper half of which there is a spiral spring S of fused silica[3] supported from a bent wire C, which is held by friction in the tube, and carrying at its lower end a platinum bucket B filled with charcoal. The temperature of the charcoal is kept constant by means of a thermostat surrounding the upper half of the glass tube. The sorption isotherm is obtained by measuring at a series of pressures the weight of gas sorbed by the charcoal as determined by the increase in length of the silica spring.

Kahlbaum's pure sugar charcoal was used in all experiments after activation either in steam or in air. The former (referred to in another communication[4] as "Wright's Steam D" charcoal) was prepared by heating at 700° in a silica flask for thirty minutes, a current of steam blown against the powdered charcoal, with frequent shaking, at the same temperature for forty-five minutes and the heating continued for ten minutes.

Another portion of the same sugar charcoal was activated by heating in a porcelain tube in an electric furnace at 1140° for twelve hours. During this time a slow stream of air was passed over the charcoal at intervals, so that about 20% of the original charcoal was oxidized. This is elsewhere[5,4] referred to as "Smith's Air C" charcoal.

In all cases the charcoal was evacuated after the apparatus had been set up, keeping the charcoal at 450° by an improvised heating coil[6] of nichrome wire embedded in a hollow tube of asbestos. The vacuum must be applied very slowly to avoid the charcoal blowing out of the bucket. Evacuation was continued until the charcoal had been exposed to a vacuum of less than 10^{-4} mm. for four or five hours. After the charcoal had stood in contact with the nitrous oxide, ethylene or nitrogen at one atmosphere pressure or more for many hours, the evacuation of the charcoal was repeated with the

---

kowski [Z. *angew. Chem.*, **38,** 1186 (1925)], ammonia, sulfur dioxide and chlorine by carbon up to several atmospheres.

[3] For details see J. W. McBain and A. M. Bakr, THIS JOURNAL, 48, 690 (1926). Silica fibers about 0.1 mm. thick and one meter long are supplied by the Silica Syndicate

[4] J. W. McBain, H. P. Lucas and P. P. Chapman, communicated to THIS JOURNAL.

[5] J. W. McBain, D. N. Jackman, A. M. Bakr and H. G. Smith, J. Phys. *Chem.*, **34 (1930).**

[6] A strip of asbestos paper about $^1/_{16}$ inch thick soaked in water was wrapped once around a glass tube and the edges kneaded together. Nichrome wire (15 feet, 15 ohms) was wound upon this and covered with further layers of soaked asbestos with the edges well kneaded together. The wet cylinder was slid off the tube by firm pressure and dried by an electric current of about two amperes.

same care as before. This is effective in displacing some of the residual impurities in the charcoal.

Sorption of Nitrous Oxide

The nitrous oxide used was obtained from a small cylinder as supplied for dental purposes.

The sorption tube **A**, Fig. **1**, was **12** mm. in internal diameter, **18** mm. in external diameter and approximately **40** cm. in length and was carefully sealed at the bottom before use, the balance being introduced from the top. Sufficient space was left below the bucket of charcoal so that liquefied gas could be present in excess and yet be far enough from the bucket to allow the temperature of the liquid to be controlled over the range -96.5 to $+20.9°$ without disturbing the temperature of the charcoal. The top of the tube was carefully drawn out, while the tube was in the clamp, until the internal diameter was **1** to 2 mm., the walls being nowhere thinner than **5** mm. on the tapering portion of the tube. The completed sorption tube was sealed onto an apparatus constructed of glass tubing and designed to allow evacuation via tap T_1 and also to allow the admission of nitrous oxide via tap T_2 at pressures up to 80 cm. of mercury. Taps T_1 and T_2 were mercury sealed, and O was a mercury trap which acted as a safety valve.

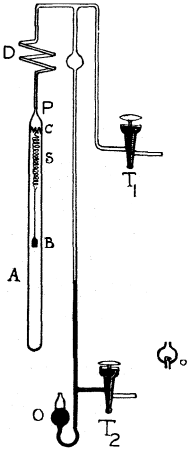

Fig. 1.—The sorption balance connections as used for nitrous oxide.

The general principle of the apparatus described above was due to Mr. H. H. M. Wright, who began the experimental work. His values for the sorption of nitrous oxide at **15°** by steam activated charcoal ("Steam D"), which had been previously evacuated to less than **0.0001** mm. at 470°, were $x/m = 0.099$ and **0.106** at one atmosphere. For the same charcoal evacuated only to **0.007** mm. at **470'** the value of x/m was **0.204** at **19** atmospheres and **15°**.

The silica spring was calibrated both before and after the experiment, but the latter calibration has invariably been used for calculating the results presented. Experience has shown that any considerable elevation in temperature produces a change in the length of such a spring, which decreases in magnitude with time and may be due to the reattainment of an equilibrium of state in the silica disturbed by the heating during bending.[7] The effect is most noticeable in the period of evacuation when the charcoal is heated to **450–500°**. In later experiments on nitrogen and ethylene the spring was not heated during evacuation, the bucket being hung on a fiber **10** cm. long from the end of the spring. It is now our custom to anneal springs for thirty to forty hours at 200° before use, as this is found to remove the effect.

The buckets B were made of the thinnest platinum foil, free from pinholes and supplied by Johnston Matthey and Co., London. They were welded upon a carbon

---

[7] I. Sawai and O. Morisawa [*Z. anorg. allgem. Chem.*, *173*, *361* (1928)] found similarly that threads of lead borate glass when first heated to temperatures between **180** and **395°** shrink on account of release of the longitudinal strains produced when they are being drawn. This effect did not occur if the thread were sufficiently loaded. A careful, extensive study of the increase in the elastic constants of fused quartz upon heating has recently been published by H. D. H. Drane, *Proc. Roy. Soc.* (London), **122A,** 274 (1929). See also the data of the Bureau of Standards quoted in *Ind. Eng. Chem., News Edition,* **8,** 14 (1930).

rod as a form and were about 15 mm. deep and 5 or 6 mm. in diameter, weighing from 0.09 to 0.12 g. and holding about 0.12 g. of charcoal.

A Kaye–Backhurst steel mercury pump, backed by a Cenco "hyvac" pump, was used, the combination readily producing 10^{-5} mm. The pumps were joined to a wide tube branching into mercury sealed taps, one of which was T_1, Fig. 1; another led to a McLeod gage reading to 10^{-5} mm. and a Pirani gage, while a third tap led to a tube of calcium chloride and phosphorus pentoxide by which air could be admitted when desired without admitting moisture.

After the second evacuation, the charcoal and tube were allowed to cool, while tap T_1 was left open, the length of the spring S read carefully with a Wilson traveling microscope,[8] three or four concordant values being obtained, and from this value the weight of gas free charcoal was calculated.

In order to introduce the nitrous oxide into the apparatus, the lower tip of the sorption tube A, Fig. 1, was cooled in liquid air, and the gas was supplied at about 80 cm. of mercury pressure through tap T_2. The mercury trap O acted as a safety valve, preventing a rise of pressure when the level of the liquid air fell, or the rate of condensation decreased for any other reason. The liquid air level was gradually raised until a column of solid nitrous oxide about 4 inches deep was obtained. Tap T_2 was then closed and T_1 opened. Tube A was pumped out to about 2 mm. and refilled with nitrous oxide several times to remove traces of nitrogen likely to come from the nitrous oxide cylinder. The sorption tube was then sealed off at P under vacuum and set up in the screen, Fig. 2. After sealing off the capillary tube, it was found advisable not to allow the internal pressure to rise above atmospheric for twelve hours. In nearly every case impatience led to blowing off the tip at some stage of the experiment.

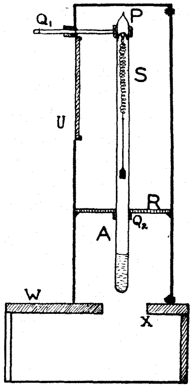

Fig. 2.—Protecting screen.

The screen, Fig. 2, consisted of a sheet-iron box 6 inches square and 18 inches long, having one side removable by undoing nuts and opening only at one end. A slit U, 0.5 inch wide, was cut in the face opposite the removable one, and a sheet of plate glass 0.25 inch thick fitted behind the slit. The box stood on the open end with slit to the front. Above the slit and also in one side about 6 inches from the bottom, two brass cylinders of 1-inch diameter were mounted. They were drilled so that the brass rods Q_1 and Q_2, 0.25 inch in diameter, could slide in them. Two ends of a steel helix were secured to the end of each rod like a spring fountain pen clip so that the tube could be slid into them and be firmly held without straining the glass. Since these rods were at right angles, it was possible to adjust the tube A very easily and allow the spring S to swing freely. An asbestos partition R was mounted below the level of the bucket and nichrome coils were introduced above the partition so that the bucket and charcoal could be warmed to any desired temperature. The screen stood upon a bench W about 7 inches high, 15 inches wide and 18 inches long, having a hole X cut in the top. In operation a Dewar vessel was raised through X to surround the liquid nitrous oxide, and the door of W replaced.

A Dewar vessel containing carbon dioxide snow and ether was used as a bath for maintaining the liquid nitrous oxide at any desired temperature below 0°. Stirring and frequent small additions of solid carbon dioxide sufficed to keep the temperature constant within 0.5" of the desired value. The temperatures were observed by a pentane thermometer which was calibrated at the time of performing the experiment by ob-

---

serving the freezing points of pure liquids. The vapor tension corresponding to the observed temperature of the liquefied nitrous oxide was obtained from the vapor tension–temperature graph determined in a previous paper,[9] and the length of the spring S was read by the traveling microscope after an interval of not less than two hours since the last change in temperature of the bath. It was found that no change in length of the spring occurred over longer periods, and values of sorption approached from either side of the equilibrium lay on the same curve. Since the same traveling microscope was used for calibrating the springs as for taking sorption measurements, no calibration of the scale was necessary, as any errors were automatically eliminated. Care was taken that all final movements of screws for fine adjustment of height or focus were carried out in the same direction. For higher pressures, necessitating baths with temperatures above 0°, mixtures of tap water and ice water were used and were maintained constant by occasional addition of small quantities of ice water.

The data for nitrous oxide are tabulated in Tables I–III, in which T is the temperature of the liquid nitrous oxide in degrees centigrade, and p is the corresponding vapor tension in atmospheres. To save space, only the first part of Table I is given in full. The apparent weight of gas sorbed, given as x uncorrected in Table I, equaled the difference in length of the spring at pressure p and the zero reading $(L_p - L_o)$ divided by the sensitivity of the spring. The sensitivity of the spring is ten times the extension produced by 0.1 g. increase in load. A correction for buoyancy must be made.

[a] Desorption experiment.

Data for the density of the vapor of nitrous oxide are given in a previous communication.[9] From the plot of pv against p the values of density in g./cc. appropriate to the pressures used in obtaining points on the sorption isotherm were calculated. These are given as ρ in Table I. The total volume displaced in cubic centimeters (the volume of the platinum composing the bucket plus the volume of the charcoal it contained) multiplied by the density gave the buoyancy correction in grams. This was added to the apparent sorption *(x* uncorrected), and the sum (x corrected) was divided by the mass of charcoal m to give values of sorption designated as x/m in the tables. The volume of the charcoal was calculated from its mass in vacuo by assuming 1.8 g./cc. as its density.

Sorption of Ethylene

The apparatus for measuring the sorption of ethylene was essentially the same as that used for nitrous oxide. Ethylene condenses very much more slowly than nitrous oxide, and hence it was condensed at 2 to 3 atmospheres pressure. Between the sorption tube A and the glass spiral D, Fig. 1, a glass T-piece of capillary tubing was introduced. The third leg of this was bent downward and again branched (see Fig. 3). At the ends of the branches two swellings were made in order that pressure tubing could be wired on safely. The swellings were drawn down into thin tips G and G_1 which were sealed and a slight scratch made on them with a file. Tip G was connected by pressure tubing Y to a closed-end mercury manometer and a cylinder of ethylene, the connecting tubing having first been swept free of air by a current of ethylene.

After the preliminary evacuation ethylene was admitted by turning open the valve of the gas cylinder and breaking the tip G. As G was so fine, no sudden rush of gas took place. The rubber connection was then transferred to the other leg and the fine tip G sealed by a small flame.

Following the second evacuation, the sorption tube was drawn off at Z, and ethylene was introduced via G_1 as before. A Dewar flask of liquid air was placed so that the lower end of the sorption tube just dipped in it, and the ethylene pressure raised to 2 or 3 atmospheres. From time to time the Dewar vessel was raised a little until a suitable depth of ethylene was obtained. Impurities in the gas were swept out by allowing the solid ethylene to melt and boil off, G having been opened. The sorption tube was then sealed off under a slight vacuum obtained by slipping over G a rubber connection to the pumps.

In order to obtain the sorption isotherm of ethylene at 0°, a piece of glass tubing, 2.5 inches in diameter, was drawn down to a neck which would just slide over the sorption tube. A length of 5 inches was left on the neck, and the resulting jacket, which gave a water-tight joint, was secured by a short piece of rubber tubing to the sorption tube at the point where the bucket of charcoal was suspended. This jacket was kept packed with ice. The spring S was thus at room temperature, the charcoal at 0°, and the end of the sorption tube containing the liquid ethylene could still be kept at any desired temperature with carbon dioxide and ether mixtures.

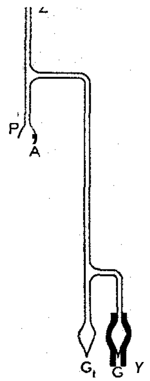

Fig. 3.—Capillary tubing introduced in apparatus for sorption of ethylene.

The experimental data found for ethylene are given in Tables IV and V. Tube I burst, which prevented the calibration of the spring from being checked. All calculations were made exactly as for nitrous oxide, and the pressure p and the density were obtained from vapor tension–temperature and p–pv graphs, respectively, which had been determined in the previous communication already mentioned in the case of nitrous oxide.

Sorption of Nitrogen

Mr. H. H. M. Wright placed the balance in a steam boiler water-level gage secured to a heavy iron stand. A passage in the upper casting communicated from the packing gland to a copper tube leading from a cylinder of compressed nitrogen via a constant pressure gas regulator. Another passage led to a gas valve by which the apparatus could be connected to the vacuum pumps by pressure tubing or isolated from them as desired. A passage in the lower casting led to a large brass cylinder bolted by a flanged joint to the casting. The silica spring was placed in the glass tube and the platinum bucket containing charcoal was suspended inside the brass cylinder by a fine fiber from the spring. A small electric heater, made by winding nichrome wire on a silica glass tube, fitted inside the cylinder and heated the charcoal to the desired temperature. This heater was calibrated before use. The leads for the heating current were led through the gaskets between the flanges, which were water-cooled to prevent decomposition of the rubber in the packing gland. Wright's data for nitrogen are graphed in Fig. 4.

A better type of apparatus was then devised. It was necessary to seek a better method of uniting glass and metal with a vacuum and pressure tight joint. Many possible joints[10,11] are described in the literature, but none were successful. A much simpler joint, Fig. 5, which is highly efficient and very easily made, was developed. A cylinder of brass 7 cm. long was drilled out to slide over the given capillary tube N (approximately 7 mm. in diameter), and a length of about 5 cm. was drilled out to 1.5 cm. diameter and tapped to take a small packing nut I, which just slipped over the capillary tube. The copper tube F was soldered into H, and the whole inverted. The capillary N was placed in position, and the brass warmed to the softening point of a good sealing wax. Sealing wax was then melted in until the space was filled, and the hot nut I screwed in about four turns, squeezing soft wax between the brass and the glass, where they were a close fit. The joint was allowed to cool without disturbance and was then ready for use. Such joints have held vacuum to 0.0005 mm. and internal pressures up to 65 atmospheres without any sign of failure or flowing of the wax. They will stand much vibration and rough treatment without failure. Waterston's "Bee Brand" Prize Medal sealing wax proved highly satisfactory.

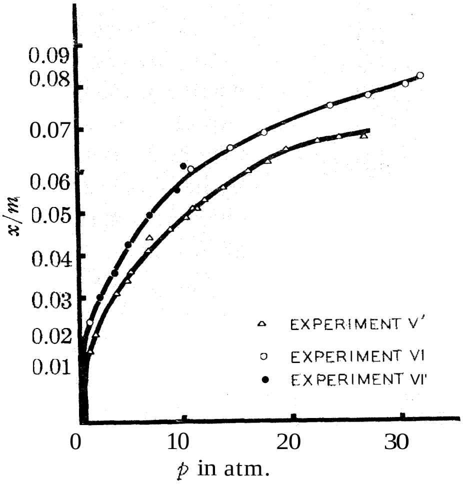

Fig. 4.—Wright's data for sorption of nitrogen by "Steam D" charcoal at 15°. Temperature of evacuation of charcoal is 500°. In Experiment V′, vacuum obtained is 0.6 mm. and time of evacuation is nineteen hours In Experiments VI and VI′, vacuum attained is 0.02 mm and time of evacuation is twenty-four hours

The sorption tube used in these experiments for measuring the sorption of nitrogen was of the same dimensions as that used for nitrous oxide but was carefully drawn out to a thick capillary at the lower end L, Fig. 6. After the introduction of the balance through the top, the upper end of the sorption tube was drawn to a thick capillary and fused onto a glass capillary N which was joined to a copper tube F by means of the special joint J (compare Fig. 5).

A small gas cylinder D, Fig. 7, was surmounted by a brass manifold carrying two good gas regulating valves V_1,V_2 and a pressure gage K reading

[11] E. C. McKelvy and C. S. Taylor, *ibid.*, 42, 1364 (1920).

to 150 atmospheres. V_2 was connected to a large gas cylinder E, and V_1 was joined to the copper tube F. The valves were carefully packed with leather washers and vacuum grease and proved capable of holding a vacuum of 0.0005 mm. The cylinders, valves, gages, unions and copper leads were supplied by the British Oxygen Company and proved satisfactory in use. The nitrogen, which had a purity of 99.5%, was obtained from the same company in cylinders charged to 120 atmospheres. This method of gas control was adopted because the automatic gas regulator previously used by Mr. Wright was very troublesome, allowing the pressure to rise slowly. Leaks, which were rare and slight, were readily compensated by hand operation before the pressure had changed more than a fraction of one atmosphere.

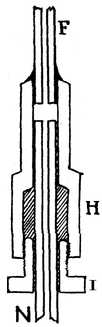

Fig. 5.—A vacuum- and pressure-tight joint for uniting glass and metal by means of sealing wax.

The glass portion of the apparatus was enclosed entirely in a sheet-iron screen with a slit covered by plate glass. A sheet of iron $^1/_{16}$ inch thick was bent into a box of square section 4" X 4" with the opening at the back. The opening was sprung out wider to pass the tube and clamp when placing the screen in position and was closed by means of wire tied around the screen.

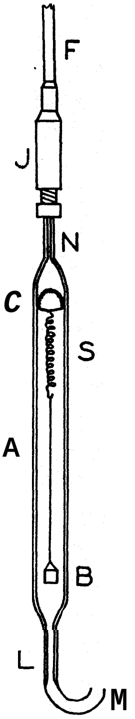

Fig. 6.—The sorption balance as used for nitrogen.

For the evacuation or outgassing of the charcoal the capillary tube L, Fig. 6, was fused to a tube M leading to the vacuum pumps. The charcoal was heated to 450° by an electric heater, and the pumps started up as described for the experiments with nitrous oxide. The valve V_1, Fig. 7, was shut during this operation. The time of evacuation was considerably longer than for nitrous oxide as, owing to small leaks, the pumps were much longer in reaching a low enough vacuum. In view of the number of mechanical joints, any pressure below 10^{-3} mm. was regarded as satisfactory, and outgassing was carried out for four to five hours at the lowest pressure obtainable. After the first outgassing, nitrogen was passed in via V_2 and V_1 from E until the pressure was one atmosphere. After fifteen hours the evacuation was repeated, the charcoal cooled, and the zero reading taken as for nitrous oxide. The tube L, Fig. 6, was carefully warmed up by the blowpipe and sealed off under vacuum, the pumps still running to carry off any gases or vapor given off by the glass.

While measuring the sorption of nitrogen, the valve V_1, Fig. 7, was always left open. The main valve of E was opened, and gas admitted by V_2

into D and A up to any desired pressure as read on K. The cylinder D served to prevent violent inrushes of gas, as its size demanded a considerable quantity of gas to produce small pressure changes. Moreover, any small leakage at valves or unions would be minimized and readily made up by small additions of gas by V_2. The length of the spring S was read after an interval of not less than one hour. A shorter period can be permitted in this experiment than in the nitrous oxide experiment, because there is no liquid–vapor equilibrium to establish in addition to the gas or vapor–solid equilibrium, the pressure being put at its final value in a minute or so. When equilibrium had been approached from both sides, the pressure was lowered by undoing a union or the packing gland of V_2 and allowing gas to leak out. This was more satisfactory than introducing another valve.

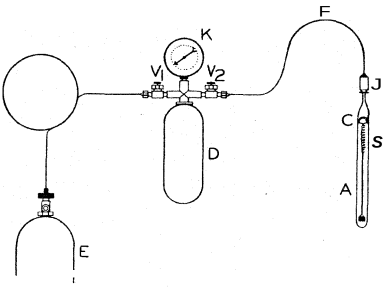

Fig 7.—Method of gas pressure control used in sorption of nitrogen

The results were calculated exactly as for nitrous oxide. The density of the nitrogen at 20° was calculated from the data on the compressibility of the gas as measured by Amagat[12] at 16°, taking 1.1650 as the density at 20° and one atmosphere pressure. By plotting the density–pressure graph up to 60 atmospheres, the density of the nitrogen at any pressure could be readily obtained.

The densities for nitrogen at −77° were calculated from the compressibility data of van Urk.[13] The equation of state of nitrogen is given as

$$PV_A = A_A + \frac{B_A}{V_A} + \frac{C_A}{V_A^2} + \frac{D_A}{V_A^4} + \dots$$

in which $A_A = 1.00043\ (1 + 0.0036618\,t)$, t being the temperature in degrees centigrade. P is in international atmospheres and V is in normal volume units at 0°. A table of values of B, C, D, etc., is given for various temperatures. The values of the constants B, C, D appropriate to the temperature of −77° were obtained by graphical interpolation. The final equation is thus

$$p = \frac{0.7206}{V} - \frac{1.115 \times 10^{-3}}{V^2} + \frac{2.682 \times 10^{-6}}{V^3}$$

the fourth term having proved negligible. By commencing with unit volume at 0°, 1 atmosphere pressure and density ρ_0 and by substituting fractions x such as 0.25, 0.025, 0.015, 0.01, etc., for V, the corresponding value of P is obtained. Obviously the density ρ of the gas at −77° under

the pressure P is ρ_0/x, x being the fraction of the volume corresponding to P. The density of nitrogen under standard conditions has the value of 1.25057 grams per liter.

The experimental data obtained from the measurements of the sorption of nitrogen by charcoal are tabulated in Tables VII–X, while Table VI contains a comparison of the conditions of outgassing the charcoal.

TABLE VI

CONDITIONS OF OUTGASSING THE CHARCOAL BEFORE MEASURING THE SORPTION OF NITROGEN

Expt.	Charcoal	Time for const. vacuum, hours	Press., mm.	Time at press., hours	Final press., mm.	Temp. of evacn., °C.	Contact cold N_2, hours

IV	Air C	3	.0001	4	.0001	490	..

In the case of Bxperiment IV the charcoal was outgassed for ten hours at 460° and 0.001 mm. vacuum, which could not be improved upon owing to a crack in a glass seal. To put this right, air was admitted, and the charcoal was cooled and re-evacuated as above ten hours later.

[a] Desorption experiment.

Discussion

The data portray true reversible equilibria, because points on the curves obtained by sorption or by desorption are indistinguishable within the experimental error. The experiments were always sufficiently prolonged for this to be the case. Somewhat higher values, less affected by high pressures, would probably have been obtained had we taken even greater precautions in the preliminary evacuation of the charcoal.[14]

The first half of the total sorbed material is taken up at low pressures, almost infinitesimal in the cases of nitrous oxide and ethylene, but we are concerned here with the behavior in the higher regions of pressure. Here the buoyancy correction for the density of the gas or vapor becomes important. This was very clearly shown in the unabridged tables where neglect of the buoyancy correction causes the uncorrected values of the sorption x to pass through a maximum and then fall off with further increase of pressure. To evaluate the correction it is necessary to know the density of the charcoal. Unfortunately, this is a matter of extreme divergence of opinion, the bulk density, not allowing for pores, being far less than unity.

The density of diamond is 3.47–3.56,[15] and that of graphite is 2.25–2.26.[16] Polanyi,[17] like A. M. Williams,[18] considers that the density of active charcoal may be 1.5, and H. Briggs[19] assumes it to be only **1.33,** whereas G. A. Hulett[20] concludes that it is 2.2, approximating that of graphite. The uncertainty arises from the divergent results obtained when the density is determined by immersing the charcoal in different liquids. The values for the density so derived range from 1.65 to 2.28. Two opposing explanations are current for this divergence. The first view is that the liquid sorbed is highly compressed and much denser than the surrounding liquid;

hence it would displace less than its own weight of ordinary liquid and, therefore, must add to the apparent density of the charcoal. According to this, the charcoal must be less dense than is ever experimentally observed. The contrary interpretation is that the solid framework of the carbon is of high density, about 2.2, but that, owing to the extreme fineness of its porosity, it is not completely penetrated by liquids. When helium at atmospheric pressure and temperature is used as the fluid displaced by the carbon,[20] the result is unaccompanied by sorption and the density found is 2.2.

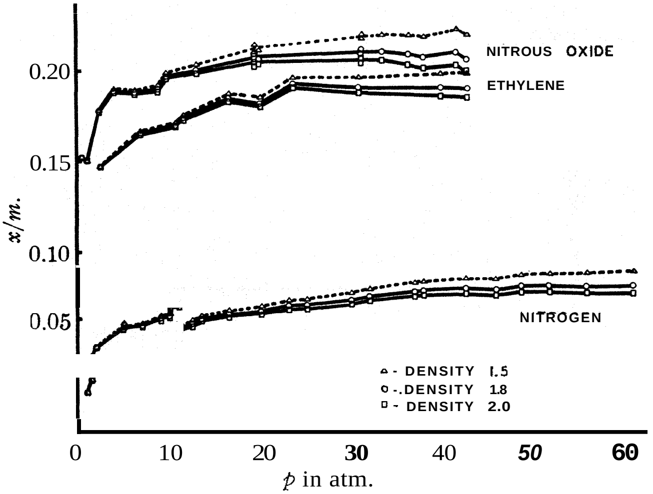

Fig. 8.—Sorption of nitrous oxide, ethylene and nitrogen at 20° assuming the density of charcoal as 1.5, 1.8 and 2.0, respectively. The data used are obtained from Tube III nitrous oxide, Tube III ethylene and Tube I nitrogen.

Although we do not know how completely nitrogen, nitrous oxide and ethylene are able to penetrate the finest porosities of the charcoal, the exact value of the density does not greatly affect the trend of our results. This is illustrated by typical data for all three substances in Fig. 8, which shows what the sorption would be if calculated assuming alternatively the densities 2.0 and 1.8, as well as the inadmissibly low value 1.5. For all three substances it is evident from Fig. 8 that the sorption becomes constant for all the higher pressures, irrespective of whether the density is taken as 1.8 or 2.0. These data, within the experimental error, exhibit a saturation value of sorption.

In Figs. 9, 10 and 11 the values for the sorption are plotted against pressure, being calculated as in the foregoing tables upon the assumed value of 1.8 for the effective density of the charcoal. A saturation value is found for all the experiments with nitrous oxide and ethylene, whereas with nitrogen the saturation value is observed only for the steam-activated charcoal.

However, the uppermost curve in Fig. 11, representing the highest values for sorption by air-activated charcoal at −77°, leads to an almost constant saturation value which would become unmistakable if any higher density were assumed for the charcoal.

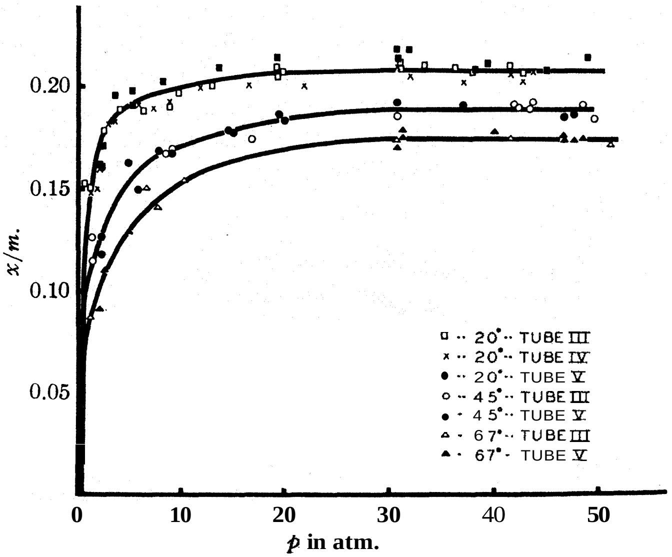

Fig. 9.—Sorption of nitrous oxide by "Steam D" charcoal.

For nitrogen with air-activated charcoal at 20° no saturation value is attained. This is not surprising when we compare the other saturation values corresponding to different temperatures and note that, although they definitely diminish with rising temperature, the highest values for the sorption of nitrogen at 20° are only half those of the corresponding saturation values at −77°. It is evident that appreciably more sorption must take place and much higher pressures must be employed before a saturation value at 20° could be reached.

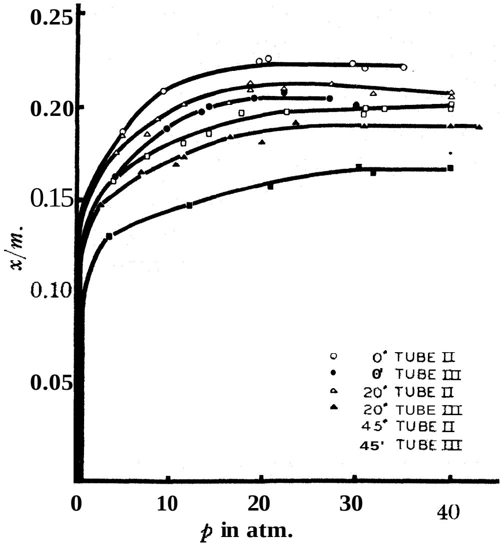

Fig. 10—Sorption of ethylene by "Air C" charcoal.

Data exhibiting a saturation value cannot adequately be represented by the ordinary "exponential" isotherm, $x/m = kp^{1/n}$. Neither can they be represented by the exacting Williams–Henry formula, $\log (x/m/p = k_1 - k_2 \times (x/m)$.

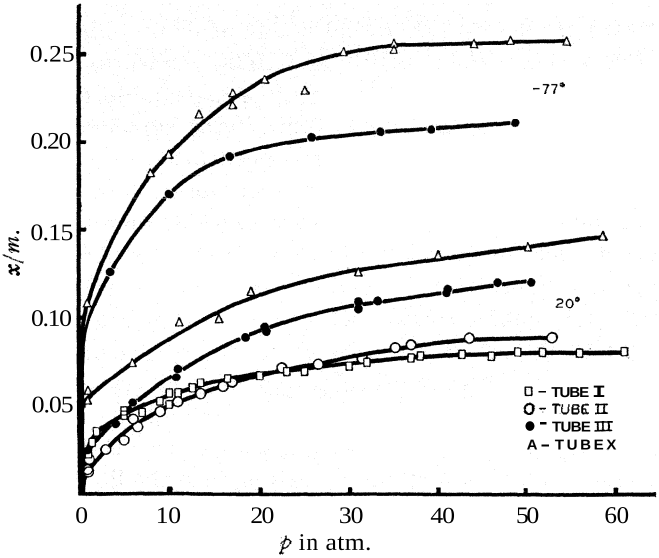

Fig. 11.—Sorption of nitrogen by charcoal. "Steam D" charcoal was used in Tubes I and II, and "Air C" in Tubes III and IV.

This formula cannot be legitimately applied where the sorption exceeds a fraction of the saturation value. The inadequacy of both formulas is illustrated in Figs. 12 and 13, where the respective formulas demand a straight line graph. A saturation value would be indicated by the Williams–Henry graph becoming vertical for that range of pressure. However, over a limited range either formula can be used to give a fair representation of the results.

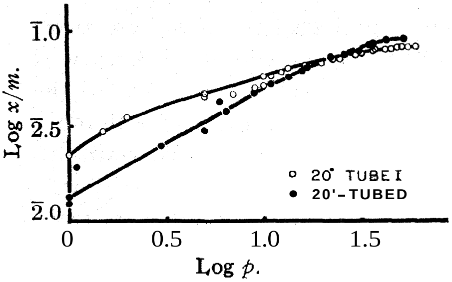

Fig. 12.—Sorption of nitrogen graphed according to the experimental formula, $x/m = kp^{1/n}$.

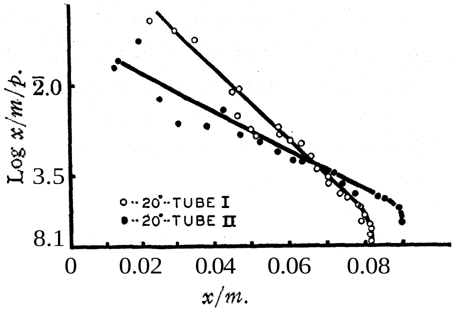

Fig. 13.—Sorption of nitrogen graphed according to the Williams–Henry formula, $\log x/m/p = (k_1 - k_2) \times x/m$.

The question will be raised as to whether some buoyancy correction should not have been introduced for the sorbed gas or vapor itself. The answer is that no such correction is admissible if the classical conception of a compressed film of sorbed material is assumed (de Saussure 1814, Mitscherlich, Bunsen, etc., Polanyi 1917 and 1928). Sorption is defined, both practically and theoretically, as the excess of material in the neighborhood of the solid over that which would obtain if the surrounding atmosphere reached the surface quite unchanged in concentration.

Nevertheless, from the standpoint of chemosorption or of a monomolecular film, it is inevitable that one should seek to distinguish between molecules which are held by sorption and those of the atmosphere which they have displaced. Considering an extreme case such as a body of liquid in contact with a crystalline surface, where the concentration of the liquid is uniform right to the crystal face, by ordinary criteria no sorption would have taken place, yet, if the molecules touching the crystal were specially oriented, they should be regarded as a sorbed monomolecular layer which has displaced an equal bulk of liquid (neglecting here the probable occurrence of oriented chains of molecules reaching into the liquid from a monomolecular layer).[21]

Applying the foregoing considerations to the present cases, the attempt may be made to estimate what the correction would be for the atmosphere displaced by the sorbed material if it is directly attached to the carbon by primary or residual valences. The weight of sorbed material is about one-fifth of that of the carbon, but its volume is uncertain. The densities of solid nitrogen, of liquid nitrogen at −190°, of liquid ethylene at −102° and of nitrous oxide at −89° are 1.0, 0.8, 0.6 and 1.2, respectively. On account of expansion, these densities would be less at the temperatures employed, but this would be partly compensated by compression at the highest pressures. Taking 1.0 and 0.6 as fair limits and assuming for these small molecules that the true density of carbon is 2.2, the combined density of carbon plus sorbed material comes to 1.8 or 1.5. These are equal to the lower densities already considered in Fig. 8 with the important difference that saturation values might still appear with the lower density, owing to the great compressibility which would necessarily accompany so low a density of the sorbed material. The higher density is, moreover, more probable if each sorbed molecule is attached directly to carbon. In other words, the results as portrayed in the graphs are not misleading over the pressure ranges so far investigated even if the actual values might have to be slightly greater and a saturation value was not quite strictly attained. The Langmuir theory supposes that a limiting value for sorption is approached asymptotically with great increase of pressure.

---

[21] J. W. McBain and G. P. Davies, THIS JOURNAL, **49**, 2230 (1927); Sir W. Hardy, *J. Gen. Physiol.*, **8**, 641 (1927); J. W. McBain, *Nature*, **120**, 362 (1927).

In Figs. 14, 15 and 16 the results are graphed in a form derived from the Langmuir equation for plane surfaces

$$\frac{x}{m} = \frac{abp}{1 + ap} \text{ or } \frac{p}{x/m} = \frac{1}{ab} + \frac{p}{b}$$

where if a and b are constants, the graphs should be straight lines. It is seen from the figures that this representation is in striking agreement with all the data. When the results for nitrogen at 20° were calculated with alternative densities, it was found that an assumed density of 1.5 did not yield a straight line but that 1.8 was satisfactory and 2.0 was even better. The intercepts of the straight lines with the ordinate on the left of the figures where $p = 0$ give a numerical value of $1/ab$, whereas the slopes of the straight lines give a numerical value of $1/b$.

The results for the sorption of nitrogen at room temperature, extending as they do up to 60 atmospheres pressure, appear to afford the opportunity for a crucial test of the classical de Saussure or Polanyi hypothesis that the sorbed gas is in the form of a compressed atmosphere obeying an ordinary equation of state such as that of van der Waals but under an excess compression due to the attractive forces of the solid. Knowing the actual behavior of nitrogen under compression from the work of Amagat and others, we can consider 1 cc. of the sorption space, that is, the region within which the attractive forces of the solid are operative, and calculate directly what the density of the nitrogen in 1 cc. would be if the average pressure inside the sorption space exceeds that of the surrounding atmosphere by any specified amount.

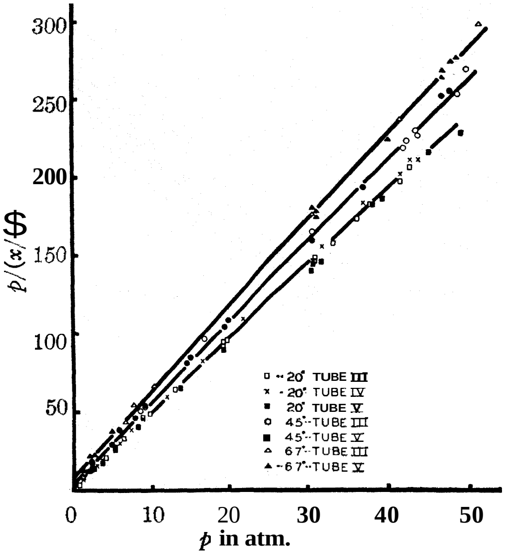

Fig. 14.—Sorption of nitrous oxide by "Steam D" charcoal graphed according to the Langmuir equation, $p/(x/m) = (1/ab) + (p/b)$.

For example, using Amagat's data for values of pv at 16° and various pressures as recorded in "International Critical Tables," the density of nitrogen at 1 atmosphere is 0.00118, and if there is an extra pressure of 1000 atmospheres in the sorption space, the density there would be that corresponding to 1001 atmospheres, namely, 0.5861. The difference in density would be attributed to sorption and would be 0.5849 for a gas pressure of 1 atmosphere. Now if the pressure of the body of the nitrogen were 60 atmospheres, with its density 0.07163, and the excess pressure in the sorption space were again 1000 atmospheres, making a total of 1060 atmospheres, the density then would be 0.5995. Once more the difference in density would be attributed to sorption, and this would amount to 0.5279 for a pressure of 60 atmospheres as compared with the 0.5849 for nitrogen under 1 atmosphere pressure.

In other words, it follows from the known behavior of nitrogen that if nitrogen in the sorption space is like nitrogen in the surrounding atmosphere, except for an extra compression of 1000 atmospheres in the sorption space, we must have observed a distinct decrease in the amount of sorption of nitrogen in our experiments at 60 atmospheres as compared with 1 atmosphere.

Actually, the behavior is wholly different. Instead of the sorption decreasing when the pressure of nitrogen is raised from 1 atmosphere to about 60 atmospheres, the sorption increases many fold. Hence our experiments at high pressures definitely disprove the assumption that the nitrogen in the sorption space is subject to an extra compressive force of the order of 1000 atmospheres.

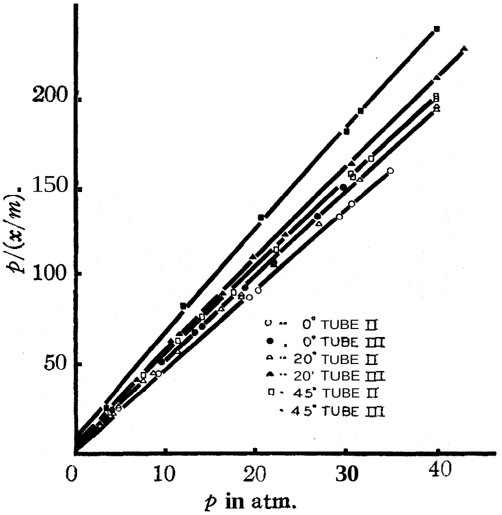

Fig. **15.--Sorption of ethylene by "Air C" charcoal graphed according to the Langmuir equation,** $p/(x/m) = (1/ab) + (p/b)$.

The same test can be applied to a statement that the excess pressure in the sorption space exceeds that in the surrounding space by, say, 100 atmospheres. Here again a slight decrease is predicted in the amount of sorption at the higher pressure, in violent discord with the facts. This apparently conclusive disproof of a conception which has remained up to the present largely a matter of opinion which was held for over a century by almost all the men of science who concerned themselves with this subject, is of such importance that we repeat the experimental data for inspection in tabular form in Table XI to compare with the typical calculations exhibited in Table XII.

It is evident from a comparison of the facts in Table XI with the known behavior of nitrogen in Table XII that they are glaringly incompatible with the conception of a sorption film differing from the surrounding atmosphere merely through compression caused by the attractive forces of the solid. It is clear that of the nitrogen sorbed by charcoal, only a negligible propor-

tion can be in the compressed state envisaged in the de Saussure–Polanyi conception, even if this compression be estimated at only 1 atmosphere. Estimates by various advocates of the compressed film theory have ranged up to 37,000 atmospheres.

Clearly the Langmuir conception, which is the only alternative explanation ever put forward for the sorption of nitrogen by charcoal, is correct. Its essence is the assumption that only such molecules are sorbed as are in direct contact with the molecules holding them. The Langmuir conception includes the possibility that further molecules may be held by the primary monomolecular layer.[22] The results and calculations of the present paper disprove, moreover, a further alternative hypothesis introduced by Polanyi

---

[22] This view was put forward by R. A. Smith in 1863 (see *Proc.* Roy. *Soc.* (London), **A112,** 301 (1928)). See also, A. B. Lamb, R. E. Wilson, and N. K Chaney, *J. Ind. Eng. Chem.*, 11, 424 (1919); I. Langmuir, *Trans. Faraday Soc.*, 17, 614 (1921); E. K. Rideal [*Nature,* 117, 627 (1926)] who compares such attraction of a magnet on a string of iron filings; F. G. Keyes and M J. Marshall [THIS JOURNAL, 49, 156 (1927)] who especially emphasize it.

in 1928 in an attempt to conform the compressed film concept with monomolecular adsorption by assuming a sideways compression of the adsorbed layer such that it would be the equivalent of a two-dimensional gas or at lower temperatures form islands of liquid.

Experiments with active charcoal do not suffice to disprove the possible existence of relatively weak forces of molecular attraction at distances greater than a molecular diameter. This is due to the extraordinarily complete development of the "porosity" of the charcoal. It must, from such data as ours, be regarded as comparable with that of an open space lattice such as dehydrated chabazite, which acts as a molecular sieve for separating large from small molecules.[23] The sorbed molecules of nitrogen must be so intimately surrounded by the atoms of carbon with which they are in contact that the designation "adsorption," which implies a surface, becomes a misnomer. There is very little difference in such a case between adsorption and absorption;[24] and if a precise word to describe sorption by charcoal were required, the new term "persorption" might be coined. Experiments on smooth surfaces, preferably crystal faces, are required to examine the residual effects which may occur at a greater distance from the surface.

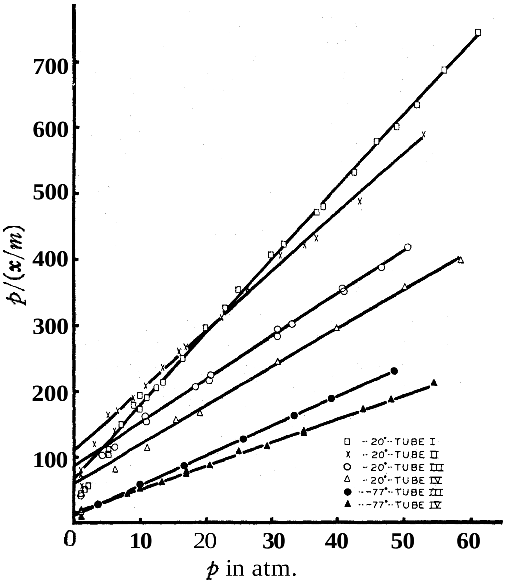

Fig. 16.—Sorption of nitrogen by charcoal graphed according to the Langmuir equation, $p/(x/m) = 1/ab + p/b$. "Steam D" charcoal was used in Tubes I and II, and "Air C" in Tubes III and IV.

Steinhoff, Z. *Krist.*, **61,** 125 (1924); **O.** Schmidt, Ebenda, **133, 263** (1928); R. Seeliger, *Physik. Z.*, **22, 563** (1921); F. Simon, Z. *physik. Chem.*, **132, 456** (1928).

[24] J. W. McBain [*Trans.* Faraday *Soc.*, 14, 202 (1919)] found that in experiments on the sorption of iodine extending over many years, during which the total sorption was doubled, the amounts taken up after the initial sorption conformed with *a* sorption isotherm rather than with a formula for true solution such as Henry's law, although the delay must have been conditioned by slow processes of diffusion. The solvent and other impurities have to diffuse out of the carbon while the solute is diffusing in and replacing them. Modern vacuum technique has not been applied in the study of sorption by solutions.

Although the preceding discussion has been confined to the gas nitrogen as a test case, the result, if recognized as valid, must extend to all cases of sorption by active charcoal.

The critical temperature and pressure of nitrous oxide are 36.5° and 71.7 atmospheres, respectively, those of ethylene 9.7° and 50.9 atmospheres and those of nitrogen −147.1° and **33.5** atmospheres. Nitrogen, therefore, has been studied far above its critical temperature, while nitrous oxide and ethylene have been studied below and above their critical temperatures. The results are all very similar. There is no noticeable influence of this critical constant in the form or position of the sorption curves whether one compares the graphs above and below the critical temperature for one substance or compares the two vapors with nitrogen. This suffices to show that capillary condensation plays no role in such cases of sorption by charcoal.

Summary

1. Using the McBain–Bakr sorption balance, the sorption of nitrogen, nitrous oxide and ethylene has been measured at pressures up to 60 atmospheres.

2. The curves for gases and vapors are similar, and no special difference is noticed when studying nitrous oxide and ethylene above and below their critical temperatures.

3. The data appear to afford a crucial disproof of the classical conception of the sorbed film as a compressed fluid. This was suggested by de Saussure in 1814 and is currently associated with the name of Polanyi. The disproof extends equally to the modification introduced by Polanyi in 1928. The behavior predicted by such hypotheses is in flagrant contradiction with the known compressibility of nitrogen and the actual sorption at 60 atmospheres as compared with that at 1 atmosphere. Only a negligible proportion of the sorbed nitrogen can be in such a state; the remainder must be directly attached as postulated in the hypotheses of Langmuir. It is, therefore, shown that the terms adsorption and absorption are equally misnomers when applied to sorption by active carbon. The dissemination of the sorbed molecules between the carbon atoms is almost as intimate but is not as uniform as that of a true solid solution. On the other hand, owing to so much of the "porosity" of active charcoal being on an atomic or molecular scale, the conception of a surface disappears. The term "persorption" is proposed if a new term is required to describe such phenomena.

4. When the data are expressed according to the definition of Gibbs or of the compressed film conception as the excess in the neighborhood of the surface over the amount corresponding to the surrounding atmosphere, saturation values are obtained for all except some of the experiments with nitrogen. When expressed in absolute amounts, according to the Langmuir conception, the saturation values become doubtful, tending to show slight increase with further rise in pressure.

5. The data over the whole range of higher pressures are adequately represented by the Langmuir formula.

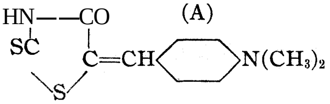
TWO DELICATE TESTS FOR THE DETECTION OF COPPER AND SOME REMARKS ON THE RHODANINE TEST OF FEIGL FOR SILVER

BY I. M. KOLTHOFF

RECEIVED NOVEMBER 22, 1929 PUBLISHED JUNE 6, 1930

I. Recently, F. Feigl[1] has described a new and very delicate test for silver with *p*-dimethylaminobenzylidene-rhodanine as a reagent (A). According to Feigl, this reagent gives in weakly acid, neutral and ammoniacal solutions, a flocculent red precipitate with silver. In 5 cc. of a weakly acid solution, one part of silver in 5,000,000 of solvent could be detected. In working with 10 cc. of solution, to which 0.5 cc. of 4 N nitric acid and 0.3 cc. of a saturated solution of the rhodanine[2] in alcohol were added, the same sensitivity was found by the writer. A solution with 1 mg. of silver in a liter produces a distinct reddish brown color (10 cc. of solution, conditions as above); with 0.5 mg. of silver per liter a weakly reddish color was noticed; with 0.2 mg. per liter the solution showed a very weak pink color after ten minutes' standing, distinctly different from the blank, which was slightly yellow. In ammoniacal solution (10 cc. of solution +1 cc. of 6 N ammonia and 0.1 cc. of indicator) the color in the presence of silver is reddish-brown and in very dilute solutions orange-brown. The sensitivity in this case is about 2 mg. of silver in a liter.



(A)

In acid medium the reagent is so sensitive toward silver that it even cannot be used as an indicator for the titration of iodide with silver solution. A weakly acid solution of 0.01 N potassium iodide to which some reagent had been added gave a dark red precipitate after addition of a few drops of 0.01 N silver nitrate. Even the silver in the complex potassium silver cyanide reacts with the rhodanine. According to Feigl, the rhodanine is quite specific for silver. This, however, is not the case, as mercury and copper salts under the right conditions can react with it in a very sensitive

---

[1] F. Feigl, *Z. anal. Chem.*, 74, 380 (1928).

[2] The reagent was prepared in the organic division of this University, according to the procedure given by Feigl. It had the same properties as a sample kindly submitted by Dr. Feigl. Instead of using a 0.03% solution of the rhodanine in acetone as described by Feigl, a saturated solution in alcohol (about 0.02%) was taken.

way. In weakly acid solution (10 cc. + 0.5 cc. of 4 N nitric acid + 0.3 cc. of reagent) mercurous mercury gives a red precipitate; 1 mg. of mercury per liter gives a faintly red color; the limit of sensitivity is 0.5 mg. per liter. Mercurous mercury even reacts in the presence of chloride; therefore, the rhodanine compound must be less soluble than mercurous chloride. Under the same conditions as described for silver and mercurous mercury, the mercuric mercury in well dissociated mercury salts gives a red color (or precipitate) with the reagent; sensitivity, 0.2 mg. of Hg^{II} per liter (in mercuric nitrate). Addition of chloride or bromide decreases the sensitivity very much. A weakly acid solution of 0.1 N mercuric chloride gives a weak pink color the intensity of which depends upon the acidity of the solution. The reaction cannot be used for a sensitive detection of mercuric nitrate in mercuric chloride. The pink color of the mercuric chloride solution becomes gradually stronger on addition of mercuric nitrate or perchlorate (complex $HgCl^+$ formation).

II. Application of the Rhodanine to the Sensitive Detection of Copper.—With cupric salts the rhodanine produces a reddish-orange color; in stronger solutions a precipitate. A solution of 1 mg. of Cu^{II} per liter gives a brown-orange color which is distinctly different from the yellow color of the blank. If comparison is made with a blank, 0.3 mg. of copper per liter can be detected. It should be mentioned that the formation of the colored product is prevented in acid medium. Even acetic acid decreases the sensitivity greatly. On the other hand, if the copper rhodanine is formed in neutral medium (or in the presence of some excess of sodium bicarbonate) it is fairly stable toward acid. An acid cupric copper solution was neutralized with an excess of sodium bicarbonate, then the reagent was added, whereupon it was acidified with acetic acid. The colors become more pronounced in the acid medium (orange-brown). Bven 0.5 mg. of Cu^{II} per liter can be detected in 5 cc. of solution if a blank treated in the same way is used for comparison. Lead does not interfere.

Cuprous copper gives much more pronounced colors with the reagent A weakly acid solution of cuprous copper containing 100 mg. of Cu^I per liter gives a purple-violet precipitate; 10 mg., red-brown; 1 mg., orange-brown; sensitivity, 0.1 mg. of Cu^I per liter. The rhodanine is very suitable for the detection of traces of copper in a solution. If we start with a cupric copper solution, the divalent ions first must be reduced. This can easily be accomplished with potassium cyanide. To 10 cc. of solution, 3 drops of 1% potassium cyanide and 0.2 cc. of indicator (saturated solution in alcohol) are added and the mixture acidified with acetic acid; sensitivity, 0.3 mg. of copper per liter (comparison with blank). The solution may be acidified with nitric acid instead of acetic acid; 0.5 mg. of copper per liter can be detected easily; the colors fade, however, much sooner than with acetic acid.

Iron interferes with this copper test on account of formation of ferro- or ferricyanide. Therefore, finally, hydrazine sulfate was used as a reagent for the reduction of cupric copper to cuprous copper.

Reagents.—Two per cent hydrazine sulfate; 0 02% rhodanine in alcohol.

Procedure.—To 10 cc. of the solution add a few drops hydrazine sulfate, sufficient 6 N ammonia to give 1 to 2 cc. in excess, 0.2 cc. of rhodanine and acidify, after **five** minutes' standing, with 30% acetic acid. The cuprous copper reacts even in the ammoniacal medium with the indicator; the color is reddish-violet (100 mg. of copper per liter) or orange-brown (10 mg. and less); sensitivity, 0.5 mg. of copper per liter. The colors are more pronounced after acidifying with acetic acid. Even a solution containing 0.3 mg. of copper per liter gives a distinct red-brown color; sensitivity, 0.1 to 0.2 mg. of copper per liter. The blank shows a yellow to brownish-yellow tinge. In order to reach the maximum sensitivity, it is necessary to let the ammoniacal solution stand for five minutes before adding the acetic acid. The reaction is so extremely sensitive that in all samples of distilled water in the laboratory, the presence of 0.2 to 0.4 mg. of copper per liter could be shown. In the experiments described in this paper, conductivity water or redistilled water from glass vessels was used as a solvent. Water thus obtained gave a negative test for copper. The reaction according to the above procedure is very suitable for the detection of copper in the presence of other cations (silver and mercury excepted). One part of copper in the presence of 2000 parts of lead, bismuth, cadmium, nickel, cobalt and manganese, respectively, could be detected easily. The precipitate formed in the presence of lead or bismuth does not interfere.

Traces of iron do not interfere. Larger amounts can be made harmless by acidifying the ammoniacal solution with phosphoric acid instead of acetic acid. The hydrous ferric oxide goes into solution as colorless complex ferric phosphate. A solution containing 1 mg. of copper and 100 mg. of ferric iron in a liter gave a distinct test for copper. It should be mentioned that the color of the cuprous compound of rhodanine is less stable in phosphoric acid than in acetic acid. It seems that the reaction according to the general procedure is very suitable for the detection of traces of copper in distilled and tap water. The copper content can be approximated by using solutions of known content for comparison.

After this work was finished, an abstract of a paper of O. Funakoshi[3] appeared in *Chemical Abstracts.* It is only stated there that cuprous copper gives a reddish-violet precipitate with rhodanine at about the same sensitivity in neutral or slightly acid solutions. Colors are obtained with concentrated solutions of cupric copper, but the products are much more soluble in water.

III. Recently S. G. Clarke and B. Jones[4] published a note concerning a new and very sensitive reaction for copper. The solution, which must be free from chloride, is neutralized and rendered faintly acid (1 drop of dilute sulfuric acid in excess) and placed in a 100-cc. Nessler glass. One gram of ammonium persulfate is dissolved in the solution; 1 cc. of a saturated alcoholic solution of dimethylglyoxime, 0.5 cc. of 0.5% silver nitrate and 2% of a 10% aqueous solution of pyridine are added and the whole stirred. Copper gives a reddish-violet color. The reaction is quite specific and sensitive to 0.1 mg. of copper in a liter. The author was able to confirm more or less the statements of Clarke and Jones. In working with 10 cc. of solution a sensitivity of 0.3 mg. of copper in a liter was noticed. **A** serious

[3] Funakoshi, Mem. *Coll. Sci., Kyoto Imp. Univ., 12,* 155 (1929); C. *A., 23, 4644* (1929).

[4] S. G. Clarke and B. Jones, *Analyst,* 54, 333 (1929).

drawback is that chloride must be absent, which limits the application of the reaction very much. Therefore, it was thought worth while to make a search for another oxidizing agent instead of persulfate. Potassium periodate[6] was found to be very suitable. The high price of this salt is no objection, as for each experiment only 4 mg. of potassium periodate are used. A systematic study showed that the amount of periodate and dimethylglyoxime have a marked influence upon the sensitivity of the reaction. In the presence of much periodate, the red color of the copper compound fades fairly rapidly. The periodate probably oxidizes the glyoxime to some product which gives the red color with copper. An excess of periodate oxidizes this compound further to a colorless product. This could be inferred from the fact that if some dimethylglyoxime was added to *a* solution which had become colorless on standing, the red color developed again. It would be interesting to know the composition of the compound which gives the red color with copper. If this oxidation product of dimethylglyoxime could be isolated, it might be expected that it would be a valuable reagent for the detection of traces of copper.

Finally, the following procedure was developed for the detection of traces of copper in distilled water.

Reagents.—Saturated solution of potassium periodate in water (0.35 g. of the salt in 100 cc. of water); 0.1% dimethylglyoxime in alcohol (the saturated solution which Clarke and Jones used contains about 1.6 g. of glyoxime in 100 g. of alcohol and is much too concentrated for our purpose). It may be mentioned that an old solution of dimethylglyoxime which had been kept for some years in an ordinary bottle gave a much less sensitive reaction. The reason was that the solution had become strongly alkaline to phenolphthalein.

Procedure.—To 10 cc. of water add 0.2 to 0.3 cc. of 0.1% dimethylglyoxime and 1 cc. of saturated potassium periodate solution. Observe the color after three to five minutes' standing. A violet-red color shows the presence of copper; sensitivity: 0.1 mg. of copper in a liter ($1:10^7$).

Notes.—(1) It makes no difference whether the dimethylglyoxime or the periodate is added first. In order to avoid confusion with nickel, it is advisable to add the dimethylglyoxime first. (2) The red-violet color develops gradually and attains a maximum sensitivity after about five minutes' standing. After long standing, the color fades. Still the procedure described can be applied for the colorimetric determination of traces of copper in distilled water if comparisons are made within fifteen minutes after addition of the reagents. In this way it was found that distilled water in this Laboratory contained 0.2 to 0.4 mg. of copper in a liter. (3) In working with a larger volume than 10 cc., even smaller amounts than 0.1 mg. of copper in a liter can be detected. (4) Small amounts of alkali chlorides and other neutral alkali salts have no influence upon the reaction. Small amounts of sodium bicarbonate (less than 1 g. in a liter) have no influence; with larger amounts the sensitivity decreases somewhat, but even in the presence of 10 *g.* of sodium bicarbonate per liter, 1 mg. of copper in a liter could be detected easily. (5) Calcium and magnesium, especially in the presence of bicarbonate

---

[6] Potassium periodate has been applied for the oxidation of manganese to permanganate. Compare especially H. H. Willard and L. H. Greathouse, **This** JOURNAL, **39,** 2366 (1917).

(tap water) interfere, as they precipitate with the periodate. This difficulty can be overcome by adding to 10 cc. of water 1 cc. of 4 *N* sulfuric acid and 50 mg. of sodium bicarbonate. In this way it could be shown that the Minneapolis tap water contains less than 0.1 mg. of copper in a liter. It is still more convenient to add a buffer solution to the water instead of the combination of sulfuric acid and bicarbonate. The more acid the solution the less sensitive is the reaction. Finally, it was found that with an acetate buffer of PH 5.8 * 0.2, good results are obtained.

Acetate Buffer.—One hundred cc. of N sodium acetate and 7 cc. of N acetic acid.

Procedure.—To 10 cc. of water, 1 cc. of buffer solution is added and then the glyoxime and the periodate as described above; the sensitivity after standing for five minutes is 0.15 mg. of copper in a liter.

The latter procedure can be applied for the detection of copper in tap water if not more than traces of zinc or lead are present; 10 mg. of zinc in a liter has very little influence (color somewhat weaker than in blank without zinc); in the presence of larger amounts of zinc, the latter is precipitated as zinc periodate and the sensitivity decreases very much. The same holds for lead. A solution with 1 mg. of copper in a liter in the presence of 10 mg. of lead per liter gives a distinct reaction though a somewhat weaker color than without lead. Ferric iron also interferes. Still 1 mg. of copper per liter in the presence of 10 mg. of iron per liter gives a distinct reaction. Addition of 1 to 2 drops of N disodium phosphate (Na_2HPO_4) before the addition of the buffer gives a great improvement. Under these conditions 1 mg. of copper in the presence of 20 mg. of iron per liter can easily be detected. Other cations such as cadmium, zinc or manganese all interfere, as they precipitate with the periodate. Therefore, the rhodanine reaction is of much more general application than the glyoxime reaction. The latter can only be applied in these cases in which the solution does not contain more than traces of other metal salts.

Summary

1. *p*-Dimethylaminobenzylidene-rhodanine is a sensitive reagent for the detection of mercurous mercury and mercuric ions. Slightly ionized mercuric salts produce only a slight color or none.

2. Salts of cupric copper give an orange-reddish or orange-brown color. The latter is more pronounced in cuprous salts. A delicate and simple test based on this reaction and sensitive to 0.1 mg. of copper in a liter has been described. The reaction is very suitable for the detection of copper in distilled water, tap water and in solutions which contain other metal ions.

3. The reaction of Clarke and Jones for copper, using dimethylglyoxime and persulfate plus silver nitrate, has been modified by using a trace of periodate as an oxidizing agent. The reaction is sensitive to 0.1 mg. of copper in a liter and is very useful for the colorimetric determination of traces of copper in distilled water. A somewhat modified procedure has been described for the detection of copper in tap water. The rhodanine test can be more generally applied than the dimethylglyoxime reaction.

THE DIELECTRIC POLARIZATION OF LIQUIDS. IX. THE ELECTRIC MOMENTS OF THE ALKYL HALIDES AND HALOGENATED METHANES

BY C. P. SMYTH AND H. E. ROGERS

RECEIVED DECEMBER 11, 1929 PUBLISHED JUNE 6, 1930

The electric moments of butyl chloride, bromide and iodide and heptyl bromide have been determined with a view to ascertaining the effect of the length of the hydrocarbon chain upon the moment of the molecule and to observing whether the variation from chloride to bromide to iodide is the same in large molecules as in small. At the same time it is possible to study the dependence of the mutual orienting effects of the molecules upon molecular size. The previously unmeasured bromine and iodine substituted methanes have been investigated in order to throw further light upon the mutual repulsion of atoms or groups in the same molecule,

Method of Measurement

The methods of measurement and calculation used in the present work have been described in the first two papers of the series[1] on dielectric polarization, and a subsequently developed cell with four different fixed capacities, which was used in some of the measurements, has been described in a later paper. The dielectric constants[2] were measured with the capacity bridge originally used, a frequency of 5×10^5 cycles, corresponding to a wave length of 600 meters, being employed as before. The errors were similar to those described in the last mentioned paper, dielectric constant values below 5 having a probable error of 0.2% and those above 5 having a probable error of 0.5%. The relative error within a given series of measurements was much smaller in both cases. Since the same type of pycnometer was used as in the earlier work, the probable error in the densities was the same, being about 0.07% in the low temperature determinations and not more than 0.03% in the measurements above 0°.

Preparation of Materials

Heptane.—Pure normal heptane was obtained from the Ethyl Gasoline Corporation. As the boiling point, refractive index, and dielectric constant of a sample were not appreciably different after washing with sulfuric acid, followed by sodium carbonate solution and water, drying over calcium chloride and finally distilling over sodium, the heptane was used without purification.

Benzene.—Merck's C. P. benzene was washed three times with concentrated sulfuric acid, followed by dilute sodium hydroxide solution and water, dried over calcium chloride and crystallized twice; m. p. 5.47°. It was then allowed to stand over sodium and distilled from it; b. p. 80.1°; n_D^{20} 1.50135.

[2] Smyth and Stoops, ibid., **51,** 3312 (1929).

Butyl Chloride.—*n*-Butyl chloride obtained from the Eastman Kodak Company was refluxed gently with concentrated sulfuric acid, distilled, washed with water, dried over calcium chloride and distilled; b. p. 77.5"; n_D^{20} 1.40148.

Butyl Bromide.—n-Butyl bromide obtained from the Eastman Kodak Company was washed with cold concentrated sulfuric acid, then with sodium carbonate solution, dried over calcium chloride and distilled; b. p. 101.0°; n_D^{20} 1.43985.

Butyl Iodide.—*n*-Butyl iodide obtained from the Eastman Kodak Company was shaken once with ice-cold concentrated sulfuric acid and eight times with dilute sodium hydroxide, washed with water, dried over calcium chloride and distilled at reduced pressure; d_4^{20} 1.616.

Heptyl Bromide.—*n*-Heptyl bromide obtained from the Eastman Kodak Company was washed with cold concentrated sulfuric acid, sodium carbonate solution, and water, dried over calcium chloride and distilled at reduced pressure. A fraction boiling within a 0.2" interval was taken; d_4^{16} 1.144; n_D^{20} 1.44972. "International Critical Tables" give d_4^{16} 1.133, in good agreement with the value d_4^{16} 1.134 obtained for the unpurified material. The purified material was treated again in the same way and the product obtained had the same density as before, d_4^{16} 1.144. This was, therefore, concluded to be the correct value for the pure material.

Methylene Bromide.—Material obtained from the Eastman Kodak Company was washed with dilute sodium carbonate solution and water, dried over calcium chloride and distilled at reduced pressure; d_4^{20} 2.4921; n_D^{20} 1.53559.

Methylene Iodide.—Kahlbaum's methylene iodide was washed with dilute sodium hydroxide solution and water, dried over calcium chloride and distilled at reduced pressure; d_4^{25} 3.3104.

Bromoform.—Material obtained from the Eastman Kodak Company was washed with concentrated sulfuric acid, followed by dilute sodium hydroxide solution and water, dried over anhydrous potassium carbonate and distilled at reduced pressure; d_4^{20} 2.889.

Iodoform.—Kahlbaum's iodoform, which melted at 119.0°, was used without purification.

Experimental Results

The densities, which showed but slight departure from a linear dependence upon temperature, were determined at approximately 25° intervals and the dielectric constants at 15° intervals. The majority of the densities, d, and dielectric constants, ϵ, in Table I were obtained at 10° intervals by graphical interpolation, and the polarizations, P_2, of the polar components were calculated from them by means of the equations

$$P_{12} = \frac{\epsilon - 1}{\epsilon + 2}\,\frac{c_1M_1 + c_2M_2}{d} \text{ and } P_2 = \frac{P_{12} - P_1}{c_2} + P_1$$

in which P_{12} is the polarization of the mixture, and c_1 and c_2, M_1 and M_2, and P_1 and P_2 are, respectively, the mole fractions, molecular weights and polarizations of the individual components. The solutions of methylene bromide, methylene iodide and bromoform were measured at the same two or three fixed temperatures and, therefore, require no interpolation to make them comparable.

Discussion of Results

When the P_2–c_2 curves are extrapolated to $c_2 = 0$, the values of P obtained, designated as P_∞, give a straight line when multiplied by T and

plotted against T (Fig. 1), as required by the Debye equation: $P = a + b/T$, in which $a = P_E + P_A$, the sum of the electronic polarization, P_E, and the atomic, P_A, and $b = 4aNp^2/9k$, N being the Avogadro number, **6.061** X 10^{23}, μ, the electric moment, and k, the molecular gas constant, **1.372** X 10^{-16}. When the equation is written in the form $(P, - a)T = b$, it is evident that it can be tested by the constancy of $(P, - a)T$, the values of which are given in Table II.

In the case of butyl iodide, a small decrease in the values of $(P, - a)T$ accompanies rising temperature at the higher temperatures, probably because of slight decomposition of the substance. Below 30° for the butyl iodide and over the entire temperature range within which the other substances are liquid, the values of $(P, - a)T$ are constant, giving further proof, if further proof is needed, of the applicability of the Debye equation to polar liquids highly diluted by non-polar.

The best values of *a* and b were obtained from the curves in Fig. 1 and the electric moments were then calculated from b. The values of P_E at infinite wave length were calculated from the molar refractions given in Landolt–Börnstein (5th ed.) by means of the equation, $P_E = [1 - \lambda_0^2/\lambda^2][(n^2 - 1)M/(n^2 + 2)d]$, in which *n* is the refractive index for light of wave length λ, λ_0 is the wave length corresponding to a characteristic vibration frequency in the ultraviolet region, and *d* is the density. As dispersion data were not available for heptyl bromide, the value of P_E at infinite wave length was estimated by subtracting 1.0, a difference analogous to those found for the other halides, from 42.20, the molar refraction for the sodium D-line. The result, 41.2, should be within 0.3 of the correct value. The atomic polarization, P_A, has been obtained by subtracting P_E'from *a*. The results are shown in Table III.

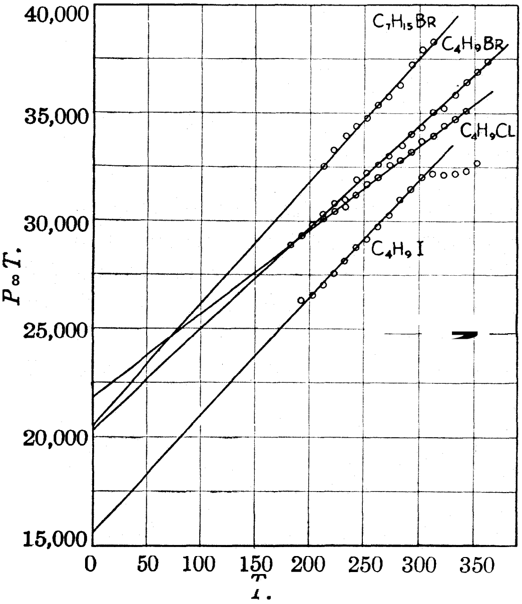

Fig. 1.—Variation of $P_\infty T$ with *T*.

TABLE III

VALUES OF FUNDAMENTAL CONSTANTS

	a	P_E	P_A	*b*	$\mu \times 10^{18}$
C_4H_9Cl	38.5	24.9	13.6	21920	1.88
C_4H_9Br	46.9	27.6	19.3	20300	1.81
C_4H_9I	54.2	32.3	21.9	15530	1.59
$C_7H_{15}Br$	56.7	41.2	15.5	20610	1.83

The values of P_A are surprisingly high and may be considerably in error, as a small change in the curve has a large effect upon *a* and, consequently, an even greater effect upon the difference, $a - P_E$, but the accuracy of the curves is such as to render a small P_A for these substances highly improbable. Moreover, a value of 12.3 has been determined with some accuracy for ethyl iodide[2] and a rough value of 11 has been found for ethyl bromide.[1] Preliminary measurements carried out in this Laboratory upon heptyl bromide in the solid state indicate a value for P_A of the same order of magnitude as that here found. In the butyl halides, the values increase from chloride to bromide to iodide, but, in view of the uncertainty of the values, great significance cannot be attached to this.

The substituted methanes were measured over too limited a range of temperature to permit of an accurate determination of a and b by plotting P_∞ against $1/T$. As is very commonly done, a was assumed equal to MR_D, the molar refraction for the D-sodium line, and the electric moment was calculated from $P_\infty - MR_D$. The values of MR_D for methylene bromide and bromoform were taken directly from Landolt–Börnstein (5th ed.), while those for methylene iodide and iodoform were calculated as the sum of the atomic refractions, the accuracy of the values thus obtained being quite sufficient for the purpose. Values of the electric moments calculated at different temperatures showed very close agreement except in the case of iodoform, the results for which are less accurate than the others because of its low solubility and decomposition in solution. The small values of the difference $P_\infty - MR_D$ for this substance increase the relative error of the moment. At 20° the value obtained was 0.84×10^{-18}, and at 70°, 0.77×10^{-18}. The necessary neglect of P_A in calculating this moment causes the mean value 0.8×10^{-18} given in Table IV to be too high. Indeed, if iodoform had a value of P_A comparable to those given in Table III, its moment would be zero. It seems probable that the true value of the moment of iodoform is little more than half the value given in Table IV, while the values for methylene bromide and iodide and bromoform are also a little high because of neglect of P_A, which, however, affects these moments less than that of iodoform because of their higher values. As most investigators have neglected P_A[3] in calculating the moment, it seems best, for the sake of comparison, to use these values, bearing in mind the fact that they are a little high, rather than to subtract fictitious values of P_A of reasonable size, which might be expected to give more nearly correct values for the moments. The good agreement of the values at different temperatures, except in the case of iodoform, indicates that they are not far from the true values. The significance of the results shown in Table IV, together with the moments of other similar molecules, will be discussed presently.

Earlier papers have discussed the variation of the polarization with concentration as evidence of the mutual effects of the polar molecules in producing orientation or association.[4] It has been shown that the orienting effect of the molecules of a liquid upon one another depends not only on the size of their electric doublets, but also upon the location of the doublet or doublets in the molecule and upon the geometrical shape of the molecule. It is interesting to compare these effects in the closely related molecules investigated in the present work.

The molecule of an alkyl halide may be regarded as containing a single electric doublet located in the neighborhood of the bond between the halogen and the carbon chain. The effect of this doublet upon neighboring molecules depends upon its moment and upon the sizes of the halogen and the hydrocarbon chain which screen its force field. The deviation of the P_{12}–c_2 curves from linearity has been used as a qualitative indication of association or orientation. The effect is so great in hexane–ethyl bromide mixtures[1] that the curve actually passes through a maximum, which flattens out with rising temperature as increased thermal agitation reduces the molecular orientation. The moment of the ethyl iodide molecule is slightly smaller than that of the bromide and the screening effect[2] of the iodine is somewhat larger than that of the bromine. Consequently, the mutual effect of the molecules is not sufficient to cause a maximum in the P_{12}–c_2 curves as in the case of ethyl bromide. When butyl chloride, bromide and iodide are compared with one another, the differences are not pronounced as the screening effect of the large butyl groups so reduces the intermolecular action that the differences between the effects of the halogens are small.

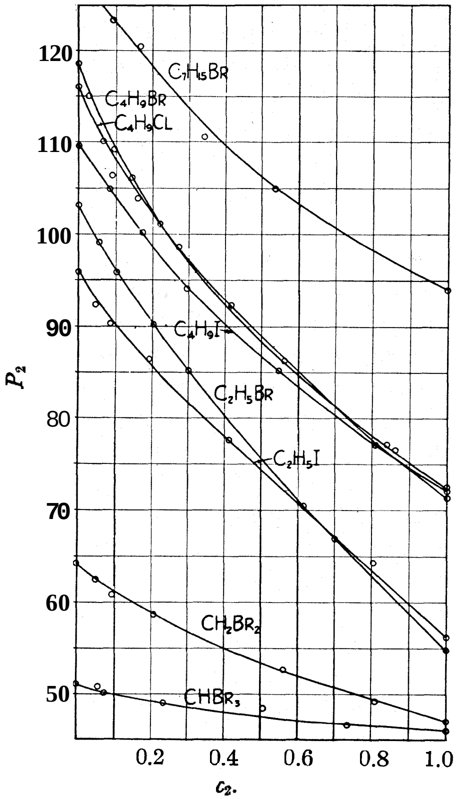

Fig. 2.—Variation of P_2 with concentration at 10°.

In comparing the P_{12}–c_2 curves for different substances, it must be borne in mind that differences in P_E affect the relative rate of change of P_2 with c_2 and hence the shape of the P_{12}–c_2 curves. Indeed, this seems to be the principal cause of the differences in these curves, for the P_2–c_2 curves in Fig. 2 show only small differences in curvature. The heptyl bromide curve has the smallest slope. The butyl halide curves have a slightly greater slope and lie close together. The ethyl bromide and ethyl iodide curves are very similar, the slope of the latter being slightly less. Differences in P_E and P_A for the different substances are responsible for the spacing of the curves.

At the bottom of the diagram lie the curves for methylene bromide and bromoform, which, because of the small size of their moments and the screening of the doublets by the bromines, show little intermolecular action. The corresponding iodine compounds are not shown, as some of their P_2 values are in error because of decomposition.

The temperature variation of P_2 for the pure substance gives further evidence of the intermolecular action. The values of P_2 for pure ethyl bromide increase slightly with rising temperature until the boiling point is approached, instead of decreasing according to the requirements of the Debye equation, because increasing thermal agitation decreases the intermolecular action which reduces the polarization. In ethyl iodide the intermolecular action is enough smaller to permit decrease of polarization with rising temperature even at the lower temperatures where its effect is greater. In the butyl halides the decrease of P_2 with rising temperature is greater and, in heptyl bromide, still greater.

The moments calculated from the values of P_∞ are given in Table IV together with a number of values previously determined, the latter being followed by their literature references.

The influence of the length of the carbon chain upon the moment of the molecule has been discussed previously, but a quantitative treatment of the theory has been attempted in the present investigation.[5] As the result of the treatment is not conclusive, the details are not given. The moments induced throughout the molecule by the principal doublet at the end of the chain and the moments induced in turn by these induced moments are calculated from the polarizabilities of the different parts of the molecule, which are obtained from the refractions associated with the bonds.[6] The calculated increase in moment due to the direct effect of the principal doublet is very small in the third carbon of the chain and negligible thereafter, which is in agreement with the absence of any increase in the observed

---

moments with increase in the size of the alkyl group beyond ethyl. However, the secondary moments induced by those already induced by the principal doublet are calculated as continuing with decreasing size through a chain much longer than two carbons. This would cause an increase in moment with increase in the size of the alkyl group far beyond ethyl, which the agreement of the values for the ethyl and the butyl halides and, in the case of the bromides, the heptyl as well, shows to be non-existent. The rough approximations necessary in these calculations are much more apt to cause serious error in the case of the secondary moments. Indeed, they are quite sufficient to cause the not inconsiderable values calculated for these secondary moments, which the experimental results show to be negligible in the longer molecules. In view of this, it may be concluded that the results of theory and experiment are not irreconcilable, but the failure to obtain positive agreement is unsatisfactory.

The moments of the chlorinated methanes were considered at a time when very inadequate values were available.[7] It was shown that, if the tetrahedral structure of the molecule remained undistorted, the moment of methylene chloride should be 1.15 times that of methyl chloride, which should be identical with that of chloroform, while that of the symmetrical carbon tetrachloride molecule should be zero. The same relations should, of course, hold among the bromine and iodine compounds. Sänger obtained a higher value for methyl chloride than that given in Table IV, but, as Sircar's value 1.69×10^{-18} agrees well with an unpublished result obtained by Dr. S. O. Morgan, the value 1.7×10^{-18} has been adopted as correct.

The deviations of the observed values from those calculated on the basis of an undistorted tetrahedral structure may be conveniently explained by resolving the system of charges making up the methylene halide molecule into two doublets with their axes in the two imaginary lines joining the halogen nuclei to the carbon nucleus. The moment of the molecule, as a whole, is the resultant of the moments of these two doublets and is, of course, smaller the larger the angle between the axes of the doublets. The distance between a carbon nucleus and the nucleus of an attached chlorine atom is calculated to be 1.70 Å.[8] If there were no distortion of the tetrahedral structure of methylene chloride, the angle between the axes of the two doublets would be 110° and the distance between the two chlorine nuclei would, therefore, be 2.78 Å. The radius of the chlorine atom calculated by Huggins[9] from x-ray data is 0.97 Å., from which the distance between the outermost electrons in the two chlorines, a very vague quantity, would be calculated as 0.84 Å. A quantity more significant for these considerations is the atomic diameter obtained from the kinetic theory of gases, which

---

[7] **Smyth,** *Phil. Mag.*, 47, 530 (1924).

[8] **Pauling,** *Z. Krist.*, 67, 377 (1928).

[9] **Huggins,** *Phys. Rev.*, 28, 1086 (1926).

might be expected to set a limit to the distance of nearest approach of the chlorine nuclei in the absence of strong forces of compression. Approximate values for this diameter may be calculated by an indirect method. The radius of the collision sphere of the argon atom determined by Rankine and Smith[10] from viscosity measurements is 1.44 Å. as compared with an atomic radius 0.93 Å. calculated by Huggins. If a proportionate difference exists for the chlorine atom, the latter has a collision sphere of radius 1.50 Å., which necessitates a distance of 3.0 Å. between the chlorine nuclei in methylene chloride if the spheres are in actual contact and uncompressed, instead of the 2.78 Å. calculated for the undistorted tetrahedral structure. A widening of the angle between the doublet axes from 110 to 124° is, therefore, required and, as a result, the moment of the molecule, as a whole, is reduced from the value calculated for the undistorted molecule, $1.15 \times 1.7 \times 10^{-18}$, to $0.94 \times 1.7 \times 10^{-18} = 1.6 \times 10^{-18}$, in agreement with the observed value. Similarly, in methylene bromide, the distance between the nuclei of the bromines and that of the carbon is given as 1.85 Å., from which the separation of the bromine nuclei may be calculated as 3.02 Å. in the absence of distortion of the tetrahedral structure. The bromine radius given by Huggins is 1.09 Å. and that of krypton is 1.06 Å., while the radius of the collision sphere of krypton found by Rankine and Smith is 1.55 Å., which figures give a radius for the sphere of repulsion of the bromine atom of 1.60 . The nuclear separation of the bromines in methylene bromide should, therefore, be 3.20 Å. instead of 3.02 Å., the angle between the doublets would be widened to 120°, and the resultant moment would be identical with that of methyl bromide. No accurate value for the latter is available in the literature, but an unpublished value determined by Dr. S. O. Morgan agrees within the limit of the experimental error with the moment of methylene bromide in Table IV. For methylene iodide, the distance between the carbon and iodine nuclei is taken as the sum of the atomic radii, 1.96 Å., and the calculation carried out as before. The angle between the doublet axes is found to be 135° and the resultant moment, therefore, 0.78 times that of methyl iodide, or $0.78 \times 1.31 \times 10^{-18} = 1.02 \times 10^{-18}$, in excellent agreement with the value in Table IV.

In similar fashion the chloroform molecule may be resolved into three doublets with their axes in the imaginary lines joining the carbon nucleus to the three chlorine nuclei which lie at the apices of an equilateral triangle. If there were no compression of the spheres of repulsion used in the calculation for methylene chloride, the carbon–chlorine bonds would be stretched even if the tetrahedral structure were so distorted that the carbon and the three chlorine nuclei were in the same plane. It appears reasonable to suppose that the hypothetical atomic spheres are somewhat compressed, but it is evident that the distortion of the tetrahedral structure of the mole-

---

[10] Rankine **and** Smith, *Phil. Mag.*, **42, 601** (1921)

cule is greater than in the case of the methylene compound, which should cause the decrease in moment below that calculated for the undistorted tetrahedral structure to be greater. The separation of the chlorine nuclei is still considerably greater than the atomic diameter estimated from x-ray data, so that there is no need to suppose that the electron shells are appreciably deformed. This is in harmony with the fact that the atomic refraction of chlorine shows no significant variation between molecules containing one, two, three and four chlorines attached to the same carbon,[11] which would certainly not be the case if the electron shells of the halogens suffered increasing deformation as the number of halogens attached to one carbon increased.

Calculation leads to similar conclusions for bromoform and iodoform, although the distortion of the tetrahedral structure in the bromoform molecule should be less than in the molecules of the other two substances. Table IV shows the much lower values for the trihalogenated molecules. The moment of bromoform differs from Morgan's unpublished value for methyl bromide, to which it should be equal if the tetrahedral structure were undistorted, by an amount smaller than the differences observed for the chlorine and iodine compounds, thereby conforming with the result of the calculation. As the inductive effect of a doublet in one part of the molecule upon the rest of the molecule has been disregarded in these calculations and in view of the speculative nature of the argument concerning the atomic dimensions and the possible errors in some of the experimental values of moments quoted, the excellence of the agreement between the observed and the calculated moments of the methylene compounds must be somewhat fortuitous. It is evident, however, that the theory of the distortion of the molecule by repulsion explains satisfactorily the moments of the halogenated methanes.

Summary

The dielectric constants and densities of several alkyl halides and halogenated methanes in heptane or benzene have been determined over a wide range of temperature, and the data have been used to calculate the polarizations of the substances and the electric moments of their molecules.

The polarizations show that the orientation or association of the polar molecules depends upon the size of the electric moments of the molecules and the screening of their doublets by the molecular structure.

In the alkyl halides no measurable increase of electric moment accompanies increase of the number of carbon atoms beyond two.

In the di- and tri-halogenated methanes, repulsive forces between the halogens distort the structures and reduce the moments of the molecules.

THE EFFECT OF SEVERAL FACTORS ON THE SOLUBILITY OF TARTRATES

BY P. H. RICHERT

RECEIVED DECEMBER 30, 1929 PUBLISHED JUNE 6, 1930

During investigations on the removal of tartrates from certain grape products, it became necessary to determine the solubility of tartrates under certain conditions. Potassium bi-tartrate and neutral calcium tartrate were the salts particularly concerned.

A review of the literature indicates that considerable data already exist on tartrate solubilities, although much of the data desired in our studies could not be found in published form.

The change of solubility with temperature has been determined for the range from 0 to 100°[1] for both salts. Solubilities in the presence of certain ions and in certain acids have been determined to some extent. The published data indicate that ions common to the salt concerned usually depress the solubility, and that neutral ions have little effect on the solubility.

No information could be found on the effect of neutral potassium tartrate on the solubility of potassium bi-tartrate. In this case the added salt has two ions in common with the salt studied. It would be expected that the solubility of the potassium bi-tartrate would be decreased to an appreciable extent by the presence of neutral potassium tartrate. The results tabulated below and shown in Fig. 1 indicate this to be the case to a very marked degree, especially at the lower concentrations of the neutral tartrate.

TABLE I

SOLUBILITY OF $KHC_4H_4O_6$ IN THE PRESENCE OF $K_2C_4H_4O_6$ AT 20°

.00805	.00354	.00260	.0357

The fact that very small concentrations of neutral tartrate greatly affect the solubility of the bi-tartrate may explain the formation of large deposits of cream of tartar in juice from mature grapes, and in grape juice after standing for some time, since under these conditions the acidity is decreased, forming the neutral tartrate which depresses the solubility of the remaining bi-tartrate.

.0238	.0485

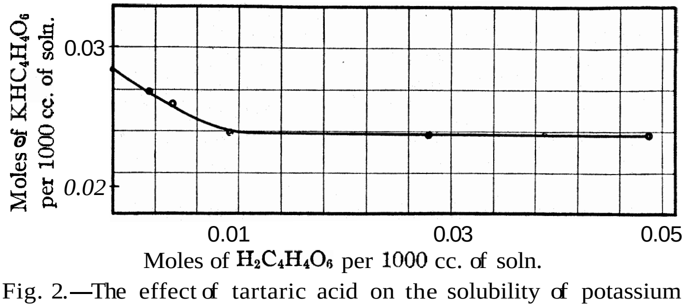

Fig. 2.—The effect of tartaric acid on the solubility of potassium bi-tartrate in water at 20°.

From the data of Table II considered in comparison with Table I, it would seem that the effect of tartaric acid is due chiefly to the ions produced, rather than to the tartaric acid molecule itself.

The solubility of potassium bi-tartrate was also determined in invert sugar solutions. The results appear in Table III and in the solid curve of Fig. 3.

TABLE III

SOLUBILITY OF $KHC_4H_4O_6$ IN INVERT SUGAR SOLUTIONS AT 20°

[a] Ref. 1, pp. 221, 222.

The dotted line in the curve indicates the theoretical solubility curve, if the solvent action were due solely to the water present. Thus it can be seen that the presence of the sugar has a slight solvent action on the potassium bi-tartrate.

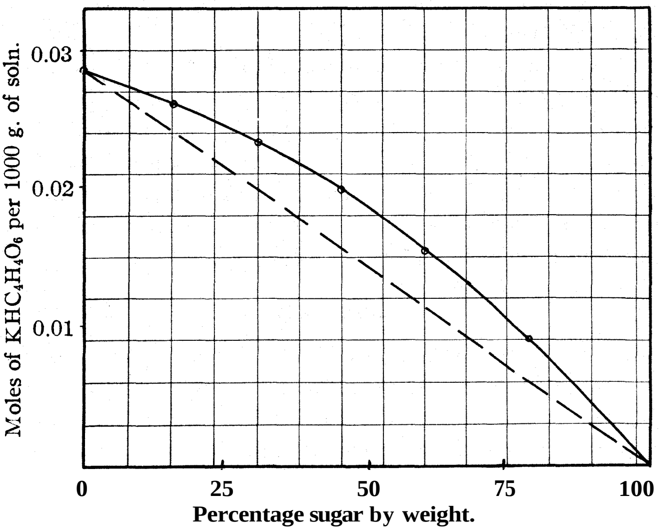

Fig. 3.—The solubility of potassium bi-tartrate in invert sugar solutions at 20°.

For calcium tartrate the solubility in hydrochloric and tartaric acids[2] has been determined for 18°. The solubility in tartaric acid solutions was

---

[2] Ref. 1, pp. 221, 222.

determined for 20° and the results are given in Table IV and in Fig. 4. The two curves seem to agree quite well.

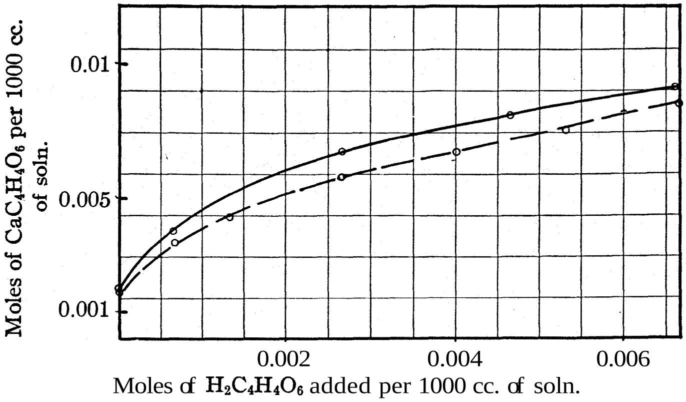

Fig. 4.—The solubility of calcium tartrate in dilute tartaric acid solutions: solid line is solubility at 20"; dotted line is solubility at 18° (Ref. a, Table IV).

Method of Analysis.—In all cases the salt of which the solubility was to be determined was added to the solution in excess. The mixture was stirred for at least an hour with a mechanical stirrer, and allowed to settle for several hours at 20° before filtering and analyzing. No precaution was taken to exclude the presence of carbon dioxide from the air, but since the solutions were all acid it was believed that carbon dioxide would have little effect. All of the data for the potassium bi-tartrate were obtained by titration with $N/10$ sodium hydroxide. For the calcium tartrate solubilities, ash determinations were made on the solutions.

Summary

The solubilities of potassium bi-tartrate in the presence of some of the substances with which it is associated in grape juice were determined. Some of these, especially the neutral tartrate, have a rather striking effect on the solubility of the bi-tartrate and this fact may help to explain the rather peculiar behavior of cream of tartar in grape juice.

Some solubility data on calcium tartrate were obtained which seem to agree well with previously published data.

THE ELECTRICAL CONDUCTANCE OF AQUEOUS SOLUTIONS OF BARIUM CHLORIDE AS A FUNCTION OF THE CONCENTRATION

BY GRINNELL JONES AND MALCOLM DOLE

RECEIVED DECEMBER 31, 1929 PUBLISHED JUNE 6, 1930

Introduction

This is the third of a series of papers on the properties of solutions of barium chloride and is part of an extensive experimental investigation of the properties of these solutions covering a wide range of concentration which was undertaken in the hope that the data when studied in the light of the new Debye–Hückel theory of electrolytes would reveal new laws for the variation of these properties with the concentration or new relationships between the properties. Barium chloride is well adapted for this purpose because the theory and the known facts indicate that the influence of interionic attraction increases greatly with the valence. The first paper[1] in this series records data on the transference numbers of the barium ion covering the range 0.01 to 1.0 molal which resulted in the discovery of a new law for the variation of the transference numbers with the concentration. The second paper[2] contains new data on the viscosity of these solutions covering the range 0.005 to 1.0 molal and a new general law for the variation of the viscosity of solutions of electrolytes with the concentration. In this paper are recorded data on the conductance of this salt covering the range 0.001 to 1.0 molal which have suggested an equation for the variation of the conductance with concentration. All of these properties of these solutions turn out to be functions of the square root of the concentration.

Experimental Part

The barium chloride was purified as already described.[3] To prepare neutral solutions of known composition the salt was dried by heating to a low red heat in a current of hydrochloric acid in a Richards[4] bottling apparatus, and cooled in a vacuum. The solutions were made by weight, using conductivity water of known conductance. After the salt had dissolved and had been well mixed by shaking, a portion was withdrawn to test its neutrality. It was found that methyl red when added to solutions of barium chloride was sensitive to a trace either of hydrochloric acid or of barium hydroxide. Therefore, methyl red was added to the sample of the solution prepared as described above and also to a solution of approximately the

same composition prepared from crystallized unheated barium chloride and the solution was rejected if the two could be distinguished. After the proper technique of drying the salt had been developed the solutions always gave the same color.

The stopper was then replaced by a special ground-glass stopper provided with two tubes, one of which extended to the bottom of the bottle and was connected by a ground joint with the conductivity cell. Air which had been bubbled through a barium chloride solution of approximately the same concentration was then blown into the bottle through the other tube. thus forcing the solution into and through the conductivity cell until the cell was well rinsed without danger of changing the composition of the solution by evaporation. The cell was then tightly closed by its own glass stoppers and placed in the thermostat at 25.00° and its resistance measured. It was then refilled and measured again. Only rarely was any change noted and in such cases the rinsing was repeated until successive fillings gave concordant results. The density of the solution was then determined by an Ostwald pycnometer to permit calculation of the concentration in moles per liter. The resistance measurements were made by the special bridge already described by Jones and Josephs[5] using all precautions recommended in that paper. The results with 1100 cycles and with 2500 cycles agreed within 0.01%.

All solutions more dilute than 0.01 molal were prepared by dilution by weight of a 0.01 molal solution.

Three different cells of the Washburn pipet type with cell constants of 144.65, 51.4953 and 1.2326 were used. The cell constants of the first two were determined by means of a 0.01 N solution of potassium chloride in accordance with the suggestion of Kraus and Parker? The cell constant of the third cell was found by intercomparison with the second. The standard reference solution had 7.4945 g. of potassium chloride dissolved in 1000.00 g. of water (both weighed in air uncorrected to vacuum). The specific conductance of this solution was taken to be 0.0128988 plus the specific conductance of the water used. This value corrects for a slight inconsistency in Kohlrausch's figures for the N KC1 and the 0.1 N KC1 standards of reference but it is based on Kohlrausch's absolute measurements.

We are aware that H. C. Parker and E. W. Parker[7] have concluded as the result of a careful investigation that the absolute measurements of the specific conductance of the standardizing solutions by Kohlrausch are in error by more than 0.1%. Parker and Parker have utilized fully the best of the earlier technique and have made important improvements in the details of procedure and valuable suggestions as to definitions of units,

but their bridge assembly has since been shown to be imperfect,[8] and the pipet cells of the type used show an apparent variation of cell constant with the resistance of the solution being measured, which was discovered by H. C. Parker[9] and Randall and Scott.[10] This Parker effect is ascribed by him to absorption at the electrodes and walls but he did not succeed in finding a practical means of avoiding the effect. Parker and Parker believe that this effect was present in the cells used in their absolute measurements (Ref. 7, p. 324), and although they attempt to minimize this error by the device of subtracting the measured resistance of two cells, they show a commendable lack of enthusiasm for this procedure, which is based on the unproved (and in our judgment unprovable) assumption that the electrode effects cause an equal error in the resistance of two cells of different cell constant and design. It therefore seemed to us premature to adopt the figures of Parker and Parker for the specific resistance of solutions of potassium chloride as a basis for determining the cell constant unless and until their results are confirmed by an independent investigation. Our opinion in this matter is not altered by the fact that the figures of Parker and Parker are used as the basis for conductance data in Vol. VI of the "International Critical Tables," which has been published during the final stages of the preparation of the manuscript of this paper.

It is believed that uncertainty of greater than 0.02% in the data on barium chloride solutions due to the Parker effect[g] was avoided by always selecting a cell which would give a resistance of above 1000 ohms and by the use of the Jones and Joseph's bridge.[11]

The data are recorded in Table I, in which each horizontal row represents a different solution and in which the columns give in order (1) the concentration in gram molecules ($BaCl_2$) per liter, *c*, based on weights in *vacuo* (the molecular weight of barium chloride being taken as 208.284); (2) the square root of the concentration, $\sqrt{c}$; (3) the density, d, absolute with vacuum corrections applied; (4) density computed from the formula given below; (5) the difference between the observed and computed density; (6) the measured molecular conductance, Λ obs.; (7) a correction to give the conductance at the nearest round concentration, $\Delta\Lambda$; (8) the corrected values at the round concentration indicated, Λr. The density

[11] The question of the cause and cure for the Parker effect has been investigated further in this Laboratory since the experimental work described in this paper was completed. This later work has disclosed that although the cells used in the research described in this paper embodied all principles of good design known at the time, they are not as free from Parker effect as some cells built in this Laboratory subsequently. A paper on cell design including a discussion of the Parker effect is now in preparation.

data when treated by the method of least squares gave $d = 0.99707 + 0.18224c - 0.00421c^2$. The maximum deviation between the observed results and computed results is 0.00006 and the average deviation is 0.00003.

The uncorrected data shown in Col. 6 are represented in Fig. 1 by the center points of the circles. In most cases the two independent determinations on solutions of nearly the same concentration are shown by a single circle because the slight differences are not visible on the scale which can be printed.

The corrections to bring the values to round concentrations were determined by plotting A against $\sqrt{c}$, the slope of the curve $d\Lambda/d\sqrt{c}$ was found at each point and the correction $M = (d\Lambda/d\sqrt{c})\Delta\sqrt{c}$ computed and applied. It will be noticed that after correction to a common round concentration each pair of solutions of similar concentration agree very well, the average deviation being only 0.025 ohm. These differences are greater in the most dilute solutions, as is to be expected on account of the greater experimental difficulties in working with dilute solutions.

Interpretation of the Data

Having obtained a set of data covering a wide range of concentration it becomes of interest to attempt to find an equation for the molar conductance as a function of the concentration which is in harmony with the data and of a form which is as simple as possible and which shows no abnormal or improbable behavior as the concentration approaches zero; and to use the best equation which can be found to estimate the limiting conductance at zero concentration. It seemed hardly necessary to carry out the laborious calculations with all of the numerous equations which have been proposed because nearly all of the empirical equations which antedate the Debye-Hückel theory are now known to be inaccurate or to be in harmony with the facts only within a quite limited range of concentration.

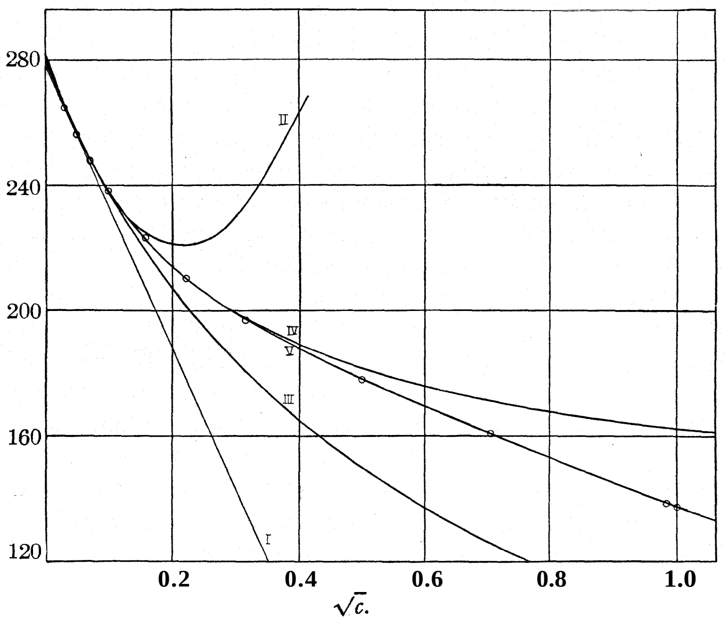

Fig. 1.—I, Kohlrausch, A = $278.75 - 449.9\sqrt{c}$; II, Debye–Hückel–Onsager, A = $280.64 - 550.12\sqrt{c} + 1265.1c$; III, Walden, A = $278.69/(1 + 1.715\sqrt{c})$; IV, Lattey, A = $281.22 - [602.8\sqrt{c}/(1 + 4.069\sqrt{c})]$; V, Jones and Dole, A = $282.13 - [636.3\sqrt{c}/(1 + 4\ 628\sqrt{c})] - 31.13\,c$.

Recently Debye and Hückel[12] have proposed a theory of electrolytes based on the hypothesis that ionization is substantially complete and that the electric forces between the ions which Arrhenius assumed to be negligible play a significant role.

The mathematical complexities of deriving definite equations on this

---

basis are very great and compel them to neglect some known physical factors in the problem and to introduce some relatively simple approximate mathematical relationships instead of using the rigid but more complicated functions. Their conclusion is that the equation

$$\Lambda = \Lambda_0 - A\sqrt{c} \tag{I}$$

is the limiting law to which the measured conductance will approach more and more closely as the concentration approaches zero. The constant A has a very complicated theoretical significance, being dependent upon the dielectric constant of the solvent, the temperature, the mobilities at infinite dilution and valence of all of the ions present, as well as several universal constants. However, the value of A as well as Λ_0 is in practice chosen to fit the data. It should be noted, however, that the theory predicts that the most important factor in determining the variation of A from salt to salt is the valence type and this prediction is borne out in practice. Indeed it has long been known that the conductance–concentration curves of all salts of the same valence types (in the absence of abnormalities such as complex formation) tend to run parallel and near together, whereas the curves for salts of different types diverge markedly.

This Equation I was discovered long ago by Kohlrausch,[13] was much used by him in extrapolating to zero concentration and is commonly called Kohlrausch's square root law. The most convenient way to test the validity of this law is to plot the observed values of the conductance against the square root of the concentration and observe how closely the points fall on a straight line. A straight line (I in Fig. 1) having the equation $\mathbf{A} = 278.75 - 449.9\sqrt{c}$, passes through the values of A at 0.001 and 0.0025, but this line deviates greatly from the data at all higher concentrations. Kohlrausch's law can, therefore, only be regarded as a limiting law which is approximately obeyed in very dilute solutions. This is evident from Col. 5 of Table II and from Fig. 1, in which our data are plotted as points within the circles and Curve I represents the equation given above. Space does not permit a detailed recapitulation and analysis of the evidence from other cases in the literature but much can be found. The case of barium chloride cited from our own data is typical rather than exceptional or peculiar.

But although Kohlrausch's law can only be regarded as a limiting law, the experimental evidence in its favor and the theoretical support which it receives from the work of Debye and Hiickel make it extremely probable that the true equation expressing the conductance as a function of the concentration when plotted A against $\sqrt{c}$ will be asymptotic at $c = 0$ with a straight line having finite negative slope. In attempting to find an

The next form of the conductance function to be considered was a modification of Kohlrausch's law having the form

$$A = \Lambda_0 - A\sqrt{c} + Bc \qquad \text{(II)}$$

This equation obviously meets the asymptotic test given above. It was first suggested by Debye and Hiickel in their early paper and used as a means of extrapolating to infinite dilution, but since the last term has no theoretical basis it may be regarded as an empirical equation. Debye and Hiickel chose values of Λ_0, A and B empirically to fit the data. Onsager[14] points out that the space lattice arrangement postulated by Debye and Hiickel must be disturbed by Brownian movement and has worked out a mathematical technique to make allowance for this disturbance and to take account of the combined relaxation of the ionic atmospheres due to the

---

[14] L. **Onsager**, *Physik. Z.*, *27*, **388** (1926); 28, 277 (1927); *Trans. Faraday Soc.*, 23, 341 (1927).

diffusion of the ions in respect to one another and to enable the effect of electrophoresis to be calculated without a knowledge of ionic radii. Onsager's derivation leads to an equation of the form of Kohlrausch's square root law in which the slope A is a complicated but explicit function of the dielectric constant and viscosity of the solvent, the temperature and the valencies and mobilities at infinite dilution of all of the ions present, as well as several universal constants. Ionic radii are, however, not involved directly. Assuming the conductance of the ions at infinite dilution to be known, Onsager has computed the slope of the Λ–$\sqrt{c}$ curves for many salts with results which agree within about 10% with the slopes found experimentally; but although this does not solve the problem of extrapolation to infinite dilution, because for this purpose we need to know the slope with an uncertainty of much less than 10% in order to find the limit of the conductance at infinite dilution, nevertheless it is of much interest.

Onsager recognizes that an equation of the form of Kohlrausch's law which he has derived is only valid as a limiting law and in order to extend its range of validity he follows Debye and Hückel in adding a term, $+Bc$, linear with the concentration. The equation

$$\Lambda = \Lambda_0 - A\sqrt{c} + Bc \qquad \text{(II)}$$

is an improvement over the Kohlrausch equation but no claim is made by its proponents that it is valid above 0.01 molal. We have found that an equation of this form

$$\Lambda = 280.64 - 550.12\sqrt{c} + 1265.1c$$

fits our data on barium chloride fairly well up to 0.01 molal (see Curve II in Fig. 1 and Cols. 6 and 7 in Table II) but it fails badly in higher concentrations. This is the equation of a parabola (when plotted Λ against $\sqrt{c}$) with a minimum value of Λ at $\sqrt{c} = 0.217$ or $c = 0.048$, whereas the data show no indication of the occurrence of a minimum. Beyond this minimum this equation gives grossly erroneous results. It is quite evident from the curves and computations that the term $+Bc$ is at fault.

The complicated and difficult derivations of this equation evidently and admittedly fail to account adequately and fully for all of the factors in the problem. In these circumstances we thought it best to attempt to find a valid equation by inductive methods from the data themselves rather than by deductive reasoning from hypotheses.

Walden[15] has proposed an equation of the form

$$\Lambda = \frac{\Lambda_0}{1 + N\sqrt{c}} \qquad \text{(III)}$$

and has presented considerable evidence in its support, especially for non-aqueous solutions. It is easy to show by differentiation that this equation conforms to the asymptotic test described above. The Walden equation

---

[15] P. Walden, *Z. physik. Chem.*, 108, 341 (1924).

can be readily transformed into $1/\Lambda = 1/\Lambda_0 + N/\Lambda_0\sqrt{c}$, which permits its validity to be tested by plotting $1/\Lambda$ against $\sqrt{c}$, and the coefficients to be readily determined. We used our data on barium chloride at c = 0.01 and below to evaluate the constants and thus obtained $A = 278.69/(1 + 1.715\sqrt{c})$. This equation comes much nearer to the experimental values at the higher concentrations than either of the forms already discussed but, nevertheless, it is not within the experimental errors either at low or high concentrations and indeed is not as good at low concentrations as Equation I or II (see Curve III in Pig. 1 and Cols. 8 and 9 in Table II).

Lattey[16] has recently suggested the form

$$\Lambda_0 - \Lambda = \frac{A}{V^{1/2} + N}$$

where $V = 1/c$ and A and N are dependent on the salt chosen and the temperature. This may be readily transformed into

$$\Lambda = \Lambda_0 - \frac{A\sqrt{c}}{1 + N\sqrt{c}} \qquad \text{(IV)}$$

Lattey in a brief paper gives calculations showing that an equation of this form, $\Lambda = 130.01 - [89.47\sqrt{c}/(1 + 1.82\sqrt{c})]$, agrees with the data of Kohlrausch and Maltby on potassium chloride up to 1 molal. He states that he has tested it on many other univalent salts and finds that it conforms to the facts up to 0.1 molal, but does not publish the proof in detail. His paper contains no indication that he has tested his equation on salts of higher valence types. This equation is obviously asymptotic to $\mathbf{A} = \Lambda_0 - A\sqrt{c}$ as $\sqrt{c}$ approaches zero. We then applied the method of least squares to the data on barium chloride up to 0.05 to determine the best values of the coefficients with the result $A = 281.22 - [602.8\sqrt{c}/(1 + 4.069\sqrt{c})]$. As will be seen from Cols. 10 and 11 of Table II and Curve IV in Fig. 1, this equation is a very substantial improvement over the other forms already discussed. The Lattey equation agrees with the data within the experimental error up to 0.05 molal, but if the constants are chosen so as to give good agreement at these concentrations the computed values of A at the higher concentrations are too great.

We noticed that these deviations of the Lattey equation seemed to be proportional to the concentration and this suggested to us that they might be remedied by adding a term, $-Bc$ giving an equation of the form

$$\Lambda = \Lambda_0 - \frac{A\sqrt{c}}{1 + N\sqrt{c}} - Bc \qquad \text{(V)}$$

The constants of this equation were determined by the method of least sauares to be

$$\Lambda = 282.13 - \frac{636.3\sqrt{c}}{1 + 4.628\sqrt{c}} - 31.13c, \text{ or}$$

$$\frac{\Lambda}{282.13} = 1 - \frac{2.1845\sqrt{c}}{1 + 4.628\sqrt{c}} - 0.1103c$$

---

[16] **R.** T. Lattey, ***Phil.*** Mag., [7] 4, 831 (1927).

This equation fits the data within 0.06 mho at all points from 0.001 to 1.0 molal. The average deviation is only 0.014%. Curve V in Fig. 1 is the graph of this equation and the experimental points are the centers of the circles. The deviations are much too small to be apparent in the graph on the scale which can be printed but are shown numerically in the last column of Table II.

A discussion of the general validity of Equation V will be postponed until new data on many salts covering a wide range of concentration can be obtained. In view of the fact that important improvements in the design of cells for the measurement of conductance have recently been effected in this Laboratory, it seems inadvisable to undertake the laborious calculations necessary to test this equation by means of the data existing in the literature. The correlation of these conductance data with our transference data will be discussed in a separate paper by the junior author.

The Viscosity Correction

In the above theoretical treatment no attempt has been made to apply to the conductance data a viscosity correction.[17] During the course of the experimental work, measurements were made to determine the viscosity of barium chloride solutions. These results have already been published.[2] Although these data were originally obtained in the expectation of using them to correct the conductance values for the viscosity changes, a careful consideration of the question suggests that a large part if not all of the viscosity correction should not be applied. By studying our viscosity data we discovered that the relative fluidity (φ) of the solution could be expressed accurately by an equation of the form

$$\varphi = 1 - A\sqrt{c} - B(c) \qquad \text{(VI)}$$

or for viscosities in dilute solutions

$$\eta = 1 + A\sqrt{c} + (B + A^2)(c) + \ldots \qquad \text{(VII)}$$

A and B are constants chosen to fit the data. For barium chloride solutions at 25°, $A = 0.02013$ and $B = 0.20087$. The square root term suggested to us that this part of the viscosity increase might be due to the electric forces existing between the ions.

Falkenhagen and Dole[18] have deduced from the Debye theory of interionic attraction that the distortion of the symmetrical ionic arrangement by means of viscous flow increases the macroscopic viscosity of the solution in proportion to the square root of the concentration; but the friction encountered by an ion moving in an electric field is determined by the microscopic viscosity of the water molecules in its immediate path and this microscopic viscosity is probably not identical with the macroscopic viscosity as determined in a viscometer.

---

[17] *See* C. A. Kraus, THIS JOURNAL, *36*, 35 (1914), for a historical review of this question.

[18] H. Falkenhagen and M. Dole, *Physik. Z.*, 30, 611 (1929).

If the electric forces between the ions really change the microscopic viscosity, then this would influence the motion of the ions and would need to be taken into account in considering the variation of conductance with concentration. In such a case it would be fallacious to use Stokes' law without allowing for the change in viscosity. But if the microscopic viscosity is unaffected by the interionic attraction, it would be erroneous to apply a viscosity correction to the data for the change in macroscopic viscosity due to the interionic attraction represented in our viscosity equation (VII) by the term $A\sqrt{c}$.

This may also be true for the Bc term of Equation VI. Thus MacInnes and Cowperthwaite[19] have found that the conductance of the chloride ion is exactly the same in 0.1 normal solutions of sodium chloride and of potassium chloride although the measured macroscopic viscosities differ by 2%. This identity of the mobility of the chloride ion in the two solutions indicates that the effective or microscopic viscosity of the medium in the path of the moving ion may be the same in the two solutions.

This evidence against applying any viscosity correction is not entirely unambiguous since the junior author has discovered in some unpublished work that ions apparently affect macroscopic viscosities quite independently of each other, at least as regards the B terms of Equation VI. If this is true, then it is possible for the chloride ion to migrate in an environment whose microscopic viscosity is determined only by the chloride on itself. and thus have the same conductance either in sodium or potassium cihloride However, new experiments must be carried out before this question can be entirely settled.

Grateful acknowledgment is made for an appropriation from the Milton Fund of Harvard University for the expenses of this work.

Summary

1. Measurements of the density and electrical conductance of aqueous solutions of barium chloride at 25° covering the range 0.001 to 1.0 molal are recorded.

2. Numerous functions which have been suggested to express the variation of the conductance with the concentration are discussed and a new function having the form, $\Lambda = \Lambda_0 - [A\sqrt{c}/(1 + N\sqrt{c})] - Bc$ is shown to be in harmony with the facts in this case, over the range 0.001 to 1.0 molal.

3. The propriety of applying a viscosity correction to measurements of conductance is discussed.

4. In this and the preceding papers of this series it is shown that the properties of aqueous solutions of barium chloride at 25° can be expressed as a function of the concentration up to 1 molal by the equations

THE OXYGEN ELECTRODE: AN ADSORPTION POTENTIAL

BY H. V. TARTAR AND MARGERY WALKER

RECEIVED JANUARY 16, 1930 PUBLISHED JUNE 6, 1930

The problem of the oxygen electrode arose, for the most part, from the study of the Grove cell: Pt, HNO_3, H_2SO_4, Zn. This cell gives, when freshly made, a potential of 1.6 to 1.7 volts. It is extremely sensitive to polarization effects, which change the potential over a considerable range and render it irreproducible. The cause of this polarization was supposed to be some reaction involving the transfer of oxygen from the gaseous to an ionic or combined state. The outcome was that the study of the oxygen electrode was approached from the standpoint of polarization reactions.

One very prevalent explanation of the behavior of this electrode is the formation of various oxides of platinum and their hydrates; the so-called "oxide theory."[1] Another theory is that the potentials are due to the formation of unstable products in the electrolyte about the electrode.[2] The experimental work described in the literature just cited affords abundant evidence that the oxygen electrode is irreversible, and cannot be classed with the hydrogen electrode or metal electrodes against solutions of their ions. As a matter of fact, there is no experimental evidence to show that there is any chemical reaction at the electrodes.

Recently, efforts based upon purely empirical considerations have been made to use the oxygen electrode in electrometric titrations involving oxidizing solutions.[3]

Work in this Laboratory has shown[4] that the value and steadiness of the potential of the oxygen electrode are influenced markedly by the flowing of the electrolyte. Further investigations have brought the writers to the belief that these potentials are due largely, if not wholly, to the adsorption on the platinum of ions from the solution; an adsorption potential. The object of this paper is to present this explanation of the anomalous behavior of the so-called oxygen electrode.

Apparatus.—The apparatus used for all the experiments except those under reduced pressure was entirely analogous to that customarily employed for the measurement of hydrogen electrode potentials. Cells having a capacity of about **50** cc. were used with stoppers which provided for gas inlet and outlet, bridge connections and electrode. Bright platinum wire was used for the most part as electrodes, though some measurements were made with platinized wire and both bright and platinized foil. Commercial oxygen was used after being passed through acidified potassium permanganate, dilute sodium hydroxide and distilled water. The cells were supported in a thermostat which was maintained at a temperature of **25** ± 0.02°. The potentials were measured with a Leeds and Northrup student type of potentiometer, and a Leeds and Northrup lamp and scale galvanometer. Readings of potentials were made on neutral, acid and alkaline solutions. These were made using chemicals of "C. P. analyzed" quality. The potentials presented are referred to the standard molal hydrogen electrode, taking the value of the normal calomel electrode equal to **−0.283** volt. They therefore represent the potential of the cell

$$\text{Pt} - O_2\text{, electrolyte, KCl (1 N), } H^+ \text{ (1 } M\text{), } H_2 - \textbf{Pt}$$

For the sake of brevity, readings have been reported at rather long time intervals. About twice as many readings were taken as appear in each table; the complete data are not essential to showing the characteristics of the various runs.

The investigations on the effect of removing dissolved gases from the electrolytes were conducted by means of the apparatus shown in Fig. 1. A water-jet filter pump was employed which reduced the pressure sufficiently to cause boiling of all the solutions used. A manometer, connected in the system, gave an average reading of 18 mm. The connecting bridge between the two cells was filled with a stiff agar jelly made with tenth molar potassium sulfate solution. This was found necessary to prevent sucking out of the conducting medium between the two cells. A similar jelly made up with molar potassium chloride was placed up to the stopcock in the connecting tube of the calomel electrode vessel. The stopcock was kept closed throughout the evacuation. Electrical contact could be readily maintained in this manner and the inconvenience and possible

---

[4] Tartar and Wellman, *J. Phys. Chem.*, **32,** 1171–1177 (1928).

source of error associated with evacuation of the calomel electrode vessel were thus avoided.

Adsorption the Cause of the Potential.—The writers propose the following explanation to account for the potential of the oxygen electrode. The platinum preferentially adsorbs ions from the solution and thus produces a potential difference between the electrode surface and the bulk of the solution. To elucidate, let us suppose that there is in solution a uni-univalent salt, the cations of which are adsorbed by the electrode in greater amount than the anions, making the electrode positively charged with respect to the solution. The ions do not form two distinct layers at the surface of the electrode, the "electrical double layer" inference found many times in the literature, but are arranged so that the concentration of each ion gradually changes with increasing distance from the metal until they finally become the same as in the bulk of the surrounding medium. The diagram in Fig. 2 will probably aid in making the conception clearer. Between o and a, the cations are in excess; and between a and d, the anions. From o to d the number of cations is equal to that of the anions, but for a lesser distance o to b, the cations are in excess. The adsorption of ions by the metal produces a potential gradient between the surface of the electrode and the point d, the magnitude and the steepness of which depend entirely upon the excess of cations preferentially adsorbed. For a negatively charged electrode the arrangement of the cations and anions would be interchanged.

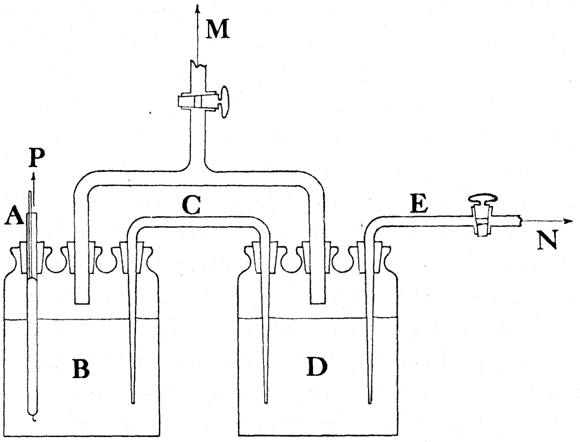

Fig. 1.—A, electrode; B, electrolyte; C, agar-filled bridge; D, KCl, about 1 *M*; E, connecting bridge filled with agar to stopcock; M, to manometer and suction pump; N, to normal calomel electrode; P, to potentiometer.

This concept of the potential of the electrode is consonant with the deductions of Debye and Hückel,[5] Gouy,[6] Powis,[7] McBain,[8] and Burton" regarding the distribution of ions in a Helmholtz double (?) layer.

The effect of the oxygen gas on the potential is due to its influence on the adsorption of ions. When the gas is dissolved in the solution, some oxygen molecules are adsorbed on the surface of the metal, thereby causing a change in the adsorption of ions from the electrolyte.

In support of the above explanation the writers submit the following evidences.

Evidence from **the** Drift of **the** Potential.--One characteristic of the electrode is that the potential changes or drifts with time. The rate of drift depends upon the electrolyte being greater with alkaline than with neutral or acid solutions Furman[3] states, and work in this Laboratory confirms his observations,[4] that the drift is from 30 to 60 millivolts per hour in alkaline solution and from 5 to 10 millivolts per hour in acid solution. Furthermore, the change is in a given direction for a particular electrolyte and is toward a greater potential difference between the electrode and the solution.

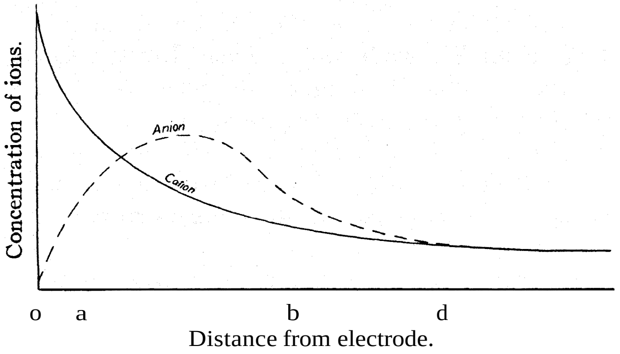

Fig. **2.**

This uni-directional drift may be considered as a consequence of the slow adjustment in the outer fringe of the ionic layer, *i. e.*, of the part b to d, Fig. 2. This is substantiated by the fact that with time, the drift becomes appreciably slower and the potential approaches a steady value. This time element is not surprising when it is considered that the ionic layer throughout which the potential gradient exists is probably many ions deep, and the forces holding the outermost ions in position become very weak.

Influence of Movement of Electrolyte upon the Steadiness of the Potential.—It has been shown by Tartar and Wellman[4] that the potential becomes more steady, ceases to drift, when there is a uni-directional flow of the electrolyte past the electrode. The potential becomes fairly constant for a given electrode in a given solution provided the rate of flow remains unchanged. This phenomenon can be explained as being due to the effect upon the distribution of the ions from the surface of the electrode. In the region a, Fig. 2, the distribution is maintained by electrical forces sufficiently great to be but little influenced by the movement of the electrolyte. Forces of less magnitude operate in the region b to d, which are more easily overcome by the movement of the solution. Thus the flow gives a shearing force opposing the electrical forces tending to maintain the potential difference from o to d and the fringe, say b to d, is swept away. This results in a more constant potential and the elimination of the drift.

Effect of Jarring the Electrode and of Small Electric Currents.—With some solutions the potential shifts markedly when the electrode is gently tapped. This effect may be accounted for in the same way as that produced by the movement of the electrolyte. The tapping moves the electrode with respect to the solution, thereby producing a change in the arrangement of the ions, particularly in the outer portion of the ionic layer (b to a).

Difficulty was experienced in reading the potentials in neutral and acid solutions. The potentiometer could be set anywhere within a range of 40 to 60 millivolts and the galvanometer show no deflection if the connecting key were tapped frequently enough. This apparent "balance," obtained both above and below the actual potential, is due to modifications in the ionic layer by the small electric current to and from the electrode when the potentiometer was "off balance."

Evidence from the Effects of Gases Other than Oxygen.—It has been suggested earlier in this paper that the influence of the oxygen gas on the value of the potential is due to the modification of the electrode surface by the adsorption of oxygen molecules. This modification is not limited to oxygen alone but should occur with other gases as well. Accordingly, investigations were conducted with nitrogen and hydrogen.

In the case of hydrogen, a neutral electrolyte was used, *viz.*, a saturated solution of potassium sulfate. The electrode was of bright platinum, which accounts for the difference between the type of readings obtained and that usually associated with the hydrogen electrode. Table I gives a set of readings, together with notations indicating manipulations of the gas and the electrode. The data show that the potential drifted markedly and was extremely sensitive to the effects of jarring and of other disturbances in the immediate vicinity of the electrode. This would indicate that hydrogen gas has a very pronounced modifying influence on the adsorption of ions by the platinum—an indication which is hardly more than would be expected in view of the relatively high adsorption of hydrogen itself on platinum. Hence the potentials are of an electrode which is functioning in part only as a hydrogen electrode, and where the predominating influence is still that of ions adsorbed from solution.

TABLE I

POTENTIAL WITH BRIGHT PLATINUM IN SATURATED POTASSIUM SULFATE IN THE PRESENCE OF HYDROGEN GAS

Time, min.	Potential, volts	Manipulations	Time. min.	Potential, volts	Manipulations
0	−0.368	Hydrogen bubbled in	102	0.367	
10	+ .162		105	.352	Hydrogen bubbled directly on electrode
30	.207	Electrode shaken			
40	.257		107	.382	
50	.182		110	.362	
80	.312		115	.342	Electrode shaken
100	.337	Hydrogen bubbled directly on electrode	130	.427	

The second gas (nitrogen) was chosen because of its inertness and comparatively low adsorption on platinum. By analogy, we expected that the potential with this gas would drift more slowly than with either oxygen or hydrogen. The data, which appear in Table II, seem to bear out this prediction.

TABLE II

POTENTIAL WITH BRIGHT PLATINUM IN SATURATED POTASSIUM SULFATE IN THE PRESENCE OF NITROGEN GAS

Time, minutes	0	5	10	15	35	65
Potential, volts	−0.395	−0.383	−0.338	−0.328	−0.300	−0.386
Time, minutes	95	125	190	310	370	
Potential, volts	−0.278	−0.265	−0.248	−0.223	−0.193	

The readings were continued for periods up to twenty hours without a definite cessation of the drift, though the rate of change became extremely slow. For the first 300–400 minutes the potential seemed to be affected but little by external disturbances, but thereafter became much more sensitive. A similar run was conducted with normal sulfuric acid and nitrogen gas, which gave the same type of results; e. g., at the end of nine hours the potential was still drifting at the rate of 12–13 millivolts per hour.

Evidence from Potentials in the Absence of Gases.—If the suggested interpretation of the effect of gases on this potential is correct, the characteristic drift should exist when no gas is present. To show this, investigations were conducted using the apparatus already described and shown in Fig. 1.

Previous to evacuation, the electrolyte was saturated with the desired gas and readings of potential taken for some time. Oxygen, hydrogen and nitrogen were used. The electrolyte was a saturated solution of potassium sulfate, so that no difficulty arose due to changes in concentration during the course of evacuation. Table III gives a summary of these results.

TABLE III

POTENTIALS WITH BRIGHT PLATINUM IN SATURATED POTASSIUM SULFATE DURING REMOVAL OF DISSOLVED GASES

Time, min.	Potential, volts (satd. with oxygen)	Potential, volts (satd. with hydrogen)	Potential, volts (satd. with nitrogen)
0	. .	. .	−0.179[d]
20	. .	. .	−0.174
30	−0.377[a]	+0.339[c]	.166[b]
50	.381	.427[b]	.164
80	.381[b]	.172	.161
100	.372	.132	.160
130	.340	.107	.158
160	.338	.008	
220	.336	−0.083	
280	.331	.113	
340	.324 .278 (5 5 hours)	157 .163 2 hours	

[a] Oxygen bubbled in. [b] Bvacuation begun. [c] Hydrogen bubbled in. [d] Nitrogen bubbled in for seven hours.

These data indicate that the cessation of the drift appears to be in no way hastened by the removal of dissolved gases from the electrolyte. Similar work of more limited extent was performed with saturated oxalic acid as the electrolyte with confirming results.

Evidence from Potential with "Immobile" Electrolytes.—If the ionic layer is of the thickness suggested, it should be possible to stabilize it by making the electrolyte less mobile or else by packing a sufficiently finely divided material about the electrode.

An attempt to steady the potential in this way was made by imbedding the electrode in finely powdered silicon dioxide covered with the electrolyte. Bright platinum electrodes were used. Oxygen was bubbled continuously through the electrolyte with the tip of the gas inlet tube below the surface of the powdered material and at a distance of not more than 8 mm. from the electrode. Neutral, acid and alkaline solutions of varying normalities were used in order to determine the dependence of the steadiness of the potential upon the concentration. In general, the more concentrated solutions gave the more stable potentials but the difference in the type of readings was not sufficiently pronounced to warrant the inclusion of all the data. Hence, potentials for only one concentration of each electrolyte will be reproduced. In each case a series of readings in the same electrolyte and without the silicon dioxide was taken simultaneously and the results of these are also given in Table IV.

TABLE IV

POTENTIALS WITH BRIGHT PLATINUM IN NEUTRAL, ACID AND ALKALINE ELECTROLYTES WITH AND WITHOUT SILICON DIOXIDE POWDER

Time, min.	Potential in electrolyte without powder, volts	Potential in electrolyte with SiO_2 powder, volts	Time, min.	Potential in electrolyte without powder, volts	Potential in electrolyte with SiO_2 powder, volts	Time, min.	Potential in electrolyte without powder, volts	Potential in electrolyte with SiO_2 powder, volts
	M/10 K_2SO_4			*N* H_2SO_4			*N* KOH	
10	−0 490	−0 516	10	−0 814	−0 696	10	+0 159	+0 119
30	.458	,515	20	.818	.683	30	.153	.116
75	.435	.516	60	.816	.683	100	.146	.114
105	,425	516	140	825	6	130	.144	.113
120	.433	.515	210	.811	.683	160	.142	.113
165	,428	.518				210	.140	.113
190	.430	.518						
300	.432	.521						

The results show that in all cases the addition of the powdered material had a stabilizing influence, more so in the alkaline and acid solutions than in the neutral. The above experiments were repeated with a coarser medium employed as a stabilizer, namely, Ottawa sand. It was found that this material had the desired effect in the alkaline and acid solutions but was of little assistance in the neutral electrolyte. Three sets of readings are given in Table V. It will be noted, however, that while the presence of the sand does not render the potential with the neutral electrolyte steady, it does stop the tendency to drift continuously.

TABLE V

POTENTIAL WITH BRIGHT PLATINUM IN NEUTRAL, ALKALINE AND ACID ELECTROLYTES IN COARSE SAND

Time, min.	Potential in *M*/10 K_2SO_4, volts	Potential in *N* KOH, volts	Potential in *N* H_2SO_4, volts
10	−0.602	+0.103	−0.730
20	.592	.106	.690
80	.583	.103	.701
100	.581	.100	.702
130	.583	.100	.702
160	.581	.100	.702
180	.582	.098	.702
210		.098	.702

The effect of powdered silicon dioxide on the potential with *platinized* platinum electrodes in alkaline and acid solution was observed; it was found that with this type of electrode surface the amount of stabilization produced in this manner was negligible.

Further experiments were made by placing bright platinum electrodes in agar jelly containing the electrolyte; tenth molar potassium sulfate and tenth normal sulfuric acid were used. The potentials were very steady and did not drift. Because of the indefinite nature of the agar jelly, it is not possible to say that the steady potentials were due wholly to the stabilization of the ionic layer.

Evidence from the Effect of Substances Reducing Interfacial Tension.—Another method for showing the role played by adsorbed ions in producing these potentials was based on the effect obtained when the interfacial tension between the electrode and the electrolyte was reduced. Two types of substances were employed; one polar and the other non-polar. These were potassium pelargonate and amyl alcohol, respectively. Since the former would interact with the acid solution, readings were taken with it only in neutral and alkaline electrolytes. The data appear in Table VI. The concentration of the pelargonate was about 0.25 g. per 100 cc. of electrolyte.

TABLE VI

POTENTIALS WITH BRIGHT PLATINUM IN NEUTRAL AND ALKALINE ELECTROLYTES WITH POTASSIUM PELARGONATE

Time, minutes		15	75	135	195	250	255
Potential, volts	in $N/10 K_2SO_4$	−0.566	−0.566	−0.566	−0.566	−0.566	−0.566
	in $N/10$KOH	+0.181	+0.203	+0.205	+0.205	+0.205	+0.205

In the case of amyl alcohol, all three electrolytes were used, and were made about 1% with respect to the amyl alcohol. Table VII contains readings taken in this manner.

TABLE VII

POTENTIALS WITH BRIGHT PLATINUM IN NEUTRAL ACID AND ALKALINE ELECTROLYTES WITH AMYL ALCOHOL

Time, min.	**Potential in $N/10$ K_2SO_4, volts**	**Potential in $N/10$ H_2SO_4, volts**	**Potential in $N/10$ KOH, volts**
10	−0.561	−0.752	+0.154
60	.558	.749	.151
90	.554	.750	.148
200	.550	.750	.147
300	.549	.751	.146

The experiments with amyl alcohol were repeated with platinized platinum with even more gratifying results; *e. g.*, in the case of sulfuric acid ($N/10$) the potential showed no change whatever, after the first twenty minutes, during 500 minutes of observation.

Summary

1. The behavior of the oxygen electrode has been explained as being due largely to the adsorption of ions; an adsorption potential.
2. Experimental evidence has been presented to support this explanation.

SOME ELECTROMOTIVE FORCE MEASUREMENTS WITH CALCIUM CHLORIDE SOLUTIONS

BY GEORGE SCATCHARD AND RALPH F. TEFFT[1]

RECEIVED JANUARY 28, 1930 PUBLISHED JUNE 6, 1930

The chemical potential, or partial molal free energy, of sodium or potassium chloride in a mixture of ethyl alcohol and water varies with changing solvent as should be expected if the deviation from ideality were due entirely to electrostatic effects. The very different behavior of hydrogen chloride may be explained simply by the existence of the hydrogen ion in solution in the form of the monohydrate.[2] So it is of interest to study calcium chloride, which has a heavily solvated solid phase in equilibrium with its solution in either solvent. Measurements were made of the electromotive force at 25° of the cell Ag, AgCl, $CaCl_2$(I), $CaHg_x$, $CaCl_2$(II), AgCl, Ag (double cell). Such measurements in aqueous solution have been published by Lucasse[3] and, since the presentation of the thesis on which this paper is based, by Fosbinder.[4] To study more closely the behavior of the amalgam electrodes, measurements were also made on the cell $CaHg_x$, $CaCl_2$, AgCl, Ag (single cell). It was expected that the chief difficulty would be due to chemical action at the amalgam electrode and that alcohol would be less reactive than water, so that a technique which proved satisfactory for aqueous solutions would work well in the alcohol mixtures. The expectations were not realized. Successful determinations were made in water, and fairly accurate ones in 46% (25 mole %) alcohol, but the behavior with 72% (50 mole %) alcohol was so different that no determinations could be made and no attempt was made to work at higher alcohol concentrations.

Apparatus and Materials

The double cell was essentially the same as that of MacInnes and Beattie[5] except that the amalgam droppers were bent into a U shape and were about 5 mm. in diameter. The single cell was half the double cell, with an amalgam dropper having a single outlet. Droppers were used with tips varying from 1 to 11 mm.

Measurements were made in an atmosphere of hydrogen. Tank hydrogen was passed over copper at about 300°. That which was to be used over the solutions was then bubbled through some solution of the same composition; that which was to be used over the amalgam was dried by passing over calcium chloride and phosphorus pentoxide.

The water used for all solutions was twice-distilled "conductivity" water. Com-

mercial alcohol was refluxed with lime for several days and then distilled. The middle portion was redistilled from aluminum amalgam, and the water content was determined from the density.

Calcium carbonate was prepared by precipitation from a solution of c. p. calcium chloride with c. p. ammonium carbonate, and was washed until free from chlorides. The stock solution of calcium chloride was prepared by the action of constant-boiling hydrochloric acid on an excess of this calcium carbonate. After the action had subsided, hydrogen was passed through for several hours. The hydrogen-ion concentration of this solution was between the methyl orange and phenolphthalein neutral points; the calcium chloride concentration was determined gravimetrically as silver chloride. The solutions of calcium chloride were prepared by weight dilution of this stock solution with water or with water and alcohol. A stream of hydrogen was passed through the diluted solution for five or ten minutes to remove any air admitted during the handling.

Mercury was purified by being passed eight times through a tower containing dilute nitric acid and mercurous nitrate, and then twice distilled in a current of air under reduced pressure. In recovering mercury from used amalgams, the distillations were omitted. The calcium amalgam, which contained 0.02–0.05% of calcium, was prepared by the electrolysis of the stock solution of calcium chloride with a mercury cathode. It was then rinsed, dried and stored in an evacuated pyrex container.

The silver–silver chloride electrodes were prepared by the method of MacInnes and Beattie,[5] and chloridized in the solution in which they were to be used except that for solutions more concentrated than 0.3 M they were chloridized in 0.1 M solution, because electrolysis in the more concentrated solutions gave a compact non-conducting layer. At least 5 electrodes were prepared in each case, and that one used which was nearest the average in electromotive force. No electrode was considered in the average which differed from the others more than 0.05 mv.

The apparatus was placed in a water thermostat maintained at 25.00 * 0.01°. The potentiometer was a Leeds and Northrup Type K with an unsaturated cadmium sulfate reference cell. This cell was frequently checked against a series of saturated cadmium sulfate cells.

Measurements with the Single Cell

The cell $CaHg_x$, $CaCl_2$, AgCl, Ag was used with approximately 0.02% calcium amalgam and 0.1 M calcium chloride in water with a series of U-shaped amalgam droppers having tips about 1, 3, 7 and 11 mm. in diameter. The rate of flow was varied from less than one drop per second to a continuous stream, and the electromotive force was also measured after flow was stopped. The electromotive force after stopping the flow was practically independent of the size of the tip. It decreased one or two-tenths of a millivolt per minute.

The 1-mm. dropper showed considerable fluctuation while the amalgam was flowing, and the electromotive force with streaming amalgam was 6 mv. less than with no flow. The 7-mm. dropper was much steadier and decreased only 2.5 mv. The 3-mm. dropper was intermediate in its behavior. The 11-mm. dropper behaved quite similarly to the 7 mm. one except that a bubble of hydrogen which formed on the surface was not carried away even with rapid flaw and, presumably for that reason, the results were more erratic, Measurements were also made on the cell $ZnHg_x$, $ZnCl_2$, AgCl, Ag with about 0.05% zinc amalgam and about 0.1 *M* aqueous $ZnCl_2$, and with a 5-mm. dropper. The electromotive force at 10 drops per second (almost continuous flow) was 0.5–0.6 mv. less than that immediately after the flow was stopped.

With the double cells the rate of flow was varied greatly, keeping the two rates as nearly equal as possible. That value was accepted which held over a large range of rates. The changes noted were probably due to small differences in the two rates, for there was no trend of the difference with the rate and visible differences between the two rates did give large changes in electromotive force. This technique was satisfactory with aqueous solutions if the rate was not too great (fast streaming) and the amalgam concentration not too small (less than 0.015%).

The direction of the change in electromotive force with changing rate of flow is surprising. Chemical action at the electrode would decrease the calcium concentration and increase that of calcium ion, and so decrease the electromotive force. The effect would be smaller the more rapid the flow, so that rapid flow should give the largest electromotive force.

The only cause which occurs to the authors which would give an electromotive force decreasing with the rate, and decreasing the more rapidly at high rates, is failure to obtain equilibrium between the surface and the bulk of the amalgam. If the interfacial tension decreases with increasing calcium content of the amalgam, the calcium will be adsorbed at the interface, and calcium will have a smaller chemical potential in a fresh surface than in the bulk liquid from which it is formed. The resulting decrease in electromotive force should be greater the more rapid the flow. This explanation also accounts for the fact that the difficulty is greater the more dilute the amalgam, for the relative unsaturation would be greater, but that it is practically independent of the salt concentration.

No measurements have been made of the interfacial tension between calcium amalgams and solutions of calcium salts. Schmidt[6] and Oppenheimer[7] have measured the surface tensions of amalgams in *vacuo*. The first found that lithium and the alkaline earth metals increase the surface tension of mercury greatly and that zinc does a little, while sodium and potassium give large decreases. The second found that lithium decreases the surface tension even more than sodium, and that calcium gives a considerable decrease. Meyer[8] measured the interfacial tension of zinc and the alkali amalgams against aqueous solutions of their salts. He found that all decrease the interfacial tension, lithium enormously. His results parallel those of Oppenheimer. The effect is in the proper direction to account

---

[6] Schmidt, *Ann. Physik*, **39**, 1108 (1912)

[7] Oppenheimer, *Z anorg. allgem Chem*, **171**, 98 (1928).

[8] Meyer, *Z. physik. Chem.*, **70**, 315 (1910).

for our observations with zinc amalgam and, if the parallelism to Oppenheimer's results may be extended to calcium amalgam, it should give a much larger effect in the same direction. This is also in accord with our observations.

Our double cell technique gave measurements in 46% alcohol reproducible only to 0.5 mv. instead of 0.1–0.2 mv., but they still seemed fairly satisfactory. With 72% alcohol, however, the discrepancies were so great that measurements were again attempted with the single cell, using a 5-mm. dropper. Two runs were made. In the concentrated run the amalgam concentration was about 0.04% and the salt concentration about 0.2 M. In the dilute one the amalgam was about 0.01% and the salt about 0.02 *M*. In both cases a scum, probably calcium hydroxide, formed on the surface of the amalgams. The fluctuations were very large, particularly at the slower rates of flow with the concentrated amalgam. The electromotive force increased with rate of flow, about 35 mv. for the concentrated and about 45 for the dilute. In both cases the increase was large even after the flow was continuous.

Since the effect of the rate of flow is so enormous, there is little chance of maintaining the two rates of flow in the double cell near enough equal to give significant results. Measurements with aqueous solutions on one side and alcoholic solutions on the other are quite out of the question since the electromotive force is changed in opposite directions by changing the rate. For this reason work on alcoholic solutions was discontinued.

Wolfenden and his co-workers[9] made measurements with a single jet electrode with sodium amalgam and a methyl alcoholic solution of sodium chloride. With 0.04% amalgam they found that the electromotive force increased about 4 mv. when the rate of flow was increased, and that the effect was independent of the salt concentration They concluded that the cause was not chemical action because the increase persisted with large rates of flow. With 0.003% amalgam they found that increasing the rate of flow sometimes increased the electromotive force somewhat more than with the concentrated amalgam and sometimes gave a decrease of the same order of magnitude.

The argument of these authors against chemical action as the cause of the effect of changing rate applies equally to our results. If adsorption is the cause, it must be adsorption of the metal ion, and it is surprising that they found practically no change for a hundred-fold increase of salt concentration. The difficulties of any explanation are enhanced by the magnitude of the effect which must be explained, for the change in electromotive force with the alcoholic calcium chloride solutions corresponds to a twenty- or thirty-fold increase of calcium ion. That such a change can result from chemical action, adsorption or the combination of the two is scarcely to be expected.

[9] Wolfenden, Wright, Kane and Buckley, Trans. *Faraday Soc.*, **23,** 491 (1927).

Measurements with the Double Cell

Since the accuracy of measurement decreases for very dilute solutions, a 0.1 M solution in water was chosen as comparison standard. Table I gives the results of the measurements with aqueous solutions. The first column gives the exact concentration of the reference solution (in moles per 1000 g. of solvent); the second column, the concentration of the second solution; the third column, the measured electromotive force; and the fourth column gives this value minus the value calculated from the Debye–Hückel equation with the constants given below. In Fig. 1 these deviations are shown graphically together with the corresponding deviations of the measurements of Lucasse and of Fosbinder, both of whom used a 0.01 M solution as reference standard. The measurement of Fosbinder at 0.0897 M and all his measurements above 1 M are omitted because the deviations are larger than the scale of the figure. The average deviation of our measurements is 0.41 mv.; below 1.0 M that of Lucasse is 0.71 mv.,

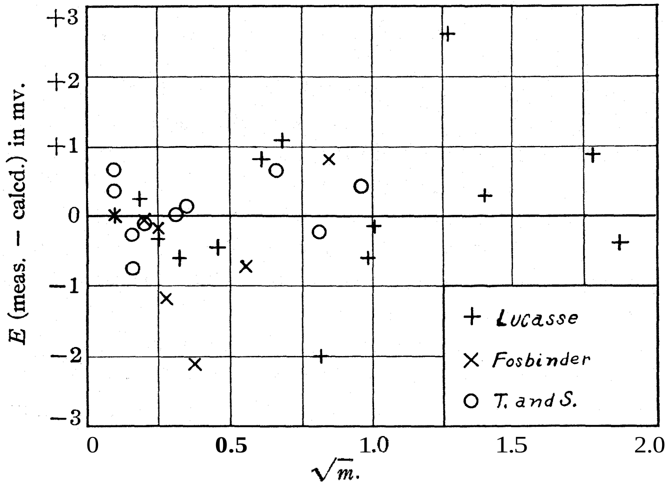

Fig. 1.—Electromotive force of calcium chloride cells.

TABLE I

ELECTROMOTIVE FORCE OF CALCIUM CHLORIDE CONCENTRATION CELLS IN WATER

m_1	m_2	E(meas.)	E(meas. − calcd.)
0.09989	0.009921	0.0761	+0.0004
.09978	.010509	.0742	+ .0007
.10041	.02594	.0439	− .0003
.09983	.02758	.0412	− .0007
.09989	.04113	02892	− .00010
.09993	.12634	− 0078	+ .0001
.10029	.4420	− 0558	+ .0007
09968	.6589	− 0768	− .0002
.10056	.9301	− 09615	+ .00043

and of Fosbinder 1.45 mv. The agreement between these independent observations gives some assurance that the electromotive force of the calcium chloride concentration cell with aqueous solutions does measure the free energy of transfer of the salt.

A concentration cell such as [Ag, AgCl, $CaCl_2$(I), $CaHg_x$], $CaCl_2$(II), AgCl, Ag in which the composition of solution (I) is kept constant during a series of measurements while solution (II) is varied may be treated as though that portion of the cell in brackets were a single electrode. This treatment is particularly convenient when the variation in solution (II) is a change in the solvent. By the theory of Debye and Hückel, the electromotive force, E, of such a cell is given by

$$E = E_0 - k \log \frac{m}{1 + wm} + \frac{A\sqrt{c}}{1 + \alpha\sqrt{c}} - \beta c - k' \qquad (1)$$

m is the number of moles of salt per kilogram of solvent, c the moles per liter of solution (both in solution 11), and w is one-thousandth of the average molecular weight of the solvent multiplied by the number of ions in one mole of salt.[10] E_0 depends upon the temperature, the nature of the solvents on the two sides and on the concentration of solution (I). The computation of the numerical constants need not be repeated here, but it is sufficient to say that for a bi-univalent electrolyte at 25° k is 0.088725 volt and k' is 0.01781 volt; if the solvent is water, w is 0.054, A is 0.1550 volt, and $\alpha = 0.568$ a, where a is the diameter of the mean collision sphere of the ions in Ångström units; in 25 mole % alcohol, w is 0.075, A is 0.310 volt, and a = 0.716 a. β is a function of the solvent composition and the temperature which must be determined from the data.

If the solvent is the same on the two sides, the constants a and β may be determined from two measurements, and E_0 is given from the fact that E must be zero when the two concentrations are equal. If the solvents are different, three measurements are necessary to determine the three constants. Equation 1 was used to determine the small correction necessary because m_1 was not exactly 0.1 M, and to determine the difference in E_0 between our measurements and those of the other workers, who used different standard concentrations.

For aqueous solutions the volume concentrations were computed by the equation $c/m = 0.99707 - 0.0214\,m - 0.0019\,m^2$, and the constants used are $a = 2.1$, which corresponds to $a = 3.70$, $\beta = 0.04$ volt, and $E_0 = -0.13217$ volt when $m_1 = 0.1$ M. Values of γ computed with these constants are given in the following paper.[11]

The results in 25 mole per cent, alcohol, with solution I in water, are given in Table II. The first column gives the concentration of the aqueous solu-

---

[10] For any one solvent, then, $m/(1 + wm)$ is proportional to the mole fraction of either ion.

[11] Scatchard and Tefft, THIS JOURNAL, 52, 2272 (1930).

TABLE II

ELECTROMOTIVE FORCE OF CALCIUM CHLORIDE CELLS IN 25 MOLE PER CENT. ALCOHOL

m_1	m_2	ρ_2	E	E_0
0.1102	0.01316	0.91995	−0.0081	−0.2219
.1003	.1192	.92798	− .0785	− .2278
.1003	.9712	.99126	− .16295	− .2244

tion, the second that of the alcoholic solution in moles per kilogram of solvent, and the third column gives the measured density, from which the volume concentrations were calculated. The fourth column gives the measured electromotive force, and the fifth E_0 calculated from Equation 1. Giving a the same value as in water, α is 2.65, and the data are fitted best by taking $\beta = 0.05$ volt. The average E_0 is –0.2247 volt. The average deviation is large, 2 millivolts, but this is not surprising in view of the extreme difficulty with 50 mole per cent. solutions.

According to Debye's theory of salting out, etc.,[12,2] the change in E_0 with changing solvent should depend upon the molecular weights of the two solvents, their dielectric constants, and the electrical radius of the ions, b, according to the equation (for a bi-univalent electrolyte)

$$E_{01} - E_{02} = 0.088725 \log \frac{M_2}{M_1} + \frac{21.50}{b}\left(\frac{1}{D_2} - \frac{1}{D_1}\right) \qquad (2)$$

For water and 25 mole per cent. ethyl alcohol, the first term is 0.01266 volt, leaving 0.0799 volt for the electrical term. The coefficient of l/b is 0.1605 volt. This gives b = 2.0 Angstrom units, which agrees with the value computed from the salting out of H_2, O_2 and CO_2.[13]

Summary

The electromotive force of the cell Ag, AgCl, $CaCl_2$ (0.1 M, aq.), $CaHg_x$, $CaCl_2$ (m), AgCl, Ag has been measured at 25° with m varying from 0.01 to 1.0 in water and in 25 mole per cent. ethyl alcohol, and the Debye theory has been applied to the results.

With aqueous solutions the potential of the calcium amalgam electrode decreases slightly with increasing rate of flow, probably because of adsorption of calcium at the interface.

With water–alcohol mixtures the potential increases rapidly with increasing rate of flow, so that accurate measurements are not possible when the alcohol concentration is large.

ELECTROMOTIVE FORCE MEASUREMENTS ON CELLS CONTAINING ZINC CHLORIDE. THE ACTIVITY COEFFICIENTS OF THE CHLORIDES OF THE BIVALENT METALS

BY GEORGE SCATCHARD AND RALPH F. TEFFT[1]

RECEIVED JANUARY 28, 1930 PUBLISHED JUNE 6, 1930

The behavior of zinc chloride in solution is of interest as it represents an intermediate step in the transition from typical strong electrolytes, such as the alkaline earth chlorides, to salts like cadmium chloride in which ion association shows an important effect. A few measurements on the cell Zn, $ZnCl_2$ (m), AgCl, Ag have been made at 0° by Jahn,[2] and several in very dilute solutions at 25° by Horsch.[3] We have made a series of measurements on the cell ZnHg (2 phase), $ZnCl_2$ (m), AgCl, Ag at 25° in which m was varied from 0.003 M to 1.48 M.

Experimental Methods

A solution of C. P. sodium carbonate was added to a solution of C. P. zinc chloride in water. The resulting precipitate was washed free from chlorides and dried at about 300° overnight, leaving a product largely zinc oxide. This was mixed with purified hydrochloric acid and boiled until no more would dissolve. The concentration of this stock solution was determined by a gravimetric chloride analysis, and the solutions used in the cells were prepared from it by weight dilution.

The stock solution was saturated with zinc oxide, and on dilution a small amount of precipitate always formed. According to Driot[4] the solid phase is $4ZnO{\cdot}ZnCl_2{\cdot}6H_2O$ at these concentrations of zinc chloride, and the solubility is given by $m_{ZnO} = 0.005\ m^2_{ZnCl_2}$. This excess concentration affects only the zinc electrode, so that the correction is 0.03 log (1 + 0.005 m), which is less than 0.1 mv. even for the most concentrated solution studied. All measurements are so corrected, however. The two most concentrated solutions, which were prepared from a more concentrated stock solution than the others so that precipitation was considerable, were each analyzed for chloride.

The zinc amalgam was prepared by the electrolysis of the stock solution, acidified with a small amount of hydrochloric acid, between a C. P. zinc anode and a mercury cathode. After the electrolysis the amalgam was washed, dried and stored in a pyrex

---

container under hydrogen. To fill the cells the amalgam was heated until it was practically one phase and withdrawn through a capillary stopcock.

The purification of other materials and the preparation of the silver–silver chloride electrodes, chloridized in the solution in which they were to be used except as noted below, the thermostat and the electrical apparatus were the same as in previous work.[5]

The electrode vessel was triplicate. Each section was shaped like an inverted h. The long arm contained the amalgam and had a platinum wire sealed through the bottom. A tube which delivered hydrogen just above the amalgam surface passed through a rubber stopper at the top. The silver chloride electrode was supported in a rubber stopper in the short arm. The three long arms were connected in a row by two series of tubes, one below and one above the liquid–gas interface. The middle section had a second side arm for the escape of hydrogen.

The nine possible electrode combinations were measured in each case except for the most dilute solutions, where the resistance was too high to permit accurate measurements from one end cell to the other. Each cell was observed for at least six hours after it was placed in the thermostat, with the hydrogen flowing continually, although the electromotive force never changed more than 0.1 mv. after the first half-hour, even in one case which was observed for several days. In the 0.003 and 0.02 M solutions one zinc electrode, and in the 0.008 M solution one silver chloride electrode, gave results so different from the other two that they were not considered. Excepting these, the average deviations for a given solution were 0.02–0.07 for all but the most dilute solution, where it reached 0.22 mv. from the average for two fillings, for one of which the silver chloride electrodes were chloridized in a more concentrated solution.

The effect of air was studied with the 0.09 M solution. The passage of air over the amalgam electrodes for twenty minutes caused a decrease of 3–5 mv. in the electromotive force, but the electromotive force began to increase as soon as the flow was stopped and after seven hours had returned to its initial value, which was not further changed by passing through hydrogen. The passage of air caused a scum to be formed on the amalgam surface. Evidently the oxygen removes zinc from the dilute amalgam to form zinc hydroxide, which is precipitated, so that the net effect is the decrease of the zinc concentration in the amalgam. As the amalgam returns to equilibrium, the electromotive force recovers. This action probably accounts for the fact that Horsch,[3] who did not eliminate oxygen, could not prepare reproducible amalgam electrodes.

Measurements

The results of our measurements are given in Table I. The first column

[5] Scatchard and Tefft, THIS JOURNAL, 52, 2265 (1930).

gives the molality, the second the measured electromotive force and the third E_0'' defined by the equation

$$E_0'' = E + 0.088725 [\log m - \log(1 + 0.054 m)] + 0.01781$$
$$= E_1 - 0.088725 \log f \qquad (1)$$

E_0'' differs from the E_0' of Lewis and Randall only by the addition of the third term, which relates the measurements to Raoult's law rather than to the assumption that the activity is proportional to the molality in an ideal solution. $0.01781 = 0.088725 \log 2^{2/3}$ serves to change from unit concentration of salt to unit mean concentration of ions. The last column gives the deviations of the measured values from those calculated by the Debye–Hückel equation for varying dielectric constant

$$E_0'' = 0.98625 + \frac{0.155\sqrt{c}}{1 + 3.5\sqrt{c}} + 0.0042c \qquad (2)$$

The values of c for these computations were determined from the densities in the "International Critical Tables," using the equation

$$\frac{c}{m} = 0.99707 - 0.0134\, m - 0.0129\, m^2 + 0.0288\, m^3$$

From 0.04 to 1.48 M the deviations are not more than 0.2 mv., which is probably as small as could be expected. For the more dilute solutions, however, the deviations become very large, and the value of E_0 obtained by this method, 0.98625 v., is certainly too high.

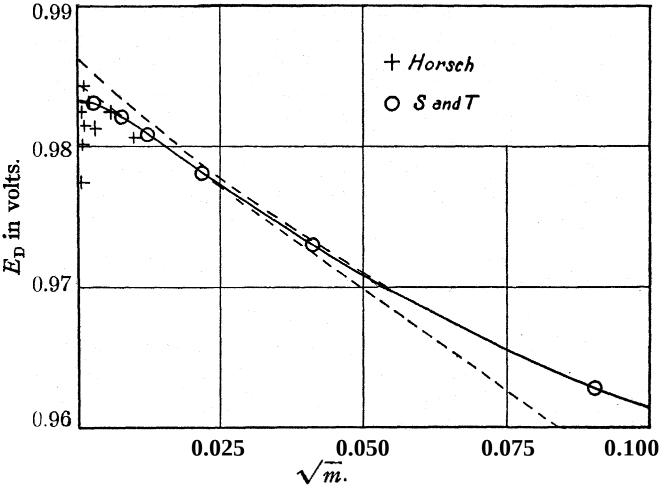

Fig. 1.—Electromotive force of zinc chloride cells.

We have followed the method of Hitchcock[6] in Fig. 1, and plotted

$$E_D = E_0'' - 0.155\sqrt{c} \qquad (3)$$

against the concentration. If the Debye–Hückel equation is approached at small concentrations, E_D should approach a straight line asymptotically

---

[6] Hitchcock, This journal, 50, 2076 (1928).

at zero concentration. The upper broken line is that of Equation 2, the lower broken line is a straight one through the points at **0.008, 0.012** and **0.02** M. The point at **0.003** M is well below the line and indicates an inflection in the curve. It would be dangerous to insert an inflection based upon a single measurement, the least accurate of the series, and the measurements of Horsch are too scattered to aid in the extrapolation. However, the points through which the line is drawn fall upon it *too **well*** in view of the deviation at the next higher concentration, so that these points themselves indicate an inflection. Accurate measurements at lower concentrations, to which our technique is not adapted, are to be desired. We believe that the evidence just given and the theoretical considerations which follow justify the inflection, and make the extrapolation along the full curve the most probable.

Chlorides of Other Bivalent Metals

The electromotive force measurements with the alkaline earth chlorides extend only to hundredth molal, so they are not useful for the comparison of the behavior in very dilute solutions. The freezing-point measurements of Hall and Harkins[7] on barium chloride up to **0.1** M are fitted within the accuracy with which they are expressed (one unit in the last place) by the Debye–Hückel equation for constant dielectric constant, assuming that at this dilution $c = m$, with **a** $=$ **4.81** Å.

$$\Theta = 1.858\, \nu\, m \left\{1 - \frac{3.445\, z_1z_2}{x^2a}\left[1 + x - \frac{1}{1+x} - 2 \ln (1 + x)\right]\right\} \qquad (4)$$

ν is the number of ions from one molecule of salt, z_1 and z_2 are their valences, $x = \mathbf{0.3242\,a}\sqrt{\mu}$, μ is the ionic strength, and a the mean effective diameter in Angstrom units. This corresponds to

$$-\log \gamma = \frac{0.485\, z_1z_2\, \sqrt{\mu}}{(1 + x)} \qquad (5)$$

The numerical constants are limited, of course, to aqueous solutions,

At **0.01** M this gives $\gamma = \mathbf{0.737}$, which may be compared with the value 0.716 obtained by Lewis and Randall from the same measurements and to the value **0.724** which we compute, in accord with earlier computations,[8] from the electromotive force measurements of Lucasse at 25°.[9] The difference between our values at 0° and at 25° is in the direction to be expected. It appears that there is no inflection for barium chloride. Strontium and calcium chlorides have larger positive deviations from the limiting law above **0.01** M and should have less tendency to irregularities at smaller concentrations.

---

[9] Lucasse, *ibid.*, 47, 743 (1925).

The measurements of Carmody[10] on lead chloride and those of Horsch[3] and of Lucasse[11] on cadmium chloride indicate considerable curvature in dilute solutions when E_D is plotted against the concentration. Figure 2 shows $E_D - E_0$ for these salts and for barium and zinc chlorides plotted against the square root of the concentration. The broken line is the Debye–Hückel limiting law. The values for cadmium and lead chlorides in dilute solutions appear to lie on straight lines. For cadmium chloride the slope of this line is greater than that of the broken line, so that extrapolation along this curve would give a limiting slope more than twice the theoretical; lead chloride would give a value about 30% too high.

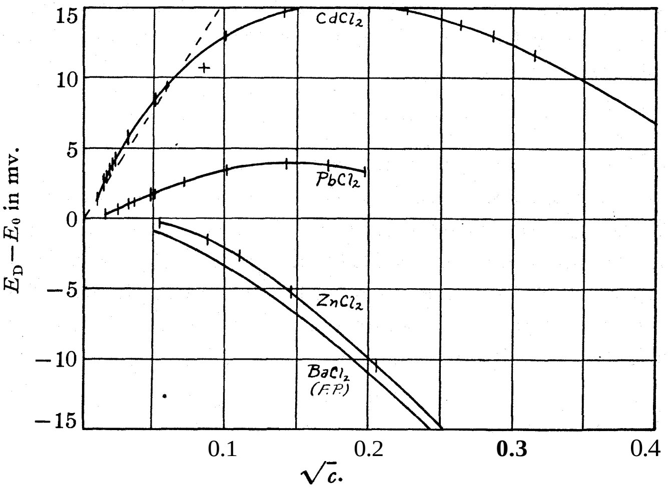

Fig. 2.—Electromotive force of chlorides of bivalent metals.

The Effect of Incomplete Ionization

Since cadmium chloride is certainly not completely ionized and the other salts may not be, the effect of incomplete dissociation on this method of treatment was studied. The effect of the formation of neutral molecules or more complicated ions increases too rapidly with the concentration to resemble the experimentally measured effects, but the formation of the primary ion is capable of explaining the measurements.

It is necessary to distinguish between those quantities computed from the true concentration of the ions, and those computed in the customary way by assuming complete ionization. To the latter we will give the ordinary symbols, while the former will be distinguished by primes. Thus f'_{21} is the true mean activity coefficient of a bi-univalent electrolyte. In calculating the activity coefficients we have assumed that all ions have the size found for barium chloride from the freezing points, that the terms

[11] Lucasse, *ibid.*, 51, 2597 (1929).

linear in the concentration are zero, and that the concentration of each species in moles per liter is 55.5 times its mole fraction, a quantity which is designated by the chemical symbol in parentheses. If μ is the ionic strength in these units

$$-\log f'_{21} = \frac{\sqrt{\mu'}}{1 + 1.56\sqrt{\mu'}} \quad \text{and} \tag{6}$$

$$-\log f'_{11} = \frac{0.5\sqrt{\mu'}}{1 + 1.56\sqrt{\mu'}} \tag{7}$$

Given the reaction $MX^{++} \rightleftharpoons M^{++} X^{-}$

$$K = \frac{(M^{++})\,(X^{-})}{(MX^{+})}\,\frac{f'^{3}_{21}}{f'^{2}_{11}} \tag{8}$$

Combining (6), (7) and (8)

$$\log \frac{(M^{++})\,(X^{-})}{(MX^{+})} = \log K + \frac{2\sqrt{\mu'}}{1 + 1.56\sqrt{\mu'}} \tag{9}$$

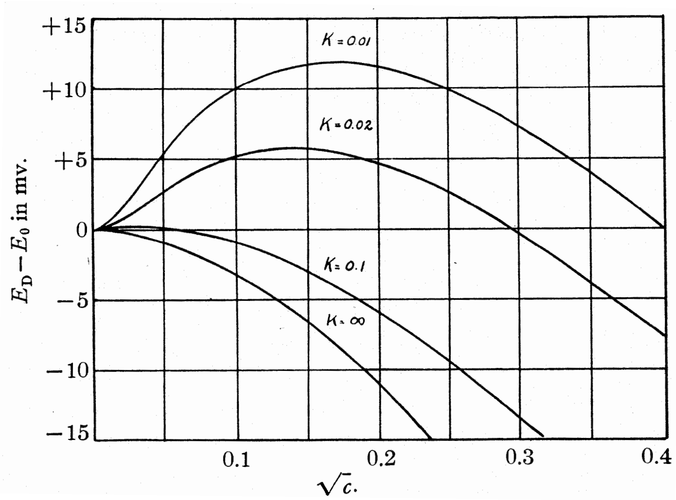

Fig. 3.—Effect of incomplete dissociation on electromotive force of 2−1 salts.

We also have the equations

$$\mu' = 3(M^{++}) + (MX)^{+} \tag{10}$$

$$(X^{-}) = 2(M^{++}) + (MX^{+}) = \mu' - (M^{++}) \tag{11}$$

For a given value of K these equations can be solved without much difficulty if μ' be taken as the independent variable, and

$$= 3[(M^{++}) + (MX^{+})]\ \frac{1 + 0.054\left[(M^{++}) + \frac{2}{3}(MX^{+})\right]}{1 + 0.054\ [(M^{++}) + (MX^{+})]^{3}}, \text{ and} \tag{12}$$

$$f_{21} = \frac{\mu' f'_{21}}{\mu} \tag{13}$$

In Fig. **3** is plotted

$$E_D - E_0 = 0.088725\,[\sqrt{\mu} - \log f] \tag{14}$$

for four values of the ionization constant, including complete dissociation.[12] The fraction of the salt in the form of the primary ion at 0.1 M is approximately 8.0, 0.3, 0.7 and 0.8. For extremely dilute solutions the limiting law still holds, but the effect of association increases very rapidly, yet soon becomes nearly constant (curves nearly parallel) because of the rapid decrease in the activity coefficients. This leads to an inflection in very dilute solutions with a considerable range through which the curves are nearly rectilinear.

The curves of Fig. 3 have the same general shape as those of Fig. 2; by proper choice of ionic size and ionization constant they might be made to fit very closely. This hardly seems worth while, but the curves of Fig. **3** were used as guides in the extrapolation of those of Fig. 2 to zero concentration. The figure shows that, even with a theory which assumes the Debye–Hiickel limiting law at zero concentration, that law can be used as a guide only in extremely dilute solutions if there is a large amount of ion association. The assumption that the activity coefficient is the same as that of a typical strong electrolyte is even more dangerous, and the assumption that the logarithm of the activity coefficient is proportional to $\sqrt{c}$ and determination of the proportionality constant from the measurements themselves is still worse.

Discussion

These inflections at very low concentrations were first noted by Bjerrum.[13] They are discussed more specifically for a salt with high valence cation dissolved in one with high valence anion by LaMer and Mason,[14] and for ions of equal valences by Gronwall, LaMer and Sandved.[15] These authors attribute the inflections to the effect of higher terms in the power series expansion of the electrical density, which are neglected in the Debye–Hiickel treatment.

The computations which these latter authors have promised for unsymmetrical salt are not yet published. An examination of their Equations 34 and 64 for $\log f\pm$ shows that the ratio of the higher-order odd terms to the first, which is the Debye–Hiickel approximation, for a 2–1 salt with no foreign ions is from $^9/_{16}$ to $^4/_9$ the ratio for a 2–2 salt, and that the leading terms in the expansion of all the even terms, which are zero for a symmetrical salt, have the sign opposite to that of the odd terms, so that they tend to compensate. A closer examination of the first even term shows that it must remain positive to a considerable concentration.

Bjerrum's approximate method makes $\log f\pm$ for a 2–1 salt very nearly

---

[12] The lowest value is nearly equal to that found for sulfuric acid (0.0115) by Sherrill and Noyes, THIS JOURNAL, ***48,*** 1861 (1926).

[13] Bjerrum, Kgl. *Danske Videnskab. Selskab, Math.-fys. Medd. VII, 9* (1926).

[14] LaMer and Mason, THIS JOURNAL, ***49,*** 410 (1927).

[15] Gronwall, LaMer and Sandved, *Physik.* Z., ***29, 358*** (1928).

the same as that for two ions with valence $\sqrt{2}$ at the same molal concentration, which is qualitatively consistent with the results of the other method. He treats the solutions as though they were incompletely dissociated with the constant for the *formation* of the binary compound depending on the size and valence in the following way

$$K' = 0.004\ \pi\ N\ (ab)^3 \int_2^b e^y y^{-4} dy$$

$$b = \frac{\epsilon^2\ z_1 z_2}{DkT}\frac{1}{a}$$

N is Avogadro's number, k the Boltzmann constant, ϵ the charge on the electron, D the dielectric constant, T the absolute temperature, z_1 and z_2 are the valences of the ions, and a is their effective mean diameter. The remainder of his computation differs only in details from that described in this article. The curves of Fig. 2 can be fitted approximately by attributing the sizes: $CdCl_2$ about 1.3 Å., $PbCl_2$ about 1.9 and $ZnCl_2$ from 3.5 to 6.

The properties of an electrolyte solution must depend on those of the solvent and of the individual ions, whether or not dissociation is complete. The original Debye–Hückel treatment, including the extensions to the higher terms cited above, considers only the dielectric constant of the solvent, and the valence and mean collision diameter of the ions. Hückel[16] has included the effect of the ions on the dielectric constant of the solutions, and the general equations of Gronwall, LaMer and Sandved include this effect for the higher terms. These treatments all consider the ions as having spherical symmetry.

There is no question but that a general treatment must consider two kinds of dissymmetry: first, that of the isolated ions, as illustrated by the nitrate and acetate ions; and second, that induced by an electrical field because of the deformability of the ion. The second effect is probably responsible for a large part of what Bronsted terms "specific interaction of ions" and in extreme cases for chemical association. Since it depends upon a very close approach of the ions, it may be expressed to a good approximation by the law of mass action.[17]

The effect of higher terms and that of deformability may each be approximated by assuming chemical combination, and the only difference is that the first makes the association constant a function of the size while the second makes it an independent parameter. Since the further effect of the size is of a smaller order, it would require great confidence in the accuracy of the experimental measurements and in the validity of the Debye method to differentiate between the two effects from measurements on a single salt.

[16] Hückel, *Physik. Z.*, 26, 93 (1925).

[17] The authors make no claim of originality for this treatment. It has been discussed more or less specifically in many places. See especially Fajans, *Trans. Faraday Soc.*, 23. 357 (1927).

The correlation of measurements on a large series of salts, when they are available, may give interesting information.

We can say with assurance that for higher valence ions part, at least, of the association constants must be attributed to the higher terms. This effect seems sufficient for the rare gas type ions, though deviations might be expected with the larger anions and high valence cations, and for some polyatomic ions. The authors believe that, whenever the assumption of spherical symmetry leads to a value of a less than two Ångström units, some other explanation should be sought, and that deformation often plays an important part in other cases. Certainly, unless the values in Table II are considerably in error two, and probably three, specific parameters (which might be the size, deformability, and effect on the dielectric constant) are required to fit both barium chloride and zinc chloride. No theory assuming spherical non-deformable ions can account for the transference number of the cadmium ion becoming negative,[18] or for the behavior of a weak electrolyte like acetic acid. It should be noted that we have no definition of association precise enough to determine the extent of it exactly or even to recognize its existence in small quantities.

Results

For the cell ZnHg (2 phase), $ZnCl_2$, AgCl, Ag we obtain $E_0 = 0.9834$ v. Combining this with Cohen's[19] value of 0.0006 v. for the difference in potential between zinc and the two-phase amalgam, and —0.2224 v. for the silver chloride electrode,[20] we obtain

$$\text{Zn, ZnCl}_2\text{, AgCl} \quad E_0 = 0.9840 \text{ v.}$$
$$\text{Zn, Zn}^{++} \quad E_0 = 0.7616 \text{ v.}$$

Lewis and Randall give the values 0.9839 and 0.7551. The close agreement of the first is somewhat of a coincidence; the difference in the second is due to the high value attributed to Horsch's silver chloride electrodes.

For the cell PbHg (2 phase), $PbCl_2$, AgCl, Ag we obtain $E_0 = 0.3430$ v. Carmody, extrapolating as a linear function of $\sqrt{m}$, obtained 0.3426.

For the cell Cd, $CdCl_2$, AgCl, Ag (Horsch) we obtain $E_0 = 0.5678$ v. Lewis and Randall give 0.5700 v.

In Table II are given values of the activity coefficient for several of the bivalent metal chlorides at rounded concentrations. The values for zinc, lead and cadmium chlorides are computed from the data discussed in this paper. The computations for calcium chloride are made from Equation 1 of the preceding paper[5] with the constants there given. For barium chloride a similar equation was used with $\alpha = 2.3$, $\beta = 0.0136$ volt, and $c/m = 0.99707 - 0.0286\,m - 0.00139\,m^2$.

[a] In a saturated solution, m = 0.03905, γ = 0.413.

Summary

The electromotive force of the cell $ZnHg_x$ (2 phase), $ZnCl_2$, $AgCl$, Ag has been measured at 25° from 0.003 to 1.5 M.

Measurements on barium chloride agree with the Debye–Hückel equation, assuming complete ionization. Those on zinc chloride, lead chloride and cadmium chloride do not, but they may be fitted by assuming incomplete dissociation of the primary ion. The effect of incomplete dissociation is calculated and values of the standard cell potentials and activity coefficients are computed. The relation of the apparent association to the "higher terms" and to the deformability of the ions is discussed.

TERNARY SYSTEMS: WATER, TERTIARY BUTANOL AND SALTS AT 30°

BY P. M. GINNINGS AND DOROTHY ROBBINS

RECEIVED FEBRUARY 5, 1930 PUBLISHED JUNE 6, 1930

Tertiary butanol has been more or less a laboratory curiosity until recent years but economical methods of manufacture from the by-products of cracking petroleum have opened up a new field of potential uses. A résumé is given by Davis and Murray[1] concerning the chemical properties, solvent powers and physiological properties of the aliphatic tertiary alcohols and their industrial possibilities. Investigation of some of the physical properties of one of these, tertiary butanol, seems to have lagged behind that relative to the chemical properties. For example, while most of the aliphatic alcohols entirely miscible with water have been investigated as regards the two liquid phase formation in the familiar salting out phenomena when an aqueous solution of the alcohol is shaken with various salts, little has been done with tertiary butanol. Search of the literature revealed that the ternary systems water, tertiary butanol and salts had been investigated only partially in one paper,[2] in which potassium chloride was the only salt tried with the tertiary butanol. Investigation of this set of ternary systems seemed desirable for two reasons: first, tertiary butanol is the only aliphatic tertiary alcohol entirely miscible with water; second, it has the highest molecular weight of any simple aliphatic alcohol that is entirely miscible with water. The other butanols are only partially miscible with water.

While there are many inorganic salts that will cause the formation of two liquid phases in the above three-component system, only ten diversified salts were investigated in detail here. Some of these salts had been used in investigations of analogous systems; some were chosen in order to find the most effective salting-out agent; and the four potassium halides were selected primarily in order to compare their respective binodal curves. The system of graphical representation of the binodal and conjugation curves, interpolation to the plait point and phase composition used here is similar to that used in the "International Critical Tables," Vol. III, p. 398.

The aliphatic alcohols entirely miscible with water are methanol, ethanol, propanol, isopropanol, 1-propenol (allyl alcohol) and tertiary butanol. Fortunately, for the sake of comparison, all of the above alcohols have now been investigated as regards their behavior with aqueous

potassium carbonate solutions. If the binodal curves of all are plotted upon the conventional triangular diagram and a perpendicular line is drawn from the alcohol–salt axis to the water apex, there will be a series of intersections between this line and the respective binodals in the following order: methanol, ethanol, isopropanol, 1-propenol, tertiary butanol and propanol. The tertiary butanol binodal lies very close to the propanol binodal. A little inspection here of the order reveals how unsaturation, branched carbon chain and progression in the homologous series affect the binodals in these ternary systems.

Sodium carbonate seems to have the highest specific salting-out effect because the binodal curve approaches nearest to the water apex. However, the ratio of the concentration of the alcohol to that of the water, in the salt-rich phase, is probably a better measure of the salting-out effectiveness; the smaller the ratio, the more effective the salt. In this respect, potassium carbonate and potassium fluoride in concentrated solutions surpass the sodium carbonate and seem to be the most effective of the ten salts investigated. This seems to be in agreement with the results from several investigations of salting-out agents.[3] In some cases, such as potassium iodide, the binodal curve terminates abruptly at both ends because the two liquid phase formation ceases. In other cases, such as potassium carbonate and potassium fluoride, the binodal curves approach the alcohol–water and water–salt axes with a very small slope. If a comparison is made of the four binodal curves of the potassium halides, the effectiveness seems to be an inverse function of the molecular weight of the potassium halide, potassium fluoride being the most effective.

Although determination of the binodal curves was the main object of this investigation, the conjugation curves were determined approximately, and also the intersection of the two, the plait point. The authors believe that the binodal curves here are in error by less than 1% in any case, and probably within 0.3% in many cases. However, the method used for the determination of the conjugation points allows a large possible error in some of the systems; this is especially true where the binodal curve follows quite closely and almost parallel to the alcohol–water axis. Here the $dC_{\text{alc.}}/dC_{\text{salt}}$ is very large, making the exact composition of the alcohol-rich phase as regards alcohol content difficult of determination by the indirect method used. Where the binodal curve is neither near nor almost parallel to the alcohol–water axis—as in the system with potassium iodide—the conjugation curve is relatively accurate. Usually, the sum of the weights of the three components in the mixture was from five to fifteen grams.

[3] Frankforter and Frary, "Orig. Com. 8th Intern. Congr. **Appl.** Chem.," 22, 87–127; C. A., **7,** 44 (1913); Frankforter and Frary, J. Phys. Chem., **17,** 402–473 (1913); Frankforter and Cohen, THIS JOURNAL, 36, 1103–1134 (1914).

Experimental

The synthetical method was used throughout in the determination of the binodal curves. Known weights of each of the three components were introduced into a tapered centrifuge tube; the salt (c. p.) from a weighing tube weighed accurately to one centigram, the tertiary butanol (Eastman) and water from their respective burets. By careful and repeated trials with much shaking, the quantities of the three components in the tube were so regulated that the second liquid phase was at the point of appearance or disappearance. Observation of the cloudiness along with the use of the centrifuge to estimate the volume of the second liquid phase seemed to be the best method for the determination of the binodal points. The tube was shaken thoroughly in a well-stirred water-bath at 30° (plus or minus 0.2°) as the last step in the determination of each binodal point. The quantities of the three components were expressed as weight percentages, and so graphed on the triangular diagram.

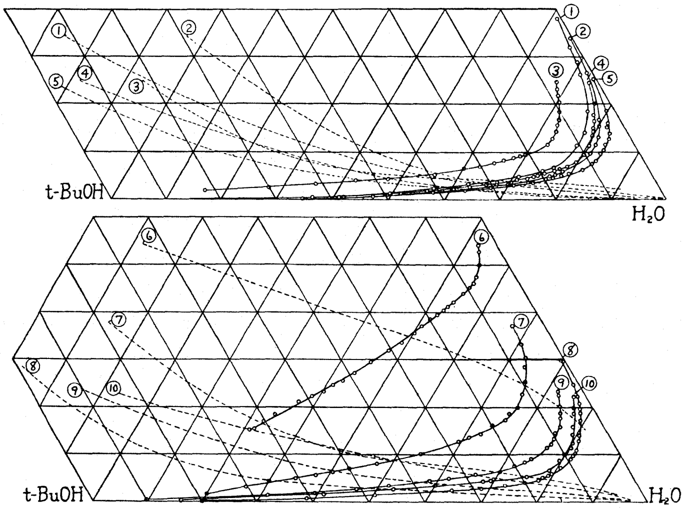

Fig. 1.—1, $(NH_4)_2SO_4$; 2, K_2CO_3; 3, NH_4Cl; 4, Na_2SO_4; 5, Na_2CO_3; 6, KI; 7, KBr; 8, KF; 9, KCl; 10, NaCl; ——, binodal; - - - - - -, conjugation.

An indirect analytical method was used for the determination of the conjugation points; indirect in the case of the alcohol-rich layer and direct in the case of the salt-rich layer. Two liquid phases were set up in equilibrium in the tube and brought to the correct temperature of 30° in the water-bath. Then a rubber stopper, perforated with two glass tubes, was inserted into the centrifuge tube, thereby producing a miniature wash bottle. By obtaining the difference between weighings (plus or minus 1 cg.), known weights of the two liquid phases were withdrawn into two weighed crucibles. Evaporation to dryness of the pair of crucibles corresponding to the two liquid phases and weighing gave the salt content of both phases. But according to the custom of preparation of the conjugation curves in the "International Critical Tables," the salt content of the salt-rich phase is plotted against the alcohol content of the alcohol-rich phase, so the alcohol content of the alcohol-rich phase was determined by notation of the salt content, reference to the binodal curve and intrapolation or extrapolation to the point required. Similarly, the segment of the conjugation curve on the opposite side of the binodal curve was obtained by plotting the alcohol content of the salt-rich phase against the salt content of the alcohol-rich phase. The intersection of the line uniting the two segments, just mentioned, with the binodal curve gave the plait point.

Summary

1. Tabular data, binodal curves, conjugation curves and plait points are given for the ternary systems of tertiary butanol and water with ten inorganic salts.

2. A comparison is made between the binodal curves of the systems water, alcohol and potassium carbonate, when the alcohol varies among the water-miscible aliphatic alcohols.

3. Potassium carbonate and potassium fluoride are the most effective salting-out agents of the ten salts investigated.

4. The value of the respective potassium halides as salting-out agents seems to be an inverse function of the molecular weight of the halide, potassium fluoride being the most effective of the four.

THE DROP WEIGHT METHOD FOR THE DETERMINATION OF SURFACE TENSION. THE EFFECT OF AN INCLINATION OF THE TIP UPON THE DROP WEIGHT

BY DAVID M. GANS AND WILLIAM D. HARKINS

RECEIVED FEBRUARY 10, 1930 PUBLISHED JUNE 6, 1930

Introduction

The drop weight method has been developed as an accurate method for the determination of surface tension. If the greatest accuracy is not required, a simple form of apparatus gives reliable measurements with ease and rapidity. For any type of work, the variation of the drop weight with the angle of inclination of the tip should be known, and so the requisite values were determined.

Results

With the apparatus and procedure described in detail elsewhere,[1] the drop weights for conductivity water were determined at 25.0°, with the tip at various angles of inclination. The angle a which the tip made with the horizontal plane was set at from 0.0 to 20.0°, and was measured to within 0.1° by the use of a level. At an angle of 3.0°, the inclination of the tip was very apparent to the eye.

Table I gives the average weights in air of one drop of water. The apparent surface tension, for an observer unaware of the tilt of the tip, may be calculated by means of the equation

$$\gamma = \frac{Mg}{2\pi r}\,\phi\left(\frac{r^3}{v}\right) \qquad (1)$$

in which M is the weight of the drop in air, g is the acceleration due to gravity, r is the radius of the tip (0.2989 cm. in the present case) and ϕ, a function of r^3/v where a is the volume of the drop, is the empirical correction factor of Harkins and Brown,[1] taken from a graph of their results. These calculated surface tensions were plotted against the corresponding angle α, and from the smoothed curve, which passed exactly through four of the points and came within 0.07 dyne of the other two, the apparent surface tention γ_α was read for each value of a employed. Since γ_α is the apparent surface tension when the dropping surface makes the angle $a!$ with the horizontal, γ_0 will be the surface tension when the dropping surface of the tip is accurately horizontal, that is, the true surface tension of water at this temperature. In Col. 3 of Table I are given the differences $\gamma_0 - \gamma_\alpha$. The apparent surface tension is obviously not very different from the true value, when a is less than 5.0°. When α is 20.0°, which is a very large

---

[1] I-Tarkins and Brown, THIS JOURNAL, 41, 499 (1919).

angle under the conditions, this difference is only 2.3% of γ_0 for the tip used.

TABLE I

AVERAGE WEIGHTS IN AIR OF ONE DROP OF WATER

α	M	$\gamma_0 - \gamma_\alpha$	$\gamma_0 - \gamma'$	$2.025 \times 10^{-4}\alpha^3$
0.0°	0.08424	0.00	0.00	0.00
6.0°	.08420	.03	− .08	.03
7.5°	.08420	.10	− .20	.09
10.0°	.08391	.23	− .18	.20
15.0°	.08333	.73	− .26	.68
20.0°	.08224	1.62	− .16	1.62

It is desirable to know, first, whether the true surface tension of water may be calculated from a measurement of the drop weight at a large angle α, and, second, how large α may be without affecting the results appreciably.

When the tip is inclined, its projection upon a horizontal plane is no longer a circle of radius r, but an ellipse of semi-major axis r and semi-minor axis r cos α. Therefore, the drop weight should not be that for a circular tip of radius r, but would more nearly correspond to that for a circular tip of radius r', where r' would be an average semi-axis of the ellipse. The surface tension should be given more accurately by

$$\gamma' = \frac{Mg}{2\pi r'}\,\phi\left(\frac{r'^3}{v}\right) \qquad (2)$$

provided the proper value of r' is known.

If the radius of the circle whose circumference is that of the ellipse is taken for r', then $r' = r\sqrt{(1 + \cos^2\alpha)/2}$ very nearly. The calculated values of $\gamma_0 - \gamma'$ are given in Col. 4 of Table I. For all values of α, Equation 2 gives results that are within 0.4% of the true surface tension. For small values of α, however, the results obtained with Equation 1 are better. If r' is taken to be the radius of the circle whose area is that of the ellipse, then $r' = r\sqrt{\cos\alpha}$. The results in this case are practically identical with those already listed in Col. 4 of Table I. Other methods for obtaining the average r' may lead to smaller values of $\gamma_0 - \gamma'$. Equation 2 thus gives a good approximation for the true surface tension.

To determine what the values of γ_α are for small angles α, equations of various forms were fitted to the data in Col. 3 of Table I. The equation

$$\gamma_0 - \gamma_\alpha = 2.025 \times 10^{-4}\alpha^3 \qquad (3)$$

for α in degrees was found to fit well, as is shown in Col. 5 of Table I. By means of this equation, the values of $\gamma_0 - \gamma_\alpha$ for the small angles in Table II are secured. The values of γ_α are also included, for 71.97 dynes per cm. as the accepted surface tension[2] of water at 25.0°. For angles of inclina-

TABLE II

VALUES FOR SMALL ANGLES

α	$2.025 \times 10^{-4}\alpha^3$	γ_α	α	$2.025 \times 10^{-4}\alpha^3$	γ_α
0.00°	0.000	71.97_0	4.00°	0.013	71.95_7
0.25°	.000	71.97_0	5.00°	.025	71.94_5
0.50°	.000	71.97_0	6.00°	.044	71.92_6
1.00°	.000	71.97_0	8.00°	.104	71.86_6
2.00°	.002	71.96_8	10.00°	.203	71.76_7
3.00°	.005	71.96_5			

tion less than 3°, the effect of the tilt on the calculated surface tension is not appreciable. Unlike other methods for the determination of surface tension, the drop weight method is thus particularly insensitive to any inclination of the measuring apparatus. The utmost precautions need not therefore be taken to insure a horizontal dropping surface, and a setting of within 2° of the horizontal, an angle quite apparent to a trained eye, will probably suffice in all cases.

Summary

Results obtained with the drop weight method for the determination of surface tension are found to be unaffected by a slight inclination of the apparatus. The effect upon the weight of a drop of a tilt of the tip of less than 3° is not appreciable. Precautions need not, therefore, be taken to set the dropping surface at an angle of less than 2° with the horizontal.

THE SURFACE TENSION OF AQUEOUS SOLUTIONS OF PARA-TOLUIDINE

BY DAVID M. GANS AND WILLIAM D. HARKINS

RECEIVED FEBRUARY 10, 1930 PUBLISHED JUNE 6, 1930

1. Introduction

During the progress of work in this Laboratory on surface phenomena, there arose a need for reliable data on the surface tension of aqueous solutions of *p*-toluidine. Such measurements had already been made by Edwards,[1] who used a modification devised by Ferguson of the capillary height method, and by Frumkin, Donde and Kulvarskaya,[2] who employed the capillary height method. The two sets of results are in very poor agreement. While Frumkin did not lay claim to great accuracy in his own determination,[3] these showed the work of Edwards to be seriously in error.

[3] Private communication.

2. Method, Apparatus, and Procedure

For the measurement of the surface tension of aqueous solutions of *p*-toluidine and similar substances, the drop weight method has certain advantages. For while such solutions wet with ease the ground-glass tip used in the drop weight method, it has been observed that solutions of even very pure *p*-toluidine wet polished glass with some difficulty. The capillary height method is therefore not suitable.

The apparatus which was employed is shown in Fig. 1, and is a modified form of the standard apparatus described by Harkins and Brown.[4] The metal box B, which contains the glass tip, adequately cleaned, and the solution, is immersed in a thermostat kept accurately at 20.0°. The ground surface of the glass tip is maintained in the horizontal plane indicated by the L-shaped level shown. Each drop is pulled over to almost full size by very gentle suction at a rubber tube attached to the metal tip-holder A. The first drop is allowed to hang for some minutes in the weighing bottle V, in order to saturate the enclosed air with the vapors from the solution. The drop is then drawn over and made as large as is possible without causing it to fall, and the level between the bottles S and V is so adjusted that the drop falls as slowly as is possible. The supply bottle S is raised or lowered for this purpose by means of the microscope stand T. This adjustment is accomplished through the pinion head P which is attached to the microscope stand by means of a small universal joint and a long metal rod that extends to the chair of the operator, who watches the formation of the drops through a small telescope, the cross hairs of which mark the maximum size of the stable drop and thus help in its control. When the required number of drops has been drawn over, the metal box is at once removed from the thermostat and opened, the weighing bottle V is chilled for exactly one minute in an ice-water mixture in order to condense most of the vapors within, and the bottle is removed, quickly stoppered and weighed.

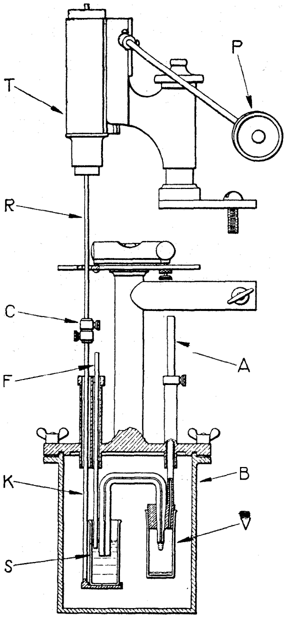

Fig. 1.—Apparatus for the accurate determination of surface tension by the drop weight method.

3. Results

In the work here reported, each determination consisted of one run of twenty drops, and another, immediately following, of five drops. The

---

[4] Harkins and Brown, THIS JOURNAL, 41, 499 (1919).

difference represented the weight, in their own saturated vapor, of fifteen drops. In this difference the errors caused by the weight of the moisture condensed on the interior of the bottle by chilling are mostly eliminated. Three such determinations were made with each solution, and the average per drop was taken as the drop weight for that solution. Of the three results, none differed from the average by as much as 0.15%, while in only two of the twenty-seven single determinations was this difference greater than 0.10%.

The drops were usually allowed to hang for twenty to thirty seconds before they were permitted to fall. That this length of time was sufficient to enable the surface of the drop to attain equilibrium with the interior of the drop was demonstrated by work with a solution, containing 0.00606 mole of p-toluidine per kilogram of water, which, since this was the most dilute solution studied, gave the slowest diffusion into the surface. The drop weight was determined for drops which maintained approximately their full size, before falling, for four minutes, and also for about twenty seconds each. The two results differed from their mean by only 0.08%. Apparently an age of one-half minute for the full-sized drop gives equilibrium of the surface with the liquid and the vapor phase.

With the solution containing 0.03376 mole of p-toluidine per kilogram of water, the drop weight of drops held at almost full size for four minutes differed from that of drops held at full size for twenty-five seconds each by only 0.06%. This demonstrates that, even for this relatively concentrated solution, oxidation of the *p*-toluidine in the surface of the drop did not take place to a sufficient extent to alter the surface tension of the solution.

The density of each solution at 20.0° was determined in duplicate with a pycnometer of approximately 20-cc. capacity, the volume of which was accurately determined with conductivity water as the standard.

Experiments were carried out over practically the entire concentration range. The results are given in Table I. In Col. 5 is listed the weight of a single drop in air saturated with the vapor from the respective solution.

TABLE I

SURFACE TENSION OF AQUEOUS SOLUTIONS OF *p*-TOLUIDINE

Soln.	Mole per kg. of water, m	Mole per kg. of soln.	Log, m	Density, g. per cc. at 20.0°	Drop weight, g.	Volume per drop, V, in cc.	r^3/v		γ in dynes per cm. at 20.0"

7	,03376	.03364	−3.3891	.99828	,066889	.06708	.3982	1.6537	57.73
8	.04935	.04909	−3.0093	,99838	.060395	,06057	.4410	1.6606	52.35
9	.06218	.06177	−2.7781	.99843	.056533	.05669	.4712	1.6641	49.10

Each value is the average of three determinations, as outlined above. In Col. 7 is given the calculated value of r^3/v where r, the radius of the tip used, is 0.29892 cm., the average of measurements made with a calibrated traveling microscope over six different diameters, and v is the volume of the drop in question. The experimentally determined correction factor Φ tabulated in Col. 8 is a function of r^3/v and was taken from a graph which plots the values of Harkins and Brown.

The equation by means of which the surface tension was calculated is

$$\gamma = \frac{Mg}{2r}\Phi$$

in which γ is the surface tension in dynes per centimeter, M is the weight in grams of the drop in air saturated with the vapors from the solution, g is the acceleration due to gravity, which is 980.28 cm. per sec. per sec. in this Laboratory, and r and Φ have the significance pointed out above.

4. Purification of Materials

The p-toluidine used was obtained from the Eastman Kodak Company and was purified from it isomers and other impurities as recommended, in general, by Berliner and May.[5] The p-toluidine was twice distilled, the end fraction being discarded each time. It was dissolved in five times its volume of ether, and the oxalate precipitated by addition of an ethereal solution of oxalic acid. The salt was washed with ether and recrystallized four times from hot water. A little oxalic acid was added to the water each time to hinder hydrolysis. The p-toluidine was liberated with sodium carbonate solution, recrystallized from hot water, steam distilled and again recrystallized from hot water. The snow-white crystals were dried in *vacuo* over stick potassium hydroxide for twelve days. The elaborate purification reduced the yield to 15%. The crystals melted at 43.6°, while the value given by the "International Critical Tables" is 43.7".

Conductivity water was used for all of the solutions, which were made up by weight.

5. Comparison with Other Data

The measurements of Edwards were obtained at temperatures between 15 and 17.5°. The values which he found for the surface tension of water are higher than the corresponding value given by the "International Critical Tables."[6] His values were, therefore, multiplied by 0.9780, which brings his average value for pure water to 73.34 dynes per centimeter, the accepted value. The densities at 20° of p-toluidine solutions are very nearly that of water, and so the densities at 16°, required for the conversion to the concentration units used in this paper, were obtained by adding to

---

[5] Berliner and May, THIS JOURNAL, 49, **1007 (1927).**

[6] "International Critical Tables," McGraw-Hill Book **Co.,** New **York, Vol. IV, p. 447.**

the density of water at 16° the difference between the densities of the corresponding solution and of water at 20°.

The data of Frumkin, Donde and Kulvarskaya were corrected in the same way, by use of the factor 1.0022.

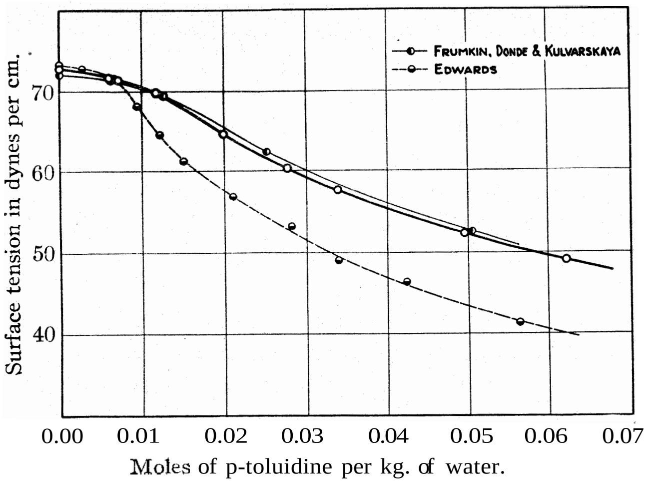

Fig. 2.—Surface tension of aqueous solutions of p-toluidine as given by different observers.

These data, together with those obtained in the present work, are given in Fig. 2. It is obvious that the results of Edwards are much too low. This difference is strikingly brought out in the logarithmic plot in Fig. 3;

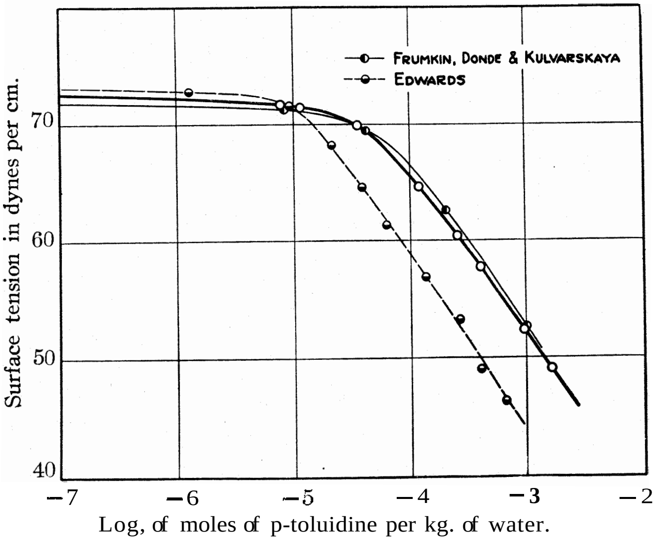

Fig. 3.—Surface tension of aqueous solutions of p-toluidine as given by different observers.

curiously enough, however, all of the three curves have almost the same slope in the straight portions of this graph.

6. Calculation of the Adsorption

The adsorption of p-toluidine at the air–solution interface may be calculated by means of the Gibbs adsorption equation

$$u = \frac{-1}{RT}\frac{d\gamma}{d \log_e a}$$

where γ is the surface tension in dynes per centimeter, a is the activity of the solute, R is the gas constant, **8.315** $\times 10^7$ ergs per mole degree, T is the absolute temperature and u is the number of moles of solute which must be added to the solution after the surface has been increased by one square centimeter, in order to bring the solution back to its initial concentration.

McBain and his co-workers[7] have found the activity of aqueous solutions of *p*-toluidine to be proportional to the concentration. While this result is probably not exact and is unexpected for a substance of the type of *p*-toluidine, the adsorption may, for the present, be calculated on this basis. In this case

$$d \log_e a = d \log_e m$$

in which m is the number of moles of solute per kilogram of water. The slope of the curve representing our data in Fig. **3** is, therefore, directly d γ/d $\log_e$ a.

The calculations are tabulated in Table II for the more concentrated solutions included in Table I. The adsorption is listed in Col. **3** as the number of moles per square centimeter of surface, in Col. 4 as the number of molecules per square centimeter of surface and in Col. **5** as the apparent surface area in sq. Å. occupied by each molecule.

TABLE II

ADSORPTION OF *p*-TOLUIDINE IN AQUEOUS SOLUTION CALCULATED BY THE GIBBS ADSORPTION EQUATION

Soln.	Mole per kg. of water, m	$\frac{-d\gamma}{d \log_e m}$	$u \times 10^{10}$	$u' \times 10^{-14}$	Area per molecule in sq. Å.	Mole per cc. of soln. 5	0.01985	12.14	4.981	3.02	33.1	0.04198	0.0120	0.05	3.07	32.6
6	.02753	13.25	5.436	3.30	30.3	.04274	.0166	.07	3.36	29.8
7	.03376	13.77	5.649	3.43	29.2	.04336	.0204	.07	3.50	28.6
8	.04935	14.10	5.785	3.51	28.5	.04490	.0297	.09	3.60	27.8
9	.06218	14.10	5.785	3.51	28.5	.04617	.0374	.11	3.62	27.6

If one square centimeter of new surface were to be instantaneously formed, a certain amount of solute would already be present in the fresh surface.

---

[7] McBain, Wynne-Jones and Pollard, "Colloid Symposium Monograph," The Chemical Catalog Company, New York, 1928, Vol. VI, p. 57.

This amount is further increased by the quantity u which is then adsorbed. The total number of molecules in each square centimeter of surface is thus the sum of these two amounts. The number already in the surface is unknown, but may be taken as approximately the two-thirds power of the number of molecules in each cubic centimeter of solution, a value given in Col. 8. This correction is not great for solutions as dilute as these, but is considerable for more soluble substances. In Col. 10 is listed the corrected apparent area in sq. Å. occupied by each molecule in the surface region.

The apparent surface area per molecule of *p*-toluidine appears to be 28 sq. Å. The work of Adam[8] with insoluble films gives the value 23.8 sq. Å. for the benzene ring perpendicular to the surface. In view of the fact that the activity of solutions of *p*-toluidine is not known accurately, this agreement is satisfactory and serves as an indication that the adsorbed solute forms a monomolecular film on the surface of the solution.

7. Summary

1. The drop weight method for the measurement of surface tension has the advantage over the capillary height method in that the former is independent of the angle of contact, and can thus be used with substances like *p*-toluidine, whose aqueous solutions do not wet glass easily.
2. A slightly improved procedure for the determination of surface tension by the drop weight method is presented.
3. Measurements of the surface tension of aqueous solutions of *p*-toluidine by means of the drop weight method are given and compared with earlier results. *p*-Toluidine is a very surface-active substance, for at 20.0° it lowers the surface tension by 8.18 dynes when dissolved in water to the extent of 0.0199 mole per kilogram of solvent, and by 23.65 dynes with 0.0622 mole.
4. By use of the Gibbs adsorption equation, the area occupied by each molecule of *p*-toluidine in the surface region is found to be 28 sq. Å. for the nearly saturated solution, which is in agreement with the area expected from other sources for a monomolecular film.

THE HEAT CAPACITIES OF ARSENIC, ARSENIC TRIOXIDE AND ARSENIC PENTOXIDE AT LOW TEMPERATURES[1]

BY C. TRAVIS ANDERSON[2]

RECEIVED FEBRUARY 11, 1930 PUBLISHED JUNE 6, 1930

In continuation of its general program of determination of the heat capacities of the various metals and oxides which are important in metallurgical processes, the Pacific Experiment Station of the U. S. Bureau of Mines has studied the metals and oxides of arsenic, antimony and bismuth at low temperatures. The thermodynamic properties of the metals and oxides of this group are of practical importance because they constitute some of the lead smelters' most difficult problems of reduction and refining, and they also have considerable theoretical interest. The present article deals only with the heat capacities of arsenic and its oxides; later papers will discuss the remaining materials in this group.

Method and Apparatus

With the exception of a few minor details, the methods and apparatus used in this work are identical with those previously described from this laboratory by Millar.[3] The apparatus was provided with a new thermocouple, which was made of wire from the same spool as Thermocouple No. 17 of Giauque, Buffington and Schulze,[4] and which was compared with No. 17 through a secondary standard at the temperature of liquid air, the melting point of toluene crystals and the melting point of ice. The secondary standard was calibrated directly against No. 17 at 28 points by Kelley.[5]

The standard cell was calibrated from time to time against another having a Bureau of Standards certificate.

Using the graphical method of Giauque and Wiebe,[6] a new temperature scale was determined for the resistance thermometer, and it is probably somewhat better than the one previously used in this Laboratory.

The volt-box correction was redetermined by substituting a standard 100-ohm resistance for the calorimeter resistance. The volt-box factor was calculated from accurate measurements of current and voltage when small amounts of electrical energy were passed through the volt-box and standard

resistance. This value is probably more reliable than that previously obtained directly by measuring the high resistance which the volt-box contains.

The heat capacity of the empty calorimeter was redetermined, using the new temperature scale.

By the use of liquid nitrogen instead of liquid oxygen it was possible to cool down to about 55°K. with the present pumping facilities. This temperature is about 5° lower than that previously reached in this Laboratory.

Materials

The sample of arsenic used contained **0.13%** antimony, no lead or silica and more than 99.8% arsenic. Its density was found to be **5.48.** A **342.9-g.** sample was studied.

The arsenic trioxide was of C. P. grade, but was resublimed. Each particle was definitely crystalline and of octahedral structure. It analyzed better than **99.8%** arsenic trioxide and had a density of **3.85.** The calorimeter was filled with a **267.4-g.** sample.

The arsenic pentoxide was a very pure material which was dried at 550° after treatment with concentrated nitric acid. It contained more than 99.7% arsenic pentoxide. The only detectable contamination was **0.2%** arsenic trioxide. It contained no antimony. The material did not consist of separate crystals, as did the arsenic trioxide, but of crystalline aggregates; **179.7** g. of the pentoxide was used. It had a density of **4.32.**

Screen tests were made on these materials and the results are shown in Table I.

TABLE I

SCREEN SIZES OF SAMPLES MEASURED

Screen size	As, %	As_2O_3	As_2O_5
+ 35	0.25	...	80.6
+ 48	..	4.5	18.0

+150	13.5	2.5	..
+200	20.0	8.0	0 7
−200	1.25	80.5	..

The Specific Heats

The heat capacities of these substances expressed in gram calories (15°) per gram formula weight are given in Table II and are shown graphically in Fig. 1. In changing joules to calories the factor[7] 1/4.184 was used. The calculations were made on the basis of O = 16 and As = 74.96.

Calculation of Entropies.—The entropy calculations were made in the usual manner. The experimental heat capacity curves were extended below the lowest measurements, so as to approach and finally coincide with Debye functions having the following parameters (Θ): for As, 275; As_2O_3,

141; As_2O_5, 240. In Table III are given the results of the entropy calculations.

TABLE III

ENTROPIES FROM EXPERIMENTAL DATA

	As		As_2O_3	
Extrap.	(0-56.2)°K.	1.20	(0–56.2)°K.	3.54
Graph.	(56.2–298.1)	7.16	(56.2–298.1)	22.04
S_{298}		8.4 ± 0.2 E. U.		25.6 ± 0.4 E. U.

	As_2O_5	
Extrap	(0–63.1) °K.	1.94
Graph.	(63.1–298.1)	23.30
S_{298}		25.2 ± 0.4 E. U.

It was found possible to fit the molal specific heat curves of the two oxides by the following combinations of Debye and Einstein functions

$$C_{As_2O_3} = D\left(\frac{141}{T}\right) + 2D\left(\frac{567}{T}\right) + 2D\left(\frac{1054}{T}\right)$$

$$C_{As_2O_5} = D\left(\frac{240}{T}\right) + 2E\left(\frac{368}{T}\right) + 2E\left(\frac{727}{T}\right) + 2D\left(\frac{1600}{T}\right)$$

The arsenic trioxide combination fits the experimental results up to 298°K., and that for arsenic pentoxide up to 125°K. Above 125°K. the experimental curve for arsenic pentoxide begins to rise above that of the function sum, probably due to $C_p - C_v$ becoming appreciable. Similarly, it may be that C_p and C_v for arsenic trioxide are very nearly equal up to 298°K.

As a means of demonstrating the average agreement between the experimental results and these combinations, the entropies at 298°K. were calculated, using these function sums. The results obtained are for arsenic trioxide 25.6 E. U., and for arsenic pentoxide 25.2 E. U., which are identical with the values previously given. In calculating the entropy of arsenic pentoxide by use of the functions, it was necessary to add an entropy difference of 0.17 unit, representing the difference between the experimental curve and the theoretical curve, in order to obtain the above values.

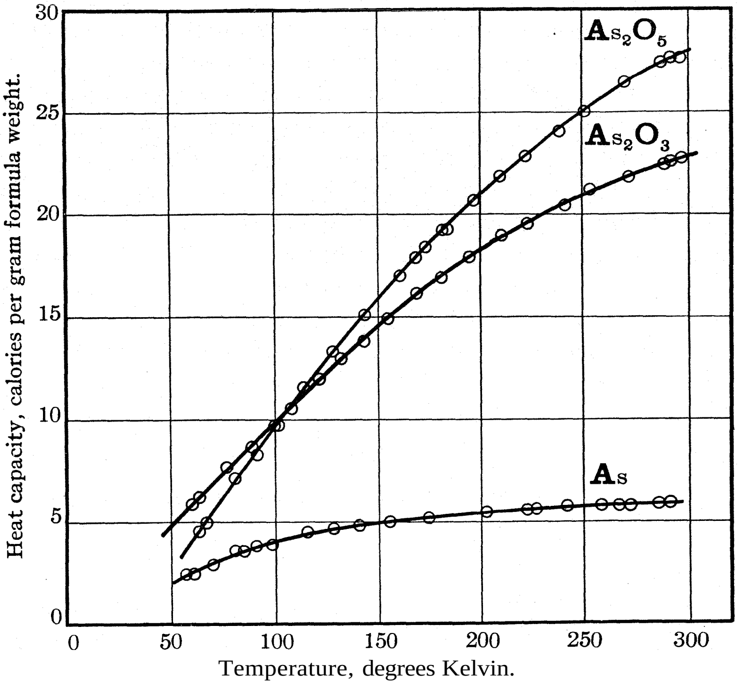

Fig. 1.—The heat capacities per gram formula weight of arsenic trioxide and arsenic pentoxide.

Related Thermal Data

The heats of formation of the oxides have been determined by Thomsen.[8] For arsenic trioxide he gives —154,700 Cal., and for arsenic pentoxide —219,400 Cal. Berthelot[9] gives —156,400 for the heat of formation of

[8] Thomsen, "Thermochemistry," Longmans, Greene and Co., London, 1908, p. *227.*

[9] Berthelot, "Thermochemie," Vol. II, 1897, p. 117.

arsenic trioxide. Schuhmann[10] determined the free energy of formation of arsenic trioxide from cell measurements. Correcting Schuhmann's result by the use of Eastman's[11] value for the free energy of formation of liquid water, ΔF°_{298} for arsenic trioxide was calculated to be $-137{,}000$ Cal. Using the integrated Gibbs–Helmholtz equation, Schuhmann calculated from the temperature coefficient of his cells, over a 20° temperature range, that the heat of formation of arsenic trioxide was $\Delta H_{298} = -153{,}800$. Previous experience at this Laboratory with oxide cells[12] has shown that free energies may be obtained from oxide cells with high precision, but because of the usually low magnitude of the cell coefficient, and the inherent fluctuations and polarizability of such cells, thermal values from this source are often not entirely satisfactory. It is justifiable, therefore, to calculate heats of formation from free energies and entropies, when these latter quantities have a high probable accuracy. In this way, using the free energy from Schuhmann's cell value, and the entropies of arsenic and arsenic trioxide, the heat of formation of arsenic trioxide was calculated as $-156{,}500$ Cal. This value agrees very well with the value of $-156{,}400$ given by Berthelot.

In the case of the pentoxide, direct free energy data are unavailable, and the free energy of formation of arsenic pentoxide was calculated from Thonisen's value of $-219{,}400$ Cal. for the heat of formation, and the entropies of arsenic and arsenic pentoxide, to be $\Delta F^{\circ}_{298} = -185{,}400$ Cal. All of the data are summarized in Table IV.

TABLE IV

SUMMARY OF ENTROPIES, FREE ENERGIES AND HEATS OF FORMATION

	S_{298}	ΔF°_{298}	ΔH°_{298}
As	8.4	....	....
As_2O_3	25.6	−137,100	−156,000
As_2O_5	25.2	−185,400	−219,400

In conclusion the author wishes to thank R. W. Millar for making the measurements on arsenic trioxide and arsenic pentoxide, and K. K. Kelley for his assistance in calibrating thermocouples, making the new temperature scale, and in fitting the Debye and Einstein curves to the experimental values.

Summary

The heat capacities of arsenic, arsenic trioxide and arsenic pentoxide from about 57 to 300° Kelvin have been determined, and the corresponding entropies calculated. The heat of formation of arsenic trioxide and the free energy of formation of arsenic pentoxide have been calculated.

THE HEAT CAPACITY OF SILICON AT LOW TEMPERATURES[1]

BY C. TRAVIS ANDERSON[2]

RECEIVED FEBRUARY 11, 1930 PUBLISHED JUNE 6, 1930

In continuation of its general program of determination of the heat capacities of the various metals and oxides which are important in metallurgical processes, the Pacific Experiment Station of the United States Bureau of Mines has studied an especially pure sample of metallic silicon.

The method and apparatus used in this work are identical with those described previously.[3]

The sample of silicon was furnished by the Electro Metallurgical Company of New York. According to their analysis, it had the following composition:

Si	99.20	C as Carbon	0.052
Fe	0 017	C as SiC	0.02
Al	0.009	Ni	Nil
Mn	Trace	Mg	Nil
Cu	Nil	O_2	0.17
Ca	<0. 01	N_2	0.009
Ti	Nil		
Cr	Nil		99.48%

The analytic determination of silicon in this grade of material is difficult, and since the probable impurities are well accounted for, the sample may actually be 99.7% pure, *i. e.*, 100% minus the known impurities. A 139.8-g. sample was studied.

Screen tests were made, and the results are shown in Table I. The density of the silicon used was 2.34.

TABLE I

SCREEN SIZES OF SILICON

Screen size	+65	+100	+150	+200	−200
Percentage	2.0	1 5	2.0	12.0	82.5

The Specific Heat

Measurements of the specific heat of silicon at low temperatures have previously been limited to six determinations of true specific heat by Nernst

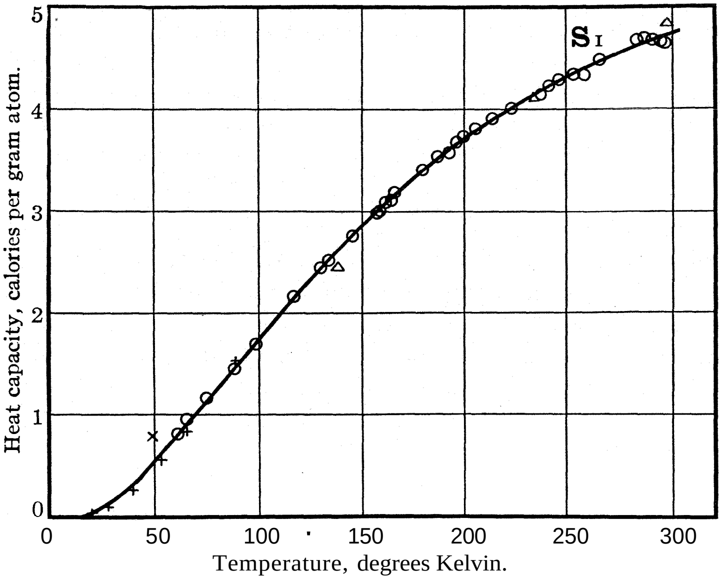
ing joules to calories for the results of this table, the factor[8] 1/4.184 was used. The calculations were made on the basis of Si = 28.1. The accuracy of the data do not warrant correction for the impurities present, none of which are significant except the silicon dioxide, and the mass content and equivalent heat corrections nearly balance out in this case.



○, Anderson; +, Nernst and Schwers; A, Russell; X, Dewar.

Fig. 1.—The heat capacity of silicon in calories per gram atom.

Calculation of Entropy.—The entropy was calculated in the conventional manner. The experimental heat capacity curve on a C_p–log T chart was extended below the lowest measurement and made to coincide with the Debye function having the parameter $\Theta = 441$. The results of these entropy calculations are

Extrapolated (0–56.2) °K.	0.288
Graphical (56.2–298.1)	4.237
Total	4.52 ± 0.05 E. U.

The result, 4.5, differs by 0.2 E. U. from the value 4.7 given by Lewis and Randall[9] calculated from the meager data existing at that time, and is thought to be of better accuracy, especially in view of the high purity of the author's sample.

The author wishes to thank R. W. Millar for making three of the experimental determinations.

THE FORMATION OF VITAMIN D BY MONOCHROMATIC LIGHT[1]

BY ABRAHAM LINCOLN MARSHALL AND ARTHUR KNUDSON

RECEIVED FEBRUARY 17, 1930 PUBLISHED JUNE 6, 1930

It has now been demonstrated fairly conclusively by the work of Rosenheim and Webster[1a] and of Hess and Windaus[2] that ergosterol is the parent substance and apparently the only sterol from which it is possible to make a preparation by irradiation with light which is effective in curing rickets. Previous to this work it was thought that cholesterol was the provitamin, but this activity has been shown to be due to the presence of about 0.05% of ergosterol in the cholesterol, which can be destroyed by brominating the cholesterol.[1,2,3]

Several investigators have experimented with the effect of monochromatic light on cholesterol. Hess and Anderson,[4] using a quartz monochromator, concluded that the upper limit of wave length which gave any effect was 3130 Å. Light of wave length 2800 and 3020 Å. produced material of marked potency. The energy density of radiation was 3.9 ergs per second per sq. mm. but the total dose is not given. Sonne and Rekling[6] have rayed rats directly with lights of various frequencies obtained from a monochromator. The wave lengths used were 366, 313, 302–297, 280, 265, 254, 248 and 227–220$\mu\mu$ obtained from a mercury arc. The area rayed was 8.1 sq. cm. and the energy density varied from 5–0.3 $\times$ 10^{-4} g. calories per sq. cm. per minute. All the rats were rayed for thirty minutes daily. In the range 302–254$\mu\mu$ the rats were exposed to approximately 1.3 X 10^6 ergs daily and were protected from rickets by the light when fed McCollum's ricket producing diet; 248$\mu\mu$ and 240$\mu\mu$ were found to have less effect and 227$\mu\mu$ no effect. However, in the last three cases the energy used was considerably less than in those cases giving complete protection; 313$\mu\mu$ had only a doubtful action and

366 no effect whatever. Fosbinder, Daniels and Steenbock[6] have rayed solid cholesterol with light of varying wave lengths obtained from a monochromator. The cholesterol was fed to rats having severe rickets over *a* ten-day period. The animals were killed and healing was detected by means of the line test. The minimum amounts of energy required to produce a measurable effect were as follows: 234 ergs at 2650 Å., $>$ 350 ergs at 2537 Å., 1170 ergs at 2800 Å. and 2730 ergs at 3020 Å.

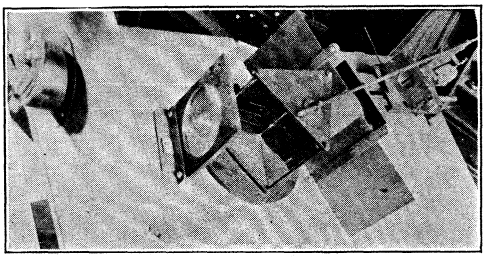

Fig. 1.—The monochromator.

In a subsequent paper[7] it was found that the quantity of radiant energy necessary to form an amount of vitamin D from ergosterol sufficient to cause demonstrable deposition of calcium in the bones of a rachitic rat was constant over the range 256–293$\mu\mu$, 700–1000 ergs being necessary.

Apparatus

A monochromator similar in design to that described by Harrison and Forbes[8] was used in this investigation.

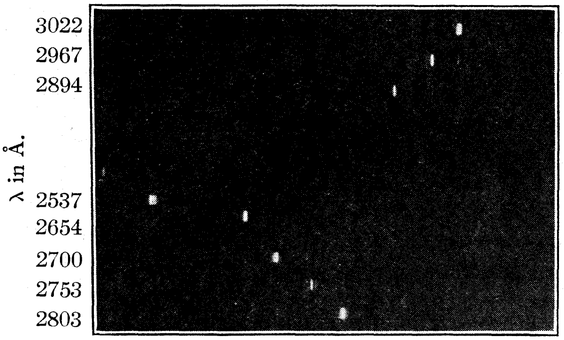

Fig. 2.—Photograph to show purity of monochromatic light obtained.

The 60° prism was made from fused quartz 135 X 135 X 135 mm. The fused quartz lenses had a ratio of focal length to diameter of 2 at 2800 Å. There was a considerable amount of spherical aberration with both lenses and this was corrected in part by the diaphragm shown in Fig. 1. This spherical aberration is largely responsible for

the considerable amount of continuous background shown in Figs. 3, 4 and 5 and for most of the impurity present in the individual lines in Fig. 2. The collimator slit was made from invar and curved slightly in order to neutralize distortion in the optical system and to obtain a vertical image at the telescope slit. Both slits were adjustable as to width. A linear Moll thermopile was mounted behind the rear slit and connected to a Moll galvanometer mounted on a Julius suspension. The lamp and scale were placed two meters from the galvanometer and the latter was found to have a current sensitivity of 10^{-9} amp. for 1 mm. deflection with a current of 1 amp. in the magnet coil. A photograph of the monochromator is given in Fig. 1. Figure 2 gives a series of spectrographs taken with a large Hilger quartz spectrograph of the light incident on the telescope slit of the monochromator at various settings using a mercury arc as light source. The times of exposure at the different settings were chosen to give roughly the same exposure on the plate for each setting, which thus gives a good idea of the degree of purity of the light obtained. The dispersion of the instrument was found to be given by the equation

$$\lambda = 1100 + \frac{11\,800}{d}$$

where d is a scale in cm showing position of telescope slit

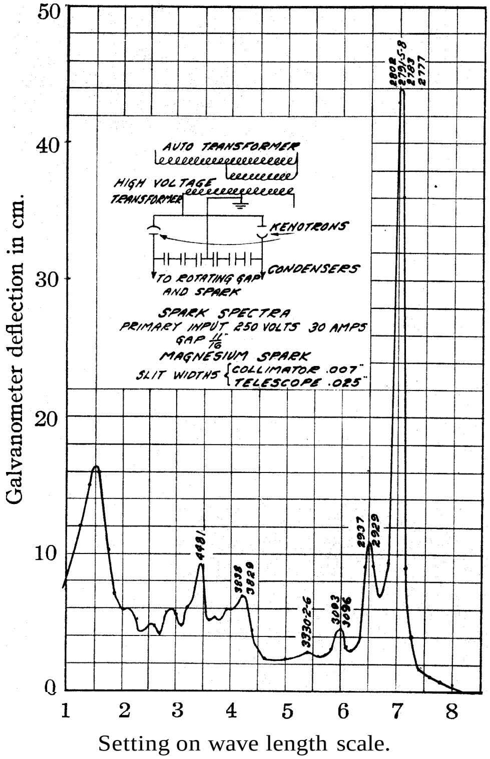

Fig. 3.—Energy distribution of magnesium spark.

Energy Calibration.—The thermopile–galvanometer system was calibrated in absolute units by means of a standard carbon lamp No. C63 supplied by the Bureau of Standards. The thermopile mounted behind the telescope slit was set at 2 meters from the lamp. The slit width was 1.22 mm. Table I gives the results of the calibration.

TABLE I

CALIBRATION OF THERMOPILE

Length of telescope slit, 27 mm. Area of slit, 33 sq. mm. 1 cm. scale deflection = $83 \times (10)^{-7}$ watt. Incident on slit = 83 ergs per second.

Lamp current, amp.	Energy incident on slit per sq. mm.	Scale reading	Incident energy/sq. mm. per cm. deflection
0.300	$47.0\ (10)^{-8}$ watt	1.85	$25.4\ (10)^{-8}$
0.400	$85.8\ (10)^{-8}$ watt	3.53	$24.3\ (10)^{-8}$
		Average	$24.8\ (10)^{-8}$

Light Sources.—In order to obtain monochromatic light of high intensity at the various wave lengths, a number of light sources were used and a brief summary of the energy distribution curves of these sources will not be out of place at this point. A magnesium spark operated by means of a rotating gap from a high voltage direct current outfit illustrated in Fig. 3 was used as a source of 2900 Å. as was also the high pressure mercury arc. The spark was operated with an energy input of 7.5 kw. Variation of the number of breaks per minute between 3600 and 24,000 made no difference in the light intensity. The capacity used was 0.30 mf.; when this was reduced to 0.002 mf. the spark would only take an input of 2.25 kw. at the original setting of the electrodes and this gave about 16% of the original light intensity. The electrodes were cylinders of magnesium $^5/_8''$ in diameter tapered at the end to an area $^1/_8'' \times {}^1/_4''$ and operated without any artificial cooling over long periods of time with very small wastage of magnesium. The energy distribution for this source is remarkable in having such a very large portion of the energy concentrated in the group of lines about 2790 Å. A number of experiments were made raying the material directly with the light from the spark. Since the absorption of ergosterol is very small for wave lengths longer than 3100 Å., this means that all the energy absorbed lies in the region 3095, 2930 and 2790 Å.; 3095 contributes 4%, 2930, 18% and 2790, 77%. This amounts to approximately monochromatic light of wave length 2800 Å. as far as ergosterol absorption is concerned.

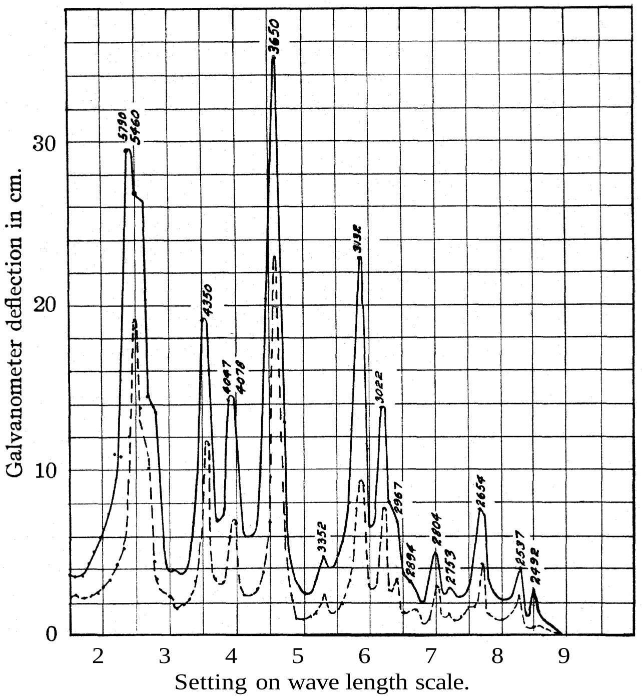

Fig. 4.—Energy distribution in mercury arc. Rating: 83 volts, 6.0 amps. Lower curve: front slit, 0.007"; rear slit, 0.010". Upper curve: front slit, 0.015"; rear slit, 0.010". Arc length, 8.5 cm.

Figure 4 illustrates the manner in which the intensity varies as the slit widths of the monochromator are changed and also give the energy distribution for the high-pressure mercury arc. From this source bands at 3022 and 2804 Å. were used. Figure 5 illustrates the energy distribution of a low-pressure mercury arc and shows that the 2536 Å. line is very strong under these conditions. It was used as a source of this wave length. A subsequent paper will discuss in detail the characteristics of this source.

A quartz cadmium arc was constructed as a source of 2300 Å. The anode consisted of an all-tungsten cylinder and a hot tungsten cathode was used as a source of electrons. The main arc tube was about 6″ long and 0.25" inside diameter. Great care was taken in baking out the lamp and distilling in cadmium to avoid any contamination by mercury. About 2 mm. pressure of neon was admitted to the arc before it was sealed off. The bulbs containing the anode and cathode were heated so that the coldest portion was at 365". This arc was operated continuously at 4 amps. and 64 volts for almost a week and showed no change in intensity at 2300 **A.** as measured by the monochromator.

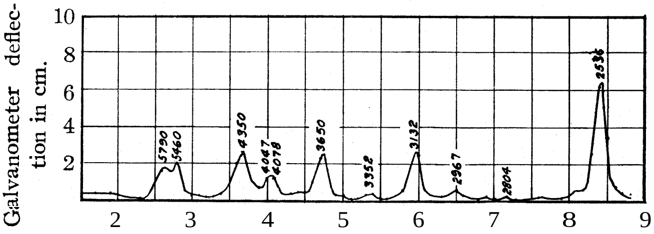

Fig. 5.—Energy distribution for low-pressure mercury arc. Mercury pressure, 0.0036 mm.; rating, 32 volts, 28.8 amps.; arc length, 30 cm.; front slit, 0.007"; rear slit, 0.025".

Experimental Technique.—A solution of ergosterol in absolute alcohol containing 20 mg. per 100 cc. of solution was used for all the work to be reported. A quartz cell 0.5 cm. thick by 1.0 cm. wide by 3.0 cm. high was used with two sides made from ground and polished plates. The cell was placed in contact with the rear slit of the monochromator and the light path through the solution was 0.5 cm. long. Of the light incident on the slit, 5% was reflected at the polished quartz surface of the cell and the remainder passed into the solution. From the absorption curve[9] for this solution given in Fig. 6, it is possible to calculate the percentage of the light incident on the slit which was absorbed by the solution; 40% was absorbed at 3022 Å., 93% at 2800 Å., 76% at 2536 Å. and **73%** at 2300 Å.

The test for antirachitic potency of the different preparations was carried out with rats, using the technique which was reported in a previous paper from these Laboratories.[10]

In brief, rickets was produced in rats by feeding them the Steenbock rachitic diet 2965 for a period of three weeks; after this time had elapsed they had usually developed a marked and uniform degree of rickets. X-

---

[9] These absorption curves were made by the courtesy of the Eastman Kodak Research Laboratory.

[10] Knudson and Moore, J. *Biol. Chem.*, **81**, 49 (1929).

ray pictures were taken of the rats before starting the experiment. The experimental period lasted for twenty-one days and x-ray pictures were again taken at the end of the period and in many cases after seven days. Comparisons were made with the radiograph, taken at the beginning of the experimental period, to judge the degree of healing. A "beginning healing" is indicated when there is a scattering of calcium salts which cast a hair-line shadow in the epiphyseal region; "moderate healing" when a narrow band shows in the epiphyseal area; advanced "healing" when about two-thirds of the epiphyseal area is filled up with deposit; and "complete healing" when the epiphyseal region is almost closed up, showing only a narrow cartilaginous area and the bone approaches its normal appearance. The radiographic technique as developed in our Laboratory is in most cases as sensitive as the line test; however, there are a few instances in which we have observed that the line test showed perceptible healing which was not visible by the radiograph.

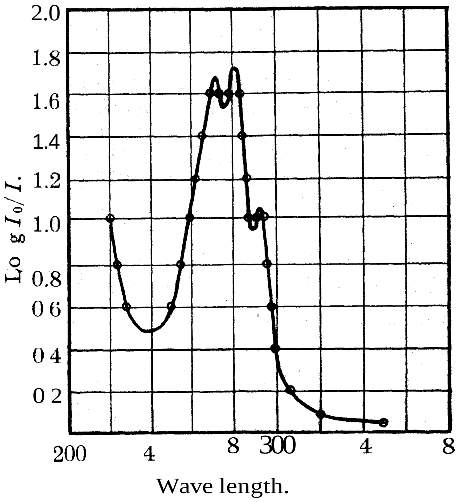

Fig. 6.—Absorption of ergosterol: 1 mg. in 10 cc. of absolute alcohol, 1-cm. layer.

Before irradiation with monochromatic light the ergosterol was dissolved in absolute alcohol and the alcoholic solution after irradiation was then added to a measured amount of olive oil. The alcohol was distilled off from the olive oil under reduced pressure, below a temperature of 60°. The test preparation dissolved in olive oil was then diluted with appropriate amounts of oil in order to have a concentration suitable for administration to the rat. In all cases we have diluted the preparations so that the dose required for administration was dissolved in 0.05 cc. of oil, and this was given directly into the mouth by means of a capillary pipet.

In arriving at the maximum potency of the preparation we would start with the dilution which we considered would give a beginning or moderate healing. We then diluted the preparations in the order of five-fold and tested them until we found a preparation that would give a beginning healing, and one that was negative. In certain instances we were unable to carry this procedure to the extinction point due to a lack of material, because of the fact that some of these preparations were radiated as long as seven days continuously, and the amount that we could irradiate at one time was 0.3 mg.

Results

Experiments were first made on the effect of varying light intensity on the minimum daily dose of radiated ergosterol necessary to show the first incidence of healing. In all exposures in a given experiment the product of intensity and time was kept constant. If the production of the vitamin varies directly with the light intensity, the minimum dose obtained from all these preparations should be constant. The magnesium spark was used as a light source and the light intensity varied by a hundredfold by moving the specimen progressively further from the source. Table II gives the result of these experiments.

TABLE II

EFFECT OF LIGHT INTENSITY ON PRODUCTION OF VITAMIN D

Time of radiation, seconds	Distance from spark. cm.	Approx. energy[11] absorbed, ergs	Daily minimum dose, mg.
2	30	2000	1/2500
20	100	2000	1/2500
200	300	10,000	1/500

In ensuing experiments the wave length was varied from 3022 Å. to 2300 Å. and the time of exposure varied 30,000-fold in some cases The data are given in Table III. Column 1 gives the light incident per second on the rear slit of the monochromator; Col. 4 the total energy absorbed by **0.3** mg. of ergosterol present in the cell during the period of radiation; Col. 6 the minimum amount of the radiated ergosterol which had to be fed daily to show perceptible healing by a radiographic method after three weeks and Col. 5 gives the amount of energy received by the ergosterol which produced this healing effect; this energy is thus the minimum amount necessary to produce a perceptible effect. Part of the experiments with 2800 Å. were performed using the magnesium spark as a source without recourse to monochromator; in this case the energies are estimated by comparison with other experiments using the monochromator.

Figure 7 shows a plot on logarithmic paper of the results of Table III. The minimum daily dose is shown as a function of the total energy absorbed by the constant amount of ergosterol which was irradiated for each experiment. The log–log plot is used to condense the wide range covered into a single plot. In the initial stages of irradiation the minimum dose varies inversely with the amount of energy absorbed; this shows that the amount of vitamin D formed is directly proportional to the light absorbed. With prolonged irradiation this linear relationship no longer holds, the net amount of vitamin D obtained being smaller for each succeeding period and finally a stage is reached where there is a loss of the

---

[11] This is the total energy absorbed by the ergosterol which was fed to the rat over a period of 21 days and which produced a beginning healing.

TABLE III

EXPERIMENTAL DATA

Light intensity, ergs/sec.	Time of exposure, sec.	λ in Å.	Total energy absorbed in cell, ergs	Minimum energy received by rat in 3 weeks	Daily minimum dose, mg.

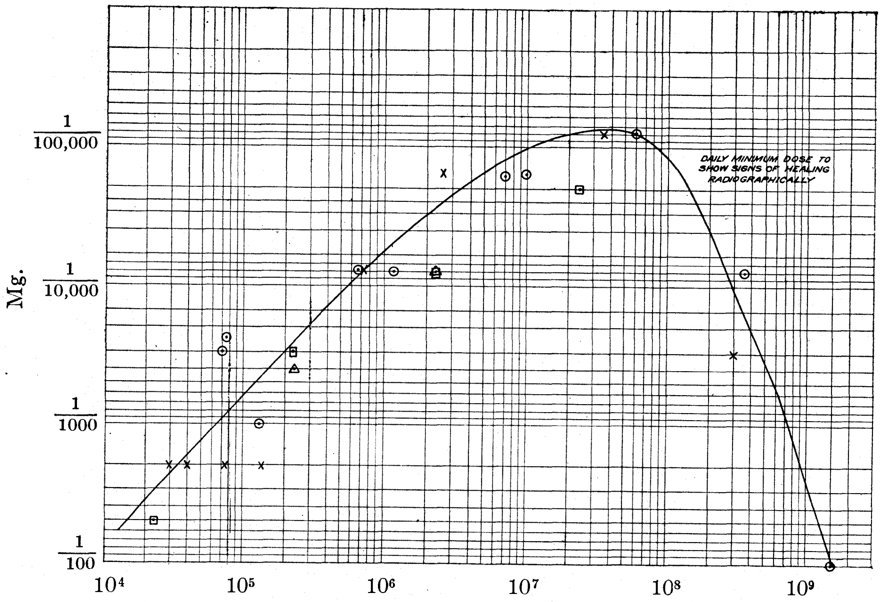
vitamin with further irradiation. It is thus evident that we are dealing with two simultaneous reactions of light: first, a synthesis of vitamin D from ergosterol and second, a destruction of the vitamin. As the reaction proceeds the ergosterol concentration is decreasing and the vitamin D increasing, so that in the later stages the destructive role of the light predominates. We have only carried out prolonged irradiations at 2800 Å. and 2536 Å., since these experiments require intense sources of light to enable one to carry them out in a reasonable time; at 2536 Å. the longest period of irradiation was seven days and to obtain a similar amount of energy at 2300 Å. would have taken five weeks. In the two cases investigated the results were identical and there is no reason to assume that the results with other frequencies would have been different. Vitamin D has to absorb light in the same wave length region as ergosterol in order to be destroyed by light of the same frequency as that which forms it. About 10^8 ergs of light energy were necessary to produce the maximum concentration of vitamin D in 1 mg. of ergosterol dissolved in 5 cc. of absolute alcohol. From these results it is now possible to state that a concentration of vitamin D corresponding to a minimum daily dose of 1/125,000 mg. is the maximum concentration which can be produced by direct irradiation of ergosterol. The results for all the wave lengths are identical within the accuracy of the biological method used for testing.

Tanret[12] gives the formula $C_{27}H_{42}O \cdot H_2O$ for ergosterol, which gives it a molecular weight of 400. One milligram of ergosterol contains 1.5×10^{18} molecules. A quantum of 2800 Å. contains 7 X 10^{-12} ergs. Two thousand ergs of 2800 Å. absorbed by ergosterol and fed to a rat with rickets over a period of three weeks produced a perceptible healing. This amount of energy contains 3 X 10^{14} quanta. The rat received 1/150 mg. of the irradiated material over a period of three weeks or about 10^{16} molecules. The purest preparation of vitamin D which has been prepared by Bourdillon and Webster[13] produced a perceptible healing with 1/20,000 mg. fed over a three-week period, so that if we assume this preparation to have been pure vitamin D, our material in this case contained about 0.7% of the vitamin or approximately 10^{14} molecules. This means that 1 quantum produces on the average 0.3 molecule of vitamin D. In another experiment where a concentration of 16% vitamin D was reached, 3.7 X 10^{17}



Total energy in ergs for 0.3 mg. of material.

quanta produced 7.2×10^{16} molecules of the vitamin, giving a quantum efficiency of 0.20. Fourteen-fold increase in the amount of radiation received by the sample increased the vitamin D concentration to 35%; in other words, 5.3×10^{18} quanta produced 16×10^{16} molecules of vitamin D instead of 1×10^{18} molecules as calculated from the quantum efficiency in the previous experiment. There were only 4.5×10^{17} molecules of ergosterol present in the cell; this means that the quantum efficiency for the transformation of vitamin D to some inert substance is greater than for its production from ergosterol. It is evident from these experiments that vitamin D must itself possess a strong absorption band in the same region as ergosterol, contrary to the work of Heilbron, Morton and Kamm.[14] Since this work was completed two papers[15,16] have been published giving experimental proof that the absorption spectrum of vitamin D occurs in the same spectral region as that of ergosterol. Smakula has shown that a solution of ergosterol from which air is not excluded completely loses its characteristic absorption spectrum after standing for a few months. He has measured the absorption spectrum of a solution of ergosterol during the course of radiation and found at first a slight decrease in absorption and then an increase followed later by a decrease and disappearance of the characteristic absorption. On the basis of a rather questionable rate of disappearance of ergosterol he calculates the absorption spectrum for vitamin D with two maxima at 293 and $260\mu\mu$. Bourdillon and Webster have examined the absorption spectra of irradiated ergosterol solutions both before and after the removal of ergosterol and have found maxima at 270 and $280\mu\mu$ which they believe to be due to vitamin D. The material with an absorption maxima at $240\mu\mu$ is formed by radiation from vitamin D and has no antirachitic action; it in turn is changed by further irradiation to a substance showing no specific absorption. The extinction coefficient for a substance which they think is mainly vitamin D is 40% greater than that of ergosterol and the absorption curve is practically the same shape. They have prepared a material whose biological action can be detected radiographically in doses of 1/400,000 mg. daily and we have assumed that this material is pure vitamin D in calculating quantum efficiencies in this paper.

Summary

1. Several intense sources are described for obtaining monochromatic light of various wave lengths.

2. The rate of production of vitamin D from ergosterol is proportional to the first power of the light intensity.

---

[14] Morton, Heilbron and Kamm, *J. Chem. Soc.*, 2000 (1927).

[15] Smakula, *Nach. Ges. Wiss. Göttingen, Math.-phys. Klasse*, 49 (1928).

[16] Bourdillon, Pischmann, Jenkins and Webster, *Proc. Roy. Soc.* (London), **104B**, 561 (1929).

3. The rate of production of vitamin D is directly proportional to the number of light quanta absorbed by ergosterol and independent of the wave length of the light used.

4. Vitamin D absorbs in the same wave length region as ergosterol and is destroyed by light of the same wave length as that which forms it.

5. The highest concentration of vitamin D which can be produced by direct irradiation of ergosterol is 35%. This is an absolute maximum and the probable value is lower.

6. The quantum efficiency is 0.3 molecules of vitamin D per quantum of light absorbed.

REDUCTION OF METAL OXIDES BY HYDROGEN

BY GUY B. TAYLOR AND HOWARD W. STARKWEATHER

RECEIVED FEBRUARY 18, 1930 PUBLISHED JUNE 6, 1930

A common method for the preparation of metal catalysts consists in first preparing a finely divided oxide and then reducing the oxide with hydrogen. Usually the lower the temperature of reduction the greater the catalytic activity. Low temperature means a slow process of reduction. The present article is concerned with a new method for studying the rate of reduction. Nearly all prior work in this field has been done by passing hydrogen over the heated oxide and collecting and weighing the water formed at definite time intervals. The present method involves following the rate of reduction by measuring the volume of hydrogen consumed.

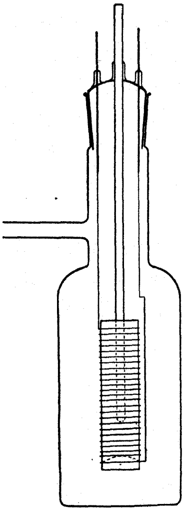

Fig. 1.

Method.—The essential feature of the apparatus is shown in Fig. 1. Platinum wire was wound on a mica cylinder to make a small electric heater, 2 by 6 cm. This heater was suspended on stout nickel wires in a pyrex vessel. The nickel wires were brazed to tungsten wires for sealing through the ground stopper of the vessel. These stout wires served both as supports and electrical leads. A small glass tube sealed to the stopper extended to the middle of the heater and served as a well for a fine-wire chromel–alumel thermocouple. The bottom of the mica cylinder was closed with a piece of platinum gauze wedged on the inside.

The rest of the apparatus consisted of a compensated gas buret, electrolytic hydrogen generator, and Hyvac pump. Electrolytic hydrogen was generated from sodium hydroxide with nickel electrodes, passed over a glowing platinum wire to free it from traces of oxygen, and dried by Dehydrite. Suitable stopcocks were prbvided so that the buret could be refilled rapidly and repeatedly during the course of a run.

The heater was charged by putting a layer of porcelain chips in the bottom, then the oxide, usually three cubic centimeters, and more chips on top. This insured a bed of reacting material in the middle of the heater surrounding the thermocouple hot-junction. The oxide was then heated in air and finally in a vacuum before admitting hydrogen to the vessel in order to drive out moisture and adsorbed gases. During a run the vessel was immersed in a bath at constant temperature, usually running tap water. The temperature of the bath definitely fixed the partial pressure of water vapor during a run just as soon as any of the water formed by the reduction condensed on the walls. Runs in an atmosphere of dry hydrogen were made by surrounding the vessel with a bath of solid carbon dioxide in methanol or by putting phosphorus pentoxide directly in the vessel.

The heat capacity of the charge and heater was only a few calories, so that it was possible to raise the temperature to 450° in three or four minutes with the current required to hold that temperature during a run. The heating current was drawn from a storage battery, and by merely keeping an ammeter at a definite mark, constant temperature was easily maintained.

In starting a run the gas buret was only partly filled with hydrogen, to allow for expansion on heating the charge. Correction for the expansion was obtained by a preliminary calibration with porcelain chips in the heater. Table I shows the complete data of a typical run. In this case the correction for expansion on heating the sample from 25 to 400° was 35 cc.; from 400 to 450° the correction was 3.5 cc.

2:26	450	5.65	15.7		275	173.7

In most cases the samples were prepared as granules 8- to 14-mesh. Unless otherwise stated all reductions were carried out in hydrogen saturated with moisture at 10 to 25°, *i. e.*, the reaction vessel was kept in running tap water. The volume of hydrogen measured for any reduction experiment includes that adsorbed by the sample above room temperature or desorbed on heating. In most cases such effects are negligible.

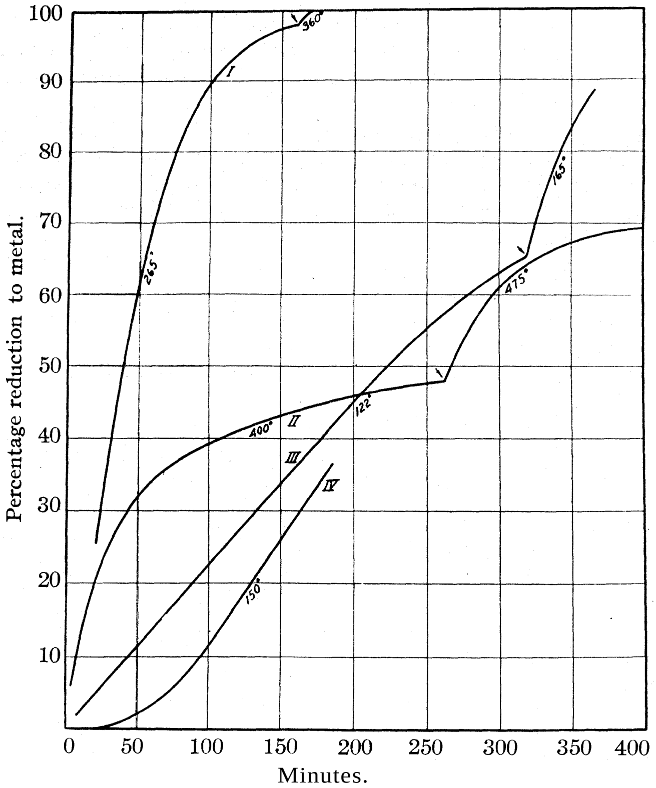

Fig. 2.—Curve I, NiO by ignition of the oxalate at 400°; II, NiO on kieselguhr; III, CuO by ignition of the oxalate; IV, CuO, wire form; ↓, temperature change.

Reduction of Single Oxides.—In Fig. 2 are shown some representative results with nickel and copper oxides in hydrogen saturated with water vapor at about 20°. Nickel oxide on a kieselguhr support proved much more difficult to reduce than a sample of unsupported material.[1] Whether the curve for copper oxide is autocatalytic in character depends largely on the individual sample. The work of Wright, Luff and Rennie[2] and of Pease and Taylor[3] shows that the reduction occurs at the metal–metal oxide

[3] Pease and Taylor, THIS JOURNAL, 43, 2179 (1921).

interface. If, at the beginning of the reduction, relatively few interfaces are developed, a curve showing an induction period followed by autoacceleration is obtained as with the wire-form sample. The result with the other sample of copper oxide, prepared from the oxalate, may be explained on the assumption of the initial formation of a large number of interfaces. One of the samples checks the observations of Pease and Taylor and the other those of Larson and Smith.[4] The mechanism of nickel oxide reduction is probably the same as that for copper oxide."

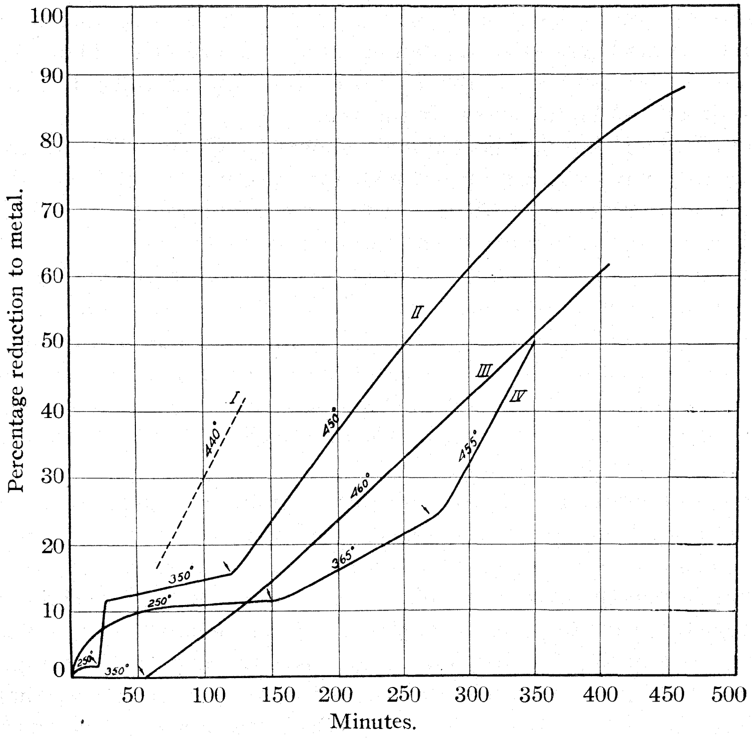

Fig. 3.—Ferric oxides. Curve I, Sample XII in dry hydrogen; II, Sample XII in wet hydrogen; III, Sample XII ignited at 900°; IV, Sample XXVII; ↓, temperature change.

Figure 3 shows some representative results on the rate of reduction of ferric oxide. Sample XII was prepared by precipitating a solution of ferric nitrate (10 g. of $Fe(NO_3)_3 \cdot 9H_2O$ per 100 g. of H_2O) with 7% ammonium hydroxide solution, washing free from nitrate, and drying at 150°. Sample XXVII was prepared from the same salt and alkali four times as

[5] Benton and Emmett, THIS JOURNAL, **46**, 2728 (1924); Pease and Taylor, *ibid.*, **44**, 2179 (1922).

concentrated. Curve II is typical of many preparations of iron oxide gel. There is a slight reduction at 250°. On raising the temperature to 350° the reduction rises sharply to 11%, which corresponds to reduction of Fe_2O_3 to Fe_3O_4. The rate then slows down. On raising the temperature to 450° the reaction proceeds steadily until all the oxide is reduced to metal. Sample XXVII, precipitated from the more concentrated solutions, reduced to Fe_3O_4 at as low as 250°.

Curve I of Fig. 3 merely shows the slope of the reduction curve at 440° when the reaction vessel was kept at $-78°$ and consequently the vapor pressure of water is less than 0.001 mm. The rate is somewhat faster than when the vessel was kept in running water (Curve II). The rate of reduction at 250 and 350° in dry hydrogen was substantially the same as in wet hydrogen and is not shown in the figure.

The effect of sintering is strikingly shown by Curve III. Sample XII was heated in an electric muffle at 900° for twenty hours and then reduced. There was no reaction at 350°. At 450° the reduction apparently goes to metal since there is no break in the curve at the Fe_3O_4 stage.

Several samples of precipitated oxide were prepared by varying the concentration, the nature of the ferric salt, or that of the alkali. All gave results similar either to Curve II or IV of Fig. 3. The use of potassium instead of ammonium hydroxide did not alter rates of reduction, and this alkali was used for coprecipitating iron and other metals. It will be noted that iron oxide is not reduced autocatalytically. Benton and Emmett[5] have already pointed this out.

Glow Phenomenon.—Nearly all our samples of ferric oxide showed the gel-glow phenomenon[6] when heated in hydrogen. Figure 4 shows the most conspicuous example. The bottom curve shows the reaction rate, the middle one the current supplied the heater, and the top the temperature registered by the thermocouple, all plotted against time. The temperature rise during the first few minutes is extremely rapid, so rapid that the actual temperature reached by the oxide is no doubt higher than that registered by the thermocouple. This effect does not occur when the material is heated in air or in vacuum. Some reduction must occur before the glow can take place. On the other hand, it is possible to reduce the sample by heating it slowly without the glow being evident. While the reaction between hydrogen and ferric oxide to give ferroso-ferric oxide is strongly exothermic, the data given in the figure show conclusively that this reaction is too slow to account for the sudden temperature rise.

Reduction of Mixed Oxides.—Mixed oxides of nickel, copper and silver with iron were prepared by coprecipitation of solutions of sulfate or nitrate

---

[6] L. Wohler, *Kolloid-Z.*, 11, 241 (1913). For a discussion of the glow phenomenon; see H. B. Weiser, "The Hydrous Oxides," McGraw-Hill Book Co., New York, 1926, pp. 78–81.

by potassium hydroxide. The precipitates were washed and then electrodialyzed until free of the negative ion. They were dried at 102° before placing in the reduction apparatus. The metals were present in about equal-atom proportions.

Figure 5 shows the effect of added nickel. It is of course impossible to tell which oxide is being reduced the faster, but the slopes of the curves at 450° indicate that the nickel accelerates the final reduction of the iron, since nickel oxide is probably completely reduced before this temperature is reached. Silver and copper gave results of similar character, hence it may be concluded that the presence of a foreign metal interface speeds iron oxide reduction. In the test with silver, silver oxide was dissociated by heating in vacuum before reduction was started.

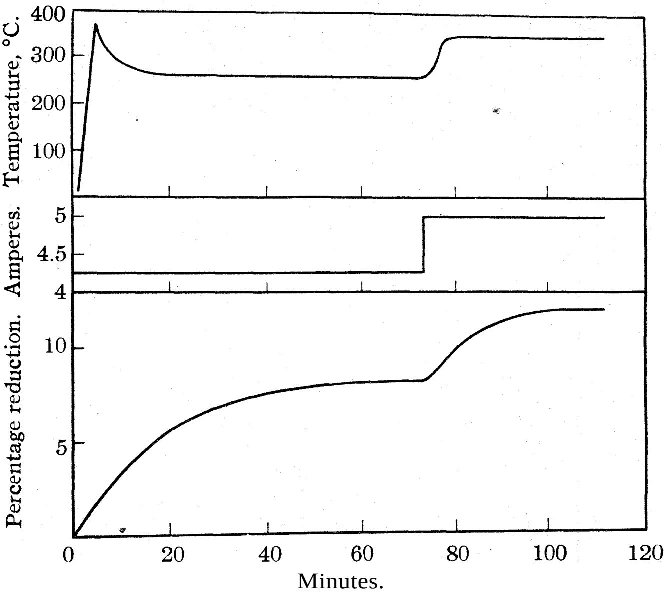

Fig. 4.—Reduction of Fe_2O_3 showing glow phenomenon.

Figure 6 shows the effects of oxides that cannot be reduced by hydrogen to metal. Mixed oxides of iron and chromium and of iron and aluminum, equimolar, were prepared by precipitation. These oxides materially lowered the rate of reduction of the iron oxide at 450°, but if the chromium oxide was mixed mechanically by grinding with ferric oxide, no such effect occurred. Emmett and Love[7] also found that even as small amounts of coprecipitated Al_2O_3 as 1.5% reduced the rate of reduction of Fe_3O_4 to metallic iron.

The curves in Fig. 6 show that the amount of hydrogen consumed at

---

[7] Emmett and Love, *J. Phys. Chem.*, **34,** 56 (1930).

360° was greater than that required to reduce the Fe_2O_3 to Fe_3O_4. 'She Cr_2O_3 in the material reduced according to Curve II was prepared from an hydroxide gel made from the sulfate and ignited to 450° in air. It was then of a dark green color, but when reduced by hydrogen it became bright green. This bright green material was used in preparing the mechanical mixture for Curve II.

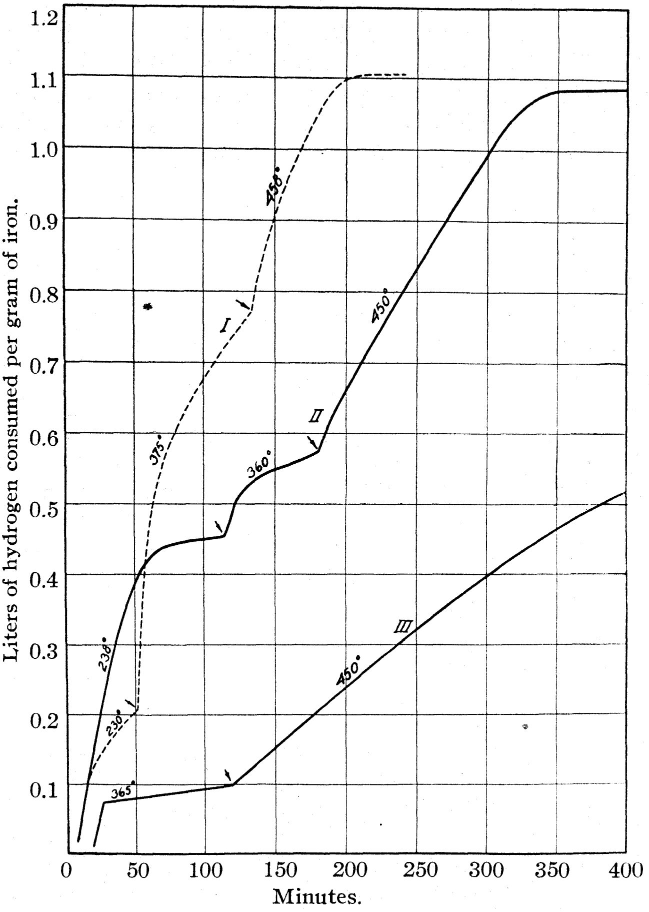

Fig. 5.—Reduction of mixed nickel and ferric oxides. Curve I, NiO–Fe_2O_3 precipitated together; II, NiO and Fe_2O_3 mixed dry; III, Fe_2O_3 alone, Sample XII; ↓ , temperature change.

A 3-g. sample of the coprecipitated Fe_2O_3-Cr_2O_3 used in obtaining Curve I was placed in the apparatus, heated to 250° in vacuum, and cooled to room temperature. Oxygen was then admitted and the sample heated, eventually to 380°; 40 cc. of oxygen was consumed, indicating oxidation of Cr_2O_3. The apparatus was then cooled to room temperature and the oxygen replaced by hydrogen. This oxidized sample was then reduced as usual, giving results similar to those shown in Curve I, save that 80 cc. additional hydrogen equivalent to the above quantity of oxygen was consumed at 238°.

It was further found that pure Cr_2O_3, after being heated in the air, liberated iodine from acidified potassium iodide solution.

Coprecipitated zinc and ferric oxides from nitrate solutions yielded a product difficult to purify. Electrodialysis could not be used to purify this material. The precipitate was washed on a filter and dried at 102°

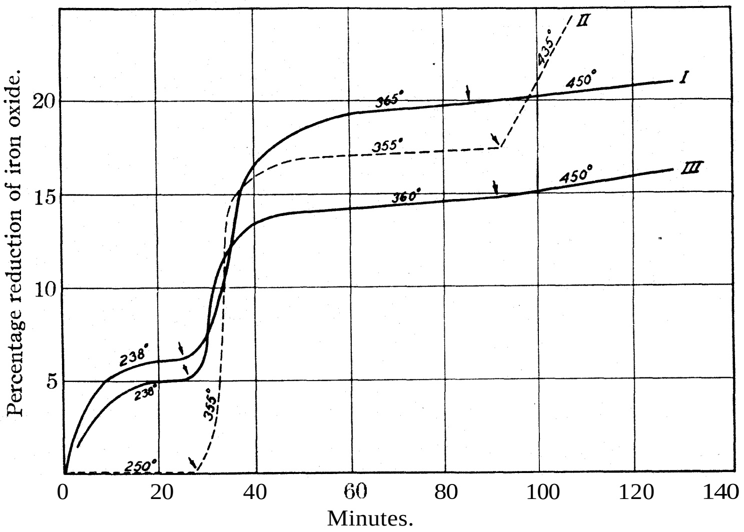

Fig. 6.—Curve I, Fe_2O_3–Cr_2O_3 coprecipitated; II, Fe_2O_3–Cr_2O_3, mechanical mixture; III, Fe_2O_3–Al_2O_3 coprecipitated; t, temperature change.

and analyzed 25% iron. The sample in the reduction apparatus was heated for ninety minutes at 250° and fifteen minutes at 350° to decompose traces of nitrates. Thereafter a reduction experiment gave a curve much like Curve II, Pig. 6. In this case the non-reducible oxide did not slow down reduction of the iron oxide at 450°.

Figure 7 shows the rate of reduction of ferrous oxide. The oxide was prepared by decomposing ferrous oxalate in a vacuum in the reduction apparatus by slow heating to 400°. It did not come in contact with air before reduction. After reduction the iron powder was brilliantly pyrophoric, giving a shower of sparks as it was poured from the heater.

There have been several instances mentioned in the recent literature indicating the reduction of zinc oxide at low temperatures. Rogers[8]

---

[8] Rogers, THIS JOURNAL, 49, 1432 (1927).

completely reduced a fused mixture of cuprous oxide and zinc oxide with hydrogen at 300°. Frolich, Davidson and Fenske[9] found evidence for the reduction of zinc oxide in the presence of copper oxide by methanol vapor at 220°. St. John[10] claims to have detected reduction of pure zinc oxide by hydrogen at as low a temperature as 310°. Taylor and Kistiakowsky[11] in their work on adsorption of hydrogen by pure zinc oxide noted gray spots formed on the oxide in a hydrogen atmosphere.

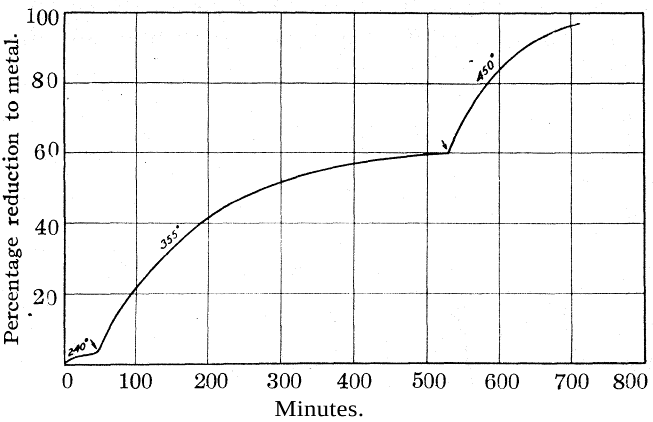

Fig. 7.—Reduction of FeO.

In view of these observations and the fact that zinc oxide is generally considered as non-reducible below the melting point of zinc, calculations were made to determine the conditions under which crystallized zinc oxide might be expected to be reduced by hydrogen.

The free energy of the reaction

$$ZnO(s) + H_2(g) = Zn(s) + H_2O(g) \qquad (1)$$

may be used to calculate the partial pressure of water vapor which must not be exceeded, if the zinc oxide is to be reduced, by the relation

$$\Delta F^\circ = -RT \ln K$$

where $K = [H_2O]/[H_2]$.

The free energy of Reaction 1 was calculated by combining the two reactions

$$ZnO(s) = Zn(s) + {}^1/_2O_2(g) \qquad (2)$$
$$H_2(g) + {}^1/_2(O_2)(g) = H_2O(g) \qquad (3)$$

For Reaction 2,[12]

$$\Delta F^\circ = 83{,}285 + 1.61T\ln T - 0.26 \times 10^{-3}T^2 - 0.645 \times 10^{-7}T^3 - 34.23\,T$$

---

[9] Frolich, Davidson and Fenske, *Ind. Eng. Chem.*, *21*, 109 (1929).

[10] St. John, *J. Phys. Chem.*, **33**, 1438 (1929).

[11] Taylor and Kistiakowsky, THIS JOURNAL, 49, 2468 (1927).

[12] Maier and Ralston, THIS JOURNAL, 48, 371 (1926).

and for Reaction 3,[13]

$$\Delta F^\circ = -57{,}410 + 0.94T \ln T + 1.65 \times 10^{-3}T^2 - 3.7 \times 10^{-7}T^3 + 3.92T$$

Adding these equations to get for Reaction 1

$$\Delta F^\circ = 25{,}875 + 2.55\ T \ln T + 1.39 \times 10^{-3}T^2 - 4.345 \times 10^{-7}T^3 - 30.311.$$

then for 300°, $\Delta F^\circ = 18{,}100$ and for 419°, the melting point of zinc, $\Delta F^\circ = 16{,}950$ calories.

In the presence of copper the compound Cu_2Zn_3, a constituent of brass can be formed. The heat capacity of brass is substantially the sum of the heat capacities of copper and zinc entering into its formation, so that ΔH may be taken equal to ΔF°, assuming the heat capacity of brass remains additive all the way to 0°K. The heat of formation of Cu_2Zn_3 is 16,000 calories,[14] so that for each gram-atom of zinc $\Delta F^\circ = -5300$.

The following table gives the calculated partial pressures of water vapor that will prevent the reduction of zinc oxide when the hydrogen pressure is one atmosphere.

EQUILIBRIUM CALCULATIONS

	°C.	ΔF°	K	Water vapor press., mm. Hg
Pure ZnO	300	18100	1.3×10^{-7}	0.0001
Pure ZnO	419	16950	$4\ 4 \times 10^{-6}$	0.0033
ZnO + Cu	300	12800	1.3×10^{-5}	0.01
ZnO + Cu	419	11650	2×10^{-4}	0.15

An experiment was carried out to see if zinc oxide alone could be appreciably reduced under the most favorable conditions possible with our apparatus. Three grams of an especially pure form of zinc oxide was heated in hydrogen at 516° for one hour while the walls of the vessel were cooled to −78° by solid carbon dioxide in methanol. The measured hydrogen consumption was less than 2 cc., which is within the experimental error under the extreme conditions of the test. After the experiment the oxide showed gray spots like those described by Taylor and Kistiakowsky.

Three samples of mixed oxides of copper and zinc were prepared as follows. No. XXIX.—A solution of copper and zinc nitrates was added to potassium hydroxide solution in calculated equivalents to insure complete precipitation. The precipitate was washed on the filter and dried at 102°; analysis: 35.46% Cu, 26.14% Zn. Before reduction it was heated in the apparatus in vacuum to decompose traces of nitrate before hydrogen was admitted.

No. XXXI.—Pure zinc and copper oxides were ground together to pass a 100-mesh sieve and made into pellets in a pill machine; analysis: 40.57% Cu, 39.12% Zn.

[14] Biltz, *Z. anorg. allgem. Chem.*, *134*, 25 (1924).

No. XXXII.—Sample was prepared the same as No. XXXI, then heated in a muffle at 900° overnight and blasted for half an hour in an oxygen–gas flame; analysis: 41.81% Cu, 38.57% Zn.

Sample No. XXIX was heated in wet hydrogen (reaction vessel in water) for 145 minutes, raising the temperature stepwise to 360°. Hydrogen equivalent to CuO in the sample was consumed at 238° and there was no further reduction at 360°. On raising the temperature to 440°, there was a small consumption of hydrogen and then no reaction in thirty minutes. The vessel was then surrounded by the cold bath at −78° and reduction proceeded steadily at 460° at a uniform rate for an hour until the experiment was discontinued. Tests with Sample XXXI under nearly the same conditions were quite similar. With phosphoric oxide in the vessel there was a slow but measurable reduction of the zinc oxide at 365°. After reducing the copper oxide in sample XXXII, condensed water was removed and phosphoric oxide put into the vessel. The reduction of the zinc oxide was then allowed to proceed for eight hours at 350°.

After the three samples were reduced, they were washed with dilute hydrochloric acid to dissolve zinc oxide and examined by x-rays. A chemical analysis of one of the samples was also made. Below are summarized the data of the examination of the reduced samples which prove that alpha brass was formed in all cases.

COMPOSITION OF REDUCED SAMPLES

	X-ray examination		Calcd. % Zn in brass from reduction data	Chemical analysis
Sample no.	Cube edge, Å.	% Zn in brass[a]		
XXIX	3 636	10	12	13% Zn, 84 5% Cu
XXXI	3.643	15	15	......
XXXII	3 625	8	9	......

[a] Calculated by comparison with data for alpha brasses given in "International Critical Tables," McGraw-Hill Book Co., New York, 1926, p. **350,** Vol. **1.**

There thus appears to be nothing mysterious about the reduction of zinc oxide in the presence of copper. It is simply a case of carrying out the reduction in a sufficiently dry atmosphere, to be on the right side of the equilibrium position. A sufficiently dry atmosphere of hydrogen in the case of zinc oxide alone, at temperatures at which it can be reduced in the presence of copper, is difficult if not impossible to realize experimentally.

The authors wish to thank Dr. A. W. Kenney of this Laboratory for making the x-ray examinations, and Dr. H. G. Tanner, also of this Laboratory, for assistance in the free-energy calculations.

Summary

1. A new method for studying the rate of reduction of metal oxides at temperatures below 500° has been described. In this method the volume of hydrogen consumed is measured.

2. Results with this method for nickel, copper, iron and zinc oxides have been presented.

3. Ferric oxide gel is reduced to ferroso-ferric oxide at 350° and to metallic iron at 450°. Ignited ferric oxide is not reduced at an appreciable rate at 350° and goes to metal at 450°.

4. Foreign metal interfaces with iron oxide accelerate the reduction to iron.

5. Alumina and chromium oxide greatly retard reduction of ferroso-ferric oxide.

6. Perric oxide gels show the glow phenomenon in hydrogen at fairly low temperatures, but not in air or in vacuum.

7. The thermodynamics of zinc oxide reduction in the presence of copper have been worked out, giving an explanation in the formation of alpha brass.

ADSORPTION OF HYDROGEN BY NICKEL AT LOW TEMPERATURES[1]

BY ARTHUR F. BENTON AND T. A. WHITE

RECEIVED FEBRUARY 19, 1930 PUBLISHED JUNE 6, 1930

Introduction

Although it is now recognized that the occurrence of catalytic reactions at solid surfaces is intimately connected with the nature and extent of the adsorptions of the reacting species and products, nevertheless, attempts to obtain a quantitative treatment of the relations involved have met with little success. The main difficulty appears to be the lack of an adequate general theory of adsorption at catalytically active surfaces.

Numerous adsorption measurements,[2] especially by Taylor and his co-workers, have shown that adsorption of gases may be accompanied by more or less "activation" of the adsorbed molecules, and that this activation is a prerequisite to any marked catalytic action of the solid. It is known that this activation is conditioned by the chemical rather than the physical properties of the substances involved, but its occurrence is unpredictable theoretically. Experimentally, however, the two limiting types of adsorption, the "secondary" type involving little or no activation and the "primary" type in which relatively great activation occurs, can be

[2] Critical summaries of the extensive work in this field may be found in the following papers: Taylor, *J. Phys. Chem.*, **28**, 897 (1924); **30**, 145 (1926); *Proc. Roy. Soc.* (London), **A113**, 77 (1926); Taylor and Kistiakowsky, *Z. physik. Chem.*, **125**, 341 (1927); Langmuir, THIS JOURNAL, **38**, 2221 (1916); **40**, 1361 (1918).

readily distinguished by the fact that at moderate temperatures and pressures the extent of adsorption is much less dependent on these variables in the latter case than in the former. This fact is interpreted to mean that in primary adsorption even at low pressures the surface is largely covered with a unimolecular or monatomic layer of adsorbed gas, whereas in the secondary type either the unimolecular layer is far from complete or multimolecular layers are formed.

It appeared to us that considerable light might be thrown on these questions by carrying out adsorption measurements on an active catalyst under conditions where one type of adsorption merged into the other, a behavior which might be expected at low temperatures or at high pressures. The present paper deals with the adsorption of hydrogen by active nickel at pressures up to one atmosphere and over a range of temperatures down to 61°K.

The adsorption of hydrogen by nickel at temperatures above 0° has received some attention from numerous investigators. Gauger and Taylor,[3] using temperatures from 25 to 305° and pressures from zero to one atmosphere, found that the adsorption reached a constant value at relatively low pressures, but that this constant value decreased as the temperature was raised. Terwen[4] concluded from these data that at higher temperatures the amount adsorbed approached asymptotically a value half that at lower temperatures, and that the adsorption occurred as atoms at the higher temperatures and as molecules at the lower.

Although the adsorption of gases by charcoal has been measured at low temperatures, mainly in connection with the production of high vacua, little has been attempted along this line with catalytically active materials. Von Hemptinne[5] brought hydrogen, and in other experiments carbon monoxide, into equilibrium with platinum at $-78°$ and then allowed the system to warm gradually to room temperature. From observations of the pressure at a series of temperatures, he concluded that the gas adsorbed at low temperatures is gradually evolved on warming, until a temperature of about $-40°$ is reached, when a rapid increase in adsorption occurs. A similar phenomenon was observed with palladium and carbon monoxide. Nikitin[6] has recently reported adsorption measurements of hydrogen on nickel at three temperatures, -185, 19 and 336°, and finds that the adsorption is less at -185 than at 19°.

Experimental Method and Apparatus

Apparatus and Procedure.—The method of measuring the adsorption was the usual one which consists in a comparison of the volume of the gas required to fill a bulb con-

taining the adsorbent at a given temperature and pressure, with the corresponding volume of an unadsorbed gas, in this case helium, which is required to fill the bulb at the same temperature and pressure. A number of measurements were made with an apparatus of the type now commonly used, which has been described by Pease.[7] To obtain more certain protection against the possibility of leaks at stopcocks, however, a modified type was constructed and employed for all experiments subsequent to Run 33.

The new apparatus, shown in Fig. 1, differs from the type used in earlier investigations in this Laboratory mainly in that all stopcocks exposed to vacuum are replaced with mercury seals. Pyrex glass is used throughout, and the capillary parts are of 1 mm. bore. The adsorption bulb A, of approximately 50 cc. capacity, communicates by capillary tubing with the mercury seal C which leads to the Töpler pump, with the closed manometer B of 6 mm. bore, and with the mercury seal E, of 16 mm. bore, the essential purpose of which is to obviate the necessity of maintaining the stopcock G under vacuum for long periods of time. The capillary at E, sloping slightly downward to the left, facilitates admission of gas from F without danger of mercury droplets being driven into the capillary D. H is a water-jacketed buret in which gas volumes are determined by measuring on the closed manometer I (6 mm. bore) the pressure exerted when the gas fills the buret to a mark on the 6-mm. tubing immediately below the water jacket. The volume readings have been corrected for the small but varying amounts of gas retained in the calibrated capillary F. The manometers and mercury seals are operated by applying air pressure or vacuum to the bulbs below them.

The procedure in determining an adsorption isotherm consists in successively admitting known amounts of gas from H through FED to the previously evacuated bulb and, after bringing the mercury levels to b and D, respectively, measuring in each case the pressure produced at equilibrium. Equilibrium was considered to be established when the pressure readings remained constant for fifteen to thirty minutes, but this supposition was frequently checked by approaching the equilibrium from higher as well as lower pressures. Between such a "run" and the succeeding one the adsorbent was evacuated for about two hours, at 200° in the case of the former of the two nickel samples employed, and at 250° for the second.

Materials.—Hydrogen was prepared by electrolysis of 15% sodium hydroxide between nickel electrodes and purified by passage in succession over heated platinized asbestos, soda-lime, calcium chloride and phosphorus pentoxide. Helium used in the free space determinations was purified by passage over heated copper and copper oxide and over active charcoal cooled with liquid air.

The nickel adsorbent was obtained by dehydrating c. p. crystalline nickel nitrate in a current of dry, carbon dioxide-free air at temperatures up to 400°, transferring the nickel oxide thus produced to the adsorption bulb, which was then sealed to the apparatus, and reducing in a stream of hydrogen for about twenty-four hours at each of the three temperatures 200, 250 and 300°. The two samples of nickel were prepared from the same batch of oxide, but reduction was stopped when the amount of water given off per hour was 2.5 mg. in the former case and 3.6 mg. in the second. The weights of metallic nickel were 23.68 and 23.10 g., respectively.

Constant Temperature Baths.—The temperature range covered by these measurements was 110 to −210°. For 110 and 56.5° toluene and acetone, respectively, boiling under atmospheric pressure, were used For temperatures from 0° down, Dewar flasks formed the bath containers: 0° was obtained with ice and water, −78.5° with solid carbon dioxide and alcohol. The intermediate temperature, −35°, was produced by periodically adding solid carbon dioxide to alcohol. For maintaining −183° liquid oxygen containing only a negligible quantity of nitrogen was employed, for −191.5°

---

[7] Pease, THIS JOURNAL, 45, 1197 (1923).

liquid air, while for lower temperatures liquid air was allowed to boil under a pressure of a few cm. of mercury.

Considerable difficulty was experienced in obtaining satisfactory thermostats at temperatures between −78.5 and −183". For a temperature around −110° fair success was arrived at with a mixture of solid and liquid carbon disulfide, but it is difficult to maintain for long periods at the true melting-point (−111.6"). The solid carbon disulfide may be conveniently prepared by pouring the partially cooled liquid into liquid air, or vice versa. For temperatures between −160 and −170° the adsorption bulb was surrounded by a hollow cylinder, closed at top and bottom and constructed of 0.25-inch brass, which was wound externally with resistance wire, covered with alundum cement, and the whole immersed in liquid air. It was found that on passing a constant small current through the resistance wire, a fairly constant temperature could be maintained, and no temperature gradients could be detected inside the cylinder.

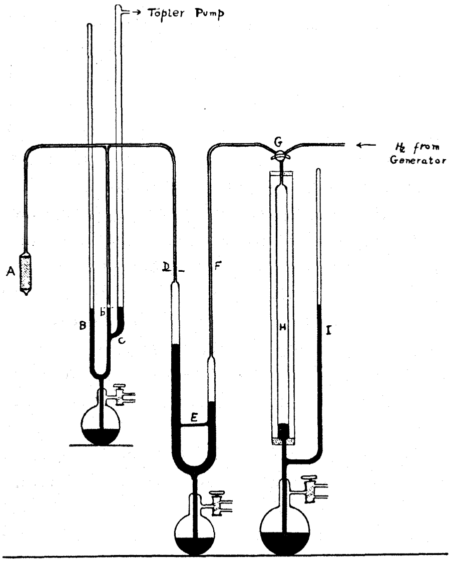

Fig. 1.—Apparatus.

Temperatures below 0° were determined with a copper-constantan thermocouple in connection with a Leeds and Northrup potentiometric temperature indicator. The couple was calibrated at 0, −78.5, −111.0 and −183°. Interpolation between these points and extrapolation below −183" were carried out with the help of a deviation curve prepared from the values given by Adams.[8] In spite of the fact that the deviations from Adams' values were very nearly a linear function of the observed e. m. f. down to −183°, continuation of the curve below this point led to a temperature of −193" for fresh liquid air, and temperatures below −200" determined in this way were obviously too low because in one experiment the calculated amount of free space exceeded the amount of gas actually in the bulb. For this reason the part of the calibration curve below −183° which we have adopted as most nearly correct, placing fresh liquid air at −191.5°, may be in error, but it is believed that this probably does not exceed ±0.5°.

Determination of Free Space.—The volume of the free space in the bulb and connecting tubing to the marks b and D, Fig. 1, was determined by filling with pure helium at each of the temperatures, 110, 0 and −78.5"; for the second adsorbent −109° was also used. Since it was feared small quantities of helium might be adsorbed at lower temperatures, the volume of gas required to fill the free space at these points was calculated by the use of the perfect gas law from each of the measurements at the higher temperatures, consideration being given to the fact that a small measured volume in the capillary tubing always remained at room temperature. The close agreement of the values calculated in this way from the various temperatures used experimentally indicates that helium is not appreciably adsorbed at the pressures employed at temperatures at least down to −109°.

Experimental Results

Typical isotherms obtained at various temperatures are shown in Figs. 2–4. The ordinates represent volumes, in cc. at 0°, 760 mm., adsorbed by 23.68 g. of nickel in case of Sample I (Runs 1–23), or by 23.10 g. for Sample II (Runs 34–52); the abscissas are the corresponding pressures in cm. of mercury at 0°. It is impracticable to present in this form the results of the entire series of 42 runs. Of this number 13 were devoted to the determination of free spaces, and about half of the remainder were redeterminations of isotherms already obtained on one or the other sample. (Runs 24–33 are omitted since they were made for a different purpose.)

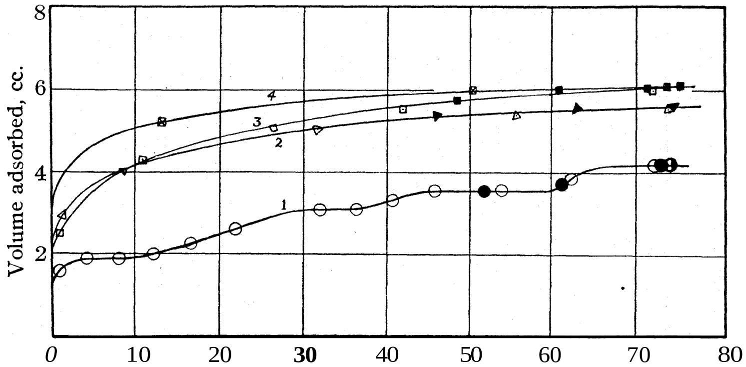

Fig. 2.—Adsorptions of hydrogen on nickel, Sample I. Curve I, −191.5° (Run 13); Curve 2, 56.5° (Run 15); Curve 3, 110° (Run 12); Curve 4, −35° (Run 16).

Reversibility with Respect to Pressure Changes.—In the majority of runs, after measurements had been made nearly up to atmospheric pressure, as large a portion of gas as practicable was withdrawn from the bulb and the course of the isotherm retraced to its upper end. In some cases this process was repeated several times. The values thus obtained are indicated in Figs. 2–4 by full black circles, triangles, etc. It will be observed that, while the exact equilibrium value was not always reached on first ascending the isotherm, nevertheless the values obtained from higher and from lower pressures agree so closely that the equilibrium isotherm can be drawn in every case with considerable confidence. This is especially true at the lower temperatures, where no evidence of hysteresis was ever observed. It is clear, therefore, that with respect to changes in pressure the adsorptions are strictly reversible.

Rate of Adsorption.—The rate of approach to equilibrium depended greatly on the experimental temperature and pressure. It is a remarkable fact that at −183 and −191.5° the pressure in the bulb became constant almost immediately after admitting the gas, whereas at both higher and lower temperatures considerably longer periods were required. It was also observed that in the higher temperature range equilibrium was reached less quickly at low pressures than at higher pressures. In the latter range times of the order of an hour were usually required, but as much as two hours was often necessary at pressures below 200–300 mm. However, at those points where the entire quantity of gas admitted to the bulb was adsorbed with a value of the final pressure practically equal to zero, shorter times were again required, of the order of half an hour.

Accuracy of Individual Isotherms.—The accuracy of any particular isotherm depends on the conditions employed. Volumes and pressures involve errors which are negligible in comparison with other factors. In those cases where the temperature remained definitely constant for long periods, as at −183, −78.5, 0, 56.5 and 110°, the limiting uncertainty is that involved in the exact establishment of equilibrium, amounting to not more than 0.1–0.2 cc. even at the higher temperatures. At the other temperatures, and particularly below −191.5° where the volume of gas in the free space is very large compared to the volume adsorbed, the limiting factor is the constancy and accuracy of the temperature. In these cases the temperature could be held constant within ±0.5°. Although the error in a single adsorption measurement produced by such a variation amounts to only 0.3 cc. at −110° and one atmosphere and proportionately less for lower pressures, nevertheless at −210° the uncertainty rises to nearly 2 cc.

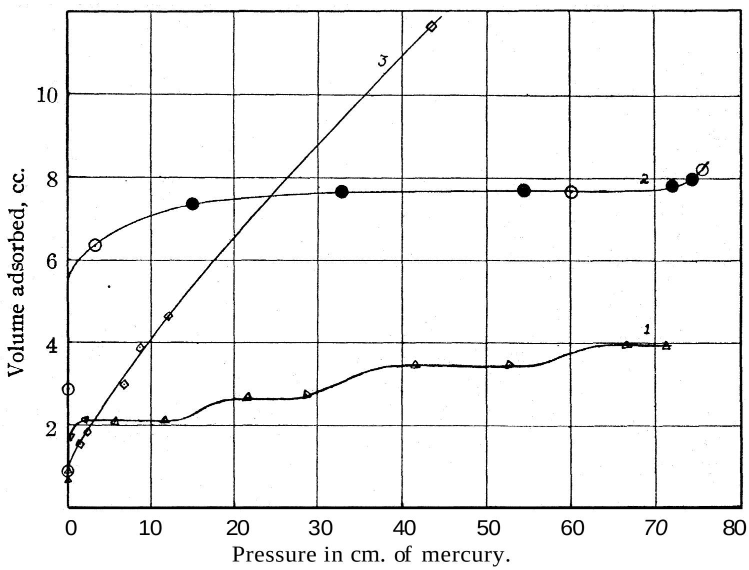

Fig. 3.—Adsorptions of hydrogen on nickel, Sample II. Curve 1, −191.5° (Run 39); Curve 2, −78.5° (Run 47); Curve 3, −209° (Run 49).

at atmospheric pressure. At this temperature there is an additional uncertainty, which is probably of even greater magnitude, in determining the absolute value of the temperature from the thermocouple calibration. For these reasons measurements below −200° must be regarded as fair approximations only, except at the lower pressures, yet the general trend of the true isotherms cannot differ greatly from those we have obtained. At all higher temperatures the accuracy is probably at least as great as that with which Figs. 2–4 can be read.

Comparison of Results for Different Temperatures.—In order to determine to what extent the values obtained for a given sample are reproducible, a large proportion of the runs (which are numbered serially in the order in which they were made) were devoted to checking earlier determinations. It was found that only a very small change in adsorption occurred in the case of Sample II. Thus the first run (34) and one near the end (50), both at 0°, gave exactly similar curves and differ only in the fact that in Run 50 about 0.3 cc. more hydrogen was adsorbed at all pressures than in Run 34. It is felt, therefore, that for this sample changes in activity with time are of the same order of magnitude as the probable error of the individual isotherms. Sample I, however, showed a steady and fairly considerable decrease in adsorptive capacity throughout, although here also only the absolute values were affected and not the shape of the isotherms. This change should be considered in comparing the curves of Fig. 2. While sufficient data have been obtained to correct systematically for this variation, it appears unnecessary to do so, since all the temperatures at which Sample I was investigated were also used with Sample II, except —35, 56.5 and 110°.

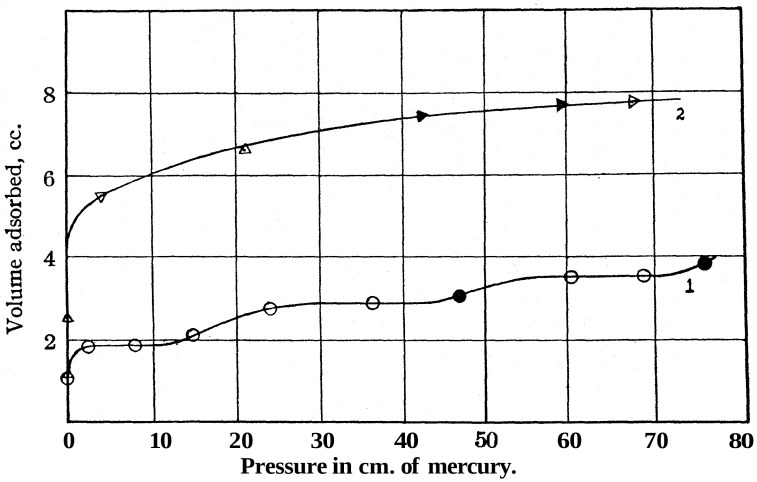

Fig. 4.—Adsorptions of hydrogen on nickel, Sample II. Curve 1, −183° (Run 52); Curve 2, 0° (Run 50).

In order to make the values for Sample I at these temperatures suitable for comparison with the data at other temperatures for Sample II, we have assumed that the ratio of the adsorptions at two temperatures is the same for each sample. This is closely the case for temperatures at which both samples were actually studied. Since several runs at 0° were made at wide intervals on each sample, this is a convenient temperature at which to make the comparison. The method will be clear from the following example. At 110° and 600 mm. pressure 7.77 cc. was adsorbed in Run 6 and 5.85 cc. in Run 12. At 0° and 600 mm. the adsorptions were 6.93 cc. in Run 11 and 6.25 cc. in Run 14. Hence at this time the decrease in adsorption amounted to about 0.3 cc. per run at this pressure. If Run 12 could have been made at the same time as Run 14, we should expect, therefore, that 5.85 − 0.6 = 5.25 cc. would have been adsorbed. Hence for Sample I the corrected value for 110° is 5.25/6.25 times the value at 0°. If we assume that this same ratio holds for Sample II, which in Run 50 took up 7.70 cc. at 0° and 600 mm., the adsorption at 110° and 600 mm. would be 5.25/6.25 X 7.70 = 6.49 cc.

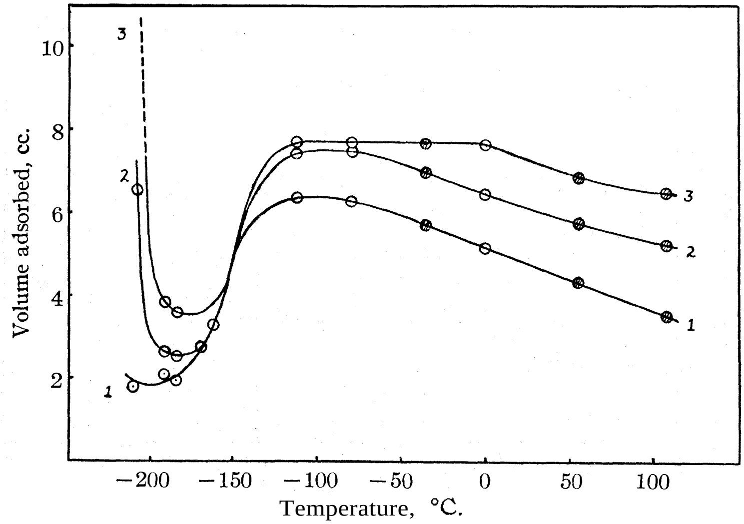

Fig. 5.—Isobars for hydrogen on nickel: Curve 1, at 2.5 cm. pressure; Curve 2, 20 cm.; Curve 3, 60 cm.

Similar calculations have been made for 25, 200 and 600 mm. pressure at the three temperatures —35, 56.5 and 110°. The values so obtained, together with those interpolated from the experimental isotherms for Sample II, are included in Fig. 5, in which the ordinates represent volumes adsorbed and the abscissas temperature, and the three curves are the isobars for 25, 200 and 600 mm., respectively.

Test of Reversibility with Respect to Temperature Change.—At the conclusion of the experiments described above, a working hypothesis to account for the observed variation of adsorption with temperature led us to an attempt to follow the equilibrium from higher to lower temperatures without intervening evacuation. In a run made at 0° in the regular way 7.40 cc. of hydrogen was adsorbed at a pressure of 631.4 mm. Without altering the amount of gas in the bulb the latter was then cooled to liquid air temperature. After apparent equilibrium had been reached, it was found that 9.85 cc. was now adsorbed at a pressure of 184.1 mm., whereas in a run (Run 39, Fig. 4) in which the gas was directly admitted to the bulb at this temperature, only 2.5 cc. was taken up at 184.1 mm. The same gas was then allowed to remain in contact with the nickel at room temperature for twenty-one hours. Following this, a remeasurement at 0° showed 8.22 cc. adsorbed at 636.2 mm., the increase over the previous value at 0° probably being due to a very slow solubility of hydrogen in the nickel. On cooling to $-186°$ the pressure became constant at 189.8 mm., at which 10.50 cc. was taken up. This increase of adsorption on cooling, 2.28 cc., agrees fairly well with the 2.45 cc. found in the previous part of the experiment. Subsequently additional gas was admitted to the bulb at $-186°$ and then withdrawn in stages. The following adsorptions were found: at 359.9 mm., 10.47 cc.; at 148.2 mm., 10.06 cc.; at 74.2 mm., 9.72 cc.

These results show that, contrary to what would be expected from a consideration of the individual isotherms, hydrogen adsorbed at 0° is not evolved on cooling to $-190°$, at least at an appreciable rate, but instead an increased adsorption occurs. This increase, 2.45 cc. and 2.28 cc. in the two trials, is of the same order of magnitude as the entire adsorption found at $-191°$ when the gas is admitted directly at this temperature. These facts strongly suggest that hydrogen can be adsorbed by nickel in two different ways, a strong binding being characteristic of the higher temperature range and a looser binding at low temperatures. The rate of change of the adsorbed gas from one form to the other is inappreciable at low temperatures.[9] For this reason either the low-temperature isotherms directly determined, or the values obtained after cooling from 0°, or perhaps both, represent metastable equilibria. It appears that the only hope of determining experimentally the values which correspond to true thermodynamic equilibrium at temperatures below $-110°$ lies in greatly extending the times of observation.

However, the fact that the isotherms are completely and quickly reversible with respect to pressure changes indicates that the metastable states are perfectly definite and in no sense mere accidental stopping-places on the

---

[9] More recently we have found that the equilibrium, which is almost immediately established at $-183°$ when hydrogen is directly admitted at this temperature, remains unchanged for at least seventy hours.

way to true equilibrium. In this respect the situation appears to be analogous to the numerous cases of chemical reactions, such as the addition of hydrogen to benzene to form cyclohexane, where the reactants and products quickly reach a definite equilibrium of undoubted significance in spite of the fact that one or more of the reacting substances is itself unstable with respect to other possible reactions.

Discussion

The major results of this investigation can readily be accounted for on the hypothesis that at the lowest temperatures the adsorption is of the secondary type, involving hydrogen molecules whose configuration is little if at all altered by the process, whereas at temperatures above −100° only primary adsorption occurs, in which the adsorbed molecules suffer a marked activation and perhaps even complete dissociation. The flatness of the 60-cm. isobar from −110 to 0° is strongly suggestive of the idea that here the nickel surface is entirely saturated with a single layer of these activated molecules. At temperatures above 0°, pressures higher than 60 cm. would evidently be necessary to complete the layer. On this view the additional hydrogen which is taken up at low temperatures after the nickel has been saturated at 0° corresponds to the partial formation of **a** second layer. The isothermal results at temperatures below −191° suggest that at still lower temperatures multimolecular layers are also capable of existence.

Between −100 and −191° the adsorption appears to consist of both types. It is obvious, however, that in this range the observed values cannot be accounted for on the basis of an equilibrium between the two types since the experiments described in the last section show that the rate at which this equilibrium is established is negligibly small. For the same reason it is impossible to consider that the results in this region represent a continuous variation in the degree of activation of the adsorbed molecules. It must be supposed that primary and secondary adsorption constitute, at least in the present example, separate and distinct types, and not merely limiting cases of a continuously variable property. (It is not meant to be implied, however, that all the hydrogen held by primary adsorption necessarily has the same chemical reactivity.) We believe that the values obtained in this intermediate range are best explained by assuming that, as the temperature is raised, a larger and larger fraction of the nickel surface is capable of producing activation in the adsorbed molecules. At the same time the secondary adsorption, which falls off much more rapidly with decreasing pressure than the primary, is continuously decreasing. The opposition of these two effects results in a minimum in the isobars, which lies at temperatures which are lower the lower the pressure.

The isotherms for temperatures above −110° show nothing unexpected except that above 0° they are considerably less flat than those obtained by

Gauger and Taylor.[3] As the temperature is raised in this region, higher and higher pressures are required to produce saturation of the surface, and a progressive change in the shape of the isotherms occurs. The curves for temperatures below −200° are typical of adsorption without activation, except that about 1 cc. of gas is adsorbed at zero pressure, a fact which presumably indicates that even at these temperatures nearly one-eighth of the surface is capable of activating the hydrogen.

The isotherms obtained at −183 and −191° warrant special mention. Owing to the almost instantaneous establishment of equilibrium and the extreme constancy of the temperature at these points, the individual values found here are probably more precise than at any other temperature. Nevertheless, smooth curves cannot be drawn through the experimental points within the limit of accidental error, which probably does not exceed 0.05 cc. Systematic errors, such as would result from deviations from the gas laws or uncertainty in determining the absolute temperature, could not account for the observed behavior. Furthermore, the anomaly is found in every isotherm at these temperatures, and only at these temperatures. For these reasons it appears that the stepwise increase of adsorption with pressure must have some physical significance. It should be pointed out, however, that the data obtained are insufficient to locate the exact course of the curves between steps, a point which is still under investigation.

The following tentative interpretation of this phenomenon may be proposed. At either temperature a fraction of the adsorbing surface, equivalent to about 1.5–2.0 cc. of gas, holds hydrogen by primary adsorption to an extent practically independent of pressure. On top of this and on the remainder of the surface, adsorption of the secondary type occurs, as indicated by its reversibility, which experiment shows does not occur at these temperatures for the primary type. It appears also that the surface is a composite one, which may perhaps be thought of as presenting a number of distinct regions of different adsorptive capacity. On each of these regions the adsorption represents an equilibrium between condensation and evaporation. If it be assumed that the rate of evaporation is very great for isolated molecules but much less when a number are adsorbed side by side, it follows that scarcely any adsorption would occur on a given region until the pressure reached a point at which the rate of condensation was sufficiently high to produce patches of neighboring adsorbed molecules. At this point further increase of pressure would quickly lead to the formation of a saturated layer. It appears that a summation of such effects on the different regions of the surface would result in an isotherm of the form found experimentally.

Summary

The adsorption of hydrogen by two samples of reduced nickel has been studied at pressures from zero to one atmosphere and at eleven tempera-

tures from 110 to $-210°$. The apparatus employed involves no stopcocks that are required to remain under vacuum more than momentarily.

At a given pressure the adsorption is relatively large at the lowest temperatures, decreases to a minimum at -200 to $-175°$ depending on the pressure, then rises to a maximum in the neighborhood of $-100°$, and finally decreases again at higher temperatures. The fact that at 600 mm. the adsorption is independent of the temperature from -110 to $0°$ is taken as evidence that here a completely saturated single layer is formed.

It is shown that the values obtained are reproducible, and readily reversible with respect to changes of pressure, particularly at the lower temperatures. However, on cooling to about $-190°$ a sample previously brought to equilibrium at $0°$, the adsorption does not decrease to the value obtained isothermally at $-190°$, but reaches a new reversible equilibrium at which larger quantities of gas are adsorbed than at $0°$.

At -191 and $-183°$ the adsorption increases with pressure in a discontinuous manner, an observation whose explanation is somewhat obscure.

The major results of the work are interpreted on the hypothesis that at the lowest temperatures the adsorption is of the "secondary," or ordinary molecular type, while at higher temperatures a progressively larger fraction of the nickel surface is capable of holding the hydrogen by adsorption of the "primary" type, involving a marked activation of the gas.

THE INCOMPATIBILITY BETWEEN ANY THEORY OF COMPLETE DISSOCIATION AND MIGRATION DATA

BY JAMES W. MCBAIN AND PIERRE J. VAN RYSSELBERGE

RECEIVED FEBRUARY 24, 1930 PUBLISHED JUNE 6, 1930

Inspection of the migration data for solutions of pure single electrolytes cannot, in general, give very conclusive evidence for or against the existence of any but the simplest ions in such solutions. In general, migration ratios are not constant throughout a range of concentrations, but it is a matter of rather arbitrary interpretation as to whether this is due to the ions being unequally affected by increase of concentration or whether the appearance of new (complex or intermediate) ions is assumed to account for the change in the gross transport number. It is only in the few rare instances, such as the well-known case of cadmium iodide where the change in transport number becomes so great that the sign of the migration is actually changed, that this method yields any conclusive proof of the existence or presence of complex ions.

It is evident that, if the migration number of a salt such as potassium chloride changes somewhat upon concentration, the change would most readily be ascribed to unequal change in the mobilities of the K^+ and Cl^- ions, whichever of the various explanations for such behavior might be adopted. The same would be true for the case of such a salt as sodium chloride, the constitution of whose solution might be expected to be very similar to that of potassium chloride. Moreover, a point which has escaped adequate appreciation, the same would be true of an examination of the movement of the common ion such as the chloride ion in a mixture of sodium and potassium chlorides. The results would be just as inconclusive as if either salt alone had been employed. The measurements of MacInnes[1] and Miss Dewey[2] are, therefore, necessarily inconclusive.

It is otherwise when the two salts are mixed in very unequal proportions, and the movement of the cation present in smaller quantity is directly measured. Here the excess of the salt present in larger proportion has the effect of largely increasing the relative concentration of any complex ions which can be formed from the lesser constituent, and, if so, the migration of the single dilute ion is greatly affected.

In our previous communication[3] we took advantage of this circunistance to test for the presence of complex ions in mixtures of such salts as magnesium and ammonium sulfates or magnesium and ammonium chlorides. For example, in a mixture of 0.05 M $MgSO_4$ with 0.93 M K_2SO_4 the magnesium actually migrates in the direction of the anode instead of going toward the cathode. This affords the most unequivocal proof possible that a negative charge appertains to most of the magnesium present. In other words, there is more transport of magnesium in negatively charged form (complex anion) than there is of ordinary magnesium ion itself. This negative movement of the material of the dilute ion (ignoring the movement of the concentrated cation or the common anion) serves, therefore, as a remarkable and trustworthy indicator for the presence of complex ions in considerable amounts in those mixtures.

Hence we must further conclude that in a solution of one of the salts

[1] D. A. MacInnes, THIS JOURNAL, 47, 1922 (1925); D. A. MacInnes, I. A. Cowperthwaite and T. Shedlovsky, *ibid*, **51**, 2671 (1929). In this connection it may be noted that MacInnes' formula appears to contain an assumption which renders it not strictly applicable to mixtures above a total concentration of 0.2 equivalent per liter, such as the higher concentrations studied by Schneider and Braley, *ibid.*, ***45***, 1121 (1923). Moreover, this formula presupposes that potassium and sodium chlorides are dissociated to the same extent, an assumption which, for example, is rejected by Nernst [*Z. physik.* **Chem., 135,** 237 (1928); Orthmann, ***Ergebnisse der exakten Naturwiss., 6,*** 189 (1927)].

[2] J. Dewey, THIS JOURNAL, 47, 1931 (1925).

[3] J. W. McBain and P. J. Van Rysselberge, *ibid.*, 50, 3009 (1928). Through inadvertence, the total amount of current passed was omitted from Table I. The coulometer readings in grams of silver deposited were, in order of the experiments listed: 0.22205, 0.16945, 1.48005, not measured, 0.3853, 0.72065, 0 03975, 1 7300, 1 0212, 0.9476, 1.0318, 1.8467, 1.7912, 0.8277, 0 7202.

alone, if complex ions are present in these mixtures in such significant amounts that they overshadow the ordinary migration of the dilute ion, we have to recognize the presence of such complexes in the solutions of the corresponding single electrolytes of the same total concentration as the mixture. Indeed, as is evident from the principle of mass action, the concentration of the complexes will be even greater in absolute amount, but, of course, the proportion relative to the total concentration is correspondingly lowered and the considerations deduced in the first two paragraphs will apply. What such measurements of transport in mixed solutions achieve is, therefore, to prove the existence of important amounts of complex ions, and that only if the migration of the single dilute ion is actually measured. Evaluation of the exact amounts of the complexes present requires the combination of supplementary methods, such as determinations of e. m. f. of the single constituents and total freezing-point lowering, conductivity, etc.[4]

The measurements communicated in the previous paper showed that the formation of complex ions is general throughout all solutions containing polyvalent ions. This, of course, would render futile any attempt to apply hypotheses of complete dissociation to solutions containing such ions save in extreme dilution, where all theories agree in assuming complete dissociation. The complex ions are probably formed by combination of ordinary undissociated molecules with ions. Mere clustering of ions through the operation of electrostatic forces (Bjerrum's term "association") appeared inadequate as an explanation of the migration effects observed, because it should result in comparable amounts of complex cations and anions being formed and leave the migration essentially unaffected.[5] Hence the results point not only to the presence of complex ions but to ordinary undissociated molecules as well. Hydration of ions as ordinarily recognized is quite inadequate to explain away these results.

The present investigation shows that the negative migration of magnesium in a mixture of magnesium sulfate with the sulfate of one of the

---

[4] We have attempted such a complete evaluation for solutions of cadmium iodide and cadmium sulfate, to be published elsewhere.

[5] An experiment was carried out on the movement of chlorine in the mixture **0.05 M $MgCl_2$ + 1.95** M $MgSO_4$. For a total current corresponding to **0.4631** g. of silver, the changes observed were: middle, +0.6%; cathode, **0.968** mg. Calculated by the usual approximation of the isohydric principle, the migration of the chlorine in the magnesium chloride is **0.95,** which is about what would be expected for a highly concentrated solution of magnesium chloride. Its chief significance is to show that there is no anomalous movement toward the cathode, whereas in all the other mixtures that have common anion instead of common cation there is a large movement of the dilute ion toward the "wrong" electrode. Hence we arrive at the important result that the effects are not symmetrical; complex anions have to be assumed in large amount, but not complex cations. This does not accord with purely physical explanations.

least hydrated ions, rubidium, is just as pronounced as before. The measurements are also extended to solutions containing only univalent ions such as mixtures of sodium and potassium chlorides.

Experimental

The migration apparatus was that used in the previous work[3] except for the chloride experiments.[6] The current of average strength, 0.05 ampere, was measured in a silver coulometer. The electrodes were of platinum except in the case of the mixture of sulfates when a copper anode was used. The solution, whose weight and composition by volume were known, was introduced into the cleaned and weighed apparatus. After the experiment about 50 cc. was withdrawn from the middle portion; 11 cc. was locked in the tap and served as a second middle portion. The anode and cathode portions were then closed with rubber stoppers and weighed. The weights of the solution in the two portions were thus known. In most experiments samples were then taken from the anode, cathode, middle and original solutions, weighed in weighed pyrex beakers and analyzed. The experiments were carried out at room temperature.

Magnesium was estimated as phosphate after precipitation with ammonium phosphate. In the first recorded experiment the precipitates obtained by the phosphate method were much heavier than expected from the composition of the pyrophosphate and the concentration of the solution. It was found that these precipitates contained rubidium, their probable formula being $3P_2O_5{\cdot}4MgO{\cdot}2Rb_2O$. In the second experiment carried out on the same mixture, the first precipitates were dissolved in hot hydrochloric acid and then reprecipitated. The usual ammonium magnesium phosphate was obtained.

Rubidium was precipitated and weighed as rubidium sodium cobalt nitrite. Analysis of the anode portions, however, gave irregular results, probably due to the presence of copper from the anode, so that the cathode results alone are recorded.

The transference numbers are calculated as in the previous paper on the approximate assumption that the current is distributed between the two constituents of the mixture in proportion to their respective concentrations and to the specific conductivities of the salts separately in concentrations equal to the total concentration of the mixture. The total current is indicated in the second column of the tables in terms of the silver deposited in the coulometers.

Mixtures of Ammonium and Potassium Iodide

Potassium iodide containing 2% equivalent ammonium iodide was chosen because of the convenient analytical method for the determination of the (NH_4) constituent. The solution is neutralized, then treated with excess of neutral, filtered formaldehyde. The ammonium salt is quantitatively decomposed, forming hexamethylenetetramine with the formation of an equivalent amount of hydriodic acid, which is directly estimated by titration. The systematic error of 2% in this method does not affect the conclusions, since the results are all obtained by difference. However, at times the reaction appears more complicated, probably due to hydrolysis or reactions at the electrodes, for duplicated points were sometimes not reproducible. Even so, though irregular, the results show qualitatively that the transference of the ammonium constituent is decreased or almost suppressed by the presence of a large excess of iodine ions due to complexes containing NH_4^+ ion. Iodine was liberated at the anode and formed a solution which diffused in the whole anode portion and to a slight extent in the middle portion. Four samples were taken of each portion, cathode, middle and anode, and directly compared with the original solution. Table II contains the migration data for the mixtures of ammonium and potassium iodides of total concentration from 0.5 to 2.0 equivalents per liter.

TABLE II

MIGRATION DATA POR MIXTURES OF POTASSIUM AND AMMONIUM IODIDES, SHOWING THAT MOVEMENT OP AMMONIUM IS LARGELY SUPPRESSED BY EXCESS OF POTASSIUM IODIDE[a].

Concn. of mixture, moles per liter	Ag, g.	Change in NH_4 content Middle, %	Cathode, mg.	Anode, mg.	Migration, n_{NH_4}
0.1 NH_4I	0.1730	...	+14.46	− 7.96	+0.501
1 NH_4I	.1330	−0.9	+10.42	−11.23	+ .531
.01 NH_4I + 0.49 KI	.4043	+ .4	.....	− 0.16	+ .11
.012 NH_4I + .588 KI	.3490	+ .7	+ 0.3	− .31	+ .26
.015 NH_4I + .735 KI	.5860	+ .1	+ .38	− .45	+ .21
.016 NH_4I + .784 KI	.5980	+ .2	+ .09	− .28	+ .14
.018 NH_4I + .882 KI	.3953	+ .66	.00	.00	.00[b]
.02 NH_4I + .98 KI	.3930	+ .3	.....	− .04	+ .03
.04 NH_4I + 1.96 KI	.5650	+ .5	.....	.11	+ .06

[a] Other experiments by Mrs. M. E. McBain (née M. E. Laing) showed a decreased migration number of the same order of magnitude. 0.01 NH_4I + 0.49 KI gave a transport number of +0.4, and 0.02 NH_4I + 0.98 KI gave transport numbers of +0.17 and +0.13 (instead of 0.5). [b] The change in the middle portion is greater than the change in the anode and cathode portions.

Mixtures of Potassium and Sodium Chlorides

The experiments of others on mixtures of chlorides have already been referred to, but it is to be noted further that all their work has been carried out with a ratio of the two salts under 4 to 1 and a total concentration of chiefly 0.1 or 0.2 N, respectively. The ratios of sodium to potassium in this work are 49, 24 or 9, to 1, the total concentration being either 2.0 or 5.0 N. The data refer to the movement of the potassium.

The apparatus used in these experiments consisted of three U-tubes connected by ground joints. These tubes were provided with ground stoppers which allowed an easy removal of three middle portions; namely, a central middle portion, an anode middle portion and a cathode middle portion, the two latter being contained in the horizontal tubes connecting the U-tubes. Both anode and cathode were made of platinum.

Potassium was precipitated and weighed as sodium potassium cobalt nitrite. It was found that potassium may be precipitated from these solutions in many different forms, corresponding to different degrees of hydration of the complex nitrite. It was also found that the composition of the precipitate increases with the time of settling, probably on account of gradual hydration. In order to obtain directly comparable results, it is necessary to carry out all the analyses under strictly identical conditions: the total volumes of the samples before precipitation must be the same; the same amount of sodium cobalt nitrite must be added to each of them; the time of settling must be the same for all the samples and should be at least twelve hours; the washing and drying of the precipitates should be carried out under constant conditions. In spite of all these precautions, a difference of about 1.3% is sometimes found between samples which should give identical weights of precipitates. This seems to be due to a difference in composition corresponding to one-third of a molecule of water.

TABLE III

MIGRATION DATA FOR MIXTURES OF POTASSIUM AND SODIUM CHLORIDES, SHOWING THAT THE MIGRATION NUMBER OF POTASSIUM CHLORIDE IS GREATLY ALTERED BY PRESENCE OF EXCESS OF SODIUM CHLORIDE

Concn. of mixture, moles per liter	Ratio, $\frac{NaCl}{KCl}$	Ag, g.	Change in K content			Migration,[a] n_K
			Middle, %	Cathode, mg.	Anode, mg.	
0 2 KCl + 1.8 NaCl	9	0.7121	<0.4	+14.39 +15.90	−14.71 −12.45	+0.407
.08 KCl + 1.92 NaCl	24	.6963	<.2	+ 5.68 + 4.59 + 6.35	− 4.31 − 4.34	+ .352
.04 KCl + 1.96 NaCl	49	.8922	...	+ 3.20 + 3.73	− 2.71	+ .352
.5 KCl + 4.5 NaCl	9	1.3479	<.2	f31 13 +30.98	−18.02 −22.62	+ .287
.2 KCl + 4.8 NaCl	24	1.6336	<.3	+17.65 +19.85 +14 47	− 8.52	+ .344

[a] The values of the transport number of potassium given in Table III are those calculated from the observed data according to the isohydric principle; they should be compared with that for potassium chloride alone, namely, 0.5.

The changes in content of potassium at the electrodes are calculated by comparing the amounts of complex nitrite given by weighed samples with the amounts of complex given by weighed samples of the original solution.

Nernst's recent modification of the theory of strong electrolytes leads to unequal degrees of dissociation for potassium and sodium chlorides, sodium chloride being more dissociated than potassium chloride. Nernst's theory affords values for the degrees of dissociation, and it was found that these degrees of dissociation obey the law of mass action.

It is interesting to see if the low values found for the movement of potassium cannot be accounted for by the decrease of the degree of dissociation of potassium chloride, due to the presence of the large amount of sodium chloride. Table IV gives the values of the (Nernst) degrees of dissociation of potassium and sodium chlorides for the concentrations used in our experiments. In the calculations it has been assumed that the dissociation of sodium chloride is not affected by the presence of the small amount of potassium chloride. The modified values of the degree of dissociation of potassium chloride, combined with the fractions of the current carried by potassium chloride on the assumption that the two salts are independent of each other, allow us to predict the transport number of potassium. It can be seen in Table IV that the predicted and measured values agree quite well.

TABLE IV

COMPARISON OF OUR OBSERVED DATA WITH THOSE PREDICTED FROM THE NERNST FORM OF THE DISSOCIATION THEORY

Concn. of mixture, moles per liter	Degree of dissociation of KCl in pure solution	KCl in mixture	NaCl	Predicted migration	Measured migration
0.2 KCl + 1 8 NaCl	0.950	0.700	0.834	0.357	0.366
0.08 KCl + 1.92 NaCl	.998	.625	.825	.308	.294
0.04 KCl + 1.96 NaCl	1.000	.605	.827	.299	.281
0.5 KCl + 4.5 NaCl	0.890	.526	.704	.287	.265
0.2 KCl + 4.8 NaCl	.950	.525	.694	.268	.268

It remains an open question whether the decrease in the degree of dissociation of potassium chloride, due to the presence of the large excess of sodium chloride, is the real explanation for the low values found for the movement of potassium or whether the agreement between the predictions of Nernst's theory and our experimental values is the result of a mere coincidence, complex ion formation having been neglected.

Mixtures of Potassium and Sodium Nitrates

One experiment was carried out on the following mixture: 0.08 N KNO_3 + 1.92 N $NaNO_3$, and the same procedure as for the mixtures of potassium chlorides was followed. Table V gives the results of this experiment.

The degrees of dissociation of pure 0.08 N KNO_3 and of pure 1.92 *N*

TABLE V

MIGRATION DATA SHOWING THAT PRESENCE OF SODIUM NITRATE LOWERS THE MIGRATION NUMBER OF POTASSIUM IN POTASSIUM NITRATE

Concn. of mixture, moles per liter	Ratio, $\frac{NaNO_3}{KNO_3}$	Ag, g.	Middle, %	Cathode, mg.	Anode, mg.	Migration n_K[a]
				+7.08		
0.08 KNO_3 + 1.92 $NaNO_3$	24	0.9678	<0.7	+8.87	−5.26	+0.396
				+7.69	−6.27	

[a] This number is that calculated on the assumption that the amount of current carried by the potassium nitrate is that calculated on the isohydric principle; it should be compared with that for pure potassium nitrate, namely, 0.613.

$NaNO_3$, according to Nernst,[7] are 96.4 and 69.9%, respectively. In the mixture, the degree of dissociation of potassium nitrate should, therefore, be 0.562. The movement of potassium should then be 0.5 X (0.562/0.964) or 0.292, when, in the calculation of the amount of current carried by potassium nitrate, the salts are considered as independent. The corresponding experimental value is 0.270.

Discussion

The migration data in Tables I–V, like those in our previous communication, show that in the majority of cases the presence of a large excess of anion reduces, suppresses or even reverses the movement of the supposed cation of a dilute solution of a strong electrolyte. These results are evidently incompatible with any assumption of complete dissociation into simple, independent ions.

Whenever the movement is reversed, more of the metal studied is being carried toward the anode than is migrating as simple ion toward the cathode. This is definite proof of the existence of complex anions, and in relatively large amount. For the reasons adduced in the previous communication these complex anions must be regarded as being formed by chemical combination of the ions with undissociated molecules present in the solution. The proportion of complex ions should increase rapidly with the concentration of the simple common anion of the mixture and, therefore, should also depend upon the degree of dissociation of the salt added in excess. Thus the addition of an ammonium or an alkali metal sulfate should cause a much greater change in migration number of a given salt than addition of such salts as copper or cadmium sulfates, as is illustrated by the experimental data. Furthermore, divalent ions show a larger tendency to complex formation than do monovalent ions.

Taking first the experiments of Table I for mixtures of sulfates, we see that excess of rubidium sulfate drives magnesium to the anode, whilst excess of magnesium drives rubidium to the anode. This shows that both magnesium sulfate and rubidium sulfate contain complex anions. The

---

[7] See Orthmann, *Ergebnisse der exakten Naturwiss.*, 6, 193 (1927).

simplest assumption is that they are represented by the formulas $Mg(SO_4)_2^{=}$ and $Rb(SO_4)^{-}$, respectively, the latter being analogous to the HSO_4^{-} ion of sulfuric acid, which was usually held responsible for the formation of persulfuric acid in electrolysis. It is clear from these and all the other data so far available that divalent ions much more readily form complex ions than do monovalent ions.

Rubidium sulfate was chosen for study because the rubidium ion is recognized to be nearly anhydrous so that it is incapable of displacing large amounts of solution toward the anode by carrying along with it corresponding amounts of water toward the cathode. Hence the effect cannot be explained away as being due to hydration of the cation present in excess.

The numerical values of the migrations in these mixtures possess only semi-quantitative significance owing to the mode of calculation from the actual movements observed. Quantitative evaluation would require a knowledge of the formulas and actual mobilities of each of the ions present in the mixture, and the greater the formation of complex ions the more would such a result depart from the rule of simple mixtures on the principle of isohydrism. This may account for such an extreme number as -1.57, but the possibility of still higher complexes has to be borne in mind.

It may be worth noting here that C. W. Davies[8] has shown that the change in conductivity of magnesium sulfate with change in concentration is incompatible with the assumption of the complete dissociation of magnesium sulfate into single ions. Onsager's[9] conductivity equation, based on the hypothesis of 100% dissociation, fails completely for magnesium and cadmium sulfates, and Davies modified the equation by taking the incomplete dissociation into consideration.

Complex anions containing copper have been detected by Rieger[10] in solutions of the double sulfate $K_2Cu(SO_4)_2$. He found that here the migration of the copper ion was much smaller than in solutions of pure copper sulfate of the same concentration and that the transference number decreases when the concentration of the double sulfate increases. This is due presumably to the presence of complex anions, $Cu(SO_4)_2^{=}$, analogous to $Mg(SO_4)_2^{=}$.

Pfanhauser[11] found that in a saturated solution of nickel ammonium sulfate, the nickel moves entirely to the anode in the form of the complex ion $Ni(SO_4)_2^{=}$. Some incomplete data relating to a 0.1 molar solution of the double sulfate show that, even at this low concentration, the nickel is largely in the form of complex ions.

Tables II and III are especially interesting in that only uni-univalent

salts are concerned. Table III refers to potassium chloride, the typical strong electrolyte. The experiments show that the presence of a large excess of Cl^- can decrease the transference of potassium ion to about 55% of its value in a solution of potassium chloride alone. Similarly, excess of potassium iodide practically suppresses the movement of ammonium ion toward the cathode. Nernst's form of the dissociation theory would predict that the transference number of potassium chloride should tend toward a definite limit as the excess of sodium chloride present is increased. It is easily shown that the relative hydrations of sodium and chlorine ion as measured in such investigations as those of Washburn[12] and Miss Taylor and Sawyer[13] could not account for more than a very small fraction of the effects here observed.

Familiar examples of complex anions derived from uni-univalent salts are the $Ag(CN)_2^=$ of double cyanides and the mixtures[10] of potassium and silver iodides in which the silver likewise migrates toward the anode.

Measurements of activity coefficients in mixtures of electrolytes afford at least qualitative information as to the possibility of incomplete dissociation. Results obtained for hydrochloric acid in presence of alkali chlorides, such as those of Harned,[14] recalculated by Lewis and Randall,[15] show that in concentrated solutions "the activity coefficient of the hydrochloric acid depends upon the specific nature of the added chloride." This would indicate that a complete dissociation does not hold in these mixtures. The results obtained by Loomis, Essex and Meacham[16] with 0.1 molar mixtures of potassium chloride and hydrochloric acid are not exactly constant when the ratio of the concentrations of the two constituents varies. In general, if Lewis and Randall's ionic strength principle can be considered as closely verified for moderate concentrations, the deviations occurring at high concentrations can be accounted for by recognizing incomplete dissociation and, at least in the case of polyvalent salts, by taking into account the existence of complex ions.

Bronsted has published two experimental papers on electromotive force[17] which are most frequently quoted in support of the hypothesis of 100% dissociation. The first paper deals with cadmium electrodes dipping into two solutions containing two different concentrations of cadmium sulfate, the total concentration in each case, however, being made up to 2.0 molar by addition of magnesium sulfate. The electromotive forces were in substantial agreement with those calculated by using the gross concentration

of cadmium sulfate in the usual Nernst formula. His very doubtfully valid procedure of correcting his results by means of the thermodynamically unpredictable cell where one of the cadmium electrodes dipped into a solution of magnesium sulfate containing no cadmium salt is only a minor objection. The chief point is that his results, according to the mass law, are equally in accord with the hypothesis of complete dissociation, or of partial dissociation, or of formation of any suggested proportion of complex ions, the last possibility being that which was shown in our previous communication to be true for these mixtures from the fact that the cadmium migrates toward the anode and is, therefore, not predominantly in the form of the positively charged cadmium ion.

Bronsted himself recognized this complete inconclusiveness or ambiguity and proceeded to make the experiments of his second paper[18] in which the chlorine electrode was dipped in two solutions of magnesium chloride of different concentration, the total concentration being made up to 4.0 N with magnesium sulfate in every case. Here Bronsted relied upon the fact that magnesium chloride is a ternary electrolyte and, therefore, would become completely dissociated at infinite dilution of magnesium chloride even in presence of the concentrated magnesium sulfate. To this standpoint no exception can be taken because more complicated modes of dissociation would merely obscure but not invalidate the final effect. However, Bronsted's numerical evaluation of his results is based upon the implicit assumption that a 0.0032 N magnesium chloride in 4.0 N solution of magnesium sulfate is 100% dissociated, and, if so, 0.1 N magnesium chloride is 99.3% dissociated. The assumption, however, begs the whole question, which is therefore seen to be one of opinion and not of experimental evidence. Migration data such as we adduce show, on the contrary, that magnesium, whether in chloride or sulfate, can be carried to the anode and, therefore, in such mixtures more of it bears a negative than a positive charge, a result fatal to any assumption of complete dissociation into simple ions.

Summary

1. In 0.05 M solutions of magnesium or rubidium sulfates, addition of a large proportion of the other sulfate causes the magnesium or rubidium to migrate away from the cathode toward the anode. In mixtures of ammonium iodide with excess of potassium iodide the movement of the ammonium may be practically suppressed. In mixtures of potassium chloride with excess of sodium chloride or of potassium nitrate with excess of sodium nitrate, the movement of the potassium may be considerably decreased.

[18] J. N. Bronsted, *Kgl. Danske Videnskab. Selskab, Math.-fys. Medd.*, **3**, *No. 9, 14 (1920); Trans. Faraday Soc.*, **44,727** *(1928).*

2. The general conclusion is that strong electrolytes form undissociated molecules and complex anions; they differ only in degree from such an extreme case as that of cadmium iodide. Electrolytes would all seem to fall within a triangle whose corners represent extreme dissociation, extremely weak electrolytes and complete formation of complex ions, respectively.

APPLICATIONS OF CERIC SULFATE IN VOLUMETRIC ANALYSIS. VIII. USE OF METHYL RED, ERIO GLAUCINE AND ERIO GREEN INDICATORS IN THE REACTION BETWEEN CERIC AND FERROUS IONS

BY N. HOWELL FURMAN AND JOHN H. WALLACE, JR.[1]

RECEIVED FEBRUARY 24, 1930 PUBLISHED JUNE 6, 1930

Introduction

A number of applications of ceric sulfate in volumetric analysis have been described recently.[1] The use of various organic substances, for example, methyl red, methylene blue and methyl orange, as irreversible oxidation-reduction indicators in the titration of trivalent antimony with ceric sulfate was proposed by Rathsberg.[2] We have shown that methyl red may be used as an indicator in the titration of hydroquinone with ceric sulfate.[3]

We have found that methyl red is an excellent indicator in the titration of ferrous salt with ceric sulfate or *vice versa.* Upon titration of a ferrous solution with ceric sulfate, the ferrous salt is oxidized first; a slight excess of ceric sulfate oxidizes the methyl red to a substance that is brownish in concentrated solution and yellow in very dilute solution. The oxidation product is destroyed upon standing in contact with an excess of ceric sulfate.

When ceric sulfate is being titrated with ferrous sulfate solution, the latter is added rapidly until the color of the ceric ion has almost disappeared. Methyl red is added, and is oxidized to the yellowish product. Upon further addition of ferrous salt, there is a transition from yellow to violet when a slight excess of ferrous salt is present. If phosphoric acid be added, the color change agrees well with the potentiometric end-point. The color change of methyl red is much more rapid than that of diphenylamine under the same conditions. In agreement with Willard and Young[4]

we find that the use of diphenylamine is unreliable in the determination of cerium with ferrous sulfate.

During the progress of our work with methyl red there appeared two publications by Knop[5] in which he suggested the use of two triphenylmethane dyes, erio glaucine and erio green, as reversible oxidation–reduction indicators in the titration of ferrocyanide with permanganate. We have found that these indicators are excellent for certain titrations with, or of, ceric sulfate.

Experimental

Ceric sulfate solutions of approximately 0.1 or 0.05 N oxidizing power and 1 N in sulfuric acid were prepared from commercial hydrated ceric oxide (45% CeO_2) and were standardized potentiometrically against pure sodium oxalate.[6]

Methyl Red as Indicator.—Two-tenths g. of a Kahlbaum preparation was treated with 100 cc. of 6 N sulfuric acid. Nearly all of the material dissolved, and the slight residue was filtered off; 0.05 cc. of the solution is adequate for a titration.

Titration of Ferrous Iron with **Ceric** Sulfate.—The data are presented in Table I.

TABLE I

TITRATION OF APPROXIMATELY 0.1 *M* MOHR'S SALT SOLUTION WITH 0.1120 *M* CERIC SULFATE

Ferrous soln., *cc.*	25	25	25	25	50	50	10	10
Initial vol., cc.	50	100	235	50	150	200	50	100
H_2SO_4 concn., *N*	0.3	0.2	0.75	3.6	1.2	1.0	0.6	0.3
Ceric soln. used	22.36	22.38	22.34	22.35	44.64	44.62	8.92	8.93
Ceric soln. calcd.	22.32	22.32	22.32	22.32	44.64	44.64	8.93	8.93

The calculated values are based on the average of four concordant potentiometric determinations. In each case 0.05 cc. of indicator was used. If the solution is stirred vigorously by hand, there is a sharp end-point even when the indicator is added at the start of the titration. It is desirable, however, to add the indicator when the ceric sulfate has begun to be consumed slowly. The determinations of Table I do not show clearly what correction, if any, should be applied when 0.1 N solutions are used. From the results with 0.05 M solutions it seems safe to apply a correction of 0.03 cc. to be subtracted from the buret reading in the titration of 0.1 M solution, this correction being approximately half of that found in Table II.

In Determinations 1–4 the ceric solution was 0.0593 N, and in Nos. 5–8, 0.0552 N. The calculated values are based on sets of four concordant

potentiometric determinations. On the average 0.06 cc. of ceric sulfate needs to be subtracted from the buret reading in order to make the indicator values coincide with the potentiometric ones. When hydrochloric acid is present, the color change is not as sharp as in sulfuric acid solution, but the change is very distinct.

The methyl red end-point is satisfactory in solutions which have been reduced with stannous chloride in excess, the excess being destroyed with mercuric chloride. A solution of ferric alum in dilute sulfuric acid required per 25 cc.: 21.69, 21.70, 21.68 cc. of 0.0948 *N* ceric solution after stannous chloride reduction, and 21.70, 21.73, 21.71 cc. of the ceric solution after passage of 25-cc. portions through a Jones reductor.

If Mohr's salt is used as a secondary standard, the correction of 0.03 cc. of 0.1 N ceric solution brings the methyl red end-point in good agreement with the potentiometric.

Ceric sulfate vs. sodium oxalatc, N	0.1079	0.1081	0.1080

Diphenylamine	30.08	30.07	30.11	30.07	30.08

of methyl red is added, and immediately afterward 25 cc. of the sulfuric–phosphoric acid mixture (150 cc. of each concentrated acid per liter) which is used in Knop's[7] diphenylamine method. The yellow color of the solution becomes much less intense, but no precipitation of cerium phosphates occurs. The ferrous sulfate is added slowly until the solution suddenly becomes pale violet. Upon standing the violet color deepens. Some results are presented in Table III.

Five one-hundredths cc. of methyl red or 0.05 cc. of 1% diphenylamine was used. The behavior of diphenylamine is erratic, and the position of the end-point depends upon the speed of titration at the end-point.

Behavior of Methyl Red on Oxidation and Reduction.—This study is still in a preliminary stage as far as the mechanism of the reaction is concerned. A brief résumé of some qualitative experiments may be of interest. Ceric sulfate appears to be the only oxidizing agent which gives the intermediate oxidation product of methyl red under the conditions used in volumetric analysis. Bromate, permanganate and chlorine carry the oxidation so far that no colored product is formed on reduction with ferrous salt. The violet-colored substance is formed when the reduction is carefully performed with stannous chloride; sulfite, on the other hand, carried the reduction to a colorless stage.

Methyl red shows the same oxidation–reduction behavior after recrystallization from glacial acetic acid, as before purification.

The violet-colored reduction product is extracted from aqueous solution by ether to give an orange-red solution, and by benzene to give a violet-red solution. In the latter solvent methyl red forms an orange or yellow extract, although largely present in the red form in the strongly acid aqueous layer. Thus far it has not been possible to obtain the violet substance in a form pure enough for analysis.

Erio Glaucine and Erio Green Indicators—Erio Glaucine A (Schulz No. 506) and Alkali Past (erio) Green A were obtained from the National Aniline and Chemical Company, New York; 0.1% aqueous solutions were prepared, and 0.5 cc. of either solution was used for a single titration. Knop[7] states that the compositions of the rose-colored oxidation products are not known. Either indicator forms a greenish-yellow color in acid solution; in pure water the colors are blue and green, respectively. A very slight excess of ceric sulfate colors either indicator rose or red; in the presence of a ferric salt the color is orange or pale rose. There is a short time interval necessary for the development of the full color change at the end-point; the danger of over-titration is slight. The results are summarized in Table IV.

The determinations were made as closely together as possible, in point of time, with alternation of indicator and potentiometric determinations.

Ceric solution used, cc.	22.99	23.03	23.00	23.03	45.98	45.89	22.99

There does not appear to be any correction to be applied in working with 0.1 *N* solutions.

The reverse titration was studied. It was found that either indicator could be added immediately before the start of a titration. The color was initially orange; when nearly all of the ceric ion had been reduced the rose tint predominated. At the end-point there was a sharp transition to yellow with a slight time interval needed for the color change.

Within the limits of error of these determinations there appears to be no indicator correction.

It seemed of interest to determine whether the presence of calomel and mercuric chloride would interfere with the functioning of the indicators. A solution of ferric alum, acidified with sulfuric acid, was prepared, and aliquot portions were reduced by the stannous chloride method with subsequent addition of excess of mercuric chloride. Portions of the solution were reduced by the Jones reductor, and an average of 23.09 cc. of 0.0945 N ceric sulfate was required per 25 cc. of alum solution.

A number of other uses of erio glaucine and erio green in titrations with ceric sulfate are being studied.

Summary

Methyl red in dilute sulfuric acid solution may be used as indicator in the titration of ferrous ion with ceric, or ***vice versa.*** In the latter case the indicator must be added near the end-point, and phosphoric acid must bc present. A correction must be applied in the former titration.

A new behavior of methyl red upon mild oxidation–reduction treatment has been described.

Erio glaucine and erio green are excellent indicators for the titration of ferrous ion with ceric, or ***vice versa.*** No correction need be applied in either case with a 0.1 N standard solution.

The three indicators are satisfactory in hydrochloric acid solution as well as in sulfuric, and in the presence of calomel and excess of mercuric chloride.

ACTIVITY COEFFICIENTS OF SODIUM, POTASSIUM AND LITHIUM CHLORIDES AND HYDROCHLORIC ACID AT INFINITE DILUTION IN WATER-METHYL ALCOHOL MIXTURES

BY GÖSTA ÅKERLÖF

RECEIVED FEBRUARY 26, 1930 PUBLISHED JUNE 6, 1930

I. Introduction

The activity coefficients of a number of the alkali halides in pure aqueous solutions have recently been redetermined with great precision by Harned.[1] He used cells of the type

$$Ag/AgX/MeX\ (m_1)/Me_yHg/MeX\ (m_2)/AgX/Ag$$

where X designates the halide and Me the alkali metal present. In the present investigation cells of the same general type have been used, but the concentration of the electrolyte was the same on both sides of the cells and the composition of the solvent used as a variable

$$Ag/AgX/MeX\ (m_1)\text{ in water}/Me_yHg/MeX\ (m_1)\text{ in water–alcohol}/AgX/Ag$$

Through suitable recombining of these cells with those for pure aqueous solutions it was possible with the use of the Debye–Hückel activity function to calculate the activity coefficients of the electrolytes employed in the water–alcohol solutions. This also gave the means of determining the activity coefficients at infinite dilution in relation to the corresponding water value which was assumed to be unity in accordance with custom. As has been predicted by the simplest theory possible, it was found that within the errors due to uncertainties of the calculation and experimental difficulties, the logarithm of the activity coefficient at infinite dilution is approximately inversely proportional to the dielectric constant of the pure water–methyl alcohol mixtures. It is the first time this has actually been shown to be the case and therefore, although expected, it is of considerable importance.

II. Experimental Methods

The methyl alcohol used was free from acetone and aldehydes; the density corresponded very closely to the accepted value for pure, absolute alcohol. As the alcohol always was used in mixture with water a correction for the very small water content of the original product was considered unnecessary. All salts used were of the analyzed variety and further purification was not carried out. Hydrochloric acid was carefully redistilled as constant-boiling mixture and middle portions were used. All solutions

were generally made up through diluting standard solutions with calculated amounts of water and alcohol. All concentrations of the electrolytes are given in molality per 1000 g. of the solvent. The methyl alcohol concentration is expressed in weight per cent.

Silver–silver chloride electrodes[2] were prepared from silver deposited on a small platinum-spiral through decomposition of silver oxide paste at 500°. The electrolysis in one molal hydrochloric acid was carried out with 10 milliamperes during two hours. Hydrogen electrodes[2] were obtained through electrolysis with a small platinum-foil in an approximately 1%, strongly acid, $PtCl_4$ solution. The amount of current used was about 0.1 amp. per sq. cm. of surface of the foil during six minutes. The alkali metal amalgams were made by the method described by Harned.[2b] The lithium amalgam was found to work fairly well without any special precautions. The design of the amalgam cells employed is given in Fig. 1. The procedure for measurements of these cells has been described sufficiently elsewhere.[2,3] The temperature for all measurements was 25.00°.

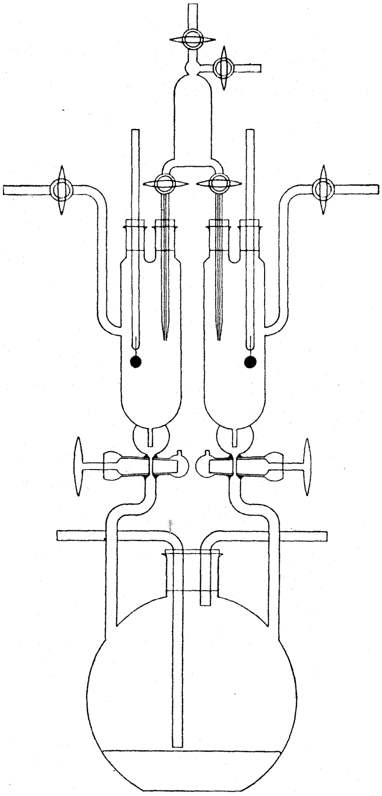

Fig. 1.—Apparatus for the amalgam cells.

III. Accuracy of the Results

The electromotive force of the amalgam cells was wholly due to the differences in the composition of the solvent used in the two half cells. The amount of solvent employed in making up the solutions varied between 600 to 800 g. Before the cells were filled the two solutions that were to be used were boiled in vacuum at room temperature during two to four minutes. The salt concentration of the pure water solution changed very slightly but the evaporation from the alcohol solution was naturally considerably greater. If the amount of solvent evaporated had been the same on both sides of

---

[2] A review of the method* and the literature for Ag/AgCl electrodes is given (a) by Harned, Ref. 1; regarding hydrogen electrodes compare also Harned and Åkerlöf, *Physik. Z.*, 27, 411 (1926); (b) Harned, THIS JOURNAL, 47, 676 (1925); preparation of lithium amalgam, Harned and Swindells, ibid., 48, 126 (1926).

[3] Åkerlöf, *ibid.*, 48, 1160 (1926).

the cell the effect of the electromotive force could scarcely have been noticed even with a very high measuring accuracy. To compensate for the larger loss on the alcohol side a slight excess of pure alcohol was added. The excess increased somewhat with the alcohol concentration and corresponded sufficiently closely with the actual loss. For dilute or fairly concentrated wateralcohol mixtures (up to 60%) this precaution worked very well. At still higher alcohol concentrations the difficulties in obtaining good results increased very rapidly. Usually the same measurement had to be repeated with new solutions three or four times and then their mean used. The measurements were carried out with a series of water-alcohol mixtures differing by 10% in alcohol content. Dividing the electromotive force by the alcohol content and plotting the values obtained against it usually gave a very smooth curve at lower alcohol concentrations. At higher ones the deviations were sometimes quite large, indicating possible errors of 2–3 millivolts. Up to 50% alcohol the errors seemed hardly to exceed 0.2–0.3 of a millivolt but systematic errors might easily have been present. For the measurements with solutions of hydrochloric acid errors due to evaporation of alcohol were unlikely to occur. Immediately before the hydrogen entered the cell it had passed through a long bubbling tower almost completely immersed in the water of the thermostat and containing about 200 cc. of the solution used. The measurements with these solutions may therefore have only the ordinary, apparent errors of 0.1--0.2 of a millivolt through the entire series.

IV. The Calculation of the Results

The limiting function of Debye–Hückel for the logarithm of the activity coefficient of a strong electrolyte is given by the well-known equation

$$\ln \gamma = -\frac{\epsilon^2 \cdot z_i^2}{k \cdot T \cdot D \cdot 2} \sqrt{\frac{8\pi \cdot N \cdot \epsilon^2 \cdot z_i^2 \cdot m}{K \cdot T \cdot D}} \text{ or } \ln \gamma = -u\sqrt{2m} \qquad (1)$$

where ϵ is the electron charge, k the Boltzmann constant, T the absolute temperature, D the dielectric constant of the medium, N the number of Avogadro, k the "mean distance of ionic approach," z_i the valence number of ions of the ith kind and m the concentration of the electrolyte. Recently Gronwall, LaMer and Sandved[4] have extended this simplified equation to the so-called terms of higher order. They showed that in cases with symmetrical ions, where very small or negative distances of ionic approach were obtained with the original Debye–Hückel theory, their extended form gave positive and constant values, which seemed to be reasonable. However, their improved equations could only be used for very dilute solutions where the dielectric constant of the medium might be assumed to remain practically unchanged with varying concentration of the electrolyte. In this concentration range the electromotive force methods of determining

---

[4] Gronwall, LaMer and Sandved, *Physik. Z.*, 29, **338** (1928).

activities are more or less unreliable and as we therefore were forced to use far higher concentrations, the equations mentioned could not be used in their present form. To obtain an equation which may be used for a large concentration range, Hückel[5] deduced an equation for the influence of the electric charges of the ions of the electrolytes. The fundamental assumption made was that the total change of the dielectric constant of the medium decreased linearly with increasing concentration. In a number of cases where the ions present had small dipole moments, this assumption was found to lead to negative dielectric constants in only fairly concentrated solutions, which is an impossibility. Nevertheless, a simplified form of Hückel's equation was shown by Hückel, Scatchard, Harned, Åkerlöf and others to be able to express the results of the activity measurements with great precision over a very large concentration range. The general form of the equation employed is

$$\log \gamma = -u\left(\frac{\Sigma\nu_i z_i^2}{\Sigma\nu_i}\right)^{3/2} \cdot \frac{\sqrt{\Sigma\nu_i c_i}}{1 + A\sqrt{\Sigma c_i z_i^2}} + B\Sigma c_i z_i^2 - \log\left(1 + \frac{M}{1000}\Sigma m_i\right)\ldots \quad (2)$$

where u is a universal constant, A and B are empirical constants, M is the molecular weight of the solvent, m and c are the concentration of the electrolyte in molality and molarity, ν_i and z_i the number and valence of ions of the ith kind. So far in all cases where this equation has been used the theoretical value of the constant u has been employed, both for aqueous and non-aqueous solutions. As an example may be mentioned the calculation of Lucasse[6a] of the activity coefficient of hydrochloric acid in methyl alcohol from the measurements of Nonhebel and Hartley,[6b] in ethyl alcohol from those of Harned and Fleysher.[6c] Lucasse concluded that a very good agreement had been obtained between observed and calculated values. The quite appreciable deviations, especially at very low acid concentrations, were attributed to experimental difficulties such as hydrogen electrode errors, etc.

When Equation 2 was applied to some of the measurements presented here, it was soon found that it could not be used with the theoretical u-values. Since most of the results were obtained for fairly dilute solutions, the term $B2m$ from Equation 2 was neglected in the case of potassium and sodium chloride solutions on account of its assumed smallness. As variables u and A were used. The measurements with lithium chloride solutions were extended over quite a large concentration range. In this case the influence of the term $B2m$ is quite considerable at higher concentrations and could not be neglected. Therefore the u-values were first determined from measurements at lower concentrations and then the A and B values from a series of results at higher ones. As the difference between calculated

---

[5] Hückel, *Physik. Z.*, 26, 93 (1925).

[6] (a) Lucasse, *Z. physik. Chem.*, **121, 254** (1926); (b) Nonhebel and Hartley, *Phil. Mag.*, [6] 50, 298, 729 (1925); (c) Harned and Fleysher, THIS JOURNAL, 47, 82 (1925).

and theoretical u-values increases rapidly with increasing alcohol concentration, the u-values for lithium chloride solutions were calculated only for the two highest alcohol concentrations employed and then interpolated to give a curve of the same form as the curve for the theoretical values. For hydrochloric acid this method of calculation was found to be unnecessary and in this case the theoretical u-values were used.

The determination of the variables u, A and B each required a separate electromotive force value that was to be obtained from the measurements in the following manner. Consider the three cells

I Ag/AgCl/MeCl (m_1)/Me$_y$Hg/MeCl (m_2)/AgCl/Ag
II Ag/AgCl/MeCl $(m_1, a\%$ alc.)/Me$_y$Hg/MeCl (m_1)/AgCl/Ag
III Ag/AgCl/MeCl $(m_2, a\%$ alc.)/Me$_y$Hg/MeCl (m_2)/AgCl/Ag

The electromotive forces of these three cells may be expressed by the equations

$$E_1 = \frac{RT}{NF} \ln \frac{\gamma_1 . m_1 \text{ (water)}}{\gamma_2 m_2 \text{ (water)}} \tag{3a}$$

$$E_2 = \frac{RT}{NF} \ln \frac{\gamma_1^* . m_1^* \text{ (alc.)}}{\gamma_1 \cdot m_1 \text{ (water)}} \tag{3b}$$

$$E_3 = \frac{RT}{NF} \ln \frac{\gamma_2^* \cdot m_2^* \text{ (alc.)}}{\gamma_2 . m_2 \text{ (water)}} \tag{3c}$$

An asterisk marks activity coefficients and concentrations in alcohol-water solutions. Subtraction of the second equation from the first one and addition of the third gives

$$E_4 = \frac{RT}{NF} \ln \frac{\gamma_2^* . m_2^* \text{ (alc.)}}{\gamma_1^* . m_1^* \text{ (alc.)}} \tag{3d}$$

Finally there is also a measurement necessary for the elimination of E_0 according to the equation

$$E_4 - E_0 = \frac{RT}{NF} \ln \gamma \cdot m \tag{3e}$$

For potassium, sodium and lithium chlorides the values of E_1 were calculated from the measurements of Harned. The measurements for hydrochloric acid gave directly the values of E_4. As previously indicated it has been customary to express the concentrations for these calculations in two units, molar and molal. In order to avoid a rather unnecessary labor, all concentrations in the following will always be expressed and used as molality. This makes the logarithmic end term in Equation 2 unnecessary for the calculations. The measurements were generally used interpolated from curves.

V. Experimental Results

In Tables I, II, III and IV are given the results of the measurements and calculations with potassium, sodium and lithium chlorides and hydrochloric acid, respectively. All measurements with cells containing hydrogen electrodes are corrected to a partial hydrogen pressure of 760 mm. of mercury. The vapor pressures of the water--methyl alcohol mixtures without electrolytes present were obtained from the measurements of Konowalow[7] in the following manner. The values for constant alcohol concen-

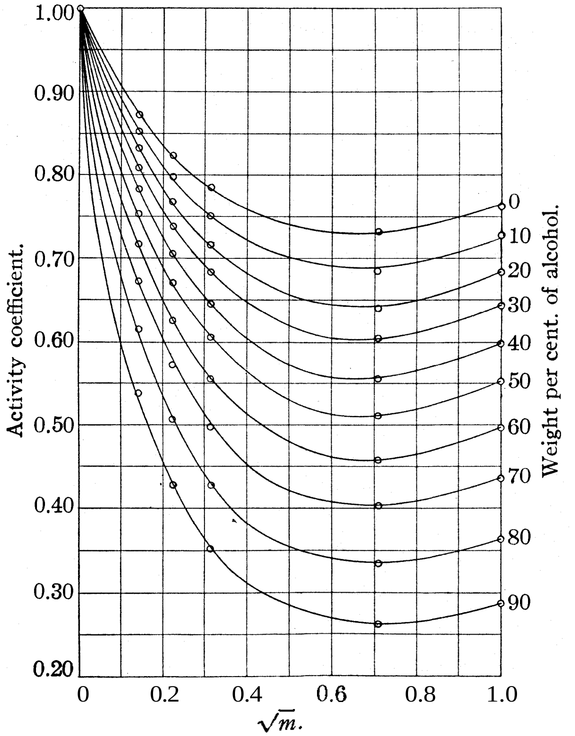

Fig. 2.—Curves for the activity coefficient of lithium chloride in water–methyl alcohol mixtures. The top curve is the one for pure water; then follow in order those for 10, 20. . . .etc., weight per sent. of alcohol.

hol concentrations in relation to each other. The figure shows that the order of distribution of the curves for the different electrolytes remains unchanged although their dispersion with increasing alcohol concentration changes by a very large amount. In this connection might be mentioned the result of a number of measurements of the activity coefficient of hydrochloric acid in acid–sodium chloride solutions at varying constant total molality and at varying alcohol concentration. The curves for the logarithm of the activity coefficient as plotted against the acid concentration

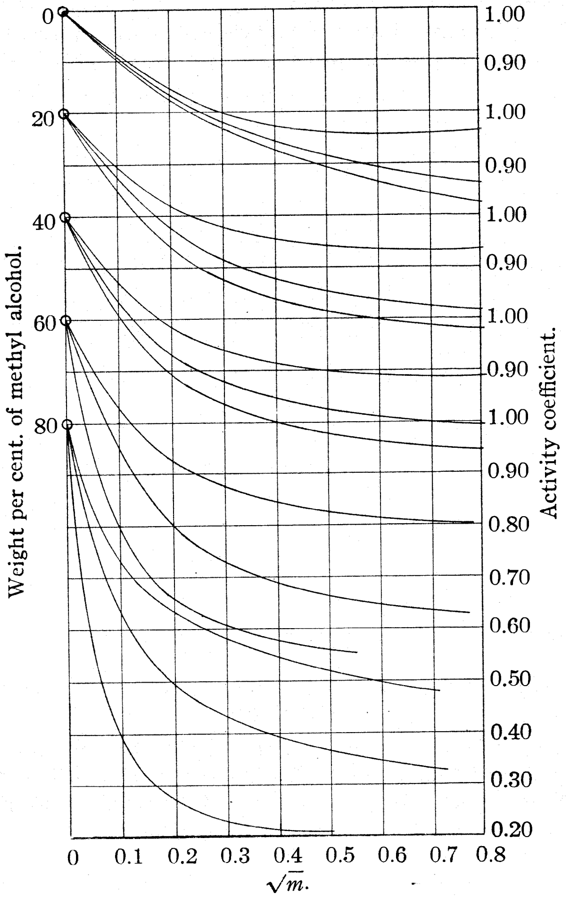

Fig. 3.—Distribution of the activity coefficient curves for potassium, sodium and hydrogen chloride in water–methyl alcohol mixtures. For each set of three curves the top one is always for hydrochloric acid, the middle one for sodium chloride. The scale is successively moved down in such a way that for a given water–alcohol mixture the circle corresponds to unity.

are straight lines and their slope is a constant independent of the total molality and alcohol concentration. In other words, strong electrolytes in alcohol solutions seem to show also in this respect the same general behavior, that has been demonstrated to be valid for water by Harned and Åkerlöf,[2a] Harned and Harris[8] and others.

Figure 4 gives the curves for the logarithm of the activity coefficients at infinite dilution in relation to unity for pure water as plotted against the inverse values of the dielectric constants of the pure water–methyl alcohol mixtures. The values for the dielectric constants were obtained from the measurements of Drude.[9] Since he found a linear variation of these constants with the alcohol concentration in weight per cent, and the temperature coefficient is not particularly well known, the pure water value was interpolated to 25°, the one for the pure alcohol taken as given by Drude for 19° and then interpolation was carried out linearly. A summary of all values used for Fig. 4 is given in Table VI. The values for log γ_∞ given in this table were calculated from the measurements for 0.02 molal solutions

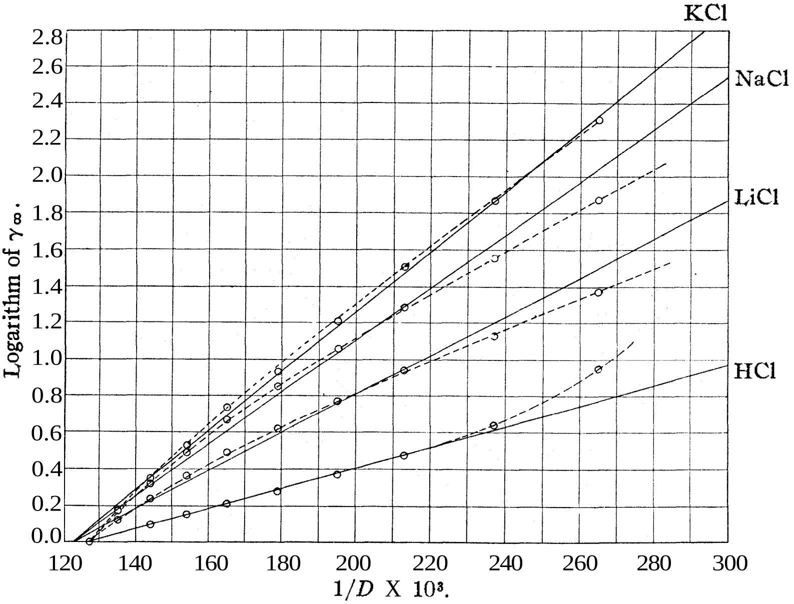

Fig. 4.—Curves for the logarithm of the activity coefficients of potassium, sodium, lithium and hydrogen chlorides at infinite dilution in water–methyl alcohol mixtures as plotted against the inverse values of the dielectric constants of these same mixtures. The dotted lines correspond to even curves through as many experimental points as possible.

in the following manner. The electromotive force values for the concentration mentioned gave first the ratios between the activity coefficients in pure water and the water–methyl alcohol mixtures, the last two values both related to unity at infinite dilution. Multiplication of the ratio obtained with the activity coefficient for 0.02 molal solutions in pure water and division with the corresponding value in water–alcohol gave for the alcohol mixture the desired value at infinite dilution.

Table VI

Mole Fraction of Methyl Alcohol *n*, Dielectric Constants *D*, their Inverse Values 1/*D* for the Pure Water–Alcohol Mixtures, Activity Coefficients of Potassium, Sodium and Lithium Chlorides and Hydrochloric Acid at Infinite Dilution in the Same Water–Alcohol Mixtures in Relation to the Corresponding Water Value Assumed to Be Unity

Discussion

The purpose of the present investigation was primarily to obtain the curves for the activity coefficient of the electrolytes used at infinite dilution as a function of the composition and dielectric properties of the solvent. To gain this result it was considered as fully justified to employ the simplest methods possible, although those selected appear to have a large theoretical disadvantage. The Debye–Hückel theory gives as a limiting function for the logarithm of the activity coefficient of a strong electrolyte in very dilute solutions: $\log \gamma = -u\sqrt{2m}$. In the case of aqueous solutions it has generally been possible to use the theoretical value for the constant u. The instances in which a very small or even negative distance of ionic approach was obtained may be due to neglect of the higher terms. Actually Gronwall, LaMer and Sandved showed for the measurements of Bray[10] with zinc sulfate solutions that a positive, constant and reasonable limiting distance could be calculated from their extended theory.

In the case of the measurements presented in this paper for potassium and sodium chloride solutions, it proved to be impossible to use the theoretical u-values of the limiting function. The equation of Gronwall, La-

---

[10] Bray, This Journal, 49, 2372 (1927).

Mer and Sandved, which should be applied only to electrolytes having anions and cations of equal valence has the following form:

$$\ln \gamma = -\frac{\epsilon^2 \cdot z^2 \cdot X}{2 \cdot k \cdot T \cdot Da(1 + X)} + \sum_{m=1}^{\infty} \left(\frac{\epsilon^2 \cdot z^2}{k \cdot T \cdot D \cdot a}\right)^{2m+1} \cdot \left[\frac{1}{2} X_{2m-1}(x) - 2m Y_{2m-1}(x)\right]$$

where a is the ionic diameter, assumed to be the same for both positive and negative ions, X and Y are very complicated functions of x = Ha,' where

$$H = \sqrt{\frac{8\pi \cdot N \cdot \epsilon^2 \cdot z^2 \cdot C}{1000 \cdot k \cdot T \cdot D}}$$

This equation might have given positive and constant ionic distances, but aside from the large difficulties for practical use, widely varying values would have been obtained for the different electrolytes used and, further, as log γ as a first approximation is inversely proportional to the dielectric constant of the medium, the concentration range over which this formula may be regarded as valid decreases rapidly with increasing alcohol concentration. Therefore, it seemed to be far simpler to use u as a variable even though this procedure brings in an apparent theoretical disadvantage. On account of the very large differences between theoretical and calculated u-values for potassium chloride solutions, the results for sodium and lithium chloride were treated in a manner similar to that for the first mentioned electrolyte. A graphical picture of the change of the u-values for the different electrolytes is shown in Fig. 5. The curve for the potassium chloride solutions deviates with increasing alcohol concentration very much from the theoretical one. Those for sodium and lithium chloride come considerably nearer the one for hydrochloric acid, which is the same as the curve given by the theory. The activity coefficients calculated in the manner described above from the empirical constants obtained agree in most cases very well with the observed values. The A- and B-values do not always give smooth curves but this should not be taken too seriously

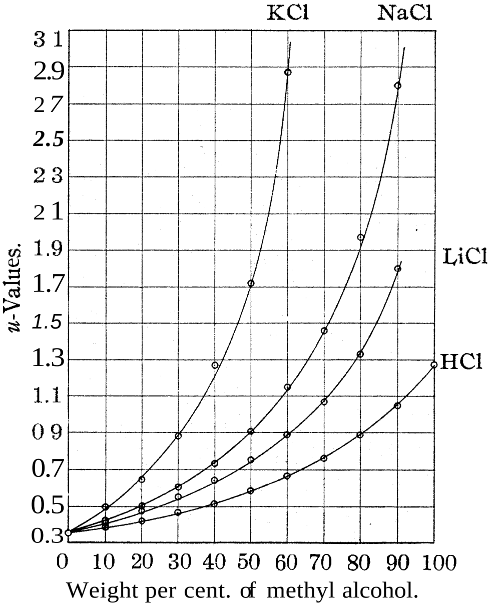

Fig 5.—Curves for the u-values used for potassium, sodium, lithium and hydrogen chlorides in water–methyl alcohol solutions. The theoretical curve is identical with the one for hydrochloric acid

on account of the disturbing influence of small experimental errors in the electromotive force measurements.

According to Debye and Hückel, in very dilute solutions the potential of one ion with respect to another of opposite sign is approximately inversely proportional to the dielectric constant of the medium and the distance between the ions. If we in our case assume that in very dilute solutions the distance two ions may approach reaches a limiting value independent of the properties of the solvent, then the logarithm of the activity coefficient of the electrolytes employed would at infinite dilution give a constant ratio with the dielectric constant of the medium. The dotted lines in Fig. 4 give the experimental curves for log γ_∞ when plotted against $1/D$. Considering the uncertainty of both the electromotive force and dielectric constant measurements as they were obtained from a single series of experiments, the deviations of the dotted lines from linearity may be regarded as fairly small at alcohol concentrations up to 80%. Above this concentration, especially, hydrochloric acid begins to show large deviations and for pure alcohol the measurements of Nonhebel and Hartley give a point that is very far above the one indicated by the extended straight line for lower alcohol concentrations. In Fig. 6 log γ_∞ is plotted against the mole fraction of the alcohol. In this case it seems to be possible that the deviations from straight lines may be attributed to experimental errors except for hydrochloric acid at high alcohol concentrations. From the

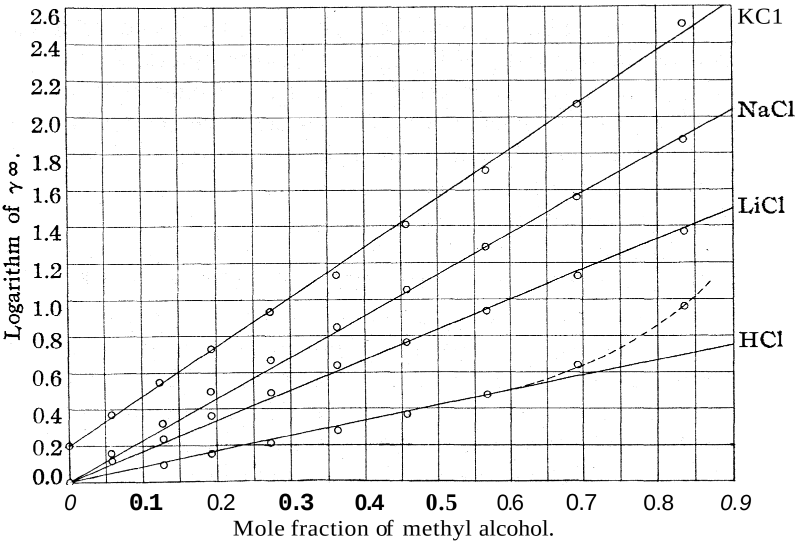

Fig. 6.—Curves for the logarithm of the activity coefficients of potassium, sodium, lithium and hydrogen chlorides at infinite dilution in water–methyl alcohol mixtures as plotted against the mole fraction of alcohol.

known activities of potassium and sodium chloride as extrapolated from the measurements of Harned for the saturated solutions of these salts in pure water, their solubilities in pure methyl alcohol give the corresponding activity coefficients in this solvent, because the activity of the solid salt is constant. The values thus obtained give, when extrapolated to zero salt concentration, coefficients which agree quite well with those predicted through extension of the straight lines in Fig. 6 to pure alcohol solutions. The solubility of lithium chloride in pure water is far too high to give a reasonably safe value for the activity at the saturation point and consequently also for the activity coefficient at infinite dilution in pure methyl alcohol, but at least the order of distribution of this point in relation to the lithium chloride curve for the wateralcohol mixtures is the expected one. The reason for the deviation of the curve for hydrochloric acid from linearity is difficult to trace. At present it seems to be somewhat improbable that the hydrogen– or silver–silver chloride electrodes could be in error. Scatchard,[11] who previously noted this behavior of hydrochloric acid, did not succeed in giving a plausible explanation.

Aside from the deviations for hydrochloric acid at high alcohol concentrations, which may be due to purely chemical causes, we thus find the theory of the inverse proportionality of the dielectric constant to the logarithm of the activity coefficient at infinite dilution to be fairly well supported by the experimental evidence. There are two questions that should be considered in relation to this result. Is the value for log γ_{∞} at constant dielectric constant independent of the solvent mixture used and further will the slope of the activity coefficient curves under the same conditions be the same in all cases? Measurements to be found in the literature that might be used for a study of these two points seem to be rather unreliable or in a given case too few and it has not been possible to deduce any definite safe information from them.

Summary

The thermodynamic properties of potassium, sodium and lithium chlorides and hydrochloric acid in water–methyl alcohol mixtures have been measured at 25° with the following cells

Ag/AgCl/MeCl *(m)* in water/Me_yHg/MeCl (*m*) in water-alc./AgCl/Ag
Ag/AgCl/HCl *(m)* in water–alcohol/H_2 (760 mm. partial pressure)

From these measurements were calculated the activity coefficients at the concentrations used, which in turn gave the values at infinite dilution in relation to the corresponding pure water value assumed to be unity.

The connection between the infinity values for the activity coefficients and the composition and dielectric properties of the water–methyl alcohol mixtures has been briefly discussed.

GERMANIUM. XXIX. GERMANIUM MONOHYDRIDE[1]

BY L. M. DENNIS AND N. A. SKOW

RECEIVED MARCH 8, 1930 PUBLISHED JUNE 6, 1930

The hydrides of the type RH_4 of carbon, silicon, germanium, tin and lead elements in the fourth group of the Periodic Table are known. Higher homologs of the type R_nH_{2n+2} of carbon, silicon and germanium have also been prepared. Carbon alone of these five elements has yielded hydrides of the type R_nH_{2n}.

Of the hydrides of the type R_nH_n, acetylene is familiar, and analogous hydrides of silicon,[2] tin[3] and lead[4] have been announced, although each deserves further study. Bradley and Weeks give for the three compounds the formulas Si_2H_2, Sn_2H_2 and Pb_2H_2 but, since no determinations of the molecular weights were made, they should for the present be represented by the general formula (RH),.

When an alloy of germanium and magnesium is treated with dilute hydrochloric acid, the chief products[5] are germanium hydrides of the type Ge_nH_{2n+2}.

Haller took up in the Cornell Laboratory some three years ago the study of the product obtained by treating an alloy of calcium and germanium with hydrochloric acid. He obtained a powder which spontaneously dissociated. No detailed study was made of it at that time.

Experimental

With the thought that an alloy of an alkali metal with germanium might yield unsaturated germanium hydrides more readily than a calcium–germanium alloy, a mixture of powdered germanium and small pieces of sodium in equi-atomic proportions was heated to 1000° in a small, special steel crucible provided with a steel cover which made an air-tight seal when bolted into place. When the cooled crucible was opened, it was found to be filled with a dense, hard, pyrophoric product, analysis and microscopic examination of which showed it to be a homogeneous alloy of the composition NaGe. *Anal.* Calcd. for NaGe: Na, **24.06;** Ge, **75.94.** Found: Na, **24.08;** Ge, **75.94.**

Sodium Germanide

The alloy is slowly acted upon by moist air, and consequently it must be kept in a tightly closed receptacle or under a dry, inert gas.

[5] Dennis, Corey and Moore, THIS JOURNAL, 46, 657 (1924).

When this sodium germanide was added to cold water, or to dilute or concentrated hydrochloric acid, a dark brown powder was formed.

When this was collected on a filter and washed with water, it decomposed with a puff but without detonation, when dried in the air. When water was removed from it by washing it on the filter first with alcohol and then with ether, it exploded with slight detonation as soon as the ether had run through the funnel.

After somewhat extensive experimentation, the analysis of the product was successfully accomplished in the following manner.

The sodium germanide was carefully ground to a fine powder in a dry agate mortar, and then was added in small portions to cold water to avoid rise of temperature during the reaction. The brown powder was then collected on a filter, washed first with water, then with alcohol and finally with ether, and, keeping it moist with ether, was rinsed with a jet of ether into B of the double U-bulb **A**, Fig. 1, which had previously been weighed while evacuated. The bulb-tube was attached to the chain by the ground joints as shown, and with M closed and R open, pure, dry carbon dioxide was passed over the sample until the ether was removed. D was closed and both B and C were evacuated through the two-way stopcock E, which was then closed. **A** was then detached and weighed. It was afterwards found that the substance slowly dissociates in a vacuum at room temperature, but as the products of the decomposition could not escape from **A**, this partial disintegration had no effect upon the weight of the sample.

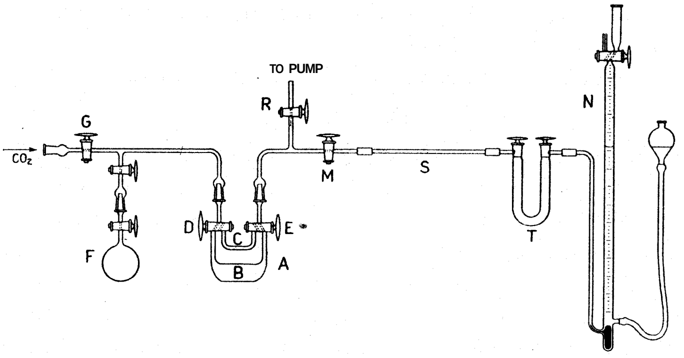

Fig. 1

A was now again attached to the chain, and all air in the connecting tubes and other parts of the apparatus was swept out by passing carbon dioxide through C and the remainder of the chain into the Schiff nitrometer N, which contained a concentrated solution of potassium hydroxide. When complete absorption of the gas in N showed that air had been removed, the stopcocks D and E were closed, and a glycerin-bath was brought up around B, which contained the sample. The bath was heated to 165°, at which temperature the substance dissociated with an explosive puff, filling the bulb with finely divided germanium and liberating hydrogen. The bath was removed, D and E were turned to communicate with B, and carbon dioxide was slowly passed through the bulb, sweeping out all gases through S and T into N. S was a thin-walled tube of quartz which was heated by a gas flame during the passage of the gases: any germanium escaping from B as a hydride was decomposed, depositing germanium on the walls of S, and liberating hydrogen, which passed on into N. T was a U-tube containing pumice and sulfuric acid for absorption of any water that the sample might still have contained.

S and T were now detached and weighed, and A was evacuated and then weighed. The hydrogen in N was measured, and its purity was then ascertained by combustion in a Dennis–Hopkins combustion pipet.

Anal. Subs., 0.1847: found, Ge (in B and S), 0.1699; H, 0.0029; H_2O, 0.0119. Subtracting from the weight of the sample the weight of water found, the results of the analysis were: Subs., 0.1728: Ge, 0.1699; H, 0.0029. Calcd. for $(GeH)_x$: Ge, 0.1699 = 98.63; H, 0.0029 = 1.37. Found: Ge, 0 1699 = 98.63; H, 0.0029 = 1.37. The results of two other analyses, calculated on the dry sample as before, were: ***Anal.*** Subs , 0.1566, 0.1004: Calcd. for $(GeH)_x$: Ge, 0.1544, 0 0990; H, 0.0021, 0 00137. Found: Ge, 0 1543 = 98.53, 0.0990 = 98.63; H, 0 0021 = 1.37; 0.00137 = 1 37.

The analyses show the substance to be germanium monohydride.

Germanium Monohydride

Prepared in the manner above described, the compound is a dark brown powder that decomposes with an explosive puff when dried in the air. In an inert gas or in a vacuum the substance dissociates only very slowly at room temperature, but when warmed to about 165° it suddenly breaks down with a slight detonation, yielding hydrogen and germanium.

Qualitative tests showed that the substance is not soluble without change in any of the usual inorganic or organic solvents. Dilute or concentrated nitric acid rapidly oxidizes the germanium to the dioxide. Concentrated solutions of alkali hydroxides are without action. Hydrogen peroxide readily oxidizes it with solution of the resulting germanium dioxide.

The following experiments were made with samples of the compound that had been freed entirely from moisture; this was accomplished by holding it for two hours at 140° in a current of carbon dioxide. Analysis of the residue showed it to be anhydrous $(GeH)_x$ of high purity.

Hydrogen chloride was without appreciable action upon the germanium monohydride at temperatures below that at which the compound dissociated.

A solution of potassium permanganate acidulated with sulfuric acid quantitatively oxidized the substance.

$$2GeH + 2KMnO_4 + 3H_2SO_4 = 2GeO_2 + K_2SO_4 + 2MnSO_4 + 4H_2O$$

Dry fluorine instantly attacked the compound with a burst of flame and the formation of germanium tetrafluoride and hydrogen fluoride.

The reaction between germanium monohydride and dry chlorine was studied in the following manner. A sample of the hydride was collected and dried in B and both B and C were then evacuated and A was weighed. The amount of chlorine called for by the equation

$$2GeH + 5Cl_2 = 2GeCl_4 + 2HCl$$

was brought into the bulb F, the chlorine was frozen by means of liquid air, and the air in the tube was pumped out through C and R. The refrigerant from around F was then removed, D was opened and chlorine was admitted in small portions into B. The monohydride reacted energetically with chlorine and disappeared when all of the gas had been admitted. If the reaction proceeds according to the equation given above, 0.0606 g. of hydrogen chloride, and 0.3566 g. of $GeCl_4$ should have been formed. The amounts found were 0.0609 g. of hydrogen chloride and 0.3562 g. of $GeCl_4$. The purity of the latter was shown by its vapor tension at 0°, 24.4 mm. The experiment was repeated, introducing smaller amounts of chlorine than were called for in the above equation, to ascertain whether lower chlorides of germanium would be formed. In each case only a portion of the monohydride was acted upon, and only $GeCl_4$ was produced.

The reaction with bromine was similar to that with chlorine, only pure $GeBr_4$ being formed even when the germanium monohydride was present in excess.

Vapor of iodine acted slowly upon the monohydride to form GeI_4.

Summary

When sodium germanide, NaGe, reacts with water, germanium monohydride $(GeH)_x$ is formed. This is a brown solid which instantly dissociates with an explosive puff when the dry, or nearly dry, substance is brought into contact with the air. When in an inert gas or a vacuum the compound dissociates only slowly. The monohydride is a strong reducing agent, and unites with the free halogens to form compounds of the type GeX_4.

The preparation of $(GeH)_x$ completes the series of hydrides of the type R_nH_n in the group carbon to lead.

THE ELECTRODE POTENTIAL OF INDIUM AGAINST INDIUM CHLORIDE SOLUTIONS

BY SHIN'ICHIRÔ HAKOMORI

RECEIVED MARCH 10, 1930 PUBLISHED JUNE 6, 1930

Upon the electrode potential of metallic indium there exist only the early inexact investigations of Erhard* and Thiel.[2] Later, Richards and Wilson[3] determined with great precision the electromotive forces of cells containing indium amalgams of various concentrations, but they did not measure the pure metal in relation to these amalgams.

This investigation was therefore undertaken for the purpose of obtaining accurate values of the electrode potential of metallic indium against solu-

[1] Erhard, *Z. anorg. Chem.*, *39*, 119 (1904).

[2] Thiel, *Wied.* **Ann.**, *14*, 504 (1881).

[3] Richards and Wilson, *Z. physik. Chem.*, *72*, 129 (1910).

tions of its chloride at various concentrations. The solutions were always given a definite concentration (0.02 f.) of hydrochloric acid, so as to eliminate any possible hydrolysis of the salt. For the other electrode silver covered with silver chloride was used. The cells measured were, therefore

$$\text{In(s), InCl}_3(c\text{ f}) + \text{HCl(0.02 f.), AgCl(s)} + \text{Ag(s)}$$

This investigation was undertaken at the suggestion of Professor A. A. Noyes. I desire to express my indebtedness to him and to Professor Don M. Yost of this Tnstitute for many useful suggestions, and to Dr. H. D. Kirschman for the preliminary work which he did on this research.

Substances and Solutions

Purification of the Indium.—A commercial sample of metallic indium was dissolved in aqua regia, the solution was evaporated to dryness, and the evaporation was repeated three times with addition of hydrochloric acid each time, so as to remove all nitric acid. The residue of indium chloride was taken up with water and the indium was precipitated as hydroxide by adding ammonium hydroxide to the hot solution. The precipitation was repeated three times, so as to remove any impurities soluble in excess of ammonia. The indium hydroxide thus obtained was dissolved in hydrochloric acid and the solution was evaporated to sirupy consistency. Then the residue was dissolved in the least quantity of water, and recrystallized ammonium thiocyanate was added. Since a red coloration showed the presence of considerable iron, the solution was extracted with pure ether until no more coloration was produced when fresh thiocyanate was added. This ether extraction would also remove any gallium or thallium possibly present. The indium chloride solution was then electrolyzed, using 5 volts and 0.5 ampere. A thick platinum wire placed in a porous cup served as anode, and a thin platinum wire with only its point dipping into the solution was used as cathode. The spongy indium thereby resulting was washed thoroughly with water, pure alcohol, and ether, and was dried and kept in a desiccator. It was used both for the indium electrode and for the preparation of indium chloride.

Preparation of the Indium Chloride.—The indium (mixed with sugar carbon when the quantity was large) was placed in a porcelain boat and'heated in a pyrex glass tube to a dull red heat in a current of well-dried chlorine gas, which was prepared by adding pure hydrochloric acid to potassium permanganate crystals. After the chlorination was complete, the indium chloride was sublimed at a red heat in a current of nitrogen into a pyrex glass receiver, which was then sealed off. Throughout all these operations moisture was carefully excluded.

Preparation of the Silver and Silver Chloride.—The silver and the silver chloride uoed in the cell were prepared according to the directions of Randall and Young[4] and kept in the dark under water.

Water and Hydrochloric Acid.—All the water used in making the solutions had been redistilled from alkaline permanganate. The hydrochloric acid used was the "C. P. analyzed," stated to contain entirely negligible quantities of impurities.

Analysis of the Indium Solution.—The method of analysis adopted was the potentiometric process developed by Bray and Kirschman.[5] It was found that the precision of the method was increased when the platinum electrode was carefully cleaned before each determination and when ample time was allowed for reaching equilibrium.

---

[4] Randall and Young, THIS JOURNAL, 50,990 (1928).

[5] Bray and Kirschrnan, *ibid.*, 49, 2739 (1927).

Apparatus and Procedure

Apparatus.—The electrode vessel was similar to those commonly used in this Laboratory.[6] It contained two indium electrodes and three silver chloride electrodes, thus making it possible to check the constancy of the respective electrodes. The electrode vessel was placed in a water thermostat whose temperature was kept at 25.00 ± 0.02°, as determined by a thermometer which had been compared with one calibrated by the Bureau of Standards.

A Leeds and Northrup Type K potentiometer was used, also a Weston cadmium standard cell of the unsaturated type certified to have an electromotive force of 1.01878 volts.

Procedure.—The spongy indium and the finely divided silver and silver chloride, before they were put into the cell, were washed several times with the solution with which the measurement was to be made. This was found to be essential in obtaining the most concordant results. Potential measurements were made after six hours and after various longer intervals during two days. The potential was found to reach the equilibrium value in twelve hours after the setting up of the cell, and to remain constant within **0.3** mv. for even forty-eight to sixty hours. The values with the three different silver chloride electrodes agreed with one another within 0.2–0.3 mv., and those with the different indium electrodes within 0.4 mv.

In some of the experiments the indium electrode was protected against the influence of dissolved atmospheric oxygen by bubbling a current of purified nitrogen through the indium solution, but this had no effect on the constancy of the potential values. The silver chloride electrode was not protected from the light.

The Observed Electromotive Forces.—The values in millivolts of the electromotive force at various times after the cell was set up are shown in Table I. It will be seen that after six hours there was very little change in the reading. The values after twenty-four hours were adopted as the final ones. The formality of the indium chloride is expressed in formula weights per liter of solution.

TABLE I

THE OBSERVED ELECTROMOTIVE FORCES AT 25°

Soln. no.	Formality of indium chloride	Electromotive force				
		6 hours	12 hours	24 hours	36 hours	48 hours
1	0.001515	735.94	736.96	737.03	....	....
2	.005332	726.60	726.60	726.44	726.31	....
3	.01104	....	....	719.11	719.43	719.41
4	.02744	....	....	706.13	706.14	706.27

Discussion of the Results

The electromotive forces E of the cells above considered should be expressed by the following equations, in which (In^{+++}) and (Cl^-) represent

---

[6] U. B. Bray, THIS JOURNAL, 49, 2372 (1927).

the molal concentrations, α_{In} and α_{Cl} are the activity coefficients (hereafter called the ***activations)*** of the two ions in the solution involved, and $\bar{E}_{In}$ and $\bar{E}_{AgCl}$ are the molal potentials of the two electrodes

$$E = \bar{E}_{In} - \bar{E}_{AgCl} - 0.01972 \log_{10} (In^{+++})(Cl^-)^3\alpha_{In}\alpha^3_{Cl} \qquad (1)$$

Or, introducing a new symbol E' and putting $\bar{E}_{In} - \bar{E}_{AgCl} = E'_0$, we get:

$$E + 0.01972 \log_{10} (In^{+++})(Cl^-)^3 = E' = E'_0 - 0.01972 \log_{10} \alpha_{In}\alpha^3_{Cl} \qquad (2)$$

Hence if the four known values of the first member of this equation are plotted against a simple function (such as the square root) of the concentration of indium chloride in the respective experiments, and if the graph is extrapolated for an indium-ion concentration of zero (and hence for a hydrochloric acid concentration of 0.02 formal), there will be obtained the electromotive force $E'_{0.02}$ of a hypothetical cell with electrodes of indium and silver chloride containing the ions In^{+++} and Cl^- each at 1 molal, but having such activations α_{In} and α_{Cl} as these ions would have in a solution 0.02 M in H^+ and 0.02 *M* in Cl^- containing no other ions. Another graphical determination of this quantity $E'_{0.02}$ may be made by plotting the first member of Equation 2 against the square root, $\sqrt{\frac{1}{2}\Sigma(cz^2)}$, of the ionic strength of the solution, and reading off the extrapolated value corresponding to an ionic strength of 0.02 molal.

Table II shows the results of the computations and the data used for constructing the plots.

TABLE II

COMPUTATIONS BASED UPON THE OBSERVED ELECTROMOTIVE FORCES

Expt. no.	Concentrations (In^{+++})	(Cl^-)	$\frac{1}{2}\Sigma(cz^2)$	Electromotive force E (obs.)	E' (calcd)	Activation product, $\alpha_{In}\alpha^3_{Cl}$ Expt.	Theory
1	0 02744	0 1023	0 1846	0 7061	0.6167	0 00106	0.0025
2	.01104	.05312	0862	,7191	.6051	.0041	.0165
3	.00533	.03600	.0520	.7264	.5962	.0116	.0417
4	.001515	.02425	,0291	.7370	.5861	.0376	.0925
From plots	.00	.02000	.02000	...	.575	(.139)	0.139
By extrap.	.00	.00	.00	...	558	1.00	1.00

The values of $E'_{0.02}$ (that is, of E' in 0.02 f. HCl), obtained by extrapolating the graphs, are 0.574 and 0.578, respectively, thus in fair agreement with each other. Adopting 0.575 as the best value of $E'_{0.02}$, the value of E'_0 at zero concentration (which is equal to the difference $\bar{E}_{In} - \bar{E}_{AgCl}$ of the two molal electrode potentials) can be found with the aid of the last part of Equation 2 by taking the value[7] of α_{Cl} equal to 0.848 and that of ***a,,*** equal to 0.228 as found by the equation,[8] $\log_{10} a = -0.357\, z^2 \sqrt{\Sigma cz^2} = -0.357$

---

[7] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, p. 382, derived experimentally the value 0.89. It might be somewhat more exact to employ this value; **but** its use increases the calculated value of E'_0 only inappreciably (from 0.558 to 0.559).

[8] Noyes, THIS JOURNAL, 46, 1099 (1924).

$\times 9 \times \sqrt{0.04}$ derived from the ion attraction theory of Debye and Hückel for very dilute aqueous solutions at 25°. A value of E_0' (at zero concentration) might also be found by extrapolating the graph to an ionic strength of zero, but the long extrapolation involved is so uncertain as to make the result of no value.

The value of E_0' so derived is **0.558** volt. Adding to this the molal electrode potential (—0.222 volt)[9] of Ag + AgCl, Cl^-, there is obtained for the molal electrode potential of In, In^{+++} the value 0.336 volt, referred to the molal hydrogen electrode.

By means of Equation 2 values of the activation product $\alpha_{In}\alpha_{Cl}^3$ in the various solutions were calculated from the values of E' and E_0'. These are recorded in the next to last column of the table. In the last column of the table are given the values of this product calculated by the following equation derived from the ion-attraction theory for very dilute solutions of a completely ionized salt of the type $InCl_3$ at 25°.

$$-\log_{10} \alpha_{In}\alpha_{Cl}^3 = 12 \times 0.357 \sqrt{\Sigma cz^2}$$

The activation product derived from the electromotive forces will be seen to decrease with increasing concentration much more rapidly than do the theoretical values derived from the dilute solution formula of the ion-attraction theory. This is the opposite of what usually occurs. It may arise from the existence of the salt in the un-ionized form, or from the formation of complex ions (such as $InCl_4^-$), in considerable quantity in the more concentrated solutions.

Summary

In this article there have been described precise measurements of the electromotive forces at 25° of cells of the type In(s), $InCl_3(c)$ + HCl (0.02 f.), AgCl(s) + Ag(s) with the molal concentration c ranging from 0.0015 to 0.0274. From the observations, by graphic extrapolation and by applying the ion-attraction theory to the results at the smallest concentration, the electromotive force of the cell In(s), In^{+++} (1 m.) || Cl^- (1 M), AgCl(s) + Ag(s) (where the molalities represent ion activities) was found to be **0.558** volt. Adding to this the potential (—0.222 volt) of Ag + AgCl, Cl^-(1 M), the molal electrode potential of In(s), In^{+++} becomes +0.336 volt referred to the molal hydrogen electrode. This places indium in the electromotive series very near thallium (0.336 against Tl^+ ion), and between cadmium (0.397) and tin (0.13) or lead (0.12).

THE MECHANISM OF THE PHOTOCHEMICAL DECOMPOSITION OF OZONE

By Hans Joachim Schumacher[1]

Received March 14, 1930 Published June ti, 1930

Introduction

Investigations concerning the photochemical decomposition of ozone have been presented by Regener,[2] E. v. Bahr,[3] Warburg,[4] Weigert,[5] Weigert and Böhm,[6] Griffith and Shutt,[7] Griffith and McWillie[8] and Kistiakowsky.[9] The results of their researches have been summarized by Kistiakowsky[9] and by Griffith and McKeown;[10] nevertheless, it is necessary to restate briefly the experimental facts before proceeding to a discussion of the mechanism.

Regener[2] has investigated the equilibrium of formation and decomposition of ozone in different regions of the ultraviolet light. The light source was an aluminum arc from which in one series of experiments all light of wave lengths $\lambda < 2100$ Å. was filtered out by a plate of calcite. As he was not particularly interested in the kinetics of the reaction, his velocity measurements are incomplete and only roughly quantitative. Nevertheless, it can be estimated that for constant light absorption the velocity of decomposition is nearly proportional to the ozone concentration. It is important to note that a positive temperature coefficient for the decomposition of ozone was obtained at total pressures of 1 atm., of which about 1–5% was ozone and the rest oxygen.

E. v. Bahr[3] has worked with highly dilute mixtures of ozone, the pressure of which was usually of the order of 1 mm. of mercury or less. The total radiation of a mercury lamp was used and the ozone concentration determined by optical measurements. Her data can be used only qualitatively because experiments of the same kind deviate from each other by about 100% due to neglect of a dark reaction, and the inaccurate method of analysis. Nevertheless, her results are important. E. v. Bahr finds that the quantum yield increases very markedly with decreasing pressure. (She measured only the velocity of the reaction, but the quantum yield and velocity

under the same conditions are, of course, proportional to each other.) At a total pressure of 20 mm. of mercury the reaction is ten to twenty times more rapid than at one atmosphere.

Weigert[5] has also investigated the decomposition of ozone in the ultraviolet, his light source being a mercury arc. The total pressure was always one atmosphere and the concentration of ozone varied from 0.9–6%. He found that when all light was absorbed, the order of the reaction was about one, whereas when the concentration of ozone was small, so that the light was not completely absorbed, the order of the reaction increased.

Weigert and Böhm[6] also studied the influence of hydrogen on the reaction and observed that the velocity of the decomposition of ozone was greatly increased. In the presence of a large excess of hydrogen the reaction rate was changed five- to ten-fold and water was formed.

Griffith[7] and co-workers have studied the decomposition of ozone in the visible range in the presence of oxygen and foreign gases at total pressures of 1 atm. When the oxygen was replaced by helium, nitrogen or carbon dioxide the velocity increased in the order $O_2 \longrightarrow N_2 \longrightarrow CO_2 \longrightarrow$ He. Kistiakowsky[8] has shown that all gases inhibit the reaction, the inhibiting influence decreasing in the order given.

Hydrogen, according to Griffith, shows qualitatively the same influence on the reaction in the visible that Griffith and Bohm found in ultraviolet light, *i. e.*, the rate of decomposition of ozone increases and water is formed.

Heretofore these results were not of much use in the development of theories to explain the reaction because monochromatic light was not used, quantum efficiencies were not determined and the other experimental conditions were not varied sufficiently. Kistiakowsky[8] has given an empirical equation for the representation of some of these results.

Quantum yields for the decomposition of ozone in monochromatic light have been determined by Warburg[4] in the ultraviolet and by Kistiakowsky[8] in the red region. The important result of Warburg's work is that at a total pressure of 1 atm. and a partial pressure of a few mm. of ozone, the quantum efficiency is, with oxygen as added gas, about 0.30 mol. $O_3/h\nu$, with nitrogen 1.09 and with helium 1.70.

Most of the experimental facts upon which the following theoretical considerations are based are found in the work of Kistiakowsky: for he varied the total pressure as well as the concentrations of the gases over a wide range and, which is more important, in his experiments the thermal decomposition of ozone was eliminated or could be estimated approximately. The velocity obtained by Warburg[4] in ultraviolet light always included a dark reaction whose rate was not determined and, as will be shown later, this is of particular importance in explaining some of his results.

The Decomposition of Ozone in Red Light.—To express the experimental data obtained in red light, Kistiakowsky has given the empirical eauation

$$-\frac{d[O_3]}{dt} = \frac{k\,I_{abs.}\,[O_3]^{1/2}}{m[X] + [O_2]}$$

in which X denotes the concentration of the added gas and m a factor less than one. The equation is valid over only a limited range of pressure and concentration; at low total pressures, for example, the velocity is nearly proportional to $I_{abs.}$. Later unpublished experiments of Kistiakowsky,[11] which represent the course of the reaction in a more satisfactory manner because of better energy measurements and the more accurate determination of the final ozone concentration, show still more pronouncedly that the given equation can be used over only a limited range. On the other hand, since it is impossible to represent the reaction by a simple equation, it must be assumed that this can be done only by an equation of several terms.

It is characteristic of the decomposition in red light that the quantum yield, even at high ozone concentration, is relatively small. The greatest values of the quantum yield are between 2 and **3** moles $O_3/h\nu$ and are obtained at relatively low total pressures and high ozone concentration.[12] At high total pressures the quantum yield decreases and at **1** atm. pressure with 50% ozone it is less than unity (Experiment 3).[12]

At total pressures below 10 mm. the quantum yield is nearly 2. In the presence of 1–2 mm. of oxygen and 8–9 mm. of ozone it is about 2.5 and in the presence of 8–9 mm. of oxygen and 1–2 mm. of ozone it is about 1.5 (unpublished experiments of Kistiakowsky). It must be emphasized that greater velocities can also be obtained at higher total pressures if oxygen is replaced by foreign gases. According to Kistiakowsky, on the basis of oxygen equal to 1, the inhibiting action of helium is represented by 0.13, nitrogen 0.3 and carbon dioxide 0.8. The essential facts already given should readily follow from the mechanism of the reaction.[13]

It is of considerable importance to know whether to assume for the primary reaction the formation of an excited molecule of ozone or an atom of oxygen. Before treating the energy relations and the ozone spectrum we shall see which of the two possibilities should be selected from the ki-

---

[11] These experiments were carried out in 1925 by Dr. Kistiakowsky in the Kaiser Wilhelm Institut für Physikalische Chemie in Berlin, but could not be interpreted *at* that time and therefore were not published.

[12] Kistiakowsky, *Z. physik. Chem.*, **117**, *348 (1925).*

[13] In this treatment a chain will be regarded as formed when more than **2** molecules of ozone react per quantum absorbed. We shall find that the measured quantum yield is not necessarily identical with the number of ozone molecules which react per quantum absorbed because ozone may also be regenerated. In spite of this difference the experimentally determined quantum yield, whose usual value is considerably less than 2, shows that there are often no chains or only a few short ones. Consequently, we can neglect chain formation without seriously limiting the validity of the theoretical treatment.

netics of the reaction. If we assume for the primary reaction the formation of an excited ozone molecule

$$O_3 + h\nu \longrightarrow O_3' \qquad (1)$$

we have only a limited number of possible reactions that may follow, namely

$$O_3' + O_3 \longrightarrow 3O_2^* \qquad (2)$$
$$O_3' + O_3 \longrightarrow 2O_3 \qquad (3)$$
$$O_3' + O_2 \longrightarrow O_3 + O_2 \qquad (4)$$

Reaction 2 may start a chain if we assume that the energy-rich oxygen molecule (O_2^*) can excite an ozone molecule. For reasons previously given we shall, however, neglect the formation of chains. Reactions 3 and 4 indicate the deactivating influence of the two gases. From this mechanism the following equation is derived

$$-\frac{d[O_3]}{dt} = \frac{I_{\text{abs.}}\,[O_3]}{(k_2 + k_3)[O_3] + k_4[O_2]}$$

If a foreign gas X is present, another term $k_5[X]$ is added to the denominator. From this equation it is evident that the total pressure should have no influence. If the oxygen–ozone ratio is constant, the quantum yield should be independent of the pressure. This is contrary to the experimental facts and, since on the assumption of excited molecules there are no other possible reactions than those already given, the formation of excited ozone molecules in the investigations previously discussed must be rejected. Thus we see that kinetic considerations lead us to assume the formation of oxygen atoms in the primary reaction.

We shall now consider the energy relations involved. The work of G. Herzberg[14] and R. Mecke[15] shows that the heat of dissociation of oxygen is below 6 volts; the value given by Mecke is 128,000 cal. per mole. The heat of decomposition of ozone is 32,000 cal. per mole. The minimum energy required by the reaction

$$O_3 \longrightarrow O_2 + O$$

is, therefore, only $(128{,}000/2) - 32{,}000 = 32{,}000$ cal., while the energy of the red light is more than 40,000 cal. (In the experiments of Kistiakowsky the mean absorption was at 6200 Å.) Of course, absorption of light of greater energy than the heat of dissociation does not necessarily require the dissociation of the molecule. This depends on the nature of the spectrum, as was first shown by Franck and his co-workers.

The ozone spectrum[16] consists of very diffuse bands in the red so that we may assume that predissociation[17,18] occurs even at these wave lengths.

These considerations show that the reaction

$$O_3 + h\nu \longrightarrow O_2 + O$$

is quite probable. Neglecting the formation of chains, only the following reactions are possible

$$O_3 + h\nu \longrightarrow O_2 + O \tag{1}$$
$$O + O_3 \longrightarrow 2O_2^* \tag{2}$$
$$O + O_2 + M \longrightarrow O_3 + M \tag{3}$$

Reaction 2 can lead to chain formation. Equation **3** is a three-body reaction where M designates the third body. In the presence of little ozone and much oxygen, the oxygen pressure may be regarded as equivalent to M. If oxygen is replaced by helium, nitrogen or any other gas, M is represented by the pressure of this gas. In polyatomic gases a first approximation for M is given by the total pressure of the mixture, since ozone has influence also. The effect of various gases is specific, due to their difference in structure and specific ability to take up internal energy by collision; but polyatomic molecules are nearly the same in this respect and differ from each other generally by a factor less than **3.**

From the preceding mechanism the following equation is derived

$$-\frac{d[O_3]}{dt} = I_{abs.} + k_2[O][O_3] - k_3[O][O_2][M]$$

$$[O] = \frac{I_{abs.}}{k_2[O_3] + k_3[O_2][M]}$$

$$-\frac{d[O_3]}{dt} = I_{abs.}\left[1 + \frac{k_2[O_3]}{k_2[O_3] + k_3[O_2][M]} - \frac{k_3[O_2][M]}{k_2[O_3] + k_3[O_2][M]}\right] \tag{I}$$

Equation I should represent the experimental facts previously mentioned. It can be regarded as a first approximation since chain formation has been neglected.

Of course, Equation I can be written

$$-\frac{d[O_3]}{dt} = I_{abs.}\left(\frac{2k_2[O_3]}{k_2[O_3] + k_3[O_2][M]}\right) \tag{II}$$

Since Equation I illustrates the mechanism better, it will be used in the following discussion.

When the ozone concentration is small and is held constant, *e.* g. $[O_3] <$ **10** mm. of mercury, and the total pressure is decreased (which means also decreasing the oxygen pressure), the third term of the equation becomes smaller and smaller and the second term approaches unity. For the limit we have

$$-\frac{d[O_3]}{dt} = I_{abs.}\ [1 + 1] \quad \text{or}$$

$$\frac{-\frac{d[O_3]}{dt}}{I_{abs.}} = 2 \text{ (Quantum Yield)} \tag{III}$$

This case corresponds to Expts. 11 and 12 in the paper of Kistiakowsky (p. **149).** The equation **(I)** shows that in this region the quantum yield is strongly influenced by pressure. With a small increase of $[O_2]$ and $[M]$ the negative term can no longer be neglected. Experiments 10 and 12 of Kistiakowsky illustrate this point; some of his unpublished experiments bring it out still more clearly. Furthermore, the experiments show that at low total pressures and very small concentrations of oxygen the quantum yield is greater than 2. This is to be expected from the proposed mechanism for under these conditions chain formation according to Reaction 2 is strongly favored. In the presence of more oxygen the activated molecules may be deactivated, so the probability of forming a chain is decreased.

Let us now consider a high total pressure and a small concentration of ozone. In this case we have

$$k_2[O_3] < k_3[O_2][M]$$

Then the equation becomes

$$-\frac{d[O_3]}{dt} = \frac{2\,I_{abs.}\,k_2[O_3]}{k_3[O_2][M]} \tag{IV}$$

In consequence of the small $[O_3]$, the total pressure and the oxygen concentration can change only to a slight extent during the reaction, which means that the denominator of Equation IV becomes constant and the rate of ozone decomposition can be given by the simple equation

$$-\frac{d[O_3]}{dt} = k\,I_{abs.}\,[O_3]$$

This case was realized in the work of Griffith and Shutt, who found that at total pressures of one atmosphere and small ozone pressures the reaction follows the equation

$$-\frac{d[O_3]}{dt} = k[O_3]^2$$

In their experiments the light absorption was proportional to the ozone concentration; hence these two equations become identical. Griffith and Shutt found at higher ozone concentration (above 5%) a decrease in the order of the reaction, which is a necessary consequence of Equations I and II. The two other limiting cases are those in which the total pressure and ozone concentration are both large or both small. In the former case with ozone concentration above 90%, a quantum yield greater than 2 should be found. At high pressure the greatest ozone concentration used was about 60% and here, as can be predicted, the quantum yield was considerably less than 2.[19] In the experiments with total pressures below 10 mm. of mercury, the quantum yield becomes much less than 2 if the ratio of oxygen to ozone is greater than five.[20]

If middle values for the oxygen and ozone pressures are employed instead of the extreme concentrations in the cases discussed above, then for con-

---

[20] Kistiakowsky, Ref. 9, p. 349, Expts. 10, 11, 12. The unpublished data show that the quantum yield is about 20% too low.

stant light absorption it is to be expected from Formula I or II that the dependence of the velocity on the ozone concentration will vary as $[O_3]^0$ to $[O_3]^1$. As can be readily seen from Equation II, inhibition by oxygen is nearly proportional to its concentration, for the total pressure [M] is $[O_3 + O_2]$ and so, as a first approximation, the whole denominator is proportional to $[O_2]^1$. Therefore we get

$$-\frac{d[O_3]}{dt} = k\frac{I_{abs.}\,[O_3]^{1/2}}{[O_2]}$$

which is identical with the empirical equation of Kistiakowsky.

As is shown by his unpublished work, the limits within which the equation holds are smaller than originally stated by Kistiakowsky. This is in agreement with our deduction of the above equation as a zero approximation.

There are difficulties involved in obtaining the exact mathematical representation of the velocity of decomposition of ozone over the whole range of pressures, for we know only little about the formation of the chains and the deactivation of the energy-rich oxygen molecules by ozone and oxygen. Furthermore, the value of the constant k_3 changes with the composition of the mixture. However, the course of the reaction is essentially represented by Equations I or II and the ratio of the velocity constants of Reactions 2, $O + O_3 \longrightarrow 202$, and 3, $O + O_2 + M \longrightarrow O_3 + M$, can be calculated. The reaction $O + O_2 \longrightarrow O_3$, which requires a three-body collision, occurs at every 10^3 to 10^4 collision at atmospheric pressure, if we assume that no heat of activation is necessary and the third body is well adapted for taking up the excess energy. Then we have[20a]

$$k_3 - \frac{1}{10^3 \times 760}$$

if the total pressure is given in mm. of mercury (in place of 10^3, 10^4 may be used). If ozone and oxygen are well adapted for taking up the excess energy, the above value of k_3 may be used in our general equation. That oxygen is capable of so doing is shown by experiments on the quenching of fluorescence,[21,22] for which oxygen is especially efficient. Likewise, from observations on the prevention of explosions in mixtures of bromine and ozone[Z3] by oxygen we must conclude that the oxygen molecule is extraordinarily able to take up and dissipate the heat of reaction.

From Equation II we get for k_2

$$k_2 = \frac{[O_2][M]\,E}{760 \times 10^3 \times (2 - E)[O_3]}$$

[20a] In the following discussion k_2 and k_3 are the ratio of the velocity constants *to* the number of two-body collisions, that is, k_2 and k_3 give the probability that reaction occurs on collision.

[a] *Z. physik. Chem.*, 117, 345 (1925).

It is to be seen that the values of k_2 are fairly constant when $E < 1.5$. Higher values of E indicate the formation of chains and in this region our equation is no longer correct. Furthermore, k_2 gradually increases toward the end of the experiment, which is to be accounted for by the fact that k_3 is assumed to be constant, whereas it really changes with the composition of the mixture. When it is considered that for the calculation of k_2 the quantum efficiency E has been used, and that the error in E is about 10 to

20%, it is realized that the constancy of k_2 is very good. For high values of E (E near 2), large deviations in k_2 are to be expected, because in the equation we have as a factor the difference $(2-E)$. The mean value for k_2 in Expts. 2, 4 and 5 is $[(5.7 + 5.8 + 4.6)/3]\,10^{-4} = 5.4 \times 10^{-4}$; in Expts. 1, 3, 4, 6 and 7, $(4.5 + 4.0 + 3.7 + 5.0 + 3.5)/5 = 4.2 \times 10^{-4}$. In the two cases different light sources were used, which may easily account for the difference in the mean values of k_2. The intensity measurements were more accurate in the unpublished experiments. We have, therefore, to assume for k_2 about 5×10^{-4}, which means that the reaction $O + O_3 \longrightarrow 2O_2$, in which O is a normal atom, occurs only on every 2000th collision. We have the important result that a highly exothermic "Elementarreaktion" does not take place on every collision.[24] Recently two other similar cases have been pointed out by Kistiakowsky.[25] The probability of the occurrence of the reactions $Cl + H_2 \longrightarrow HCl + H$ and $O + H_2 \longrightarrow OH + H$ is also less than 10^{-3}.

The Influence of Foreign Gases.—When oxygen is replaced by foreign gases which do not react with ozone, the quantum efficiency is always greater than that obtained with oxygen. The influence of helium is extraordinarily remarkable, for its inhibiting effect is only $^1/_8$ that of oxygen. From the experiments of Jost[26] it is found that the recombination of bromine atoms is only slightly favored by helium. Hence, it may be readily assumed that also in the case of ozone the effect of helium is given by its influence on the efficiency of the three-body reaction $O + O_2 \longrightarrow O_3$. If helium is the third body the efficiency of the reaction may be one order of magnitude less than with oxygen. The effect of the other foreign gases may depend upon the same phenomenon. Recently it has been shown that the recombination of chlorine atoms[27] is less favored by nitrogen than by oxygen, and similarly in the case of ozone the effect of nitrogen is noticeably less than that of oxygen.

Another argument for the correctness of the idea developed is found in a comparison of the light reaction with the thermal[28] reaction. For the dark reaction the primary process is

$$O_3' + O_3 \longrightarrow 3O_2$$

where O_3' represents a thermally excited ozone molecule. The heat of activation of the thermal reaction is about 28,000 cal. If we assume that there are also excited ozone molecules in the photochemical reaction, then we should expect that foreign gases in both cases would have the same

effect. However, just the contrary is found. In the thermal reaction all foreign gases accelerate the decomposition, the velocity increasing with increased pressure of the added gas. The acceleration is the smallest for helium. In the light reaction, as previously indicated, it is quite different. All foreign gases inhibit the reaction, the velocity of which decreases in proportion to the amount of the added gas. The inhibiting effect of helium is the smallest. Compared with the oxygen experiments the velocity increases because the inhibiting influence of oxygen is extraordinarily large. By the assumption that in the photochemical reaction oxygen atoms are formed whereas the thermal reaction involves excited molecules, the different behavior in the two cases can be satisfactorily explained.[28]

The Reaction with Hydrogen.—The thermal reaction is only slightly influenced by hydrogen, while in the photochemical reaction, in the red as well as in the ultraviolet, the rate is greatly increased and water is formed.[29] The difference in behavior with respect to hydrogen in the thermal and photochemical reactions may be explained by assuming that excited ozone molecules do not react with hydrogen whereas oxygen atoms react.[30] Yet the reaction $O + H_2 \longrightarrow OH + H$, where O is a normal oxygen atom, occurs only very seldom as was shown by the experiments of Kistiakowsky and my own observations.[31] However, it may be assumed that water is formed according to the reaction $O + O_2 + H_2 \longrightarrow H_2O + O_2$, which is in agreement with the experiments of Weigert, and Griffith and Shutt. They found that in the presence of much hydrogen the rate of water formation becomes constant and practically all of the oxygen formed by the decomposition of ozone is transformed into water. We may have, therefore, for the predominant reactions

$$O_3 + h\nu \longrightarrow O_2 + O \qquad (1)$$

$$O + O_2 + H_2 \longrightarrow H_2O + O_2 \qquad (2)$$

The decomposition of ozone is strongly decreased by Reaction 2, since the reaction $O + O_2 + M \longrightarrow O_3 + M$, which regenerates ozone, is suppressed. The quantum efficiency in the investigated region in the absence of hydrogen is very small, hence a ten-fold increase in the velocity by hydrogen is not surprising. In the ultraviolet, where excited oxygen atoms are formed, the reaction $O + H_2 \longrightarrow OH + H$ may also occur." Our present knowledge of the reactions $O + H_2$ and $O_2 + H_2$, however, is not sufficient to give with certainty the real mechanism of water formation.

The Effect of Temperature.—According to the proposed mechanism there should be no or only a very small temperature coefficient at low pressures where three-body collisions (Reaction 3) would seldom occur and

where the oxygen atoms, therefore, would always have an opportunity for reacting with ozone molecules. At higher pressures, however, a small but larger temperature coefficient should be found, because the reaction $O + O_2 + M \longrightarrow O_3 + M$ is practically independent of temperature, while the reaction $O + O_3 \longrightarrow 2O_2$ must be influenced by temperature. The unpublished experiments of Kistiakowsky show an increase of the temperature coefficient in the expected direction. (As was pointed out in the introduction, a small positive temperature coefficient at high pressures was also found by Regener.)

In conclusion, it may be said that the decomposition of ozone in red light is satisfactorily represented by the mechanism given.

The Decomposition **of** Ozone in Ultraviolet.—An exact interpretation of the decomposition of ozone in ultraviolet light is rather difficult because of the scarcity of quantitative data. Kistiakowsky has already pointed out the analogy between the reactions in red and ultraviolet light. There are only two important differences: (I) the higher quantum efficiency in the ultraviolet—the only available experiments are with small concentrations of ozone at atmospheric pressure and here the quantum yield is ten times that obtained in red light under the same conditions; *(2)* the influence of water vapor. According to Warburg[4] the decomposition of ozone is more rapid in the presence of moisture, whereas Kistiakowsky, in the red, observed no difference in behavior of dry or wet gases. By analogy with the reaction in the red and because of the fact that the absorption spectrum contains very diffuse bands, we may assume that the primary process in the ultraviolet is also $O_3 + h\nu \longrightarrow O_2 + O$. The acceleration of the reaction rate by a decrease in pressure, observed by E. v. Bahr,[3] may then be readily explained. At low pressures the reaction $O_2 + O + M \longrightarrow O_3 + M$, which removes oxygen atoms and regenerates ozone, occurs less often since it requires a three-body collision. This is, of course, equivalent to an increase in the velocity of decomposition. The influence of nitrogen and helium, both of which increase the quantum yield compared with oxygen, is to be explained in the same manner as for the reaction in red light, *i.* e., nitrogen and especially helium are less adapted than oxygen in taking up the energy in a three-body collision.

The higher quantum efficiency in the ultraviolet may be explained in the following way. In the red we must expect that by the reaction $O_3 + h\nu \longrightarrow O_2 + O$ only a normal oxygen atom is formed, whereas in the ultraviolet the oxygen atom can contain much more energy, for the difference in energy between red ($\lambda \sim 620$ Å.) and ultraviolet ($\lambda \sim 2537$ Å.) is about 70 cal. Consequently, the reaction $O_3 + O \longrightarrow 2O_2$ which, as has been previously pointed out, occurs at every 2×10^3 collision, can now take place more frequently. From Warburg's experiments it can be calculated that the probability of the occurrence of this reaction is about 5×10^{-2}, assuming that the reaction $O + O_2 + O_2 \longrightarrow O_3 + O_2$ at a pressure of 1 atm. occurs at every 10^3 collision.

The reaction $O + O_3 \longrightarrow 2O_2^*$ is the only one that can initiate chains; therefore, the probability of chain formation is greater in the ultraviolet, where this reaction takes place more frequently than in the red. Another reason for the high velocity in the ultraviolet is to be found in the fact that the reaction of ozone with an excited oxygen atom can form oxygen molecules with 80 cal. excess energy, while in the reaction with a normal atom the excited oxygen molecule may have at the maximum 50 cal., since it is quite plausible to assume that the probability that ozone is excited by an oxygen molecule for reaction or decomposition is increased with increase in energy content of the latter. From the above considerations the higher quantum efficiency in the ultraviolet light is readily understandable. Warburg found at a total pressure of 1 atm., 90% O_2 and 10% O_3, the quantum yield **3.5.**

It is impossible to discuss the chains in detail since the behavior of concentrated ozone mixtures needs to be known and no experiments in this region are available.

The author has set up equations for $d[O_3]/dt$ for every possible reaction scheme considering the reactions between O_3, O, O_2 and O_2^*. Equations with more than four constants are always obtained and, as the value of some of these constants is not known, it is easy to represent the general course of the reaction by choosing suitable values for them. It is, however, impossible to find an equation which gives, for small concentrations of ozone ($\leqq$ 0.5%) and high oxygen pressures, a constant quantum yield and also describes the course of the reaction. Warburg found for ozone concentrations between 0.2 and 0.5% a constant quantum yield of 0.28; at higher concentrations, however, the velocity depends greatly on the ozone concentration and even for $O_3 \sim 0.75\%$ a quantum yield of 0.48 is obtained. This sudden transition to a zero order reaction is highly improbable. Furthermore, his results do not agree with those obtained by Regener and v. Bahr, who found a dependence of the velocity on the ozone concentration even in very dilute ozone mixtures. In the experiments of Warburg, as he himself states, there was always present an uncontrollable dark reaction which, with the long exposure necessary for a measurable amount of reaction to take place at low pressures, would be sufficiently large to obscure any expected small change in the quantum yield. It would, however, be very desirable to have these experiments repeated.

If the observation that water vapor accelerates the decomposition is correct, it can be accounted for by the reaction of excited oxygen atoms with water vapor.

In conclusion it may be said that the decomposition of ozone in the ultraviolet, as well as the influence of foreign gases and total pressure, can be explained if the primary reaction is assumed to be a dissociation into an excited oxygen atom and an oxygen molecule. It must, however, be emphasized that further experiments in this region would be of great use in order to elucidate the details of chain formation.

The author is greatly indebted to Dr. G. B. Kistiakowsky for permission to use his unpublished experiments. Thanks are also due Dr. O. R. Wulf of Washington, who kindly communicated the results of his investigations of the spectrum of ozone, and Dr. E. O. Wiig for translating the paper into English.

Summary

1. A critical survey of the experimental data involving the photochemical decomposition of ozone has been given.

2. The kinetics of the reaction have been explained on the assumption that the ozone spectrum shows predissociation and that the primary process is therefore $O_3 + h\nu \longrightarrow O_2 + O$. In red light a normal oxygen atom is assumed to be formed and in the ultraviolet an excited atom.

3. The probability of the occurrence of the reaction $O + O_3 \longrightarrow 2O_2$ has been calculated to be 5×10^{-4} if the oxygen atom is normal and it is assumed that the reaction $O + O_2 \longrightarrow O_3$ occurs only in a three-body collision.

4. The influence of temperature and of foreign gases has been discussed. The effect of gases which do not react with ozone can be interpreted by their specific influence on the three-body reaction $O + O_2 + M \longrightarrow O_3 + M$.

PREPARATION AND PROPERTIES OF LEAD PERCHLORATE

BY H. H. WILLARD AND J. L. KASSNER[1]

RECEIVED MARCH 17, 1930 PUBLISHED JUNE 6, 1930

Introduction

Lead perchlorate was first prepared by Serullas[2] by heating lead oxide with perchloric acid. It was also prepared by Marignac[3] and Roscoe[4] by adding lead carbonate to perchloric acid and evaporating to a sirupy liquid. Roscoe was the first to point out the fact that lead perchlorate is extremely deliquescent. The formula of the salt which he obtained was $Pb(ClO_4)_2\cdot$-

$3H_2O$. There is no record of any other hydrate of lead perchlorate, although Hoffmann[5] interpreted Roscoe's figures as corresponding to the formula, $Pb(ClO_4)_2{\cdot}1.5H_2O$.

Two forms of basic lead perchlorate have been described by Marignac,[3] Weinland[6] and Weinland and Stroh.[7] Marignac prepared the basic salts by boiling a concentrated solution of normal perchlorate with a slight excess of lead carbonate and evaporating the filtrate. The formula of his salt was $PbO.Pb(ClO_4)_2.2H_2O$. Rammelsberg[S] also prepared this same salt. Weinland[6,7] prepared basic lead perchlorates to which he ascribed the formulas, $Pb_2(ClO_4)_2(OH)_2{\cdot}1.5H_2O$ and $Pb_3(OH)_4(ClO_4)_2$. He prepared the first by treating lead oxide with more than one and less than two equivalents of perchloric acid. The latter was prepared by treating three moles of lead oxide with two moles of perchloric acid and crystallized in two forms as described by Marignac.[3]

Experimental

Preparation of Normal Lead Perchlorate.—Lead perchlorate was prepared by adding to lead nitrate about 1% excess over the calculated amount of perchloric acid and evaporating to remove all nitric acid. Lead nitrate of C. P. grade was twice recrystallized with centrifugal drainage and washing. Perchloric acid (72%) of a high degree of purity was further purified by fractional distillation in a vacuum. It was diluted with a little water, added to the lead nitrate and the solution evaporated until fumes of perchloric acid were given off. The lead nitrate did not entirely dissolve in the acid at first but gradually went into solution as the evaporation progressed. The solution was tested for nitrate from time to time by adding a drop of it to a solution of diphenylamine in concd. sulfuric acid, and the fuming was continued until no test for nitrate was obtained.

Removal of **Excess** Perchloric Acid.—Owing to the great solubility of the salt, it was found impossible to remove the excess of perchloric acid even by two recrystallizations. It could not be volatilized by heating because anhydrous lead perchlorate, stable up to 200°, begins to decompose above that temperature into lead chloride and lead oxide, evolving both oxygen and chlorine, and also because the last traces of acid, becoming anhydrous, readily decompose into chlorine and oxygen, contaminating the salt with chloride. Moreover, the salt containing excess of perchloric acid was decomposed slightly when dehydrated in a vacuum in the presence of phosphorus pentoxide.

The obvious method of neutralizing the excess of acid by the addition of lead oxide or carbonate is not readily applicable in this case, because these substances are readily soluble in a solution of lead perchlorate, forming soluble basic salts and there is no way of knowing when just the proper amount has been added except by making rather troublesome analyses of the solution.

Because perchloric acid dihydrate, unlike the anhydrous acid, is very stable, it seemed probable that the excess of acid could be removed by passing a stream of moist air over the fused salt, as was done by Richards and Willard——ith lithium perchlorate.

This was found to be satisfactory and because it is the most effective method for many perchlorates, it will be described in some detail.

A heater was constructed from a 20 X 30 cm. beaker which was wrapped with damp sheet asbestos and wound with seventy turns of chromel ribbon, 0.2 × 1.6 mm. The heating unit for the bottom of the beaker was made by coiling together chromel ribbon and a strip of asbestos 1 cm. wide to form a disk of suitable size which, while damp, was pressed against the bottom of the beaker. The two heating units could be connected either in series or in parallel. The beaker was insulated by asbestos wool, held in place by sheet asbestos, and the whole supported on a base of asbestos board. The beaker was covered with a quartz plate. Air purified by passing it through a solution of silver nitrate and a soda-lime tower was passed through water at about 100° by bubbling it through a three-necked Woulff bottle, electrically heated by a winding of No. 28 chromel wire, and supplied with water from a large stock bottle. The moist air passed through a delivery tube extending to within 5 cm. of the bottom of the large beaker.

The lead perchlorate solution, free from nitrate, was evaporated below 125° until it contained only a little more water than was required to form the trihydrate. This solution was then placed in the heater described above, on a support 10 cm. high, and steamed for three hours at about 160°. At the end of this time the salt was free from acid and a nephelometric test[10] showed that it contained only a few thousandths of one per cent. of chloride.

If more than 1% excess of acid is used in preparing lead perchlorate, longer steaming will be necessary. The vapor pressure of water in the air passing through the heater must be high enough to prevent complete dehydration of the salt; otherwise considerable chloride will be formed.

In order to determine accurately the amount of free acid, a sample of 3 to 4 g. of the salt was dissolved in about 7 cc. of water free from carbon dioxide. The lead was precipitated as sulfate by the addition of excess of neutral sodium sulfate, and removed by filtration. The acid in the filtrate was determined colorimetrically by using brom thymol blue as indicator and 0.001 N hydrochloric acid and sodium hydroxide as standard solutions.

Crystallization of Lead Perchlorate.—Lead perchlorate is extremely soluble in water and the trihydrate melts at 83–84°. In order to obtain a satisfactory yield of crystals the amount of water present must be carefully regulated. It was found best to start with a known weight of lead nitrate and for every 500 g. of lead perchlorate trihydrate, to allow 8 to 10 g. excess of water. A semi-fluid mass was then obtained on cooling to 0°. The crystals were drained centrifugally in platinum cups and a yield of 58% was obtained. The trace of chloride originally present could not be detected nephelometrically after crystallization. The yield decreased rapidly as the amount of water increased beyond that required to form the trihydrate. For example, in the above case, 555 g. of the salt was present, and if 26 g. of water instead of 10 g. was present, no crystals appeared on cooling to 0°.

Preparation of Anhydrous Lead Perchlorate.—Lead perchlorate trihydrate, dried at room temperature with phosphorus pentoxide in a vacuum for nine months, was not completely dehydrated. To increase the rate of dehydration by drying in a vacuum at a higher temperature the following apparatus was devised. A flanged pyrex cylinder[11] 60 cm. long by 12.5 cm. inside diameter and 0.5 cm. thick, was provided with covers to which were fused glass stopcocks. The flanges and covers were so carefully ground that, using only a trace of grease, the cylinder maintained a vacuum. This cylinder was placed in an electric oven 25 × 30 × 28 cm., made of "transite" asbestos board. The

---

[10] Richards and Wells, *Am. Chem. J.*, 31, 235 (1904).

[11] Specially made by the Corning Glass Works.

oven was wired in two units, the sides and bottom with twenty turns of No. 28 chromel wire and the top with twenty-two turns. There was a mica window on top and another on one side. The advantage of this apparatus was that the central portion of the cylinder, containing the salt to be dehydrated, could be heated to the desired temperature, while the ends, containing the desiccant, phosphorus pentoxide, were relatively cool.

Because anhydrous lead perchlorate takes up moisture with such extraordinary rapidity, it was necessary to handle it only in very dry air. A large tight box was constructed of wood with a plate glass top and large enough to manipulate three ordinary desiccators. It was provided with a door, made air tight by means of a soft rubber gasket. There were two "manipulating arm-holes" in which long-sleeved rubber gloves were fastened air tight. A sulfuric acid manometer was provided for observing the pressure. Air, dried successively by calcium chloride and phosphorus pentoxide. was passed into the box for a few hours before and during use.

Lead perchlorate trihydrate was placed in an evaporating dish supported in the center of the cylindrical pyrex desiccator described above. Phosphorus pentoxide placed in the cool ends of the cylinder served to remove the moisture. The oven was adjusted to maintain a temperature of 65°. It was evacuated to a pressure of 35 mm. and the drying continued for nineteen hours. The salt was then removed and weighed on a platform balance in the manipulating box. When the hydrated salt had lost about one-third of its water of hydration, the temperature was raised to 100° for eight hours and then to 120° for fourteen hours. Analysis of the salt at this time showed 50.73% of lead compared with a theoretical value of 51.02% for the anhydrous salt. The heating was continued at 120° for twenty-four hours and at the end of this time the salt contained 51.02% lead.

Analysis of Anhydrous Lead Perchlorate.—While still hot, the salt was removed from the vacuum desiccator and placed in an ordinary desiccator containing phosphorus pentoxide. This was then placed in the manipulating box along with a similar desiccator containing two tared weighing bottles with carefully ground stoppers. After flushing out the box with dry air, a sample was transferred to the weighing bottle, and replaced in the desiccator. The stoppers were so well ground that there was no gain in weight during the process of weighing.

The amount of lead in the salt was determined by precipitating it as lead sulfate and weighing on a Gooch crucible. Duplicate analyses gave 51.016 and 51.020% of lead as compared to a theoretical value of 51.02%.

Anhydrous lead perchlorate is white and when exposed to air takes up moisture with amazing rapidity, forming the monohydrate and trihydrate. It is stable at 200° but begins to decompose at about 250° into lead chloride and lead oxide, evolving both oxygen and chlorine. It fuses at 270–275°, and above this completely decomposes.

Preparation of Lead Perchlorate Monohydrate.—Lead perchlorate trihydrate was partially dried at room temperature in a vacuum desiccator with phosphorus pentoxide. It then contained a little more water than corresponded to the monohydrate (6.77% instead of 4.25%, calculated from a determination of lead). The pentoxide was then replaced by a large excess of anhydrous lead perchlorate and the desiccator evacuated. The salt was allowed to remain in this desiccator for fifteen months and then analyzed for lead and perchlorate.

To obtain samples without exposure to atmospheric moisture, the manipulating box was used as before. Lead was determined as sulfate and the perchlorate by precipitation with "nitron" as described by Storm[12] and also by removing the lead electrolytically and then titrating the acid with standard alkali using methyl red as indicator. The results were as follows. Calcd.: Pb, 48.85%; ClO_4, 46.90%. Found: Pb, 48.85,

---

[12] Storm, U. S. Bur. of Mines, Bull. 96, 1916, p. 65.

48.85; ClO_4, 47.06 (nitron), 46.67 (acid titration). A test of the methods of determining perchlorate showed that the nitron method, using twice the theoretical amount of reagent, was excellent and that no correction for solubility loss was necessary if the precipitate was transferred by means of the filtrate and washed with 10 cr. of ice water, added in 1–2 cc. portions, using slight suction. The removal of lead electrolytically tended to give slightly low results, perhaps due to slight loss by spraying. Precipitation of the lead by means of hydrogen sulfide and removal of the latter by boiling gave good results. No matter what method is used. the determination of perchlorate is less accurate than that of lead.

The melting point of $Pb(ClO_4)_2 \cdot H_2O$ was found to be 153–155". The above data prove the existence of this hydrate, which has not previously been obtained, and indicate that there is no lower hydrate.

Preparation of Lead Perchlorate **Trihydrate.**—A sample of lead perchlorate which had just been recrystallized was used. It contained 12.10% water as compared with 11.74% for the trihydrate. It was placed in a vacuum desiccator over a large excess of the monohydrate and the desiccator evacuated. It was allowed to stand for twelve months and then analyzed. Calcd.: Pb, 45.03; ClO_4, 43.73. Found: Pb, 45.17, 45.15; ClO_4 (nitron), 43.55, (acid titration), 43.20. The melting point of the trihydrate was 83–84°. The above data show the existence of the trihydrate and that another hydrate does not exist between the tri- and monohydrate.

Preparation of Basic Lead Perchlorate, $Pb_3(OH)_4(ClO_4)_2$.—This salt was prepared by saturating a hot solution of perchloric acid with lead oxide. The excess lead oxide was filtered out of the hot solution using a hot water funnel. On cooling, the basic salt crystallized in large irregular crystals. It was centrifuged in platinum cups and washed twice on the centrifuge with hot water. The salt was then crystallized from carbon dioxide-free water, centrifuged and washed. Weinland and Stroh[7] state that this salt may be prepared by treating three moles of lead oxide with two moles of perchloric acid. When attempting to prepare other basic lead salts than those described by Weinland, it was discovered that this same salt could also be prepared by using lead oxide and perchloric acid in the molecular ratio of four to three. When the ratio of lead oxide to perchloric acid was less than 4 to 3 and greater than 2 to 3, a mixture of the above basic salt and another, described later, was obtained This shows that the limits of the ratio for this basic salt are between 4 of oxide to 3 of acid and the saturation point of hot perchloric acid with lead oxide. The results of analysis are as follows. Calcd.: Pb, 69.96; ClO_4, 22.39; OH, 7.65. Found: Pb, 70.05, 70.00; ClO_4, 22.38, 23.36; OH, 7.65, 7.60.

The direct determination of hydroxyl was carried out as follows. The salt was dissolved in a slight excess of $N/10$ nitric acid. The solution was diluted and the lead precipitated as lead sulfate by adding excess of neutral sodium sulfate. After warming for a time it was cooled in ice and filtered. The excess acid was titrated with $N/10$ sodium hydroxide using phenolphthalein as indicator. It was observed that if the salt was dissolved in water, a turbidity appeared, probably due to a trace of carbonate, and if $N/10$ nitric acid was added slowly to the hot solution, the disappearance of the turbidity could almost be used as the end-point of the titration. It disappeared a trifle too soon, the difference being about 0.07 cc. of $N/10$ acid. Neither Marignac nor Weinland reported a determination of the hydroxyl group.

Preparation of $\mathbf{Pb_2(OH)_2(ClO_4)_2 \cdot 1.5H_2O}$.—Weinland and Stroh[7] state that this salt may be prepared from a solution of lead oxide in the calculated quantity of perchloric acid. An attempt was made to prepare this salt by his method, and also by varying the ratio of lead oxide to perchloric acid. Although the analysis indicated the existence of a salt of the above composition, it was not conclusive. The variation in the results seemed to indicate a mixture rather than a salt of definite composition.

The Solubility of Lead Perchlorate.—A slight excess of lead perchlorate trihydrate was added to water in a glass tube, which was sealed up and rotated for several days in a thermostat at 25 ±0.005°. After settling for several days, some of the clear liquid was transferred to a pycnometer with a carefully ground stopper consisting of a tube with a capillary bore. The capacity of the pycnometer at 25" was found to be 9.9783 g. of water, or 10.0180 cc. The weight of lead perchlorate solution required to fill it was 27.7950 g., or 27.8029 g. corrected to vacuum. The calculated density is 2.7753. The solution was transferred to a beaker, precipitated as lead sulfate, filtered and weighed on a Gooch crucible after heating at 600°. The corrected weight of $PbSO_4$ was 16.9111 g., equivalent to 22.6464 g. of $Pb(ClO_4)_2$ or 25.6603 g. of $Pb(ClO_4)_2 \cdot 3H_2O$. The following table shows the solubility calculated from these figures.

TABLE I

SOLUBILITY OF LEAD PERCHLORATE IN WATER AT 25°

Density, 25°/4°, 2.7753

	G per 100 cc. of soln.	G. per 100 g. of soln.	Mole per 100 cc. of soln.	Mole per 100 g. of soln.
$Pb(ClO_4)_2$	226.103	81.472	0.55676	0 20061
$Pb(ClO_4)_2 \cdot 3H_2O$	256.200	92.315		

Thiel and Stoll[13] called attention to the high density of the saturated solution and suggested its use as a heavy liquid for determining the specific gravity of organic substances. They stated that a solution saturated at 15° had a density of about 2.6 and contained 78% of lead perchlorate.

Anhydrous lead perchlorate is readily soluble in many organic solvents but work along this line was discontinued after the violent explosion of an almost saturated solution of this salt in anhydrous methyl alcohol. This solution was prepared by adding the perchlorate in small amounts to the alcohol, cooling after each addition because considerable heat was given off during this process. The solution was cooled in ice to see if crystals would form. This did not occur, and the solution was allowed to warm up to room temperature. A little more of the salt was added and when the flask was disturbed the contents exploded.

Summary

1. Anhydrous lead perchlorate, the mono- and trihydrates, have been prepared in a high degree of purity and their properties studied.
2. One basic lead perchlorate, $Pb_3(OH)_4(ClO_4)_2$, was prepared.
3. A method of determining the hydroxyl group in the basic salt is described.
4. The solubility of lead perchlorate in water at 25° is 81.472 g. per 100 g. of solution and the density is 2.7753.
5. A solution of anhydrous lead perchlorate in anhydrous methyl alcohol is explosive.

STUDIES IN AZO INDICATORS[1]

BY E. E. HARRIS, H. W. HAUGEN AND B. E. FAHL

RECEIVED MARCH 17, 1930 PUBLISHED JUNE 6, 1930

Since Sørensen's studies using indicators for the determination of hydrogen-ion concentrations, there has been a constantly widening use of indicators for the measurements in various fields. One of the difficulties has been that it required several different types of indicators having entirely different color changes to cover the PH range from 1.0 to 14.0. Each of these has individual characteristics which make knowledge gained from the use of one useless when it is necessary to use another. If a satisfactory series of indicators with the same color change could be prepared which would cover the whole PH range, their use would be greatly simplified. Certain groups are known to affect the color of dyes and should alter the color change of indicators. This paper is the report of a study made to determine the effect of substitution in the benzene nucleus and the position of this substitution on indicators of the methyl orange and methyl red type. Published work of this nature has been given in the paper of A. Thiel,[2] this deals with substitutions in naphthylamino-azobenzene. Several compounds which contribute to such a study are included in the work of Clark.[3]

Studies in Derivatives of Methyl Orange

Methyl orange has long been used as an indicator and several theories have been proposed for its color changes.4 The following work is to determine the effect of changing the position of the "diazo" group relative to the sulfonic acid group about the benzene ring on the ease of the electron shift, and also to determine the effect, if any, when substituent groups are introduced into either the benzene sulfonic acid part of the molecule or the dimethylaniline part, on this electron shift.

The method which was used for preparing the various diazo compounds was a modification of the one described in Gattermann.[5] The hydrogen-ion concentration at which color change took place was determined by a modification of the method of Fales and Mudge.[6]

Experimental Part

OBSERVATIONS

Diazo compound	PH between which color change took place
Methylorange	2.8–4.1
p-Dimethylamino-azobenzene-*o*-sulfonic acid	2.8–4.1[8]
Ethyl orange	2.8–4.5[9]
p-Dimethylamino-azobenzene-2-sulfonic acid	3.5–4.47
p-Dimethylaminobenzene-azo-4-methyl-benzene-2-sulfonic acid..	2.8–4.4[7]
p-Dimethylaminobenzene-azo-4-methylbenzene-2-sulfonic acid	2.9–4.1
p-Dimethylaminobenzene-azo-4-nitrobenzene-2-sulfonic acid	2.5–4.0
p-Dimethylaminobenzene-azo-4-methylbenzene-3-sulfonic acid	2.8–4.1
p-Dimethylaminobenzene-azo-4-aminobenzene-3-sulfonic acid	2.2–2.5

Studies in Derivatives of Methyl Red

It appears that methyl red undergoes two color changes while changing colors. This has been accounted for in the color theories of Stieglitz, Thiel[4] and Hantzsch. There are several references[10] in the literature for the preparation of methyl red but the method given by Clark and Kirner[11] seemed the best to follow. In many of the derivatives several modifications were necessary.

The method used for determining the indicator constant was by colorimeter[12] for that concentration when half of the indicator had changed.

EXPERIMENTAL OBSERVATIONS

Indicator	Approximate indicator constant
Methyl red[13]	6.05×10^{-6}
2-Carboxybenzene-azo-dimethyltoluidine	6.19×10^{-6}
5-Nitro-2-carboxybenzene-azodimethylanilne	3.04×10^{-5}
4-Nitro-2-carboxybenzene-azodimethylaniline..	$3\ 07 \times 10^{-5}$
m-Carboxybenzene-azodimethylaniline..	2.32×10^{-3}
p-Carboxybenzene-azodimethylaniline	$4\ 5 \times 10^{-3}$
p-Dimethylamino-azobenzene-*p*-phenylacetic acid	1.07×10^{-3}
p-Dimethylamino-azobenzene-*p*-bromo-*p*-phenylacetic acid	$4\ 37 \times 10^{-4}$

---

[7] The value of the mid-point as determined by a modification of the Gillespie colorimeter as described in Clark, Ref. 3, p. 69, was 3.31, C. S. Slater, Master's "Thesis," University of North Dakota (unpublished).

[8] This compound seems to have many advantages over methyl orange for clear-cut color changes as an indicator for the same range.

[9] Value 3.5–4.5, given in Clark, Ref. 3, p. 86.

[10] Rupp and Loose, *C. A.*, **3**, 523 (1909); Tizard, *C. A.*, 5, 1222 (1911); Rupp, *C. A.*, **10**, 2214 (1912).

[11] Clark and Kirner, "Organic Syntheses," John Wiley and Sons, Inc., New York, **1922**, Vol. II.

[12] This colorimeter was for two-color indicators as designed by G. A. Abbott of North Dakota and constructed by Bausch and Lomb.

[13] This value agrees with that of Clark, *C. A.*, **11**, 1443 (1918); THIS JOURNAL, 46, 581 (1924), but is much higher than the value obtained in a different manner by Theil and Dassler, *C. A.*, 18, 56 (1924).

Conclusions

1. Substitution of methyl groups produces very little effect on the hydrogen-ion concentration at which the indicator changes color.

2. The position of the acid group produces the greatest change in indicator properties. When in the ortho position the change takes place at the higher PH, when in para lower and lowest in meta.

3. The introduction of strongly negative groups such as the nitro group causes a change at a lower *P*H.

THE CHAIN CHARACTERISTICS OF THE ETHYLENE–OXYGEN REACTION

BY ROBERT SPENCE[1] AND HUGH S. TAYLOR

RECEIVED MARCH 21, 1930 PUBLISHED JUNE 6, 1930

It is now well known that many reactions once thought to be of the simple classical type actually occur by a chain mechanism. Generally speaking, the existence of these chains has been demonstrated in one or more of three ways, by measuring the quantum yield in photochemical experiments, by studying the unusual kinetics of gaseous reactions, or by introducing some active material or "trigger" to start the chains. In the case of hydrocarbon oxidations, the photochemical method is not very convenient experimentally. Before making a study of the kinetics of these reactions it was considered advisable to demonstrate their chain character in a direct manner by the last of the methods mentioned above. The use of ozone as a "trigger" in gaseous reactions was first developed by Semenoff and Rjabinin[2] in the combustion of sulfur. An attempt has been made to apply ozone as a "trigger" to the ethylene–oxygen system at temperatures where sufficient reaction takes place to be measurable but well below the ignition point. Under these conditions ozone has an extremely short life, so that the actual amount employed in starting chains may be very much smaller than the amounts actually introduced into the gas stream. We would therefore obtain only a lower limit of ozone efficiency and of chain length in this manner.

Ethylene and oxygen (from cylinders), at measured rates of flow, and dried over phosphorus pentoxide, were passed through *a* reaction vessel maintained at a definite temperature in a furnace, then through a weighed tube of phosphorus pentoxide for a given time, the increase in weight being noted. With everything else constant, the oxygen was then partially

---

[2] Semenoff and Rjabinin, *Z. physik. Chem.*, **1B**, 193 (1928).

ozonized by passing through a Brody's ozonizer and the increase in weight of the absorption tube again noted. This increase was many times the former increase, as the appended Table I shows.

TABLE I

OXIDATION OF ETHYLENE IN PRESENCE AND ABSENCE OF OZONE

T, °C.	C_2H_4 O_2	Normal increase (*a*), g.	Using O_3 (*b*), g	Ratio b/a	Time, min
298	1:2.5	00020	0 1290	64 5	30
298	1:2	0020	0878	87 5	15
350	1:2	0030	.1350	45 0	15
358	1:2	.0032	0506	15 8	15
388	1:2	0152	Exploded	..	15

Assuming that all the ozone introduced into the gas stream reacted to give water, the increase in fifteen minutes due to ozone alone would be 0.12 g.; hence these experiments do not afford conclusive proof of the existence of a chain mechanism. The explosion is significant in view of the fact that ethylene and oxygen normally do not explode until temperatures over 500° are reached. With ozone present, the system becomes very sensitive to shocks around 400° and often exploded at the turning of a stopcock.

In another series of experiments the solid and liquid products of the reaction were frozen out by a carbon dioxide–ether trap and the remaining gases analyzed. The ozonizer was calibrated so that any desired concentration could be obtained by varying the current in the 4000-volt transformer. To prevent explosions, the apparatus was made of thick-walled barometer tubing (2-mm. bore) as far as possible and, in order to prevent decomposition of the ozone before it reached the furnace, the oxygen inlet tube was cooled by water circulating through a lead coil surrounding the inlet. The reaction chamber was also considerably smaller than in the first series of experiments, having a capacity of about 8 cc. instead of 150 cc. To prevent explosions due to sudden pressure variations at the moment when a gas sample was to be collected, the gas was first allowed to stream from the furnace into the air. With the stopcock leading to the analysis buret open, the exit to the air was slowly closed by tightening a clip on a small rubber tube attached to the air exit. When the dead space of the collecting system was thoroughly swept out, a sample was collected in the gas buret in a given time, the pressure being maintained as far as possible constant throughout the procedure. The products collected in the trap appeared to be mainly formaldehyde and small amounts of a white solid, possibly a polymer. Carbon dioxide was absorbed by alkali in the gas buret, ethylene removed by bromine water and all the remaining gas except a small residue could be absorbed by pyrogallol. In order to make the two measurements under as nearly the same conditions as possible, oxygen, for the sake of rapidity, was generally obtained by difference, a few check determinations being made at intervals. Results are given in Table II. The effect of increasing temperature causes an apparent shortening of the chains but this is no doubt due to the thermal decomposition of the ozone. All the values derived for the chain length are greater than unity and hence constitute direct evidence for the existence of reaction chains in hydrocarbon combustions; a small amount of ozone reacting is able to cause additional amounts of oxygen to take part in the reaction.

Since this work was completed, a study of the oxidation of ethylene from the standpoint of reaction kinetics has been published by Thompson and Hinshelwood.[3] They conclude that "between 400 and 500° the oxidation is probably a chain reaction." They suggest that "the first stage in the reaction is the formation of an unstable peroxide; if this reacts with more oxygen the chain ends, but if it reacts with ethylene, unstable hydroxylated molecules are formed which continue the chain." They conclude "that from a consideration of the temperature coefficient and the influence of foreign gases on the rate of reaction that the chains are probably not of great length." The present experiments therefore constitute an important line of auxiliary evidence with respect to the chain characteristics of this hydrocarbon oxidation and supplement the data already supplied by Pease[4] with respect to the chain nature of the oxidation of the saturated hydrocarbons.

We desire to acknowledge our indebtedness to the Commonwealth Fund which provided one of us (R. S.) with the Fellowship with the aid of which this work became possible.

Summary

The use of ozone as an initiator of reaction between ethylene and oxygen at temperatures below the normal reaction temperature in absence of ozone has been studied.

The results are consistent with the hypothesis that the oxidation process is a chain reaction.

SOLUBILITY OF LEAD SULPATE, CHROMATE AND MOLYBDATE IN NITRIC AND IN PERCHLORIC ACID

BY H. H. WILLARD AND J. L. KASSNER[1]

RECEIVED MARCH 24, 1930 PUBLISHED JUNE 6, 1930

It has been shown by Thiel and Stoll[2] that the difference in potential between lead electrodes in 0.05 molar solutions of lead perchlorate and nitrate is 0.016 volt. From this they calculated the ratio of the concentrations of Pb^{++} in the two solutions to be 1:0.28. In connection with other work the present authors had noticed that lead sulfate, chromate and molybdate were less soluble in perchloric acid than in nitric acid of the same concentration. In order to investigate this matter more thoroughly, with the possibility of utilizing the results in analytical separations, the solubilities of these salts were determined in perchloric and in nitric acids of different concentrations, both with and without the addition of a common ion.

Experimental

Preparation of Lead Sulfate.—Lead sulfate was prepared by adding simultaneously from two burets dilute solutions of sulfuric acid and lead perchlorate to 800 cc. of slightly acidified water, with vigorous stirring. This gave a fairly coarse precipitate. It was washed with water five times by decantation, centrifuged in platinum cups and washed four times on the centrifuge.

Preparation of Lead Chromate.—Lead chromate was prepared in the same manner as lead sulfate, using lead perchlorate and potassium dichromate. The lead chromate was washed with water eight times by decantation, four times on the centrifuge, dried in a vacuum over phosphorus pentoxide and analyzed by electrometric titration with ferrous sulfate. The average of two closely agreeing analyses gave 16.09% chromium, compared to a theoretical value of **16.08%.**

Preparation of Lead **Molybdate.**—Lead molybdate was prepared in a similar manner by adding lead perchlorate and ammonium molybdate to hot water acidified with perchloric acid. After boiling the solution for a few minutes, the precipitate was washed eight times by decantation with hot 2% ammonium nitrate solution, centrifuged, and

---

[1] From a dissertation submitted by J. L. Kassner to the Graduate School of the University of Michigan in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry.

[2] Thiel and Stoll, *Z. anorg. allgem. Chem.*, **139, 317 (1924).**

washed eight times on the centrifuge. Since it has been pointed out by Weiser[3] that lead molybdate occludes ammonium molybdate, the salt was further purified by stirring about 10 g. in a liter of normal perchloric acid for twenty-four hours After it had settled, a 500-cc sample of the clear solution was analyzed for lead and molybdenum and found to contain an excess of the latter, which must have been occluded as ammonium molybdate and subsequently extracted by the acid. The lead molybdate which had been stirred in perchloric acid was centrifuged and washed with hot 2% ammonium nitrate. After ignition it was analyzed, lead and molybdenum being separated by the sulfide method.[4]

Anal. Calcd.: PbO, 60.78. Pound: 80.72, 60.76, 60.69, average, 60.72. Calcd.: MoO_3, 39.22. Found: 39.18, 39.14, 39.11, average, 39.14.

The lead molybdate possessed a yellowish-white tinge. This was also observed by Weiser.[3]

Preparation of Nitric and Perchloric Acids.—c. P. perchloric and nitric acids were redistilled in a vacuum. The different concentrations were made up from these by means of a hydrometer, using for perchloric acid the table by van Emster[5] and for nitric acid the densities given by Lunge and Ray.[6] The hydrometers were calibrated to read directly to 0.0005 at 15.5° and it was possible to estimate to 0.0001. The accuracy of this method of making up the acid concentrations was checked by titrating with standard alkali. The maximum error was about 0.002 M for higher concentrations and much less than this for the very dilute solutions.

Solubility Determinations.—Lead sulfate, lead chromate and lead molybdate were each placed in liter flasks and rotated with known concentrations of nitric and perchloric acids, respectively, in a thermostat which was not observed to vary as much as 0.001'. The water used in the acid solutions was twice distilled, using a block tin condenser and a quartz receiver. The flasks were closed with well ground stoppers covered with sheet rubber to keep the water in the thermostat from contact with the ground-glass joint. They were rotated for fifteen hours, then supported in a vertical position for two hours and the salt allowed to settle. Although the supernatant liquid was clear, the solutions were filtered through a platinum sponge filtering crucible into which they were siphoned directly from the flasks, the first portion being discarded. In this way it was possible to obtain samples absolutely free from particles of salt. A 500-cc. sample was taken for the low solubilities, and a 250- or 100-cc. sample for some of the higher ones. The results shown are the average of closely agreeing duplicates.

Solubility of Lead Sulfate in Perchloric and Nitric Acids.—Saturation of the solutions was carried out in quartz flasks with ground stoppers. After rotating lead sulfate in the thermostat as described, a 500-cc. sample was measured out, 1 cc. of concentrated sulfuric acid added and the solution

[6] Lunge and Ray, *Z. angew. Chem., 4,* 165 (1891).

concentrated in a quartz evaporating dish to about 23 cc. It was then transferred to a tared crucible, evaporated to dryness by means of a ring burner, and ignited at low red heat. It was possible to reproduce the weight of the crucible to within 0.05 mg. when the tare was ignited and cooled in the same way as the sample before each weighing. If the tare was not ignited each time, the variation was 0.1 mg. or more.

Solubility of Lead Sulfate **Using** a Common **Ion.**—The procedure was essentially the same except that the solutions were made up carefully from standard solutions so that when they were mixed and diluted to the required amount, the normalities would be as indicated in the tables. All the samples in which sulfuric acid furnished the common ion were analyzed by direct evaporation as explained above, except in a few cases in which the solubility was so low that lead was determined colorimetrically as sulfide.[7]

As there were no interfering substances present, the procedure was much simplified. A 500-cc. sample of the clear supernatant liquid was evaporated on the hot-plate and fumed until all the sulfuric acid was removed. The residue of lead sulfate was dissolved in ammonium acetate solution and diluted until the concentration of lead ion was low enough to determine colorimetrically, as determined by a preliminary test. Of this diluted solution, 25, 50 or 100 cc. (depending on the amount of lead present) was made ammoniacal with 5 cc. excess of concentrated ammonia water and diluted to a definite volume, as 100 cc. Lead sulfide was precipitated by adding 4 or 5 drops of the sodium sulfide solution. A standard was prepared in the same way and its color compared with that of the unknown. A blank was run in each case on the unknown before adding sodium sulfide. It was possible to check results within 5%.

In the solubilities in which lead perchlorate and lead nitrate furnished the common ion, it was necessary to determine the sulfate ion. This was done by removing most of the lead electrolytically from the original solution, concentrating the sample to about 75 cc. and removing the remaining lead. The solution was partially neutralized with sodium carbonate, after which the sulfate was precipitated with barium chloride. The weight of lead sulfate was calculated from the weight of barium sulfate obtained. The results are shown in Tables I and II.

It is interesting to note that the solubility of lead sulfate in perchloric acid increases up to a 2.0 M solution of acid and then decreases again, while the solubility of lead sulfate in nitric acid continues to increase with increasing acid concentration. Lead sulfate is much less soluble in perchloric acid than in nitric acid of the same concentration.

Solubility of Lead Chromate.—Saturation of the solutions with lead chromate was carried out in glass flasks with ground stoppers. The

amount of lead chromate dissolved in the various concentrations of perchloric acid was determined by adding potassium iodide and titrating the iodine liberated with sodium thiosulfate using starch as indicator. For those in nitric acid the lead chromate was titrated electrometrically with 0.1 or 0.01 N ferrous sulfate. The solutions were concentrated to 150–200 cc., with addition of sulfuric acid when necessary, and cooled in ice before titrating. When lead perchlorate and lead nitrate furnished the common ion, the chromate was determined by electrometric titration with ferrous sulfate. When sodium dichromate was used, the solution was analyzed for lead by reducing the dichromate with hydroxylamine hydrochloride, adjusting the acidity of the solution, and precipitating the lead with hydrogen sulfide. The lead sulfide was filtered, washed and dissolved in dilute nitric acid. This solution was boiled, neutralized and diluted to a suitable definite volume. Lead was then determined colorimetrically as described above. The results are shown in Tables III and IV.

In the case of lead chromate the solubility in perchloric acid increases up to 4.0 M acid and then begins to decrease, while the solubility in nitric acid continues to increase with increasing concentration of acid. Lead chromate is much less soluble in perchloric acid than in nitric acid of the same concentration.

Solubility of Lead Molybdate.—The solubility determinations of lead molybdate were carried out like those for lead chromate, and the supernatant liquid analyzed for both lead and molybdenum. This was done by adding 4–6 cc. of concentrated sulfuric acid and evaporating to remove the perchloric acid or nitric acid. The solution was diluted, the lead sulfate filtered off, washed with 0.5% sulfuric acid, ignited and weighed. If molybdenum is carried down it is detected by a bluish tinge around the edge of the precipitate during ignition. After adjusting the acidity of the filtrate, the molybdenum was reduced to a trivalent salt by passing it through a Jones reductor, received in a ferric alum and phosphoric acid solution and titrated with permanganate.[8] Perchloric acid must be absent because it oxidizes trivalent molybdenum even in dilute solution. The solubilities were discontinued at 1 *M* nitric and 3 *M* perchloric acid, because the molybdate seemed to be decomposed by the more concentrated acids, forming MoO_3.

Two methods were used for determining the solubilities of lead molybdate when lead perchlorate and lead nitrate furnished the common ion. First, when the concentration of the salt giving the common ion was not greater than 0.05 M, the procedure was the same as that above, except that the supernatant liquid was analyzed only for molybdenum. With lower solubilities, where greater accuracy was required, the colorimetric method of King[9] was used, with certain modifications. A 500-cc. sample was prepared by evaporating to fumes with a slight excess of sulfuric acid. The lead sulfate was filtered off and the molybdenum determined colorimetrically. Fifty cc. of the solution containing 2–3 cc. of concd. hydrochloric acid, about 2 cc. of concd. sulfuric acid and 1.5 g. of potassium thiocyanate was placed in a separatory funnel with the ether and cooled to 0°; 1 cc. of stannous chloride solution was added and the mixture shaken immediately. Two ether extractions were made, using 70 and 30 cc., respectively, but no color was obtained in the second.

When sodium molybdate furnished the common ion, the lead was separated by a double precipitation with alkaline sulfide,[4] converted into sulfate, dissolved in ammonium acetate to free it from silica, and determined colorimetrically.[7]

The results are shown in Tables V and VI.

Lead molybdate, like the sulfate and chromate, is much less soluble in

perchloric acid than in nitric acid of the same concentration. The solubilities could not be carried far enough to determine whether it would pass through a maximum in perchloric acid as with lead sulfate and chromate.

The solubilities suggest a number of quantitative separations which are now being investigated.

Summary

1. The solubilities of lead sulfate, chromate and molybdate have been determined in perchloric and nitric acids, both with and without the addition of a common ion.

2. All these salts are much less soluble in perchloric acid than in nitric acid of the same concentration.

3. Both the sulfate and chromate pass through a maximum solubility in perchloric acid, and then, as the concentration of acid increases, the solubility decreases.

THE VAPOR PRESSURE OF ALLENE AS A FUNCTION OF TEMPERATURE

BY ROBERT LIVINGSTON AND G. B. HEISIG

RECEIVED MARCH 28, 1930 PUBLISHED JUNE 6, 1930

Since there are at present no data on the vapor pressure of allene available in the literature, it seemed worth while to determine its vapor pressure at a series of temperatures, using a sample of the pure compound which was prepared by one of us (G. B. H.) in connection with a study of its radiochemical and photochemical properties.

The allene was prepared by the action of a suspension of zinc dust on 2,3-dibromo-propene-1. The latter substance was prepared according to the method of Lespieau and Bourguel.[1] The gas was condensed and sealed off in pyrex flasks. One of these flasks was later sealed to the all-glass apparatus and the gas was admitted to the apparatus by means of a magnetic breaking device. The allene was condensed in a liquid-air trap and distilled several times using liquid air as the condensing agent. Any permanent gases present were removed after each condensation by pumping off at a pressure of 10^{-5} mm. The higher-boiling substances were discarded in each distillation and the middle fraction of the final sample was used in this determination

The vapor pressures were measured with an open mercury manometer which was read with an accurate cathetometer. A correction of 1.4 mm. was made for capillary depression. The barometric pressure was recorded at half-hour intervals during the course of the work. The pressure measurements were reproducible within 0.2 mm. The tube containing the liquid allene was surrounded by a Dewar flask filled with an ether–alcohol mixture. The temperature of this bath was adjusted by adding solid carbon dioxide. The temperature measurements, which were reproducible within 0.1°, were made with an accurate platinum resistance thermometer, which was made and calibrated at the Cryogenic Laboratory of the U. S. Bureau of Mines. The calibrations were checked, at the time these measurements were made, at the ice point, 0.0°, and at the freezing point of carefully purified chloroform, −63.5°.

The observed values of the pressure and temperature are listed in the

TABLE I

VAPOR PRESSURE OF ALLENE AS A FUNCTION OF TEMPERATURE

T, °C.	−76 0	−65 4	−55 7	−45 4	−40 2	−36 5
P, mm. (obs.)	85 1	162 4	278 6	469 9	600 8	703 8
P, mm. (calcd)	85 1	162 5	279 3	469 9	599 6	709.6

[1] Lespieau and Bourguel, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1925, Vol V, p 49.

first two lines of Table I. Each of these values is the average of five or six independent measurements. It is improbable that the errors in the absolute values of the pressure and temperature are greater than 2 mm. and 0.2°, respectively.

The values of the pressure given in the last line were computed from the linear equation

$$\log P = -\frac{0.05223}{T} \times 20{,}852 + 7.455$$

The constants of this equation were obtained directly from the experimental measurements (not the averaged values) by the "method of averages." This equation yields, by a short extrapolation, a value at the normal boiling point of −35.0'.

Lespieau and Chavanne[2] measured the boiling points of both allene ($H_2C{=}C{=}CH_2$) and allylene ($CH_3C{\equiv}CH$). For allene they obtained a value of −32.0°, three degrees higher than the value presented here. Their work is not presented in sufficient detail to make a criticism of their experimental methods possible. It is noteworthy that their value for allylene (−23.5') is 4° higher than that based upon the very careful measurements of Maass and Wright.[3] It is not surprising that the vapor pressure equation obtained from the data of Maass and Wright for allylene

$$\log P = -\frac{0.05223}{T} \times 21{,}372 + 7.429$$

differs only slightly from that presented here for the closely related isomer, allene.

Summary

The vapor pressure of pure allene has been measured for the temperature range −76.1 to −36.5,° and these data have been fitted to a linear equation.

STUDY OF THE ADSORPTION OF WATER VAPOR AND CARBON DIOXIDE BY SAMPLES OF MANGANESE DIOXIDE AND HOPCALITE CATALYSTS

BY C. E. LANNING[1]

RECEIVED APRIL 12, 1930 PUBLISHED JUNE 6, 1930

Some time ago work in this Laboratory showed the great activity of manganese dioxide either alone or when mixed with other metallic oxides as an oxidizing catalyst.

These catalysts are capable of considerable variation as to composition but all possess a fineness of texture that renders them highly porous. Owing to their highly porous nature they tend to adsorb vapors readily and in the presence of gases having a considerable tension of water vapor, for instance, are likely to become "poisoned" by the condensation of liquid within the pores of the material. For this reason it was a matter of some interest to investigate the adsorption isotherms of these substances, especially with respect to water vapor and carbon dioxide.

Finely divided manganese dioxide has played a prominent role in the preparation of the most active catalysts of this type; also the conditions under which this oxide is prepared affect considerably its catalytic activity. Among the factors influencing the catalytic activity of the product is the alkalinity of the medium in which the oxide is prepared and consequently the amount adsorbed by the oxide. This effect of alkali might be to alter the degree of subdivision of the manganese dioxide or to alter the character of its surface. It was thought that the effect of alkali treatment on the structure of manganese dioxide could be determined by a careful study of the adsorption isotherms of the manganese dioxide after various treatments and in this way information gained that would be useful in preparing catalysts of this type. In addition it was hoped that such study would throw some light on the poisoning of the catalyst by water vapor, the possible poisoning by carbon dioxide, and the existence of definite hydrates of manganese dioxide which might have some influence on the activity of the catalyst.

Materials

The manganese dioxide was prepared according to the method of Frèmy,[2] which has been found to give uniformly a very finely divided product and to produce the most active catalyst. All samples were taken from this material. In each case the sample was screened and the granules between six and ten mesh selected for experimentation. These were kept in sealed bottles until used.

Sample 1.—The oxide was separated from adhering water as completely as possible

---

[1] The above article forms part of the author's dissertation submitted in June, **1920,** for the Ph.D. degree and the work was carried out at the suggestion of J. C. W. Frazer.

[2] Fremy, *Compt.* rend., 82, **1231 (1876).**

on a Büchner funnel with a water pump. It was then placed in a press and subjected for forty-eight hours to a pressure of several tons per square inch. It was then removed and dried in an air-bath at 110° for three hours.

Sample 2.—The oxide was separated from liquid water on a Büchner funnel as above and dried for three hours in an air-bath at 140°.

Sample 3.—The oxide was dried on a Büchner funnel as above and for three hours in an air-bath at 140°. The material was then placed in a U-tube and for several days a current of a 1% mixture of carbon monoxide and nitrogen was passed over it at a temperature of 140°. Nitrogen was selected as a diluent to guard against overheating and prevent reoxidation.

Sample 4.—The oxide was dried as far as possible on a Büchner funnel. It was then suspended in a 0.1 N solution of sodium hydroxide, stirred thoroughly and allowed to stand for twenty-four hours. It was again dried as much as possible on a Buchner funnel and then for three hours in an air-bath at 140°.

Sample 5.—This sample was the catalyst, containing 63% MnO_2 and 37% Ag_2O.

Experimental

That these materials are very sensitive to changes in the moisture content of the air is shown by the following table giving results obtained by exposing two samples to the atmosphere alongside each other.

TABLE I

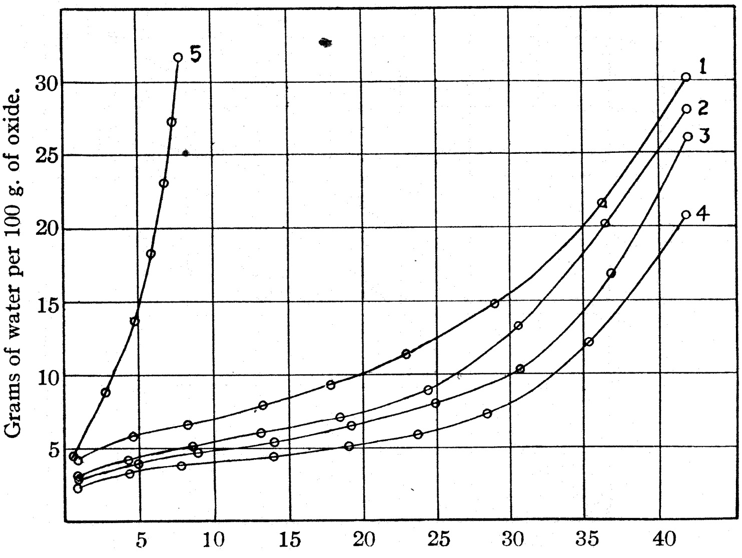
Part I. Adsorption of Water Vapors

The apparatus used for the study of the adsorption of water vapor consisted of a series of ten glass bulbs containing sulfuric acid of different but known concentrations, to establish definite vapor pressures in the system. The concentration of acid used varied from pure water in Bulb 1 to concentrated sulfuric acid in Bulb 10. These bulbs were all sealed to the apparatus and each could be shut off from the remainder of the system by a mercury trap. The sample to be investigated was weighed into a small glass bulb which was provided with a ground-glass stopper and a side tube with a stopcock, which was attached to the system by means of a ground-glass joint. The whole apparatus was contained in an air-bath, the temperature of which was kept constant within 0.10 of a degree. Before beginning the measurements permanent gases were removed from all parts of the system, including the sulfuric acid contained in the bulbs mentioned above, and the small bulb containing the sample. The removal of the air dissolved in the bulb containing pure water, and those containing dilute sulfuric acid, was much more difficult than the removal from the bulb containing strong sulfuric acid; in fact, the permanent gases were given off quite readily from strong sulfuric acid, and the ease with which the dissolved gases could be removed appeared to vary, rather regularly, with the concentration of the acid. The removal of the permanent gases from the whole system is of very great importance, as it has been found that a small concentration of these permanent gases greatly delays the establishment of equilibrium. The manipulation of all parts of the apparatus was accomplished without the necessity of opening the bath. The vapor pressures in the system were determined by means of a cathetometer. The temperature of the bath during this investigation was 35°. The experimental results are shown below in Pig. 1, where, for comparison, there is included a graph of the values obtained by Anderson[3] at 18° for silica gel.



Pig. 1.—Adsorption of water vapor at 35°.

Part II. The Adsorption of Carbon Dioxide

The apparatus used for this part of the investigation was essentially that described by Patrick and McGavack.[4] The bulb containing the sample under investigation was kept at 0° by immersion in ice contained in a Dewar flask. The carbon dioxide used was obtained from a small cylinder of the gas, after allowing the permanent gases to escape as completely as possible. Here, again, permanent gases were removed completely from

[3] Anderson, *Z. physik.* Chem., 88, 191 (1914).

[4] Patrick and McGavack, THIS JOURNAL, 42, 946 (1920).

the whole system before the experiments were begun. The apparatus was carefully calibrated so that, from readings taken with the cathetometer, all of the data could be obtained for the accurate determination of the volume of carbon dioxide introduced into the system and the amount adsorbed at each stage by the sample. The results obtained are given in the form of curves in Pig. 2; again for comparison, the data on the adsorption of carbon dioxide by silica gel, as determined by Patrick,[5] were given. The only departure made in the regular routine procedure adopted was in the case of the sample which in its preparation had been exposed to a solution of caustic soda. In this case the sample was exposed for a considerable length of time to the action of carbon dioxide, which was subsequently pumped out of the apparatus before the experiment was begun.

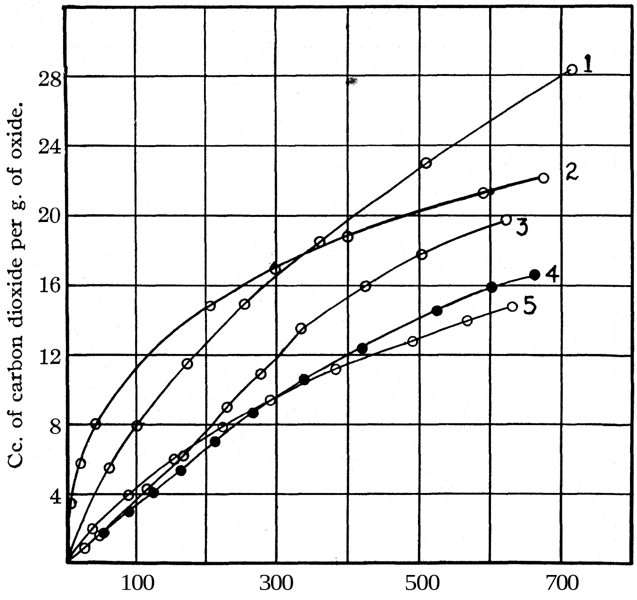


Fig. 2.—Adsorption of carbon dioxide at 0°.

Discussion

Since each point on the curves was duplicated, it is reasonably sure that they represent equilibrium conditions. This conclusion is made more definite because of the care taken in the complete removal of permanent gases from the system. Other work in this Laboratory has shown that in the presence of permanent gases it is very difficult to get true equilibrium in adsorption of vapors. These results show: (1) the highly porous, finely divided nature of all of these samples. Calculation of the approximate size

---

[5] Patrick, "Inaugural Dissertation," Gottingen, 1914.

of the pores from the experimental data given above is not regarded as justifiable, but does indicate that the internal surface of these oxides is very high. (2) The adsorption curve of the sample prepared in the presence of caustic soda does not differ materially from the other curves, and the effect of alkali in depressing the catalytic activity of these oxides cannot be due to a change in the physical structure of the oxide. Other work in this Laboratory[6] has shown that when finely divided manganese dioxide is prepared in the absence of alkali it is extremely active catalytically. The effect of the alkali adsorption must, therefore, be that of a so-called "catalytic poison." **(3)** There is no evidence from any of these curves for the existence of definite hydrates.

Summary

The author has investigated the adsorption of water vapor and carbon dioxide on samples of finely divided manganese dioxide and mixtures of this oxide with other metallic oxides. The results are given in the form of curves and the shape of these curves shows that in neither case is there evidence of the formation of definite chemical compounds, but brings out clearly the very fine porosity of these substances.

CYANOGEN IODIDE AS AN IMPURITY IN IODINE. ITS DETECTION AND ELIMINATION

BY SAMUEL MORRIS, E. B. CALLAGHAN, AND LUCILE DUNLAP

RECEIVED APRIL 14, 1930 PUBLISHED JUNE 6, 1930

Cyanogen iodide is commonly considered one of the chief impurities in commercial iodine. According to Dammer[1] iodine has been known to contain as high as 28.75% of this impurity. Baxter,[2] in his work on the atomic weight of iodine, took great care to eliminate cyanogen iodide. In the method which he used, iodine was suspended in water and treated with hydrogen sulfide, which formed hydriodic acid and, in case cyanogen iodide was present, hydrocyanic acid also. The separation of these two acids, as employed by Baxter, involved long-continued boiling and was based upon the separation of hydrochloric and hydrocyanic acids by the method of Richards and Singer.[3]

In the present paper, study was made first of the separation of known mixtures of hydriodic and hydrocyanic acids. This suggested a procedure for the detection of small quantities of –CN in iodine, which was worked out

[6] Whitesell, THIS JOURNAL, 45, 2841 (1923).

[1] Dammcr, "Handbuch der Anorg. Chem.," Vol. I, p. 542.

[2] Baxter, THIS JOURNAL, 26, 1579 (1904); 27, 876 (1905).

upon samples of iodine with a known content of –CN, and then used for the detection of this impurity in samples of iodine on the market.

Materials

Iodine 1.—Mallinckrodt's C. P. iodine.

Iodine 2.—C. P. iodine which was further purified by reduction to hydriodic acid and subjection to long-continued boiling to remove any possible hydrocyanic acid.

Iodine 3.—Crude Chilean iodine obtained from Mallinckrodt Chemical Works.

Iodine 4.—Seaweed iodine obtained in 1920 from the U. S. Kelp Products Company, Summerland, California.

Iodine 5.—Baker's C. P. iodine.

Cyanogen Iodide.—The general method of preparation by Linnemann[4] was followed and a very pure product was obtained.

Experimental

By reducing mixtures of known weights of iodine and cyanogen iodide with hydrogen sulfide, mixtures of hydriodic and hydrocyanic acids of known concentrations were obtained. These mixtures were boiled in a balloon flask connected with an ordinary water-cooled condenser. The volume of the undistilled mixture was kept practically constant by adding water from time to time. Successive portions (10 to 12 cc.) of the distillate were collected and these tested for –CN by the ordinary qualitative test involving the formation of Prussian blue.

Preliminary experiments, the results of which are not recorded in this paper, showed that upon distilling dilute mixtures of hydriodic and hydrocyanic acids, the hydrocyanic acid was concentrated in the first portions of the distillate. After about two hours of boiling, the concentration of the hydrocyanic acid in the distillate was so low that 10-cc. portions failed to show any test for the acid.

In all experiments in Table I the above procedure was carried out, except that in Expts. 6 to 9 no ICN was added. In Expts. 1 to 5, Table I, the percentage of ICN added in succeeding experiments was steadily decreased.

[4] Linnemann, *Ann.*, 120, 36 (1861).

The test for –CN in Expt. 5 was so slight, even in Portion I of the distillate, that the limit of detectability by this procedure, was considered substantially reached.

Since upon distilling mixtures of hydriodic and hydrocyanic acids the latter acid is concentrated in the first portion of the distillate, it seemed likely that by repeated redistillation the hydrocyanic acid could be concentrated in a small volume. To test this out, the first distillate was collected over a period of about nine hours and was large in volume. This in turn was distilled, but for a shorter time, resulting in a smaller distillate. After ten similar operations about 15 cc. remained, which was tested for –CN. This procedure was employed in all experiments in Table II, instead of the procedure involving a single distillation as used in Table I, and resulted in the detection of a considerably smaller percentage of –CN. The least amount detected by single distillation was 0.0006% in Expt. 5, while by repeated distillation, in Expt. 14, 0.00015% was detected.

TABLE II

RESULTS OF EXPERIMENTS

Expt.	HI and HCN soln , cc	Iodine, g	Iodine sample	ICN added, g	ICN, %	–CN, %	Times redistilled	–CN in final distillate
10	1500	226 0	5	None			10	None
11	1500	450 0	5	None			10	None
12	1500	450 0	2	0 0081	0 0018	0 000305	10	Present
13	1500	450 0	2	0016	00035	.00006	10	None
14	3000	902 0	2	0081	00089	00015	10	Present

In Expts. 6 to 11 samples of iodine from various sources on the market today were examined for –CN, but none was found. A larger sample of iodine of seaweed origin was desired for Expt. 9 but could not be obtained.

Summary

1. Hydriodic and hydrocyanic acids, in dilute solution, can be separated by boiling.
2. A procedure is given by which a small percentage of –CN in iodine (approximately 0.00015%) may be detected by the Prussian blue test.
3. No cyanogen iodide could be detected in samples of iodine on the market today.

THE REACTION BETWEEN NITROGEN AND HYDROGEN IN THE PRESENCE OF MERCURY VAPOR AND THE RESONANCE RADIATION OF MERCURY

BY W. ALBERT NOYES, JR.

RECEIVED APRIL 24, 1930 PUBLISHED JUNE 6, 1930

In a previous article[1] some experiments on the reaction between nitrogen and hydrogen in the presence of mercury vapor and the resonance radiation of mercury were described. It was pointed out that formation of ammonia was not observed either when a flow method was used or with low temperatures and low pressures of nitrogen, hydrogen and mercury vapor. Only at pressures of one atmosphere and higher and at the temperature of boiling mercury was there any observable formation of ammonia. In the article it was assumed that the important step was the formation of atomic hydrogen through the agency of excited mercury. A reconsideration[2] made it seem possible that the walls of the vessel may have exerted some influence on the reaction. Positive results, obtained under different conditions, have been reported by Hirst[3] and Willey and Rideal.[4]

Subsequently, Taylor and Marshall[5] have shown that monatomic hydrogen produced through the agency of excited mercury will not react with nitrogen to form ammonia under different experimental conditions. Bonhoeffer[6] has also shown that monatomic hydrogen produced by Wood's method[7] will not react with nitrogen to form ammonia.

All of these researches may be interpreted as showing that the production of monatomic hydrogen is not sufficient to initiate the reaction between hydrogen and nitrogen.[8] Recently, however, articles by Gaviola[9] and Beutler and Rabinowitsch[10] have given a possible explanation for the formation of ammonia under the conditions of the previous experiments.[1]

In Gaviola's experiments[9] the NH band at 3360–3370 Å. was observed in a mixture of N_2 and H_2 in the presence of excited mercury. The intensity of this band was proportional to the square of the intensity of the exciting light, a fact which led him to propose the primary mechanism $N_2 + 2Hg' = 2N + 2Hg$. The maximum energy available from two mercury atoms in

the 2^3P_1 state corresponds to 9.8 volts, so that the heat of dissociation of nitrogen must represent a value lower than this amount. The heat of dissociation of nitrogen has been revised downward during the past few years and is now fixed at a probable value in the neighborhood of 9 volts.[11] Beutler and Rabinowitsch propose a mechanism involving two metastable mercury atoms (2^3P_0) each possessing an energy of 4.64 volts. This mechanism they give as follows: 2Hg (4.64 v.) = Hg (9.1 v.) + Hg + 0.18 v. and 2Hg (4.64 v.) + N_2 = N + N + 2Hg + 0.18 v. The production of monatomic nitrogen and the undoubted production of monatomic hydrogen should lead to the formation of some ammonia.[8] The first step may be N + H = NH (by triple collision or on the walls) or N + H_2 = NH + H, followed by NH + H_2 = NH2 + H and NH_2 + H_2 = NH_3 + H or by other processes involving triple collisions. It is not improbable that all of these reactions are possible energetically.

We may now inquire as to whether this mechanism agrees at all with the previously found facts.[12] The increase in total pressure would have the effect of broadening the absorption line of mercury, thereby increasing the amount of radiation absorbed and increasing the chance of reaction. Another effect would be the conversion of excited 2^3P_1 atoms into metastable 2^3P_0 atoms by collision. Since these have a longer life, the process described by Beutler and Rabinowitsch would become somewhat more probable. In addition the absorption would take place in a region nearer the walls, thereby effecting an increase in concentration of energy-rich atoms in a small region and increasing the probability of processes involving two of them.

It is to be noted that only small amounts of ammonia were formed, approximately the amount required at thermodynamic equilibrium. This is to be expected, since the excited mercury is known to cause the decomposition of this substance.'' Hence a steady state would be expected under a given set of conditions with the amount of ammonia at a low value.

Summary

Possible explanations for the previously reported formation of ammonia from nitrogen and hydrogen in the presence of mercury vapor and the resonance radiation of mercury have been discussed.

NOTES

A Note on the Density of **Glycine.**—A search of the literature and various handbooks reveals considerable confusion with reference to the density of glycine.

Landolt–Börnstein–Roth–Scheel give the density as 1.60. In the "International Critical Tables" the density is given as 1.160 at 20°. The value given by the "Handbook of Chemistry and Physics" is 1.161 at 15°. Beilstein gives the density of glycine as 1.161. Curtius[1] determined the density of glycine, obtaining the values of 1.1607.

The density of glycine was desired at 50°. The pycnometer method using xylene as the liquid being displaced was employed. Data were obtained with three different materials.

Eastman practical glycine gave an average value of 1.623 as the density at 50°, Eastman purified 1.5767, and Pfanstiehl purified 1.5740, the mean of the purified materials being 1.5753.

These results indicate a value of 1.5753 as the density, at 50°, of purified glycine. The results also seem to point to a typographical error in the original publication of Curtius, this value apparently being the source of the values given in the various handbooks.

Differential Fractional Distillation.—Several authors[1] have shown that the original method of plotting potentiometric titration data (the electromotive force, E, against the volume of reagent, V) could be improved upon by plotting the slope of the above curve, $\Delta E/$ AV, as a function of V. The point of interest in the first type of curve is the point of inflection, while in the second type the point of interest is a sharp maximum. It seems that the common practice in plotting data from fractional distillation is to plot the volume of the distillate, V, against the temperature, T. In this curve, the boiling point of a component is a point of inflection. By direct analogy to the potentiometric titration, the author wishes to suggest that the fractional distillation data can be more readily interpreted if the slope of that curve, $\Delta V/$ AT, is plotted against T. In this derived curve the boiling point of each component would be a sharp maximum,

Inorganic Lubricants. I. Amalgams.—The great specific gravity and the fluidity of mercury have long permitted its use as a floating and lubricating liquid in the support of astronomical and other heavy moving instruments. Bearings have been operated in a bath of mercury as lubricant.[1] It has been proposed also to use a film of mercury or amalgam as lubricant on metal bearings,[2] as well as "soft metals" such as copper–zinc amalgams.[3]

For some laboratory operations, such as those involving gases from which aqueous and organic vapors must be excluded, mercury or its fluid amalgams would be found useful as a lubricant for glass stopcocks and ground joints, except for the difficulty in obtaining an adherent film of the metal over the ground-glass surface and so securing the sealing of the joint. This difficulty may, however, be largely overcome in the following manner.

Carefully clean and dry the ground surfaces and then heavily silver them with ammoniacal silver nitrate and rochelle salt solution. Surfaces not to be silvered and passage openings may be protected by a thin layer of paraffin or ceresin wax. Immersion in as many as three to five fresh silvering solutions is usually necessary in order to secure the thickness of silvering required, although this depends upon the exact silvering formula used; too thick deposits obviously lessen the tightness of fit. After each deposition of metal the surface should be well rinsed in distilled water, but otherwise not disturbed.

The silvered surfaces finally obtained are then allowed to dry. Wax coatings on the passage openings should be entirely removed at this time. Amalgam paste or liquid is then dropped on the concave ground surface and the grinding parts are brought together and rotated gently with little contact pressure. Amalgamation of the silver rapidly takes place, and is complete when the motion is smooth and non-gritty, yielding a coherent film over the parts in contact, and tight lubrication.

These amalgamated surfaces are, as a rule, not permanent, but with care will endure through a number of operations lasting over several days, particularly if more amalgam is occasionally applied. They are rapidly destroyed on contact with aqueous solutions of many salts or with acid gases, and may not be used successfully with such materials, although when pure

mercury is employed instead of an amalgam, an acid-resisting film is formed the ordinary life of which, however, is shorter than that of films formed with complex liquid amalgams.

The complex amalgam employed may be almost any dilute mercury solution. One such is a mixture of 5 g. of solder, 5 g. of Wood's metal, 2.5 g. of zinc and 80 g. of mercury, solution being effected with heat. Such a liquid also has the curious property of wetting clean, polished glass surfaces with ease.

STUDIES IN QUINOLINE SYNTHESES

BY WILLIAM LYALL BARR

RECEIVED JULY 25, 1929 PUBLISHED JUNE 6, 1930

Historical.—The Skraup synthesis is variously formulated as involving intermediate formation of (I) acrolein anil, (II) β-anilinopropionaldehyde or (III) the anil of this aldehyde. The literature affords no definite evidence for the formation of a type I intermediate; there are results compatible with the formation of an intermediate of either type II or type III, but not of type I. Thus Murmann[1] obtained 2-phenylquinoline, not 4-phenylquinoline, by the condensation and oxidation of cinnamaldehyde and aniline, and Blaise and Maire[2] formed 4-ethylquinoline from anilinoethyl ethyl ketone heated with aniline hydrochloride.

From the work of Beyer, Engler and Riehm, and Knoevenagel, the last named investigator has shown[3] that quinoline formation from simple ketones or aldehydes and aromatic amines proceeds by the intermediate formation of ketylidene or alkylidene anils, which form dimerides and then quinoline derivatives; *e.* g., from aniline and acetone

Baehr, *ibid.*, 55, 1912 (1922); Knoevenagel and Goos, *ibid.*, 55, 1929 (1922); Knoevenagel, Wagner and v. Baehr, *ibid.*, 56, 2414 (1923).

Any mesityl oxide or similar condensation product of the aldehyde or ketone is broken down to give the simple anil. The dimerides here mentioned are akin to the type III intermediate.

Another piece of evidence for the formation of the type III intermediate is the production of quinoline by Konig and Seifert[4] from $C_6H_5NHCH{=}CHCH{=}NC_6H_5$ heated with zinc chloride.

Theoretical.—Formation of a type I compound would involve reaction at only one double bond of a conjugate system, which is improbable, especially at a high temperature. Condensation of aniline with acrolein may be expected to be by the usual 1,4-addition. Polarity effects would lead to $C_6H_5NHCH_2CH{=}CHOH$, which can rearrange to the type II compound; but at the high temperature of the reaction, in the presence of aniline and the dehydrating agent, sulfuric acid, it is exceedingly unlikely that the aldehyde group would remain unattacked during the comparatively slow process of ring formation. Furthermore, as will be shown later, β-anilinopropionaldehyde polymerizes spontaneously to a substance from which no quinoline can be obtained.

Interaction of this aldehyde with aniline, however, would yield the type III compound, able to form quinoline by oxidation and splitting off of aniline, as shown by the work of Knoevenagel and of Konig and Seifert.

Experimental

In this work quinoline was detected in neutral aqueous emulsion or solution by the production with potassiomercurie iodide solution of a white amorphous precipitate which became yellow and crystalline on addition of dilute hydrochloric acid.[5] Recrystallized from hot water, this precipitate from quinoline melted at 144–146°.

The product of the direct interaction of acrolein and aniline, described by Mann,[6] was first studied; the observations that this base yielded no quinoline on treatment with sulfuric acid and arsenic oxide or nitrobenzene (Mann) or chromic acid (Konig) were confirmed. A similar negative result was found on oxidation with acid permanganate or ferric chloride. This base, $C_{18}H_{20}ON_2$, is evidently far more complex than the Skraup intermediate.

An attempt was made to carry out the series of reactions

$$C_6H_5NH_2 + ClCH_2CH_2CH(OEt)_2 \longrightarrow C_6H_5NHCH_2CH_2CHO \longrightarrow C_6H_5NHCH_2CH_2CH{=}NC_6H_5$$

Raeth's work[7] on this type of condensation of chloro-acetals with aromatic amines is spoiled by inconsistent nomenclature; and Konig and

[7] Raeth, ***Ber.***, 57, 550, 715 (1924).

Buchheim[8] have shown that in some of his work Raeth failed to identify the product correctly, and that no cyclization had occurred.

Direct interaction in dry ethereal solution of 1 mole of aniline and 1 mole of β-chloropropionacetal yielded aniline hydrochloride and, presumably, acrolein acetal. Use of excess aniline (2.5 moles) yielded aniline hydrochloride and a brown viscous liquid which, after removal of most of the aniline by distillation in *vacuo,* changed to a dark red solid gum, soluble in alcohol and acetone, which would not crystallize or distil without decomposition even *in vacuo.* The last traces of aniline could not be removed; yield, 20–25%; N, 7.0% (anilinopropionacetal, N, 6.3%). This crude residue yielded a tiny amount of quinoline on treatment with sulfuric acid and arsenic oxide or nitrobenzene. As free aniline was present, no conclusion can be drawn as to the-mechanism of the reaction.

Acid hydrolysis of this substance yielded, instead of β-anilinopropionaldehyde, a pink sticky gum which gave no aldehyde tests. An apparent polymer of this aldehyde was obtained by interaction of the chloro-acetal and a large excess of aniline in ether shaken with a saturated solution of sodium bicarbonate; distillation of the mixed bases in steam removed aniline and effected hydrolysis, leaving a brown resin soluble only in acetone and nitrobenzene; N, 9.4%; mol. wt. in nitrobenzene, 495 (anilinopropionaldehyde, N, 9.4%; mol. wt., 149). This aniline-free substance yielded no quinoline.

All attempts to condense the crude anilinopropionacetal base with aniline by the action of concd. hydrochloric acid or 70% sulfuric acid proved unsuccessful. Hence the type III intermediate was not obtained, and no conclusion can be drawn as to its place in the Skraup synthesis.

Attempts were made to effect cyclization with propionanilide and with allylaniline.

Propionanilide could not be made to undergo ring formation by heating with zinc dust, or with nitrobenzene and zinc chloride or sulfuric acid; nor by passing through a hot tube in air alone or over lead oxide.

Koenigs obtained quinoline from allylaniline vapor passed over lead oxide in a hot tube. Cyclization to quinoline was attempted under the conditions of the Skraup reaction.

Ten g. of allylaniline and 20 g. of sulfuric acid with 8 g. of nitrobenzene or 20 g. of arsenic oxide dried at 170° were refluxed for several hours, and the dark viscous mixture worked up for quinoline. There was much charring and production of tarry matter. Quinoline was detected in small quantities in every case; yield, about 1%. Picric acid was tried in place of nitrobenzene (*vide* Murmann), but it made the reaction explosively violent.

Based on a preparation of acrolein by Wohl and Mylo[10] from glycerol vapor passed over heated magnesium sulfate, a synthesis of quinoline was attempted from the vapors of aniline and glycerol aspirated in air or carbon dioxide over magnesium sulfate at 370–400°, with nitrobenzene vapor or lead oxide as oxidizing agent. No quinoline could be detected in the products of the reaction.

To try to reduce the number of distillations in steam in the Skraup synthesis from three to two, transformation of excess aniline to phenol with nitrous acid was tried in the

---

[8] König and Buchheim, *Ber.,* 58,2868 (1925)

[9] Koenigs, *ibid.,* 12, 453 (1879).

[10] Wohl and Mylo, *ibid.,* 45, 2046 (1912).

acid reaction mixture after distillation in steam to remove nitrobenzene and dilution with water. These attempts were unsuccessful, for though excess nitrous acid was shown to be present, the resulting quinoline contained a considerable amount of aniline. The destruction of aniline was incomplete even with the clear reaction mixture obtained by the method of Cohn and Gustavson.[11]

The author wishes to express his grateful thanks to Dr. J. K. H. Inglis for his kind interest and helpful advice in this investigation.

Summary

1. As neither β-anilinopropionaldehyde nor its acetal or anil could be obtained pure, nothing can be concluded as to the constitution of the Skraup intermediate.
2. Allylaniline can yield small quantities of quinoline by oxidation in solution.

NITRIDATION STUDIES. I. INTRODUCTION. II. MERCURIC NITRIDE AND BISMUTH NITRIDE AS NITRIDIZING AGENTS[1]

BY IMAN SCHURMAN AND W. CONARD FERNELIUS

RECEIVED DECEMBER 12, 1929 PUBLISHED JUNE 6, 1930

I. INTRODUCTION

The term "nitridation" or "nitridation reaction"[2] has been applied to all those reactions which for the ammonia system of compounds are essentially similar to oxidation reactions for the familiar water compounds or for those reactions in which nitrogen plays a part analogous to that played by oxygen in ordinary simple processes of oxidation.

Numerous examples of nitridation reactions are known.[3]

The only agents to be examined to any extent, however, are hydrazoic

---

[11] Cohn and Gustavson, THIS JOURNAL, 50, 2709 (1928).

[1] The material presented in this paper is from a portion of a thesis submitted by Iman Schurman in partial fulfilment of the requirements for the Degree of Master of Science at The Ohio State University.

[2] (a) Browne and Welsh, THIS JOURNAL, 33, 1728 (1911); Franklin, *J. Phys. Chem.*, *27*, 169 (1923); cf. Goldberg, THIS JOURNAL, 34, 886 (1912). Turrentine [*ibid.*, 34, 386 (1912)] calls hydrazoic acid a nitridizing agent because many of the reactions of hydrazoic acid are similar to those of nitric acid, an oxidizing agent. (b) Cady and Taft [*Science*, 62, 403 (1925)] have proposed the terms "electronation" and "delectronation" to be used in place of "reduction" and "oxidation" in the broad sense. Accordingly "nitridation" would be a particular type of "delectronation."

acid (ammono nitric acid) and a solution of iodine in liquid ammonia which undoubtedly contains iodo-amine, H_2NI, ammono hypoiodous acid.[4] In addition, certain electrolytic nitridations have been carried out.[5]

The present investigation was undertaken in an endeavor to increase our knowledge concerning nitridation and particularly to discover new nitridizing agents.

II. MERCURIC NITRIDE AND BISMUTH NITRIDE AS NITRIDIZING AGENTS

Mercuric oxide is a substance sometimes used as a mild oxidizing agent.[6] Its ammonia analog, mercuric nitride, should then be a mild nitridizing agent. The explosiveness of mercuric nitride[7] when dry is in harmony with this view. Hydrazobenzene was chosen as a substance to be nitridized because it has been oxidized to azobenzene by means of mercuric oxide[8] and nitridized electrolytically in liquid ammonia solution.[2b]

A preliminary nitridation using a solution of iodine in liquid ammonia showed that hydrazobenzene is easily converted into azobenzene. Mercuric nitride reacts with hydrazobenzene in accordance with the equation

$$3C_6H_5NHHNC_6H_5 + Hg_3N_2 \longrightarrow 3Hg + 3C_6H_5N{=\!=}NC_6H_5 + 2NH_3$$

p-Hydrazotoluene is likewise nitridized to *p*-azotoluene by both iodine and mercuric nitride.

Another nitride showing a considerable degree of instability is bismuth nitride.[9] In preparing this substance Franklin found that it is always contaminated with metallic bismuth as a result of its spontaneous decomposition. In harmony with this behavior of bismuth nitride, the present investigation shows that both hydrazobenzene and *p*-hydrazotoluene are nitridized to the corresponding azo compounds in liquid ammonia solution by bismuth nitride.

Whenever an hydrazo compound was added to either of the nitride precipitates, the solution above the insoluble nitride became dark red. Such behavior undoubtedly indicates either that mercuric and bismuth nitrides—although very insoluble in liquid ammonia—are, nevertheless, sufficiently soluble to give a weakly basic solution, or that the potassium amide had not been entirely removed from these nitride precipitates although the

[9] Franklin, Ref. 7, p 847.

number of washings should have been sufficient to remove it. White and Knight[10] observed a similar coloration when a solution of hydrazobenzene or azobenzene was treated with a sodium solution and attributed their results to the formation of a salt, $C_6H_5N(Na)\text{-}N(Na)C_6H_5$. When a solution of hydrazobenzene or *p*-hydrazotoluene is treated with a solution of potassium amide, a brown coloration develops. Cady and Taft observed a similar coloration with sodium amide and hydrazobenzene. The present investigation has shown that this reaction with the alkali metal amides is a reversible one so that the hydrazo compounds, like triphenylmethane,[11] serve as very sensitive indicators of the Ostwald type in liquid ammonia. In pure liquid ammonia or in the presence of an ammonium salt (an acid) the hydrazo compounds yield a light brownish-yellow solution, while in the presence of soluble bases, even at very low concentrations, the deep red-brown color of the alkali metal salt appears. Even potassium hydroxide, whose solubility in ammonia is exceedingly low, imparts a distinct brown color to the solution of hydrazobenzene. Sodium peroxide is also sufficiently soluble in liquid ammonia to give a similar coloration.[2b]

Hexamethylenetetramine, amylene, styrene and azoxybenzene in liquid ammonia show no reaction with mercuric nitride over the space of one week.

Experimental

In carrying out the reactions described in this paper the familiar methods used by Franklin and his co-workers[12] have been employed. In one leg of a two-legged reaction tube was placed a convenient amount of purified and dried mercuric iodide or bismuth iodide; in the other, an excess of potassium, contained in a short length of glass tubing, together with a spiral of iron wire. On distilling ammonia into the reaction tube both the iodide and the potassium dissolved. In the presence of the iron wire catalyst the potassium was rapidly converted, usually in a half hour, into the soluble potassium amide.

After partially opening the stopcock for a moment to release the pressure of the evolved hydrogen, the solution of potassium amide was poured into the leg containing the iodide—an excess of potassium amide was necessary to prevent the formation of ammono-basic salts. The nitride precipitated and settled rapidly.

$$3HgI_2 + 6KNH_2 \longrightarrow Hg_3N_2 + 4NH_3 + 6KI$$
$$BiI_3 + 3KNH_2 \longrightarrow BiN + 2NH_3 + 3KI$$

These precipitates were washed by decantation with fresh ammonia about

[12] Franklin, *ibid.*, **27**, 831 (1905); **29**, 1275 (1907); **35**, 1460 (1913); J. *Phys. Chem.*, *15*, 510 (1911); 16, 694 (1912); Fitzgerald, THIS JOURNAL, **29**, 1694 (1907); Bohart, J. *Phys. Chem.*, *19*, 539 (1915).

five times, to free them of potassium iodide and potassium amide. The solvent was next distilled into the leg containing the precipitated nitride. This leg was then cooled in a bath of liquid ammonia which was open to the atmosphere and the leg containing the washings was opened and cleaned. Finally the hydrazo compound was added and this leg resealed. After the seal had cooled, the other leg of the tube was removed from the liquid ammonia and allowed to warm to room temperature. The hydrazo compound was dissolved in ammonia and the solution poured over the nitride. The final reaction product was obtained by allowing all of the ammonia to evaporate from the tube, or by distilling the solvent into the opposite leg and cooling this leg in an open bath of ammonia. In either case the end of the tube was scratched with a file and broken off by means of a piece of hot glass.

The azo compounds were purified by recrystallization either from ligroin or liquid ammonia. Azobenzene and p-azotoluene are only slightly soluble in liquid ammonia at the temperature of an open bath of the liquid (about $-40°$).

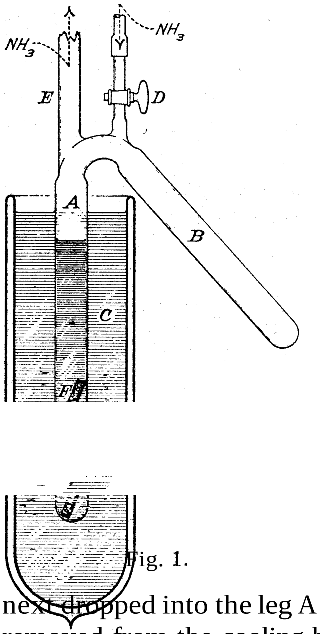

Fig. 1.

For those experiments in which iodine was used as the nitridizing agent, a two-legged reaction tube fitted with an addition tube was employed (Fig. 1). The tube was sealed up with the hydrazo compound in leg **A.** After distilling ammonia into the tube, leg A, was cooled in an open bath of liquid ammonia. With a stream of gaseous ammonia entering at D, the end of the addition tube, E, was cracked off with a bit of hot glass. Short pieces of glass tubing packed with the desired weight of iodine were next dropped into the leg A and tube E resealed.[13] After the tube had been removed from the cooling bath and allowed to warm to room temperature, the iodine slowly dissolved and reacted with the solution.[14]

The hydrazobenzene and *p*-hydrazotoluene used in this research were prepared by reducing the corresponding azo compound with zinc dust in a hot alcoholic alkaline solution[15] and recrystallizing from alcohol; m. p. of hydrazobenzene, 129°; *p*-hydrazotoluene, 124'. The values listed in the "International Critical Tables" are 131 and 126°, respectively.

---

[13] Such a modification of the usual procedure is necessary because iodine liquefies in a stream of gaseous ammonia and forms a dangerously explosive mixture.

[14] This is the technique employed by Strain (Ref. 3), although not described fully by him.

[15] Gattermann, "Practical Methods of Organic Chemistry," translated by Schober and Babasinian, **3d** English ed frqm 11th German ed., 1928, p. 228.

Hydrazobenzene and Iodine.—To a solution of 0.2 g. of hydrazobenzene in liquid ammonia was added an excess of iodine. After all of the iodine had dissolved (three hours), the solution was cooled in an open-bath of liquid ammonia. The lowering of the temperature caused the separation of orange crystals (m. p. 68°). A mixture of equal quantities of these crystals and azobenzene fm. p. 68°) melted at 68°.

p-Hydrazotoluene and Iodine.—To an ammonia solution containing **0.14** g. of p-hydrazotoluene was added an excess of iodine. Overnight all of the iodine had disappeared and orange crystals had separated out. After washing three times with fresh ammonia, these crystals melted at 144°; when mixed with p-azotoluene, melting at 144°, the mixture melted at 144°.

Hydrazobenzene and Mercuric Nitride.—To the mercuric nitride prepared from **1.22** g. of the iodide was added **0.18** g. of hydrazobenzene in ammonia solution. At the end of two days, small globules of metallic mercury were visible in the bottom of the reaction tube. The ammonia-soluble product upon recrystallization from ligroin melted at 67.5°. An equal mixture of these crystals and azobenzene, melting at 68°, melted at **67.5".**

***p*-Hydrazotoluene** and Mercuric Nitride.—Two and one-tenth g. of mercuric iodide was converted to the nitride and treated with an ammonia solution containing **0.22** g of p-hydrazotoluene. At the end of two days finely divided mercury as well as a precipitate of p-azotoluene was visible in the tube. The latter product after extraction with ammonia and recrystallization from ligroin gave orange-yellow crystals which melted at 143°. A mixture of equal quantities of these crystals and those of *p*-azotoluene (m. p. **144")** melted at **143.5°**.

Hydrazobenzone and Bismuth Nitride.—To the bismuth nitride obtained from **1.32** g. of the iodide was added a solution containing **0.51** g. of hydrazobenzene. The mixture was allowed to stand for two days. The reaction product recrystallized from ligroin gave **0.483** g. of red crystals which melted at 67°; yield, 95%. A mixture of these crystals and an equal quantity of azobenzene melted at 67°.

Hydrazotoluene and Bismuth Nitride.—One and three-tenths grams of bismuth iodide and an excess of potassium were sealed in opposite legs of a reaction tube and ammonia distilled into the leg containing the iodide. During the subsequent distillation of ammonia from this leg into that containing the potassium small yellow needle crystals were observed in the iodide leg. Such a behavior indicates the probable existence of a moderately soluble ammono-basic iodide of bismuth.[16] The solution of *p*-hydrazotoluene remained in contact with the nitride for two days. On recrystallizing the reaction product from ligroin, orange-yellow crystals were obtained which melted at **143°**; a mixed melting point with p-azotoluene gave **143.5'.**

Hydrazobenzene as an Indicator.—In the legs of a three-legged reaction tube were sealed **0.5** g. of ammonium nitrate, a small amount of hydrazobenzene and **0.3** g. of potassium, respectively. After the conversion of the potassium to the amide, a drop of this solution was added to the yellow solution of hydrazobenzene. Immediately a reddish-brown color developed. Upon the careful addition of a drop of ammonium nitrate, the hydrazobenzene solution resumed its original yellow color. With the same sample of indicator, this process of discharging the color induced by bases was repeated several times.

Small amounts of hydrazobenzene and potassium hydroxide were sealed in a one-legged reaction tube and ammonia was distilled onto the mixture. The solution was colored dark brown.

***p*-Hydrazotoluene** as an Indicator.—A three-legged tube similar to the one de-

---

[16] Franklin and Cady [Tars JOURNAL, 26, **512** (1904)] report a similar ammono-basic bismuth nitrate.

scribed abovr was charged with ammonium chloride, *p*-hydrazotoluene and potassium amide. The same induction and discharge of color were observed as in the case above.

Summary

1. Mercuric nitride and bismuth nitride have been shown to have the properties of nitridizing agents.

2. Hydrazobenzene and *p*-hydrazotoluene have been nitridized to the corresponding azo compounds in liquid ammonia solution using iodine, mercuric nitride and bismuth nitride.

3. Because of the formation of highly colored salts, both hydrazobenzene and hydrazotoluene may be used as sensitive acid-base indicators in liquid ammonia solutions.

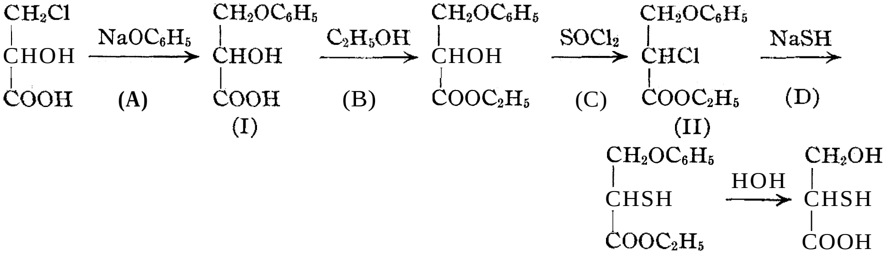
THE MONOPHENYL ETHERS OF GLYCERIC ACID

BY C. FREDERICK KOELSCH

RECEIVED JANUARY 11, 1930 PUBLISHED JUNE 6, 1930

Investigations on the oxidation of β-thioglyceric acid, whose preparation was described in a previous paper,[1] showed the desirability of extending the study there outlined to the still unknown α-thioglyceric acid. It was considered feasible to attempt the preparation of this compound through the following reactions:



$$\begin{array}{c}CH_2Cl\\|\\CHOH\\|\\COOH\end{array}\xrightarrow[(A)]{NaOC_6H_5}\underset{(I)}{\begin{array}{c}CH_2OC_6H_5\\|\\CHOH\\|\\COOH\end{array}}\xrightarrow[(B)]{C_2H_5OH}\begin{array}{c}CH_2OC_6H_5\\|\\CHOH\\|\\COOC_2H_5\end{array}\xrightarrow[(C)]{SOCl_2}\underset{(II)}{\begin{array}{c}CH_2OC_6H_5\\|\\CHCl\\|\\COOC_2H_5\end{array}}\xrightarrow[(D)]{NaSH}\begin{array}{c}CH_2OC_6H_5\\|\\CHSH\\|\\COOC_2H_5\end{array}\xrightarrow{HOH}\begin{array}{c}CH_2OH\\|\\CHSH\\|\\COOH\end{array}$$

Reactions A, B and C were carried out successfully. Reaction D did not proceed as indicated; when ethyl α-chloro-β-phenoxypropionate (II) was treated with sodium hydrosulfide, a practically quantitative yield of phenol was obtained. The remainder of the reaction mixture was a black tar, the constituents of which are as yet unidentified. A study of this reaction is in progress.

This paper deals with the substances obtained in Reaction A. The reaction between p-chlorolactic acid and sodium phenoxide gave a satisfactory yield of β-phenoxylactic acid (I), but when the reaction mixture was worked over, it was found that this was not the sole product. Along

---

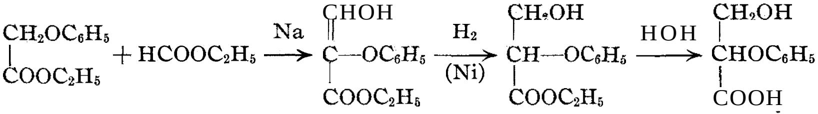
[1] Koelsch, THIS JOURNAL, 52, 1105 (1930).

with the β-phenoxylactic acid melting at 157.5–159°, there was obtained about 1% of a more soluble acid melting at 107–109°. The analysis and neutral equivalent of this compound indicated that it was isomeric with β-phenoxylactic acid.

On treatment with hydriodic acid, the low-melting acid gave phenol and β-iodopropionic acid, the same products which were obtained by a similar treatment of β-phenoxylactic acid. It seemed probable, therefore, that the low-melting compound was a-phenoxyhydracrylic acid (IV).

That the acid melting at 157.5–159° was the expected β-phenoxylactic acid was proved by converting it into the chloro ester (II) which was dehalogenated to give ethyl β-phenoxypropionate. The acid resulting from the hydrolysis of this ester was identified as β-phenoxypropionic acid by comparison with a sample prepared from β-bromopropionic acid.

That the acid melting at 107–109° was a-phenoxyhydracrylic acid was shown by its synthesis according to the following series of reactions



$$\begin{array}{l}CH_2OC_6H_5\\ |\\ COOC_2H_5\end{array} + HCOOC_2H_5 \xrightarrow{Na} \begin{array}{l}CHOH\\ \|\\ C{-}OC_6H_5\\ |\\ COOC_2H_5\\ \text{(III)}\end{array} \xrightarrow[(Ni)]{H_2} \begin{array}{l}CH_2OH\\ |\\ CH{-}OC_6H_5\\ |\\ COOC_2H_5\end{array} \xrightarrow{HOH} \begin{array}{l}CH_2OH\\ |\\ CHOC_6H_5\\ |\\ COOH\\ \text{(IV)}\end{array}$$

The reduction of formylphenoxyacetic ester (III) with zinc dust and acetic acid, with amalgamated zinc and acetic acid, or with amalgamated aluminum in neutral solution caused phenol to be eliminated from the molecule. The o-benzoate of the enol was unaffected by amalgamated aluminum. The reduction of the free enol was finally accomplished by using molecular hydrogen in the presence of catalytic nickel.

The first explanation for the formation of a-phenoxyhydracrylic acid which suggested itself was that the β-chlorolactic acid used was contaminated with a-chlorohydracrylic acid, and that the sodium phenoxide reacted with this to replace the halogen atom directly with the phenoxyl radical. Certain facts militating against this explanation may be brought forward. The β-chlorolactic acid[1,2] used was prepared from a-monochlorohydrin obtained by the action of hydrogen chloride on glycerol.[3] This monochlorohydrin subjected to the further action of hydrogen chloride gives a dichlorohydrin which has been shown to be nearly free of the α,β-compound.[4] Hence the monochlorohydrin used contained very little of the β-isomer, which would be the precursor of a-chlorohydracrylic acid. Although the above evidence does not preclude the possibility; that only 1%

---

[2] The acid melting at 45–72" obtained from the oxidation was used without recrystallization. The unsharp melting point is considered to be caused by the presence of oxalic acid and, mainly, water.

[3] Conant and Quayle, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1923, Vol. II, p. 33.

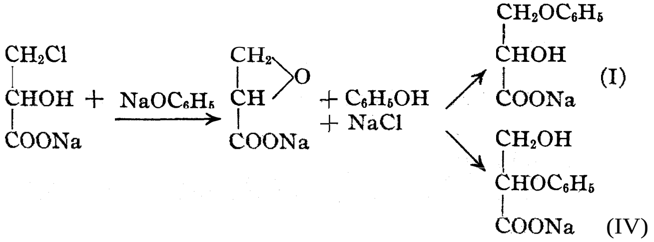
[4] Conant and Quayle, THIS JOURNAL, 45, 2771 (1923).

of a-chlorohydracrylic acid may be present, Melikoff's experiments indicate that this acid would yield β-phenoxylactic acid rather than α-phenoxyhydracrylic acid.

Melikoff[5] treated a-chlorohydracrylic acid with ammonia and was able to isolate only iso-serine, $CH_2NH_2—CHOH—COOH$, from the reaction mixture. He postulated that the α-chlorohydracrylic acid first lost hydrogen chloride, forming glycidic acid, which compound then added ammonia to form *iso*-serine.[6] Melikoff showed that glycidic acid added ammonia thus and considered this as evidence for the correctness of his assumed reaction mechanism.

According to the partition principle of Michael,[7] the addition of an unsymmetrical reagent to an unsymmetrical unsaturated compound (or ethylene oxide) gives rise to two isomers, the amount of each isomer thus produced being in proportion to the amount of chemical energy set free in its formation.

If a reaction mechanism analogous to that postulated by Melikoff is considered in the light of the partition principle, Reaction **A** may be formulated



This formulation appears to account most satisfactorily for the formation of both β-phenoxylactic acid and a-phenoxyhydracrylic acid in the reaction which is reported here.

Experimental

β-Phenoxylactic and a-Phenoxyhydracrylic Acids from β-Chlorolactic Acid.—A mixture of 600 g. of phenol, 400 g. of β-chlorolactic acid and a solution of 360 g. of sodium hydroxide in two liters of water was refluxed for two hours, acidified and the excess phenol removed by steam distillation. Cooling the solution gave crude β-phenoxylactic acid. The mother liquor contained β-phenoxylactic acid, a-phenoxyhydracrylic acid and sodium chloride, which were separated by evaporation and fractional crystallization. The a-phenoxyhydracrylic acid crystallized out only after the volume of the solution had been reduced to some 150 ml.

The crude β-phenoxylactic acid after treatment with charcoal, crystallized from water in colorless plates melting at 157.5–159° (uncorr.); yield, 400–425 g.

Anal. Calcd. for $C_9H_{10}O_4$: C, 59.33; H, 5.49. Found: C, 59.35; H, 5.90. Mol. wt. (by titration). Calcd.: 182. Found: 185.5.

---

[5] Melikoff, *Ber.*, 13, 1265 (1880).

[6] The same result has been obtained more recently with α-bromohydracrylic acid and ammonia [Neuberg and Mayer, Biochem. *Z.*, **3,** 119 (1907)].

[7] Michael, J. *prakt. Chem.*, [2] 60, 290 (1899).

A solution of the compound in concentrated sulfuric acid was colorless until warmed, when it became deep violet-red.

The crude α-phenoxyhydracrylic acid was separated from tarry impurities by extraction with hot toluene. It was finally crystallized from chloroform, from which solvent it was deposited in fine needles melting at 107–109°; yield, 3.8–6.0 g.

Anal. Calcd. for $C_9H_{10}O_4$: C, 59.33; H, 5.49. Found: C, 59.00; H, 5.61. Mol. wt. (by titration). Calcd.: 182. Found: 183, 183.5.

[a] From the acid by the method of E. Fischer and Speier, Ber., 28, 3252 (1895), using hydrogen chloride. [b] From the methyl ester and concd. aqueous ammonia. [c] From the acid by heating for four hours at 190° with a slight excess of aniline. [d] Sintered at 122°. A mixture with an equal amount of @-phenoxylactanilide melted at 107–111°. [e] This compound could be obtained colorless for analysis only by crystallization from water, in which the colored impurities were insoluble. Four hundred ml. of boiling water was necessary to dissolve 0.4 g. of the substance; it was noted that all of the derivatives of β-phenoxylactic acid were much less soluble than the corresponding derivatives of a-phenoxyhydracrylic acid.

A solution of the compound in concd. sulfuric acid was colorless until warmed, when it became rose-red.

Reaction of β-Phenoxylactic and a-Phenoxyhydracrylic Acids with Hydriodic Acid.—Although heating β-phenoxylactic acid with hydrochloric acid or with hydrobromic acid gave only black resins, similar treatment with hydriodic acid gave substances which were characterized successfully. The solution resulting from heating 5 g. of β-phenoxylactic acid with 20 ml. of hydriodic acid (d 1.96) in a sealed tube at 120–125° for four hours was diluted with water, decolorized with sulfur dioxide, and extracted with ether. By washing this extract with sodium carbonate and sodium hydroxide, there were obtained 4.0 g. of a mixture of unchanged β-phenoxylactic acid and β-iodopropionic acid, and 1.4 g. of phenol (identified as phenyl benzoate). Since the mixture of acids could not be separated into its constituents by fractional crystallization, a portion (2.7 g) was heated for three hours at 180" with aniline (4.0 g.), giving a mixture of neutral β-phenoxylactanilide with basic β-anilinopropionanilide[8] which were easily separated. The latter compound was identified by analysis of its hydrochloride (calcd.: Cl, 12.84; found: Cl, 12.84) and by mixed melting points with the same compound prepared from β-bromopropionic acid and aniline.

The treatment of a-phenoxyhydracrylic acid (4.7 g.) with hydriodic acid was similar to that described immediately above. There were obtained 1.5 g. of phenol, and 3.4 g. of mixed acids. A hot benzene solution of a portion of the latter deposited a small amount of α-phenoxyhydracrylic acid (m. p. 95–100°; mixed m. p. 100–104°); the β-iodopropionic acid remaining in the benzene melted, after crystallization from warm water, at 80–81°. The remainder of the mixed acids was treated with aniline, the resulting anilides being separated and identified as before.

Esters of α-Chloro-β-phenoxypropionic Acid.—The general method of Darzens[9] for the replacement of the hydroxyl group with chlorine by the use of thionyl chloride and pyridine was applied successfully to the methyl and ethyl esters of β-phenoxylactic acid. The properties and analyses of the twice distilled esters are given in the accompanying table.

TABLE II

PROPERTIES AND ANALYSES OF ESTERS

No.	Ester	B. p., °C. (16 mm.) (uncorr.)	Yield, %	d_{25}^{25}	n_D^{25}
1	Methyl	153–154	77	1.2177	1.5166
2	Ethyl	165–167	55	1.1812	1.5091

No	M_D Calcd	M_D Obs	Pormula	Cl (Carius), % Calcd.	Cl (Carius), % Found
1	53 34	53 25	$C_{10}H_{11}O_3Cl$	16 53	16 41
2	57 94	57 77	$C_{11}H_{13}O_3Cl$	15 53	16 36, 16 65, 16 54[a]

[a] The third analysis of the compound was made on a sample purified by an additional distillation; the constants of this sample were identical with those measured for the twice distilled ester. The low yield and high chlorine content were probably caused by not cooling the mixture sufficiently during the addition of the thionyl chloride.

Dehalogenation of Ethyl α-Chloro-β-phenoxypropionate.—A mixture of 10 g. of ethyl α-chloro-β-phenoxypropionate, 20 g. of dry alcohol, 10 g. of acetic acid, 10 g. of zinc dust and a little copper carbonate was refluxed for eight hours. The mixture was then filtered and concentrated on a steam-bath. The addition of water precipitated an oil which distilled at 120–145° (15 mm.). A second distillation gave 3.4 g.

[8] Cj. Autenrieth and Pretzell, *Ber.*, 36, 1262 (1903).

[9] Darzens, *Compt.* rend., 152, 1601 (1911).

of a halogen-free fraction boiling at 175–177" (50 mm.); d_{25}^{25} 1.0821; n_D^{25} 1.5055; M_D, calcd., 53.00; obs , 53.22. The boiling point of ethyl p-phenoxypropionate is reported to be 170° (40 mm.).[10]

The acid obtained by the hydrolysis of the ester with a mixture of equal weights of acetic acid, water and sulfuric acid melted alone or mixed with a sample of β-phenoxypropionic acid prepared from β-bromopropionic acid at 96–97° (uncorr). The melting point of this acid is reported to be 98°.[10]

Ethyl a-Phenoxy-p-hydroxyacrylate ("Formylphenoxyacetic Ester," III).—This compound was prepared by the method of Johnson and Guest[u] by the action of sodium on a mixture of ethyl formate and ethyl phenoxyacetate in ether. Contrary to the statement[12] that the compound could not be distilled under reduced pressure without decomposition, it was found that no decomposition took place when the distillation was carried out with the aid of an efficient water pump. This was shown by distilling the compound repeatedly, under which treatment the boiling point was not changed; the thrice distilled compound gave a benzoate identical with that obtained from the crude undistilled product. The following constants were observed: b. p., 148–150° (11 mm.); d_{25}^{25} 1.1637; n_D^{25} 1.5210; M_D calcd. (keto), 53.18; (enol), 54.13; obs., 54.43.

Anal. Calcd. for $C_{11}H_{12}O_4$: C, 63.46; H, 5.77. Found: C, 63.45; H, 5.83.

Benzoate.—This compound was prepared from the ester by the Schotten–Baumann reaction. It crystallized from dilute alcohol in fine needles which melted at 76–77°.

Anal. Calcd. for $C_{18}H_{16}O_5$: C, 69.24; H, 5.13. Found: C, 68.93; H, 5.11.

Ethyl a-Phenoxyhydracrylate from Ethyl Formylphenoxyacetate.—The oxymethylene compound was reduced in alcohol solution with hydrogen in the presence of catalytic nickel at a pressure of 150 atmospheres and at a temperature of 100°.[13] On distillation, the product boiled at 168–170° (10 mm.); d_{25}^{25} 1.1558; n_D^{25} 1.5125; M_D, calcd., 54.52; obs., 54.56; found: C, 62.50; H, 6.67. These constants agree well with those obtained for ethyl α-phenoxyhydracrylate prepared from β-chlorolactic acid (cf. Table I, No. 2).

The reagents usually employed for the reduction of oxymethylene compounds gave unsatisfactory results in the present instance. An ether solution of formylphenoxyacetic ester (10 g.) was treated with amalgamated aluminum according to the procedure described by W. Wislicenus.[14] From the ether solution there was obtained only phenol, which gave, on benzoylation, 8.0 g. of pure phenyl benzoate. The reduction of the oxymethylene compound in glacial acetic acid with zinc dust or amalgamated zinc led to a like result.

Phenoxyhydracrylamide (found: N, 7.49) prepared by ammonolysis of the ester was identical (mixed m. p.) with that obtained from p-chlorolactic acid (cf. Table I No. 3). Saponification of the ester gave the free acid (found: C, 59.01; H, 5.54) which melted at 109–110°; a mixture with an equal amount of the acid obtained from β-chlorolactic acid melted at 108–110°. The acid obtained by reduction gave a colorless solution in concd. sulfuric acid, which became yellow on warming. The color reaction and slightly low melting point of the acid prepared from β-chlorolactic acid are probably

caused by the presence of a small amount of β-phenoxylactic acid which could not be removed by fractional crystallization.

The assistance given by Professor S. M. McElvain during the course of this work is gratefully acknowledged.

Summary

The monophenyl ethers of glyceric acid, β-phenoxylactic acid and α-phenoxyhydracrylic acid, and a number of their derivatives have been prepared and characterized.

The possibility that both of these isomers may be formed simultaneously in the reaction between β-chlorolactic acid and sodium phenoxide has been pointed out.

THE INFLUENCE OF CERTAIN NEUTRAL SALTS UPON THE ACTIVITY OF MALT AMYLASE

BY H. C. SHERMAN, M. L. CALDWELL AND M. CLEAVELAND

RECEIVED JANUARY 30, 1930 PUBLISHED JUNE 6, 1930

Recent work[1] has shown that pancreatic amylase not only is dependent for its activity upon the presence of electrolytes but that it differs markedly in its response in activity to the presence of different salts. In view of this fact and of the recent findings of several investigators[2] that the influence of electrolytes upon enzymic activity is dependent on several interrelated factors, it seemed of special interest to continue our studies of typical starch-splitting enzymes of plant and animal origin by ascertaining whether quantitative differences might also be obtained in the action of malt amylase by the presence or absence of certain salts when the other factors were very fully controlled in the light of all present knowledge. One phase of this work, that dealing with the influence of acetate and phosphate upon the activity of malt amylase, has already been described.[2] The results of the quantitative study of the influence of other salts upon the activity of malt amylase are reported briefly here.

Experimental

The general procedure employed in this investigation consisted in allowing the enzyme to act at 40° (±0.01°) for thirty minutes upon 2% starch solutions which differed among themselves with respect to either the salt content or the hydrogen-ion activity or both as explained below. At the

[2] Sherman, Caldwell and Boynton, *ibid.*, 52, 1669 (1930), and references therein contained.

expiration of this half-hour period, the extent to which the starch had been converted to reducing sugars, mainly maltose,[3] was established according to the gravimetric method previously described[4] and this was taken as the measure of the relative activity of the enzyme.

The hydrogen-ion activities of the substrates were adjusted by mixtures of sodium acetate and acetic acid, present in a total concentration of 0.01 M acetate. Such mixtures had been shown[2] to be satisfactory for work with this enzyme. By changing the proportions of equimolar sodium acetate and acetic acid, it was possible to adjust the solutions to different desired hydrogen-ion activities without changing the total concentration of acetate. The total concentration of 0.01 *M* acetate was chosen for several reasons. It had been found to afford the desired buffer effect and at the same time was low enough not to interfere with the study of the influence of other salts. Previous work had also shown[2] that acetate as well as phosphate exerts a very slight favorable influence upon malt amylase. This influence, in the case of acetate, is practically constant through a wide zone of concentrations including 0.01 M, which is therefore a suitable concentration to use. The hydrogen-ion activities of all solutions were measured electrometrically. In all of the experiments here reported, the conditions of time, temperature and the concentrations of starch, enzyme and total acetate were constant.

As regards the factors which were varied, the plan of the work was as follows: (1) in order to determine whether or not sodium chloride has any influence upon the activity of malt amylase, direct comparisons were made of the enzymic activity (a) at graded hydrogen-ion activities in the presence and absence of the salt at fixed concentrations, and (b) in the presence of graded concentrations of the salt at fixed hydrogen-ion activities. (2) The other neutral salts studied, potassium chloride, sodium nitrate and sodium sulfate, were compared in a similar manner as to their effect upon the hydrolysis of starch with malt amylase. The enzymic activity in the presence of these salts at a single concentration and hydrogen-ion activity was compared with that exerted in the absence of salt both at the same hydrogen-ion activity and at the optimal hydrogen-ion activity for the enzyme and conditions here employed. (3) Finally, the effect of different concentrations of each salt upon the activity of malt amylase was established at each of three hydrogen-ion activities: (a) at the optimum, (b) on the alkaline side of the optimum, (c) on the acid side of the optimum.

A dry preparation of malt amylase, purified from dialyzed malt extract according to a modification of the method described by Sherman and Schlesinger,[5] was used.

[3] Sherman and Punnett, THIS JOURNAL, 38, 1877 (1916).

[4] Sherman and Walker, *ibid.*, 43, 2461 (1921).

[5] Sherman and Schlesinger, *ibid.*, 37, 643 (1915).

All reagents were carefully purified. The salts were of the highest purity obtainable and were recrystallized three times in all cases with the exception of sodium chloride, which was prepared and purified by the method of Richards and Wells.[6] Soluble starch which constituted the substrate was washed repeatedly and air dried. Redistilled water was used for all solutions.

Results with Sodium Chloride.—Parallel measurements of the activity of the enzyme in the presence of 0.01 *M* sodium chloride and in its absence, each at closely graded hydrogen-ion activities from PH 4.0 to PH 6.2, showed that the enzymic activity was greater in the presence of the sodium chloride in the more acid solutions, PH 4.3 to PH 4.0, and in the more alkaline solutions, PH 5.1 to PH 6.2. In solutions of intermediate reaction from approximately PH 4.3 to PH 5.1, however, the presence of sodium chloride had no appreciable influence upon the activity of the enzyme. These solutions correspond approxiniately to the optimal hydrogen-ion activity previously established[2] for this enzyme in the presence of this concentration of acetate. Similar results were obtained in a series of experiments with 0.02 M sodium chloride. Thus sodium chloride in concentrations of 0.01 and 0.02 M did not increase the activity of the enzyme at the optimal, but rendered it more active in solutions of less favorable, hydrogen-ion activity.

This was also found to be true when, in another series of experiments, the influence of several concentrations of sodium chloride (0.01, 0.02, 0.05, 0.07 and 0.10 *M*) was carefully and repeatedly measured: at the optimal hydrogen-ion activity (PH 4.5), in solutions more acid (PH 4.0) and in solutions less acid (PH 5.5).

At its optimal hydrogen-ion activity, the enzyme was as active without as with the sodium chloride; but the presence of this salt helped to overcome the retarding influence of an unfavorable hydrogen-ion activity upon the action of the enzyme.

This was demonstrated for all of the five concentrations of sodium chloride tested (0.01 to 0.10 M), the lower concentrations of the salt appearing more favorable on the acid, and the higher concentrations on the more alkaline side.

If the activity of the enzyme at its optimal hydrogen-ion activity (PH 4.5) be taken as 100%, its activity at PH 4.0 was 89% without added salt and 99% with 0.01 M sodium chloride; while at PH 5.5 the activity of the enzyme was 77% without neutral salt and 97% with 0.10 M sodium chloride.

Thus malt amylase showed a practically optimal action through a wider range of hydrogen-ion activity when sodium chloride was present in suitable concentration than it did in the absence of the salt.

Results with Potassium Chloride.—The influence of potassium chloride

---

[6] Richards and Wells, THIS JOURNAL, 27, 459 (1905).

was studied in the same way as that of sodium chloride and with nearly the same results. The differences between the data obtained with these two salts were no greater than might reasonably be allowed for experimental error, but the average activity of the enzyme was in most cases slightly higher in the presence of the potassium, than of the sodium, salt.

Results with Sodium Sulfate.—At the optimal hydrogen-ion activity, P_H 4.5, the average enzymic activity was slightly higher in the presence of 0.01 M to 0.10 M sodium sulfate than in its absence, but here again, as in the case of potassium chloride, the differences were so small as to be of doubtful significance. At hydrogen-ion activities on either side of the optimum, (*viz.*, P_H 4.0 and P_H 5.5, respectively) the activity of the enzyme was increased by the presence of the sulfate (0.01 to 0.10 M), but this favorable influence was less than that exerted by the same concentrations of sodium or potassium chloride under the same conditions and decreased with increasing concentrations of the salt in solutions on the acid side of the optimum.

Results with Sodium Nitrate.—Sodium nitrate was found to have a less favorable influence upon the activity of malt amylase than the same concentrations of sodium or potassium chloride when tested under the same conditions.

Summary and Conclusions

The influence of sodium chloride, potassium chloride, sodium sulfate and sodium nitrate upon the saccharogenic activity of malt amylase has been investigated and special consideration has been given to the influence of changes in hydrogen-ion activity and salt concentration.

Under the experimental conditions here described, neutral salts are not essential to the activity of malt amylase nor do they increase the saccharifying action of the enzyme above that shown in their absence at the optimal hydrogen-ion activity.

The activity of malt amylase was increased at unfavorable hydrogen-ion activities by the presence of these salts, but not to the same extent by different salts. Those studied here may be arranged according to the decreasing magnitude of their effect upon the activity of the enzyme at unfavorable hydrogen-ion activities as follows: sodium and potassium chlorides, sodium sulfate, sodium nitrate.

In solutions of unfavorable hydrogen-ion activity, the addition of sodium chloride in the concentrations most favorable to the action of the amylase (0.01 M at P_H 4.0 or 0.10 M at P_H 5.5) restored the enzyme to an activity practically equal to that obtaining in the absence of salt at the optimal hydrogen-ion activity, P_H 4.5. Thus with the addition of the proper amount of sodium chloride, malt amylase exerts its highest activity in solutions differing more widely in hydrogen-ion activity than in its absence.

The findings here reported explain the contradictory evidence presented by various workers from time to time regarding the influence of salts upon the activity of this enzyme and emphasize anew the importance of controlling the hydrogen-ion activities of the solutions in which the enzyme action occurs.

The influence of salts upon the activity of malt amylase appears to be specific.

These findings as a whole establish quite definitely a difference, in dependence of optimal activity upon neutral salts, between pancreatic and malt amylases, which are being studied in detail as representative and analogous enzymes of animal and plant origin, respectively.

DIALKYL BARBITURIC ACIDS

BY H. A. SHONLE, ANNA K. KELTCH AND E. E. SWANSON

RECEIVED FEBRUARY 10, 1930 PUBLISHED JUNE 6, 1930

Nearly a hundred different 5,5-disubstituted barbituric acid derivatives have been prepared in the quarter of a century since Fischer and Dilthey[1] and Fischer and von Mering[2] found that certain of these derivatives could be used therapeutically as sedatives and hypnotics. These investigators were aware that certain of the compounds were more active as hypnotics than others and that the effect could be markedly changed by varying the chemical nature of the substituent radical.

Subsequent investigations[3] have shown that those barbituric acids in which the sum of the C atoms in the two substituent groups is 6, 7 or 8 are the most effective. When evaluated on rats, cats, rabbits or mice, by the intravenous or subcutaneous injection of their sodium salts, this group shows, in most instances, a wider margin of safety between the anesthetic or down dose and the toxic dose than does, for example, diethylbarbituric acid.

The investigation was started in 1927 for the purpose of studying the various isomeric amyl-ethyl and amyl-allyl derivatives of the barbituric acids because of the commercial availability of certain of the amyl alcohols, and to extend the study of the secondary alkyl-ethylbarbituric acid series.[4]

In view of Hsueh and Marvel's[5] statement relative to *sec.*-butylethylbarbituric acid we carefully repeated our work and found that this acid does not melt at 197°, as stated by them, but that after repeated crystallization *sec.*-butyl-ethylbarbituric acid melted at 164–165° (corr.). Our former figure[3b] of 158° (uncorr.) had been obtained with a limited amount of substance.[6]

In repeating this former work of ours we found that if we introduced the *sec.*-butyl group in ethylmalonic ester, we obtained a satisfactory yield of *sec.*-butylethylmalonic ester, which yielded *sec.*-butylethylbarbituric acid melting at 164°. However, if we reversed the procedure, we were able to introduce but an insignificant amount of the ethyl group into the *sec.*-butylmalonic ester, and could not separate any of the diethyl *sec.*-butylethylmalonate by fractional distillation. The barbituric acid prepared from the higher-boiling fraction of the ester was physiologically inert, melted at about 190° and proved on analysis to be *sec.*-butylbarbituric acid contaminated with a trace of *sec.*-butylethylbarbituric acid. It was possible to introduce the allyl group into this *sec.*-butylbarbituric acid, *sec.*-butylallylbarbituric acid having the correct melting point being obtained on recrystallization.

It was likewise found impossible to introduce the ethyl group into the *sec.*-amyl- or the cyclopentylmalonic esters or the allyl group into *sec.*-butylmalonic ester. To all outward appearance the reaction was normal, sodium bromide being deposited as usual. The reaction occurred, however, between the aliphatic bromide and the sodium ethylate instead of between the aliphatic bromide and the sodium *sec.*-butylmalonic ester, which indicates that the equilibrium was displaced toward the sodium ethylate since it reacted with the alkyl bromide. This may be interpreted as an instance of steric hindrance, or as an instance of the difference in the negativity of the secondary aliphatic substituted as compared to the primary aliphatic substituted malonic esters.

Experimental

Alcohols.—In view of the improbability of successfully purifying the commercial *sec.*-amyl alcohols by fractionation, the synthetic *sec.*-amyl alcohols prepared by the Grignard method at the Eastman Kodak Laboratories were used. Di-*n*-propylcarbinol and methylbutylcarbinol were likewise obtained from the same source. Cyclo-

ing of the American Chemical Society, September, **1929**, This Journal, **52**, 1676 (1930), including propylmethylcarbinyl- and *sec.*-butylcarbinyl-ethylbarbituric acids and the esters from which they were prepared.

[5] Hsueh and Marvel, *ibid.*, 50, 855 **(1928)**.

[6] Dr. Marvel was kind enough to send us a sample of his acid and the ester from which it was prepared. Investigation showed that the 197° melting acid was almost physiologically inert, and analyzed as *sec.*-butylbarbituric acid which melts at 197°. The ester had a boiling point and refractive index much closer to dietbyl *sec.*-butylmalonate than to diethyl *sec.*-butylethylmalonate.

pentanol was prepared by reducing, in the presence of a platinum catalyst,[7] cyclopentanone obtained from adipic acid.[8] The other alcohols, obtained from various sources, presented no unusual aspects.

Alkyl Bromides.—The primary alkyl bromides were prepared according to the method of Kamm and Marvel,[9] while the secondary alkyl bromides were prepared by the Norris[10] method.

When the work was initiated, the authors had not considered that rapidly distilling a secondary alcohol with hydrobromic acid would produce other than the corresponding bromide in a degree of purity satisfactory for synthetic work. It was noted at that time, however, that the malonic esters and barbituric acids prepared from 2-bromo- and 3-bromopentane which had been made by the above method had similar physical characteristics. Dr. M. S. Kharasch, in discussing these reactions with one of us, pointed out that even rapidly distilling either of the 2 or 3-pentanols with hydrobromic acid should result in a rearrangement tending to give the same equilibrium mixture of 2 and 3-bromopentane, the exact proportions of the isomers depending on the conditions of the reaction.

We were later informed of the quantitative determination made by Dr. Sherrill and her co-workers,[11] now published, in which the values of the D line of 2-bromopentane and 3-bromopentane were shown to be at 20°, 1.4412 and 1.4443, respectively. Since Lucas, Simpson and Carter[12] have shown that there is a linear relation between the composition and refractive index, one can determine by calculation that the bromide obtained by Sherrill from diethylcarbinol and hydrobromic acid was a mixture of 71% 2-bromopentane and 29% 3-bromopentane, while that obtained from propylmethylcarbinol was a mixture of 81% 2-bromopentane and 19% 3-bromopentane.

It is evident that the preparation of *sec.*-amyl bromides by the usual methods results in mixtures and this circumstance doubtless obtains for the higher secondary bromides. In order to be sure then of the homogeneity of secondary bromides, one should use the method of Kharasch as described in detail by Sherrill, which gave as judged by the refractive index a 2-bromopentane slightly purer than that obtained by Lucas and Moyse.[13]

When the bromopentane obtained by rapidly distilling propylmethylcarbinol with 48% hydrobromic acid was washed and dried as directed by Sherrill, and fractionated,

[11] (a) Sherrill, Otto and Pickett, ibid., **51,** 3023 (1929); (b) Sherrill, Baldwin and Haas, *ibid.,* **51,** 3034 (1929).

[12] Lucas, Simpson and Carter, *ibid.,* **47,** 1462 (1925).

[13] Lucas and Moyse, *ibid.,* **47,** 1459 (1925).

two main cuts were obtained, one boiling at 117–118°, having a refractive index n_D^{20} 1.4416, the other boiling at 118–118.5°, with a refractive index n_D^{20} 1.4418, corresponding, respectively, to 87 and 81% of 2-bromopentane. In another trial, a 118–119° cut from technical propylmethylcarbinol was used. The two main cuts of the bromide boiled at 116.5–117°, with a refractive index n_D^{20} 1.4413, and 117–117.5°, with a refractive index n_D^{20} 1.4415, corresponding, respectively, to 97 and 90% of 2-bromopentane.

On distilling diethylcarbinol with 48% hydrobromic acid, a bromopentane is obtained which on fractionating gave a main fraction boiling at 117°, with a refractive index n_D^{20} 1.4433, corresponding to 68% of 3-bromopentane. However, when diethylcarbinol, obtained from technical alcohol, was used, the resulting bromides could be separated into two main fractions, one boiling at 115–116°, having a refractive index n_D^{20} 1.4419, and the other boiling at 116–117°, having a refractive index n_D^{20} 1.4425, corresponding, respectively, to 77 and 58% of 2-bromopentane.

This explains then why malonic esters prepared from these secondary alkyl bromides had a wider range of refractive indices and boiling points than did the malonic esters containing primary alkyl groups. Since the *sec.*-hexyl and -heptyl bromides used in this research were prepared in an analogous manner, similar rearrangements may have occurred.

When isopropylmethylcarbinol is distilled from 48% hydrobromic acid, the distillate is a mixture of amylene, *tert.*-amyl bromide and some 2-bromo-3-methylbutane.[14]

Mono-alkyl Malonic Esters.—The usual methods of preparing the mono-alkyl substituted malonic esters were employed,[15] no marked differences being observed in the yields from the primary and secondary aliphatic bromides. In actual practice it is unnecessary to use an amount of alcohol more than 10 times the weight of the sodium. The yields of the mono-substituted esters were generally greater than of the corresponding disubstituted esters and the reaction was completed in less time.

Dialkyl Malonic Esters.—The usual method of preparing the disubstituted malonic esters was employed when primary bromides were used. The use of iso-amyl chloride instead of iso-amyl bromide in the preparation of diethyl iso-amylethylmalonate did not lower the yield. When the *sec.*-amyl or -hexyl bromides were used the yields by the above methods were quite low, although the secondary group was introduced last. If, however, most of the alcohol was removed from the sodium salt of the mono-substituted ester before the bromide was added, the yields were bettered.

Diethyl hydroxyethylethylmalonate was obtained in a 27% yield when ethylene chlorohydrin was caused to react in the usual manner with sodium diethyl ethylmalonate. In contrast to diethyl hydroxyethylmalonate, it can be distilled under vacuum without decomposition. A better yield would undoubtedly be obtained if benzene were used in place of the alcohol.

Mono-substituted Barbituric Acids.—The mono-substituted barbituric acids were prepared by condensing the mono-substituted malonic esters with urea in absolute alcohol in the presence of sodium ethylate,[1] gently reflusing for two to three hours. Too prolonged refluxing causes a poor yield. They were isolated and purified in the usual manner.

Disubstituted Barbituric Acids.—Certain of the allyl-alkyl barbituric acids were prepared by the interaction of allyl bromide on the sodium salt of the desired mono-

---

[14] Wischnegradsky, ***Ann.***, 190, 328 (1878), obtained tertiary halides instead of secondary halides on treating isopropylmethylcarbinol with aqueous hydrochloric and hydriodic acids at 40°.

[15] Adams and Kamm, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1924, Vol. IV, p. 11.

substituted barbituric acid[16] The most satisfactory yields were obtained when the barbituric acid was dissolved in a molecular quantity of 25 to 35% aqueous potassium hydroxide, to which was added somewhat in excess of a mole of allyl bromide and alcohol to about 10% of the total volume. The reaction was carried out in a shaking machine, from forty to fifty hours' time being required. Without the alcohol the reaction proceeded more slowly. The disubstituted acids were isolated and purified in the usual manner.

Most of the disubstituted barbituric acids were prepared by Fischer's method with the exception that a prolonged refluxing in a boiling water bath or on the sand-bath advantageously replaced the briefer period of heating in an autoclave. In some instances, after refluxing for one hour, most of the alcohol was removed under vacuum and the solid residue was heated in a boiling water-bath for four hours.

Technique.—In carrying out the fractional distillation under vacuum it was found that the refractive index was a better measure of purity than the pressure and boiling point. Consequently fractionation was repeated until a middle portion having a constant refractive index (or relatively constant in the instance of esters having a secondary group) was obtained.

The refractive indices were determined with an Abbé refractometer, with the temperature held constant to 0.2°. Duplicate observations taken on different days checked within one point in the fourth place.

The fractional distillation was carried out with the Fischer and Harries[17] apparatus which permits the fractionation to proceed while samples are being removed. Instead of the Claisen flask, a 200- or 500-cc. round-bottomed pyrex flask was used to which was attached a 30-cm. column.[18] The temperature was recorded by an Anschütz thermometer, the stem of which was entirely contained within the top of the fractioning column. During the course of the fractional distillation, even though the temperature was constant, repeated small cuts were made in order to obtain more data on the refractive index of the distillate.

No attempt was made to obtain the ultimate analysis of the esters since they were to be used as intermediates. The constancy of boiling point and refractive index served as the basis for making the cuts. Two or more preparations of each of the esters and barbituric acids have been made during the course of this investigation.

The mono- and disubstituted malonic esters prepared are given in Tables I and II. The yields are reported only for the ester having the described physical properties. In every instance refractionation of the lower cuts would have increased the yield.

TABLE IV

DISUBSTITUTED BARBITURIC ACIDS

Barbituric acid derivative	Yield, %	Melting point, °C. (corr.)	Nitrogen, % Calcd.	Found	
Propylmethylcarbinyl-ethyl[a]	52	128.5–130	12.39	12.50	12.59
Diethylcarbinyl-ethyl"	36	127–129	12.39	12.00	11.88
Sec.-butylcarbinyl-ethyl[4b]	54 5	136–138	12.39	12.57	12.59
Cyclopentyl-ethyl	73	182–183	12.50	12.40	12.48
n-Butylmethylcarbinyl-ethyl	42	121–123	11.66	12.17	1208
β-Hydroxyethyl-ethyl[b]	67	178	...	....	
Propylmethylcarbinyl-allyl	50	86–88	11.76	12.01	12.04
Diethylcarbinyl-ally1	..	Wax-like	11.76	....	
Cyclopentyl-allyl	23	161–163	11.86	11.63	11.58
n-Butyl-allyl[c]	58	125–125.5	...	....	

[a] German Patent 293,163 describes both of these barbituric acids but gives a melting point of 162° for the diethylcarbinyl-ethylbarbituric acid. [b] It was found possible to prepare the β-hydroxyethyl-ethylbarbituric acid in the usual manner from diethyl hydroxyethylmalonate. Cretcher, Koch and Pittenger, THIS JOURNAL, 47, 3083 (1925), using an indirect method, obtained a melting point of 176" (corr.) for this acid. [c] Prepared from diethyl n-butyl-allylmalonate instead of by the action of allyl bromide on potassium n-butylbarbiturate, as described by Volwiler.[3c]

most 1% above the theoretical and melted around 158°. An acid melting about 10° lower was also obtained; both were physiologically active.

n-Butylmethylcarbinyl-ethylbarbituric acid. When the crude acid was recrystallized from a benzene–gasoline solution and then from dilute alcohol, two fractions were obtained; the major fraction melted at 122.5°, and had 12.08 and 12.17% of nitrogen, while the minor fraction melted at 106° and had 11.70 and 11.95%. Both were equally effective as hypnotics. The higher-melting product is presumed to be the *n*-butylcarbinyl-ethylbarbituric acid isomer.

Discussion

The disubstituted barbituric acids described are readily soluble in hot benzene (in contrast to the slight solubility of the mono-substituted) and can be crystallized from benzene or dilute alcohol. The one exception was the diethyl-allylbarbituric acid which precipitated as an oil, hardening on standing. These barbituric acids are almost insoluble in water, but dissolve readily in dilute sodium hydroxide solutions.

That the aqueous solutions of the alkali metal salts of the disubstituted barbituric acids are not indefinitely stable does not seem to be generally recognized outside of the chemical laboratory. Solutions of some of these salts show evidences of decomposition after a few days' standing. When a 5 or 10% solution of the sodium salt is boiled but for a short time, the ring is ruptured and ammonia is evolved. After a more prolonged boiling, a solid separates out as the solution cools. In the case of sodium iso-amyl-ethylbarbiturate, this solid was shown to be iso-amyl-ethylacetylurea. The amount of the precipitate which occurs after boiling an aqueous solution is not a measure of the full extent of the ring cleavage.

Initial decomposition can be detected by slowly adding a 1:10 solution of hydrochloric acid to the cold solution of the sodium barbiturate until the precipitation of the barbituric acid is complete, filtering off the precipitate, washing it with water and drying for a few hours at 70 and 80°. If there has been any decomposition the melting point will be lower than that of the pure barbituric acid initially used to prepare the salt. Since the difference may be only a few degrees, the melting points of the control and the test sample should be run at the same time.

It is essential in preparing solutions for biological study that any excess of alkali over one molar proportion should be avoided, that only a minimum amount of warming should be employed, and that only freshly prepared solutions be used.

Various salts of ammonia, mono-alkyl- and dialkylamines were prepared by dissolving the above-described barbituric acids in an excess of a solution of the volatile base and then evaporating the excess of the base and solvent until the solid salt was obtained. It was found that unless the salt was protected from exposure to air, the loss of the volatile base continued, leaving a mixture of the barbituric acid and the salt which was not water soluble.[19]

The addition of alcohol or glycerin to aqueous solutions of the various sodium barbiturates lessens the rate of decomposition. If, further, a weak organic acid is added to just short of the point of precipitation, the stability is further increased because of the lowering of the alkalinity. In this way solutions of the salts of more labile barbituric acids may be stabilized for some months. An absolute alcoholic solution of a sodium barbiturate does not decompose on boiling. The different barbituric acids exhibit varying rates of decomposition under the same conditions, those with a greater molecular weight usually being the more readily decomposed.

The alkali metal salts are best prepared by concentrating under vacuum non-aqueous solutions of equimolar proportions of the alkali metal hydrox-

---

[19] Kubli, U. S. Patent 1,316,047, has prepared various alkylamine salts of barbituric acids with the expectation of overcoming the decomposition caused by the strong alkaline solution of the sodium salts. We have observed that the ampouled solution of Somnifen, an alkylamine salt of allyl-isopropylbarbituric acid, has decomposed in standing, forming the usual alkali-insoluble precipitate.

ide and the barbituric acid until the salt is obtained in solid form. The alkali metal salts of the barbituric acids of higher molecular weight are more hygroscopic than those of a lower molecular weight.

The calcium and magnesium salts are less soluble than the sodium, potassium or lithium salts, and may be prepared by adding the calculated amount of a soluble salt of the desired alkaline earth metal to a solution of the sodium barbiturate, and concentrating until a precipitate of the alkaline earth barbiturate occurs.[20]

No attempt will be made to report extensive pharmacological data, nor will any theory be advanced as to the mode of action of the barbituric acids. However, the exceedingly prompt effect following intravenous injections of solutions of their sodium salts and the relatively delayed appearance of unchanged barbituric acid in the urine are presumptious of the functioning of the intact molecule.

The effective and fatal doses were obtained by injecting intraperitoneally into white rats freshly prepared 2% solutions of the sodium salts of the various barbituric acids. Animals of about 100 g. weight, which had been starved for twenty-four hours previous to the injection, were used. The effective dose reported (M. E. D.) is that amount which will abolish reflexes when the inner ear is touched with a thin wooden applicator. (This depth of anesthesia is not sufficient to permit indiscriminate operative procedures to be carried out.) The M. L. D. is that dose which caused the death of all or a majority of animals on that dose. Variations of as much as 75% in the amount of the identical lot of barbituric acid required to produce anesthesia and death have been noted when this lot was tested at varying periods throughout a year.[21] The percentage of the M. L. D. required to produce anesthesia at these various periods, however, was not materially different. The data reported in Table V were obtained under controlled conditions so that the doses may be compared with one another, taking into consideration that the usual biological variations obtain in these experiments in which the number of animals are employed is limited.

No sedative or hypnotic effect was noted when large doses of the monosubstituted barbituric acids were injected. The replacement of a hydrogen in the β-position in one ethyl group of diethylbarbituric acid by an hydroxyl group results in the loss of the hypnotic activity. The animals did not exhibit any toxic symptoms at the doses injected.

It will be noted that diethylbarbituric acid and phenylethylbarbituric acid give a similar value for M. L. D./M. E. D. and it is this fact that has

---

[20] Quade, U. S. Patent 1,461,831, prepared the calcium and magnesium diethylbarbiturate by digesting an aqueous solution of diethylbarbituric acid with calcium oxide or magnesium carbonate and concentrating the filtrate, a method quite satisfactory for the more soluble barbituric acids.

[21] These variations were probably due to differences in strains of rats, seasonal changes, etc.

TABLE V

PHARMACOLOGICAL DATA[a]

Barbituric acid derivative	No of animals	M E D., mg per kg.	M L. D , mg per kg.	% of M L D. required to abolish ear reflexes	M. L. D. / M. E D.
Diethyl	32	300	400	75	1.33

[a] We are indebted to W. E. Fry for his careful and painstaking work in administering the solutions of the sodium salts and in observing the condition of the animals at regular intervals after the administration of each compound.

[b] Boedecker and Ludwig, *Arch. exp. path. Pharmakol.*, **139,** 361 (1929), mention this acid.

undoubtedly led to the many statements that the various barbituric acids are not essentially different in their action.

It is possible by varying the substituent groups to change or modify the pharmacological properties of the barbituric acids. Dimethyl and hydroxyethyl-ethylbarbituric acids are devoid of hypnotic activity, while di-iso-amylbarbituric acid causes only muscular incoördination. Propylmethylcarbinyl-ethylbarbituric acid is eight times as active as diethylbarbituric acid, and twice as active as iso-amyl-ethylbarbituric acid. n-Butylmethylcarbinyl-ethylbarbituric acid is three times as active as its isomer, di-n-butylbarbituric acid. *Sec.*-butyl-ethylbarbituric acid is twice as effective as n-butyl-ethylbarbituric acid. While three-fourths of the M. L. D. of diethyl and phenyl-ethylbarbituric acid is required to produce a state of anesthesia in rats, only two-fifths of the M. L. D. of the various amyl-ethylbarbituric acids are required. Death after the administration of a fatal dose of the amyl-ethylbarbituric acids occurs usually within the hour, while with diethylbarbituric acid it is delayed for ten to twenty-four hours. On the other hand, animals recover from a sub-lethal dose of iso-amyl-ethylbarbituric acid in half the time required for recovery from diethylbarbituric acid, indicating that the body is able to destroy or eliminate the one more readily than the other. Eddy,[22] who administered various barbituric acids orally to cats, noted that they did not act in an identical manner. Loevenhart,[23] found that iso-amyl-ethylbarbituric acid was more than five times as effective as diethylbarbituric acid in protecting rabbits against death from procaine hydrochloride.

When considered from a molecular basis, the differences are even more significant; for example, a molecule of iso-amyl-ethylbarbituric acid is five times as effective as a molecule of diethylbarbituric acid, while a molecule of propylmethylcarbinyl-ethylbarbituric acid is ten times as effective in producing anesthesia in rats.

These changes, caused by varying the substituent groups, have been observed in mice, rats and dogs. It is quite probable that in man somewhat similar relationships hold qualitatively if not quantitatively. The selection of the most suitable member of that group having the highest therapeutic index, for medical use, must be dependent on additional pharmacological factors.

In considering the isomeric amyl-alkylbarbituric acids, slight variations only are noted in the therapeutic index. It is probable that a 10% variation in this ratio may occur due to biological variations beyond the control of the investigator. Consequently one could not ascribe the differences obtained in the therapeutic index to differences in the structure of the amyl groups. With the isomeric butyl-ethylbarbituric acids the differences in the therapeutic index seem too wide to be ascribed solely to biological variation and indicate the superiority of the *sec.*-butyl group in this series. In the butyl-alkyl series, Volwiler's[3c] data show that while the *sec.*-butyl-allylbarbituric acid was effective at a lower dose than was the iso- or *n*-butyl derivative, it had the lowest ratio for M. L. D./M. E. D. This is in contrast to the butyl-ethyl series in which the *sec.*-butylethylbarbituric acid gives the highest therapeutic ratio.

The most striking effect was the observation that the *sec.*-butylethyl and both the propylmethylcarbinyl and the diethylcarbinylethyl and allylbarbituric acids were effective in half the amount required for the primary isomers. In contrast to this, isopropylmethylcarbinyl and cyclopentyl-ethylbarbituric acids were no more effective than the primary isomers, while the cyclopentyl-allyl-barbituric acid was almost as effective as the propyl-methylcarbinyl isomers. The pharmacological significance of this difference in the action of the secondary groups is being investigated.

The therapeutic indices of the *sec.*-butyl, *sec.*-amyl and *sec.*-hexyl deriva-

[23] Knoefel, Herrick and Loevenhart, *ibid.*, **33**, 265 (1928).

tives show a slight decrease as the molecular weight increases, although less of the *sec.*-amyl derivative is required to produce anesthesia than of the *sec.*-butyl or the *sec.*-hexyl derivatives.

The writers wish to express their appreciation to Dr. G. H. A. Clowes, Director of the Lilly Research Laboratories, for his suggestions.

Summary

1. The following new esters of diethylmalonate have been prepared and described: diethylcarbinyl, cyclopentyl, n-butyl-allyl, β-hydroxyethyl-ethyl, diethyl-carbinyl-ethyl, isopropylmethylcarbinyl-ethyl, cyclopentyl-ethyl, n-butylmethylcarbinyl-ethyl, di-n-propylcarbinyl-ethyl, phenyl-ethyl-ethyl and n-heptyl-ethyl.

2. The following new barbituric acids have been prepared and described: cyclopentyl, cyclopentyl-ethyl, n-butyl-methylcarbinyl-ethyl, propylmethylcarbinyl-allyl, diethylcarbinyl-allyl, and cyclopentyl-allyl barbituric acids.

3. No marked difference was found in the ratio, M. L. D./M. E. D. of the various isomeric amyl-ethyl or allyl barbituric acids. The ratio obtained for the amyl group was, however, double that obtained for diethyl or phenyl-ethylbarbituric acid. The secondary isomers usually were effective at a much lower dose than were the primary.

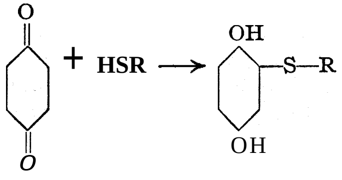
TWO ISOMERIC QUINONEDITHIOGLYCOLIC ACIDS

By E. Gebauer-Fuelnegg and Helene Jarsch

Received February 10, 1930 Published June 6, 1930

In the course of some work on the formation and properties of a variety of thioindigoid derivatives, the preparation of a 1,4-benzoquinone-2,5-dithioglycolic acid was attempted.

Usually the arylthioglycolic acids are prepared by alkaline condensation of the corresponding mercaptan with monochloro-acetic acid. As to the method of preparing the quinonedithioglycolic acids a general procedure was given by German Patent 175,070. According to this patent, p-quinones are found to react with substances represented by the general formula RSH (R representing an acid radical) as indicated by the equation



This reaction is said to proceed further when a second mole of quinone oxidizes the hydroquinone-monothioderivative to the corresponding quinone. A third and fourth RS group is said to be introduced by this method with primary formation of the corresponding hydroquinone derivatives by repeating the reaction.

The patent mentioned a variety of substances to be used as RSH. However, no reference could be found for the reaction with thioglycolic acid, which apparently is of possible value. In fact, the reaction did not proceed, as we found, in the way indicated by the general equation given, since under all circumstances tested the reaction product consisted chiefly of two isomeric 1,4-benzoquinonedithioglycolic acids, which were separated by their different solubilities in ether.

Upon treatment of the two isomers with dehydrating agents, they behave differently. The one which forms the main part of the reaction yields finally an intensely violet substance if added to an excess of chlorosulfonic acid. It dyes cotton (vat dye) as well as wool (acid dye) a greenish-blue color. The fact that condensation actually occurred makes it most likely that the isomer in question is the 1,4-benzoquinone-2,5-dithioglycolic acid (2,6-substitution is unlikely but possible).

The second isomer upon treatment in the above manner yielded no colored substance. Its structure therefore is given as the 1,4-benzoquinone-2,3-dithioglycolic acid.

The dual behavior of the thioindigoid dye prepared from the 2,5-isomer as noted above possibly gives a clue as to the structure of the dye obtained, even though it was not obtained in a sufficient degree of purity to insure reliable analysis. It will be discussed elsewhere.

The 1,4-benzoquinone-2,5-(2,6?)-dithioglycolic acid was found to exist in two modifications: brown needles (from ether by precipitation with ligroin below 30–40°) and a red powder m. p. 171 (from other solvents at elevated temperatures). The two modifications can be converted into each other and crystallized from water in deep violet, sometimes nearly black, needles containing one mole of water; the water of crystallization is lost at 50–60° with formation of the intensely red colored modification mentioned above.

Experiments

Preparation and Behavior of the **Two** Isomeric **1,4-Benzoquinone-dithioglycolic** Acids.[1]—After a number of preliminary experiments varying the relative amounts of the components, temperature of the reaction and solvents to be used, the following procedure was finally adopted for the preparation and isolation of the two isomeric quinone dithioglycolic acids. Ten grams of quinone were dissolved in 100 cc. of chloroform and 8.6 g. of thioglycolic acid dissolved in 100 cc. of chloroform was added. The reaction mixture first turned greenish-black (quinhydrone) but began to deposit a red precipitate

---

[1] The preliminary experiments were carried out with H. A. Beatty.

after thirty-six hours. After seventy hours the mixture was filtered and dried in a vacuum. Upon extraction with ether for twenty-four hours in a Soxhlet apparatus, a red residue was left. This residue was then extracted with benzene several times to insure its freedom from hydroquinone and repeatedly recrystallized from water. Finally violet (black) needles were obtained melting at 205" (const.). The figures obtained by the analysis correspond well with the values for a I,4-benzoquinonedithioglycolic acid.

Anal. Subs., 5 205 mg.: CO_2, 7.904 mg.; H_2O, 1.461 mg. Subs., 0.1016: $BaSO_4$, 0.1697. Calcd. for $C_{10}H_8O_6S_2$: C, 41.04; H, 2.80, S, 22 26. Found: C, 41.42; H, 3.14; S, 21.59.

The ether extract was evaporated to dryness and extracted with benzene in a Soxhlet apparatus. The extraction was stopped when all of the hydroquinone present was dissolved. The residue finally gave, on repeated recrystallization from water, violet (black) needles which melted at 171° and analyzed well for 1,4-benzoquinonedithioglycolic acid plus one mole of water.

Anal. Subs., 5.181 mg.: CO_2, 7.591 mg.; H_2O, 1.578 mg Calcd. for $C_{10}H_8O_6S_2 \cdot H_2O$: C, 39.19; H, 3.29. Found: C, 39.96; H, 3.41.

The water of crystallization is lost at about 60° with the formation of a bright red substance. Its formation is also noticeable when the melting point is determined. These red needles analyze well for a water-free quinonedithioglycolic acid.

Anal. Subs., 5.301 mg.: CO_2, 8.066 mg.; H_2O, 1.606 mg. Calcd. for $C_{10}H_8O_6S_2$: C, 41.66; H, 2.80. Found: C, 41.50; H, 3.39. Subs., 0.0155: after drying in a vacuum of 13 mm. to constant weight, 0.0145; diff , 0.0010. Calcd. for $C_{10}H_8O_6S_2 \cdot H_2O$: H_2O, 5.89. Found: H_2O, 6 45.

Upon the recrystallization from water of both isomers an appreciable amount of substance is lost, the mother liquors become brown and contain decomposition products of the original acid. These mother liquors, upon acidification, dye wool a clear and fast brown color; the substances found have not been investigated.

The hydrated and water-free modifications are interconvertible. Both forms dissolve in ether giving an orange-red solution and are precipitated from such solutions in the form of brown needles by an excess of ligroin. These needles apparently represent a second water-free modification (containing no solvent of crystallization). It is stable only at low temperatures, since it was found that when the ligroin precipitation is carried out at 40° the red modification is obtained immediately. The brown modification upon recrystallization from water also yields the violet (black) needles containing one mole of water.

The two isomeric quinonedithioglycolicacids described are the main products of the reaction. There are, however, other substances formed and found in the various extracts and mother liquors. Their isolation has not yet been attempted due to the comparatively small amounts formed.

The 1,4-benzoquinonedithioglycolic acid, m. p. 205°, was treated in the usual manner with chlorosulfonic acid but was found not to condense. The acid, therefore. is most likely the 1,4-benzoquinone-2,3-dithioglycolic acid

The second isomer, m. p. 171°, condensed readily upon heating with an excess of chlorosulfonic acid for twelve hours at 50–70°. The thioindigoid dye was isolated. This isomer therefore represents a 1,4-benzoquinone-2,5(2,6?)-dithioglycolic acid.

Summary

Two isomeric benzoquinonedithioglycolic acids have been prepared. Their structures are given and their properties described. Upon condensa-

tion with chlorosulfonic acid the 1,4-benzoquinone-2,5-(2,6?)-dithioglycolic acid forms a thioindigoid dye.

THE EFFECT OF DISSOCIATED WATER VAPOR ON CERTAIN VEGETABLE OILS

BY G. I. LAVIN AND E. EMMET REID

RECEIVED FEBRUARY 15, 1930 PUBLISHED JUNE 6, 1930

Introduction

Bonhoeffer[1] has shown that atomic hydrogen will attack the double bond in a straight-chain compound like oleic acid. Watermann and Bertram[2] found that active hydrogen (dried) caused the oleic acid to undergo a polymerization along with the hydrogenation. Wood[3] has conducted some experiments with cottonseed oil and atomic hydrogen and obtained a white solid. In a recent paper Urey and Lavin[4] have shown that water vapor dissociated in a discharge tube is an energetic reducing agent and it is the purpose of this note to describe some experiments carried out with dissociated water vapor and cottonseed oil.

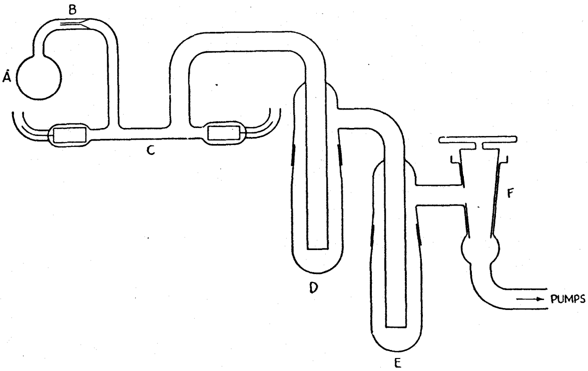

Fig. 1.—Apparatus for treatment of oils with dissociated water vapor.

Apparatus.—The apparatus used is shown in the accompanying diagram. It consists essentially of a source of water vapor A, a capillary B, discharge tube C and traps E and F.

---

[3] Private communication.

[4] Urey and Lavin, THIS JOURNAL, 51, **3290 (1929).**

Experimental

The cottonseed oil was poured into the first trap E, so that it formed a film on the walls; the second trap F was cooled with dry ice and ether to protect the pumps from water vapor. Under the influence of the active gas from the discharge the oil was almost immediately converted into a solid.

The reaction takes place rapidly and appears to go best on the walls; the product forms as a tightly stretched film or skin. A small piece of iron was placed in the bulk of the oil and by the use of an electromagnet it was possible to stir the mass and so renew the oil surface. With this arrangement it was easy to observe the continued formation of the film.

The product is a white solid, fibrous and resilient. It is insoluble in water and in all of the organic solvents tried and can be washed free of unchanged oil by ether. When the solid is shaken with ether it seems to absorb the ether and swells somewhat. The substance does not melt but chars. Under the same conditions olive oil, linseed oil and castor oil yield white, insoluble substances which have similar properties.

Summary

It has been shown that cottonseed oil is attacked by the active gas from a water vapor discharge tube. Fibrous substances are produced which are insoluble in ether and other organic solvents. Olive oil, linseed oil and castor oil yield similar compounds.

THE ACTION OF THE SYSTEM $Mg + MgBr_2$ UPON TRIPHENYLCARBINOL, TRIPHENYLBROMOMETHANE AND UPON TRIPHENYLMETHYL[1]

BY M. GOMBERG AND W. E. BACHMANN

RECEIVED FEBRUARY 17, 1930 PUBLISHED JUNE 6, 1930

The method used by Conant[2] for the reduction of carbinols directly to free radicals suggested that a similar reduction, but in non-aqueous solvents, might be accomplished by the system $Mg + MgBr_2$.[3] Triphenylmethyl was actually produced in this manner from triphenylcarbinol, but its formation, we found, was brought about by a secondary reaction, and not by direct reduction of the carbinol.

When a solution of triphenylcarbinol in a mixture of ether and benzene

---

[1] From a paper presented before the Division of Organic Chemistry, American Chemical Society, at the third Organic Symposium, Princeton, New Jersey, December 9, 1929.

[2] Conant, THIS JOURNAL, 45, 2466 (1923).

[3] From experiments by Dr. F. J. Van Natta, this Laboratory.

is heated with magnesium bromide alone, the basic salt, $MgBr(OH)\cdot(C_2H_5)_2O$, precipitates from the solution, and the reaction proceeds to the extent of 75–80%, as follows

$$(C_6H_5)_3COH + MgBr_2 \longrightarrow (C_6H_5)_3CBr + MgBr(OH) \qquad (1)$$

When, however, the carbinol is heated with a mixture of $MgBr_2 + Mg$, and the reaction product is treated with water in absence of air, there results a mixture, in varying proportions, of triphenylmethyl and triphenylmethane. The former was interpreted as originating from the action of metallic magnesium on carbinol bromide (Equation 2), and the methane as coming from some triphenylmethylmagnesium bromide (Equation 3); triphenylchloromethane is well known to give an analogous Grignard reagent.

$$2(C_6H_5)_3CBr + Mg \longrightarrow 2(C_6H_5)_3C + MgBr_2 \qquad (2)$$

$$(C_6H_5)_3CBr \xrightarrow{Mg} (C_6H_5)_3CMgBr \xrightarrow{HOH} (C_6H_5)_3CH + MgBr(OH) \qquad (3)$$

Our erstwhile interpretation that Reactions 2 and 3 are merely competing reactions became untenable when it was found that the longer the reaction mixture (carbinol + Mg + $MgBr_2$) is heated, the less triphenylmethyl and the more triphenylmethane (i. e., Grignard reagent) is obtainable. Instead of competing, the triphenylmethyl represents, it seemed, an intermediate stage in the formation of the final magnesium compound

$$(C_6H_5)_3CBr \xrightarrow{Mg} (C_6H_5)_3C \xrightarrow[MgBr_2]{Mg} (C_6H_5)_3CMgBr \qquad (4)$$

In order to test this conclusion we studied in detail the reaction between triphenylbromomethane and magnesium.

One gram-mole of the carbinol bromide was found to react with one gram-atom of magnesium, and the Grignard reagent is produced in practically quantitative yield. However, when only one-half that amount of metal is used, no Grignard reagent is present at the end of the reaction and the solution contains only triphenylmethyl and magnesium bromide, as may be represented by Equation 2, although the mechanism may, in reality, be more complex than indicated (see page 2459). If an additional one-half gram-atom of magnesium is now added at this stage, the triphenylmethyl is completely converted into triphenylmethylmagnesium bromide. Obviously, the second part of the process must consist in the reaction

$$2(C_6H_5)_3C + MgBr_2 + Mg = 2(C_6H_5)_3CMgBr \qquad (5)$$

This inference has been verified by experiment. Pure triphenylmethyl has been found to react with the binary system quantitatively in accordance with Equation 5.

The failure to recognize that triphenylmethyl is an intermediate *stage* in the production of triphenylmethylmagnesium halide has been the cause of the many perplexing contradictions in the discussion on this subject by Schmidlin and Chichibabin.[4]

That free radicals with a transitory existence play an important role in the mechanism whereby a Grignard reagent is formed has been previously suggested by us:[5] (a) MgX_2 (activator) + Mg $2MgX$, or in absence of activator, $RX + Mg = R + MgX$; (b) $RX + MgX = R + MgX_2$; (c) $R + R = RR$; (d) $R + MgX = RMgX$, (c) and (d) being two competing reactions. Recently Kinney[6] and Gilman and co-workers[7] have interpreted the formation of the Grignard reagent substantially in accordance with our hypothesis. The latter investigators also remark that "it is possible to prepare triphenylmethylmagnesium iodide from triphenylmethyl and magnesious iodide,"[8] but no experimental details are given.

The results here presented constitute a realization of our surmise—*a Grignard reagent can be produced from a free radical and the system* $MgX_2 + Mg$.

Experimental

Triphenylmethylmagnesium Bromide

Schmidlin, who first prepared triphenylmethylmagnesium chloride, found it necessary to use iodine as an activator and to heat the mixture of the reactants for several hours or, otherwise, instead of the normal "&modification," there was produced much of the "a-modification," presumably a quinonoid isomer. This so-called or-modification, in our opinion, is largely the ether complex of triphenylmethyl.

We now find that the carbinol bromide reacts far more readily than the chloride. No activator is needed, the reaction proceeds at room temperature, and more rapidly on gentle warming. The triphenylmethylmagnesium bromide is only slightly soluble in ether, but is soluble in a mixture of one part of ether and two parts of benzene, and we used largely such a mixture. For more rapid reaction, magnesium powder or ribbon was employed, but for study of the rate of reaction we used magnesium rods, about 1.5 X 0.7 cm.; the rods could be quickly removed from the solutions in large test-tubes, weighed and replaced for continuation of the experiment. **A** number of experiments were carried out, varying the amount of magnesium used and varying the time allowed for the reaction from a few minutes to over a year. It was definitely established that not more than a gram-atom of magnesium enters into the reaction under any conditions (Equation 3).

Triphenylbromomethane, 16.2 g., and 1.34 g. of magnesium ribbon (calcd. 1.22 g.) in a mixture of 25 cc. of ether and 50 cc. of benzene were heated on a steam-bath. The

[8] Gilman and Fothergill, *ibid*, 51, 3152 (1929). The same information, in the same terms, was communicated in a letter to one of us (G) in February, 1929, when the results described in this paper had been already well established in this Laboratory.

solution was protected against access of air and against light in order to prevent decomposition of the triphenylmethyl. The reaction was apparently completed in less than one hour. The clear solution was filtered from the slight excess of magnesium through a sintered glass funnel and hydrolyzed, all in an atmosphere of nitrogen. The loss in weight of the magnesium was 1.20 g. The $Mg(OH)_2$ in the hydrolyzed mixture required for neutralization 48.7 cc. of N H_2SO_4, calcd. 50.0 cc. The crude triphenylmethane, obtained on evaporation of the ether–benzene solution, was recrystallized from benzene; weight 15.66 g., which is equivalent to 11.74 g. of benzene-free triphenylmethane. The quantity of the latter, the amount of $Mg(OH)_2$ and the weight of metallic magnesium that had dissolved show that the yield of the Grignard reagent was 96–97%.

In another experiment, the triphenylmethylmagnesium bromide was carbonated and the yield of triphenylacetic acid was practically quantitative.

Triphenylmethylmagnesium bromide and iodide can be readily prepared from the chloride. An equivalent amount of the corresponding magnesium halide is added to the solution of the carbinol chloride, whereupon magnesium chloride precipitates. The latter does not interfere with the subsequent course of the reaction. Activation by means of iodine, when the carbinol chloride is employed, is undoubtedly equivalent to adding magnesium iodide.

Isolation of the Grignard Reagent.—When to a concentrated solution of triphenylmethylmagnesium bromide in benzene–ether a further amount of ether is added, the etherate of the Grignard reagent comes down as granular crystals. For purposes of analysis it was prepared as follows. A rod of magnesium was allowed to react at room temperature with a solution of 8 g. of triphenylbromomethane in 75 cc. of ether–benzene (2 :) After one day the rod was coated with a deposit of large colorless transparent prisms. When a sufficiently large crop of these crystals had collected, they were detached from the rod, freed from some triphenylmethyl by washing with ether, and dried in a current of nitrogen. For analysis, a sample was hydrolyzed and the resulting products—triphenylmethane, $Mg(OH)_2$ and bromo ion were determined.

Anal. Subs., 1.592 g. Calcd. for $(C_6H_5)_3CMgBr \cdot 2(C_2H_5)_2O$: $(C_6H_5)_3C$, 49.1; Mg, 4.9; Br, 16.1. Found: $(C_6H_5)_3C$, 48.7; Mg, 4.9; Br, 16.2.

Triphenylmethyl from Triphenylbromomethane and Magnesium

Triphenylbromomethane (1 Mole) + Mg (0.5 Atom).—A mixture of 16.2 g. of triphenylbromomethane and 0.6 g. of magnesium ribbon in 25 cc. of ether and 50 cc. of benzene was heated on the steam-bath. In half an hour all the magnesium disappeared. No magnesium hydroxide was produced when the mixture was hydrolyzed; consequently, no Grignard reagent had been present. Air was passed into the ether–benzene solution, and 10.4 g. of pure triphenylmethyl peroxide was obtained, which, assuming an 80% yield, corresponds to about 12.2 g. of triphenylmethyl, calcd. 12.15. No triphenylmethane was found in the filtrate from the peroxide.

We have represented the formation of triphenylmethyl by Equation 2. Actually, the mechanism may be more complex. Indeed, Schmidlin has shown that triphenylmethylmagnesium chloride can enter into reaction with triphenylchloromethane, giving rise to triphenylmethyl, and he ascribed to this reaction the presence of any triphenylmethyl in admixture with his preparations of the Grignard reagent

$$(C_6H_5)_3CMgX + (C_6H_5)_3CX = 2(C_6H_5)_3C + MgX_2 \qquad (6)$$

With our reagents we find that this reaction proceeds rapidly and completely. When to a solution of triphenylmethylmagnesium bromide an equivalent amount of triphenylbromomethane is added and the mixture is warmed for a few minutes, triphenylmethyl results in quantitative yield.

In view of the rapidity of Reaction 6, it seems quite likely that triphenylmethyl is produced not as represented in Equation 2 but by inter-reaction of Grignard reagent, initially formed, and unchanged triphenylbromomethane, *i. e.*, in two successive steps represented by the equations (3) and (6), respectively.

Triphenylmethyl + Mg + $MgBr_2$ (or MgI_2)

A number of experiments were performed on solutions of the free radical which had been prepared either according to Equation 6 or from triphenylchloromethane by means of silver or zinc. The results were quite satisfactory, but in order to make certain that our solutions of the radical were entirely free from any possible admixture of carbinol halide, the work was repeated with pure triphenylmethyl that had been recrystallized from acetone.

To a solution of 14.3 g. of triphenylmethyl in 60 cc. of benzene was added a solution of 9 g. of anhydrous magnesium bromide (prepared from $HgBr_2$ + Mg)[9] in 40 cc. of benzene and 60 cc. of ether. A small quantity of crystals precipitated, presumably a molecular compound of triphenylmethyl and $MgBr_2$. A coil of magnesium ribbon was introduced into the solution, and the mixture was gently heated on the steam-bath in an atmosphere of nitrogen; the upper end of the reflux condenser was connected to a mercury trap. The reaction started immediately and the mixture was heated for three hours. According to Equation 5, 0.71 g. of metallic magnesium should have reacted; found, 0.66 g., or 93% of the calculated value. The filtered solution was decomposed with water. The magnesium hydroxide so produced required 56.8 cc. of N H_2SO_4, calcd. 58.4 cc., and there were obtained 13.7 g. of pure triphenylmethane and 0.7 g. of triphenylmethyl peroxide.

In another experiment 9.0 g. of triphenylmethyl dissolved 0.445 g. of Mg (calcd. 0.450), and there was obtained on hydrolysis of the reaction product 7.9 g. of triphenylmethane.

Isolation and Analysis of the Triphenylmethylmagnesium Bromide.—Thirteen grams of crystalline triphenylmethyl was added to a solution of 9 g. of $MgBr_2$ in 120 cc. of ether–benzene (2:1), and the solution was heated for several hours with somewhat more than the required amount of magnesium ribbon. To the filtered solution was added a single crystal of triphenylmethylmagnesium bromide (obtained from triphenylbromomethane + magnesium), when sudden crystallization took place and in a short time the solution was half-filled with glistening prisms. The crystals were filtered, washed repeatedly with pure ether, and dried in a stream of nitrogen. The compound was found to be identical with the triphenylmethylmagnesium bromide obtained directly from triphenylbromomethane.

Anal. Subs., 14.56 g. Calcd. for $(C_6H_5)_3CMgBr\cdot 2(C_2H_5)_2O$: $(C_6H_5)_3C$, 49.1; Mg, 4.9; Br, 16.1. Found: $(C_6H_5)_3C$, 49.2; Mg, 4.7; Br, 16.1.

Triphenylmethyl + Mg + $MgBr_2$ at Room Temperature.—Ten and three-tenths grams of triphenylmethyl was added to a solution of 4.6 g. of $MgBr_2$ in 120 cc. of ether–benzene (1:2), containing 0.67 g. of magnesium ribbon. In one week at room temperature there was dissolved 0.50 g. of magnesium, and there was produced a 97% yield of triphenylmethylmagnesium bromide.

Triphenylmethyl + Mg + MgI_2.—A mixture of 12.2 g. of triphenylmethyl, 11 g. of magnesium iodide and 2.5 g. of magnesium ribbon in 150 cc. of ether-benzene (1:2) was heated on the steam-bath for several hours. The magnesium loss was 0.61 g., calcd., 0.608. Hydrolysis of the reaction product yielded 11 g. of triphenylmethane.

Reaction with Carbon Dioxide.—A solution of triphenylmethylmagnesium iodide was prepared from 12 2 g. of triphenylmethyl. A stream of dry carbon dioxide was

---

[9] Gomberg and Bachmann, THIS JOURNAL, 49,2586 (1927).

passed into this solution for three hours; during this time a large amount of light yellow precipitate appeared. Decomposition with dilute acid gave a product from which 12 g. of pure triphenylacetic acid was obtained.

Relative Proportions of $(C_6H_5)_3C$ and $(C_6H_5)_3CMgBr$

It is now obvious that in the process of "grignarding" triphenylbromomethane, no Grignard reagent is present until after one-half of the entire amount of magnesium has reacted. After the half-way mark, generation of Grignard reagent can come about only as a consequence of the reaction between triphenylmethyl and the system Mg + $MgBr_2$. This reaction proceeds to completion in virtue of the fact that Step c (p. 2457) is, in this case, reversible: R + R RR. The relative quantities of free radical and of triphenylmethylmagnesium bromide that are present at any time during the reaction may be expressed graphically as in Fig. 1.

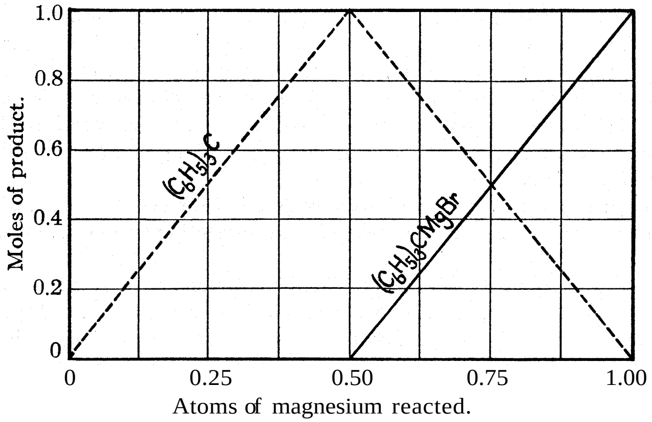

Fig. 1.—Amounts of triphenylmethyl and Grignard reagent in the reaction between triphenylbromomethane and magnesium.

Experiments conducted at room temperature and interrupted before a whole gram-atom of magnesium had reacted gave results which are in accordance with the curves. The following special experiment gave the two components in the ratio as anticipated, 50% each.

Triphenylbromomethane (1 Mole) + Mg (0.75 Atom).—Triphenylbromomethane, 16.2 g., and 0.912 g. of magnesium ribbon were heated together in 75 cc. of ether–benzene. In less than an hour all of the metal disappeared. The magnesium hydroxide produced on hydrolysis required 25.0 cc. of N H_2SO_4 for neutralization. This corresponds to a 50% yield of $(C_6H_5)_3CMgBr$ (see Fig. 1). From the benzene solution, after passing air into it, there were obtained 5.88 g. of triphenylmethyl peroxide (**calcd.** 6.5) and 6.0 g. of triphenylmethane (calcd. 6.1).

Summary

It has been shown that triphenylcarbinol reacts in anhydrous solvents **with** magnesium bromide and forms triphenylbromomethane.

Triphenylbromomethane reacts with metallic magnesium far more readily than the chloride, and gives rise to triphenylmethylmagnesium bromide. This has been isolated in crystalline state and analyzed.

The formation of triphenylmethylmagnesium bromide takes place in two successive stages: (a) formation of triphenylmethyl; (b) formation, from that, of the magnesium compound, $2\ R_3C + Mg + MgX_2 = 2\ R_3CMgX$. The formation of the triphenylmethyl is in itself most probably the result of two successive reactions: $R_3CX + Mg = R_3CMgX$; $R_3CMgX + R_3CX = 2\ R_3C + MgX_2$.

The formation of triphenylmethylmagnesium halide from triphenylmethyl and the system $Mg + MgX_2$ lends much support to the hypothesis that the action of the binary system is through the intermediate formation of the active compound MgX.

TOXICAROL. A CONSTITUENT OF THE SOUTH AMERICAN FISH POISON CRACCA (TEPHROSIA) TOXICARIA[1]

BY E. P. CLARK

RECEIVED FEBRUARY 17, 1930 PUBLISHED JUNE 6, 1930

In connection with a survey of fish poisoning plants as sources of insecticides now in progress in this Laboratory, a chemical examination of the roots of Cracca (*Tephrosia*) *toxicaria* was made.[2] It was shown that this plant material contains a crystalline substance which in high dilutions is toxic to fish. The crude crystals had a greenish-yellow color and a melting point of 200–203°. Closer examination revealed that the material was composed of at least two substances. The one that occurs in much the greater proportion is a bright canary yellow, optically inactive compound which has a melting point of 219° (corr.). It has the molecular formula $C_{23}H_{22}O_7$ and has one hydroxyl and two methoxyl groups. The name toxicarol has been assigned to it.

The second substance is a pale green crystalline compound which is separated from toxicarol only with difficulty. Owing to the small quantity of the plant available it was impossible to obtain sufficient crystalline material to carry the fractionation of the second substance to a state of certain analytical purity. Its optical properties, however, were readily determined, and from these data it was shown that the substance was identical with an optically inactive dimethoxy compound having the formula $C_{23}H_{22}O_6$ which is found in *Derris* and *Cube* roots.

---

[1] The name *Tephrosia* Pers. is antedated by *Cracca* and under the American code of Botanical Nomenclature all species of *Tephrosia* should bear the generic name *Cracca*.

[2] The material was received from the Department of Agriculture, Georgetown, British Guiana, through the American Vice Consul, Harold R. Brown.

It is of interest to note that the molecular formula for toxicarol differs from the formula of rotenone by one oxygen atom only, whereas the formula for the second compound is identical with that of rotenone. Furthermore, both substances have two methoxyl groups, as does rotenone, and both are approximately as toxic to fish. These considerations, together with the fact that all three substances are found in *Derris,* indicate that possibly some common structural relationships exist among the three bodies. Further work, now in progress, is expected to throw more light upon this matter.

Experimental

Fifty grams of the ground roots of *Cracca toxicaria* were completely exhausted with ether. The resulting extract, after the removal of the solvent, was dissolved in 30 cc. of hot methanol and then made alkaline with 10 cc. of an aqueous 5% sodium hydroxide solution. The mixture was immediately heated to its boiling point, causing a tarry substance to separate. The supernatant liquid was decanted, diluted with three volumes of water, made acid to congo red with sulfuric acid and extracted with chloroform. The chloroform extract was washed with water, dried with sodium sulfate, filtered and evaporated to a small volume. Several volumes of methanol were then added to the concentrate and the solution was evaporated to a volume of approximately 10 cc. Upon allowing the liquid to cool, crystallization began at once. The yield was 0.65 g. or 1.3% of the drug taken. As stated before, the product had a greenish-yellow color and a melting point of 200–203°.

Pure toxicarol was obtained from this material by dissolving the crude crystals in hot chloroform, filtering the solution through norite, again heating the solution to its boiling point and then adding about 12 volumes of boiling alcohol. The solution was maintained in a state of vigorous boiling until it became practically free from chloroform, at which time toxicarol began to crystallize. The process was soon completed, and the crystals were filtered from the boiling liquid. The product thus obtained had a melting point of about 215". Two or three recrystallizations of this material by the method just given resulted in a product having a constant melting point of 219° (corr.). It consists of bright, greenish-yellow, six-sided plates and rods whose refractive indices are: n_α, 1.580 (frequent); n_β, 1.618 (common); and n_γ, >1.768, all ±0.003. In parallel polarized light with crossed nicols the extinction is inclined and the elongation is negative. Double refraction is very strong. Many of the plates are so thin that only first order white and yellow colors are shown. Frequently plates remain bright in all positions when the stage is rotated. In convergent polarized light with crossed nicols the large plates show distinct biaxial interference figures with a large axial angle. The optic sign is positive.[3]

Anal. Calcd. for $C_{23}H_{22}O_7$: C, 67.30; H, 5.41; CH_3O (2), 15.1. Found: C, 67.09; H, 5.41; CH_3O, 15.3.

Toxicarol Benzoate.—Two cc. of benzoyl chloride was added to a solution of 2 g. of toxicarol in 20 cc. of hot pyridine. After an hour the reaction mixture was poured into 300 cc. of water, causing the separation of an oil. This was removed from the mother liquor by decantation and dissolved in 75 cc. of boiling alcohol. Upon cooling, 1.5 g. of toxicarol benzoate, having a melting point of 200°, separated. This was recrystallized

---

[3] The optical data recorded in this communication were determined by George L. Keenan of the Food, Drug and Insecticide Administration of the U. S. Department of Agriculture. Appreciation is acknowledged for this valuable cooperation.

from its solution in chloroform by the addition of 5 volumes of methanol. It separated in rosets of fine colorless needles whose melting point was 202° (corr.). The yield was 1.35 g. Its refractive indices are n_α, 1.590; n_β, indeterminate; n_γ, 1.702. An intermediate value n,, 1.650, is also common. In parallel polarized light with crossed nicols the extinction is inclined and the sign of elongation is positive.
